for acute therapy. It may or may not terminate the tachycardia but almost always slows the rate. In stable patients in whom these drugs do not terminate the arrhythmia, a pacing catheter can be inserted pervenously into the right ventricular apex, and the tachycardia can be terminated by overdrive pacing.

Although programmed stimulation has been used to select the appropriate antiarrhythmic agent to prevent recurrent, sustained VT, recent data suggest ICD implantation is more effective. As such, drugs are used in patients in whom ICDs are contraindicated or according to patient preference. These drugs may also be used as adjunctive therapy with ICDs to suppress recurrent ventricular or coexisting supraventricular arrhythmias.

Antitachycardia pacing has been used as a means to terminate tachycardias that have been reproducibly terminated by pacing in the electrophysiology laboratory. Automatic antitachycardia pacing devices are not used alone because pacing during VT may accelerate tachycardia, converting a stable arrhythmia into an unstable one and resulting in severe hemodynamic compromise. However, devices combining antitachycardia pacing with an ICD (see below) afford a "backup" means of terminating unstable arrhythmias.

The advent of endocardial catheter and intraoperative mapping led to the development of surgical techniques for the management of VT. Even though most patients with VT and ischemic heart disease have markedly impaired left ventricular function and multivessel coronary artery disease, the operative mortality rate has ranged between 8 and 15%. Following operation, >90% of survivors are controlled either off (two-thirds of patients) or on (one-third) antiarrhythmic agents that were previously ineffective in controlling these rhythms. With the development of radiofrequency ablation and refinement of mapping criteria to locate the critical sites of the VT circuit precisely, catheter ablation can be performed as a curative procedure in selected patients. In experienced centers, cure of VT in these *selected* patients approaches 75%.

Specific Types of VT *Torsades de pointes* (Fig. 214-12) refers to VT characterized by polymorphic QRS complexes that change in amplitude and cycle length, giving the appearance of oscillations around the baseline. This rhythm is, by definition, associated with QT prolongation. The latter may result from electrolyte disturbances (particularly hypokalemia and hypomagnesemia), use of a variety of antiarrhythmic drugs (especially quinidine), phenothiazines and tricyclic antidepressants, liquid protein diets, intracranial events, and bradyarrhythmias, particularly third-degree AV block. It may also occur as a congenital anomaly that most often presents with torsades de pointes (syncope or sudden death) at a young age.

The electrocardiographic hallmark is polymorphic VT preceded by marked QT prolongation, often in excess of 0.60 s. These patients often have multiple episodes of nonsustained polymorphic VT associated with recurrent syncope, but they may also develop VF and sudden cardiac death.

TREATMENT

This should be directed at removing the precipitating factors, i.e., correcting metabolic abnormalities and removing drugs that have induced the prolonged QT interval. In the setting of drug-induced torsades de pointes, atrial or ventricular overdrive pacing and the administration of magnesium have also been useful in terminating and preventing the arrhythmia. For patients with the congenital prolonged QT interval syndrome, β-adrenergic blocking agents have been the mainstay of therapy; agents that shorten the QT interval may also be useful (e.g., phenytoin). Cervicothoracic sympathectomy has been proposed as a form of therapy for congenital prolonged QT syndrome, but it is not often effective as the sole therapy. Pacing in combination with beta blockers and sympathectomy has been used by some investigators when beta blockers fail, but it is not uniformly successful and results in a Horner's syndrome. ICDs with dual-chambered pacing capability and beta blockers have become the treatment of choice for patients with recurrent episodes despite beta blockers.

Polymorphic tachycardias associated with normal QT intervals in patients with ischemic heart disease that are initiated by "R-on-T" VPCs are probably caused by reentry, and their treatment is totally different. They should not be considered torsades de pointes. In such cases, class I or III agents may be the most effective form of therapy and should be administered in full antiarrhythmic doses. However, these arrhythmias may also result from acute, severe ischemia and will only respond to abolition of the ischemia, usually by revascularization. Another group of patients has recently been defined who have polymorphic VT initiated by short coupled VPCs during exercise or other catecholamine states due to triggered activity associated with release of Ca^{2+} from the sarcoplasmic reticulum. This is a lethal syndrome requiring an implantable defibrillator.

Accelerated idioventricular rhythm, also termed *slow VT*, with a rate that ranges from 60 to 120 beats/min, usually occurs in acute myocardial infarction, often during reperfusion. It may also be seen following cardiac operations; in patients with cardiomyopathy, rheumatic fever, or digitalis intoxication; and in patients with no evidence of heart disease. The rhythm is usually transient and rarely causes significant hemodynamic compromise or symptoms. Treatment is rarely necessary and should usually be considered only if symptoms arise due to impaired hemodynamics, most commonly due to AV dissociation. In most cases, atropine can accelerate the sinus rate to overdrive the ventricular rhythm.

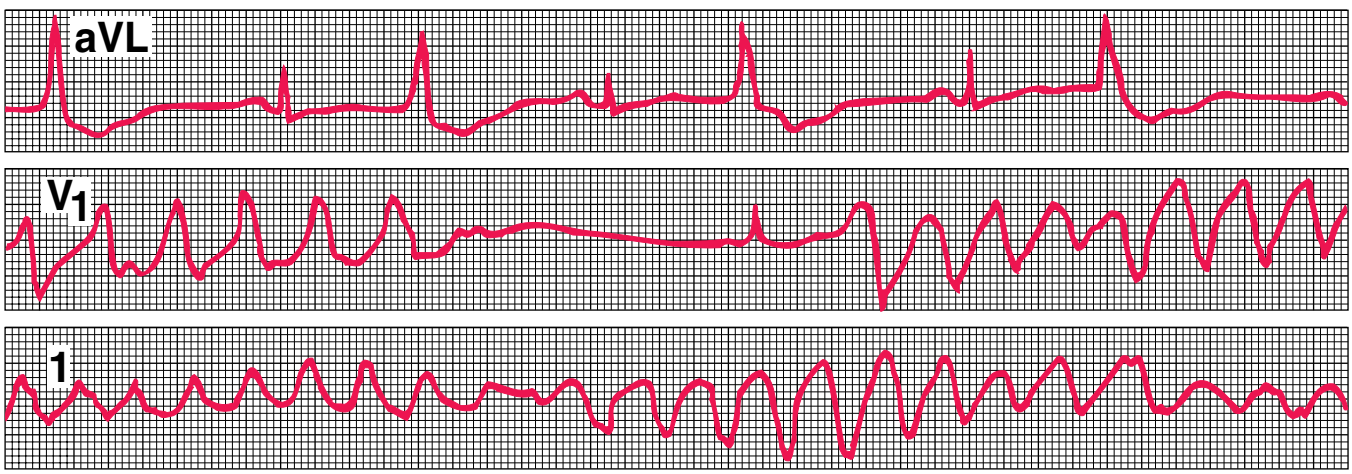

FIGURE 214-12 Rhythm strips of patients with drug (disopyramide)-induced torsades de pointes. The polymorphic ventricular tachycardia is associated with very long QT intervals.

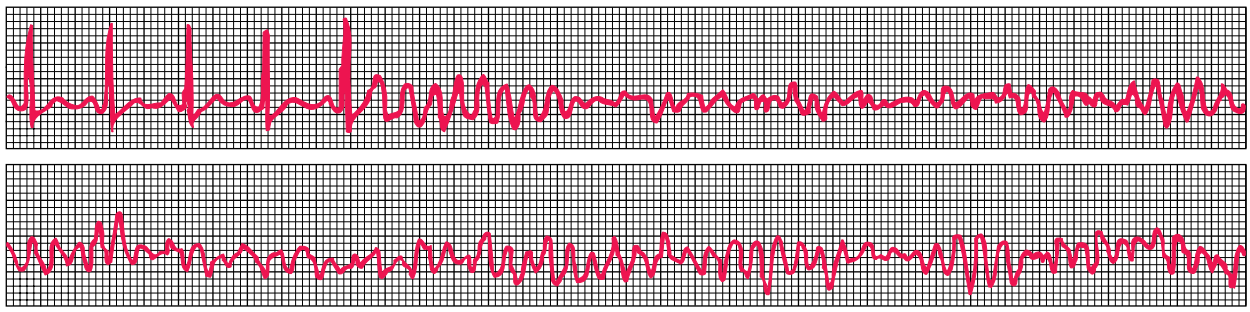

FIGURE 214-13 Ventricular fibrillation. In a patient with coronary disease, ventricular fibrillation is initiated by an early ventricular premature complex that produces a rapid polymorphic ventricular tachycardia, which rapidly degenerates to ventricular fibrillation (note the undulating baseline with indistinguishable systole and diastole).

VENTRICULAR FLUTTER AND VENTRICULAR FIBRILLATION (Fig. 214-13; see also Chap. 256) These arrhythmias occur most often in patients with ischemic heart disease. They also occur following administration of antiarrhythmic drugs, particularly those that induce prolonged QT intervals and torsades de pointes (see above), in patients with severe hypoxia or ischemia, and in those with WPW syndrome who develop AF with an extremely rapid ventricular response (p. 1345). Electrical accidents frequently cause cardiac arrest due to the development of VF. The onset of these arrhythmias is rapidly followed by loss of consciousness and, if untreated, death. Episodes of cardiac arrest recorded during Holter monitoring reveal that approximately three-fourths of the sudden deaths are due to VT or VF.

In patients with nonischemic VF, the onset usually begins with a short run of rapid VT, which is initiated by a relatively late coupled VPC. In patients with acute myocardial infarction or ischemia, however, VF is usually precipitated by a single early ventricular complex beat falling on the T wave (the vulnerable period), which produces a rapid VT that degenerates into VF (Fig. 214-13).

The clinical setting in which VF occurs is important. Most patients who have primary VF within the first 48 h of the onset of acute infarction have a good long-term prognosis, with a very low rate of recurrence or sudden cardiac death. Their short-term mortality may, however, be slightly increased. In contrast, patients who experience VF unassociated with the development of acute myocardial infarction have a recurrence rate of 20 to 30% in the year following the event (Chap. 256).

Ventricular flutter usually appears as a sine wave with a rate between 150 and 300 beats/min. These oscillations make it impossible to assign a specific morphology to the arrhythmia and in some cases to distinguish it from rapid VT. VF is recognized by grossly irregular undulations of varying amplitudes, contours, and rates (Fig. 214-13). Electrophysiologic studies have demonstrated that regardless of the apparent gross irregularity on the surface ECG, VF usually starts out with a rapid repetitive sequence of VT that ultimately breaks down into multiple wavelets of reentry.

Electrophysiologic studies have been useful in patients who have been resuscitated from cardiac arrest. In approximately 70% of patients with prior infarction, programmed stimulation can reproducibly initiate a sustained VT. Ablation may be possible in some of these patients, particularly if the VT can be slowed so that it can be mapped. Several recent secondary prevention trials have demonstrated superior survival (3 years) in patients treated with ICDs versus amiodarone (Table 214-6). However, in patients with ejection fractions >35% or <20%, survival was comparable.

TABLE 214-6 *Trials of ICD Therapy for Secondary Prevention in VT/VF Patients*

	AVID	CIDS	CASH
Protocol	ICD vs. empiric amiodarone or sotolol (mainly amiodarone)	ICD vs. empiric amiodarone	ICD vs. empiric amiodarone, metoprolol, and propafenone[a]
Sample size	n = 1016 AAD = 509 ICD = 507	n = 659 Amiodarone = 331 ICD = 328	n = 346 Amiodarone = 92 Metoprolol = 97 Propafenone[a] = 58 ICD = 99
Patient inclusion criteria	Survivors of VF VT with syncope VT with EF ≤ 40%	Survivors of VF VT with syncope VT with EF ≤ 35% and cycle length ≤ 400 ms	Survivors of VF (no EF requirement)
Mortality in "drug" or "control" arm	17.7% 25.3% 35.9% 1 year 2 years 3 years	30% 3 years	19.6% 2 years
Mortality in ICD arm	10.7% 18.4% 24.6% 1 year 2 years 3 years	25% 3 years	12.1% 2 years
Reduction in mortality with ICD	39% 27% 31% 1 year 2 years 3 years	20% 3 years	37% 2 years

[a] Following an interim analysis in March, 1992, enrollment in propafenone arm was discontinued because mortality was increased significantly over mortality in the ICD arm.

Note: EF, ejection fraction; ICD, implanted cardioverter/defibrillator; VF, ventricular fibrillation; VT, ventricular tachycardia.

GENETIC CONSIDERATIONS Many advances have been made in the identification of genes responsible for syndromes associated with VTs and sudden cardiac death. Specific examples include the congenital long QT syndrome (LQTS), hypertrophic obstructive cardiomyopathy (Chap. 221), arrhythmogenic right ventricular dysplasia, catecholamine-related VT/VF, and the *Brugada syndrome* (Table 214-7). The latter is a recently described disorder characterized by the electrocardiographic profile of a pseudo right bundle branch block pattern with ST elevation and terminal T-wave inversion in leads V_1–V_3 (Fig. 214-14). The clinical presentation is VF in patients with structurally normal hearts. A mutation in the cardiac sodium channel, SCN 5A, is believed to be responsible. While the same gene is responsible for the LQTS, the mutation is different in the two syndromes.

TREATMENT

PHARMACOLOGIC ANTIARRHYTHMIC THERAPY Prior to initiation of pharmacologic antiarrhythmic therapy, potential aggravating factors such as transient metabolic abnormalities, CHF, or acute ischemia must be corrected; in some cases this may suffice to control arrhythmias. In addition, the potential role of drugs as a cause or exacerbating factor in the development of the arrhythmia must be considered. It must be recognized that we do not have a good understanding of the effects of antiarrhythmic agents on the spontaneous onset of tachyarrhythmias. In some cases, they may facilitate the onset.

Antiarrhythmic drugs are used in three principal situations: (1) to terminate an acute arrhythmia, (2) to prevent recurrence of an

arrhythmia, and (3) to prevent a life-threatening arrhythmia for which the patient is perceived to be at risk but which has never occurred.

Most currently available antiarrhythmic agents (Table 214-4) have a relatively low toxic/therapeutic ratio; all can exert proarrhythmic effects (Table 214-8) and therefore may exacerbate underlying arrhythmias. Serum levels can be determined for most currently available antiarrhythmic agents. Standards for therapeutic and toxic levels can serve only as a rough guide for selecting the appropriate dose in any individual patient. In the final analysis, the therapeutic level in a given patient is the concentration that achieves the desired antiarrhythmic effect, and the toxic level for each patient is the concentration at which undesirable side effects occur. Since many adverse effects are directly related to drug concentrations, the lowest serum level that achieves an effective antiarrhythmic response should be chosen.

TABLE 214-7 *Genetically Determined Arrhythmia Syndromes*

Disease	*Inheritance*	*Involved Gene*	*Protein*
LQT	Autosomal dominant	KVLQT 1	I_{KS} K channel
		HERG	I_{Kr} K channel
		SCN5A	I_{Na} Na channel
		LQT 4	Unknown
		minK	I_{KS} K channel
		MiRP1	I_{Kr} K channel
	Autosomal recessive (with neural deafness)	KVLQT 1	I_{KS} K channel
		MinK	I_{KS} K channel
	Drug-induced	HERG	I_{Kr} K channel
		MiRP1	I_{Kr} K channel
Brugada syndrome	Autosomal dominant	SCN5A	I_{Na} Na channel
Catecholamine VT	Autosomal dominant	RyR2	Ryanodine receptor
	Autosomal recessive	CASQ2	Calsequestran receptor
Arrhythmogenic RV dysplasia	Autosomal dominant	Unknown genes	
Hypertrophic cardiomyopathy	Autosomal dominant	Multiple cardiac sarcomeric genes (troponin T, troponin I, myosin heavy chain, myosin binding protein C, α tropomyosin)	

In order to determine the therapeutic level for a patient, one must have a standard to judge drug efficacy. For a patient with an incessant arrhythmia, antiarrhythmic drugs may be administered empirically until the arrhythmia is suppressed. If a reproducible precipitating factor such as exercise can be identified, serial drug testing during such a provocative maneuver may be performed. Unfortunately, most arrhythmias are sporadic and occur unpredictably without identifiable precipitating factors. In these cases, if one waits to observe spontaneous recurrences on each antiarrhythmic drug, assessment of drug efficacy may require months. This type of assessment of efficacy may be adequate for arrhythmias that are not life-threatening such as AF or SVT. In the current era, most patients with ventricular arrhythmia have ICDs, and recurrence can be monitored through ICD arrhythmic logs. However, this mode of assessment is inadequate for arrhythmias that compromise hemodynamic stability, result in syncope, or cause cardiac arrest.

CLASSIFICATION OF ANTIARRHYTHMIC DRUGS A number of classifications of antiarrhythmic drugs have been proposed; the most frequently used is a modification of one proposed by Vaughan-Williams (Table 214-2). This classification is based in part on the ability of antiarrhythmic drugs to modify the cardiac cellular (1) excitatory currents (Na^+ or Ca^{2+}), (2) action potential duration, and (3) automaticity (phase 4 depolarization). These effects of the drugs on isolated cardiac cells are thought to account for some of the antiarrhythmic properties of the drugs. Thus depression of excitatory currents by class I and class IV antiarrhythmics results in slowing of conduction velocity and may interrupt arrhythmias by blocking conduction in areas of marginal excitability, where conduction velocity is already slow. Class III antiarrhythmics allegedly exert their action by increasing refractoriness through prolongation of the action potential duration. However, this classification has a number of limitations. The electrophysiologic effects of these drugs in vivo may differ from their effects on isolated cells. Also, the effects of heart rate and fiber geometry are not considered. Not all drugs (e.g., adenosine) fit into the classifications. Finally, some drugs (e.g., amiodarone) exhibit properties consistent with multiple classes. The uses, actions, and toxic actions of currently available antiarrhythmic drugs are summarized in Tables 214-4 and 214-7.

ELECTRICAL THERAPY OF TACHYARRHYTHMIAS ■ Pacemakers Cardiac pacing can be used to terminate and, in selected cases, prevent recurrent supraventricular and ventricular arrhythmias. Because many tachyarrhythmias appear to be due to a reentrant mechanism with the impulse traveling in a circuit, a properly timed paced impulse can penetrate and prematurely depolarize part of the circuit, rendering it refractory to the next circulating wavefront and thereby interrupting the circus movement. Pacing therapy for arrhythmias is generally reserved for patients whose arrhythmias are refractory to drug therapy and who remain hemodynamically stable during the tachycardia. All forms of pacing therapy require repeated demonstration of their effectiveness and reliability in terminating the arrhythmias during electrophysiologic testing prior to implantation of the pacing device.

The type of pacing device and modality selected for arrhythmia termination depend on (1) the rate of the tachycardia (rates >160 beats/min are rarely terminated by a single premature stimulus), (2) the type of arrhythmia (atrial flutter and VT are rarely terminated by single extrastimuli), and (3) concomitant drug therapy.

Because many tachycardias cannot be terminated by single premature stimuli, pacemakers have been developed that allow for multiple extrastimuli (burst pacing) to be introduced. In the current era, antitachycardia pacing is used almost exclusively for ventricular arrhythmias because of the success of radiofrequency ablative therapy for supraventricular arrhythmias.

Cardiac pacing has also been used to prevent ventricular tachyarrhythmias. Polymorphic VT associated with a long QT interval and bradycardia (torsades de pointes, p. 1351) is most likely to respond. Pacing the atrium and/or ventricle at rates between 90 and 120 beats/min appears to increase the homogeneity of electrical recovery and markedly reduces the propensity for a recurrence of arrhythmias.

FIGURE 214-14 Brugada syndrome. Note ST elevation with terminal T wave inversion in leads V_1–V_3 mimicking right bundle branch block.

TABLE 214-8 *Toxicity of Most Frequently Used Antiarrhythmic Agents*

Drug	Nonarrhythmic Toxicity	Proarrhythmic Toxicity			
		TDP[a]	A Flutter 1:1	VT/VF	Bradycardia
Digoxin	Anorexia, nausea, vomiting, visual changes	Atrial tachycardia, VT, AV nodal block, accelerated junctional rhythms, atrial and ventricular premature depolarizations; acceleration of ventricular rate during atrial fibrillation or flutter in the presence of preexcitation			
Quinidine[b]	Anorexia, nausea, vomiting, diarrhea, cinchonism, tinnitus, hearing and visual changes, thrombocytopenia, hemolytic anemia, rash, potentiation of digoxin levels	2%	++	++	+
Procainamide[b]	Lupus erythematosus–like syndrome, anorexia, nausea	2%	+	++	+
Disopyramide[b]	Anticholinergic actions: dry mouth, urinary retention, visual disturbances (avoid in narrow-angle glaucoma) constipation, congestive heart failure	2%	+	++	+
Lidocaine	Dizziness, confusion, delirium, seizures, coma; side effects potentiated by liver and heart failure	—	—	—	+[b]
Mexiletine	Ataxia, tremor, gait disturbances, rash, vomiting	—	—	—	—
Flecainide	Dizziness, nausea	Rare	+++	++	++
Propafenone[c]	Taste disturbance, bronchospasm	Rare	+++	++	++
Amiodarone	Pulmonary infiltrates and fibrosis, hepatitis, hypo- and hyperthyroidism, photosensitivity, peripheral neuropathy, tremor	Rare	+++	+++	+++
Sotalol	Bronchospasm	+++	+	+	+++

[a] TDP (torsades de pointes) occurs most often in the setting of slow heart rates, QT prolongation, and hypokalemia or hypomagnesemia and at the time of conversion from atrial fibrillation to sinus rhythm. QT prolongation and torsades de pointes are not dose-related phenomena. QRS prolongation is a dose-related phenomenon also and will occur at toxic concentrations. QT and WRS intervals should be monitored and dose reductions made for interval prolongations.
[b] May suppress sinus node function in patients with underlying sinus node dysfunction. May suppress escape foci in patients with complete heart block.
[c] Avoid in patients with prior myocardial infarction and depressed left ventricular function. Use in combination with AV nodal blocking agent to limit risk of atrial flutter with 1:1 conduction.
Note: A flutter 1:1, atrial flutter with 1:1 atrioventricular (AV) conduction; VT/VF, ventricular tachycardia/ventricular fibrillation.

Pacemakers may be self-contained or energized by an external radiofrequency source. The self-contained pacemaker may function automatically [i.e., it incorporates an arrhythmia-recognition program (circuit)], or it may be activated by an external magnet. The major advantage of a fully automatic system is that there is no need for the patient to recognize the arrhythmia in order for termination to occur. The advantages of the externally activated system (rarely used today) include (1) the decreased risk of unnecessary treatment because of faulty sensing, and (2) the opportunity to initiate monitoring at the time of attempted termination of arrhythmia. This type of monitoring is frequently helpful if pacing techniques are employed to terminate VT, given the risk of acceleration of the arrhythmia by pacing.

The limitations of pacing therapy are primarily related to (1) the changes in the characteristics of the arrhythmia over time such that programmed pacing parameters no longer terminate the tachycardia; (2) the risk of acceleration of the tachycardia with the development of AF when stimulating the atrium and the development of rapid VT and VF when stimulating the ventricles; and (3) inappropriate recognition of supraventricular tachyarrhythmias as VTs, leading to delivery of therapy unnecessarily, which can initiate VT or VF. Future pacing generators that can perform cardioversion and defibrillation will increase the applicability of pacing therapy for the treatment of arrhythmias (see below).

Cardioversion and Defibrillation Electrical cardioversion and defibrillation remain the most reliable methods for terminating arrhythmias. By depolarizing all or at least a large portion of excitable myocardium in a near homogeneous fashion, the electrical shock can interrupt reentrant arrhythmias. External cardioversion is routinely performed by placing two paddles 12 cm in diameter in firm contact with the chest wall, with one paddle usually located to the right of the sternum at the level of the second rib and the other in the left anterior axillary line in the fifth intercostal space. If the patient is conscious, a short-acting anesthetic or an amnesic drug should be administered to prevent patient discomfort. A person skilled in maintaining an airway should be present.

Energy is delivered synchronously with the QRS complex for all arrhythmias except ventricular flutter and VF, since asynchronous shocks can produce VF. The amount of energy used will vary with the type of tachycardia being treated. With the exception of AF, SVTs can frequently be terminated with energy levels in the range of 25 to 50 W·s, while AF usually requires ≥100 W·s for termination. For terminating VT, energy levels ≥100 W·s should probably be employed. While energies as low as 25 W·s may be used successfully, they also have a higher incidence of producing VF or AF. At least 200 W·s of energy should be used for initial attempts at terminating VF. If the initial shock fails, all repeated attempts at defibrillation should be with the maximum energy that the defibrillator is capable of delivering (320 to 400 W·s). As noted earlier, biphasic cardioversion has proven more effective with lower energy requirements than monophasic cardioversion.

Indications for cardioversion depend on the clinical setting and the patient's general condition. Any tachycardia (except sinus tachycardia) that produces hypotension, myocardial ischemia, or heart failure warrants consideration of prompt termination using external cardioversion. Arrhythmias that fail to terminate with pharmacologic therapy may also be terminated by electrical cardioversion. Transient bradycardias and supraventricular and ventricular irritability following cardioversion are common and usually do not warrant antiarrhythmic intervention.

Implanted Cardioverter/Defibrillator ICD devices have been developed that will promptly recognize and terminate life-threatening ventricular arrhythmias. These devices can deliver <1 to 40 W·s, the amount of which can be programmed. Current devices have antitachycardia pacing capabilities such that VT can be sensed and terminated without resorting to a painful shock. In such devices, high-energy shocks are reserved for hypotensive VT, acceleration of VT, or failure to terminate VT after a programmed duration (Fig. 214-15). ICDs are generally implanted transvenously, in a manner similar to pacemakers. Clinical trials testing the function of these devices in patients with drug-refractory ventricular arrhythmias have demonstrated survival from sudden death at 1 year ranging between 92 and 100%. Currently, ICDs

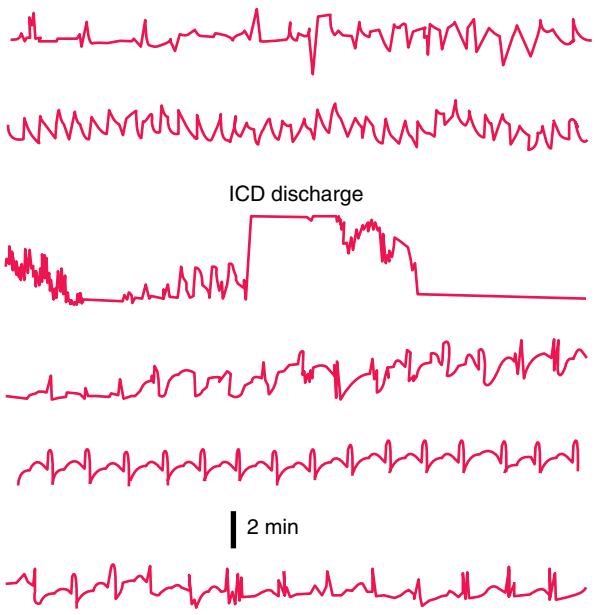

FIGURE 214-15 Normally functioning implantable defibrillators. A continuous Holter monitoring tracing is shown. On the top strip, a rapid polymorphic tachycardia is initiated which beats more uniformly. The automatic implantable cardioverter/defibrillator (ICD) senses the rhythm and delivers a shock which restores sinus rhythm.

should be considered for patients with VT that is not hemodynamically tolerated. As mentioned earlier, recent randomized trials suggest that ICDs confer improved mortality over amiodarone in patients with hemodynamically untolerated VT and a cardiac arrest not due to reversible causes (Table 214-9). Finally, they are indicated for patients with depressed left ventricular function, prior myocardial infarction, and nonsustained and sustained VT at electrophysiologic study (Table 214-9). A more recent study has defined a mortality benefit conferred by ICDs in patients with coronary artery disease and severly depressed ventricular function, regardless of the presence of nonsustained VT in electrophysiologic study results. Guidelines for their use are given in Table 214-10.

The most frequent problem with the ICD has been its inappropriate discharge in the absence of sustained ventricular arrhythmias. Additional potential problems include an increase in defibrillation threshold and decrease in tachycardia rates below the rate cut-off of the device in response to many antiarrhythmic drugs. Permanently implanted ventricular pacemakers may interfere with the device's ability to sense VF. This can be avoided by using committed bipolar pacing systems that are better able to sense local ventricular activity. Diagnostic features of newer, all-in-one devices are able to identify the probable cause of an inappropriate ICD discharge (e.g., AF, SVT, fractured lead) and to adjust pharmacologic therapy or reprogram the device to avoid such inappropriate shocks. These newer devices have the capability to take a "second look" prior to shock delivery and thus may abort delivery for self-terminating arrhythmias. In addition, the range of candidates suitable for implantation will be expanded because the newer devices have the capability of shock therapy for patients whose arrhythmias do not cause loss of consciousness.

Newer generations of ICDs are smaller and frequently allow placement of a second lead in the right atrium. This lead senses atrial activity and provides enhanced discrimination of atrial from ventricular electrical activity. This enhanced discrimination of SVT from VT prevents inappropriate shocks for SVT that may be misinterpreted as VT and allows the device to switch from a dual-chamber to a single-chamber device should an SVT-like AF develop. These dual-chamber devices also allow AV sequential pacing.

DEVICES FOR HEART FAILURE MANAGEMENT (See also Chap. 216) The addition of a lead in the coronary sinus to pace the left ventricle at the same time that the right ventricle is being paced is called *cardiac resynchronization*. This technique has proven complementary to standard pharmacologic management of CHF. Resynchronization with biventricular pacing can be instituted with a pacemaker or ICD.

Ablative Therapy for Arrhythmias Catheter-based mapping techniques have provided a nonoperative approach to the identification and cure of a variety of arrhythmias. In fact, catheter ablation techniques are now the procedures of choice for symptomatic patients with (1) concealed or manifest (WPW) bypass tracts; (2) AV nodal reentrant SVT; (3) typical atrial flutter; and (4) poorly controlled ventricular responses to atrial arrhythmias, most commonly AF. Successful ablation of bypass tracts and modifications of the AV node by radiofrequency energy are extremely successful and cost-effective and are the procedure of choice for patients with recurrent episodes. The creation of AV block with implantation of a pacemaker is the method of choice in managing patients with AF and poorly controlled ventricular response. Idiopathic VTs and some VTs that are associated with coronary artery disease are also amenable to ablation, but the result is less successful than for ablation of SVTs.

Surgical therapy is now relegated to cases of sustained VT associated with coronary artery disease when operative intervention is needed for coronary bypass surgery and/or aneurysmectomy or VT associated with specific structural abnormalities [e.g., idiopathic left ventricle aneurysm, status post (s/p) surgery for tetralogy of Fallot]. It may also be undertaken for the unusual instances of failed catheter ablation for SVTs associated with bypass tracts and for AF.

TABLE 214-9 *Trials of ICD Therapy for Primary Prevention of Sudden Cardiac Death*

	MADIT	*MUSTT*	*MADIT II*
Protocol	ICD vs conventional (AAD, primary empirical amiodarone)	EP-guided Rx (AAD, ICD) vs. control	ICD vs. conventional drug therapy (beta blockers), ACD inhibitor

TABLE 214-10 Guidelines for ICD Implantation

CLASS 1[a]	
1. Cardiac arrest due to VF or VT not due to a transient or reversible cause. 2. Spontaneous sustained VT in association with structural heart disease. 3. Syncope of undetermined origin with clinically relevant, hemodynamically significantly sustained VT or VF induced at EP study when drug therapy is ineffective, not tolerated, or not preferred.	4. Nonsustained VT in patients with coronary disease, prior myocardial infarction, LV dysfunction, and inducible VT or sustained VT at electrophysiological study that is not suppressible by a class I antiarrhythmic drug. 5. Spontaneous sustained VT in patients who do not have structured heart disease that is not amenable to other treatments.
CLASS 2[a]	
1. Patients with LV ejection fraction ≤30%, at least 1 month post-MI and 3 months post-coronary artery revascularization.*	
CLASS 2[b]	
1. Cardiac arrest presumed to be due to VF when EP testing is precluded by other medical conditions. 2. Severe symptoms (e.g., syncope) attributable to ventricular tachyarrhythmia in patients awaiting cardiac transplantation. 3. Familial or inherited conditions with a high risk for life-threatening ventricular tachyarrhythmias such as long QT syndrome or hypertrophic cardiomyopathy.	4. Nonsustained VT with coronary artery disease, prior MI, and LV dysfunction, and inducible sustained VT or VF at EP study. 5. Recurrent syncope of undetermined etiology in the presence of ventricular dysfunction and inducible ventricular arrhythmias at EP study, when other causes of syncope have been excluded. 6. Syncope of unexplained etiology or family history of unexplained death in association with typical or atypical right bundle branch block and ST-segment elevations (Brugada syndrome).
CLASS 3[c]	
1. Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. 2. Incessant VT or VF. 3. VF or VT resulting from arrhythmias amenable to surgical or catheter ablation; e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right ventricular outflow tract VT, idiopathic LV tachycardia, or fascicular VT.	4. Ventricular tachyarrhythmias due to a transient or reversible disorder when correction of the disorder is considered feasible and likely to substantially reduce the risk of recurrent arrhythmia.

[a] Evidence and/or agreement that procedure is indicated.
[b] Divergence in evidence opinion that procedure is indicated.
[c] Evidence/agreement that procedure is not indicated or is harmful.
Note: EP, electrophysiology; ICD, implantable cardioverter/defibrillator; LV, left ventricular; MI, myocardial infarction; VF, ventricular fibrillation, VT, ventricular tachycardia.

215 NORMAL AND ABNORMAL MYOCARDIAL FUNCTION

Eugene Braunwald

CELLULAR BASIS OF CARDIAC CONTRACTION

THE CARDIAC ULTRASTRUCTURE

About three-fourths of the ventricular *myocardium* is composed of individual striated muscle cells (myocytes), normally 60 to 140 μm in length and 17 to 25 μm in diameter (Fig. 215-1*A*). Each fiber contains multiple, rodlike cross-banded strands (myofibrils) that run the length of the fiber and are, in turn, composed of serially repeating structures, the sarcomeres. The cytoplasm between the myofibrils contains other cell constituents (Fig. 215-1*B*), such as the single centrally-located nucleus, numerous mitochondria, and the intracellular membrane system, the sarcoplasmic reticulum.

The *sarcomere*, the structural and functional unit of contraction, is delimited by two adjacent dark lines, the Z lines (Fig. 215-1*C*). The distance between Z lines varies with the degree of contraction or stretch of the muscle and ranges between 1.6 and 2.2 μm. Within the confines of the sarcomere are alternating light and dark bands, giving the myocardial fibers their striated appearance under the light microscope. At the center of the sarcomere is a dark band of constant length (1.5 μm), the A band, which is flanked by two lighter bands, the I

bands, which are of variable length. The sarcomere of heart muscle, like that of skeletal muscle, is made up of two sets of interdigitating myofilaments (Fig. 215-1*D*). Thicker filaments, composed principally of the protein myosin, traverse the A band. They are about 10 nm (100 Å) in diameter, with tapered ends, and measure 1.5 to 1.6 μm in length. Thinner filaments, composed primarily of actin, course from the Z line through the I band into the A band. They are approximately 5 nm (50 Å) in diameter and 1.0 μm in length. Thus there is overlapping of thick and thin filaments only within the A band, while the I band contains only thin filaments (Fig. 215-1*C*). On electron-microscopic (EM) examination, bridges may be seen to extend between the thick and thin filaments within the A band.

THE CONTRACTILE PROCESS

The sliding model for muscle contraction rests on the fundamental observation that the thick and thin filaments are constant in overall length during both contraction and relaxation. With activation, the actin filaments are propelled further into the A band. In the process, the A band remains constant in length, whereas the I band shortens and the Z lines move toward one another.

The *myosin* molecule is a complex, asymmetric fibrous protein with a molecular weight of about 500,000; it has a rodlike portion that is about 150 nm (1500 Å) in length with a globular portion at its end (Fig. 215-1*D*). This globular portion of the myosin forms the bridges between the myosin and actin and is the site of ATPase activity. In forming the thick myofilament, which is composed of ~300 longitudinally stacked myosin molecules, the rodlike segments of the myosin molecules are laid down in an orderly, polarized manner, leaving the globular portions projecting outward so that they can interact with actin to generate force and shortening (Fig. 215-2).

Actin has a molecular weight of about 47,000. The thin filament is composed of a double helix of two chains of actin molecules wound about each other on a larger molecule, tropomyosin, which serves as a "backbone" to the thin filament. A group of these regulatory proteins, troponins C, I, and T, are spaced at regular intervals on this filament (Fig. 215-3). In contrast to myosin, actin has no intrinsic enzymatic activity, but it has the ability to combine reversibly with myosin in the presence of ATP and Ca^{2+}. The latter activates the myosin ATPase, which in turn breaks down ATP, the energy source for contraction. In relaxed muscle this interaction is inhibited by tropomyosin. *Titin* (Fig. 215-1*D*) is a large, flexible, myofibrillar protein that connects myosin to the Z line. Its stretching is believed to contribute to the elasticity of the heart.

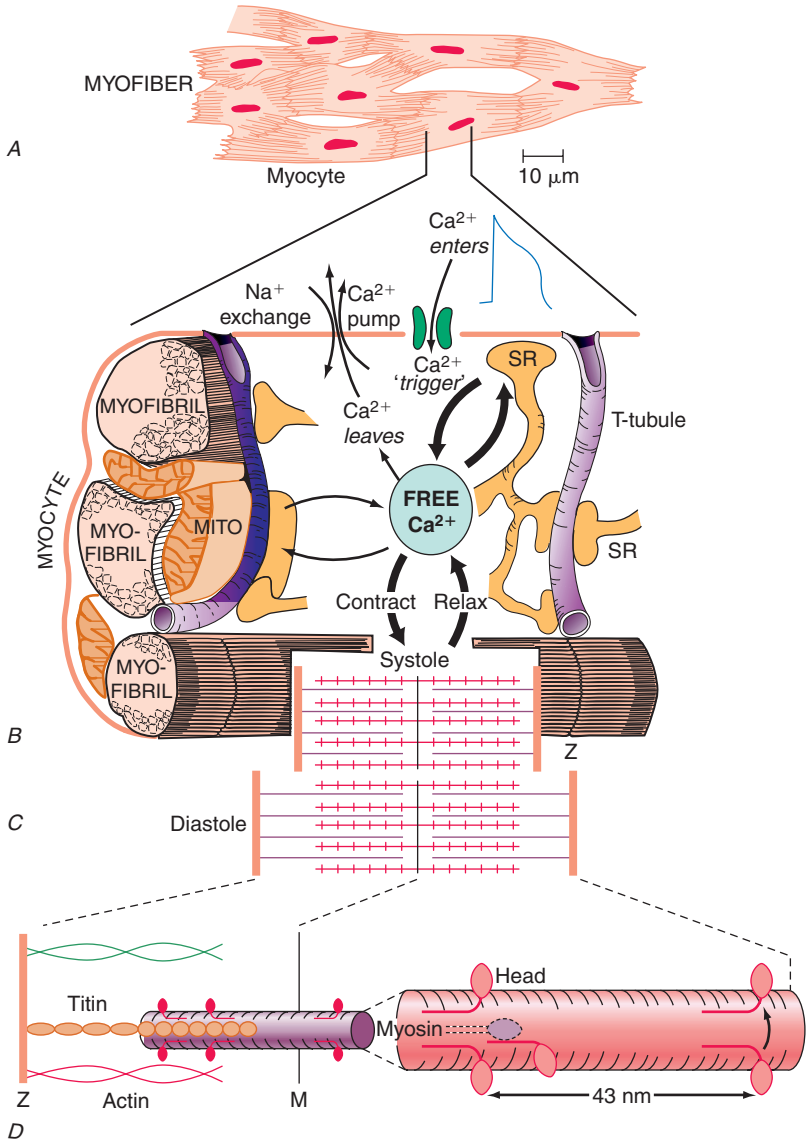

FIGURE 215-1 *A.* Microscopic evidence of heart muscle. *B.* Cardiac contraction and relaxation result from changing concentrations of Ca^{2+} ions in the myocardial cytosol. Ca^{2+} ions are shown schematically as entering via the calcium channel, which opens in response to the wave of depolarization that travels along the sarcolemma. These Ca^{2+} ions "trigger" the release of more calcium from the sarcoplasmic reticulum (SR) and thereby initiate a contraction-relaxation cycle. Eventually, the small amount of calcium that has entered the cell leaves, predominantly by a Na^+-Ca^{2+} exchanger with a lesser role for the sarcolemmal calcium pump. *C.* The varying actin-myosin overlap is shown for systole and diastole. *D.* The myosin heads, attached to the thick filaments, interact with the thin actin filaments. *(Copyright 2001 LH Opie. Reprinted with permission.)*

During activation of the myocyte, Ca^{2+} becomes attached to troponin C, which results in a conformational change in the regulatory protein tropomyosin; the latter in turn exposes the actin cross-bridge interaction sites. Repetitive interaction between myosin heads and actin filaments is termed *cross-bridge cycling*, which results in sliding of the actin along the myosin filaments, ultimately causing muscle shortening and/or the development of tension. The splitting of ATP, which is synthesized in the mitochondria, then dissociates the myosin cross-bridge from the actin. In the presence of ATP (Fig. 215-2), linkages between actin and myosin filaments are made and broken cyclically as long as sufficient Ca^{2+} is present; these linkages cease when $[Ca^{2+}]$ falls below a critical level, and the troponin-tropomyosin complex once more prevents interactions between the myosin cross-bridges and the actin filaments. Intracytoplasmic Ca^{2+} is a principal mediator of the inotropic state of the heart. The fundamental action of most positive inotropic drugs, including the digitalis glycosides, β-adrenergic agonists, and phosphodiesterase inhibitors, is to raise the $[Ca^{2+}]$ in the vicinity of the myofilaments.

The *sarcoplasmic reticulum* (SR) (Fig. 215-1*B*) is a complex network of anastomosing intracellular channels that invests the myofibrils. Its longitudinally disposed membrane-lined tubules are closely applied to the surfaces of individual sarcomeres but have no direct continuity with the outside of the cell. However, closely related to the SR, both structurally and functionally, are the transverse tubules, or T system, formed by tubelike invaginations of the sarcolemma that extend into the myocardial fiber along the Z lines, i.e., the ends of the sarcomeres.

CARDIAC ACTIVATION

In the inactive state, the cardiac cell is polarized, i.e., the interior has a negative charge relative to the outside of the cell, with a transmembrane potential of −80 to −100 mV (Chap. 213). The sarcolemma, which in the resting state is largely impermeable to Na^+, has a Na^+-

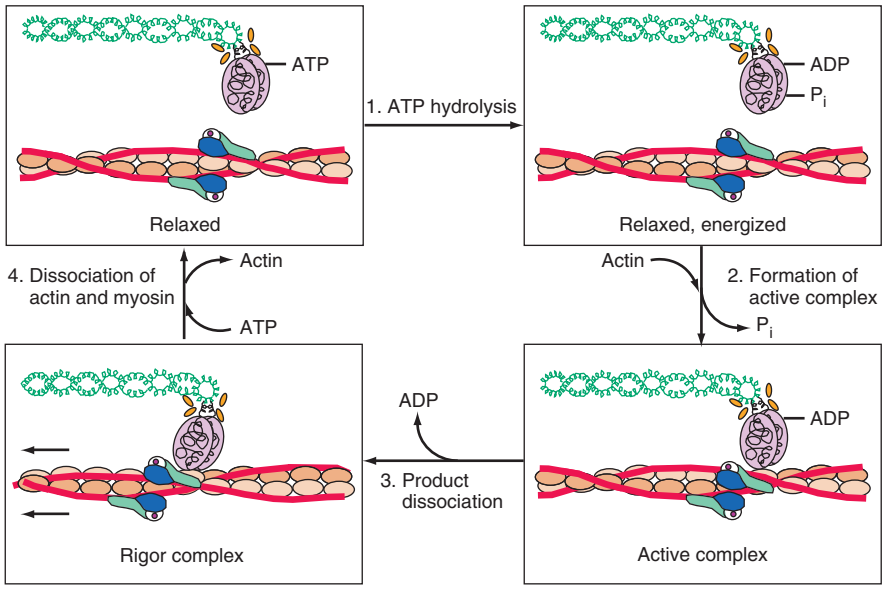

FIGURE 215-2 Four steps in cardiac muscle contraction and relaxation. In relaxed muscle (*upper left*), ATP bound to the myosin cross-bridge dissociates the thick and thin filaments. *Step 1:* Hydrolysis of myosin-bound ATP by the ATPase site on the myosin head transfers the chemical energy of the nucleotide to the activated cross-bridge (*upper right*). When cytosolic Ca^{2+} concentration is low, as in relaxed muscle, the reaction cannot proceed because tropomyosin and the troponin complex on the thin filament do not allow the active sites on actin to interact with the cross-bridges. Therefore, even though the cross-bridges are energized, they cannot interact with actin. *Step 2:* When Ca^{2+} binding to troponin C has exposed active sites on the thin filament, actin interacts with the myosin cross-bridges to form an active complex (lower right) in which the energy derived from ATP is retained in the actin-bound cross-bridge, whose orientation has not yet shifted. *Step 3:* The muscle contracts when ADP dissociates from the cross-bridge; this step leads to the formation of the low-energy rigor complex (lower left), in which the chemical energy derived from ATP hydrolysis has been expended to perform mechanical work (the "rowing" motion of the cross-bridge). *Step 4:* The muscle returns to its resting state, and the cycle ends when a new molecule of ATP binds to the rigor complex and dissociates the cross-bridge from the thin filament. This cycle continues until calcium is dissociated from troponin C in the thin filament, which causes the contractile proteins to return to the resting state with the cross-bridge in the energized state. *[From AM Katz, in WS Colucci (ed): Heart Failure: Cardiac Function and Dysfunction, in Atlas of Heart Diseases, 3d ed, E Braunwald (series ed). Philadelphia, Current Medicine, 2002. Reprinted with permission.]*

and K^+-stimulating pump energized by ATP that extrudes Na^+ from the cell; this pump plays a critical role in establishing the resting potential. Thus, on the inside of the cell $[K^+]$ is relatively high and $[Na^+]$ is far lower, while in the extracellular milieu $[Na^+]$ is high and $[K^+]$ is low. At the same time, in the resting state, the extracellular $[Ca^{2+}]$ greatly exceeds the free intracellular $[Ca^{2+}]$. →***The four phases of the action potential are discussed and illustrated in Chapter 213.***

During the plateau of the action potential (phase 2) there is a slow inward current through L-type Ca^{2+} channels in the sarcolemma (Fig. 215-4). The absolute quantity of Ca^{2+} that crosses the surface membrane is relatively small and itself appears to be insufficient to bring about full activation of the contractile apparatus. The depolarizing current not only extends across the surface of the cell but penetrates deeply into the cell by way of the ramifying T system; this Ca^{2+} current triggers the release of much larger quantities of Ca^{2+} from the SR, a process termed *Ca^{2+}*-induced Ca^{2+} release.

The Ca^{2+} released from the SR then diffuses toward the myofibrils, where, as already described, it combines with troponin C. By repressing this inhibitor of contraction, Ca^{2+} activates the myofilaments to shorten. During repolarization the activity of the Ca^{2+} pump in the SR reaccumulates Ca^{2+} against a concentration gradient, and the Ca^{2+} is stored by its attachment to a protein *calsequestrin*. This is an energy-requiring process that lowers the $[Ca^{2+}]$ in the vicinity of the myofibrils to a level that inhibits the actin-myosin interaction responsible for contraction and in this manner leads to relaxation. Also, there is an exchange of Ca^{2+} for Na^+ at the sarcolemma, reducing the cytoplasmic $[Ca^{2+}]$. Thus, the combination of the cell membrane, transverse tubules, and SR, with their ability to transmit the action potential, to release, and then to reaccumulate Ca^{2+}, appears to play a fundamental role in the rhythmic contraction and relaxation of heart muscle.

The ATP formed from substrate oxidation is the principal source of energy for almost all of the mechanical work of contraction performed by the myocardial cell. The high-energy phosphate stores in ATP are in equilibrium with those in creatine phosphate. The activity of myosin ATPase determines the rate of forming and breaking of the actin-myosin cross-bridges and ultimately the velocity of muscle contraction.

THE ROLE OF MUSCLE LENGTH

In cardiac muscle, indeed in all striated muscle, the force of contraction depends on initial muscle length. The sarcomere length associated with the most forceful contraction is approximately 2.2 μm. At this length the two sets of myofilaments of the sarcomere are configured so as to provide the greatest area for their interaction (Fig. 215-1). The length of the sarcomere also regulates the extent of activation of the contractile system, i.e., its sensitivity to Ca^{2+}. According to this concept, termed *length-dependent activation*, at the optimal sarcomere length of 2.2 μm, the myofilament sensitivity to Ca^{2+} is also maximal.

The relation between the initial length of the muscle fibers and the developed force is of prime importance for the function of heart muscle. This forms the basis of the Frank-Starling relation (Starling's law of the heart), which states that, within limits, the force of ventricular contraction is a function of the end-diastolic length of the cardiac muscle; in the intact heart the latter is closely related to the ventricular end-diastolic volume.

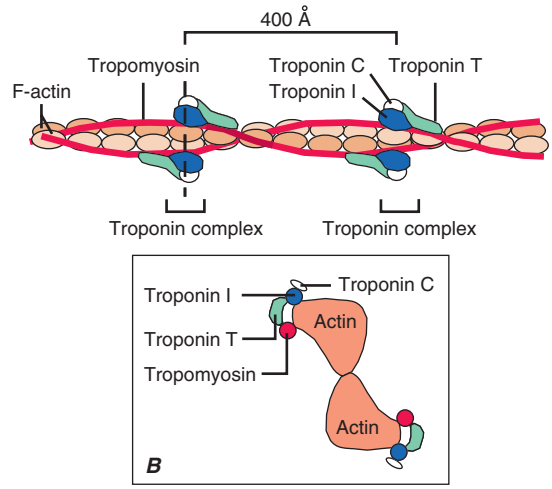

FIGURE 215-3 Structure of the thin filament. *A.* The "backbone" of the thin filament, seen in a longitudinal view, is F-actin, which contains two strands of actin monomers (blue and white). Troponin complexes, made up of one molecule each of troponin C, troponin I, and troponin T, are distributed at approximately 40 nm (400 Å) intervals along the thin filament. Elongated tropomyosin molecules (solid line in the grooves between the two actin strands). *B.* A cross-section of the thin filament at the level where the troponin complexes are located shows probable relationships between actin, tropomyosin, and the three components of the troponin complex. The strength of the bond linking troponin I and actin varies, depending on whether Ca^{2+} is bound to troponin C. *[Adapted from AM Katz, Molecular and cellular basis of contraction, in WS Colucci (ed): Heart Failure: Cardiac Function and Dysfunction, in Atlas of Heart Diseases, 3d ed, E Braunwald (series ed). Philadelphia, Current Medicine, 2002. Reprinted with permission.]*

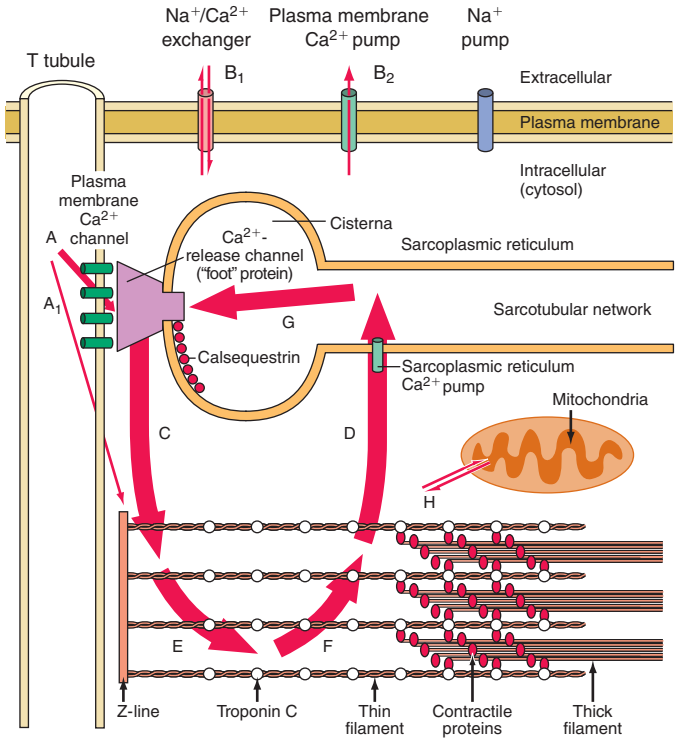

FIGURE 215-4 The Ca^{2+} fluxes and key structures involved in cardiac excitation-contraction coupling. The *arrows* denote the direction of Ca^{2+} fluxes. The thickness of each arrow indicates the magnitude of the calcium flux. Two Ca^{2+} cycles regulate excitation-contraction coupling and relaxation. The larger cycle is entirely intracellular and involves Ca^{2+} fluxes into and out of the sarcoplasmic reticulum, and Ca^{2+} binding to and release from troponin C. The smaller extracellular Ca^{2+} cycle occurs when this cation moves into and out of the cell. The action potential opens plasma membrane Ca^{2+} channels to allow passive entry of Ca^{2+} into the cell from the extracellular fluid (*arrow A*). Only a small portion of the Ca^{2+} that enters the cell directly activates the contractile proteins (*arrow* A_1). The extracellular cycle is completed when Ca^{2+} is actively transported back out to the extracellular fluid by way of two plasma membrane fluxes mediated by the sodium-calcium exchanger (*arrow* B_1) and the plasma membrane calcium pump (*arrow* B_2). In the intracellular Ca^{2+} cycle, passive Ca^{2+} release occurs through channels in the cisternae (*arrow C*) and initiates contraction, and active Ca^{2+} uptake by the Ca^{2+} pump of the sarcotubular network (*arrow D*) relaxes the heart. Diffusion of Ca^{2+} within the sarcoplasmic reticulum (*arrow G*) returns this activator cation to the cisternae, where it is stored in a complex with calsequestrin and other calcium-binding proteins. Ca^{2+} released from the sarcoplasmic reticulum initiates systole when it binds to troponin C (*arrow E*). Lowering of cytosolic $[Ca^{2+}]$ by the SR cause this ion to dissociate from troponin (*arrow F*) and relaxes the heart. Ca^{2+} may also move between mitochondria and cytoplasm (H). *(Adapted from Katz, with permission.)*

MYOCARDIAL MECHANICS AND CARDIAC FUNCTION

THE FORCE-VELOCITY CURVE

The mechanical activity of cardiac muscle may be expressed externally in two ways: shortening and tension development. In both skeletal and cardiac muscle the velocity of shortening is inversely related to the development of tension, an expression of the so-called force-velocity relation. Expressed simply, the greater the load the muscle is called upon to lift, the lower its velocity (and extent) of shortening, and vice versa. However, the contractile activity of cardiac muscle is readily altered under physiologic conditions by changes in resting fiber length and by changes in the contractility, both of which shift the myocardial force-velocity curve.

VENTRICULAR EJECTION

Analysis of the heart as a pump has classically centered on the relation between the end-diastolic volume of the ventricle (which is related to the length of the muscle fibers) and its stroke volume (the Frank-Starling relation). The end-diastolic or "filling" pressure of the ventricle is sometimes used as a surrogate for the end-diastolic volume. In the heart-lung preparation the stroke volume varies directly with the diastolic fiber length (preload) and inversely with the arterial resistance (afterload), and as the heart fails it delivers a progressively smaller stroke volume from a normal or even elevated end-diastolic volume. The relation between the ventricular end-diastolic pressure and the stroke work of the ventricle (the ventricular function curve) provides a useful definition of the level of *contractility* of the intact heart. An increase in ventricular contractility is accompanied by a shift of the ventricular function curve upward and to the left [greater stroke work at any level of ventricular end-diastolic pressure (or volume), or lower end-diastolic pressure at any level of stroke work], while depression of contractility is characterized by a shift downward and to the right (Fig. 215-5).

Increased impulse traffic in the cardiac adrenergic nerves stimulates ventricular function as a consequence of the release of norepinephrine from adrenergic nerve endings in the heart. Norepinephrine activates myocardial β receptors and through the Gs-stimulated guanine nucleotide binding protein activates the enzyme adenylate cyclase, which leads to the formation of the intracellular second messenger cyclic AMP from ATP (Fig. 215-6). Cyclic AMP, in turn, activates protein kinase, which causes a more rapid, forceful contraction by phosphorylating the Ca^{2+} channel in the myocardial sarcolemma, thereby enhancing the influx of Ca^{2+} into the myocyte. Ca^{2+} acts on the contractile apparatus, as described on p. 1359. Cyclic AMP also phosphorylates the SR protein phospholamban, which increases the uptake of Ca^{2+} by the SR, increasing the rate of relaxation and providing larger quantities of Ca^{2+} in the SR to be released by subsequent depolarization and thereby further stimulating contraction. Adrenergic activation is evidenced by tachycardia, increased rates of ejection and filling, and a reduction in cardiac dimensions.

ASSESSMENT OF CARDIAC FUNCTION

Several techniques are available for defining impaired cardiac function. The cardiac output and stroke volume may be depressed in the presence of heart failure (HF), but not uncommonly these variables are within normal limits. A more sensitive index is the ejection fraction, i.e., the ratio of stroke volume to end-diastolic volume (normal

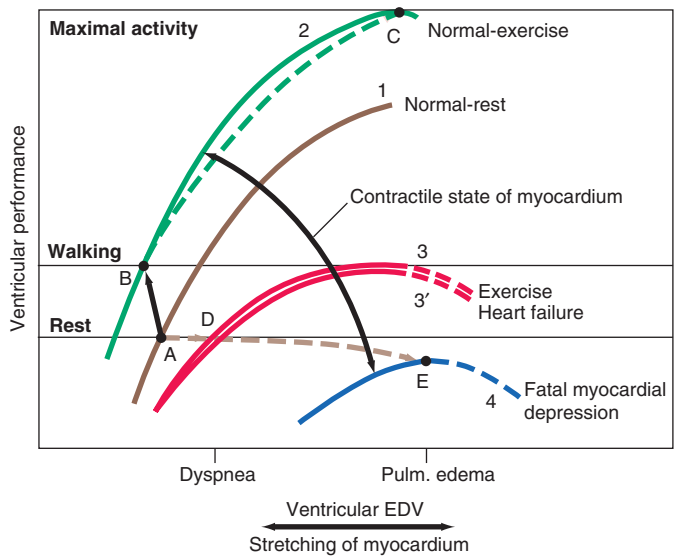

FIGURE 215-5 Diagram showing the interrelations among influences on ventricular end-diastolic volume (EDV) through stretching of the myocardium and the contractile state of the myocardium. Levels of ventricular EDV associated with filling pressures that result in dyspnea and pulmonary edema are shown on the abscissa. Levels of ventricular performance required when the subject is at rest, while walking, and during maximal activity are designated on the ordinate. The broken lines are the descending limbs of the ventricular-performance curves, which are rarely seen during life but which show the level of ventricular performance if end-diastolic volume could be elevated to very high levels. For further explanation see text. *(Modified from E Braunwald et al: Mechanisms of Contraction of the Normal and Failing Heart. Boston, Little, Brown, 1976.)*

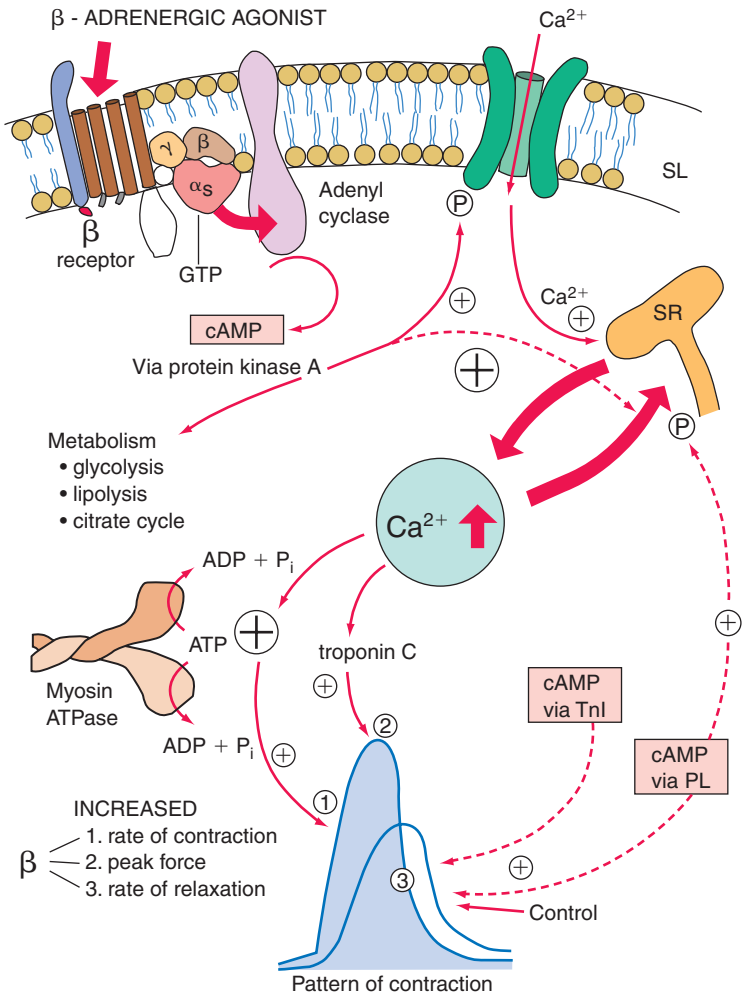

FIGURE 215-6 Signal systems involved in positive intropic and lusitropic (enhanced relaxation) effects of β-adrenergic stimulation. When the β-adrenergic agonist interacts with the β receptor, a series of G protein-mediated changes leads to activation of adenylate cyclase and formation of cyclic AMP (cAMP). The latter acts via protein kinase A to stimulate metabolism (left) and to phosphorylate the Ca^{2+} channel protein (right). The result is an enhanced opening probability of the Ca^{2+} channel, thereby increasing the inward movement of Ca^{2+} ions through the sarcolemma (SL) of the T tubule. These Ca^{2+} ions release more calcium from the sarcoplasmic reticulum (SR) to increase cytosolic Ca^{2+} and to activate troponin C. Ca^{2+} ions also increase the rate of breakdown of ATP to ADP and inorganic phosphate (P_i). Enhanced myosin ATPase activity explains the increased rate of contraction, with increased activation of troponin C explaining increased peak force development. An increased rate of relaxation is explained because cyclic AMP also activates the protein phospholamban, situated on the membrane of the SR, that controls the rate of uptake of calcium into the SR. The latter effect explains enhanced relaxation (lusitropic effect). P, phosphorylation; PL, phospholamban; SL, sarcolemma; SR, sarcoplasmic reticulum; TnI, troponin I. *(Copyright 2001, L Opie. Reprinted with permission.)*

value = 67 ± 8%), which may be estimated by radiocontrast or radionuclide angiography or echocardiography, and it is frequently depressed in systolic heart failure even when the stroke volume itself is normal. Alternatively, the abnormally elevated ventricular end-diastolic volume (normal value = 75 ± 20 mL/m^2) or end-systolic volume (normal value = 25 ± 7 mL/m^2) signify impairment of left ventricular systolic function. A limitation of measuring cardiac output, ejection fraction, and ventricular volumes is that these variables are influenced strongly by ventricular loading conditions. Thus, a depressed ejection fraction and lowered cardiac output may be observed in patients with normal ventricular function but reduced preload, as occurs in hypovolemia, or with increased afterload, as occurs in acutely elevated arterial pressure.

Noninvasive techniques, particularly echocardiography and radionuclide angiography (Chap. 211), are of great value in the clinical assessment of myocardial function. They provide measurements of end-diastolic and end-systolic volumes, global ejection fraction, and systolic shortening rate and they allow assessment of ventricular filling (see below), as well as regional contraction and relaxation. The latter measurements are particularly important in ischemic heart disease which usually causes regional myocardial damage.

The end-systolic left ventricular pressure-volume relationship is a particularly useful index of ventricular performance since it is independent of both preload and afterload (Fig. 215-7). At any level of myocardial contractility, left ventricular end-systolic volume varies inversely with end-systolic pressure; as contractility declines, end-systolic volume (at any level of end-systolic pressure) rises.

EXERCISE A useful technique for evaluating ventricular performance involves the measurement of the circulatory changes that occur during exercise. In persons with normal cardiac function, the cardiac output rises by more than 500 mL/min for each 100 mL increase in O_2 consumption per minute. The left ventricular end-diastolic pressure at rest is less than 12 mmHg and usually changes little during exercise. The failing left ventricle, on the other hand, is characterized by an elevation of end-diastolic pressure during exercise to above 12 mmHg, accompanied by a subnormal increase in cardiac output related to the increase in minute O_2 consumption. The overall performance of the cardiopulmonary system in delivering oxygen to the metabolizing tissue can also be estimated by measuring the maximal O_2 consumption achieved during escalating treadmill exercise ($\dot{V}_{maxO_2}$). Normal values exceed 20 mL/min per kg, while values under 10 mL/min per kg represent severe impairment of function, usually seen in patients with severe heart failure and a poor prognosis.

The potential value of stressing the left ventricle to assess its performance is emphasized by the fact that the normal ranges of left ventricular end-diastolic pressure, cardiac index, and ventricular stroke work in the resting state are wide, with values that frequently overlap those seen in patients with ventricular dysfunction.

DIASTOLIC FUNCTION (Fig. 215-8)

This important variable is best assessed by continuously measuring the flow velocity across the mitral valve using Doppler echocardiography. Normally, the velocity of inflow is more rapid in early diastole than during atrial systole; with impaired relaxation the rate of early diastolic filling declines, while the rate of presystolic filling rises. With severe impairment of filling the pattern is "pseudo-normalized" and early ventricular filling becomes more rapid as left atrial pressure upstream to the stiff left ventricle rises (Fig. 211-4).

CONTROL OF CARDIAC PERFORMANCE AND OUTPUT

The extent of shortening of heart muscle and, therefore, the stroke volume of the intact ventricle are determined by three major influences: (1) the length of the muscle at the onset of contraction, i.e., the preload; (2) the contractility of the muscle, i.e., the position of its force-velocity-length relation; and (3) the tension that the muscle is called upon to develop during contraction, i.e., the afterload. Ventricular filling is influenced by the extent and speed of myocardial relaxation, which in turn is determined by the rate of uptake of Ca^{2+} by the SR; the latter may be enhanced by adrenergic activation and reduced by ischemia. Filling may also be impeded by the stiffness of the ventricular wall, which may be increased by ventricular hypertrophy and conditions that infiltrate the ventricle, such as amyloid, or by an extrinsic constraint (e.g., pericardial compression) (Fig. 215-8).

VENTRICULAR END-DIASTOLIC VOLUME (PRELOAD)

At any level of contractility, the performance of the myocardium is influenced profoundly by ventricular end-diastolic fiber length and therefore by diastolic ventricular volume, i.e., by operation of the

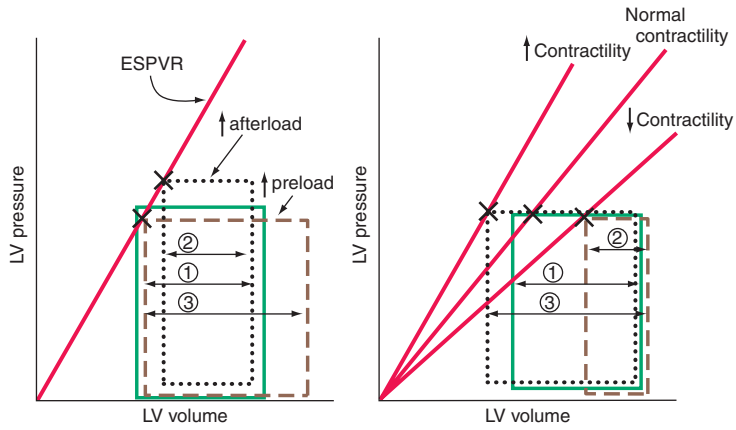

FIGURE 215-7 The responses of the left ventricle to increased afterload, increased preload, and increased and reduced contractility are shown in the pressure-volume plane. ESPVR, end-systolic pressure-volume relation; E_{ES}, the slope of the end-systolic pressure-volume relation. *Left*. Effects of increases in preload and afterload on the pressure-volume loop. Since there has been no change in contractility, ESPVR is unchanged. With an increase in afterload, stroke volume falls (1 ⟶ 2); with an increase in preload, stroke volume rises (1 ⟶ 3). *Right*. With increased myocardial contractility, the normal ESPVR moves to the left of the normal line (lower end-systolic volume at any end-systolic pressure) and stroke volume rises (1 ⟶ 3). With reduced myocardial contractility, the ESPVR moves to the right; end-systolic volume is increased and stroke volume falls (1 ⟶ 2).

Frank-Starling mechanism (Fig. 215-5). The following are the major determinants of ventricular preload in the intact organism:

TOTAL BLOOD VOLUME When blood volume is depleted, as in hemorrhage or dehydration (Chap. 253), venous return to the heart declines and ventricular end-diastolic volume (preload) falls, as does ventricular performance, as reflected in stroke volume, cardiac output, and ventricular work.

DISTRIBUTION OF BLOOD VOLUME The ventricular end-diastolic volume is influenced by the distribution of blood volume between the intra- and extrathoracic compartments. This distribution in turn is influenced by the following:

1. *Body position*. Gravitational forces pool blood in dependent portions of the body; upright posture augments extrathoracic at the expense of intrathoracic blood volume and reduces ventricular work.
2. *Intrathoracic pressure*. Normally, mean intrathoracic pressure is negative, which increases thoracic blood volume and enhances the return of blood to the heart, particularly when this pressure becomes more negative during inspiration. Elevation of intrathoracic pressure, as occurs during the Valsalva maneuver, prolonged bouts of coughing, or positive-pressure ventilation, has the opposite effect.
3. *Intrapericardial pressure*. When this pressure is elevated, as in pericardial tamponade (Chap. 222), there is interference with cardiac filling, and the resultant reduction in ventricular diastolic volume reduces stroke volume and ventricular work.
4. *Venous tone*. The venous system is not a simple system of passive conduits between the systemic capillary bed and the right atrium. Instead, the smooth muscle in the walls of the venules and veins responds to a variety of neural and humoral stimuli. Venoconstriction occurs during muscular exercise, deep respiration, fright, or hypovolemic shock, enhancing venous return to the heart and thereby effecting ventricular performance.
5. *The pumping action of skeletal muscle*. During muscular exercise the contracting skeletal muscles squeeze blood out of the venous bed and, with the aid of the venous valves, displace it centrally, thereby increasing intrathoracic blood volume, ventricular end-diastolic volume, and ventricular work.

ATRIAL CONTRACTION Vigorous, appropriately-timed atrial contraction augments ventricular filling and end-diastolic volume. The atrial contribution to ventricular filling, the so-called "atrial kick," is of particular importance in patients with concentric ventricular hypertrophy. In such patients, the loss of atrial systole (as occurs with the development of atrial fibrillation) reduces ventricular end-diastolic pressure and volume, ultimately lowering myocardial performance.

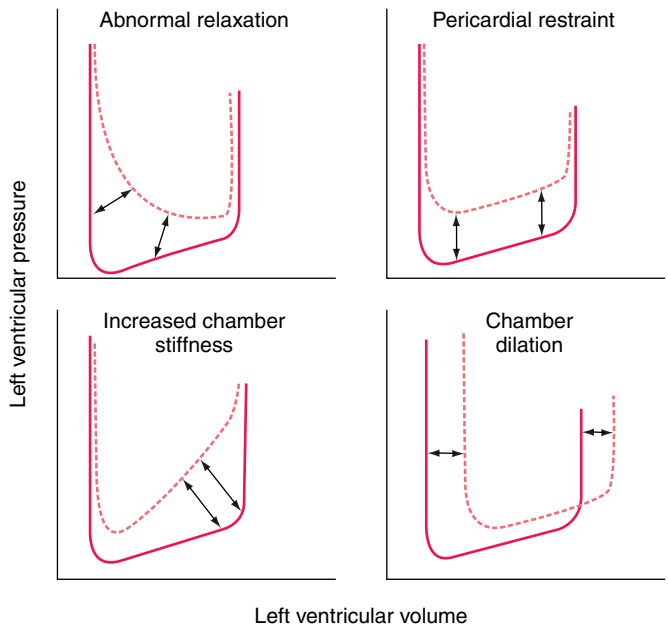

FIGURE 215-8 Mechanisms that cause diastolic dysfunction reflected in the pressure-volume relation. The bottom half of the pressure-volume loop is depicted. Solid lines represent normal subjects; dashed lines represent patients with diastolic dysfunction. *(From MR Zile: Diastolic dysfunction: detection, consequences, and treatment: II. Diagnosis and treatment of diastolic function. Mod Concepts Cardiovasc Dis 59:1, 1990. Reprinted with permission.)*

MYOCARDIAL CONTRACTILITY

A number of factors determine the level of ventricular performance at any given ventricular end-diastolic volume, i.e., the position of the ventricular function curve (Fig. 215-5) as well as the position of the left ventricular end-systolic pressure-volume relation (Fig. 215-7). These influences may be considered to operate by modifying myocardial force-velocity relations. In the final analysis, most of these influences act by altering the $[Ca^{2+}]$ in the vicinity of the myofilaments, which in turn trigger cross-bridge cycling (p. 1359).

ADRENERGIC NERVE ACTIVITY The quantity of norepinephrine released by adrenergic nerve endings in the heart is determined by the adrenergic nerve impulse traffic; norepinephrine acts on the β-adrenergic receptors in the myocardium. This mechanism is the most important one that acutely modifies myocardial contractility under physiologic conditions.

CIRCULATING CATECHOLAMINES When it is stimulated by adrenergic nerve impulses, the adrenal medulla releases catecholamines, which augment both heart rate and myocardial contractility when they reach the heart.

FORCE-FREQUENCY RELATION Myocardial contractility is also influenced by the rate and rhythm of cardiac contraction. The contractility of the normal (but to a lesser extent the failing) heart is augmented by an increase in frequency of contraction, and ventricular extrasystoles result in post-extrasystolic potentiation, presumably by increasing the quantity of Ca^{2+} that enters the cardiac cell.

EXOGENOUSLY ADMINISTERED INOTROPIC AGENTS Isoproterenol, dopamine, dobutamine, and other sympathomimetic agents, cardiac glycosides, Ca^{2+}, and the phosphodiesterase inhibitors amrinone and milrinone all

improve the contractility and therefore may be used to stimulate ventricular performance.

PHYSIOLOGIC DEPRESSANTS Included among these are severe myocardial hypoxia, ischemia, and acidosis. Acting either singly or in combination, these conditions depress myocardial contractility and left ventricular work at any given ventricular end-diastolic volume.

PHARMACOLOGIC DEPRESSANTS These include many antiarrhythmic drugs such as procainamide and disopyramide; calcium antagonists such as verapamil; β-adrenergic blockers; and large doses of barbiturates, alcohol, and general anesthetics as well as many other drugs.

MYOCARDIAL DEPRESSION Although the fundamental mechanisms responsible for depression of myocardial contractility in most cases of chronic congestive heart failure secondary to prolonged ventricular overload or cardiomyopathy remain to be elucidated it is now apparent that in this condition the inotropic state of individual myocytes is depressed, and as a consequence the ventricular performance at any ventricular preload and afterload is lowered.

VENTRICULAR AFTERLOAD

The stroke volume is ultimately a function of the extent of ventricular fiber shortening. In the intact heart, as in isolated cardiac muscle, the extent (and velocity) of shortening of ventricular muscle fibers at any level of preload and of myocardial contractility are inversely related to the afterload, i.e., the load that opposes shortening. In the intact heart the afterload may be defined as the tension or stress developed in the ventricular wall during ejection. It is determined by the aortic pressure as well as by the volume and thickness of the ventricular cavity. Laplace's law indicates that the tension of the myocardial fiber is a function of the product of the intracavitary ventricular pressure and ventricular radius divided by the wall thickness. Therefore, at any given level of aortic pressure, the afterload on a dilated left ventricle of normal thickness is higher than that on a normal-sized ventricle. Conversely, at the same aortic pressure and ventricular diastolic volume, the afterload of a hypertrophied ventricle is lower than of a normal chamber. The aortic pressure, in turn, is determined by the peripheral vascular resistance, the physical characteristics of the arterial tree, and the volume of blood it contains at the onset of ejection.

The critical role played by the ventricular afterload in cardiovascular regulation is shown in Fig. 215-9. As already noted, elevations of both preload and contractility increase myocardial fiber shortening, while increases in afterload reduce it. The extent of myocardial fiber shortening and left ventricular size are the determinants of stroke volume. Arterial pressure, in turn, is related to the product of cardiac output and systemic vascular resistance, while afterload is a function of left ventricular volume, wall thickness, and arterial pressure. An increase in arterial pressure induced by vasoconstriction, for example, augments afterload, which opposes myocardial fiber shortening, reducing stroke volume. This in turn tends to limit the increase in pressure.

When myocardial contractility becomes impaired and the ventricle dilates, afterload rises and limits cardiac output. Increased afterload may result from neural and humoral stimuli that occur in response to a fall in cardiac output. This increased afterload may reduce cardiac output further while increasing myocardial O_2 requirements, and can initiate a vicious circle in patients with ischemic heart disease and limited myocardial O_2 supply. Treatment with vasodilators has the opposite effect; by reducing afterload, cardiac output rises (Chap. 216).

Under normal circumstances, the various influences acting on cardiac performance enumerated above interact in a complex fashion to maintain cardiac output at a level appropriate to the requirements of the metabolizing tissues; interference with a single mechanism may not influence the cardiac output. For example, a moderate reduction of blood volume or the loss of the atrial contribution to ventricular contraction can ordinarily be sustained without a reduction in the cardiac output at rest. Under these circumstances, other factors, such as increases in the frequency of adrenergic nerve impulses to the heart, in heart rate, and in venous tone will, in a normal individual, serve as compensatory mechanisms and sustain cardiac output.

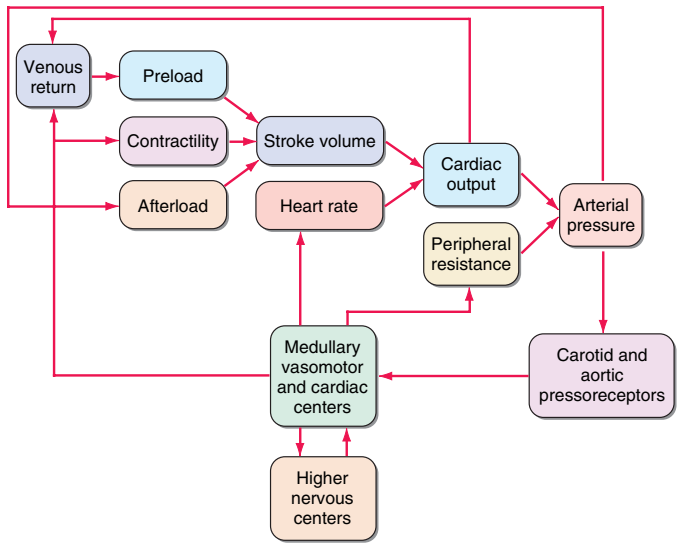

FIGURE 215-9 Interactions in the intact circulation of preload, contractility and afterload in producing stroke volume. Stroke volume combined with heart rate determines cardiac output, which, in turn, when combined with peripheral vascular resistance, determines arterial pressure for tissue perfusion. The characteristics of the arterial system also contribute to afterload, an increase of which reduces stroke volume. The interaction of these components with carotid and aortic arch baroreceptors provides a feedback mechanism to higher medullary and vasomotor cardiac centers and to higher levels in the central nervous system to affect a modulating influence on heart rate, peripheral vascular resistance, venous return, and contractility. *[From MR Starling: Physiology of myocardial contraction, in WS Colucci and E Braunwald (eds). Atlas of Heart Failure: Cardiac Function and Dysfunction, 3d ed, Philadelphia: Current Medicine, 2002, pp 19–35. EXERCISE

Hyperventilation, the pumping action of the exercising muscles, and venoconstriction during exercise all augment venous return and hence ventricular filling and preload (Fig. 215-5). Simultaneously, the increase in the adrenergic nerve impulse traffic to the myocardium, the increased concentration of circulating catecholamines, and the tachycardia that occur during exercise combine to augment the contractility of the myocardium (Fig. 215-5, curves 1 and 2) and lead to an elevation of stroke work and stroke volume, without change or even a reduction of end-diastolic pressure and volume (Fig. 215-5, points A and B). Vasodilatation occurs in the exercising muscles, thus tending to limit the increase in arterial pressure that would otherwise occur as cardiac output rises to levels as high as five times greater than basal during maximal exercise. This vasodilatation ultimately allows the achievement of a greatly elevated cardiac output during exercise, at an arterial pressure (afterload) only moderately higher than in the resting state.

THE FAILING HEART

Although heart failure (HF) may be readily described as a clinical syndrome, characterized by well-known symptoms and physical signs (Chap. 216), a precise physiologic or biochemical definition is far more difficult. However, from the clinical point of view, HF may be considered to be the condition in which *an abnormality of cardiac structure or function is responsible for the inability of the heart to fill with or eject blood at a rate commensurate with the requirements of the metabolizing tissues*.

Abnormalities during systole and/or diastole may be present in HF. In so-called *systolic heart failure* (p. 1369), an impairment of myocardial contractility causes weakened systolic contraction, which leads,

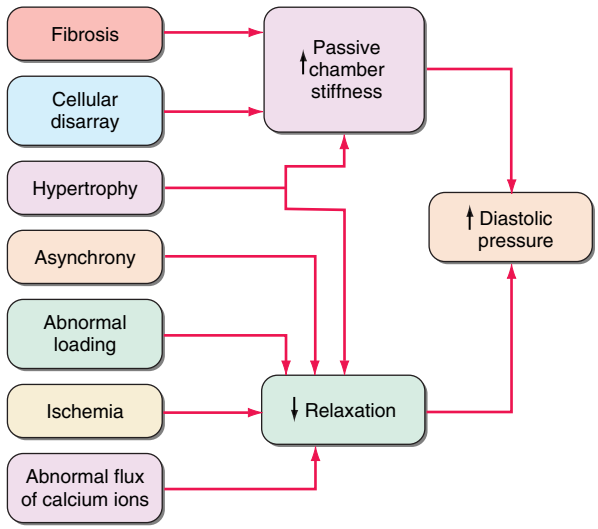

FIGURE 215-10 Mechanisms responsible for diastolic dysfunction in hypertrophic and ischemic heart disease. These factors, alone or in combination, contribute to the increased left ventricular chamber stiffness and impaired myocardial relaxation. As a result, left ventricular diastolic pressures are increased and filling is impaired. *[From WH Gaasch, EC Schick: Heart failure with normal left ventricular ejection fraction: A manifestation of diastolic dysfunction, in MH Crawford et al (eds). Cardiology. London, Mosby, 2001, pp 6.1–6.8. Reprinted with permission.]*

ultimately, to a reduction in stroke volume and cardiac output, inadequate ventricular emptying, cardiac dilatation, and often elevation of ventricular diastolic pressure. Idiopathic dilated cardiomyopathy (Chap. 221) and cardiogenic shock secondary to acute myocardial infarction (Chap. 255) are the prototypes of chronic and acute systolic HF, respectively.

In *diastolic heart failure* (p. 1369), the principal abnormality is impaired relaxation and filling of the ventricle, which leads to an elevation of ventricular diastolic pressure at any given diastolic volume (Fig. 215-8). Failure of relaxation can be functional and transient, as during ischemia, which reduces the ATP required for the SR pump to lower cytoplasmic [Ca^{2+}]. Chronically impaired ventricular filling can be caused by a stiffened, thickened ventricle and a number of conditions illustrated in Fig. 215-10. Typical conditions in which diastolic HF occurs are restrictive cardiomyopathy secondary to infiltrative conditions, such as amyloidosis or hemochromatosis, and hypertrophic cardiomyopathy (Chap. 221). The concentric hypertrophy associated with chronic hypertension can also impair ventricular filling. In many patients with cardiac hypertrophy and dilatation, systolic and diastolic HF coexist; the left ventricle both empties and fills abnormally.

MECHANISMS OF HEART FAILURE

ADAPTIVE AND MALADAPTIVE MECHANISMS

A number of mechanisms aid the heart faced with an increased hemodynamic burden (such as pressure or volume overload) or one that has sustained loss of myocardium or contractility. On a short-term basis many of these responses are adaptive (beneficial). However, on a long-term basis these responses are often maladaptive (deleterious) (Table 215-1).

1. The *Frank-Starling mechanism* operates through an increase in preload (p. 1361). As outlined above, an increase in the end-diastolic volume of the ventricle is associated with stretching of the sarcomeres, which increases the interaction between actin and myosin filaments and their sensitivity to Ca^{2+}, thereby enhancing contraction. However, ventricular dilatation may become maladaptive when it becomes excessive, as may occur in severe valvular regurgitation, dilatation increases wall stress through the operation of Laplace's law and thereby reduces shortening.
2. *Compensatory hypertrophy* occurs in hemodynamic overload, which in turn restores elevated ventricular wall stress to normal (Fig. 216-1). If the hypertrophy is insufficient to restore wall stress to normal, the ventricle dilates and this increases wall stress further, leading to a vicious circle. Also, severe ventricular hypertrophy may impair ventricular filling and cause myocardial ischemia.
3. In *ventricular remodeling* there are changes in the size, mass, and configuration of the ventricle as a consequence of hemodynamic changes following mechanical overload, hypertension, cardiomyopathy, and myocardial infarction. Remodeling is triggered by myocyte growth, interstitial fibrosis and apoptosis (Table 215-2), ischemia, vasoactive peptides, and fibrosis. A change to a more spherical shape, which decreases the effectiveness of ejection, is common in the remodeled ventricle.
4. *Redistribution of a subnormal cardiac output* away from the skin, skeletal muscle, and kidneys with maintenance of blood flow to the most vital organs, i.e., the brain and the heart, occurs. The vasoconstriction, however, may increase afterload, thereby reducing cardiac output further.

REDUCTION IN CARDIAC EFFICIENCY The common forms of low-output systolic HF, secondary to coronary atherosclerosis, hypertension, cardiomyopathy, and certain valvular and congenital lesions, are characterized by a reduction in the external work performed by the heart, while myocardial oxygen consumption remains normal or nearly so. Therefore, the external efficiency, i.e., the ratio of external work performed to energy consumed, is often depressed.

ALTERATIONS IN ENERGY METABOLISM When HF occurs in the presence of acute or chronic ischemia, it can be attributed to reduced supply of oxygen with a resultant reduction of ATP generation. Severe ventricular hypertrophy and/or dilatation from any etiology can contribute to ischemia, especially in the subendocardium, and this can impair both ventricular contraction and filling. In some forms of HF without ischemia, myocardial energy stores in the form of creatine phosphate are decreased, as is the activity of the enzyme creatine kinase required for the shuttling of high-energy phosphate between creatine phosphate and ADP, suggesting that reductions in myocardial energy reserves may play a role in nonischemic conditions as well.

ALTERATIONS IN SARCOMERIC PROTEINS Hemodynamic overload, neurohormonal and/or cytokine stimulation and gene mutations in familial cardiomyopathies may all reinduce the expression of fetal sarcomeric

TABLE 215-1 *Short-Term and Long-Term Responses to Impaired Cardiac Performance*

Response	*Short-term Effects (mainly adaptive; hemorrhage, acute heart failure)*	*Long-term Effects (mainly deleterious; chronic heart failure)*
Salt and water retention	Augments preload	Pulmonary congestion, anasarca
Vasoconstriction	Maintains pressure for perfusion of vital organs (brain, heart)	Exacerbates pump dysfunction, increases cardiac energy expenditure
Sympathetic stimulation	Increases heart rate and ejection	Increases energy expenditure
Cytokine activation	Vasodilatation	Skeletal muscle catabolism, deterioration of endothelial function, impaired contraction, LV remodeling.
Hypertrophy	Unloads individual muscle fibers	Deterioration and death of cardiac cells: cardiomyopathy of overload
Increased collagen	May reduce dilatation	Impairs relaxation

LV, left venticle.

TABLE 215-2 *Factors that Lead to the Progressive Remodeling of the Left Ventricle*

Mechanism of Progressive Remodeling and Heart Failure			
Cell Growth	*Fibrosis*	*Apoptosis*	*Counter-regulatory Factors*
Angiotensin II	Angiotensin II	TNF-α	ANP
Catecholamines	Endothelin	*Fas* ligand	Bradykinin
Endothelin	Aldosterone		Nitric oxide
TNF-α	TGF-β		BNP
Growth hormone			
IGF			
Cardiotrophin-1			
Mechanical stretch			

Growth of cardiac myocytes is a primary feature and is due to a number of growth factors, including neurohormones and cytokines as well as mechanical stretch. Fibrosis is promoted by activation of the renin-angiotensin-aldosterone axis and through activation of endothelin and TGF-β. Apoptosis regulation is altered via changes in the expression of *p53*, *Bcl-2*, and *Bax* genes, perhaps as a consequence of increases in TNF-α acting to stimulate the *Fas* ligand. Programmed cell death is enhanced, producing cell drop-out. Counter-regulatory forces, including atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) are activated. Nitric oxide, driven by bradykinin and ANP, may have antigrowth properties and hold uncontrolled growth in check to some extent; however, on balance, cardiac myocytes elongate, which contributes to left ventricular remodeling. IGF, insulin-like growth factor.

proteins whose contractility is depressed. It has been postulated that these alterations in sarcomeric proteins cause systolic HF. A reduction of myosin ATPase activity, which may be caused by an alteration in the expression of troponin T and/or of myosin light chain kinase 2, may also lower the rate of interaction between myosin and actin myofilaments and impair muscle shortening.

MYOCARDIAL CELL DEATH When a sufficiently large portion of ventricular myocardium becomes nonfunctional or necrotic, as occurs transiently during ischemia (Chap. 226) and permanently in myocardial infarction (Chap. 228), total ventricular performance at any given level of end-diastolic volume becomes depressed. Apoptosis of myocytes, like the reinduction of fetal sarcomeric proteins, can be caused by hemodynamic overload, excessive neurohormone and/or cytokine stimulation, as well as by severe ischemia. As a consequence of cell death, whatever the mechanism, the load on surviving myocytes is increased, setting the stage for a vicious circle of repeated cell death.

ABNORMALITIES OF EXCITATION-CONTRACTION COUPLING Substantial evidence supports the view that in many forms of heart failure the delivery of Ca^{2+} to the contractile sites is disturbed, thereby impairing cardiac performance. However, the molecular basis of this abnormality—indeed of the subcellular structures involved, i.e., the sarcolemma, T tubules, and/or SR—has yet to be defined. There is, however, evidence for a reduction in the activity of the Ca^{2+} release (ryanodine) channel in the SR and of messenger RNAs of the proteins regulating Ca^{2+} movements. The latter include the sarcolemmal Na^{+}-Ca^{2+} channels, and the activity of the SR Ca^{2+} uptake pump (SERCa-2a), which play critical roles in the movement of Ca^{2+} between the SR and the cytoplasm. Impaired expression of the genes encoding these proteins can impair both myocardial contraction and relaxation and thereby contribute to the development of HF.

NEUROHUMORAL AND CYTOKINE ADJUSTMENTS

A reduction in cardiac performance evokes a series of neurohumoral adjustments, which may at different times be adaptive or maladaptive (Table 215-1). These adjustments are adaptive when they maintain arterial perfusion pressure in the face of a sudden reduction of cardiac output. However, they are maladaptive when they increase the hemodynamic burden and oxygen requirements of the failing ventricle and when they exacerbate myocardial injury (Fig. 215-11).

THE ADRENERGIC NERVOUS SYSTEM In patients with HF the levels of circulating norepinephrine may be markedly elevated, reflecting the increased activity of the adrenergic nervous system. This increased activity supports ventricular contractility in acute HF that is intensified when large doses of β-adrenergic blocking agents are administered acutely, providing evidence for the protective action of adrenergic nervous activation. However, the chronic adrenergic stimulation that occurs in HF may increase afterload by raising vascular resistance, cause cardiac arrhythmias, and may damage myocytes further, perhaps by increasing myocardial energy expenditures and Ca^{2+} overload. Gradually increasing doses of β blockers are of benefit in patients with chronic HF (Chap. 216).

The density of β_1 adrenergic receptors, their coupling to G proteins, and the concentration of cardiac norepinephrine stores are all reduced in chronic, severe HF. These changes are accompanied by a reduction in the activity of adenylate cyclase, which may lower the intracellular concentration of cyclic AMP (Fig. 215-6). The reduction in turn depresses the activation of protein kinase, the phosphorylation of Ca^{2+} channels and transarcolemmal Ca^{2+} entry. It also reduces the phosphorylation of phospholamban, a protein in the SR, which in its unphosphorylated state inhibits the reuptake of Ca^{2+} by the SR. Changes in the G proteins, which couple the β receptor to adenylate cyclase (which is responsible for the production of cyclic AMP), may also occur in HF, with increased activity of the inhibitory subunit of the proteins.

THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM When cardiac output declines, the renin-angiotensin-aldosterone system (Chap. 321) is activated. Concentrations of both circulating angiotensin II and aldosterone are increased, the former contributing to excess vasoconstriction and the latter to the retention of salt and water and perhaps to cardiac fibrosis (Table 215-1). The local (tissue) renin-angiotensin system is also activated in HF and angiotensin II exerts a local cardiotoxic effect by stimulating G_q proteins that activate phospholipase C, which in turn activates protein kinase C. The latter stimulates cardiac hypertrophy and causes ventricular remodeling. Patients with HF are usually improved by blocking this system with angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers, and aldosterone antagonists (Chap. 216).

ENDOTHELIN AND TUMOR NECROSIS FACTOR α The concentration of circulating endothelin, a polypeptide that is a very powerful vasoconstrictor, is increased in HF and it contributes to the excessive afterload. The overexpression of a number of cytokines also appears to play a

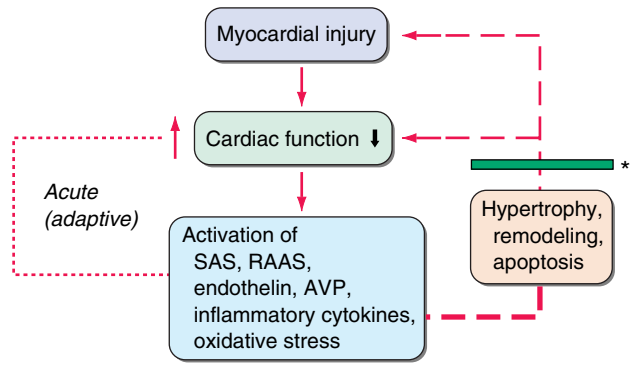

FIGURE 215-11 Interplay between cardiac function and neurohumoral and cytokine systems. Myocardial injury, of many etiologies, can depress cardiac function, which in turn causes activation of the sympathoadrenal system (SAS) and the renin-angiotensin-aldosterone system (RAAS) and the elaboration of endothelin, arginine vasopressin (AVP), and cytokines such as tumor necrosis factor (TNF) α. In acute heart failure (*left*), these are adaptive and tend to maintain arterial pressure and cardiac function. In chronic heart failure (*right*) they cause maladaptive hypertrophic remodeling and apoptosis, which cause further myocardial injury and impairment of cardiac function. The horizontal line on the right (*) shows that chronic maladaptive influences can be inhibited by angiotensin converting enzyme inhibitors, β-adrenergic blockers, angiotensin type I receptor blockers, and aldosterone antagonists.

prominent role in the pathogenesis of HF. It has now been well established that patients with HF exhibit elevated levels of TNF-α, both in the circulation and in cardiac muscle; the pathophysiologic significance of this finding is just unfolding. Transgenic mice with overexpressed cardiac TNF-α exhibit systolic dysfunction, myocarditis, ventricular dilatation, HF, and shortened survival. The infusion of TNF-α impairs ventricular function. However, thus far, blockade of endothelin and TNF-α have not been shown to improve the outcome of patients with HF.

VASODILATOR PEPTIDES A number of vasodilator peptides are released by the dilated heart. Best known are the natriuretic peptides atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP). When stretch receptors in the atria (site of ANP and BNP stores) and ventricles (site of BNP stores) are stimulated, these hormones (or their prohormones) are released and act on specific natriuretic peptide receptors, which increase the concentrations of cyclic GMP in the kidney, adrenal glomerulosa, vascular smooth muscle, and platelets. Urine volume and sodium excretion are augmented, vascular resistance is reduced, and the release of renin and the secretion of aldosterone are reduced. These effects, while beneficial, are not sufficiently powerful to neutralize the sodium-retaining and vasoconstrictor influences of the aforementioned neurohumoral systems activated in HF. Elevated circulating concentrations of ANP and particularly BNP correlate with a poor prognosis in HF. The direct administration of recombinant BNP in acute pulmonary edema is promising.

Figure 215-11 illustrates current concepts of neurohumoral-cytokine activation in HF. The activation of the adrenergic nervous system and the renin-angiotensin-aldosterone system and the enhanced elaboration of endothelin and arginine vasopressin appear to be adaptive in *acute*, severe HF. However, they all appear to exert a maladaptive response in chronic HF. Inflammatory cytokines and oxidative stress are emerging as potent noxious stimuli as well. Together they result in a vicious circle, causing myocyte hypertrophy, remodeling, and cell death, the latter often due to myocardial apoptosis (see below), all resulting in further impairment of cardiac function and myocardial injury. Agents that interfere with the adverse effects of these stimuli on cardiac function, especially β-adrenergic blockers, ACE inhibitors, angiotensin receptor blockers, aldosterone receptor blockers, and perhaps arginine vasopressin blockers appear to be capable of blocking this vicious circle.

ABNORMALITIES OF THE INTERNAL AND EXTERNAL SKELETONS Both hemodynamic overload and mutations of genes encoding cytoskeletal proteins interfere with the regulation of myocyte architecture and thereby interfere with contraction and relaxation. Proliferation of the *extracellular matrix* occurs in myocardial infarction, longstanding hypertension, and a variety of cardiomyopathic disorders. Since this matrix forms the extracellular "skeleton" of the heart, its excessive proliferation can interfere with both systolic shortening and diastolic lengthening. Thus abnormalities of both the internal and external skeleton can contribute to the progression of HF.

HEART FAILURE—A DISTURBANCE OF THE MYOCARDIAL PUMP

(See also Chap. 216)

In the final analysis, in systolic HF the basic problem is depression of the myocardial force-velocity relationship and of the length–active tension curve, reflecting reductions in myocardial contractility (Fig. 215-5, curves 1 to 3, Fig. 215-7, right). In diastolic HF there is upward displacement of the diastolic pressure–volume relation (Fig. 215-8). In many instances, cardiac output and external ventricular performance at rest are within normal limits but are maintained at these levels only by an increased end-diastolic fiber length and an elevated ventricular end-diastolic volume, i.e., through the operation of the Frank-Starling mechanism (Fig. 215-5, points A to D). The elevation of left ventricular preload is associated with increases in the pulmonary capillary pressure, contributing to the dyspnea experienced by patients with HF, while elevation of right ventricular preload raises systemic venous pressure and contributes to the development of edema. The improvement of contractility that normally accompanies augmented adrenergic activity during exercise is attenuated or even prevented by norepinephrine depletion and downregulation of myocardial β receptors, which occur in severe HF (Fig. 215-5, curves 3 and 3′).

The factors that augment ventricular filling during exercise in the normal individual push the failing myocardium along its flattened length–active tension curve. Although the function of left ventricle may be improved at this higher diastolic volume, through the operation of the Frank-Starling mechanism, this improvement occurs only as a consequence of an inordinate elevation of ventricular end-diastolic volume and pressure and, therefore, of the pulmonary capillary pressure. The latter intensifies dyspnea and limits the intensity of exercise that the patient can perform. Left ventricular failure becomes fatal when the myocardial length–active tension curve is depressed (Fig. 215-5, curve 4) to the point at which cardiac performance fails to satisfy the requirements of the peripheral tissues even at rest, and/or the left ventricular end-diastolic and pulmonary capillary pressures are elevated to levels that result in pulmonary edema (Fig. 215-5, point E).

216 HEART FAILURE AND COR PULMONALE

Eugene Braunwald

HEART FAILURE

Heart failure (HF) is a clinical syndrome in which an abnormality of cardiac structure or function is responsible for the inability of the heart to eject or fill with blood at a rate commensurate with the requirements of the metabolizing tissues. HF results in a constellation of clinical manifestations, including, in various combinations, circulatory congestion, dyspnea, fatigue, and weakness. The severity of the clinical manifestations are commonly described according to criteria developed by the New York Heart Association.

HF is a major public health problem in industrialized nations. It appears to be the only common cardiovascular condition that is increasing in prevalence and incidence in North America and Europe. In the United States, HF is responsible for almost 1 million hospital admissions and 50,000 deaths annually. Since HF is more common in the elderly, its prevalence is likely to continue to increase as the population ages.

HF is frequently, but not always, caused by a defect in myocardial contraction, and then the term *myocardial failure* is appropriate. The

latter may result from a primary abnormality in heart muscle, as occurs in the cardiomyopathies, or in viral myocarditis (Chap. 221). HF also results commonly from coronary atherosclerosis, which interferes with cardiac contraction by causing myocardial infarction and ischemia. HF may also occur in congenital, valvular, and hypertensive heart disease in which the myocardium is damaged by the long-standing hemodynamic overload. In other patients with HF, however, a similar clinical syndrome is present but without any detectable abnormality of *myocardial* function. In some cases the normal heart is suddenly presented with a mechanical load that exceeds its capacity, such as an acute hypertensive crisis, rupture of an aortic valve leaflet, in endocarditis or with a massive pulmonary embolism. HF in the presence of normal systolic function also occurs in chronic conditions in which there is impaired filling of the ventricles due to a mechanical abnormality such as tricuspid and/or mitral stenosis without myocardial involvement, endocardial fibrosis, and some forms of hypertrophic cardiomyopathy (see Fig. 215-8).

CAUSES OF HEART FAILURE

UNDERLYING CAUSES Although HF may occur as a consequence of most forms of heart disease, in the United States and Western Europe, ischemic heart disease is responsible for about three-quarters of all cases. Cardiomyopathies are second in frequency, while congenital, valvular, and hypertensive heart disease are less common causes. It is important to identify potentially treatable underlying causes of HF, such as the latter three groups of disorders.

PRECIPITATING CAUSES In evaluating patients with HF, it is important to identify not only the *underlying* but also the *precipitating cause*. Frequently, clinical manifestations of HF are seen for the first time in the course of an acute disturbance that places an additional load on a myocardium that is chronically excessively burdened. Such a heart may be adequately compensated under normal circumstances but have little additional reserve, the additional load imposed by a precipitating cause results in further deterioration of cardiac function. The ten most common precipitating causes are described below.

1. *Infection*. Patients with pulmonary vascular congestion due to left ventricular failure are more susceptible to pulmonary infection than are normal persons; however, any infection may precipitate HF. The resulting fever, tachycardia, hypoxemia, and the increased metabolic demands may place a further burden on an overloaded, but compensated, myocardium of a patient with chronic heart disease.

2. *Arrhythmias*. These are among the most frequent precipitating causes of HF. They exert a deleterious effect on cardiac function through a variety of mechanisms: (a) Tachyarrhythmias reduce the time available for ventricular filling, contributing especially to diastolic HF; they may also cause ischemic myocardial dysfunction in patients with ischemic heart disease. (b) The dissociation between atrial and ventricular contractions characteristic of many brady- and tachyarrhythmias results in the loss of the atrial booster pump mechanism, i.e., the "atrial kick," thereby raising atrial pressures. (c) Cardiac performance may become further impaired because of the loss of normally synchronized ventricular contraction in any arrhythmia associated with abnormal intraventricular conduction (see resynchronization therapy below). (d) Slowing of the heart rate associated with complete atrioventricular block or other severe bradyarrhythmias reduces cardiac output unless stroke volume rises reciprocally; this compensatory response is limited in myocardial dysfunction, even in the absence of overt HF.

3. *Physical, Dietary, Fluid, Environmental, and Emotional Excesses*. The sudden augmentation of sodium intake as with a large holiday meal, the inappropriate discontinuation of drugs or other therapy for HF, blood transfusions, physical overexertion, excessive environmental heat or humidity, and emotional crises all may precipitate HF in patients who were previously compensated.

4. *Myocardial Infarction*. In patients with chronic but compensated ischemic heart disease, a new infarct, sometimes otherwise silent clinically, may further impair ventricular function and precipitate HF (Chap. 228).

5. *Pulmonary Embolism*. Physically inactive patients with low cardiac output are at increased risk of developing thrombi in the veins of the lower extremities or the pelvis. Pulmonary emboli may result in further elevation of pulmonary arterial pressure, which in turn may produce or intensify ventricular failure. In the presence of pulmonary vascular congestion, such emboli also may cause pulmonary infarction (Chap. 244).

6. *Anemia*. In the presence of anemia, the oxygen needs of the metabolizing tissues can be met only by an increase in the cardiac output (Chap. 52). Such an increase may be sustained by a normal heart. However, a diseased, overloaded, but otherwise compensated heart may be unable to augment sufficiently the volume of blood that it delivers to the periphery. In this manner, the combination of anemia and previously compensated heart disease can precipitate HF and lead to inadequate delivery of oxygen to the periphery.

7. *Thyrotoxicosis and Pregnancy*. Similar to anemia and fever, thyrotoxicosis and pregnancy are also high cardiac output states. The development or intensification of HF in a patient with previously compensated heart disease may actually be one of the first clinical manifestations of hyperthyroidism (Chap. 320). Similarly, HF may occur for the first time during pregnancy in women with rheumatic valvular disease, in whom cardiac compensation may return following delivery (Chap. 6).

8. *Aggravation of Hypertension*. Rapid elevation of arterial pressure, as may occur in some instances of renal hypertension or upon abrupt discontinuation of antihypertensive medication in patients with essential hypertension, may result in cardiac decompensation.

9. *Rheumatic, Viral, and Other Forms of Myocarditis*. Acute rheumatic fever and a variety of other inflammatory or infectious processes affecting the myocardium may precipitate HF in patients with or without preexisting heart disease (Chaps. 221 and 302).

10. *Infective Endocarditis*. The additional valvular damage, anemia, fever, and myocarditis that often occur as a consequence of infective endocarditis may, singly or in combination, precipitate HF (Chap. 109).

A systematic search for these precipitating causes should be made in every patient with the new development or recent intensification of HF. If properly recognized, the precipitating cause of HF usually can be treated effectively. Therefore, the prognosis in patients with HF in whom a precipitating cause can be identified, treated, and eliminated is more favorable than in patients in whom the underlying disease process has progressed to the point of producing HF without a detectable precipitating cause.

HF resembles but should be distinguished from (1) conditions in which there is circulatory congestion secondary to abnormal salt and water retention but in which there is no disturbance of cardiac function *per se*, as occurs in renal failure; and (2) noncardiac causes of inadequate cardiac output, such as hypovolemic shock (Chap. 253).

The ventricles respond to chronic hemodynamic overload with the development of hypertrophy (Fig. 216-1). When the ventricle is called on to deliver an elevated cardiac output for prolonged periods, as in valvular regurgitation, it develops *eccentric hypertrophy*, i.e., cavity dilatation, with an increase in muscle mass so that the ratio between wall thickness and ventricular cavity diameter remains relatively constant early in the process. With chronic pressure overload, as in valvular aortic stenosis or untreated hypertension, *concentric ventricular hypertrophy* develops; in this condition the ratio between wall thickness and ventricular cavity size increases. In both eccentric and concentric hypertrophy, wall tension is initially maintained at a normal level and cardiac function may remain stable for many years. However, myocardial function may ultimately deteriorate, leading to HF. Often at this time, the ventricle dilates and the ratio between wall thickness and cavity size declines, leading to increased stress on each unit of myocardium, further dilatation, and a vicious cycle is initiated. Remodeling of the ventricle occurs with a change to a more spherical

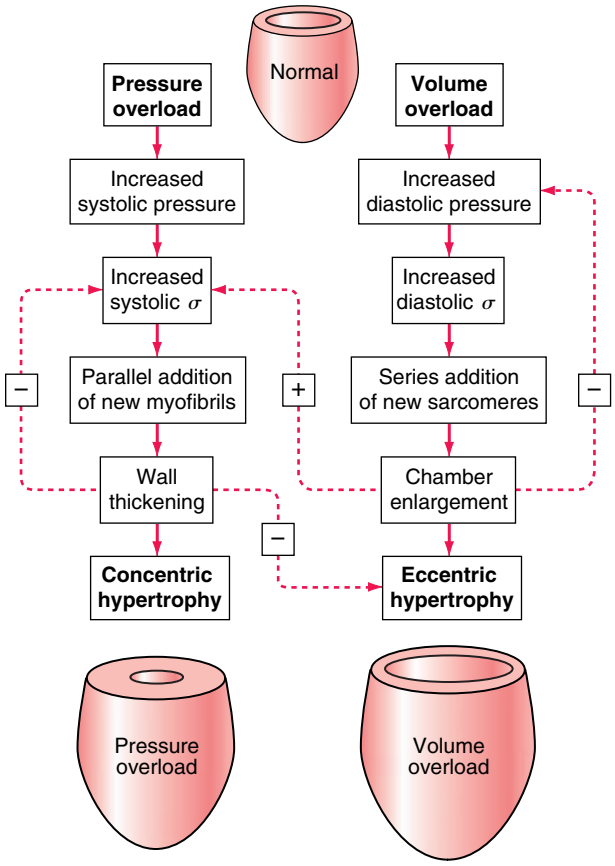

FIGURE 216-1 Patterns of ventricular hypertrophy. Specific patterns of ventricular remodeling occur in response to the imposed augmentation in work load. A pattern of hypertrophic growth characterized as concentric, in which increased mass is out of proportion to chamber volume, is particularly effective in reducing systolic wall stress (σ) under conditions of heightened pressure load. In contrast, in volume overload conditions, in which the major stimulus is diastolic loading, a predominant finding is a great increase in the cavity size or volume. Although there can be extensive increases in mass, the relationship between mass and volume is either preserved or, in severe cases, reduced. The fundamental response is generated by cellular hypertrophy. However, the configuration of the new contractile tissue is specific and offsets the mechanical stimulus. *[Modified from W Grossman et al in NR Alpert (ed): Perspectives in Cardiovascular Research. Myocardial Hypertrophy and Failure, vol 7. New York, Raven Press, 1993, with permission.]*

shape, which increases the hemodynamic stresses on the wall and may cause or intensify mitral regurgitation. Activation of endogenous neurohormonal systems and cytokines (Chap. 215) appears to be involved in ventricular remodeling and thereby the progression of HF. Remodeling is particularly prominent in patients with transmural myocardial infarction, in whom the infarcted area stretches and the remaining viable portion of the ventricle dilates.

FORMS OF HEART FAILURE

HF may be described as *systolic* or *diastolic*, *high-output* or *low-output*, *acute* or *chronic*, *right-sided* or *left-sided*, and *forward* or *backward*. These descriptors are often useful in a clinical setting, particularly early in the patient's course, but the differences often become blurred late in the course of chronic HF.

SYSTOLIC VERSUS DIASTOLIC FAILURE The distinction between these two forms of HF relates to whether the principal abnormality is the inability of the ventricle to contract normally and expel sufficient blood (systolic failure) or to relax and fill normally (diastolic failure). The manifestations of systolic failure relate to an inadequate cardiac output with weakness, fatigue, reduced exercise tolerance, and other symptoms of hypoperfusion, while in diastolic HF the manifestations relate principally to the elevation of filling pressures in the left and/or right ventricles. Diastolic HF is usually defined as HF in patients with an ejection fraction >50%.

Diastolic HF (see Fig. 215-8) may be caused by increased resistance to ventricular inflow and reduced ventricular diastolic capacity (constrictive pericarditis and restrictive, hypertensive, and hypertrophic cardiomyopathy), impaired ventricular relaxation (acute myocardial ischemia), and myocardial fibrosis and infiltration (restrictive cardiomyopathy). Diastolic HF occurs more frequently in women than men, especially elderly women with hypertension. In most patients with HF, abnormalities both of contraction and relaxation coexist.

LOW-OUTPUT VERSUS HIGH-OUTPUT HEART FAILURE *Low-output HF* occurs secondary to ischemic heart disease, hypertension, dilated cardiomyopathy, and valvular and pericardial disease, while *high-output HF* occurs in patients with reduced systemic vascular resistance, i.e., hyperthyroidism, anemia, pregnancy, arteriovenous fistulas, beriberi, and Paget's disease. In clinical practice, however, low-output and high-output HF cannot always be readily distinguished. The normal range of cardiac output is wide (2.2 to 3.5 L/min per m^2); in many patients with low-output HF, the cardiac output may actually be just above the lower limit of normal range at rest (although lower than it had been previously), but fails to rise normally during exertion. On the other hand, in patients with so-called high-output HF, the output may not exceed the upper limits of normal (although it would have been abnormally elevated had it been measured before HF supervened); instead, it may have fallen to within normal limits with HF.

The hemodynamic burden placed on the myocardium by many forms of high-output heart failure resembles that produced by chronic aortic regurgitation. In addition, thyrotoxicosis and beriberi may also impair myocardial metabolism directly, while very severe anemia may interfere with myocardial function by producing myocardial anoxia, especially in the subendocardium and in the presence of underlying obstructive coronary artery disease.

ACUTE VERSUS CHRONIC HEART FAILURE An example of causes of *acute HF* are the sudden rupture of a cardiac valve leaflet secondary to trauma or infective endocarditis or a massive myocardial infarction in a patient who previously had no cardiac dysfunction. In acute HF the sudden reduction in cardiac output often results in systemic hypotension without peripheral edema. *Chronic HF* is typically observed in patients with dilated cardiomyopathy or multivalvular heart disease and develops or progresses slowly. Vascular congestion is common in chronic HF, but arterial pressure is ordinarily well maintained until very late.

RIGHT-SIDED VERSUS LEFT-SIDED HEART FAILURE Many of the clinical manifestations of HF result from the accumulation of fluid upstream to (behind) the ventricles that is initially affected. For example, patients in whom the left ventricle is hemodynamically overloaded (e.g., aortic regurgitation) or weakened due to myocyte loss (e.g., postmyocardial infarction) develop dyspnea and orthopnea as a result of pulmonary congestion, a condition referred to as *left-sided HF*. When the underlying abnormality affects the right ventricle primarily (e.g., primary pulmonary hypertension secondary to chronic pulmonary thromboembolism), symptoms resulting from pulmonary congestion are uncommon, and edema, congestive hepatomegaly, and systemic venous distention, i.e., clinical manifestations of *right-sided HF*, are prominent. The muscle bundles composing both ventricles are continuous, and both ventricles share a common wall, the interventricular septum. The biochemical changes that occur in the myocardium in HF (Chap. 215) usually occur in the myocardium of *both* ventricles. Therefore, when HF has existed for months or years, localization of excess fluid behind one ventricle may no longer exist.

BACKWARD VERSUS FORWARD HEART FAILURE A controversy has revolved around the mechanism of the clinical manifestations resulting from HF. The concept of *backward HF* contends that in HF, one or the other ventricle fails to discharge its contents or fails to fill normally. As a consequence, the pressures in the atrium and venous system behind (upstream to) the failing ventricle rise, and retention of sodium and

water occurs as a consequence of the elevation of systemic venous and capillary pressures and the resultant transudation of fluid into the pulmonary or systemic interstitial space. On the other hand, proponents of the *forward HF* hypothesis maintain that the clinical manifestations of HF result directly from an inadequate discharge of blood into the arterial system. According to this concept, salt and water retention is a consequence of diminished renal perfusion and excessive proximal and distal tubular reabsorption of sodium, the latter through activation of the renin-angiotensin-aldosterone system (RAAS) (Chap. 32).

The rate of onset of HF often influences the clinical manifestations. For example, when a large portion of the left ventricle is suddenly destroyed, as in myocardial infarction, the patient may succumb to acute pulmonary edema, a manifestation of *backward failure*. If the patient survives the acute insult, clinical manifestations resulting from a chronically depressed cardiac output, including the abnormal retention of fluid within the systemic vascular bed, may develop, which is a manifestation of *forward failure*.

SALT AND WATER RETENTION (See also Chap. 32) When the volume of blood pumped by the left ventricle into the systemic vascular bed is reduced, a complex sequence of adjustments occurs that ultimately results in the abnormal accumulation of fluid. This may be considered a two-edged sword. Many of the troubling clinical manifestations of HF, such as pulmonary congestion and edema, are secondary to this excessive retention of fluid (see Fig. 32-1). However, this abnormal fluid accumulation and the expansion of blood volume that accompanies it also constitute an important compensatory mechanism that tends to maintain cardiac output and therefore perfusion of the vital organs. Except in the terminal stages of HF, the ventricle operates on an ascending, albeit depressed and flattened, function curve (see Fig. 215-5), and the augmented ventricular end-diastolic volume characteristic of HF must be regarded as helping to maintain the reduced cardiac output, despite causing pulmonary and/or systemic venous congestion.

CLINICAL MANIFESTATIONS OF HEART FAILURE

RESPIRATORY DISTURBANCES ■ Dyspnea (Chap. 29) In early HF, dyspnea is observed only during exertion, when it may simply represent an aggravation of the breathlessness that occurs normally. As HF advances, dyspnea occurs with progressively less strenuous activity and ultimately it is present even at rest. The principal difference between exertional dyspnea in normal persons and in patients with HF is the degree of exertion necessary to induce this symptom. Cardiac dyspnea is observed most frequently in patients with elevations of pulmonary venous and capillary pressures who have engorged pulmonary vessels and interstitial accumulation of interstitial fluid. The activation of receptors in the lungs results in the rapid, shallow breathing characteristic of cardiac dyspnea. The oxygen cost of breathing is increased by the excessive work of the respiratory muscles required to move air into and out of the congested lungs. This is coupled with the diminished delivery of oxygen to these muscles, a consequence of a reduced cardiac output. This imbalance may contribute to fatigue of the respiratory muscles and the sensation of shortness of breath.

Orthopnea This symptom, i.e., dyspnea in the recumbent position, is usually a later manifestation of HF than exertional dyspnea. Orthopnea results from the redistribution of fluid from the abdomen and lower extremities into the chest during recumbency, which increases the pulmonary capillary pressure, combined with elevation of the diaphragm. Patients with orthopnea must elevate their head on several pillows at night and frequently awaken short of breath and/or coughing if their head slips off the pillows. Orthopnea is usually relieved by sitting upright, and some patients report that they find relief from sitting in front of an open window. In advanced HF, patients cannot lie down at all and must spend the entire night in a sitting position.

Paroxysmal (Nocturnal) Dyspnea This term refers to attacks of severe shortness of breath and coughing that generally occur at night, usually awaken the patient from sleep, and may be quite frightening. Though simple orthopnea may be relieved by sitting upright at the side of the bed with legs dependent, in the patient with paroxysmal nocturnal dyspnea, coughing and wheezing often persist even in this position. Paroxysmal nocturnal dyspnea may be caused in part by the depression of the respiratory center during sleep, which may reduce ventilation sufficiently to lower arterial oxygen tension, particularly in patients with interstitial lung edema and reduced pulmonary compliance. *Cardiac asthma* is closely related to paroxysmal nocturnal dyspnea and nocturnal cough and is characterized by wheezing secondary to bronchospasm—most prominent at night. *Acute pulmonary edema* (Chaps. 29 and 255) is a severe form of cardiac asthma due to marked elevation of pulmonary capillary pressure leading to alveolar edema, associated with extreme shortness of breath, rales over the lung fields, and the expectoration of blood-tinged fluid. If not treated promptly, acute pulmonary edema may be fatal.

Cheyne-Stokes Respiration Also known as *periodic respiration* or *cyclic respiration*, Cheyne-Stokes respiration is characterized by diminished sensitivity of the respiratory center to arterial P_{CO_2}. There is an apneic phase, during which the arterial P_{O_2} falls and the arterial P_{CO_2} rises. These changes in the arterial blood stimulate the depressed respiratory center, resulting in hyperventilation and hypocapnia, followed in turn by recurrence of apnea. Cheyne-Stokes respiration occurs most often in patients with cerebral atherosclerosis and other cerebral lesions, but the prolongation of the circulation time from the lung to the brain that occurs in HF, particularly in patients with hypertension and coronary artery disease, also appears to contribute to this form of disordered breathing.

OTHER SYMPTOMS ■ Fatigue and Weakness These nonspecific but common symptoms of HF are related to the reduction of skeletal muscle perfusion. Exercise capacity is reduced by the limited ability of the failing heart to increase its output and deliver oxygen to the exercising muscles.

Abdominal Symptoms Anorexia and nausea associated with abdominal pain and fullness are frequent complaints and may be related to the congested liver and portal venous system.

Cerebral Symptoms Patients with severe HF, particularly elderly patients with cerebral arteriosclerosis, reduced cerebral perfusion, and arterial hypoxemia, may develop alterations in the mental state characterized by confusion, difficulty in concentration, impairment of memory, headache, insomnia, and anxiety. *Nocturia* is common in HF and may contribute to insomnia.

PHYSICAL FINDINGS (See Chap. 209) In mild or moderately severe HF, the patient appears in no distress at rest except feeling uncomfortable when lying flat for more than a few minutes. In severe HF, the pulse pressure may be diminished, reflecting a reduction in stroke volume, and the diastolic arterial pressure may be elevated as a consequence of generalized vasoconstriction. In severe acute HF, systolic hypotension may be present, with cool, diaphoretic extremities, and Cheyne-Stokes respiration. There may be cyanosis of the lips and nail beds (Chap. 31) and sinus tachycardia. *Systemic venous pressure* is often abnormally elevated, and this may be reflected in distention of the jugular veins. In the early stages of HF, the venous pressure may be normal at rest but may become abnormally elevated, with sustained pressure on the abdomen (positive abdominojugular reflux).

Third and fourth heart sounds are often audible but are not specific for HF, and *pulsus alternans*, i.e., a regular rhythm with alternation of strong and weak cardiac contractions and therefore alternation in the strength of the peripheral pulses, may be present. This sign of severe HF may be detected by sphygmomanometry and in more severe cases even by palpation; it frequently follows an extrasystole and is observed most commonly in patients with cardiomyopathy, hypertensive, or ischemic heart disease.

Pulmonary Rales Moist, inspiratory, crepitant rales and dullness to percussion over the lung bases are common in patients with HF and el-

evated pulmonary venous and capillary pressures. In patients with pulmonary edema, rales may be heard widely over both lung fields; they are frequently coarse and sibilant and may be accompanied by expiratory wheezing. Rales may, however, be caused by many conditions other than left ventricular failure. Some patients with longstanding HF and elevated pulmonary vascular pressures have no rales because of increased lymphatic drainage of alveolar fluid.

Cardiac Edema (See Chap. 32) This is usually symmetric and dependent in HF, occurring in the legs, particularly in the ankles and pretibial region in ambulatory patients, in whom it is most prominent in the evening. In patients who are bedridden, cardiac edema occurs in the sacral region.

Hydrothorax and Ascites Pleural effusion in HF (hydrothorax) results from the elevation of pleural capillary pressure and the resultant transudation of fluid into the pleural cavities. Since the pleural veins drain into *both* the systemic and pulmonary veins, hydrothorax occurs most commonly with marked elevation of pressure in both venous systems but may also be seen with marked elevation of pressure in either venous bed. It occurs more frequently in the right pleural cavity than in the left. *Ascites* also occurs as a consequence of transudation and results from increased pressure in the hepatic veins and the veins draining the peritoneum (Chap. 39). Among patients with HF, ascites occurs most frequently in those with constrictive pericarditis and those with tricuspid valve disease.

Congestive Hepatomegaly Like edema, an enlarged, tender, pulsating liver also accompanies systemic venous hypertension. With prolonged, severe hepatomegaly, as in patients with tricuspid valve disease or chronic constrictive pericarditis, enlargement of the spleen, i.e., congestive splenomegaly, may also occur.

Jaundice This is a late finding in HF and is associated with elevations of both direct and indirect bilirubin. It results from impairment of hepatic function secondary to hepatic congestion and the hepatocellular hypoxia associated with central lobular atrophy. Hepatic enzymes are frequently elevated. If hepatic congestion occurs acutely, the jaundice may be severe and the enzymes strikingly elevated.

Cardiac Cachexia With severe chronic HF there may be marked weight loss and cachexia because of: (1) elevation of the metabolic rate, which results in part from the extra work performed by the respiratory muscles, the increased O_2 needs of the hypertrophied heart, and/or the discomfort associated with severe HF; (2) anorexia, nausea, and vomiting due to congestive hepatomegaly and abdominal fullness and/or digitalis intoxication (see below); (3) impairment of intestinal absorption due to congestion of the intestinal veins; (4) elevation of circulating concentrations of cytokines such as tumor necrosis factor; and (5) rarely, due to protein-losing enteropathy in patients with particularly severe failure of the right side of the heart.

Other Manifestations With reduction of blood flow, the skin, especially in the extremities, may be cold, pale, and diaphoretic. Urine flow is depressed, contains albumin, has a high specific gravity, and a low concentration of sodium. In addition, prerenal azotemia may be present. In patients with long-standing severe HF, depression and sexual dysfunction are common.

DIFFERENTIAL DIAGNOSIS The diagnosis of congestive HF may be established by observing some combination of the clinical manifestations of HF described above, together with the findings characteristic of one of the underlying forms of heart disease. Table 216-1 shows the Framingham criteria, which are useful in the diagnosis of HF. Since chronic HF is often associated with cardiac enlargement, the diagnosis should be questioned, but is by no means excluded, when all chambers are normal in size. HF is sometimes difficult to distinguish from *pulmonary disease*, and the differential diagnosis is discussed in Chap. 29. *Pulmonary embolism* also presents many of the manifestations of HF, but hemoptysis, pleuritic chest pain, a right ventricular lift, and the characteristic mismatch between ventilation and perfusion on lung scan should point to this diagnosis (Chap. 244).

TABLE 216-1 *Framingham Criteria for Diagnosis of Congestive Heart Failure*[a]

MAJOR CRITERIA
Paroxysmal nocturnal dyspnea
Neck vein distention
Rales
Cardiomegaly
Acute pulmonary edema
S_3 gallop
Increased venous pressure (>16 cmH_2O)
Positive hepatojugular reflux
MINOR CRITERIA
Extremity edema
Night cough
Dyspnea on exertion
Hepatomegaly
Pleural effusion
Vital capacity reduced by one-third from normal
Tachycardia ($\geq$120 bpm)
MAJOR OR MINOR
Weight loss $\geq$4.5 kg over 5 days' treatment

[a] To establish a clinical diagnosis of congestive heart failure by these criteria, at least one major and two minor criteria are required.
Source: KKL Ho et al, Circulation 88:107, 1993.

Ankle edema may be due to varicose veins, cyclic edema, or gravitational effects (Chap. 32), but in patients with these conditions, there is no jugular venous hypertension at rest or with pressure over the abdomen. Edema secondary to *renal disease* can usually be recognized by appropriate renal function tests and urinalysis and it is rarely associated with elevation of venous pressure. Enlargement of the liver and ascites occur in patients with *hepatic cirrhosis* and also may be distinguished from HF by normal jugular venous pressure and the absence of a positive abdominojugular reflux.

BRAIN NATRIURETIC PEPTIDE (BNP) Pre pro-BNP is formed in the ventricles and, with myocyte stretch, is broken down to N-terminal-pro-BNP (NT-pro-BNP) and BNP. These hormones are highly accurate for identifying or excluding HF with high sensitivity and specificity and add significant independent predictive power when added to the chemical features. BNP is particularly valuable in differentiating cardiac from pulmonary causes of dyspnea. The availability of a bedside assay makes BNP useful in evaluating patients in the Emergency Department.

APPROACH TO THE PATIENT

In addition to a detailed clinical examination, a two-dimensional echocardiogram with Doppler flow studies is of critical importance in determining the underlying causes of HF and in assessing the severity of ventricular systolic and/or diastolic dysfunction, as well as valvular dysfunction. Such ultrasound studies are part of the workup of all patients in whom the diagnosis of HF is considered. The electrocardiogram is rarely normal in systolic HF. The chest roentgenogram is helpful in detecting cardiomegaly and pulmonary congestion. BNP is extremely useful in diagnosis, prognosis, and monitoring therapy.

Rx TREATMENT

A simple rule for the treatment of all patients with HF cannot be formulated because of its varied etiologies, hemodynamic features, clinical manifestations, and severity. The treatment of HF may be divided into five components: (1) general measures; (2) correction of the underlying cause; (3) removal of the precipitating cause; (4) prevention of deterioration of cardiac function; and (5) control of the congestive HF state. An example of correction of the underlying course is the

surgical repair or replacement of a deformed valve. An example of removal of a precipitating cause is the restoration of sinus rhythm in a patient with atrial fibrillation and a rapid ventricular rate. An approach that applies to many patients is shown in Table 216-2 and Fig. 216-2.

GENERAL MEASURES Every effort should be made to prevent HF, not only by treating hypertension and other coronary risk factors (Chap. 225) but also by the administration of angiotensin-converting enzyme (ACE) inhibitors (or, in patients who are intolerant of them, angiotensin receptor blockers, ARBs), even in asymptomatic patients with a history of atherosclerotic vascular disease, diabetes mellitus, or hypertension.

General measures in patients with HF include moderate dietary Na^+ restriction (see below), daily measurement of weight to aid in the adjustment of diuretic dosage, as well as immunization with influenza and pneumococcal vaccines to prevent respiratory infection. Education of the patient and family about the condition and the critical importance of close attention to compliance with the medical regimen and supervision of outpatient care by a specially trained nurse or physician assistant have all been found to be helpful. Excessive alcohol, temperature extremes, and tiring trips should be avoided.

Activity In acute, severe HF, meals should be small in quantity, but more frequent, and every effort should be made to diminish anxiety; sometimes drugs such as diazepam (2 to 5 mg tid) for several days are useful. Physical and emotional rest tends to lower arterial pressure and reduce the load on the myocardium by diminishing the requirements for cardiac output. Reduced physical exertion should be continued for several days after the patient's condition has stabilized. The hazards of phlebothrombosis and pulmonary embolism which occur with bed rest may be reduced with anticoagulants, leg exercises, and elastic stockings. *Absolute* bed rest is rarely required or advisable, and even the patient with severe HF should ordinarily be encouraged to sit in a chair. In ambulatory patients with chronic, moderately severe HF, additional periods of rest on weekends frequently allow continuation of gainful employment. A scheduled nap or rest following lunch and the avoidance of particularly strenuous exertion are often helpful.

Once the patient has become compensated, regular isotonic exercise such as walking or riding a stationary-bicycle ergometer as tolerated should be strongly encouraged. Some trials of exercise training have led to encouraging results with reduced symptoms, increased exercise capacity, and improved quality of life. Weight reduction by restriction of caloric intake in obese patients with HF also diminishes cardiac work load and is an essential component of the therapeutic program.

CONTROL OF EXCESSIVE FLUID Many of the clinical manifestations of HF result from expansion of the extracellular fluid volume. A negative Na^+ balance can be achieved in such patients by reducing the dietary intake and increasing the urinary excretion of this ion with the aid of diuretics. Rarely, in severe HF, mechanical removal of extracellular fluid by means of thoracentesis and paracentesis may be necessary.

Diet In patients with mild HF, symptomatic improvement may result simply from reducing the sodium intake. The normal diet contains approximately 6 to 10 g NaCl per day; this intake can be reduced in half simply by excluding salt-rich foods and salt added at the table. Further reduction of the ordinary dietary intake of NaCl to approximately one-fourth of normal may be achieved if, in addition, NaCl is omitted from cooking. In patients with severe HF who have fluid accumulation despite vigorous diuretic therapy (see below), the dietary intake of NaCl should be reduced to 1 g/d. In order to achieve this, milk, cheese, bread, cereals, canned vegetables and soups, some salted cuts of meat, and some fresh vegetables (including spinach, celery, and beets) must be eliminated. A variety of fresh fruit, green vegeta-

TABLE 216-2 *Stages in the Evolution of Heart Failure/Recommended Therapy by Stage*

Stage A →		Stage B →		Stage C →		Stage D
At high risk for heart failure but without structural heart disease or symptoms of HF Patients with hypertension coronary artery disease diabetes mellitus *or* Patients using cardiotoxins with FHx CM	Structural heart disease	Structural heart disease but without symptoms of HF Patients with previous MI LV systolic dysfunction asymptomatic valvular disease	Symptoms of HF develop	Structural heart disease with prior or current symptoms of HF Patients with known structural heart disease shortness of breath and fatigue, reduced exercise tolerance	Refractory symptoms of HF at rest	Refractory HF requiring specialized interventions Patients who have marked symptoms at rest despite maximal medical therapy (e.g., those who are recurrently hospitalized or cannot be safely discharged from the hospital without specialized interventions)
THERAPY						
Treat hypertension Encourage smoking cessation Treat lipid disorders Encourage regular exercise Discourage alcohol intake, illicit drug use ACE inhibition		All measures under stage A ACE inhibitors in appropriate patients Beta-blockers		All measures under stage A Drugs for routine use: Diuretics ACE inhibitors Beta-blockers Digitalis Dietary Salt restriction		All measures under stages A, B, and C Mechanical assist devices Heart transplantation Continuous (not intermittent) IV inotropic infusions for palliation Hospice care

Abbreviations: HF, heart failure, FHxCM, family history of cardiomyopathy; ACE, angiotensin-converting enzyme; MI, myocardial infarction; LV, left ventricular; IV, intravenous.

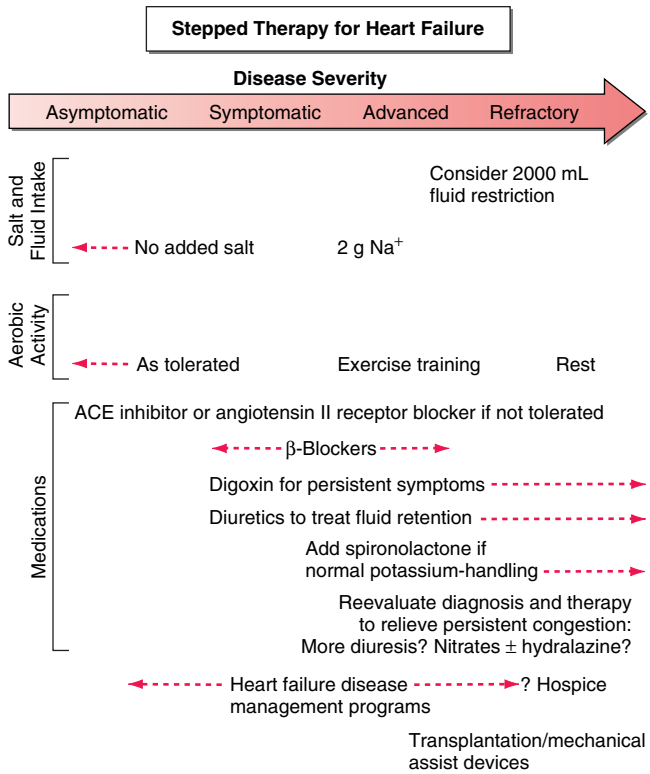

FIGURE 216-2 The step diagram demonstrates addition of therapies in relation to the clinical severity of heart failure with reduced left ventricular ejection fraction. Angiotensin-converting enzyme (ACE) inhibitors are prescribed at every level of disease severity. Angiotensin receptor-blocking agents (ARBs) are a reasonable alternative for patients who cannot tolerate ACE inhibitors due to angioedema or severe cough. β-Adrenergic blocking agents are prescribed for patient with mild to moderate symptoms of heart failure, but they are not initiated in patients with severe symptoms of heart failure unresponsive to stabilization with other therapies. Diuretics are prescribed to maintain fluid balance, with spironolactone added in patients with severely symptomatic disease when renal function and potassium handling are preserved. When severe symptoms persist, patients may benefit from addition of nitrates with or without hydralazine. Transplantation and mechanical assist devices are relevant to only a very small population with advanced heart failure. Restriction of sodium and fluid intake is increasingly required as heart failure becomes more severe. Heart failure management programs are most cost-effective in patients at high risk for repeated heart failure hospitalization. *(From A Nohria et al, 2002, with permission.)*

bles, specially processed breads and milk, and NaCl substitutes are permissible. Late in the course of HF, dilutional hyponatremia may develop in patients who are unable to excrete an H_2O load, sometimes because of excessive secretion of antidiuretic hormone. In such cases, both H_2O and NaCl must be restricted.

Diuretics (See also Chap. 230) These agents should be given to achieve euvolemia and reduce or prevent edema and jugular venous distention. A variety of diuretics is available (Tables 216-3 and 230-8), and almost all are effective in patients with mild HF. However, in the more severe forms of HF, the selection of diuretics is more difficult, and abnormalities in serum electrolytes must be watched for. On the other hand, overtreatment with diuretics must be avoided, since the resultant hypovolemia may reduce cardiac output, interfere with renal function, and produce profound weakness and lethargy.

THIAZIDE DIURETICS These agents are useful by themselves in patients with mild HF and in combination with other diuretics in patients with severe HF. In patients with chronic mild HF, the continued administration of a thiazide diuretic abolishes or diminishes the need for *rigid* dietary Na^+ restriction, although salty foods and table salt still should be avoided. Thiazide diuretics reduce the reabsorption of Na^+ and Cl^- in the first half of the distal convoluted tubule and a portion of the cortical ascending limb of the loop of Henle, and H_2O follows the unreabsorbed salt. However, thiazides can cause excretion of a hypertonic urine and contribute to dilutional hyponatremia. As a consequence of increased delivery of Na^+ to the distal nephron, Na^+-K^+ exchange is enhanced, and kaliuresis results.

K^+ depletion and metabolic alkalosis (the latter due to increased H^+ secretion as a substitute for the depleted intracellular stores of K^+) are the chief adverse metabolic effects following prolonged administration of the thiazides, and also of metolazone, and of the loop diuretics. Hypokalemia may seriously enhance the dangers of digitalis intoxication (see below), and induce fatigue and lethargy; it may be prevented by oral supplementation with KCl or preferably by the addition of a K^+-retaining diuretic. Other side effects of thiazides include reduction of the excretion of uric acid, which may lead to hyperuricemia, and impaired glucose tolerance. Skin rashes, thrombocytopenia, and granulocytopenia have also been reported.

Thiazide diuretics are effective and useful in the treatment of HF as long as the glomerular filtration rate exceeds approximately one half of normal. Chlorothiazide (25 to 50 mg/d) is especially useful since it may be administered once daily.

METOLAZONE This quinethazone derivative has a site of action and potency similar to the thiazides but is effective in the presence of moderate renal failure. Both metolazone and thiazides potentiate the diuretic efficacy of intravenous loop diuretics.

FUROSEMIDE, BUMETANIDE, AND TORSEMIDE These "loop" diuretics are similar physiologically but differ chemically from one another. They reversibly inhibit the reabsorption of Na^+, K^+, and Cl^- in the thick ascending limb of Henle's loop, apparently by blocking a cotransport system in the luminal membrane. They may induce renal cortical vasodilatation and can produce rates of urine formation that may be as high as one-fourth of the glomerular filtration rate. Metabolic alkalosis may be caused by a large increase in the urinary excretion of Cl^-, H^+, and K^+. Hypokalemia, hyperuricemia, and hyperglycemia are observed occasionally, as with thiazide diuretics. The reabsorption of free H_2O is decreased. These three drugs are usually effective both intravenously and by mouth, and are excreted in the bile and urine. Weakness, nausea, and dizziness may complicate the administration of all loop diuretics.

These powerful diuretics are useful in all forms of HF, particularly in patients with otherwise refractory HF and pulmonary edema. They have been shown to be effective in patients with hypoalbuminemia, hyponatremia, hypochloremia, and with reductions in glomerular filtration rate, and to produce a diuresis in patients in whom thiazide diuretics and potassium-sparing diuretics, alone and in combination, are ineffective. In patients with refractory HF, the action of loop diuretics may be potentiated by intravenous administration and by the addition of other diuretics, i.e., thiazides, metozalone, and the potassium-sparing diuretics.

POTASSIUM-SPARING DIURETICS These agents act on the distal tubule and cortical collecting ducts, are relatively weak, and therefore are rarely indicated as sole agents. Spironolactone resemble aldosterone structurally and acts by competitive inhibition of aldosterone, thereby blocking the exchange between Na^+ and both K^+ and H^+ in the distal tubules and collecting ducts. Amiloride and triamterene have a similar effect but act directly on the distal tubule/collecting duct. These agents produce a Na^+ diuresis, and in contrast to the thiazides, metolazone and the thiazides result in K^+ *retention*.

Potassium-sparing diuretics are most effective when administered in combination with loop and/or thiazide diuretics. The opposing action of these drugs on urine and serum potassium makes possible a sodium diuresis without either hyper- or hypokalemia when spironolactone and one of these other agents are administered in combination. Also, since potassium-sparing diuretics act on the distal tubule, they are particularly effective when used in combination with one of the other diuretics that act more proximally. Spironolactone, triamterene, and amiloride should *not* be administered to patients with serum $K^+ > 5$ mmol/L, renal failure, or hyponatremia. Reported complications include nausea, epigastric distress, mental confusion, drowsiness,

TABLE 216-3 *Common Medications for Heart Failure*

Medication	Initial Dose	Maximum Dose
Loop diuretics		
Furosemide	20–40 mg 1–2 times daily PO; 20 mg IV	400 mg/d; 80 mg IV
Bumetanide	0.5–1.0 mg 1–2 times daily PO; 0.5 mg IV	10 mg/d; 2 mg IV
Torsemide	10 mg 1–2 times daily PO; 5 mg IV	200 mg/d; 20 mg IV
Supplemental thiazides		
Metolazone	2.5 mg 1–2 times daily	10 mg/d
Hydrochlorathiazide	25 mg/d	100 mg/d
Chlorthalidone	50 mg/d	100 mg/d
Spironolactone (only with loop diuretics)	25 mg/d or every other day	25 mg twice daily, occasionally higher for refractory hypokalemia
Angiotensin-converting enzyme inhibitors		
Captopril	6.25 mg/d or every other day	50–100 mg 4 times daily
Enalapril maleate	2.5 mg twice daily	10–20 mg twice daily
Fosinopril sodium	5–10 mg/d	40 mg/d
Lisinopril	2.5–5.0 mg/d	20–40 mg/d
Quinapril hydrochloride	10 mg twice daily	40 mg twice daily
Ramipril	1.25–2.5 mg/d	10 mg/d
β-Blockers		
Bisoprolol	1.25 mg/d	10 mg/d
Carvedilol	3.125 mg twice daily	25–50 mg twice daily
Metoprolol tartrate	6.25 mg twice daily	75 mg twice daily
Metoprolol CR/XL*	12.5–25 mg/d	200 mg/d
Digoxin	0.125 mg every other day to 0.25 mg/d	0.50 mg/d to avoid toxic effects
Other vasodilators		
Isosorbide dinitrate	10 mg 3 times daily	80 mg 3 times daily
Sublingual isosorbide	2.5 mg as occasion requires or prior to exercise to decrease dyspnea	
Hydralazine	25 mg 3 times daily	150 mg 4 times daily

* CR/XL indicates controlled-release extended release metoprolol succinate

Source: Modified from Nohria A et al, 2002; data adapted from Hunt et al: ACC/AHA Guidelines for the Evaluation and Management of Chronic Heart Failure in the Adult. *J Am Coll Cardiol*. 38:2101, 2001

gynecomastia, and erythematous eruptions. As mentioned below, a lower dose of spironolactone (25 mg/d), which exerts little if any diuretic effect, has been shown to prolong life in patients with advanced HF (Table 216-3).

Triamterene and *amiloride* exert renal effects similar to those of spironolactone. However, their action does not depend on the presence of aldosterone. The effective dose of triamterene is 100 to 200 mg/d, and that of amiloride is 5 to 10 mg/d. Side effects include nausea, vomiting, diarrhea, headache, granulocytopenia, eosinophilia, and skin rash. Combination therapy, e.g., spironolactone and hydrochlorothiazide in a single tablet (e.g. Aldactazide) have proved popular.

When *choosing a diuretic*, an orally administered loop diuretic, thiazide or metolazone are the agents of choice in the treatment of chronic cardiac edema of mild to moderate degree in patients without hyperglycemia, hyperuricemia, or hypokalemia. Spironolactone, triamterene, and amiloride potentiate the thiazide and loop diuretics. In severe HF, the combination of a loop diuretic, a thiazide, and a potassium-sparing diuretic is required. In acute HF, especially pulmonary edema, intravenous loop diuretics are often effective.

PREVENTION OF DETERIORATION OF MYOCARDIAL INFARCTION *Chronic* activation of the renin-angiotensin-aldosterone system (RAAS) and of the adrenergic nervous systems in HF cause ventricular remodeling, further deterioration of cardiac function and/or potentially fatal arrhythmias (Chap. 215). Drugs that block these two systems have been found to be useful in the management of HF (Tables 216-2 and 216-3).

Angiotensin-Converting Enzyme (ACE) Inhibitors ACE inhibitors play a central role in the prevention and treatment of HF at almost all stages. In addition to slowing maladaptive remodeling of the injured or abnormally burdened ventricle, ACE inhibitors reduce the impedance to left ventricular ejection. These drugs may be particularly helpful in (but are by no means limited to) patients with systolic HF due to myocardial infarction, hypertension, and valvular regurgitation. In patients with systolic HF who are treated with ACE inhibitors, cardiac output rises, the pulmonary wedge pressure falls, the signs and symptoms of HF are relieved, and a new steady state is achieved in which cardiac output is higher and afterload lower with no or only mild reduction of arterial pressure.

The administration of ACE inhibitors has been shown to prevent or retard the development of HF in patients with left ventricular dysfunction without HF, to reduce symptoms, enhance exercise performance, and to reduce long-term mortality and the need for rehospitalization in patients with HF, in patients shortly after acute myocardial infarction as well as in patients with vascular disease who are at high risk for recurrent events. These beneficial effects are related only in part to the salutary hemodynamic effects, i.e., the reduction of preload and afterload. The major effect of ACE inhibitors appears to be on inhibition of local (tissue) renin-angiotensin systems. Once begun and an optimal dose has been reached (Table 216-3) an ACE inhibitor should be maintained indefinitely. However, ACE inhibition should *not* be used in hypotensive patients.

Angiotensin Receptor Blockers In patients who cannot tolerate ACE inhibitors because of cough, angioneurotic edema, leukopenia, an angiotensin II receptor blocker (type AT1) antagonist may be used instead and appears to be equally effective.

Aldosterone Antagonist The activation of the RAAS in HF increases not only the circulating and tissue angiotensin II but also aldosterone. The latter, in addition to causing Na^+ retention and worsening edema (Chaps. 32 and 321), causes sympathetic activation, myocardial, vascular, and perivascular fibrosis, and reduces arterial compliance. In one large multicenter trial in patients with HF with recent or current class IV symptoms and reduced ejection fraction who were receiving ACE inhibitors, diuretics and digoxin, the addition of spironolactone, 25 mg/d reduced total mortality, as well as sudden death and death from pump failure. Since spironolactone is also a useful, albeit weak, diuretic (see above), its widespread use in severe systolic HF should be considered.

Beta-Adrenoceptor Blockers While the abrupt administration of large doses of beta-adrenergic receptor blockers can intensify HF, especially acute HF, the administration of gradually escalating doses has been reported to improve the symptoms of HF, and to reduce all-cause death, cardiovascular death, sudden death, rehospitalization for HF, and pump failure death in patients with chronic heart failure already receiving ACE inhibitors (Table 216-3). These drugs are indicated in patients with moderately severe HF (classes II and III), but are not indicated with unstable HF, in hypotensive patients (systolic pressure < 90 mmHg), in patients with severe fluid overload, in patients who have required recent treatment with an intravenous inotropic agent, and in patients with sinus bradycardia, atrioventricular block, or a bronchospastic disorder.

Three beta-adrenergic blockers (metoprolol, bisoprolol and carvedilol) have been shown to improve survival in patients with HF. The

first two are selective and block only β_1 receptors, while the third blocks both β_1 and β_2 receptors as well as α receptors, thereby causing mild vasodilation. Carvedilol also appears to exert antioxidant activity.

Before commencing beta-blocker therapy, patients should be stabilized on an ACE inhibitor, diuretics and possibly digoxin. They should be begun in very low doses, e.g., carvedilol 3.125 mg bid or metoprolol XL 12.5 mg qd and titrated upward slowly every 2 to 4 weeks. During titration, the patients should be observed closely for hypertension, bradycardia, and worsening HF. Approximately 15% of patients cannot tolerate beta blockade, and an equal number cannot tolerate target doses (carvedilol 25 mg bid and metoprolol XL 200 mg). In the latter, low-dose beta-blocker therapy is preferred to no therapy.

Once a maintenance dose has been achieved, administration of the beta blocker should be continued indefinitely. If treatment of a patient on a beta blocker with a positive inotropic agent is required, a phosphodiesterase III inhibitor (see below) should be used.

ENHANCEMENT OF MYOCARDIAL CONTRACTILITY ■ Digitalis The improvement of myocardial contractility by means of cardiac glycosides is useful in the control of HF. Cardiac glycosides inhibit the monovalent cation transport enzyme–coupled Na^+, K^+-ATPase and increase intracellular $[Na^+]$; the latter, in turn, increases intracellular $[Ca^{2+}]$ through a Na^+-Ca^{2+} exchange carrier mechanism. The increased myocardial $[Ca^{2+}]$ augments Ca^{2+} released to the myofilaments during excitation and, therefore, invokes a positive inotropic response (Chap. 215). Cardiac glycosides causes increased automaticity and ectopic impulse activity. They also prolong the effective refractory period of the atrioventricular node and thereby slow ventricular rate in atrial flutter and fibrillation.

Digitalis is effective in patients with systolic HF complicated by atrial flutter and fibrillation and a rapid ventricular rate, who benefit both from slowing of the ventricular rate and from the positive inotropic effect. Although digitalis does not improve survival in patients with systolic HF and sinus rhythm, it reduces symptoms of HF and the need for hospitalization. Digitalis is of *little* or *no* value in patients with HF, sinus rhythm, and the following conditions: hypertrophic cardiomyopathy, myocarditis, mitral stenosis, chronic constrictive pericarditis, and any form of diastolic HF.

Digoxin, which has a half-life of 1.6 days, is filtered in the glomeruli and secreted by the renal tubules. Significant reductions of the glomerular filtration rate reduce the elimination of digoxin and, therefore, may prolong digoxin's effect, allowing it to accumulate to toxic levels, unless the dose is reduced.

DIGITALIS INTOXICATION This is a serious and potentially fatal complication. Advanced age, hypokalemia, hypomagnesemia, hypoxemia, renal insufficiency, hypercalcemia, and acute myocardial infarction all may reduce tolerance to digitalis. Chronic digitalis intoxication may be insidious in onset and is characterized by anorexia, nausea, and vomiting, exacerbations of HF, weight loss, cachexia, neuralgias, gynecomastia, yellow vision, and delirium.

The most frequent disturbances of cardiac rhythm are ventricular premature beats, bigeminy, ventricular tachycardia, and, rarely, ventricular fibrillation. Atrioventricular block and nonparoxysmal atrial tachycardia with variable atrioventricular block are characteristic of digitalis intoxication; withdrawal of the drug and treatment with β-adrenoceptor blocker or lidocaine are indicated. If hypokalemia is present, potassium should be administered cautiously by the oral route. Fab fragments of purified, intact digitalis antibodies are a potentially lifesaving approach to the treatment of severe intoxication.

The administration of quinidine, verapamil, amiodarone, and propafenone to patients receiving digoxin raises the serum concentration of the latter, increasing the propensity to digitalis intoxication. The dose of digitalis should be reduced by half in patients receiving these drugs.

Sympathomimetic Amines Two sympathomimetic amines that act largely on β-adrenergic receptors—dopamine and dobutamine—improve myocardial contractility and are effective in the management of severe, acute HF. They must be administered by constant intravenous infusion and can be given for several days to patients with intractable, severe HF, particularly those with a reversible component, such as exists in patients who have undergone cardiac surgery, as well as to patients with acute myocardial infarction and shock or pulmonary edema (Chap. 255), and they may be used in patients with refractory HF as a "bridge" to cardiac transplantation. The administration of sympathomimetic amines should be accompanied by careful and continuous monitoring of the electrocardiogram, arterial pressure, and, if possible, pulmonary artery wedge pressure.

Dopamine is a naturally occurring, immediate precursor of norepinephrine and has a combination of actions that makes it particularly useful in the treatment of a variety of hypotensive states and HF. At very low doses (i.e., 1 to 2 μg/kg per min), it dilates renal and mesenteric blood vessels through stimulation of specific dopaminergic receptors, thereby augmenting renal and mesenteric blood flow and sodium excretion. In the range of 2 to 10 μg/kg per min, dopamine stimulates myocardial β_1 receptors but induces relatively little tachycardia, while at higher doses it also stimulates α-adrenergic receptors and elevates arterial pressure.

Dobutamine is a synthetic sympathomimetic agent that acts on β_1, β_2, and α_1 receptors. It exerts a potent inotropic action, has only a modest cardio accelerating effect, and lowers peripheral vascular resistance. Since it simultaneously raises cardiac output, it may not lower systemic arterial pressure in patients with severe HF. Dobutamine, given in continuous infusions of 2.5 to 10 μg/kg per min, is useful in the treatment of acute HF without hypotension.

A major problem with all sympathomimetics is the loss of responsiveness, apparently due to "downregulation" of adrenergic receptors, which becomes evident within 8 h of continuous administration. This problem may be managed by intermittent therapy.

Phosphodiesterase Inhibitors These bipyridines, amrinone and milrinone, are noncatecholamine, nonglycoside agents that exert both *positive* inotropic and vasodilator actions by inhibiting phosphodiesterase III, an enzyme that breaks down intracytoplasmic cyclic AMP, the second messenger which is critical to adrenergic stimulation. These agents are administered intravenously; by simultaneously stimulating cardiac contractility and dilating the systemic vascular bed they reverse the major hemodynamic abnormalities associated with HF. Amrinone and milrinone may be administered for the same conditions in which dopamine or dobutamine are useful; they may be employed together with and potentiate the sympathomimetics.

VASODILATORS Direct vasodilators may be useful in patients with severe, acute HF who demonstrate systemic vasoconstriction despite ACE inhibitor therapy. The ideal vasodilator for the treatment of *acute* HF should have a rapid onset and brief duration of action when administered by intravenous infusion; sodium nitroprusside (0.1 to 3.0 μg/kg per min) qualifies as such a drug, but its use requires careful monitoring of the arterial pressure and, if possible, of the pulmonary artery wedge pressure. Intravenous nitroglycerin (beginning at 20 μg/min and titrated upwards to achieve the desired result or a maximum of 400 μg/min) and nesiritide (recombinant BNP, I.V. bolus = 2 μg/kg followed by 0.01 μg/kg per min) are effective vasodilators. The combination of hydralazine (up to 100 mg tid orally) and isosorbide dinitrate (up to 60 mg tid orally) may be useful for chronic oral administration.

VENTRICULAR RESYNCHRONIZATION Intraventricular conduction is depressed in about one-fourth of patients with chronic HF. This depression is manifest in prolongation of the QRS complex to more than 120 ms, leading to dyssynchrony of cardiac contraction, which further impairs cardiac contraction and thereby aggravates HF. "Resynchronization" with a device that has three pacing leads (right atrium, right ventricle, and cardiac vein, which provides left ventricular stimulation) has been shown to improve performance in patients with HF. This device, which has been approved by the FDA, has been demonstrated

to increase ejection fraction as well as the distance walked in 6 min, improved functional New York Heart Association class, and the quality of life. Hospitalization for worsening HF and/or requiring use of intravenous medication were reduced in half. Device placement was not possible or complications occurred in 8% of patients. Devices that incorporate the ability to achieve resynchronization and internal cardioversion-defibrillation are now also available and may simultaneously improve contraction and prevent sudden death due to ventricular fibrillation in patients with HF (see below).

MANAGEMENT OF ARRHYTHMIAS Premature ventricular contractions and episodes of asymptomatic ventricular tachycardia are common in advanced HF. Sudden death, presumably due to ventricular fibrillation, is responsible for about one-half of all deaths in this condition. The remainder are due to failure of the cardiac pump. The management of arrhythmias should commence with correction of electrolyte and acid-base disturbances (Chaps. 41 and 42), especially diuretic-induced hypokalemia, as well as digitalis intoxication (see above). Treatment with class I antiarrhythmics such as quinidine, procainamide, or flecainide (Chap. 214) is *contraindicated* because these drugs are proarrhythmic in patients with HF. Amiodarone, a class III antiarrhythmic, on the other hand, is well tolerated and is the drug of choice for patients with HF and atrial fibrillation.

Patients who have been resuscitated from sudden death, those with syncope or presyncope due to ventricular arrhythmias, and those with asymptomatic ventricular tachyarrhythmias in whom ventricular tachycardia can be induced during electrophysiologic testing should be strongly considered for the implantable automatic defibrillator (ICD). The MADIT II trial showed a 30% reduction in all-cause mortality in patients with a prior myocardial infarction and a left ventricular ejection fraction ≤30% in whom an ICD had been implanted. Although the societal costs of treating the majority of all such patients with a prophylactic ICD will be immense, this may soon become the treatment of choice in patients with severe systolic HF. The addition to the device of the capacity for "back-up pacing" may prevent sudden death due to bradyarrhythmias. (See also Chap. 214.)

Anticoagulants Patients with severe HF are at increased risk of pulmonary emboli secondary to venous thrombosis and of systemic emboli secondary to intracardiac thrombi and should be treated with warfarin. Patients with HF and atrial fibrillation, previous venous thrombosis, and pulmonary or systemic emboli are at especially high risk and should receive heparin followed by warfarin.

DIASTOLIC HEART FAILURE The major goal in the treatment of this condition is to eliminate or reduce the causes of diastolic dysfunction, such as ventricular hypertrophy, fibrosis, or ischemia. The second goal is to reduce pulmonary and/or systemic venous congestion, a major consequence of diastolic dysfunction. Dietary Na^+ restriction and diuretics are useful for this purpose. Slowing of heart rate with beta blockers or nondihydropyridine calcium antagonists is also important since it provides more time for ventricular filling.

REFRACTORY HEART FAILURE When the response to ordinary treatment as described above is inadequate, HF is considered to be refractory. Before assuming that this condition simply reflects terminal myocardial depression, careful consideration must be given to several possibilities: (1) an underlying or precipitating cause that may be amenable to specific surgical or medical therapy, such as infective endocarditis, thyrotoxicosis, or silent aortic or mitral stenosis has been overlooked; and (2) complications of overly vigorous therapy, such as digitalis intoxication, hypovolemia, or electrolyte imbalance. Recognition and proper treatment of the aforementioned problems, if they exist, are likely to restore responsiveness to therapy.

Patients with refractory HF ordinarily require hospital management (Table 216-4). The combination of an intravenously administered vasodilator such as nitroglycerin, niseritide, *or*. of a phosphodiesterase inhibitor (amrinone or milrinone), together with a sympathomimetic amine (dopamine or dobutamine) often results in additive effects, raising cardiac output and lowering filling pressure further.

TABLE 216-4 Therapeutic Options for Patients with Refractory Heart Failure

Combination diuretics	Left ventricular or biventricular pacing
Additional vasodilators	Novel cardiac surgery
Positive inotropic agents	Ventricular remodeling surgery
Mechanical circulatory support	Dynamic cardiomyoplasty
Cardiac transplantation	Mitral valve repair

Source: From MM Givertz, JN Cohn in EM Antman (ed): *Cardiovascular Therapeutics*, 2d ed. Philadelphia, Saunders, 2002, with permission.

In hospitalized patients with refractory HF, therapy guided by hemodynamic measurements provided by a balloon flotation (Swan-Ganz) catheter may be helpful. The goal of manipulating diuretics, inotropic agents, and vasodilators is to achieve a pulmonary capillary wedge pressure of 15 to 18 mmHg, a right atrial pressure of 5 to 8 mmHg, a cardiac index >2.2 L/min per m^2, and a systemic vascular resistance of 800 to 1200 dyne · s/cm^5. Once these values are achieved, an attempt should be made to convert the patient from intravenous to oral vasodilator therapy.

ASSISTED CIRCULATION/CARDIAC TRANSPLANTATION When patients with HF become unresponsive to a combination of all the aforementioned therapeutic measures, are in New York Heart Association class IV, and are deemed unlikely to survive one year, they should be considered for assisted circulation and/or cardiac transplantation (see Chap. 217). Prolonged left ventricular assistance may be used as a "bridge to transplantation." In a small (~10%) of patients receiving this therapy, there is sufficient improvement in cardiac function after two or three months to allow recovery after withdrawal of the device.

Treatment of Acute Pulmonary Edema →*Cardiogenic pulmonary edema is described in Chap. 29. Its management is described in Chap. 255.*

PROGNOSIS

The prognosis in patients with HF depends primarily on the nature of the underlying heart disease and on the presence or absence of a precipitating factor that can be treated. When one of the latter can be identified and removed, the outlook for immediate survival is far better than if HF occurs without any obvious precipitating cause. The long-term prognosis is more favorable when the underlying forms of heart disease, e.g., valvular heart disease, can be treated effectively. When this is not possible, the prognosis can be estimated by observing the response to treatment. When patients can be rendered free of congestion, survival may be 80% at two years. Survival may be as low as 50% at six months in patients with refractory symptoms (Fig. 216-3).

Other factors that have been shown to be associated with a poor

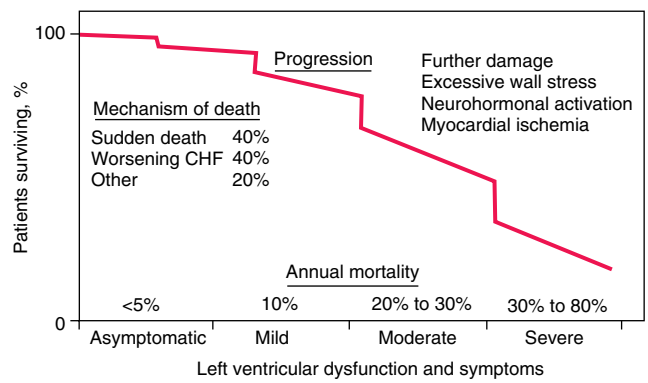

FIGURE 216-3 The natural history of congestive heart failure (CHF). Once left ventricular systolic dysfunction is present, it usually progresses, albeit not predictably. As left ventricular dysfunction progresses and symptoms increase, mortality rate increases and the process becomes inexorable. Myocyte loss and fibrosis become irreversible. An effective preventive measure must be introduced before onset or early in the course of progressive left ventricular dysfunction. *(From BM Massie, NH Shah: Curr Opin Cardiol 11:221, 1996; with permission.)*

prognosis include a severely depressed ejection fraction (<15%), a reduced maximal O_2 uptake (<10 mL/kg per min), the inability to walk on a level and at a normal pace for more than 3 min, reduced serum Na^+ concentration (<133 mEq/L), reduced serum K^+ (<3 meq/L), a markedly elevated (>500 pg/mL) BNP, as well as frequent ventricular extrasystoles. If sudden cardiac death is prevented by implantation of an ICD, patients may later go on to develop and succumb to pump failure and the number of such patients is likely to grow. When all available therapeutic measures have been exhausted, comfort care, sometimes in a hospice, with continued infusions of inotropic agents, diuretics, and the administration of anxiolytics and analgesics should be considered.

COR PULMONALE

Cor pulmonale is defined as enlargement of the right ventricle (RV) secondary to abnormalities of the lungs, thorax, pulmonary ventilation, or circulation. It sometimes leads to RV failure, with an elevation of transmural RV end-diastolic pressure.

NORMAL FUNCTION OF THE PULMONARY CIRCULATION

PATHOPHYSIOLOGY The stroke volume of the RV, as of the left, is regulated by its preload, contractility, and afterload (Chap. 215). Since the RV is a relatively thin, compliant reservoir, acute changes in venous return (e.g., an increase with inhalation and decline with exhalation) can occur with little change in transmural RV pressure. However, the ability of the RV to increase its systolic pressure is limited. Normally, the RV afterload, which is closely related to the pulmonary artery pressure, is low. The pulmonary artery pressure normally rises slightly when blood is displaced into the chest at the start of exercise; on assuming recumbency; or with cold, anxiety, or pain. A driving pressure of only about 5 cmH_2O between the pulmonary artery (15 cmH_2O) and the left atrium (10 cmH_2O) normally propels the entire cardiac output of approximately 5 L/min at rest through the lungs, and only a modest increase in pressure is necessary to drive a flow of up to 25 L/min through the pulmonary capillary bed during maximal exercise.

The severity of RV enlargement in cor pulmonale is a function of the increase in afterload. When the pulmonary vascular resistance is elevated and relatively fixed, as in pulmonary vascular or severe parenchymal lung disease, an elevation in cardiac output, as occurs with physical exertion, can elevate pulmonary artery pressure markedly. RV afterload may be augmented when the lungs are hyperinflated, as in chronic obstructive lung disease (COLD), due to the compression of the alveolar capillaries and the lengthening of the pulmonary vessels (Chap. 242). RV afterload can also increase when lung volume is reduced following extensive pulmonary resection, as well as in restrictive lung diseases in which pulmonary vessels are compressed and distorted. RV afterload rises with hypoxic pulmonary vasoconstriction caused by hypoxia or acidosis, which are important causes of pulmonary hypertension (Chap. 220).

The elevation of RV afterload responsible for cor pulmonale is caused principally by pulmonary vascular or parenchymal disease.

PULMONARY VASCULAR DISEASES In these conditions the RV afterload is elevated as a consequence of restriction to pulmonary blood flow. In cor pulmonale secondary to pulmonary vascular disease, pulmonary hypertension is usually more severe than in pulmonary parenchymal disease. Chronic cor pulmonale secondary to pulmonary vascular disease may result from repeated pulmonary emboli, pulmonary vasculitis, pulmonary vasoconstriction secondary to high altitude, congenital heart disease with left-to-right shunting (e.g., atrial or ventricular septal defect, patent ductus arteriosus; Chap. 218), as well as pulmonary venoocclusive disease. When the cause of elevated pulmonary vascular resistance responsible for cor pulmonale cannot be defined, the condition is referred to as *primary pulmonary hypertension* (Chap. 220).

COR PULMONALE DUE TO PULMONARY EMBOLI This condition is associated with two distinct syndromes.

Acute Cor Pulmonale It has been estimated that in the United States about 50,000 people die each year from pulmonary thromboembolism (Chap. 244). Probably half die within the first hour from acute right heart failure due to massive or multiple emboli. A sudden, large embolic burden causes a low-output state resulting from the RV's inability to generate the pressure necessary to drive blood through the acutely compromised pulmonary vascular bed. Depression of cardiac output can also occur with a moderate-sized embolism if the pulmonary circulation has been critically compromised by previous pulmonary vascular or parenchymal disease. The RV begins to fail when systolic pressure is forced to double acutely, i.e., to exceed approximately 50 mmHg. Acute RV failure secondary to pulmonary embolism is suggested by the history of the sudden onset of severe dyspnea and cardiovascular collapse in a patient with, or predisposed to, venous thrombosis.

Clinical Manifestations Acute RV failure causes pallor, sweating, hypotension, and a rapid pulse of small amplitude. The neck veins are distended and often exhibit prominent *v* waves secondary to tricuspid regurgitation. The liver may be pulsatile, distended, and tender. A systolic murmur of tricuspid regurgitation along the left sternal border may be accompanied by a presystolic (S_4) gallop sound. Arterial blood gas frequently shows reduced Pa_{O_2} due to ventilation/perfusion mismatching and a low Pa_{CO_2} due to hyperventilation.

℞ TREATMENT

The treatment of pulmonary embolism is described in Chap. 244. In acute cor pulmonale [and in RV failure due to acute RV infarction (Chap. 228)], an increase in RV preload can be achieved by a cautious expansion of blood volume, which helps to maintain cardiac output. When hypoxic pulmonary vasoconstriction contributes to pulmonary hypertension, inhalation of 100% O_2 reduces RV afterload.

CHRONIC COR PULMONALE SECONDARY TO PULMONARY VASCULAR DISEASE In contrast to acute, massive thromboembolism, when the elevation in pulmonary vascular resistance and the RV hypertrophy develop gradually, higher pulmonary vascular pressures, sometimes even approaching systemic arterial levels, may be generated. Chronic cor pulmonale can be caused by recurrent, medium-sized emboli that fail to lyse, but organize, resulting in chronic thromboembolic pulmonary hypertension. Particles from intravenous drug abuse, parasites, or tumor tissue that embolizes into the pulmonary vascular bed may also cause persistent pulmonary hypertension. Chronic cor pulmonale can also be caused by *primary pulmonary hypertension* (Chap. 220) or any chronic widespread vasculitis, such as occurs in association with collagen vascular disorders and that may affect the pulmonary vascular bed, particularly the CREST syndrome (Chap. 303).

Clinical Manifestations Dyspnea and tachypnea are characteristic features of pulmonary hypertension secondary to pulmonary vascular disease. They may be distressing during mild exertion or even at rest and are *not* relieved by sitting upright. An unproductive cough is another frequent complaint. Anterior chest pain, due to acute dilation of the root of the pulmonary artery or RV ischemia, can occur. The elevation in systemic venous pressure can cause hepatomegaly and ankle edema.

Occasionally there is cyanosis due to arterial hypoxemia and low cardiac output. An RV heave may be palpable along the left sternal border or in the epigastrium, and a high-pitched pulmonary ejection click may be audible to the left of the upper sternum. The second (pulmonary) component of the second heart sound is intensified and may be palpable; fixed, narrow splitting of the second heart sound and a right ventricular protodiastolic gallop (S_3) that may increase during inspiration can be present. A systolic murmur of tricuspid regurgitation, which is augmented by inspiration, is often audible; occasionally, a diastolic murmur of pulmonary regurgitation is also heard. Prominent *a* (and sometimes also *v*) waves in the jugular venous pulse are evident. The onset of RV failure is reflected by an increase of venous pressure, the development of larger *v* waves associated with increasing tricuspid regurgitation, a positive hepatojugular reflux, and a gallop

rhythm with both third and fourth heart sounds. These physical findings of RV failure can disappear rapidly when pulmonary artery pressure is reduced by relief of hypoxemia.

Laboratory Examination On *radiologic examination* the pulmonary trunk and hilar vessels are enlarged, as is the descending right pulmonary artery. Ventilation and perfusion lung scans and systemic venography showing deep vein thrombosis in the lower extremities are helpful in confirming the diagnosis of embolic pulmonary vascular disease. In the presence of severe pulmonary hypertension, the *electrocardiogram* (ECG) shows P pulmonale, right axis deviation, and RV hypertrophy (Chap. 210).

Echocardiography allows measurement of the thickness of the RV wall and may show enlargement of the RV cavity in relation to the left. The interventricular septum may be displaced leftward and may move paradoxically during the cardiac cycle. Pulmonary artery and RV systolic pressure can be estimated from measurement of the peak tricuspid regurgitant flow and pulmonic regurgitant flow with Doppler echocardiography.

Magnetic resonance imaging is useful for measuring RV mass, wall thickness, cavity volume, and ejection fraction.

Cardiac catheterization provides precise measurement of pulmonary vascular pressures, calculation of pulmonary vascular resistance, and their responses to oxygen and vasodilators. Catheterization is sometimes helpful in patients with cor pulmonale to exclude congenital and left heart diseases, and it allows pulmonary angiography to be carried out to confirm the nature of the pulmonary vascular obstruction. Measurements of pulmonary vascular pressure and flow during exercise may reveal abnormal pressure increments of pulmonary artery systolic and diastolic and RV diastolic pressures and an inadequate response to cardiac output.

Lung biopsy can be useful in demonstrating vasculitis in some types of pulmonary vascular disease such as the collagen vascular diseases, rheumatoid arthritis, and Wegener's granulomatosis.

PARENCHYMAL PULMONARY DISEASES Cor pulmonale may be caused by both obstructive and restrictive lung diseases, more frequently the former. In these conditions there are usually only modest elevations of pulmonary artery pressure. The development of cor pulmonale confers a poor prognosis on patients with respiratory disease, not because RV failure cannot be treated, but because it reflects the seriousness of the underlying pulmonary disease.

Rx TREATMENT (See Chap. 242)

Acute respiratory infection, often the precipitant of RV failure, must be treated promptly and vigorously. Alveolar hypoxia at rest and during exertion and sleep should be corrected by improving alveolar ventilation through relieving the airflow obstruction and by judiciously increasing the inspired O_2 concentration. Long-term O_2 therapy is helpful in patients with severe COLD and reduces pulmonary artery pressure and pulmonary vascular resistance. Bronchodilators and antibiotics lessen airflow obstruction, and diuretics relieve the edema. Loop diuretics must be used with care since they may cause a metabolic alkalosis and thereby blunt the respiratory drive. Digitalis should be used cautiously in the presence of overt RV failure, and small phlebotomies should be considered when the hematocrit exceeds 55 to 60%. Inhalation of nitric oxide and infusion of prostacyclin are undergoing evaluation as agents to reduce pulmonary hypertension.

217 CARDIAC TRANSPLANTATION AND PROLONGED ASSISTED CIRCULATION

Sharon A. Hunt

Advanced or end-stage heart failure is an increasingly frequent sequela as progressively more effective palliation for the earlier stages of heart disease and prevention of sudden death associated with heart disease become more widely recognized and employed (Chap. 216). When patients with end-stage or refractory heart failure are identified, the physician is faced with the decision of advising compassionate end-of-life care or choosing to recommend extraordinary life-extending measures. For the occasional patient who is relatively young and without serious comorbidities, the latter may represent a reasonable option. Current therapeutic options are limited to cardiac transplantation (with the option of mechanical cardiac assistance as a "bridge" to transplantation), but the option of permanent mechanical assistance of the circulation is not far off.

CARDIAC TRANSPLANTATION

Surgical techniques for orthotopic transplantation of the heart were devised in the 1960s and taken into the clinical arena in 1967. The procedure did not gain widespread clinical acceptance until the introduction of "modern" and more effective immunosuppression in the early 1980s. By the 1990s the demand for transplantable hearts met, and then exceeded, the available donor supply and peaked at 4400 annually worldwide in the early 1990s and declined to about 3000 in 2002.

SURGICAL TECHNIQUE Donor and recipient hearts are excised in virtually identical operations with incisions made across the atria and atrial septa at the midatrial level (leaving the posterior of the atria in place)

and across the great vessels just above the semilunar valves. The donor heart is generally "harvested" in an anatomically identical manner by a separate surgical team and transported from the donor hospital in a bag of iced saline solution and then is reanastomosed into the waiting recipient in the orthotopic or normal anatomical position. The only change in surgical technique since this method was first described has been a movement in recent years to move the right atrial anastamosis back to the level of the superior and inferior vena cavae in order to better preserve right atrial geometry and prevent atrial arrhythmias. This method of implantation leaves the recipient with a surgically denervated heart that does not respond to any direct sympathetic or parasympathetic stimuli but does respond to circulating catecholamines. The physiologic responses of the denervated heart to the demands of exercise are atypical but quite adequate to carry on normal physical activity.

DONOR ALLOCATION SYSTEM In the United States the allocation of donor organs is accomplished under the supervision of the United Network for Organ Sharing (UNOS), a private organization under contract to the federal government. The United States is divided geographically into eleven regions for donor heart allocation. Allocation of donor hearts within a region is decided according to a system of priority that takes into account (1) the severity of illness, (2) geographic distance from the donor, and (3) patient time on the waiting list. A physiologic limit of approximately 3 h of "ischemic" (out of body) time for hearts precludes a national sharing of hearts. This allocation system design is reissued annually and is responsive to input from a variety of constituencies, including donor families and transplant professionals.

At the current time, higher priority according to severity of illness is assigned only to patients requiring hospitalization for intravenous inotropic support either with a pulmonary artery catheter in place for hemodynamic monitoring or without hemodynamic monitoring. All other patients have priority according to their time on the waiting list, and matching is achieved only according to ABO blood group compatibility and gross body size compatibility.

INDICATIONS/CONTRAINDICATIONS Heart failure is an increasingly common cause of death, particularly in the elderly. Most patients who reach what has recently been categorized as stage D, or refractory end-stage heart failure, are appropriately treated with compassionate end-of-life care. A subset of such patients who are younger and without significant comorbidities can be considered as candidates for heart transplantation. Exact criteria vary in different centers but generally take into consideration the patient's physiologic age and the existence of comorbidities such as peripheral or cerebrovascular disease, obesity, diabetes, cancer, or chronic infection.

RESULTS A registry organized by the International Society for Heart and Heart-Lung Transplantation has tracked worldwide and U.S. survival rates after heart transplantation since 1982. The most recent update reveals 83% and 76% survival 1 and 3 years posttransplant or a posttransplant "half-life" of 9.3 years (Fig. 217-1). The quality of life in these patients is generally excellent, with well over 90% of patients in the registry returning to normal and unrestricted function following transplantation.

IMMUNOSUPPRESSION Medical regimens employed to provide suppression of the normal immune response to a solid organ allograft vary from center to center and are in a constant state of evolution as more effective agents with improved side-effect profiles and less toxicity are introduced. All currently used regimens are nonspecific, providing general hyporeactivity to foreign antigens rather than donor-specific hyporeactivity and the attendant, and unwanted, susceptibility to infections and malignancy. Most cardiac transplant programs currently use a three-drug regimen including a calcineurin inhibitor (cyclosporine or tacrolimus), an inhibitor of T cell proliferation or differentiation (azathioprine, mycophenolate mofetil, or sirolimus), and at least a short initial course of glucocorticoids. Many programs also include an initial "induction" course of polyclonal or monoclonal anti-T cell antibodies in the perioperative period to decrease the frequency or severity of early posttransplant rejection. Most recently introduced have been monoclonal antibodies (daclizumab and basiliximab), which block the interleukin 2 receptor and may provide prevention of allograft rejection without additional global immunosuppression.

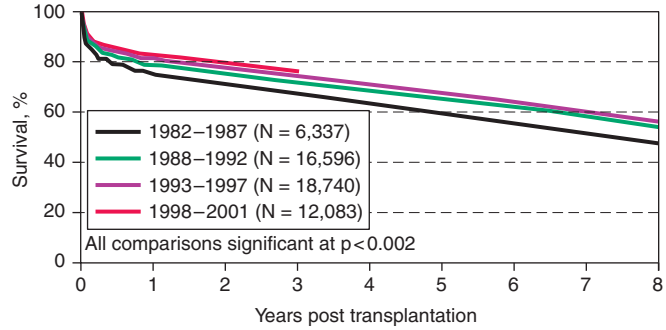

FIGURE 217-1 Actuarial survival for heart transplants performed between 1982 and 2001 by era of transplantation. (*Data by permission from United Network for Organ Sharing/International Society for Heart and Heart-Lung Transplantation Registry.*)

Diagnosis of cardiac allograft rejection is usually made with the use of endomyocardial biopsy, either done on a surveillance basis or in response to clinical deterioration. Therapy consists of augmentation of immunosuppression, the intensity and duration of which is dictated by the severity of the rejection.

LATE POSTTRANSPLANT MANAGEMENT ISSUES Increasing numbers of heart transplant patients are surviving for years following transplantation and constitute a population of patients with long-term management issues.

Allograft Coronary Artery Disease Despite having young donor hearts, cardiac allograft recipients are prone to develop coronary artery disease (CAD). This CAD is generally a diffuse, concentric, and longitudital process that is quite different from "ordinary" atherosclerotic CAD, which is more focal and often eccentric. The underlying etiology is most likely primarily immunologic injury of the vascular endothelium, but a variety of risk factors influence its existence and progression. It is hoped that newer and improved immunosuppressive modalities will reduce the incidence and impact of these devastating complications, which currently account for the majority of late posttransplant deaths. Palliation of the disease with percutaneous interventions is probably safe and effective in the short term. Because of the denervated status of the organ, patients rarely experience angina pectoris, even with advanced stages of the disease.

Retransplantation is the only definitive form of therapy for advanced allograft CAD, but inferior survival rates after retransplantation and the scarcity of donor hearts make the decision to pursue retransplantation a difficult one in an individual patient, as well as a difficult ethical issue.

Malignancy The occurrence of an increased incidence of malignancy is a well-recognized sequela of any program of chronic immunosuppression, and organ transplantation is no exception. Lymphoproliferative disorders are among the most frequent posttransplant complications and, in most cases, seem to be driven by the Epstein-Barr virus. Effective therapy includes reduction of immunosuppression (a clear "double-edged sword" in the setting of a life-sustaining organ), antiviral agents, and traditional chemo- and radiotherapy. Most recently, specific antilymphocyte (CD20) therapy has shown great promise. Cutaneous malignancies (both basal cell and squamous cell carcinomas) also occur with increased frequency in transplant recipients and can pursue very aggressive courses. The role of decreasing immunosuppression for treatment of these cancers is much less clear.

Infections The use of currently available nonspecific immunosuppressive modalities to prevent allograft rejection naturally results in an increased susceptibility to infectious complications in transplant recipients. Although their incidence has decreased since the introduction of cyclosporine, infections with unusual and opportunistic organisms remain the major cause of death during the first postoperative year and remain a threat to the chronically immunosuppressed patient through-

out life. Effective therapy depends on careful surveillance for early signs and symptoms of opportunistic infection and an extremely aggressive approach to obtaining a specific diagnosis as well as expertise in recognizing the more common clinical presentations of cytomegalovirus, *Aspergillus*, and other opportunistic infectious agents.

PROLONGED ASSISTED CIRCULATON

The modern era of mechanical circulatory support can be traced back to 1953 when cardiopulmonary bypass was first used in a clinical setting and ushered in the possibility of brief periods of circulatory support to permit open heart surgery. There have subsequently been developed a variety of extracorporeal pumps to provide circulatory support for brief periods of time. The use of a mechanical device to support the circulation for more than a few hours got off to a slow start in the 1980s when the first artificial hearts were introduced with much publicity but failed to produce the hoped-for treatment of end-stage heart disease. Subsequently, technology evolved to provide mechanical assistance to (rather than replacement of) the failing ventricle, although newer versions of the total artificial heart are now once again in preliminary clinical trials.

Although conceived of initially as alternatives to biologic replacement of the heart, left ventricular assist devices (LVADs) were introduced as, and are still employed primarily as, temporary "bridges" to heart transplantation in candidates who begin to fail medical therapy before a donor heart becomes available. Several devices are approved by the U.S. Food and Drug Administration (FDA) and are currently in widespread use. Those that are implantable within the body are compatible with hospital discharge and offer the patient chance for life at home while waiting for a donor heart. However successful such "bridging" is for the individual patient, it does nothing to alleviate the scarcity of donor hearts, and the ultimate goal in the field remains that of providing a reasonable alternative to biologic replacement of the heart—one that is widely and easily available and cost effective.

AVAILABLE DEVICES In the United States there are currently three FDA-approved devices that are used as bridges to transplantation. None as yet are totally implantable, and, because of this need for transcutaneous connections, all share a common problem with infectious complications. Likewise, all share some tendency to thromboembolic complications as well as the expected possibility of mechanical device failure common to any man-made machine.

The Thoratec LVAD (Thoratec Corp., Pleasanton, CA) is an extracorporeal pump that takes blood from a large cannula placed in the left ventricular apex and propels it forward through an outflow cannula inserted into the ascending aorta. The pump itself sits in the paracorporeal position on the abdomen and is attached to a device console cart with wheels, allowing for limited ambulation. The extracorporeal nature of this pump allows it to be used for small adults for whom the intracorporeal pumps would be too large.

The Novacor LVAD (WorldHeart Inc., Oakland, CA) also takes blood from the left ventricular apex through a cannula and propels it into the ascending aorta through a second cannula. With this device the pump itself is placed in a surgically created pocket in the preperitoneal fascia in the abdomen. A drive line that connects to the power source is tunneled subcutaneously and usually exits in the right upper quadrant of the abdomen.

The HeartMate LVAD (Thoratec Corp., Pleasanton, CA) uses a configuration identical to that of the Novacor device (Fig. 217-2). Differences between the two have to do with the materials used and the tendency for thromboembolic complications. Both commonly lead to hospital discharge and an outpatient wait for a donor heart.

RESULTS The use of these devices in the United States is limited mainly to patients with postcardiac surgery shock and those who are "bridged" to transplantation. Approximately 6000 patients per year receive support devices after cardiac surgery, with hospital survival rates between 20 and 40%. Approximately 300 to 400 patients per year have devices placed as bridges to transplantation, with an overall discharge rate of 50 to 70% from implantation through transplantation.

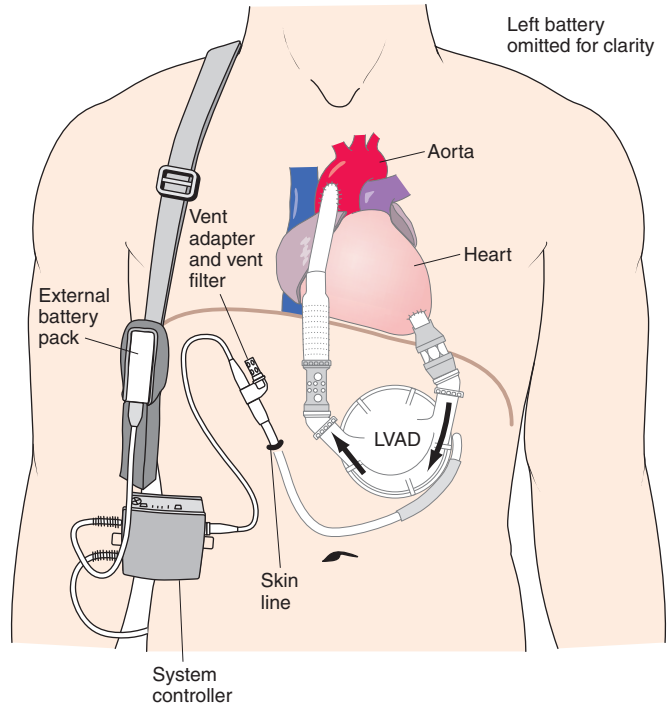

FIGURE 217-2 Diagram of HeartMate left ventricular assist device. (*Reprinted with permission from Thoratec Corp., Pleasanton, CA.*)

GOALS Future developments in this field can be expected in two directions. First, newer generations of the pumps will likely be smaller and simpler mechanically and, most important, totally implantable. Several much smaller devices, which use a mechanical propeller to provide axial, or non-pulsatile, flow of blood, are already in clinical trials. Second, use of the pumps as "permanent" (destination) therapy in patients with end-stage heart failure who are not considered eligible for transplantation will likely happen in the near future. In a randomized trial of long-term circulatory support with the HeartMate device in such patients, survival with the device was superior to continued medical management. FDA approval of the HeartMate device as permanent circulatory support for patients not eligible for transplantation was granted in 2002. Eventually it is hoped that improved assist devices will be accepted as valid alternatives to biologic replacement of the heart even in transplant-eligible patients and help to modify the supply/demand mismatch for cardiac replacement therapy.

218 CONGENITAL HEART DISEASE IN THE ADULT

John S. Child, William F. Friedman

Congenital heart disease complicates ~1% of all live births. It occurs in about 4% of offspring of women with congenital heart disease. Substantial numbers of affected infants reach adulthood because of successful medical and/or surgical management, or because the alteration caused in cardiovascular physiology is well tolerated.

ETIOLOGY Congenital cardiovascular malformations are generally the result of aberrant embryonic development of a normal structure, or failure of such a structure to progress beyond an early stage of embryonic or fetal development. Malformations are due to complex multifactorial genetic and environmental causes. Recognized chromosomal aberrations and mutations of single genes account for <10% of all cardiac malformations (Table 218-1).

The presence of a cardiac malformation as one component of the multiple system involvement in Down's, Turner's, and the trisomy 13-15(D1) and 17-18 (E) syndromes may be anticipated in occasional pregnancies by detection of abnormal chromosomes in fetal cells obtained from amniotic fluid or chorionic villus biopsy. Identification in such cells of the enzyme disorders characteristic of Hurler's syndrome, homocystinuria, or type II glycogen storage disease may also allow one to predict cardiac disease.

PATHOPHYSIOLOGY The anatomic and physiologic changes in the heart and circulation due to any specific congenital cardiocirculatory lesion are not static but rather progress from prenatal life to adulthood. Thus, malformations that are benign or escape detection in childhood may become clinically significant in the adult. For example, the functionally normal, congenitally bicuspid aortic valve may thicken and calcify with time, resulting in significant aortic stenosis; or the well-tolerated left-to-right shunt of an atrial septal defect may not result in cardiac decompensation, with or without pulmonary hypertension, until the fourth or fifth decade.

Pulmonary Hypertension This is a common companion of many congenital cardiac lesions, and the status of the pulmonary vascular bed is often the principal determinant of the clinical manifestations, the course, and the feasibility of surgical repair. Increases in pulmonary arterial pressure result from elevation of pulmonary blood flow and/or resistance, the latter due sometimes to an increase in vascular tone but usually the result of obstructive, obliterative structural changes within the pulmonary vascular bed. Because pulmonary vascular obstructive disease can be the determining factor in assessing the advisability of operation, it is important to quantitate and compare pulmonary to systemic flows and resistances in patients with severe pulmonary hypertension. The causes of pulmonary vascular obstructive disease are unknown, although increased pulmonary blood flow, increased pulmonary arterial blood pressure, elevated pulmonary venous pressure, erythrocytosis, systemic hypoxemia, acidosis, and the bronchial circulation have been implicated. The designation *Eisenmenger syndrome* is applied to patients with a large communication between the two circulations at the aortopulmonary, ventricular, or atrial levels and bidirectional or predominantly right-to-left shunts because of high-resistance and obstructive pulmonary hypertension. No specific treatment has proved beneficial for obstructive pulmonary vascular disease, although newer pulmonary vasodilators and both single lung transplantation with intracardiac defect repair and total heart-lung transplantation are under investigation (Chaps. 217 and 248).

Erythrocytosis The chronic hypoxemia in cyanotic congenital heart disease results in *erythrocytosis* due to increased erythropoietin production (Chap. 31). The commonly used term *polycythemia* is a misnomer because white cell counts are normal and platelet counts are normal to decreased. Cyanotic patients with erythrocytosis may have compensated or decompensated hematocrits. Compensated erythrocytosis with iron-replete equilibrium hematocrits rarely result in symptoms of hyperviscosity at hematocrits <65% and occasionally not even with hematocrits ≥70%. Therapeutic phlebotomy is rarely required in compensated erythrocytosis. In contrast, patients with decompensated erythrocytosis fail to establish equilibrium with unstable, rising hematocrits and recurrent hyperviscosity symptoms. Therapeutic phlebotomy, a two-edged sword, allows temporary relief of symptoms but begets instability of the hematocrit and compounds the problem by iron depletion. Iron-deficiency symptoms are usually indistinguishable from those of hyperviscosity; progressive symptoms after recurrent phlebotomy are usually due to iron depletion with hypochromic microcytosis. Iron depletion results in a larger number of smaller (microcytic) hypochromic red cells that are less capable of carrying oxygen and less deformable in the microcirculation. Because these microcytes are less deformable in the microcirculation and there are more of them relative to the plasma volume, the viscosity is greater than for an equivalent hematocrit with fewer, larger, iron-replete, deformable cells. As such, iron-depleted erythrocytosis results in increasing symptoms due to decreased oxygen delivery to the tissues.

Hemostasis is abnormal in cyanotic congenital heart disease, due in part to the increased blood volume and engorged capillaries, abnormalities in platelet function and sensitivity to aspirin or nonsteroidal anti-inflammatory agents, and abnormalities of the extrinsic and intrinsic coagulation system. Oral contraceptives are contraindicated for cyanotic women because of the enhanced risk of vascular thrombosis.

The risk of stroke is greatest in children <4 years with cyanotic heart disease and iron deficiency, often with dehydration as an aggravating cause. In contrast, adults with cyanotic congenital heart disease do not appear to be at increased risk for stroke, unless there are excessive injudicious phlebotomies, inappropriate use of aspirin or anticoagulants, or the presence of atrial arrhythmias or infective endocarditis.

Symptoms of hyperviscosity can be produced in any cyanotic patient with erythrocytosis if dehydration causes a reduction of plasma volume. Phlebotomy, when required for symptoms of hyperviscosity not due to dehydration or iron deficiency, is a simple outpatient removal of 500 mL of blood over 45 min with isovolumetric replacement with isotonic saline (5% dextrose if congestive heart failure exists). Acute phlebotomy without volume replacement is contraindicated. Iron repletion in decompensated iron-depleted erythrocytosis ameliorates iron-deficiency symptoms but must be done gradually to avoid a sudden excessive rise in hematocrit and resultant hyperviscosity.

Pregnancy The physiologic alterations during normal gestation (Chap. 6) can create symptoms and physical findings that may be attributed erroneously to heart disease. Dyspnea due to the hormonal influence of progesterone and elevation of the diaphragm in association with peripheral edema and fatigability may be attributed inappropriately to heart failure. The jugular venous pulsations normally become more apparent after the twentieth week. Elevation of the diaphragm can cause basal rales (which disappear with deep breathing). Both ventricles are more easily palpated due to the normal increase in ventricular volumes and elevation of the diaphragm. Third heart sounds, already relatively frequent in normal nongravid young women, increase in frequency and intensity with pregnancy because of increased heart rate and volume of flow across the mitral and tricuspid valves. Midsystolic murmurs across the pulmonary outflow tract and supraclavicular systolic murmurs are caused by increased cardiac output. Venous hums and mammary souffles are usual during pregnancy.

These normal circulatory changes may impinge upon the woman's cardiac reserve. The mother is most at risk if she has a cardiovascular lesion associated with pulmonary vascular disease and pulmonary hypertension (e.g., Eisenmenger's physiology or mitral stenosis) or left

TABLE 218-1 *Syndromes with Associated Cardiovascular Involvement*

Syndrome (Genetic Locus)	Major Cardiovascular Manifestations	Major Noncardiac Abnormalities
HERITABLE AND POSSIBLY HERITABLE		
Ellis–van Creveld	Single atrium or atrial septal defect	Chondrodystrophic dwarfism, nail dysplasia, polydactyly
TAR (thrombocytopenia-absent radius)	Atrial septal defect, tetralogy of Fallot	Radial aplasia or hypoplasia, thrombocytopenia
Holt-Oram (12q21–q3)	Atrial septal defect (other defects common)	Skeletal upper limb defect, hypoplasia of clavicles
Kartagener	Dextrocardia	Situs inversus, sinusitis, bronchiectasis
Laurence-Moon-Biedl-Bardet	Variable defects	Retinal pigmentation, obesity, polydactyly
Noonan (12q24)	Pulmonic valve dysplasia, cardiomyopathy (usually hypertrophic)	Webbed neck, pectus excavatum, cryptorchidism
Tuberous sclerosis (type 1—9q); type 2—16p)	Rhabdomyoma, cardiomyopathy	Phakomatosis, bone lesions, hamartomatous skin lesions
Multiple lentigines (LEOPARD) syndrome	Pulmonic stenosis	Basal cell nevi, broad facies, rib anomalies, deafness
Rubenstein-Taybi (16p13.3)	Patent ductus arteriosus (others)	Broad thumbs and toes, hypoplastic maxilla, slanted palpebral fissures
Familial deafness	Arrhythmias, sudden death	Sensorineural deafness
Weber-Osler-Rendu (9q33)	Arteriovenous fistulas (lung, liver, mucous membranes)	Multiple telangiectasias
Apert (10q26)	Ventricular septal defect	Craniosynostosis, midfacial hypoplasia, syndactyly
Crouzon (10q26, 4p16.3)	Patent ductus arteriosus, aortic coarctation	Ptosis with shallow orbits, craniosynostosis, maxillary hypoplasia
Hypertrophic cardiomyopathy (locus heterogeneity, 14q11.2–12, 1q32, 15q22, 11p11.2, etc.)	Asymmetric septal hypertrophy	Family history of sudden death
Incontinentia pigmenti	Patent ductus arteriosus	Irregular pigmented skin lesions, patchy alopecia, hypodontia
Alagille (arteriohepatic dysplasia) (20p12)	Peripheral pulmonic stenosis, pulmonic stenosis	Biliary hypoplasia, vertebral anomalies, prominent forehead, deep-set eyes
Catch-22 (DiGeorge) (22q11)	Interrupted aortic arch, tetralogy of Fallot, truncus arteriosus	Thymic hypoplasia or aplasia, parathyroid aplasia or hypoplasia, abnormal facies
Shprintzen (velocardiofacial) (22q11.2)	Ventricular septal defect, tetralogy of Fallot, right aortic arch	Cleft palate, prominent nose, slender hands, learning disability
Williams (7q11.23)	Supravalvular aortic stenosis, peripheral pulmonic stenosis	Mental deficiency, elfin facies, loquacious personality, hoarse voice
Long QT (Jervell and Lange-Nielsen, Romano-Ward) (11p15.5, 7q35, 3p21, 21q22)	Long QT interval, ventricular arrhythmias	Family history of sudden death, congenital deafness (not in Romano-Ward)
Friedreich's ataxia (9q)	Hypertrophic or dilated cardiomyopathy; conduction defects	Ataxia, speech defect, degeneration of spinal cord dorsal columns
Muscular dystrophy	Cardiomyopathy	Pseudohypertrophy of calf muscles, weakness of trunk and proximal limb muscles
Cystic fibrosis (7q)	Cor pulmonale	Pancreatic insufficiency, malabsorption, chronic lung disease
Sickle cell anemia	Cardiomyopathy, mitral regurgitation	Hemoglobin SS
Conradi-Hunermann	Ventricular septal defect, patent ductus arteriosus	Asymmetrical limb shortness, early punctate mineralization, large skin pores
Cockayne	Accelerated atherosclerosis	Cachectic dwarfism, retinal pigment abnormalities, photosensitivity dermatitis
Progeria	Accelerated atherosclerosis	Premature aging, alopecia, atrophy of subcutaneous fat, skeletal hypoplasia
CONNECTIVE TISSUE DISORDERS		
Cutis laxa	Peripheral pulmonic stenosis	Generalized disruption of elastic fibers, diminished skin resilience, hernias
Ehlers-Danlos (2q31)	Arterial dilatation and rupture, mitral regurgitation	Hyperextensible joints, hyperelastic and friable
Marfan (15q21.1)	Aortic dilatation, aortic and mitral incompetence	Gracile habitus, arachnodactyly with hyperextensibility, lens subluxation
Osteogenesis imperfecta (4.17)	Aortic incompetence	Fragile bones, blue sclerae
Pseudoxanthoma elasticum	Peripheral and coronary arterial disease	Degeneration of elastic fibers in skin, retinal angioid streaks
INBORN ERRORS OF METABOLISM		
Pompe disease	Glycogen storage disease of heart	Acid maltase deficiency, muscular weakness
Homocystinuria	Aortic and pulmonary arterial dilatation, intravascular thrombosis	Cystathionine synthetase deficiency, lens subluxation, osteoporosis
Mucopolysaccharidoses: Hurler; Hunter	Multivalvular and coronary and great artery disease, cardiomyopathy	Hurler: Deficiency of α-L-iduronidase, corneal clouding, coarse features, growth and mental retardation Hunter: Deficiency of L-iduranosulfate sulfatase, coarse facies, clear cornea, growth and mental retardation

(continued)

TABLE 218-1—*(Continued)*

Syndrome (Genetic Locus)	Major Cardiovascular Manifestations	Major Noncardiac Abnormalities
Morquio; Scheie; Maroteaux-Lamy	Aortic regurgitation	Morquio: Deficiency of *N*-acetylhexosamine sulfate sulfatase, cloudy cornea, severe bone changes involving vertebrae and epiphyses Scheie: Deficiency of α-L-iduronidase, cloudy cornea, normal intelligence, peculiar facies Maroteaux-Lamy: Deficiency of arylsulfatase B, cloudy cornea, osseous changes
CHROMOSOMAL ABNORMALITIES		
Trisomy 21 (Down syndrome)	Endocardial cushion defect, atrial or ventricular septal defect, tetralogy of Fallot	Hypotonia, hyperextensible joints, mongoloid facies, mental retardation
Trisomy 13 (D)	Ventricular septal defect, patent ductus arteriosus, double-outlet right ventricle	Single midline intracerebral ventricle with midfacial defects, polydactyly, nail changes, mental retardation
Trisomy 18 (E)	Congenital polyvalvular dysplasia, ventricular septal defect, patent ductus	Clenched hand, short sternum, low arch dermal ridge pattern on fingertips, mental retardation
Cri du chat (short-arm deletion-5)	Ventricular septal defect	Cat cry, microcephaly, antimongoloid slant of palpebral fissures, mental retardation
XO (Turner)	Coarctation of aorta, bicuspid aortic valve, aortic dilatation	Short female, broad chest, lymphedema, webbed neck
XXXY and XXXXX	Patent ductus arteriosus	XXXY: Hypogenitalism, mental retardation, radial-ulnar synostosis XXXXX: Small hands, incurving of fifth fingers, mental retardation
SPORADIC DISORDERS		
VATER association	Ventricular septal defect	Vertebral anomalies, anal atresia, tracheo-esophageal fistula, radial and renal anomalies
CHARGE association	Tetralogy of Fallot (other defects common)	Colobomas, choanal atresia, mental and growth deficiency, genital and ear anomalies
Cornelia de Lange	Ventricular septal defect	Micromelia, synophrys, mental and growth deficiency
TERATOGENIC DISORDERS		
Rubella	Patent ductus arteriosus, pulmonic valvular and/or arterial stenosis, atrial septal defect	Cataracts, deafness, microcephaly
Alcohol	Ventricular septal defect (other defects)	Microcephaly, growth and mental deficiency, short palpebral fissures, smooth philtrum, thin upper lip
Dilantin	Pulmonic stenosis, aortic stenosis, coarctation, patent ductus arteriosus	Hypertelorism, growth and mental deficiency, short phalanges, bowed upper lip
Thalidomide	Variable	Phocomelia
Lithium	Ebstein's anomaly, tricuspid atresia	None

ventricular (LV) outflow tract obstruction (e.g., aortic stenosis) but also risks death with any malformation that may cause heart failure or a hemodynamically important arrhythmia (Table 218-2). The fetus is most at risk in the presence of maternal cyanosis, heart failure, or pulmonary hypertension. Women with aortic coarctation or Marfan's syndrome are at risk for aortic dissection. Patients with cyanotic heart disease, pulmonary hypertension, or Marfan's syndrome should not become pregnant; those with correctable lesions should be counseled about the risks of pregnancy with an uncorrected malformation versus repair and later pregnancy. The effect of pregnancy in postoperative patients depends on the outcome of the repair including the presence and severity of residua, sequelae, or complications. Contraception is an important topic with such patients. Tubal ligation should be considered in those in whom pregnancy is strictly contraindicated.

INFECTIVE ENDOCARDITIS (See also Chap. 109) Routine antimicrobial prophylaxis is recommended for most patients with congenital heart disease whether operated on or not. Antibiotic prophylaxis is not uniformly effective. Nonetheless, it is recommended for all dental procedures, gastrointestinal and genitourinary surgery, and diagnostic procedures such as proctosigmoidoscopy and cystoscopy. The clinical and bacteriologic profile of infective endocarditis in patients with congenital heart disease has changed with the advent of intracardiac surgery and of prosthetic devices. Two major predisposing causes of infective endocarditis are a susceptible cardiovascular substrate and a source of bacteremia. Prophylaxis includes both chemotherapeutic (antimicrobial) and nonchemotherapeutic (hygienic) measures. Meticulous dental and skin care is required.

TABLE 218-2 *Tolerance of Pregnancy by Patients with Various Congenital Cardiac Malformations*

Well Tolerated	Intermediate Effect	Poorly Tolerated
NYHA class I	NYHA class II–III	NHYA class IV
Left-right shunts without PHTN	Repaired transposition of the great arteries	Right-left shunt, unrepaired cyanotic heart disease
Aortic or mitral valvular regurgitation (mild-moderate)	Fontan repairs	PHTN and/or pulmonary vascular disease (e.g., Eisenmenger's, "primary PHTN")
Pulmonic or tricuspid regurgitation (if low pressure, even severe)	Aortic or mitral stenosis (moderate)	Aortic or mitral stenosis (severe)
Pulmonic stenosis (mild-moderate)	Ebstain's anomaly	Pulmonic stenosis (severe)
Well-repaired tetralogy of Fallot		Marfan's or aortic coarctation

Note: NYHA, New York Heart Association; PHTN, pulmonary hypertension.

EXERCISE Advice on athletics and exercise is governed by the nature of the exercise and by the type and severity of the congenital cardiovascular lesion. Patients with lesions characterized by LV outflow tract obstruction, if more than mild to moderate, or pulmonary vascular disease, risk syncope or even sudden death. In Fallot's tetralogy, isotonic exercise–induced decrease in systemic vascular resistance relative to the right ventricular (RV) outflow obstruction augments the right-to-left shunt, increases hypoxemia, and causes an increase in subjective breathlessness due to the response of the respiratory center to the changes in blood gases and pH.

INSURABILITY AND EMPLOYABILITY Most patients with congenital heart disease must pay significantly more than standard life insurance rates, assuming their anomaly places them in a category that companies have determined is eligible for insurance. A paucity of actuarial survival data beyond adolescence for persons with most congenital cardiac lesions that have undergone operative repair has made it difficult to convince insurance companies to offer reasonable cost insurance even to individual patients whose long-term prognosis is quite good.

Employment is affected by the patient's physical capacity relative to the type of job sought. Job discrimination exists, often because the employer is reluctant to accept health insurance responsibilities. Eligibility for some occupations is governed by public safety regulations, e.g., airline pilots, bus drivers.

SPECIFIC CARDIAC DEFECTS

Table 218-3 provides a classification of cardiac anomalies that recognizes the general categories of clinical presentation, functional consequences, and site of origin of congenital defects.

Categorizing the defect(s) in an individual patient requires an answer to a number of basic questions. Is the patient acyanotic or cyanotic? Is pulmonary arterial blood flow increased or not? Does the malformation originate in the left or right side of the heart? Which is the dominant ventricle? Is pulmonary hypertension present or not? With the above information as a foundation, the use of more refined

TABLE 218-3 Classification of Congenital Heart Disease

ACYANOTIC WITH LEFT-TO-RIGHT SHUNT

I. Atrial level shunt
  A. Atrial septal defect
    1. Ostium primum
    2. Ostium secundum
    3. Sinus venosus
  B. Atrial septal defect with mitral stenosis (Lutembacher's syndrome)
  C. Partial anomalous pulmonary venous connection
II. Ventricular level shunt
  A. Ventricular septal defect
    1. Inlet septum
    2. Muscular septum
    3. Perimembranous septum
    4. Infundibular septum
  B. Ventricular septal defect with aortic regurgitation
  C. Ventricular septal defect with left ventricular to right atrial shunt
III. Aortic root to right heart shunt
  A. Ruptured sinus of Valsalva aneurysm
  B. Coronary arteriovenous fistula
  C. Anomalous origin of the left coronary artery from the pulmonary trunk
IV. Aortopulmonary level shunt
  A. Aortopulmonary window
  B. Patent ductus arteriosus
V. Multiple level shunts
  A. Complete common atrioventricular canal
  B. Ventricular septal defect with atrial septal defect
  C. Ventricular septal defect with patent ductus arteriosus

ACYANOTIC WITHOUT A SHUNT

I. Left heart malformations
  A. Congenital obstruction to left atrial inflow
    1. Pulmonary vein stenosis
    2. Mitral stenosis
    3. Cor triatriatum
  B. Mitral regurgitation
    1. Atrioventricular septal (endocardial cushion)
    2. Congenitally corrected transposition of the great arteries
    3. Anomalous origin of the left coronary artery from the pulmonary trunk
    4. Miscellaneous (double-orifice mitral valve, congenital perforations, accessory commissures with anomalous chordal insertion, congenitally short or absent chordae, cleft posterior leaflet, parachute mitral valve, etc.)
  C. Primary dilated endocardial fibroelastosis
  D. Aortic stenosis
    1. Discrete subvalvular
    2. Valvular
    3. Supravalvular
  E. Aortic valve regurgitation
  F. Coarctation of the aorta
II. Right heart malformations
  A. Acyanotic Ebstein's anomaly of the tricuspid valve
  B. Pulmonic stenosis
    1. Subinfundibular
    2. Infundibular
    3. Valvular
    4. Supravalvular (stenosis of pulmonary artery and its branches)
  C. Congenital pulmonary valve regurgitation
  D. Idiopathic dilatation of the pulmonary trunk

CYANOTIC

I. Increased pulmonary blood flow
  A. Complete transposition of the great arteries
  B. Double-outlet right ventricle of the Taussig-Bing type
  C. Truncus arteriosus
  D. Total anomalous pulmonary venous connection
  E. Single ventricle without pulmonic stenosis
  F. Common atrium
  G. Tetralogy of Fallot with pulmonary atresia and increased collateral arterial flow

diagnostic techniques such as transthoracic (precordial) and transesophageal echocardiography and Doppler imaging, magnetic resonance imaging, and/or hemodynamic study and angiocardiography leads to a precise anatomic and functional assessment.

ACYANOTIC CONGENITAL HEART DISEASE WITH A LEFT-TO-RIGHT SHUNT

ATRIAL SEPTAL DEFECT This common cardiac anomaly in adults occurs more frequently in females. The *sinus venosus* type occurs high in the atrial septum near the entry of the superior vena cava and is associated frequently with anomalous connection of pulmonary veins from the right lung to the junction of the superior vena cava and right atrium. *Ostium primum* anomalies are a form of atrioventricular septal defect that lie immediately adjacent to the atrioventricular valves, either of which may be deformed and incompetent. Ostium primum defects occur commonly in patients with Down's syndrome, although the more complex atrioventricular septal defects with a common atrioventricular valve and a posterior defect of the basal portion of the interventricular septum are more characteristic of this chromosomal defect. The most common atrial septal defect involves the fossa ovalis, is midseptal in location, and is of the *ostium secundum type*. This type of defect should not be confused with a *patent foramen ovale*. Anatomic obliteration of the foramen ovale ordinarily follows its functional closure soon after birth, but residual "probe patency" is a normal variant; atrial septal defect denotes a true deficiency of the atrial septum and implies functional and anatomic patency.

The magnitude of the left-to-right shunt through an atrial septal defect depends on the defect size, the diastolic properties of both ventricles, and the relative impedance in the pulmonary and systemic circulations. The left-to-right shunt causes diastolic overloading of the right ventricle and increased pulmonary blood flow.

Patients with atrial septal defect are usually asymptomatic in early life, although there may be some physical underdevelopment and an increased tendency for respiratory infections; cardiorespiratory symptoms occur in many older patients. Beyond the fourth decade, a significant number of patients develop atrial arrhythmias, pulmonary arterial hypertension, bidirectional and then right-to-left shunting of blood, and cardiac failure. Patients exposed to the chronic environmental hypoxia of high altitude tend to develop pulmonary hypertension at younger ages. In some older patients, left-to-right shunting across the defect increases as progressive systemic hypertension and/or coronary artery disease result in reduced compliance of the left ventricle.

Physical Examination Examination usually reveals a prominent right ventricular impulse and palpable pulmonary artery pulsation. The first heart sound is normal or split, with accentuation of the tricuspid valve closure sound. Increased flow across the pulmonic valve is responsible for a midsystolic pulmonary outflow murmur. The second heart sound is widely split and is relatively fixed in relation to respiration. A middiastolic rumbling murmur, loudest at the fourth intercostal space and along the left sternal border, reflects increased flow across the tricuspid valve. In patients with ostium primum defects, an apical thrill and holosystolic murmur indicate associated mitral or tricuspid incompetence or a ventricular septal defect.

The physical findings are altered when an increase in the pulmonary vascular resistance results in diminution of the left-to-right shunt. Both the pulmonary and tricuspid murmurs decrease in intensity, the pulmonic component of the second heart sound and a systolic ejection sound are accentuated, the two components of the second heart sound may fuse, and a diastolic murmur of pulmonic regurgitation appears. Cyanosis and clubbing accompany the development of a right-to-left shunt.

In adults with an atrial septal defect and atrial fibrillation, the physical findings may be confused with the findings of mitral stenosis with pulmonary hypertension because the tricuspid flow murmur and widely split second heart sound may be mistakenly thought to represent the diastolic murmur of mitral stenosis and the mitral "opening snap," respectively.

Electrocardiogram In patients with an ostium secundum defect, the electrocardiogram (ECG) usually shows right axis deviation and an rSr′ pattern in the right precordial leads representing delayed posterobasal activation of the ventricular septum and enlargement of the RV outflow tract. An ectopic atrial pacemaker or first-degree heart block occurs occasionally in patients with defects of the sinus venous type. In patients with an ostium primum defect, the RV conduction defect is characteristically accompanied by left axis deviation and by superior orientation and counterclockwise rotation of the QRS loop in the frontal plane. Varying degrees of RV and right atrial (RA) hypertrophy may occur with each type of defect, depending on the height of the pulmonary artery pressure. *Chest roentgenograms* reveal enlargement of the right atrium and right ventricle, dilatation of the pulmonary artery and its branches, and increased pulmonary vascular markings.

Echocardiogram This test shows pulmonary arterial and RV dilatation, and anterior systolic (paradoxical) or flat interventricular septal motion if a significant RV volume overload is present. The defect may be visualized directly from subcostal, right parasternal, or apical echocardiographic windows. In most institutions, two-dimensional echocardiography, supplemented by conventional or color Doppler flow examination, has supplanted cardiac catheterization as the confirmatory test for atrial septal defect. Transesophageal echocardiography is indicated if the transthoracic echocardiogram is ambiguous, which is often the case with sinus venosus defects. Cardiac catheterization is then performed if inconsistencies exist in the clinical data, if significant pulmonary hypertension or associated malformations are suspected, or if coronary artery disease is a possibility.

℞ TREATMENT

Operative repair, usually with a patch of pericardium or of prosthetic material, or percutaneous transcatheter device closure, ideally in children ages 3 to 6, should be advised for all patients with uncomplicated secundum atrial septal defects in whom there is significant left-to-right shunting, i.e., pulmonary-to-systemic flow ratios ~2.0:1.0. Excellent results may be anticipated, at low risk, even in patients >40 years, in the absence of pulmonary hypertension. Patients with ostium primum defects, cleft, deformed, and incompetent valves require repair in addition to patch closure of the atrial defect. Intraoperative transesophageal echocardiography is used to monitor the surgical results of atrioventricular valve repair. Closure should not be carried out in patients with small defects and trivial left-to-right shunts or in those with severe pulmonary vascular disease without a significant left-to-right shunt.

Patients with atrial septal defect of the sinus venosus or ostium secundum types rarely die before the fifth decade. During the fifth and sixth decades the incidence of progressive symptoms, often leading to severe disability, increases substantially. Medical management should include prompt treatment of respiratory tract infections, antiarrhythmic medications for atrial fibrillation or supraventricular tachycardia, and the usual measures for hypertension, coronary disease, or heart failure (Chap. 216), if these complications occur. The risk of infective endocarditis is quite low unless the defect is complicated by valvular regurgitation or has recently been repaired with a patch (Chap. 109).

VENTRICULAR SEPTAL DEFECT Defects of the ventricular septum are common as isolated defects and as one component of a combination of anomalies. The opening is usually single and situated in the membranous portion of the septum. The functional disturbance is dependent primarily on its size and on the status of the pulmonary vascular bed, rather than on the location of the defect. Only small or moderate-size defects are usually seen initially in adulthood as most patients with isolated large defects come to medical and, often, surgical attention very early in life.

A wide spectrum exists in the natural history of ventricular septal defect, ranging from spontaneous closure to congestive cardiac failure

and death in early infancy. Within this spectrum is the possible development of pulmonary vascular obstruction, RV outflow tract obstruction, aortic regurgitation, and infective endocarditis. Spontaneous closure is more common in patients born with a small ventricular septal defect and occurs in early childhood in most patients.

Patients with large ventricular septal defects and pulmonary hypertension are those at greatest risk for developing pulmonary vascular obstruction. Thus, large defects should be corrected surgically early in life when pulmonary vascular disease is still reversible or not yet developed. In patients with severe pulmonary vascular obstruction (Eisenmenger syndrome), symptoms in adult life consist of exertional dyspnea, chest pain, syncope, and hemoptysis. The right-to-left shunt leads to cyanosis, clubbing, and erythrocytosis. In all patients, the degree to which pulmonary vascular resistance is elevated before operation is a critical factor determining prognosis. If the pulmonary vascular resistance is one-third or less of the systemic value, progression of pulmonary vascular disease after operation is unusual. However, if a moderate to severe increase in pulmonary vascular resistance exists preoperatively, either no change or a progression of pulmonary vascular disease is common postoperatively.

RV outflow tract obstruction develops in ~5 to 10% of patients who present in infancy with a moderate to large left-to-right shunt. With time, as subvalvular RV outflow tract obstruction progresses, the findings in these patients begin to resemble more closely those of the cyanotic tetralogy of Fallot.

In ~5% of patients, incompetence of the aortic valve results from insufficient cusp tissue or prolapse of the cusp through the interventricular defect; the aortic regurgitation then complicates and usually dominates the clinical course.

Two-dimensional *echocardiography* with conventional or color Doppler examination can usually define the number and location of defects in the ventricular septum and detect associated anomalies. Hemodynamic and angiographic study may be employed to assess the status of the pulmonary vascular bed and clarify details of the altered anatomy.

Rx TREATMENT

Surgery is not recommended for patients with normal pulmonary arterial pressures with small shunts (pulmonary-to-systemic flow ratios of <1.5 to 2.0:1.0). Operative correction is indicated when there is a moderate to large left-to-right shunt with a pulmonary-to-systemic flow ratio >1.5:1.0 or 2.0:1.0, in the absence of prohibitively high levels of pulmonary vascular resistance.

PATENT DUCTUS ARTERIOSUS The ductus arteriosus is a vessel leading from the bifurcation of the pulmonary artery to the aorta just distal to the left subclavian artery. Normally, the vascular channel is open in the fetus but closes immediately after birth. The flow across the ductus is determined by the pressure and resistance relationships between the systemic and pulmonary circulations and by the cross-sectional area and length of the ductus. In most adults with this anomaly, pulmonary pressures are normal and a gradient and shunt from aorta to pulmonary artery persist throughout the cardiac cycle, resulting in a characteristic thrill and a continuous "machinery" murmur with a late systolic accentuation at the upper left sternal edge. In adults who were born with a large left-to-right shunt through the ductus arteriosus, pulmonary vascular obstruction (Eisenmenger syndrome) with pulmonary hypertension, right-to-left shunting, and cyanosis have usually developed. Severe pulmonary vascular disease results in reversal of flow through the ductus; unoxygenated blood is shunted to the descending aorta; and the toes, but not the fingers, become cyanotic and clubbed, a finding termed *differential cyanosis*. The leading causes of death in adults with patent ductus are cardiac failure and infective endocarditis; occasionally severe pulmonary vascular obstruction may cause aneurysmal dilatation, calcification, and rupture of the ductus.

Rx TREATMENT

In the absence of severe pulmonary vascular disease and predominant left-to-right shunting of blood, the patent ductus should be surgically ligated or divided. Transcatheter closure using coils, buttons, plugs, and umbrellas has become commonplace for appropriately shaped defects. Thoracoscopic surgical approaches are considered experimental. Operation should be deferred for several months in patients treated successfully for infective endocarditis, because the ductus may remain somewhat edematous and friable.

AORTIC ROOT TO RIGHT HEART SHUNTS The three most common causes of aortic root to right heart shunts are congenital aneurysm of an aortic sinus of Valsalva with fistula, coronary arteriovenous fistula, and anomalous origin of the left coronary artery from the pulmonary trunk. *Aneurysm of an aortic sinus of Valsalva* consists of a separation or lack of fusion between the media of the aorta and the annulus of the aortic valve. Rupture usually occurs in the third or fourth decade of life; most often the aorticocardiac fistula is between the right coronary cusp and the right ventricle, but occasionally, when the noncoronary cusp is involved, the fistula drains into the right atrium. Abrupt rupture causes chest pain, bounding pulses, a continuous murmur accentuated in diastole, and volume overload of the heart. Diagnosis is confirmed by two-dimensional and Doppler echocardiographic studies; cardiac catheterization quantitates the left-to-right shunt, and thoracic aortography visualizes the fistula. Medical management is directed at cardiac failure, arrhythmias, or endocarditis. At operation, the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a prosthesis.

Coronary arteriovenous fistula, an unusual anomaly, consists of a communication between a coronary artery and another cardiac chamber, usually the coronary sinus, right atrium, or right ventricle. The shunt is usually of small magnitude, and myocardial blood flow is not usually compromised. Potential complications include infective endocarditis, thrombus formation with occlusion or distal embolization, rupture of an aneurysmal fistula, and rarely, pulmonary hypertension and congestive failure. A loud, superficial, continuous murmur at the lower or midsternal border usually prompts a further evaluation of asymptomatic patients. Doppler echocardiography demonstrates the site of drainage; if the site of origin is proximal, it may be detectable by two-dimensional echocardiography. Retrograde thoracic aortography or coronary arteriography permits identification of the size and anatomic features of the fistulous tract, which may be closed by suture or transcatheter obliteration.

The third anomaly causing a shunt from the aortic root to the right heart is *anomalous origin of the left coronary artery from the pulmonary artery*. Myocardial infarction and fibrosis commonly lead to death within the first year, though up to 20% of patients survive to adolescence and beyond without surgical correction. The diagnosis is supported by the ECG findings of an anterolateral myocardial infarction. Operative management of adults consists of coronary artery bypass with an internal mammary artery graft or saphenous vein–coronary artery graft.

ACYANOTIC CONGENITAL HEART DISEASE WITHOUT A SHUNT

CONGENITAL AORTIC STENOSIS Malformations that cause obstruction to LV outflow include congenital valvular aortic stenosis, discrete subaortic stenosis, supravalvular aortic stenosis, and hypertrophic obstructive cardiomyopathy (Chap. 221).

Valvular Aortic Stenosis This malformation occurs three to four times more often in males than in females. The congenital bicuspid aortic valve, which is not necessarily stenotic, is one of the most common congenital malformations of the heart, although it may go undetected in early life. Because bicuspid valves may become stenotic with time or be the site of the infective endocarditis, the lesion may be difficult to distinguish in adults from acquired rheumatic or degenerative calcific aortic stenosis.

The dynamics of blood flow associated with a congenitally deformed, rigid aortic valve commonly lead to thickening of the cusps and, in later life, to calcification. Hemodynamically significant obstruction causes concentric hypertrophy of the LV wall. The ascending aorta is often dilated, misnamed "poststenotic" dilatation; this is due to histologic abnormalities similar to those in Marfan syndrome, and may result in aortic dissection. →***The clinical manifestations and hemodynamic abnormalities are discussed in Chap. 219.***

TREATMENT

The medical management of congenital valvular aortic stenosis includes prophylaxis against infective endocarditis and, in patients with diminished cardiac reserve, the administration of digitalis and diuretics and sodium restriction while awaiting operation. A dilated aortic root may require beta blockers. If severe aortic stenosis is present, strenuous physical activity should be avoided even when the patient is asymptomatic, and participation in competitive sports should probably be restricted in patients with milder degrees of obstruction. Aortic valve replacement is indicated in adults with critical obstruction, i.e., with an aortic valve area <0.5 cm^2/m^2, with symptoms secondary to LV dysfunction or myocardial ischemia, or with hemodynamic evidence of LV dysfunction. In asymptomatic children or adolescents or young adults with critical aortic stenosis without valvular calcification or these features, aortic balloon valvuloplasty is often useful (Chap. 229). If surgery is contraindicated in older patients because of a complicating medical problem such as malignancy or renal or hepatic failure, balloon valvuloplasty may provide short-term improvement. It may serve as a bridge to aortic valve replacement in patients with severe heart failure.

Subaortic Stenosis The most common form of subaortic stenosis is the *idiopathic hypertrophic* variety, also termed *hypertrophic cardiomyopathy*, which is present at birth in about one-third of the patients and is discussed in Chap. 221. In contrast, both clinically and physiologically, the *discrete* form of subaortic stenosis resembles valvular aortic stenosis. The lesion usually consists of a membranous diaphragm or fibrous ring encircling the LV outflow tract just beneath the base of the aortic valve. Echocardiography demonstrates the subaortic obstruction; Doppler studies show turbulence proximal to the aortic valve and also detect and quantitate the pressure gradient and severity of aortic regurgitation. Treatment consists of excision of the membrane or fibrous ridge.

Supravalvular Aortic Stenosis This anomaly consists of a localized or diffuse narrowing of the ascending aorta originating just above the level of the coronary arteries at the superior margin of the sinuses of Valsalva. In contrast to other forms of aortic stenosis, the coronary arteries are subjected to elevated systolic pressures from the left ventricle, are often dilated and tortuous, and are susceptible to premature atherosclerosis. In most patients a genetic defect for the anomaly is located in the same chromosomal subunit as elastin on chromosome 7.

COARCTATION OF THE AORTA Narrowing or constriction of the lumen of the aorta may occur anywhere along its length but is most common distal to the origin of the left subclavian artery near the insertion of the ligamentum arteriosum. Coarctation occurs in ~7% of patients with congenital heart disease, is twice as common in males as in females, and is most frequent in patients with gonadal dysgenesis. Clinical manifestations depend on the site and extent of obstruction and the presence of associated cardiac anomalies, most commonly a bicuspid aortic valve. Aneurysmal arterial dilatation of the circle of Willis produces a high risk of sudden rupture and death.

Most children and young adults with isolated, discrete coarctation are asymptomatic. Headache, epistaxis, cold extremities, and claudication with exercise may occur, and attention is usually directed to the cardiovascular system when a heart murmur or hypertension in the upper extremities and absence, marked diminution, or delayed pulsations in the femoral arteries are detected on physical examination. Enlarged and pulsatile collateral vessels may be palpated in the intercostal spaces anteriorly, in the axillae, or posteriorly in the interscapular area. The upper extremities and thorax may be more developed than the lower extremities. A midsystolic murmur over the anterior part of the chest, back, and spinous processes may become continuous if the lumen is narrowed sufficiently to result in a high-velocity jet across the lesion throughout the cardiac cycle. Additional systolic and continuous murmurs over the lateral thoracic wall may reflect increased flow through dilated and tortuous collateral vessels. The ECG usually reveals LV hypertrophy. Roentgenograms may show a dilated left subclavian artery high on the left mediastinal border and a dilated ascending aorta. Indentation of the aorta at the site of coarctation and pre- and poststenotic dilatation (the "3" sign) along the left paramediastinal shadow are almost pathognomonic. Notching of the ribs, an important radiographic sign, is due to erosion by dilated collateral vessels. Two-dimensional echocardiography from para- or suprasternal windows identifies the site and length of coarctation, while Doppler studies record and quantitate the pressure gradient. Transesophageal echocardiography and magnetic resonance imaging or three-dimensional computed tomography allow visualization of the length and severity of the obstruction and the associated collateral arteries. In adults, cardiac catheterization is indicated primarily to evaluate the coronary arteries.

The chief hazards result from severe hypertension and include the development of cerebral aneurysms and hemorrhage, dissection and/or rupture of the aorta, premature coronary arteriosclerosis, LV failure, and infective endocarditis.

TREATMENT

Treatment is usually surgical; resection and end-to-end anastomosis or subclavian flap angioplasty are used commonly, although it may be necessary to use a tubular graft, patch, or bypass conduit if the narrowed segment is long. Systemic hypertension postoperatively, in the absence of residual coarctation, appears to be related to the duration of preoperative hypertension. Percutaneous balloon dilatation is controversial in native unoperated aortic coarctation but commonly successful for postsurgical recoarctation, often with deployment of a stent.

PULMONARY STENOSIS WITH INTACT VENTRICULAR SEPTUM Obstruction to RV outflow may be localized to the supravalvular, valvular, or subvalvular levels or occur at a combination of these sites. Multiple sites of narrowing of the peripheral pulmonary arteries are a feature of *rubella embryopathy* and may occur with both the familial and sporadic forms of supravalvular aortic stenosis. Valvular pulmonic stenosis is the most common form of isolated RV obstruction.

The severity of the obstructing lesion, rather than the site of narrowing, is the most important determinant of the clinical course. In the presence of a normal cardiac output, a peak systolic transvalvular pressure gradient between 50 and 80 mmHg is considered to be moderate stenosis; levels below and above that range are classified as mild and severe, respectively. Patients with mild pulmonic stenosis are generally asymptomatic and demonstrate little or no progression in the severity of obstruction with age. In patients with more significant stenosis, the severity may increase with time. Symptoms vary with the degree of obstruction. Fatigue, dyspnea, RV failure, and syncope may limit the activity of older patients, in whom moderate or severe obstruction may prevent an augmentation of cardiac output with exercise. In patients with severe obstruction, the systolic pressure in the right ventricle may exceed that in the left ventricle, since the ventricular septum is intact. RV ejection is prolonged with moderate or severe stenosis, and the sound of pulmonary valve closure is delayed and soft. RV hypertrophy reduces the compliance of that chamber, and a forceful RA contraction is necessary to augment RV filling.

A fourth heart sound, prominent *a* waves in the jugular venous pulse, and, occasionally, presystolic pulsations of the liver reflect vigorous atrial contraction. The clinical diagnosis is supported by a left

parasternal lift and harsh systolic crescendo-decrescendo murmur and thrill at the upper left sternal border, typically preceded by a systolic ejection sound, if the obstruction is valvular. The holosystolic decrescendo murmur of tricuspid regurgitation may accompany severe pulmonic stenosis, especially in the presence of congestive heart failure. Cyanosis usually reflects right-to-left shunting through a patent foramen ovale or atrial septal defect. In patients with supravalvular or peripheral pulmonary arterial stenosis, the murmur is systolic or continuous and is best heard over the area of narrowing, with radiation to the peripheral lung fields.

The ECG may be helpful in assessing the degree of RV obstruction. In mild cases, the ECG is often normal, whereas moderate and severe stenoses are associated with right axis deviation and RV hypertrophy. A ventricular strain pattern, as well as high-amplitude P waves in leads II and V_1, indicating RA enlargement, are associated with severe stenosis. The chest roentgenogram with mild or moderate pulmonic stenosis often shows a heart of normal size and normal vascularity of the lungs. In the presence of valvular stenosis, dilatation of the main and left pulmonary arteries may be evident, in part poststenotic and in part due to intrinsic tissue weakness. With severe obstruction and resultant RV failure, RA and RV enlargement are generally evident. The pulmonary vascularity may be reduced with severe stenosis, RV failure, and/or a right-to-left shunt at the atrial level. Two-dimensional echocardiography visualizes pulmonary valve morphology; the outflow tract pressure gradient can be estimated by Doppler ultrasonography.

℞ TREATMENT

The cardiac catheter technique of balloon valvuloplasty (Chap. 212) is usually effective. Direct surgical relief of moderate and severe obstruction may be accomplished at a low risk. Multiple stenoses of the peripheral pulmonary arteries are usually inoperable, but narrowing of a single branch or at the bifurcation of the main pulmonary trunk may be surgically corrected or undergo balloon dilatation and stenting.

CYANOTIC CONGENITAL HEART DISEASE WITH INCREASED PULMONARY BLOOD FLOW

COMPLETE TRANSPOSITION OF THE GREAT ARTERIES In this condition the aorta arises from the right ventricle to the right of and anterior to the pulmonary artery, which emerges from the left ventricle (Fig. 218-1, *left panel*). This results in two separate and parallel circulations, and some communication between them must exist after birth to sustain life. Most patients have an interatrial communication, two-thirds have a patent ductus arteriosus, and about one-third have an associated ventricular septal defect. Transposition is more common in males and accounts for ~10% of cyanotic heart disease.

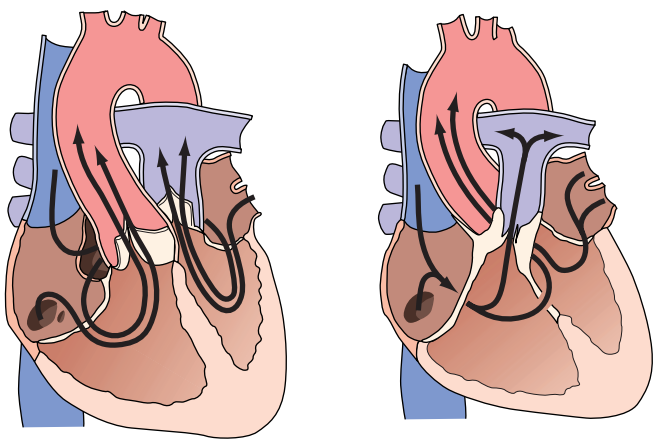

FIGURE 218-1 Complete transposition of the great arteries is depicted in the left panel. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. The only mixing between the two circulations occurs across a patent foramen ovale. In the right panel, the tetralogy of Fallot drawing illustrates the two most important anatomic findings, a large ventricular septal defect and RV outflow tract obstruction. A right-to-left shunt is shown across the ventricular septum.

The course is determined by the degree of tissue hypoxia, the ability of each ventricle to sustain an increased work load in the presence of reduced coronary arterial oxygenation, the nature of the associated cardiovascular anomalies, and the status of the pulmonary vascular bed. Pulmonary vascular obstruction develops by 1 to 2 years of age in patients with an associated large ventricular septal defect or large patent ductus arteriosus in the absence of obstruction to LV outflow.

℞ TREATMENT

The balloon or blade catheter or surgical creation or enlargement of an interatrial communication in the neonate is the simplest procedure for providing increased intracardiac mixing of systemic and pulmonary venous blood. Systemic–pulmonary artery anastomosis may be indicated in the patient with severe obstruction to LV outflow and diminished pulmonary blood flow. Intracardiac repair may be accomplished by rearranging the venous returns (intraatrial switch, i.e., Mustard or Senning operation) so that the systemic venous blood is directed to the mitral valve and thence to the left ventricle and pulmonary artery, while the pulmonary venous blood is diverted through the tricuspid valve and right ventricle to the aorta. The late survival after these repairs is good, but late sudden death is the most worrisome feature. Preferably, this malformation is corrected in infancy by transposing both coronary arteries to the posterior artery and transecting, contraposing, and anastomosing the aorta and pulmonary arteries (arterial switch operation). For those patients with a ventricular septal defect in whom it is necessary to bypass a severely obstructed LV outflow tract, corrective operation employs an intracardiac ventricular baffle and extracardiac prosthetic conduit to replace the pulmonary artery (Rastelli procedure).

SINGLE VENTRICLE This is a family of complex lesions with both atrioventricular valves or a common atrioventricular valve opening to a single ventricular chamber. Associated anomalies include abnormal great artery positional relationships, pulmonic valvular or subvalvular stenosis, and subaortic stenosis.

Survival to adulthood depends on a relatively normal pulmonary blood flow, yet normal pulmonary resistance, and good ventricular function. Modifications of the Fontan approach are generally applied to carefully selected patients with creation of a pathway(s) from the systemic veins to the pulmonary arteries.

CYANOTIC CONGENITAL HEART DISEASE WITH DECREASED PULMONARY BLOOD FLOW

TRICUSPID ATRESIA This malformation is characterized by atresia of the tricuspid valve, an interatrial communication, and, frequently, hypoplasia of the right ventricle and pulmonary artery. The clinical picture is usually dominated by severe cyanosis due to obligatory admixture of systemic and pulmonary venous blood in the left ventricle. The ECG characteristically shows RA enlargement, left axis deviation, and LV hypertrophy.

Atrial septostomy and palliative operations to increase pulmonary blood flow, often by anastomosis of a systemic artery or vein to a pulmonary artery, may allow survival to the second or third decade. A Fontan atriopulmonary or total cavopulmonary connection may then allow functional correction in those patients with normal or low pulmonary arterial resistance pressure and good LV function.

EBSTEIN'S ANOMALY Characterized by a downward displacement of the tricuspid valve into the right ventricle, due to anomalous attachment of the tricuspid leaflets, the Ebstein tricuspid valve tissue is dysplastic and results in tricuspid regurgitation. The abnormally situated tricuspid orifice produces an "atrialized" portion of the right ventricle lying between the atrioventricular ring and the origin of the valve, which is continuous with the RA chamber. Often the right ventricle is hypoplastic. Although the clinical manifestations are variable, some patients come to initial attention because of progressive cyanosis from

right-to-left atrial shunting, or symptoms due to tricuspid regurgitation and RV dysfunction, or paroxysmal atrial tachyarrhythmias with or without atrioventricular bypass tracts ("WPW" syndrome). Diagnostic findings by two-dimensional echocardiography include the abnormal positional relation between the tricuspid and mitral valves with apical displacement of the septal tricuspid leaflet. Tricuspid regurgitation is quantitated by Doppler examination. Surgical approaches include prosthetic replacement of the tricuspid valve when the leaflets are tethered or repair of the native valve.

TETRALOGY OF FALLOT The four components of the tetralogy of Fallot are malaligned ventricular septal defect, obstruction to RV outflow, aortic override of the ventricular septal defect, and RV hypertrophy (Fig. 218-1, *right panel*).

The severity of RV outflow obstruction determines the clinical presentation. The severity of hypoplasia of the RV outflow tract varies from mild to complete (pulmonary atresia). Pulmonary valve stenosis and supravalvular and peripheral pulmonary arterial obstruction may coexist; rarely there is unilateral absence of a pulmonary artery (usually the left). A right-sided aortic arch and descending aorta occur in ~25% of patients with tetralogy.

The relationship between the resistance of blood flow from the ventricles into the aorta and into the pulmonary vessels plays a major role in determining the hemodynamic and clinical picture. Thus, the severity of obstruction to RV outflow is of fundamental significance. When the obstruction is severe, the pulmonary blood flow is reduced markedly, and a large volume of desaturated systemic venous blood is shunted from right to left across the ventricular septal defect. Severe cyanosis and erythrocytosis occur, and symptoms and sequelae of systemic hypoxemia are prominent. In many infants and children the obstruction is mild but progressive.

The ECG ordinarily shows RV and, less often, RA hypertrophy. Radiologic examination characteristically reveals a normal-sized, boot-shaped heart (*coeur en sabot*) with prominence of the right ventricle and a concavity in the region of the pulmonary conus. The pulmonary vascular markings are typically diminished, and the aortic arch and knob may be on the right side. Two-dimensional echocardiography from the parasternal or subcostal windows demonstrates the malalignment of the ventricular septal defect and the subpulmonary stenosis. Selective angiocardiography with RV injection provides architectural details of the RV outflow tract, pulmonary valve and annulus, and caliber of the main branches of the pulmonary artery; coronary arteriography identifies the anatomy and course of the coronary arteries.

℞ TREATMENT

Factors that may complicate the treatment of patients with tetralogy of Fallot include infective endocarditis, paradoxic embolism, excessive erythrocytosis, coagulation defects, and cerebral infarction or abscess. Corrective operation is advisable at some point for almost all patients with this anomaly. Successful correction avoids progressive infundibular obstruction, delayed growth, and complications due to hypoxemia and excessive erythrocytosis. The size of the pulmonary arteries rather than the age or size of the infant or child is the most important determinant in establishing candidacy for primary repair. Pronounced hypoplasia of the pulmonary arteries is a relative contraindication for an early corrective surgical procedure. When this problem is present, a palliative operation, such as creation of a systemic arterial–pulmonary arterial shunt, is carried out and is usually followed by complete correction, which can be carried out at a lower risk later in childhood.

OTHER FORMS OF CONGENITAL HEART DISEASES

CONGENITALLY CORRECTED TRANSPOSITION The two fundamental anatomic abnormalities in this malformation are transposition of the ascending aorta and pulmonary trunk and inversion of the ventricles. This arrangement results in desaturated systemic venous blood passing from the right atrium through the mitral valve to the left ventricle and into the pulmonary trunk, whereas oxygenated pulmonary venous blood flows from the left atrium through the tricuspid valve to the right ventricle and into the aorta. Thus, the circulation is corrected functionally. The clinical presentation, course, and prognosis of patients with congenitally corrected transposition vary depending on the nature and severity of any complicating intracardiac anomalies and of development of dysfunction of the systemic subaortic RV. Ebstein-type anomalies of the left-side tricuspid atrioventricular valve, with progressive regurgitation, ventricular septal defect, obstruction to outflow from the venous ventricle, and congenital heart block are often associated with corrected transposition. The diagnosis of the malformation and associated lesions can be established by two-dimensional echocardiography and Doppler examination.

MALPOSITIONS OF THE HEART Positional anomalies refer to conditions in which the cardiac apex is in the right side of the chest (*dextrocardia*), or at the midline (*mesocardia*), or in which there is a normal location of the heart in the left side of the chest but abnormal position of the viscera (*isolated levocardia*). Knowledge of the position of the abdominal organs and of the branching pattern of the main stem bronchi is important in categorizing these malpositions. When dextrocardia occurs without situs inversus, when the visceral situs is indeterminate, or if isolated levocardia is present, associated, often complex, multiple cardiac anomalies are usually present. In contrast, mirror-image dextrocardia is usually observed with complete situs inversus, which occurs most frequently in individuals whose hearts are otherwise normal.

SURGICALLY MODIFIED CONGENITAL HEART DISEASE

Because of the enormous strides in cardiovascular surgical techniques that have occurred in the past 20 years, a large number of long-term survivors of corrective operations in infancy and childhood have reached adulthood. These patients are often challenging because of the diversity of anatomic, hemodynamic, and electrophysiologic residua and sequelae of cardiac operations.

The proper care of the survivor of operation for congenital heart disease requires that the clinician understand the details of the malformation before operation; pay meticulous attention to the details of the operative procedure; and recognize the postoperative residua (conditions left totally or partially uncorrected), the sequelae (conditions caused by surgery), and the complications that may have resulted from the operation. With the exception of ligation and division of an uncomplicated patent ductus arteriosus, almost every other surgical repair of an anomaly leaves behind or causes some abnormality of the heart and circulation that may range from trivial to serious. Intraoperative transesophageal echocardiography assists in detecting unsuspected lesions, in monitoring the repair, and in verifying a satisfactory result or directing further repair. Thus, even with results that are considered clinically to be good to excellent, continued long-term postoperative follow-up is advisable.

Table 218-4 lists the categories of common late postoperative problems. Cardiac operations importantly involving the atria, such as closure of atrial septal defect, repair of total or partial anomalous pulmonary venous return, or venous switch corrections of complete transposition of the great arteries (the Mustard or Senning operations), may be followed years later by sinus node or atrioventricular node dysfunction or by atrial arrhythmias. Intraventricular surgery may also result in electrophysiologic consequences, including complete heart block necessitating pacemaker insertion to avoid sudden death. In ad-

TABLE 218-4 Potential Late Postoperative Problems

Residual shunts	Arrhythmias and conduction defects
Residual ventricular outflow obstruction	Myocardial dysfunction
Residual valvular anomalies	Prosthetic valve malfunction
Systemic arterial hypertension	Prosthetic conduit obstruction
Pulmonary vascular obstruction	Infective endocarditis

dition, valvular problems may arise late after initial cardiac operation. An example is the progressive stenosis of an initially nonobstructive bicuspid aortic valve in the patient who underwent aortic coarctation repair. Such aortic valves may also be the site of infective endocarditis. After repair of the ostium primum atrial septal defect, the cleft mitral valve may become progressively incompetent. Tricuspid regurgitation may also be progressive in the postoperative patient with tetralogy of Fallot if RV outflow tract obstruction was not relieved adequately at initial surgery. In many patients with surgically modified congenital heart disease, inadequate relief of an obstructive lesion, or a residual regurgitant lesion, or a residual shunt will cause or hasten the onset of clinical signs and symptoms of myocardial dysfunction. Despite a good hemodynamic repair, many patients with a subaortic right ventricle develop RV decompensation and signs of "left heart failure." In many patients, particularly those who were cyanotic for many years before operation, a preexisting compromise in ventricular performance is due to the original underlying malformation.

A final category of postoperative problems involves the use of prosthetic valves, patches, or conduits in the operative repair. The special risks include infective endocarditis, thrombus formation, and premature degeneration and calcification of the prosthetic materials. There are many patients in whom extracardiac conduits are required to correct the circulation functionally and often to carry blood to the lungs from the right atrium or right ventricle. These conduits may develop intraluminal obstruction, and, if they include a prosthetic valve, it may show progressive calcification and thickening.

219 VALVULAR HEART DISEASE

Eugene Braunwald

The role of physical examination in the evaluation of patients with valvular disease is also considered in Chap. 209; of electrocardiography (ECG) in Chap. 210; of echocardiography in Chap. 211; and of cardiac catheterization and angiography in Chap. 212.

MITRAL STENOSIS

ETIOLOGY AND PATHOLOGY Two-thirds of all patients with mitral stenosis (MS) are female. MS and mixed MS and mitral regurgitation (MR) are generally rheumatic in origin; very rarely, MS is congenital. Pure or predominant MS occurs in approximately 40% of all patients with rheumatic heart disease. In other patients with rheumatic heart disease, lesser degrees of MS may accompany MR and aortic valve lesions. With reductions in the incidence of acute rheumatic fever, particularly in temperate climates and developed nations, the incidence of MS is declining. However, it remains a major problem in developing nations, especially in tropical and semitropical climates.

In rheumatic stenosis the valve leaflets are diffusely thickened by fibrous tissue and/or calcific deposits. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and these changes, in turn, lead to narrowing at the apex of the funnel-shaped ("fish-mouth") valve. Although the initial insult to the mitral valve is rheumatic, the later changes may be a nonspecific process resulting from trauma to the valve caused by altered flow patterns due to the initial deformity. Calcification of the stenotic mitral valve immobilizes the leaflets and narrows the orifice further. Thrombus formation and arterial embolization may arise from the calcific valve itself, but more frequently arise from the dilated left atrium (LA) in patients with atrial fibrillation (AF).

PATHOPHYSIOLOGY In normal adults the mitral valve orifice is 4 to 6 cm^2. In the presence of significant obstruction, i.e., when the orifice is less than approximately 2 cm^2, blood can flow from the LA to the left ventricle (LV) only if propelled by an abnormally elevated left atrioventricular pressure gradient (see Fig. 212-2), the hemodynamic hallmark of MS. When the mitral valve opening is reduced to 1 cm^2, often referred to as "critical" MS, a LA pressure of approximately 25 mmHg is required to maintain a normal cardiac output (CO). The elevated pulmonary venous and pulmonary arterial (PA) wedge pressures reduce pulmonary compliance, contributing to exertional dyspnea. The first bouts of dyspnea are usually precipitated by clinical events that increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure (see below). To assess the severity of obstruction, both the transvalvular pressure gradient and the flow rate must be measured (Chap. 212). The latter depends not only on the CO but on the heart rate as well. An increase in heart rate shortens diastole proportionately more than systole and diminishes the time available for flow across the mitral valve. Therefore, at any given level of CO, tachycardia including that resulting from atrial fibrillation augments the transvalvular gradient and elevates further the LA pressure. Similar considerations apply to the tricuspid stenosis.

The LV diastolic pressure and ejection fraction (EF) are normal in isolated MS. In MS and sinus rhythm, the elevated LA and PA wedge pressures exhibit a prominent atrial contraction (*a* wave) and a gradual pressure decline after mitral valve opening (*y* descent) (see Fig. 212-2). In severe MS and whenever pulmonary vascular resistance is significantly increased, the pulmonary arterial pressure (PAP) is elevated at rest and rises further during exercise, often causing secondary elevations of right ventricle (RV) end-diastolic pressure and volume.

Cardiac Output In patients with moderately severe MS (mitral valve orifice 1.2 cm^2 to 1.7 cm^2), the CO is normal or almost so at rest but rises subnormally during exertion. In patients with critical MS, particularly those in whom pulmonary vascular resistance is strikingly elevated, the CO is subnormal at rest and may fail to rise or may even decline during activity.

Pulmonary Hypertension The clinical and hemodynamic features of MS are influenced importantly by the level of the PAP. Pulmonary hypertension results from (1) passive backward transmission of the elevated LA pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); (3) interstitial edema in the walls of the small pulmonary vessels; and (4) organic obliterative changes in the pulmonary vascular bed. Severe pulmonary hypertension results in tricuspid regurgitation (TR) and pulmonary incompetence as well as right-sided heart failure.

SYMPTOMS In temperate climates the latent period between the initial attack of rheumatic carditis (in the increasingly rare circumstances in which a history of one can be elicited) and the development of symptoms due to MS is generally about two decades; most patients begin

to experience disability in the fourth decade of life. Studies carried out before the development of mitral valvotomy revealed that once a patient with MS became seriously symptomatic, the disease progressed continuously to death within 2 to 5 years. In economically deprived areas, in tropical and subtropical climates, particularly on the Indian subcontinent, in Central America, and in the Middle East, MS tends to progress more rapidly and frequently causes serious symptoms in patients less than 20 years of age. In contrast, slowly progressive MS in the elderly is being recognized with increasing frequency in the United States and Western Europe.

When valvular obstruction is mild, the physical signs of MS may be present without symptoms. However, even in patients whose mitral orifices are large enough to accommodate a normal blood flow with only mild elevations of LA pressure, marked elevations of this pressure leading to dyspnea and cough may be precipitated by severe exertion, excitement, fever, severe anemia, paroxysmal atrial fibrillation and other tachycardias, sexual intercourse, pregnancy, and thyrotoxicosis. As MS progresses, lesser stresses precipitate dyspnea, and the patient becomes limited in daily activities. The redistribution of blood from the dependent portions of the body to the lungs, which occurs when the recumbent position is assumed, leads to orthopnea and paroxysmal nocturnal dyspnea. *Pulmonary edema* develops when there is a sudden surge in flow across a markedly narrowed mitral orifice. When moderately severe MS has existed for several years, *atrial arrhythmias* occur with increasing frequency. The development of permanent AF often marks a turning point in the patient's course and is generally associated with acceleration of the rate at which symptoms progress.

Hemoptysis (Chap. 30) results from rupture of pulmonary-bronchial venous connections secondary to pulmonary venous hypertension. It occurs most frequently in patients who have elevated LA pressures without markedly elevated pulmonary vascular resistances and is almost never fatal. *Recurrent pulmonary emboli* (Chap. 244), sometimes with infarction, are an important cause of morbidity and mortality late in the course of MS. *Pulmonary infections*, i.e., bronchitis, bronchopneumonia, and lobar pneumonia, commonly complicate untreated MS. *Infective endocarditis* (Chap. 109) is rare in isolated MS.

Pulmonary Changes In addition to the aforementioned changes in the pulmonary vascular bed, fibrous thickening of the walls of the alveoli and pulmonary capillaries occurs commonly in MS. The vital capacity, total lung capacity, maximal breathing capacity, and oxygen uptake per unit of ventilation are reduced (Chap. 234), and the latter fails to rise normally during exertion. Pulmonary compliance falls further as pulmonary capillary pressure rises during exercise. In some patients, airway resistance is abnormally increased and the diffusing capacity may be reduced. These changes in the lungs are due, in part, to increased transudation of fluid from the pulmonary capillaries into the interstitial and alveolar spaces. However, the increased capacity of the pulmonary lymphatic system to drain excess fluid retards the development of alveolar edema.

Thrombi and Emboli *Thrombi* may form in the left atria, particularly in the enlarged atrial appendages of patients with MS. Embolization occurs much more frequently in patients with AF, in older patients, and in those with a reduced cardiac output (CO). However, systemic embolization may be the presenting complaint in otherwise asymptomatic patients with mild MS. Rarely, a large pedunculated or a freefloating thrombus may suddenly obstruct the stenotic mitral orifice and cause syncope, angina, and changing auscultatory signs with alterations in position.

PHYSICAL FINDINGS (See also Chap. 209) ■ **Inspection and Palpation** In patients with severe MS, there may be a malar flush with pinched and blue facies. In patients with sinus rhythm and severe pulmonary hypertension or associated tricuspid stenosis (TS), the jugular venous pulse reveals prominent *a* waves due to vigorous right atrial systole. The systemic arterial pressure is usually normal or slightly low. An RV tap along the left sternal border signifies an enlarged RV. A diastolic thrill is frequently present at the cardiac apex, with the patient in the left lateral recumbent position.

Auscultation The first heart sound (S_1) is generally accentuated and snapping, and slightly delayed. The pulmonary component of the second heart sound (P_2) is often accentuated, and the two components of the second heart sound (S_2) are closely split or fixed. A pulmonary systolic ejection click may be heard in patients with severe pulmonary hypertension. The opening snap (OS) of the mitral valve is most readily audible in expiration at, or just medial to the cardiac apex. This sound generally follows the sound of aortic valve closure (A_2) by 0.05 to 0.12 s. The time interval between A_2 and OS varies inversely with the severity of the MS. The OS is followed by a low-pitched, rumbling, diastolic murmur, heard best at the apex with the patient in the left lateral recumbent position (see Fig. 209-5*B*). It is accentuated by mild exercise (e.g., a few rapid situps) carried out just before auscultation. In general, the duration of this murmur correlates with the severity of the stenosis. In patients with sinus rhythm, the murmur often reappears or becomes reaccentuated during atrial systole. Soft grade I or II/VI systolic murmurs are commonly heard at the apex or along the left sternal border in patients with pure MS and do not necessarily signify the presence of MR. Hepatomegaly, ankle edema, ascites, and pleural effusion, particularly in the right pleural cavity, may occur in patients with MS and RV failure.

Associated Lesions With severe pulmonary hypertension, a pansystolic murmur produced by functional TR may be audible along the left sternal border. Characteristically, this murmur is accentuated by inspiration and diminishes during forced expiration (Carvallo's sign); it should not be confused with the apical pansystolic murmur of MR. When the S_1 and/or the OS are soft or absent in a patient with mitral valve disease who also has an apical systolic murmur, it is likely that significant MR and/or serious calcification of the deformed mitral valve leaflets are present. When the CO is markedly reduced in MS, the typical auscultatory findings, including the diastolic rumbling murmur, may not be detectable (silent MS), but they may reappear as compensation is restored. The *Graham Steell murmur* of pulmonary regurgitation (PR), a high-pitched, diastolic, decrescendo blowing murmur along the left sternal border, results from dilatation of the pulmonary valve ring and occurs in patients with mitral valve disease and severe pulmonary hypertension. This murmur may be indistinguishable from the more common murmur produced by aortic regurgitation (AR).

LABORATORY EXAMINATION ■ **EKG** In MS and sinus rhythm, the P wave usually suggests LA enlargement (see Fig. 210-8). It may become tall and peaked in lead II and upright in lead V_1 when severe pulmonary hypertension or TS complicates MS and right atrial (RA) enlargement occurs. The QRS complex is usually normal. However, with severe pulmonary hypertension, right axis deviation and RV hypertrophy are often present.

Echocardiogram (See also Chap. 211) This is the most sensitive and specific noninvasive method for diagnosing MS. Transthoracic two-dimensional color flow Doppler echocardiographic imaging and Doppler ultrasound provide critical information, including an estimate of the transvalvular gradient and of mitral orifice size, the presence and severity of accompanying MR, the extent of restriction of valve leaflets, their thickness, the degree of distortion of the subvalvular apparatus, and the anatomic suitability for balloon mitral valvotomy (see below). In addition, echocardiography provides an assessment of the size of the cardiac chambers, an estimation of the LV function, an estimation of the PAP, and an indication of the presence and severity of associated valvular lesions. Transesophageal echocardiography provides superior images and should be employed when transthoracic imaging is inadequate for guiding therapy.

TABLE 219-1 *Summary of Useful Medical Treatments in Valvular Heart Disease*

Lesion	Symptom Control	Secondary Prevention and Natural History
Mitral stenosis	Diuretics for heart failure; Digoxin, β blockers, and rate-limiting calcium antagonists for rate control in atrial fibrillation	Penicillin prophylaxis against recurrent episodes of rheumatic fever; Anticoagulants to prevent systemic thromboembolism.
Mitral regurgitation	Diuretics and vasodilators (usually ACE inhibitors) for heart failure	No proven treatment
Aortic stenosis	Diuretics for heart failure; nitrates and β blockers for angina	No proven treatment but lipid lowering therapy may slow progression of calcific aortic stenosis
Aortic regurgitation	Diuretics and vasodilators (usually ACE inhibitors) for heart failure	Vasodilators (nifedipine or ACE inhibitors) to protect the left ventricular myocardium and delay the need for surgery

Source: NA Boon, P Bloomfield: The medical management of valvular heart disease. Heart 87:395, 2002, with permission

Roentgenogram The earliest changes are straightening of the left border of the cardiac silhouette, prominence of the main pulmonary arteries, dilatation of the upper lobe pulmonary veins, and backward displacement of the esophagus by an enlarged LA. In severe MS, however, all chambers and vessels upstream to the narrowed valve are prominent. Kerley B lines are fine, dense, opaque, horizontal lines that are most prominent in the lower and midlung fields and that result from distention of interlobular septa and lymphatics with edema when the resting mean LA pressure exceeds approximately 20 mmHg.

DIFFERENTIAL DIAGNOSIS Like MS, significant MR may also be associated with a prominent diastolic murmur at the apex, but in MR this diastolic murmur commences slightly later than in patients with MS, and there is often clear-cut evidence of LV enlargement. An apical pansystolic murmur of at least grade III/VI intensity as well as an S_3 suggests significant associated MR. Similarly, the apical middiastolic murmur associated with AR (*Austin Flint murmur*) may be mistaken for MS. TS, which occurs rarely in the absence of MS, may mask many of the clinical features of MS.

Atrial septal defect (Chap. 218) may be mistaken for MS; in both conditions there is often clinical, EKG, and roentgenographic evidence of RV enlargement and accentuation of the pulmonary vascularity. The widely split S_2 of atrial septal defect may be confused with the mitral OS, and the diastolic flow murmur across the tricuspid valve may be mistaken for the mitral diastolic murmur. However, the absence of LA enlargement and of Kerley B lines and the demonstration of fixed splitting of S_2 all favor atrial septal defect over MS.

Left atrial myxoma (Chap. 223) may obstruct LA emptying, causing dyspnea, a diastolic murmur, and hemodynamic changes resembling those of MS. However, patients with an LA myxoma often have features suggestive of a systemic disease, such as weight loss, fever, anemia, systemic emboli, and elevated serum IgG concentrations. The auscultatory findings may change markedly with body position. The diagnosis can be established by the demonstration of a characteristic echo-producing mass in the LA with two-dimensional echocardiography.

CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Left heart catheterization is useful when there is a discrepancy between clinical and echocardiographic findings. It is helpful in assessing associated lesions such as aortic stenosis (AS) and aortic regurgitation (AR). Catheterization and coronary arteriography are not usually necessary to aid in the decision about surgery in younger patients with typical findings of severe obstruction on clinical examination and echocardiography. In males over 45 years of age, females over 55 years of age, and younger patients with coronary risk factors, especially those with positive noninvasive stress tests for myocardial ischemia, coronary angiography is usually advisable preoperatively to detect patients with critical coronary obstructions that should be bypassed at the time of operation. Catheterization and LV angiography are also indicated in most patients who have undergone balloon mitral valvotomy or previous mitral valve operations and who have redeveloped serious symptoms.

℞ TREATMENT

Penicillin prophylaxis of β-hemolytic streptococcal infections (Chap. 302) to prevent rheumatic fever and prophylaxis for infective endocarditis (Chap. 109) are important for all patients (Table 219-1). In symptomatic patients, some improvement usually occurs with restriction of sodium intake and maintenance doses of oral diuretics. Digitalis glycosides usually do not benefit patients with MS and sinus rhythm but are helpful in slowing the ventricular rate of patients with AF. Beta blockers or nondihydropyridine calcium antagonists (e.g., verapamil or diltiazem) are useful in this regard. Warfarin to an INR of 2-3:1 should be administered for at least 1 year to patients with MS who have suffered systemic and/or pulmonary embolization and permanently to those with AF.

If AF is of relatively recent origin in a patient whose MS is not severe enough to warrant balloon mitral valvotomy or surgical valvotomy, reversion to sinus rhythm pharmacologically or by means of electrical countershock is indicated. Usually this reversion should be undertaken after the patient has had 3 weeks of anticoagulant treatment. Conversion to sinus rhythm is rarely helpful in patients with severe MS, particularly those in whom the LA is especially enlarged or in whom AF has been present for more than 1 year, since sinus rhythm is rarely sustained in such patients.

Mitral Valvotomy Unless there is a contraindication, mitral valvotomy is indicated in symptomatic patients with isolated MS whose effective orifice is less than approximately 1.0 cm^2/m^2 body surface area, or <1.7 cm^2 in normal-sized adults. Mitral valvotomy can be carried out by two techniques: percutaneous balloon mitral valvotomy and surgical valvotomy. In balloon mitral valvotomy (Figs. 219-1 and 219-2), a catheter is directed into the LA after transseptal puncture and a single or double balloon (Inoue balloon) is directed across the valve and inflated in the valvular orifice. Ideal patients have relatively mobile, thin leaflets with no or little calcium, without extensive subvalvular thickening and with no or mild MR. The short- and long-term results of this procedure in appropriate patients are similar to those of surgical valvotomy, but with less morbidity and a lower mortality rate. Therefore, balloon valvotomy has become the procedure of choice for such patients. Transthoracic echocardiography is helpful in identifying patients for the percutaneous procedure (Fig. 219-3).

In patients in whom percutaneous valvotomy is not possible, unsuccessful, or in those with restenosis, an "open" valvotomy using cardiopulmonary bypass is necessary. In addition to opening the valve

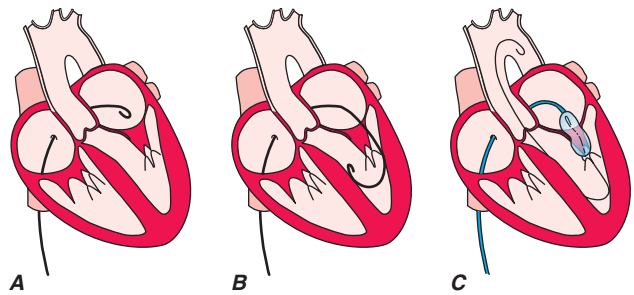

FIGURE 219-1 Technique of double balloon mitral valvuloplasty. *A.* The position of the guidewire in the left atrium after left atrial puncture using the Brockenbrough needle. *B.* The position of the guidewire as it is advanced into the left ventricle across the stenotic mitral valve. C. Partial inflation of a balloon catheter across the stenotic mitral valve. *[From JP Srebro, TA Ports, Catheter-balloon valvuloplasty, in K Chatterjee et al (eds): Cardiology: An Illustrated Text. Philadelphia, Lippincott, 1991.]*

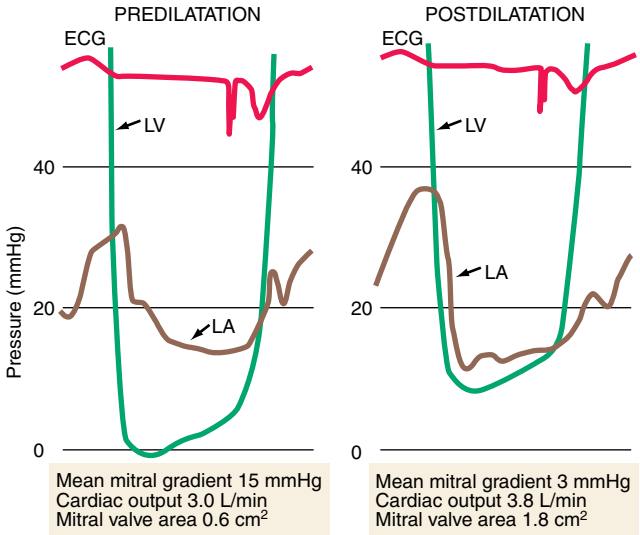

FIGURE 219-2 Simultaneous left atrial (LA) and left ventricular (LV) pressure before and after balloon mitral valvuloplasty in a patient with severe mitral stenosis. *(Courtesy of Raymond G. McKay, MD).*

commissures, it is important to loosen any subvalvular fusion of papillary muscles and chordae tendineae and to remove large deposits of calcium, thereby improving valvular function, as well as to remove atrial thrombi. The mortality rate is approximately 2%.

Successful valvotomy, whether balloon or surgical, usually results in striking symptomatic and hemodynamic improvement and prolongs survival. However, there is no evidence that the procedure improves the prognosis of patients with slight or no functional impairment. Therefore, unless recurrent systemic embolization or severe pulmonary hypertension has occurred, valvotomy is *not* recommended for patients who are entirely asymptomatic. When there is little symptomatic improvement after valvotomy, it is likely that the procedure was ineffective, that it induced MR, or that associated valvular or myocardial disease was present. About half of all patients undergoing mitral valvotomy require reoperation by 10 years. In the pregnant patient with MS, valvotomy should be carried out if pulmonary congestion occurs despite intensive medical treatment.

Mitral valve replacement (MVR) is necessary in patients with MS and significant associated MR, those in whom the valve has been severely distorted by previous transcatheter or operative manipulation, or those in whom the surgeon does not find it possible to improve valve function significantly. Since the operative mortality rate of isolated MVR is still approximately 6% (Table 219-2), and since there are long-term complications of valve replacement, patients in whom preoperative evaluation suggests the possibility that MVR may be required should be operated on only if they have critical MS, i.e., an orifice ≤ 1 cm^2 area and are in New York Heart Association class III, i.e., symptomatic with ordinary activity despite optimal medical therapy. The overall 10-year survival of surgical survivors is approximately 70%. Long-term prognosis is worse in older patients and those with marked disability and striking depression of the cardiac index preoperatively.

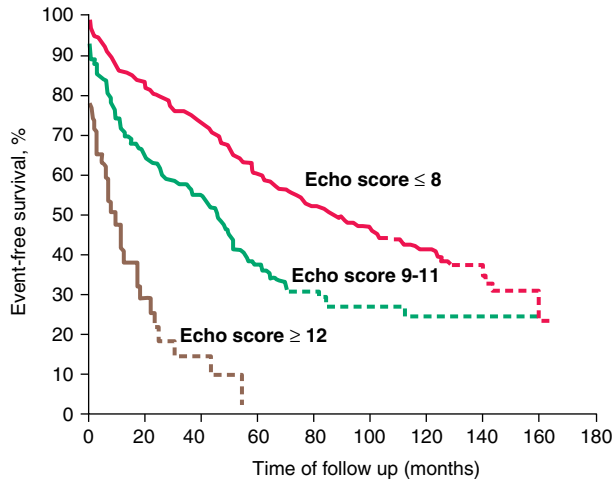

FIGURE 219-3 Event-free survival following percutaneous balloon mitral valvuloplasty. The echo score is derived from examining leaflet rigidity, thickening, calcification and the extent of subvalvular disease and grading each from 1 (not detectable) to 4 (very severe) and calculating the total. The minimum score is 4 and the maximum is 16. Event-free survival is survival without mitral valve replacement or repeat balloon valvuloplasty. *(From Palacios et al 2002.)*

TABLE 219-2 *Mortality Rates After Valve Replacement and Repair*

Operative Category	Number	Operative Mortality (%)
AVR (isolated)	26,317	4.3
MVR (isolated)	13,936	6.4
Multiple valve replacement	3,840	9.6
AVR + CAB	22,713	8.0
MVR + CAB	8,788	15.3
Multiple valve replacement + CAB	1,424	18.8
AVR + any valve repair	938	7.4
MVR + any valve repair	1,266	12.5
Aortic valve repair	597	5.9
Mitral valve repair	4,167	3.0
Tricuspid valve repair	144	13.9

Note: AVR, aortic valve replacement; CAB, coronary artery bypass; MVR, mitral valve replacement.

MITRAL REGURGITATION

ETIOLOGY Chronic rheumatic heart disease is the cause of severe MR in only about one-third of cases and occurs more frequently in males. The rheumatic process produces rigidity, deformity, and retraction of the valve cusps and commissural fusion, as well as shortening, contraction, and fusion of the chordae tendineae. MR may occur as a congenital anomaly (Chap. 218), most commonly as a defect of the endocardial cushions (atrioventricular cushion defects). MR is frequently secondary to ischemia. Thus, it may occur as a consequence of ventricular remodeling or with fibrosis of a papillary muscle in patients with healed myocardial infarction. It may develop acutely in patients with acute infarction involving the base of a papillary muscle. Transient MR also may occur during periods of ischemia involving a papillary muscle or the adjacent myocardium and may accompany bouts of angina pectoris. MR may occur with marked LV enlargement of any cause in which dilatation of the mitral annulus and lateral displacement of the papillary muscles interfere with coaptation of the valve leaflets, most commonly ischemia. In hypertrophic cardiomyopathy, the anterior leaflet of the mitral valve is displaced anteriorly during systole, causing MR (Chap. 221). Calcification of the mitral annulus of unknown cause, presumably degenerative, which occurs most commonly in elderly women, also can be responsible for significant MR. Acute MR may occur secondary to infective endocarditis involving the valve leaflets or chordae tendineae, or as a consequence of trauma. Mitral valve prolapse (MVP), an important cause of MR, is considered in the next section.

Irrespective of cause, severe MR is often progressive, since enlargement of the LA places tension on the posterior mitral leaflet, pulling it away from the mitral orifice and thereby aggravating the valvular dysfunction. Similarly, LV dilatation increases the regurgitation, which in turn enlarges the LA and LV further, causing chordal rupture and resulting in a vicious circle; hence the aphorism, "mitral regurgitation begets mitral regurgitation."

PATHOPHYSIOLOGY The resistance to LV emptying is reduced in patients with MR. As a consequence, the LV is decompressed into the LA during ejection, and with the reduction in LV size during systole, there

is a rapid decline in LV tension. The initial compensation to acute MR is more complete LV emptying. However, LV volume increases progressively as the severity of the regurgitation increases and as LV function deteriorates. This increase in LV volume is often accompanied by a reduced forward CO. The regurgitant volume varies directly with the LV systolic pressure and the size of the regurgitant orifice; as mentioned above, the latter, in turn, is influenced profoundly by the extent of LV dilatation. Since ejection fraction (EF) rises in severe MR in the presence of normal LV function, even a modest reduction in this parameter (<60%) reflects significant dysfunction.

The *v* wave in the LA pressure pulse is usually prominent (see Fig. 212-3). During early diastole, as the distended LA empties, there is a particularly rapid *y* descent (as long as there is no associated MS). In chronic MR, there is often an increase in LV compliance, so that LV volume rises with little elevation in LV diastolic pressure. The effective (forward) CO is usually reduced in seriously symptomatic patients. A brief, early diastolic atrioventricular pressure gradient (often accompanying a murmur) may occur in patients with pure MR as a result of the very rapid flow of blood across a normal-sized mitral orifice.

The prompt appearance of contrast material in the LA after its injection into the LV signifies the presence of MR. The regurgitant volume can be measured by determining the difference between the total LV stroke volume, estimated angiocardiographically, and the effective forward stroke volume determined by the Fick method (Chap. 212). In severe cases, as much as 50% of the total LV stroke volume regurgitates with each beat. Qualitative, but clinically useful, estimates of the severity of regurgitation may be made by observation on cineangiograms of the degree of LA opacification after the injection of contrast material into the LV. Color flow Doppler imaging is most commonly used for this purpose (see below).

Left ventricular contractility becomes reduced, sometimes irreversibly, with longstanding MR. The compliance, i.e., the pressure-volume relationship of the LA and pulmonary venous bed affects the clinical picture. Patients with acute MR usually have *normal or reduced LA compliance*, with little enlargement of the LA, but marked elevation of the LA pressure, particularly of the *v* wave. Severe pulmonary congestion and pulmonary edema are common in this group. Patients with a *marked increase in LA compliance* are at the opposite end of the spectrum, having longstanding, severe MR, marked enlargement of the LA, and normal or only slightly elevated LA and PA pressures. These patients usually complain of severe fatigue and exhaustion secondary to a low CO, while symptoms resulting from pulmonary congestion are less prominent; AF is almost invariably present. Most common are patients whose clinical and hemodynamic features are intermediate between those in the two aforementioned groups.

SYMPTOMS Fatigue, exertional dyspnea, and orthopnea are the most prominent complaints in patients with chronic, severe MR. Systemic embolism occurs less frequently than in MS. Right-sided heart failure, with painful hepatic congestion, ankle edema, distended neck veins, ascites, and TR, occur in patients with MR who have associated pulmonary vascular disease and marked pulmonary hypertension. In patients with acute, severe MR, LV failure with acute pulmonary edema is common.

PHYSICAL FINDINGS The arterial pressure is usually normal, and in patients with severe MR the arterial pulse may show a sharp upstroke. The jugular venous pulse shows abnormally prominent *a* waves in patients with sinus rhythm and marked pulmonary hypertension and prominent *v* waves in those with accompanying severe TR. A systolic thrill is often palpable at the cardiac apex, the LV is hyperdynamic with a brisk systolic impulse and a palpable rapid-filling wave, and the apex beat is often displaced laterally. An RV tap and the shock of pulmonary valve closure may be palpable in patients with marked pulmonary hypertension.

Auscultation The S_1 is generally absent, soft, or buried in the systolic murmur. In patients with severe MR, the aortic valve may close prematurely, resulting in wide splitting of the S_2. An OS indicates associated MS but does not exclude predominant regurgitation. A low-pitched S_3 occurring 0.12 to 0.17 s after the aortic valve closure sound, i.e., at the completion of the rapid-filling phase of the LV, is believed to be caused by the sudden tensing of the papillary muscles, chordae tendineae, and valve leaflets and is an important auscultatory feature of severe MR. The S_3 may be followed by a short, rumbling, diastolic murmur, even in the absence of MS. A fourth heart sound is often audible in patients with acute, severe MR of recent onset who are in sinus rhythm. A presystolic murmur is not ordinarily heard with isolated MR but is present in patients with sinus rhythm and associated MS.

A systolic murmur of at least grade III/VI intensity, is the most characteristic auscultatory finding in severe MR. It is usually holosystolic (see Figs. 209-4 and 209-5*A*), but it may be decrescendo and cease in late systole in patients with acute, severe MR. In MR due to papillary muscle dysfunction or MVP, the systolic murmur commences in midsystole (see below). The systolic murmur is usually most prominent at the apex and radiates to the axilla. However, in patients with ruptured chordae tendineae or primary involvement of the posterior mitral leaflet, the regurgitant jet strikes the LA wall adjacent to the aortic root. In this situation, the systolic murmur is transmitted to the base of the heart and therefore may be confused with the murmur of AS. In patients with ruptured chordae tendineae the systolic murmur may have a cooing or "sea gull" quality, while a flail leaflet may cause a murmur with a musical quality. The systolic murmur of MR is intensified by isometric strain but is reduced during the Valsalva maneuver.

LABORATORY EXAMINATION ■ Electrocardiogram In patients with sinus rhythm there is evidence of LA enlargement, but RA enlargement also may be present when pulmonary hypertension is severe. Chronic, severe MR is generally associated with AF. In many patients there is no clear-cut electrocardiographic evidence of enlargement of either ventricle. In others, the signs of LV hypertrophy are present.

Echocardiogram Color flow Doppler imaging is the most accurate noninvasive technique for the detection and estimation of MR. Two-dimensional echocardiography is useful for assessing the cause of MR and for estimating LV function from end-systolic and end-diastolic volumes and EF. The LA is usually enlarged and/or exhibits increased pulsation while the LV may be hyperdynamic. Findings that help to determine the etiology of MR, such as mitral annular calcification and LV dyskinesis in ischemic MR, can often be identified by two-dimensional echocardiography. With ruptured chordae tendineae or a flail leaflet, coarse, erratic motion of the involved leaflets may be noted. Vegetations associated with infective endocarditis, incomplete coaptation of the anterior and posterior mitral leaflets, and annular calcification, as well as MR secondary to LV dilatation, aneurysm, or dyskinesis may be recognized. Transesophageal imaging provides greater detail than transthoracic imaging (see Fig. 211-3). The echocardiogram in patients with MVP is described in the next section.

Roentgenogram The LA and LV are the dominant chambers; late in the course of the disease, the former may be massively enlarged and forms the right border of the cardiac silhouette. Pulmonary venous congestion, interstitial edema, and Kerley B lines are sometimes noted. Marked calcification of the mitral leaflets occurs commonly in patients with longstanding combined MR and MS. Calcification of the mitral annulus may be visualized.

℞ TREATMENT

MEDICAL (Table 219-1) The nonsurgical management of patients with severe MR begins with restricting those physical activities that regularly produce dyspnea and excessive fatigue, reducing sodium intake, and enhancing sodium excretion with the appropriate use of diuretics (Chap. 216). Vasodilators and digitalis glycosides increase the

forward output of the failing LV. Intravenous nitroprusside or nitroglycerin reduce afterload and thereby the volume of regurgitant flow and are useful in stabilizing patients with acute and/or severe MR. Angiotensin-converting enzyme (ACE) inhibitors are useful in the treatment of chronic MR. The same considerations as in patients with MS apply to the reversion of AF to sinus rhythm. In the late stages of heart failure anticoagulants and leg binders are used to diminish the likelihood of venous thrombi and pulmonary emboli. Endocarditis prophylaxis is important. In patients with severe MR secondary to dilated cardiomyopathy, intensive medial therapy can reduce the severity of MR.

SURGICAL In the selection of patients with severe MR for surgical treatment, the chronic, often slowly progressive nature of the condition must be balanced against the immediate and long-term risks associated with the operation. Patients with MR who are asymptomatic or who are limited only during strenuous exertion and whose LV functions are normal are not considered to be candidates for surgical treatment, since their condition may remain stable for years. By contrast, unless there are contraindications, surgical treatment should be offered to patients with severe MR whose limitations do not allow fulltime employment or the performance of normal household activities despite optimal medical management. Surgical treatment of severe MR should be considered even in asymptomatic patients or those with mild symptoms when LV dysfunction is progressive, with LV EF declining below 60% and/or end-systolic cavity dimension on echocardiography rising above 45 mm. In patients with impaired LV function, the risk of surgery rises, the recovery of LV performance is incomplete, and the long-term survival is reduced (Fig. 219-4). However, conservative management has little to offer these patients, so operative treatment may be indicated and occasionally, the clinical and hemodynamic improvement that follows surgical treatment of patients with advanced disease is dramatic. However, unless chordal continuity can be preserved, operation is contraindicated in patients whose LV ejection fraction has declined to below 30%. Though most patients who survive surgery appear to be greatly improved, some degree of myocardial dysfunction often persists.

When surgical treatment is contemplated, left-sided heart catheterization and angiocardiography may be helpful in confirming the presence of severe MR in patients in whom there is a discrepancy between the clinical picture and the echocardiographic findings; these procedures may also aid in detecting and assessing the severity of associated valve lesions. Importantly, coronary arteriography identifies patients who require concomitant coronary revascularization.

Surgical treatment of MR, especially that caused by valves that are markedly deformed, with shrunken, calcified leaflets secondary to rheumatic fever, requires MVR with a prosthesis. However, in an increasing number of patients, particularly those with severe annular dilatation, flail leaflets, MVP, ruptured chordae, or infective endocarditis, reconstruction of the mitral valve apparatus (mitral valvuloplasty) and/or mitral annuloplasty with an annuloplasty ring may be successful. Valve reconstruction should be carried out whenever feasible since the operative risk is about half (~3%) of that associated with MVR (Table 219-1). Also, reconstruction spares the patient the long-term adverse consequences of valve replacement, i.e., thromboembolic and hemorrhagic complications in the case of mechanical prostheses and late valve failure necessitating repeat valve replacement in the case of bioprostheses. In addition, by preserving the integrity of the papillary muscles, subvalvular apparatus and chordae tendinae, mitral repair and valvuloplasty maintains LV function. In asymptomatic patients with preserved left ventricular function, surgical treatment can be considered as long as mitral repair seems feasible and pulmonary hypertension or recent atrial fibrillation are present.

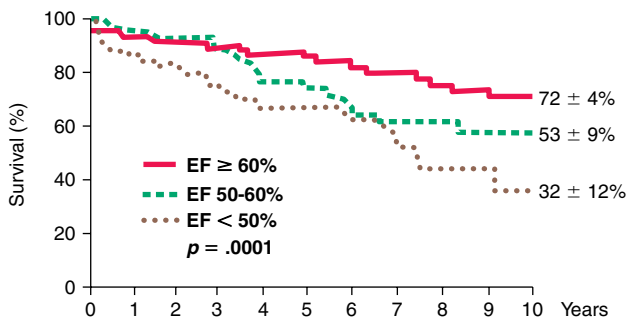

FIGURE 219-4 Late survival rates of patients surviving surgical correction of MR according to preoperative echocardiographic ejection fraction (EF). *(From M Enriquez-Sarano et al: Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. MITRAL VALVE PROLAPSE

MVP, also variously termed the *systolic click-murmur syndrome*, *Barlow's syndrome*, *floppy-valve syndrome*, and *billowing mitral leaflet syndrome*, is a relatively common, but highly variable clinical syndrome resulting from diverse pathogenic mechanisms of the mitral valve apparatus. Among these are excessive or redundant mitral leaflet tissue, which is commonly associated with myxomatous degeneration and greatly increased concentrations of acid mucopolysaccharide. MVP is a frequent finding in patients with heritable disorders of connective tissue, including the Marfan syndrome (Chap. 342), osteogenesis imperfecta, and the Ehler-Danlos syndrome. In most patients with MVP, however, myxomatous degeneration is confined to the mitral (or less commonly the tricuspid or aortic) valves without other clinical or pathologic manifestations of disease. The posterior leaflet is usually more affected than the anterior, and the mitral valve annulus is often greatly dilated. In many patients, elongated redundant chordae tendineae cause or contribute to the regurgitation.

In most patients with MVP, the cause is unknown, but in some it appears to be a genetically determined collagen tissue disorder. A reduction in the production of type III collagen has been incriminated, and electron microscopy has revealed fragmentation of collagen fibrils. MVP may be associated with thoracic skeletal deformities similar to but not as severe as those in the Marfan syndrome, including a high-arched palate and alterations of the chest and thoracic spine, including the so-called straight back syndrome. MVP also may occur as a sequel of acute rheumatic fever, in ischemic heart disease, and in cardiomyopathies, as well as in 20% of patients with ostium secundum atrial septal defect.

MVP may lead to excessive stress on the papillary muscles, which in turn leads to dysfunction and ischemia of the papillary muscles and the subjacent ventricular myocardium. Rupture of chordae tendineae and progressive annular dilatation and calcification also contribute to valvular regurgitation, which then places more stress on the diseased mitral valve apparatus, thereby creating a vicious circle. The electrocardiographic changes (see below) and ventricular arrhythmias appear to result from regional ventricular dysfunction related to increased stress placed on the papillary muscles.

CLINICAL FEATURES MVP is more common in females. It affects individuals in a wide age range but most commonly those between the ages of 14 and 30 years. The clinical course is often benign. MVP may also be observed in older (>50 years) patients, often males, and in them MR is more often severe and requires surgical treatment. There is an increased familial incidence for some patients, suggesting an autosomal dominant form of inheritance. MVP encompasses a broad spectrum of severities, ranging from only a systolic click and murmur and mild prolapse of the posterior leaflet of the mitral valve to severe MR due to chordal rupture and massive prolapse of both leaflets. In many patients, this condition progresses over years or decades.

Most patients are asymptomatic and remain so for their entire lives. However, MVP is now the most common cause of isolated severe MR requiring surgical treatment in North America. Arrhythmias, most commonly ventricular premature contractions and paroxysmal supraventricular and ventricular tachycardia, have been reported and may

cause palpitations, light-headedness, and syncope. Sudden death is a very rare complication. Many patients have chest pain that is difficult to evaluate. It is often substernal, prolonged, poorly related to exertion, and rarely resembles angina pectoris. Transient cerebral ischemic attacks secondary to emboli from the mitral valve due to endothelial disruption have been reported. Infective endocarditis may occur in patients with MR associated with MVP.

Auscultation The most important finding is the mid- or late (nonejection) systolic click, which occurs 0.14 s or more after the S_1 and is thought to be generated by the sudden tensing of slack, elongated chordae tendineae or by the prolapsing mitral leaflet when it reaches its maximum excursion. Systolic clicks may be multiple and may be followed by a high-pitched, late systolic crescendo-decrescendo murmur, which occasionally is "whooping" or "honking," and is heard best at the apex. The click and murmur occur earlier with standing, during the strain of the Valsalva maneuver, and with any intervention that decreases LV volume, exaggerating the propensity of mitral leaflet prolapse. Conversely, squatting and isometric exercise, which increase LV volume, diminish MVP, and the click-murmur complex is delayed and may even disappear. Some patients have a midsystolic click without the murmur; others have the murmur without a click. Still others have both sounds at different times.

LABORATORY EXAMINATION The ECG most commonly is normal but may show biphasic or inverted T waves in leads II, III, and aVF, and occasionally supraventricular or ventricular premature contractions. *Two-dimensional echocardiography* is particularly effective in identifying the abnormal position and prolapse of the mitral valve leaflets. A useful echocardiographic definition of MVP is systolic displacement (in the parasternal view) of the mitral valve leaflets by at least 2 mm into the LA superior to the plane of the mitral annulus. Thickening of the mitral valve leaflets identifies a subgroup of patients at higher risk of infective endocarditis and the development of severe MR. Prolapse of the tricuspid and/or aortic valve may be found. *Color-imaging* and *Doppler studies* are helpful in revealing and evaluating accompanying MR. *Angiocardiography* generally shows prolapse of the posterior and sometimes of both mitral valve leaflets.

Rx TREATMENT

The management of patients with MVP consists of the asymptomatic patient without severe MR or arrhythmias and the prevention of infective endocarditis with antibiotic prophylaxis in patients with a systolic murmur and/or thickening of mitral valve leaflets on endocardiography. Beta blockers sometimes relieve chest pain. If symptomatic tachyarrhythmias have occurred, antiarrhythmic agents as dictated by electrophysiologic studies should be administered. If the patient is symptomatic from severe MR, mitral valve repair (or rarely, replacement) is indicated. Antiplatelet aggregation agents such as aspirin should be given to patients with transient ischemic attacks, and if these are not effective, anticoagulants should be used.

AORTIC STENOSIS

AS occurs in about one-fourth of all patients with chronic valvular heart disease; approximately 80% of adult patients with symptomatic valvular AS are male.

ETIOLOGY AS in adults may be due to degenerative calcification of the aortic cusps. It may be congenital in origin or it may be secondary to rheumatic inflammation. *Age-related degenerative calcific AS* (also known as senile or sclerocalcific AS) is now the most common cause of AS in adults in North America and Western Europe. About 30% of persons >65 years exhibit aortic valve sclerosis, many of whom have a systolic murmur of AS but without obstruction, while an additional 2% exhibit frank stenosis. On histologic examination these valves frequently exhibit inflammatory changes similar to those seen in atherosclerotic vessels. Interestingly, risk factors for atherosclerosis, such as age, male sex, smoking, diabetes mellitus, hypertension, increased LDL, reduced HDL cholesterol, and elevated C-reactive protein are all risk factors for aortic valve calcification.

The *congenitally affected valve* may be stenotic at birth (Chap. 218) and may become progressively more fibrotic, calcified, and stenotic. In other cases the valve may be congenitally deformed, usually bicuspid, without serious narrowing of the aortic orifice during childhood; its abnormal architecture makes its leaflets susceptible to otherwise ordinary hemodynamic stresses, which ultimately lead to valvular thickening, calcification, increased rigidity, and narrowing of the aortic orifice.

Rheumatic endocarditis of the aortic leaflets produces commissural fusion, sometimes resulting in a bicuspid valve. This condition in turn, makes the leaflets more susceptible to trauma and ultimately leads to fibrosis, calcification, and further narrowing. By the time the obstruction to LV outflow causes serious clinical disability, the valve is usually a rigid calcified mass, and careful examination may make it difficult or even impossible to determine the etiology of the underlying process. Rheumatic AS is almost always associated with involvement of the mitral valve and by associated severe AR.

OTHER FORMS OF OBSTRUCTION TO LEFT VENTRICULAR OUTFLOW Besides valvular AS, three other lesions may be responsible for obstruction to LV outflow.

1. *Hypertrophic cardiomyopathy* (Chap. 221). This condition is characterized by marked hypertrophy of the LV and involves in particular the interventricular septum; it may cause subaortic obstruction.
2. *Discrete congenital subvalvular AS* (Chap. 218). This congenital anomaly is produced by either a membranous diaphragm or a fibrous ridge just below the aortic valve.
3. *Supravalvular AS* (Chap. 218). This uncommon congenital anomaly is produced by narrowing of the ascending aorta or by a fibrous diaphragm with a small opening just above the aortic valve.

PATHOPHYSIOLOGY The obstruction to LV outflow produces a systolic pressure gradient between the LV and aorta. When severe obstruction is suddenly produced experimentally, the LV responds by dilatation and reduction of stroke volume. However, in patients the obstruction may be present at birth and/or increase gradually over the course of many years, and LV output is maintained by the presence of concentric LV hypertrophy. This serves as a useful compensatory mechanism because it reduces toward normal the systolic stress developed by the myocardium. A large transaortic valvular pressure gradient may exist for many years without a reduction of CO or LV dilatation; ultimately, however, these changes occur.

A peak systolic pressure gradient >50 mmHg in the face of a normal cardiac output or an effective aortic orifice less than approximately 1.0 cm^2 or <0.6 cm^2/m^2 body surface area, i.e., less than approximately one-third of the normal orifice, is generally considered to represent severe obstruction to LV outflow. The elevated LV end-diastolic pressure observed in many patients with severe AS signifies the presence of LV dilatation and/or diminished compliance of the hypertrophied LV wall. A large *a* wave in the LA pressure pulse is usually present. Although the CO at rest is within normal limits in most patients with severe AS, it usually fails to rise normally during exercise. Loss of an appropriately timed, vigorous atrial contraction, as occurs in AF or atrioventricular dissociation, may cause a rapid progression of symptoms. Late in the course the CO and LV–aortic pressure gradient decline, and the mean LA, PA, and RV pressures rise.

The hypertrophied LV muscle mass elevates myocardial oxygen requirements. In addition, even in the absence of obstructive coronary artery disease, there may be interference with coronary blood flow. This is because the pressure compressing the coronary arteries exceeds the coronary perfusion pressure, often causing ischemia, especially in the subendocardium, and during tachycardia, both in the presence and in the absence of coronary arterial narrowing.

SYMPTOMS AS is rarely of clinical importance until the valve orifice has narrowed to approximately 0.5 cm^2/m^2 body surface area in adults. Even severe AS may exist for many years without producing any symptoms because of the ability of the hypertrophied LV to generate the elevated intraventricular pressures required for a normal stroke volume.

Most patients with pure or predominant AS have gradually increasing obstruction for years but do not become symptomatic until the sixth to eighth decades. Exertional dyspnea, angina pectoris, and syncope are the three cardinal symptoms. Often there is a history of insidious progression of fatigue and dyspnea associated with gradual curtailment of activities. *Dyspnea* results primarily from elevation of the pulmonary capillary pressure caused by elevations of LV diastolic pressures secondary to reduced compliance. *Angina pectoris* usually develops somewhat later and reflects an imbalance between the augmented myocardial oxygen requirements and reduced oxygen availability; the former results from the increased myocardial mass and intraventricular pressure, while the latter may result from accompanying coronary artery disease, which is not uncommon in patients with AS, as well as from compression of the coronary vessels by the hypertrophied myocardium. Therefore, angina may occur in severe AS even without obstructive epicardial coronary artery disease. *Exertional syncope* may result from a decline in arterial pressure caused by vasodilatation in the exercising muscles and inadequate vasoconstriction in nonexercising muscles in the face of a fixed CO, or from a sudden fall in CO produced by an arrhythmia.

Since the CO at rest is usually well maintained until late in the course, marked fatigability, weakness, peripheral cyanosis, and other clinical manifestations of a low CO are usually not prominent until this stage is reached. Orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, i.e., symptoms of LV failure, also occur only in the advanced stages of the disease. Severe pulmonary hypertension leading to RV failure and systemic venous hypertension, hepatomegaly, AF, and TR are usually late findings in patients with isolated, severe AS.

When AS and MS coexist, the reduction of cardiac output induced by MS lowers the pressure gradient across the aortic valve and thereby masks many of the clinical findings produced by AS. Left heart catheterization is helpful in defining the relative importance of each valvular abnormality.

PHYSICAL FINDINGS The rhythm is generally regular until very late in the course; at other times, AF should suggest the possibility of associated mitral valve disease. The systemic arterial pressure is usually within normal limits. In the late stages, however, when stroke volume declines, the systolic pressure may fall and the pulse pressure narrow. Systemic hypertension is unusual in patients with severe AS. The peripheral arterial pulse, as palpated in the carotid or brachial arteries, rises slowly to a delayed sustained peak (pulsus parvus et tardus) (see Fig. 209-2). In the elderly, the stiffening of the arterial wall may mask this important physical sign. A palpable double systolic arterial pulse, the so-called bisferiens pulse, excludes pure or predominant AS and signifies dominant AR. In the late stages of AS, when the pulse pressure is reduced, the pulse amplitude may be so small that the anacrotic nature of the pulse and the delay in its upstroke may become difficult to appreciate. In many patients the *a* wave in the jugular venous pulse is accentuated. This results from the diminished distensibility of the RV cavity caused by the bulging, hypertrophied intraventricular septum.

The LV impulse is usually active and displaced laterally, reflecting the presence of LV hypertrophy. A double apical impulse may be recognized, particularly with the patient in the left lateral recumbent position. A systolic thrill is generally present at the base of the heart, in the jugular notch, and along the carotid arteries. In patients who do not have marked pulmonary emphysema, a thick chest wall, thoracic deformity, or heart failure, the absence of a systolic thrill suggests that the AS is relatively mild.

Auscultation An early systolic ejection sound, actually the OS of the aortic valve, is frequently audible in children and adolescents with congenital noncalcific valvular AS. This sound usually disappears when the valve becomes calcified and rigid. As AS increases in severity, LV systole may become prolonged so that the aortic valve closure sound no longer precedes the pulmonic valve closure sound, and the two components may become synchronous, or aortic valve closure may even follow pulmonic valve closure, causing paradoxic splitting of the S_2 (Chap. 209). The sound of aortic valve closure can be heard most frequently in patients with AS who have pliable valves, and calcification diminishes the intensity of this sound. Frequently, an S_4 is audible at the apex and reflects the presence of LV hypertrophy and an elevated LV end-diastolic pressure; an S_3 generally occurs when the LV dilates.

The murmur of AS is characteristically an ejection (mid) systolic murmur that commences shortly after the S_1, increases in intensity to reach a peak toward the middle of ejection, and ends just before aortic valve closure (see Figs. 209-4 and 209-5*A*). It is characteristically low-pitched, rough and rasping in character, and loudest at the base of the heart, most commonly in the second right intercostal space. It is transmitted upward along the carotid arteries. Occasionally, it is transmitted downward and to the apex where it may be confused with the systolic murmur of MR. In almost all patients with severe obstruction, the murmur is at least grade III/VI. In patients with mild degrees of obstruction or in those with severe stenosis with heart failure in whom the stroke volume and therefore the transvalvular flow rate are reduced, the murmur may be relatively soft and brief.

LABORATORY EXAMINATION ■ Electrocardiogram In most patients with severe AS there is LV hypertrophy (see Fig. 210-9). In advanced cases, ST-segment depression and T-wave inversion (LV "strain") in standard leads I and aVL and in the left precordial leads are evident. However, there is no close correlation between the ECG and the hemodynamic severity of obstruction, and the absence of ECG signs of LV hypertrophy does not exclude severe obstruction.

The key findings are LV hypertrophy and, in patients with valvular calcification (i.e., most adult patients with symptomatic AS), multiple, bright, thick, echoes from within the aortic root. Eccentricity of the aortic valve cusps is characteristic of congenitally bicuspid valves. Transesophageal imaging usually displays the obstructed orifice extremely well. The transaortic valvular gradient can be estimated by Doppler echocardiography. LV dilatation and reduced systolic shortening reflect impairment of LV function. Echocardiography is also useful for identifying valvular abnormalities such as MS and AR, which sometimes accompany AS, and for differentiating valvular AS from obstructive hypertrophic cardiomyopathy.

Roentgenogram The chest roentgenogram may show no or little overall cardiac enlargement for many years, since the development of concentric LV hypertrophy is the initial response to obstruction to LV outflow. Hypertrophy without dilatation may produce some rounding of the cardiac apex in the frontal projection and slight backward displacement in the lateral view; critical AS is often associated with poststenotic dilatation of the ascending aorta (Fig. 211-5). Aortic calcification is usually readily apparent on fluoroscopic examination or by echocardiography; the absence of valvular calcification in an adult suggests that severe valvular AS is not present. In later stages of the disease as the LV dilates, there is increasing roentgenographic evidence of LV enlargement; pulmonary congestion; and enlargement of the LA, PA, and right side of the heart.

Catheterization Catheterization of the left side of the heart and coronary arteriography should generally be carried out in patients suspected of having severe AS who are being considered for operative treatment. These investigations are especially indicated in the following:

1. *Patients with clinical signs of AS and symptoms of myocardial ischemia*, in whom associated coronary artery disease is suspected. An

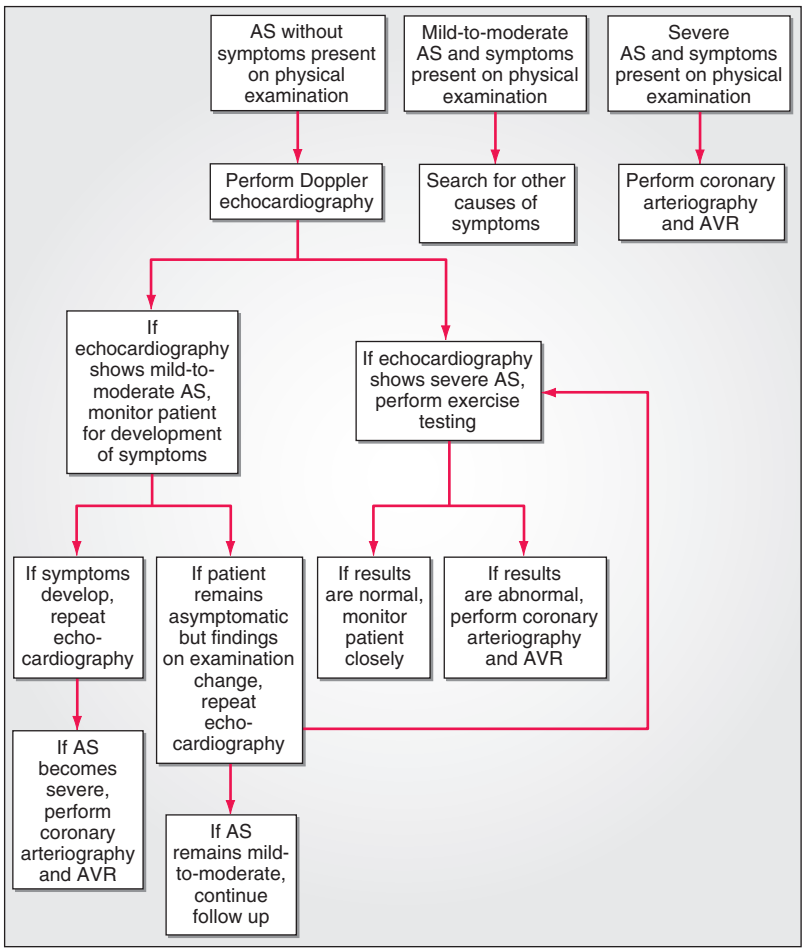

FIGURE 219-5 Algorithm for the management of aortic stenosis. AS, aortic stenosis; AVR, aortic valve replacement. *(From Carabello, 2002.)*

effort should be made to determine whether AS or coronary atherosclerosis is primarily responsible for the symptoms. Coronary arteriography should be carried out to identify patients who require coronary bypass grafting at the time of aortic valve surgery.

2. *Patients with multivalvular disease*, in whom the role played by each valvular deformity should be defined to aid in the planning of definitive operative treatment.

3. *Young, asymptomatic patients with noncalcific congenital AS*, to define with precision the severity of obstruction to LV outflow, since operation [which does not usually require aortic valve replacement (AVR)] or balloon valvotomy may be indicated if severe AS is present, even in the absence of symptoms. Balloon valvotomy may follow left heart catheterization immediately.

4. *Patients in whom it is suspected that the obstruction to LV outflow may not be at the aortic valve* but rather in the sub- or supravalvular regions.

NATURAL HISTORY Death in patients with severe AS occurs most commonly in the seventh and eighth decades. Based on data obtained at postmortem examination in patients before surgical treatment became widely available, the average time to death after the onset of various symptoms was as follows: angina pectoris, 3 years; syncope, 3 years; dyspnea, 2 years; and congestive heart failure, 1.5 to 2 years. Moreover, in >80% of patients who died with AS, symptoms had existed for <4 years. Congestive heart failure was considered to be the cause of death in one-half to two-thirds of patients. Among adults dying with valvular AS, sudden death, which presumably resulted from an arrhythmia, occurred in 10 to 20% and at an average age of 60 years. However, most sudden deaths occur in patients who had previously been symptomatic; thus sudden death is very uncommon (3 per 1000 patient years) in asymptomatic patients with severe AS. Obstructive calcific AS is a progressive disease, with an annual reduction in valve area of approximately 0.1 mm^2/year.

TREATMENT

Medical Treatment (Fig. 219-5, Table 219-1) In patients with severe AS (<0.5 cm^2/m^2), strenuous physical activity should be avoided, even in the asymptomatic stage. Sodium restriction, the cautious administration of diuretics and digitalis glycosides are indicated in the treatment of congestive heart failure, but care must be taken to avoid volume depletion since this may cause a marked reduction of CO. Nitroglycerin is helpful in relieving angina pectoris. Retrospective studies have shown that patients with degenerative calcific AS who receive HMG-CoA reductase inhibitors ("statins") exhibit slower progression of leaflet calcification and aortic valve area reduction than those who do not. Treatment with these relatively safe agents should be considered while the results of clinical trials are awaited.

Surgical Treatment The most critical decision in the management of AS concerns the advisability of surgical treatment which, in most adults with calcific AS and severe obstruction consists of AVR. However, these patients should be followed carefully for the development of symptoms and by serial echocardiograms for evidence of deteriorating LV function. Operation is generally indicated in patients with severe AS (valve area <1.0 cm^2 or 0.6 cm^2/m^2 body surface area) who are symptomatic, those who exhibit LV dysfunction, as well as those with an expanding poststenotic aortic root, even if they are asymptomatic. In patients without heart failure, the operative risk of AVR is approximately 4% (Table 219-2). In most instances, it is prudent to postpone operation in patients with severe calcific AS who are asymptomatic and who exhibit normal LV function, i.e., EF >50%, since they may continue to do well for many years. The risk of surgical mortality exceeds that of sudden death in asymptomatic patients. However, AVR can be carried out in asymptomatic patients with severe stenosis who undergo coronary artery bypass grafting.

Operation should, if possible, be carried out before frank LV failure develops; at this late stage, the aortic valve pressure gradient declines as the stroke volume and ejection fraction decline. In such patients, the operative risk is high (15 to 20%), and evidence of myocardial disease may persist even when the operation is technically successful. Furthermore, long-term postoperative survival also correlates inversely with preoperative LV dysfunction. Nonetheless, in view of the even worse prognosis of such patients when they are treated medically, there is usually little choice but to advise surgical treatment, especially in patients in whom contractile reserve can be demonstrated by dobutamine echocardiography. In patients in whom severe AS and coronary artery disease coexist, relief of the AS and revascularization of the myocardium by means of aortocoronary bypass grafting may result in striking clinical and hemodynamic improvement.

Because many patients with calcific AS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary function before AVR is recommended. The mortality rate depends to a substantial extent on the patient's preoperative clinical and hemodynamic state. The 10-year survival rate of patients with AVR is approximately 60%. Approximately 30% of bioprosthetic valves evidence primary valve failure in 10 years, requiring rereplacement, and an approximately equal percentage of patients with mechanical prostheses develop significant hemorrhagic complications as a consequence of treatment with anticoagulants.

Percutaneous Balloon Aortic Valvuloplasty This procedure is preferable to operation in children and young adults with congenital, noncalcific AS. It is not commonly used in adults with severe calcific AS because

of a high restenosis rate, but has on occasion been used successfully in patients as a "bridge to operation" in patients with severe LV dysfunction who are too ill to tolerate surgery.

AORTIC REGURGITATION

ETIOLOGY AR may be caused by primary valve disease or by primary aortic root disease.

Primary Valve Disease Approximately three-fourths of patients with pure or predominant valvular AR are males; females predominate among patients with primary valvular AR who have associated mitral valve disease. In approximately two-thirds of patients with AR the disease is rheumatic in origin, resulting in thickening, deformity, and shortening of the individual aortic valve cusps, changes that prevent their proper opening during systole and closure during diastole. A rheumatic origin is less common in patients with isolated AR. Patients with congenital membranous subaortic stenosis often develop thickening of the aortic valve leaflets, which makes the valves particularly susceptible to endocarditis. AR also may occur in patients with rheumatoid spondylitis and in patients with congenital bicuspid aortic valves. Prolapse of an aortic cusp, resulting in progressive chronic AR, occurs in approximately 15% of patients with ventricular septal defect (Chap. 218). Congenital fenestrations of the aortic valve occasionally produce mild AR.

Acute AR may result from infective endocarditis, which can develop on a valve previously affected by rheumatic disease, a congenitally deformed valve, or, rarely, on a normal aortic valve, and perforate or erode one or more of the leaflets. Although traumatic rupture of the aortic valve is an uncommon cause of acute AR, it does represent the most frequent serious lesion in patients surviving nonpenetrating cardiac injuries. The coexistence of hemodynamically significant AS with AR usually excludes all the rarer forms of AR because it occurs almost exclusively in patients with rheumatic or congenital AR. In patients with AR due to primary valvular disease, dilatation of the aortic annulus may occur secondarily and intensify the regurgitation.

Primary Aortic Root Disease AR, both acute and chronic, also may be due entirely to marked aortic dilatation, i.e., aortic root disease, without primary involvement of the valve leaflets; widening of the aortic annulus and separation of the aortic leaflets are responsible for the AR (Chap. 231). Cystic medial necrosis of the ascending aorta, which may or may not be associated with other manifestations of the Marfan syndrome, idiopathic dilatation of the aorta, osteogenesis imperfecta, and severe hypertension all may widen the aortic annulus and lead to progressive AR. Occasionally, AR is caused by retrograde dissection of the aorta involving the aortic annulus. Syphilis and rheumatoid ankylosing spondylitis may be associated with cellular infiltration and scarring of the media of the thoracic aorta, leading to aortic dilatation, aneurysm formation, and severe regurgitation. In syphilis of the aorta, now a very rare condition (Chap. 153), the involvement of the intima may narrow the coronary ostia, which in turn may be responsible for myocardial ischemia.

PATHOPHYSIOLOGY The total stroke volume ejected by the LV (i.e., the sum of the effective forward stroke volume and the volume of blood that regurgitates back into the LV) is increased in patients with AR. In patients with wide-open (free) AR, the volume of regurgitant flow may equal the effective forward stroke volume. In contrast to MR, in which a fraction of the LV stroke volume is delivered into the low-pressure LA, in AR the entire LV stroke volume is ejected into a high-pressure zone, the aorta. An increase in the LV end-diastolic volume (increased preload) constitutes the major hemodynamic compensation for AR. The dilatation and eccentric hypertrophy of the LV allows this chamber to eject a larger stroke volume without requiring any increase in the relative shortening of each myofibril. Therefore, severe AR may occur with a normal effective forward stroke volume and a normal left ventricular EF [total (forward plus regurgitant) stroke volume/end-diastolic volume], together with an elevated LV end-diastolic pressure and volume. However, through the operation of Laplace's law (which holds that myocardial wall tension is the product of intracavitary pressure and LV radius), LV dilatation increases the LV systolic tension required to develop any given level of systolic pressure. Ultimately, these adaptive measures fail. As LV function deteriorates, the end-diastolic volume rises further and the forward stroke volume and EF decline. Deterioration of LV function often precedes the development of symptoms. Considerable thickening of the LV wall also occurs with chronic AR, and at autopsy the hearts of these patients may be among the largest encountered, sometimes weighing >1000 g.

The reverse pressure gradient from aorta to LV, which drives the AR flow, falls progressively during diastole (see Fig. 212-4), accounting for the decrescendo nature of the diastolic murmur. Equilibration between aortic and LV pressures may occur toward the end of diastole in patients with severe AR, particularly when the heart rate is slow, and the LV end-diastolic pressure may be elevated, occasionally to extremely high levels (>40 mmHg). Rarely, in acute, severe AR, the LV pressure exceeds the LA pressure toward the end of diastole, and this reversed pressure gradient closes the mitral valve prematurely or causes diastolic MR.

In patients with severe AR, the effective forward CO usually is normal or only slightly reduced at rest, but often it fails to rise normally during exertion. Early signs of LV dysfunction include reduction in the EF, determined by echocardiography or radionuclide angiography. In advanced stages there may be considerable elevation of the LA, PA wedge, PA, and RV pressures and lowering of the forward CO at rest.

Myocardial ischemia may occur in patients with AR because myocardial oxygen requirements are elevated by both LV dilatation and elevated LV systolic tension. However, a large fraction of coronary blood flow occurs during diastole, when arterial pressure is subnormal, thereby reducing coronary perfusion pressure. This combination of increased oxygen demand and reduced supply may cause myocardial ischemia, particularly of the subendocardium, even in the absence of concomitant coronary artery disease.

HISTORY A family history may frequently be elicited from patients with AR associated with the Marfan syndrome. A history compatible with infective endocarditis may sometimes be elicited from patients with rheumatic or congenital involvement of the aortic valve, and the infection often precipitates or seriously aggravates preexisting symptoms. Ankylosing spondylitis is usually self evident.

In patients with *acute, severe AR*, as may occur in infective endocarditis or trauma, the LV cannot dilate sufficiently to maintain stroke volume, and LV diastolic pressure rises rapidly with associated elevations of LA and PA wedge pressures. Pulmonary edema and/or cardiogenic shock may develop rapidly.

Chronic, severe AR may have a long latent period, and patients may remain relatively asymptomatic for as long as 10 to 15 years. However, uncomfortable awareness of the heartbeat, especially on lying down, may be an early complaint. Sinus tachycardia during exertion or with emotion, or premature ventricular contractions may produce particularly uncomfortable palpitations, as well as head pounding. These complaints may persist for many years before the development of exertional dyspnea, usually the first symptom of diminished cardiac reserve. The dyspnea is followed by orthopnea, paroxysmal nocturnal dyspnea, and excessive diaphoresis. Anginal chest pain occurs frequently in patients with severe AR, even in younger patients, and it is not necessary to invoke the presence of coronary artery disease to explain this symptom in patients with severe AR. Anginal pain may develop at rest as well as during exertion. Nocturnal angina may be a particularly troublesome symptom, and it may be accompanied by marked diaphoresis. The anginal episodes can be prolonged and often do not respond satisfactorily to sublingual nitroglycerin. Systemic fluid accumulation, including congestive hepatomegaly and ankle edema, may develop late in the course of the disease.

PHYSICAL FINDINGS In severe AR, the jarring of the entire body and the bobbing motion of the head with each systole can be appreciated, and

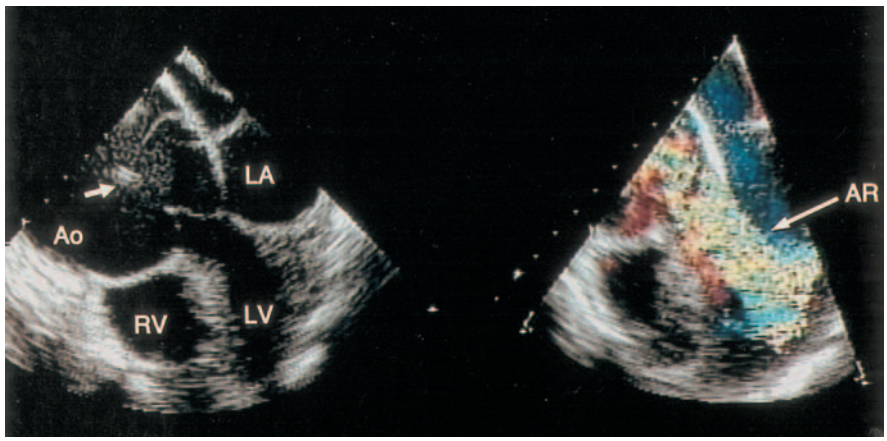

FIGURE 219-6 Transesophageal echocardiographic view of a patient with a dilated aorta, aortic dissection, and severe aortic regurgitation. The *arrow* points to the intimal flap that is seen in the dilated ascending aorta. *Left:* the long axis apex down view of the black and white two-dimensional image in diastole. *Right:* color flow imaging that demonstrates a large mosaic jet of aortic regurgitation. AO, aorta; RV, right ventricle; AR, aortic regurgitation.

the abrupt distention and collapse of the larger arteries are easily visible. The examination should be directed toward the detection of conditions predisposing to AR, such as the Marfan syndrome, rheumatoid ankylosing spondylitis, and ventricular septal defect.

Arterial Pulse A rapidly rising "water-hammer" pulse, which collapses suddenly as arterial pressure falls rapidly during late systole and diastole (Corrigan's pulse), and capillary pulsations, an alternate flushing and paling of the skin at the root of the nail while pressure is applied to the tip of the nail (Quincke's pulse), are characteristic of free AR. A booming, "pistol-shot" sound can be heard over the femoral arteries (Traube's sign), and a to-and-fro murmur (Duroziez's sign) is audible if the femoral artery is lightly compressed with a stethoscope.

The arterial pulse pressure is widened, with an elevation of the systolic pressure, sometimes to as high as 300 mmHg, and a depression of the diastolic pressure. The measurement of arterial diastolic pressure with a sphygmomanometer may be complicated by the fact that systolic sounds are frequently heard with the cuff completely deflated. However, the level of cuff pressure at the time of muffling of the Korotkoff sounds (Phase IV) generally corresponds fairly closely to the true intraarterial diastolic pressure. The severity of AR does not always correlate directly with the arterial pulse pressure, and severe regurgitation may exist in patients with arterial pressures in the range of 140/60 mmHg. As the disease progresses and the LV end-diastolic pressure rises markedly, the arterial diastolic pressure may actually rise also, since the aortic diastolic pressure cannot fall below the LV end-diastolic pressure. For the same reason, *severe*, *acute* AR may also be accompanied by only light widening of the pulse pressure.

Palpation The LV impulse is heaving and displaced laterally and inferiorly. The systolic expansion and diastolic retraction of the apex are prominent and contrast with the sustained systolic thrust characteristic of severe AS. A diastolic thrill is often palpable along the left sternal border, and a prominent systolic thrill may be palpable in the jugular notch and transmitted upward along the carotid arteries. This systolic thrill and the accompanying murmur are due to the markedly increased blood flow across the aortic orifice and do not necessarily signify the coexistence of AS. In many patients with pure AR or with combined AS and AR, the carotid arterial pulse is bisferiens, i.e., with two systolic waves separated by a trough.

Auscultation In patients with severe AR, the aortic valve closure sound (A_2) is usually absent. An S_3 and systolic ejection sound are frequently audible, and occasionally, an S_4 also may be heard. The murmur of chronic AR is typically a high-pitched, blowing, decrescendo diastolic murmur, heard best in the third intercostal space along the left sternal border (see Fig. 209-5*B*). In patients with mild AR, this murmur is brief, but as the severity increases, generally becomes louder and longer, indeed holodiastolic. When the murmur is soft, it can be heard best with the diaphragm of the stethoscope and with the patient sitting up, leaning forward, and with the breath held in forced expiration. In patients in whom the AR is caused by primary valvular disease, the diastolic murmur is usually louder along the left than the right sternal border. However, when the murmur is heard best along the right sternal border, it suggests that the AR is caused by aneurysmal dilatation of the aortic root. "Cooing" or musical diastolic murmurs suggest eversion of an aortic cusp vibrating in the regurgitant stream.

A midsystolic ejection murmur is frequently audible in AR. It is generally heard best at the base of the heart and is transmitted along the carotid vessels. This murmur may be quite loud without signifying aortic obstruction; it is often higher pitched, shorter, and less rasping in quality than the ejection systolic murmur heard in patients with predominant AS. A third murmur frequently heard in patients with severe AR is the *Austin Flint murmur*, a soft, low-pitched, rumbling middiastolic bruit. It is probably produced by the diastolic displacement of the anterior leaflet of the mitral valve by the AR stream but does not appear to be associated with hemodynamically significant mitral obstruction and, in contrast to the diastolic murmur of MS, it is not accompanied by an OS or loud S_1. The auscultatory features of AR are intensified by isometric exercise such as strenuous handgrip, which augments systemic resistance, and reduced by inhalation of amyl nitrite.

In *severe*, *acute* AR, the elevation of LV end-diastolic pressure may lead to early closure of the mitral valve, an associated middiastolic sound, a soft or absent S_1, a pulse pressure that is not particularly wide, and a soft, short diastolic murmur of AR.

LABORATORY EXAMINATION ■ EKG In patients with severe, chronic AR, the EKG signs of LV hypertrophy become manifest (Chap. 210). In addition, these patients frequently exhibit ST-segment depression and T-wave inversion in leads I, aVL, V_5, and V_6 ("LV strain"). Left axis deviation and/or QRS prolongation denote diffuse myocardial disease, generally associated with patchy fibrosis, and usually signify a poor prognosis.

Echocardiogram The extent and velocity of wall motion are normal or even supernormal, until myocardial contractility declines. A rapid, high-frequency fluttering of the anterior mitral leaflet produced by the impact of the regurgitant jet is a characteristic finding. The echocardiogram is also useful in determining the cause of AR, by detecting dilatation of the aortic annulus (Fig. 219-6). Thickening and failure of coaptation of the leaflets also may be noted. Color flow Doppler echocardiographic imaging is very sensitive in the detection of AR, and Doppler echocardiography is helpful in assessing its severity. Serial two-dimensional echocardiography is valuable in assessing LV performance and in detecting progressive myocardial dysfunction.

Roentgenogram In severe chronic AR, the apex is displaced downward and to the left in the frontal projection, and frequently the cardiac shadow extends below the left diaphragm. LV enlargement also may be apparent in the left anterior oblique and lateral projections, in which the LV is displaced posteriorly and encroaches on the spine. In patients in whom primary valvular disease is responsible for the AR, the ascending aorta and aortic knob may be moderately dilated. When AR is caused by primary disease of the aortic wall, aneurysmal dilatation of the aorta may be noted, and the aorta may fill the retrosternal space in the lateral view.

Cardiac Catheterization and Angiography In addition to providing an accurate confirmation of the magnitude of regurgitation and the status of

LV function, the condition of the coronary arterial bed should ordinarily be evaluated preoperatively.

TREATMENT

Medical Treatment (Table 219-1) Although operation constitutes the definitive treatment of AR and should be carried out before the development of heart failure, the latter usually responds briefly to treatment with digitalis glycosides, salt restriction, diuretics, and vasodilators, especially ACE inhibitors. Digitalis also may be indicated in patients with severe regurgitation and dilated left ventricles without frank LV failure. Cardiac arrhythmias and infections are poorly tolerated in patients with severe AR and must be treated promptly and vigorously. Although nitroglycerin and long-acting nitrates are not as helpful in relieving anginal pain as they are in patients with ischemic heart disease, they are worth a trial. Long-acting nifedipine has been found to delay the need for operation. Patients with syphilitic aortitis should receive a full course of penicillin therapy (Chap. 153).

Surgical Treatment In deciding on the advisability and proper timing of surgical treatment, two points should be kept in mind: (1) patients with chronic AR usually do not become symptomatic until *after* the development of myocardial dysfunction, and (2) when delayed too long, surgical treatment often does not restore normal LV function. Therefore, in patients with severe AR, careful clinical follow-up and noninvasive testing with echocardiography at approximately 6-month intervals are necessary if operation is to be undertaken at the optimal time, i.e., *after* the onset of LV dysfunction but *prior* to the development of severe symptoms. Operation can be deferred as long as the patient both remains asymptomatic and retains normal LV function. In general, operation should be carried out even in asymptomatic patients with progressive LV dysfunction and a left ventricular ejection fraction (LVEF) $<55\%$ or a LV end-systolic volume >55 mL/m^2. These parameters have been referred to as the "55/55 rule."

AVR with a suitable mechanical or tissue prosthesis is generally necessary in patients with rheumatic AR and in many patients with other forms of regurgitation. Rarely, when a leaflet has been perforated during infective endocarditis or torn from its attachments to the aortic annulus by thoracic trauma, surgical repair may be possible. When AR is due to aneurysmal dilatation of the annulus and ascending aorta rather than to primary valvular involvement, it may be possible to reduce the regurgitation by narrowing the annulus or by excising a portion of the aortic root without replacing the valve. More frequently, however, regurgitation can be eliminated only by replacing the aortic valve, excising the dilated or aneurysmal ascending aorta responsible for the regurgitation, and replacing it with a graft. This formidable procedure entails a higher risk than isolated AVR.

As in patients with other valvular abnormalities, both the operative risk and the late mortality are largely dependent on the stage of the disease and on myocardial function at the time of operation. The overall operative mortality for isolated AVR is 4.3% (Table 219-2). However, patients with marked cardiac enlargement and prolonged LV dysfunction experience an operative mortality rate of approximately 10% and a late mortality rate of approximately 5% per year due to LV failure despite a technically satisfactory operation. Nonetheless, because of the very poor prognosis with medical management, even patients with LV failure should be considered for operation.

Patients with acute, severe AR require prompt surgical treatment, which may be lifesaving.

TRICUSPID STENOSIS

TS, a relatively uncommon valvular lesion in North America and Western Europe, is more common in tropical and subtropical climates, especially in southern Asia and in Latin America. It is generally rheumatic in origin and is more common in females than in males. It does not occur as an isolated lesion and is usually associated with MS. Hemodynamically significant TS occurs in 5 to 10% of patients with severe MS; rheumatic TS is commonly associated with some degree of TR.

PATHOPHYSIOLOGY A diastolic pressure gradient between the RA and RV can be recorded with a double-lumen cardiac catheter. It is augmented when the transvalvular blood flow increases during inspiration and declines during expiration. A mean diastolic pressure gradient of 4 mmHg is usually sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion. Unless sodium intake has been restricted and diuretics administered, this venous congestion is associated with ascites and edema, sometimes severe. In patients with sinus rhythm, the RA *a* wave may be extremely tall and may even approach the level of the RV systolic pressure. The CO at rest is usually depressed and it fails to rise during exercise. The low CO is responsible for the normal or only slightly elevated LA, PA, and RV systolic pressures despite the presence of MS. Thus, the presence of TS can mask the hemodynamic and clinical features of the MS which usually accompanies it.

SYMPTOMS Since the development of MS generally precedes that of TS, many patients initially have symptoms of pulmonary congestion. Amelioration of these symptoms should raise the possibility that TS may be developing. Characteristically, patients complain of relatively little dyspnea for the degree of hepatomegaly, ascites, and edema that they have. However, fatigue secondary to a low CO and discomfort due to refractory edema, ascites, and marked hepatomegaly are common in patients with TS and/or TR. In some patients, TS may be suspected for the first time when symptoms of RV failure persist after an adequate mitral valvotomy.

PHYSICAL FINDINGS

Since TS usually occurs in the presence of other obvious valvular disease, the diagnosis may be missed unless it is specifically searched for. Severe TS is associated with marked hepatic congestion, often resulting in cirrhosis, jaundice, serious malnutrition, anasarca, and ascites. Congestive hepatomegaly and, in cases of severe tricuspid valve disease, splenomegaly are present. The jugular veins are distended, and in patients with sinus rhythm there may be giant *a* waves. The *v* waves are less conspicuous, and since tricuspid obstruction impedes RA emptying during diastole, there is a slow *y* descent. In patients with sinus rhythm there may be prominent presystolic pulsations of the enlarged liver as well.

On auscultation, the pulmonic valve closure sound is not accentuated, and occasionally, an OS of the tricuspid valve may be heard approximately 0.06 s after pulmonic valve closure. The diastolic murmur of TS has many of the qualities of the diastolic murmur of MS, and since TS almost always occurs in the presence of MS, the less common valvular lesion may be missed. However, the tricuspid murmur is generally heard best along the left lower sternal margin and over the xiphoid process and is most prominent during presystole in patients with sinus rhythm. The diastolic murmur is reduced in amplitude as the stethoscope is inched laterally, only to intensify or reappear as the mitral murmur at the apex. The murmur of TS is augmented during inspiration, and it is reduced during expiration and particularly during the strain of Valsalva maneuver, when tricuspid blood flow is reduced.

LABORATORY EXAMINATION The ECG features of RA enlargement (Chap. 210) include tall, peaked P waves in lead II, as well as prominent, upright P waves in lead V_1. The *absence* of ECG evidence of right ventricular hypertrophy (RVH) in a patient with right-sided heart failure who is believed to have MS should suggest associated tricuspid valve disease. The chest roentgenogram in patients with combined TS and MS shows particular prominence of the RA and superior vena cava without much enlargement of the PA and with less evidence of pulmonary vascular congestion than occurs in patients with isolated MS. On echocardiographic examination, the tricuspid valve is usually thickened; the transvalvular gradient can be estimated by Doppler echocardiography.

℞ TREATMENT

Patients with TS generally exhibit marked systemic venous congestion; intensive salt restriction and diuretic therapy are required during the preoperative period. Such a preparatory period may diminish hepatic congestion and thereby improve hepatic function sufficiently so that the risks of operation are diminished. Surgical relief of the TS should be carried out, preferably at the time of surgical mitral valvotomy or MVR, in patients with moderate or severe TS who have mean diastolic pressure gradients exceeding approximately 4 mmHg and tricuspid orifices less than 1.5 to 2.0 cm^2. TS is almost always accompanied by significant TR. Open-heart repair may permit substantial improvement of tricuspid valve function. If this cannot be accomplished, the tricuspid valve may have to be replaced with a prosthesis, preferably a large bioprosthetic valve.

TRICUSPID REGURGITATION

Most commonly, TR is functional and secondary to marked dilatation of the tricuspid annulus. Functional TR may complicate RV enlargement of any cause, including inferior wall infarcts that involve the RV. It is commonly seen in the late stages of heart failure due to rheumatic or congenital heart disease with severe pulmonary hypertension, as well as in ischemic heart disease, cardiomyopathy, and cor pulmonale. It is in part reversible if pulmonary hypertension is relieved. Rheumatic fever may produce organic TR, often associated with TS. Infarction of RV papillary muscles, tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, infective endocarditis, and trauma all may produce TR. Less commonly, TR results from congenitally deformed tricuspid valves, and it occurs with defects of the atrioventricular canal as well as with Ebstein's malformation of the tricuspid valve (Chap. 218).

As is the case for TS, the clinical features of TR result primarily from systemic venous congestion and reduction of CO. With the onset of TR in patients with pulmonary hypertension, symptoms of pulmonary congestion diminish, but the clinical manifestations of right-sided heart failure become intensified. The neck veins are distended with prominent *v* waves; and marked hepatomegaly, ascites, pleural effusions, edema, systolic pulsations of the liver, and a positive hepatojugular reflux are common. A prominent RV pulsation along the left parasternal region and a blowing holosystolic murmur along the lower left sternal margin, which may be intensified during inspiration and reduced during expiration or the strain of the Valsalva maneuver, are characteristic findings; AF is usually present.

The ECG usually shows changes characteristic of the lesion responsible for the enlargement of the RV that leads to TR, e.g., inferior wall myocardial infarction or severe RVH. Echocardiography may be helpful by demonstrating RV dilatation and prolapsing or flail tricuspid leaflets; the diagnosis of TR can be made by color flow Doppler echocardiography, and the severity estimated by Doppler examination. The latter is also useful in estimating PA pressure. Roentgenographic examination usually reveals enlargement of both the RA and RV.

In patients with severe TR, the CO is usually markedly reduced, and the RA pressure pulse may exhibit no *x* descent during early systole but a prominent *c-v* wave with a rapid *y* descent. The mean RA and the RV end-diastolic pressures are often elevated.

℞ TREATMENT

Isolated TR, in the absence of pulmonary hypertension, such as that occurring as a consequence of infective endocarditis or trauma, is usually well tolerated and does not require operation. Indeed, even total excision of an infected tricuspid valve may be well tolerated for several years if the PA pressure is normal. Treatment of the underlying cause of heart failure usually reduces the severity of functional TR by reducing the size of the tricuspid annulus. In patients with mitral valve disease and TR secondary to pulmonary hypertension and massive RV enlargement, effective surgical correction of the mitral valvular abnormality results in lowering of the PA pressures and gradual reduction or disappearance of the TR without direct treatment of the tricuspid valve. However, recovery may be much more rapid in patients with severe secondary TR if, at the time of mitral valve surgery, tricuspid annuloplasty (generally with the insertion of a plastic ring), open tricuspid valve repair, or, in the rare instance of severe organic tricuspid valve disease, tricuspid valve replacement is performed. Surgical treatment of the TR also should be carried out in patients with severe regurgitation secondary to deformity of the tricuspid valve due to rheumatic fever, particularly those *without* severe pulmonary hypertension.

PULMONIC VALVE DISEASE

The pulmonic valve is affected by rheumatic fever far less frequently than are the other valves, and it is uncommonly the seat of infective endocarditis. The most common *acquired* abnormality affecting the pulmonic valve is regurgitation secondary to dilatation of the pulmonic valve ring as a consequence of severe pulmonary hypertension. This produces the *Graham Steell murmur*, a high-pitched, decrescendo, diastolic blowing murmur along the left sternal border, which is difficult to differentiate from the far more common murmur produced by AR. It is usually of little hemodynamic significance; indeed, surgical removal or destruction of the pulmonic valve by infective endocarditis does not produce heart failure unless serious pulmonary hypertension is also present. The *carcinoid syndrome* may cause pulmonic stenosis and/or regurgitation. →***Congenital pulmonic stenosis is discussed in Chap. 218.***

VALVE REPLACEMENT

The results of replacement of any valve are dependent primarily on (1) the patient's myocardial function and general medical condition at the time of operation; (2) the technical abilities of the operative team and the quality of the postoperative care; and (3) the durability, hemodynamic characteristics, and thrombogenicity of the prosthesis. Increased operative mortality is associated with advanced age, comorbidity (e.g., pulmonary or renal disease, the need for nonvalvular cardiovascular surgery, diabetes mellitus) as well as with higher levels of preoperative functional disability and pulmonary hypertension. Late complications of valve replacement include paravalvular leakage, thromboemboli, bleeding due to anticoagulants, mechanical dysfunction of the prosthesis, and infective endocarditis.

The considerations involved in the choice between a bioprosthetic (tissue) and artificial mechanical valve are similar in the mitral and aortic sites and in the treatment of stenotic, regurgitant, or mixed lesions. All patients who have undergone replacement of any valve with a mechanical prosthesis are at risk of thromboembolic complications and must be maintained permanently on anticoagulants, a treatment that imposes a hazard of hemorrhage. The primary advantage of bioprostheses over mechanical prostheses is the virtual absence of thromboembolic complications 3 months after implantation, and except for patients with chronic AF, few such instances have been associated with their use. The major disadvantage of bioprosthetic valves is their mechanical deterioration, the incidence of which is inversely proportional to the patient's age. This results in the need to replace the prosthesis in 30% of patients by 10 years and in 50% by 15 years. Because this complication is age-related, bioprostheses are ordinarily not used in patients under 65 years but are particularly useful in the elderly (>70 years), in whom there is more concern about chronic anticoagulation than about long-term (>20 years) valve durability. Patients between 65 and 70 years should be evaluated on a case-by-case basis as to the use of a bioprosthetic or mechanical valve. Bioprosthetic valves are also indicated in women who expect to become pregnant, as well as others in whom anticoagulation may be contraindicated. Alternative bioprostheses are xenografts [i.e., porcine aortic valves; cryopreserved, mounted bovine pericardium; homograft (allograft) aortic valves obtained from cadavers as well as pulmonary autografts transplanted into the aortic position.]

In patients without contraindications to anticoagulants, particularly

those under 65 years, a mechanical prosthesis may be preferable. Many surgeons now select the St. Jude prosthesis, a double-disk tilting prosthesis, for replacement of both aortic and mitral valves because of favorable hemodynamic characteristics and possible association with lower thrombogenicity.

220 PULMONARY HYPERTENSION

Stuart Rich

Pulmonary hypertension, an abnormal elevation in pulmonary artery pressure, may reflect an increase in left heart filling pressure in the presence of normal pulmonary vascular resistance, pulmonary vascular or parenchymal disease with an elevation in pulmonary vascular resistance, or a combination of these initiating factors. Whether the pulmonary hypertension arises from cardiac, pulmonary, or intrinsic vascular disease, it generally is a feature of advanced disease. Because the causes of pulmonary hypertension are so diverse, it is essential that the etiology underlying the pulmonary hypertension be clearly determined before embarking on treatment. Recent data suggest that mild increases in pulmonary artery pressure also occur with age as the pulmonary circulation becomes less compliant.

Cor pulmonale (Chap. 216) is a term used to indicate right ventricular (RV) enlargement secondary to any underlying cardiac or pulmonary disease. Pulmonary hypertension is the most common cause of cor pulmonale. Advanced cor pulmonale is associated with the development of RV failure.

PATHOPHYSIOLOGY The right ventricle responds to an increase in resistance within the pulmonary circulation by increasing RV systolic pressure as necessary to preserve cardiac output. The increase in pulmonary vascular resistance may be attributed to excessive production of vascular growth factors, mechanical obstruction of the pulmonary arteries, hypoxia, or other stimuli. Over time, chronic changes occur in the pulmonary circulation resulting in remodeling of the vasculature, which can sustain or promote pulmonary hypertension even if the initiating factor is removed.

On occasion a patient may have marked elevations in pulmonary artery pressure in association with obstructive or interstitial lung disease, essential hypertension, ischemic heart disease, or valvular heart disease. Although it may appear that the pulmonary hypertension is out of proportion to the underlying associated condition, it likely represents a pulmonary vasoconstrictor response to the associated condition, which serves as a trigger of the pulmonary arteriopathy. The distinction is important because the treatment of pulmonary hypertension should include treating the underlying associated cause whenever possible.

The ability of the right ventricle to adapt to increased vascular resistance is influenced by several factors including age and the rapidity of the development of pulmonary hypertension. For example, a large acute pulmonary thromboembolism can result in RV failure and shock, whereas chronic thromboembolic disease of equal severity may result in only mild exercise intolerance. Coexisting hypoxemia from lung disease or myocardial ischemia from coronary artery disease can impair the ability of the ventricle to compensate. The onset of clinical RV failure, usually manifest by peripheral edema, is associated with a poor outcome.

DIAGNOSIS A thorough diagnostic evaluation of all potential causes of pulmonary hypertension should be undertaken (Fig. 220-1). The most

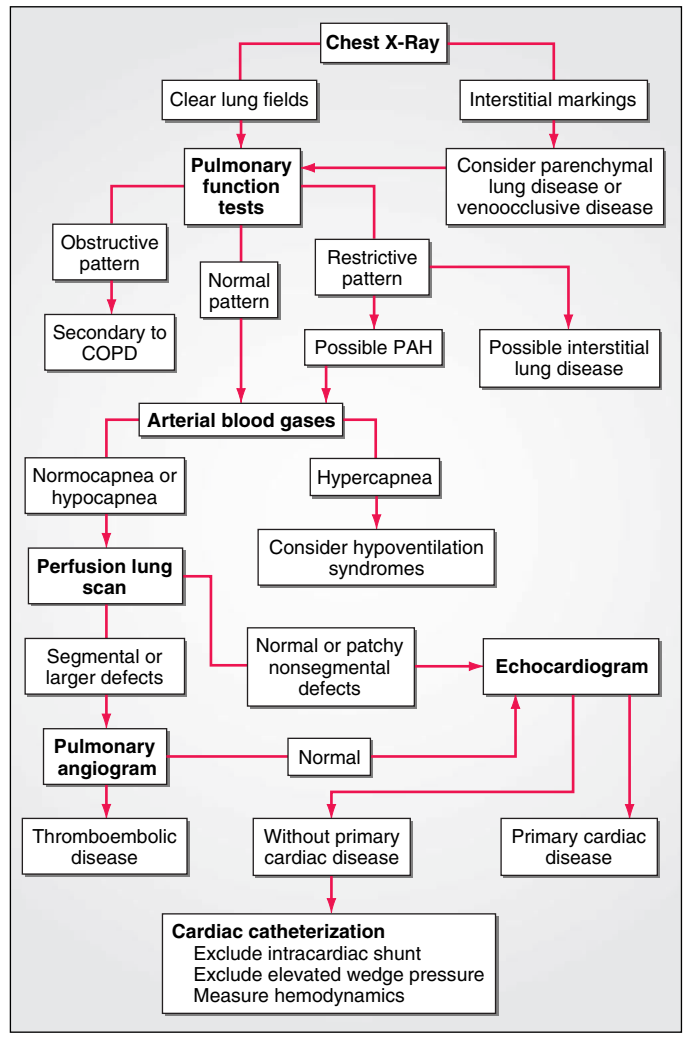

FIGURE 220-1 An algorithm for the workup of a patient with unexplained pulmonary hypertension. (*Adapted with permission from Rich.*)

common symptom attributable to pulmonary hypertension is exertional dyspnea. Other common symptoms are fatigue, angina pectoris that may represent RV ischemia, syncope, near syncope, and peripheral edema.

The physical examination typically reveals increased jugular venous pressure, a reduced carotid pulse, and a palpable RV lift. Most patients have an increased pulmonic component of the second heart sound and a right-sided fourth heart sound (Chap. 209). Tricuspid regurgitation is a clinical feature of RV failure. Peripheral cyanosis and/or edema tend to occur in later stages of the disease. The presence of clubbing can be a clinical clue that the patient has underlying congenital heart disease or hypoxemic lung disease.

Laboratory Findings The chest x-ray generally shows enlarged central pulmonary arteries. The lung fields may or may not reveal other pathology. The electrocardiogram usually reveals right axis deviation and RV hypertrophy. The echocardiogram commonly demonstrates RV and right atrial enlargement, a reduction in left ventricular (LV) cavity size, and a tricuspid regurgitant jet that can be used to estimate RV systolic pressure. Pulmonary function tests are helpful in documenting underlying obstructive airways disease or severe restrictive lung disease. Hypoxemia and an abnormal diffusing capacity for carbon monoxide are common findings of pulmonary hypertension of most causes. A perfusion lung scan is almost always abnormal in patients with thromboembolic pulmonary hypertension (Chap. 244). However, diffuse patchy filling defects of a nonsegmental nature can often be seen in longstanding pulmonary hypertension in the absence of thromboemboli. Laboratory tests should also be performed, including antinuclear antibody and HIV testing. Because of the high frequency of thyroid abnormalities in patients with primary pulmonary hypertension, it is recommended that the thyroid-stimulating hormone level be determined as well.

Cardiac Catheterization This procedure is mandatory for accurate measurement of pulmonary artery pressure, cardiac output, and LV filling pressure, as well as for exclusion of an underlying cardiac shunt. Because of the difficulty in obtaining accurate pulmonary capillary wedge pressures in patients with pulmonary vascular disease, it is desirable to perform a left heart catheterization to identify an elevation of LV end-diastolic pressure as the cause of the pulmonary hypertension. It is also recommended that patients with pulmonary arterial hypertension undergo drug testing with a short-acting pulmonary vasodilator at the time of cardiac catheterization to determine the extent of pulmonary vasodilator reactivity (Fig. 220-2). Inhaled nitric oxide, intravenous adenosine, and intravenous epoprostenol appear to have similar effects in reducing pulmonary artery pressure acutely with little effect on the systemic vascular bed. Nitric oxide is generally administered via inhalation in 10 to 20 parts per million. Adenosine is given as an infusion of doses of 50 μg/kg per min and increased every 2 min until side effects develop. Epoprostenol is given in doses of 2 ng/kg per min and increased every 30 min until side effects develop. Maximal physiologic effectiveness of the drug is determined at the highest tolerated dose. Patients who respond can usually be treated with calcium channel blockers and have a more favorable prognosis.

It is a misperception that the preferred treatment of pulmonary hypertension from any cause is vasodilators, which is the common approach to treating essential hypertension. While vasodilators may benefit selected patients, successful therapies of pulmonary hypertension include those that improve RV function, normalize cardiac output, and improve oxygenation in addition to therapies directed toward inhibiting the vasoproliferative process in the pulmonary vascular bed.

PULMONARY ARTERIAL HYPERTENSION

The causes of pulmonary arterial hypertension (Table 220-1) include primary pulmonary hypertension, pulmonary hypertension associated with the collagen vascular diseases, congenital systemic to pulmonary shunts, portal hypertension, HIV infection, anorexigen use, and persistent pulmonary hypertension of the newborn. These patients share a common histopathology that includes pulmonary vascular abnormalities involving the endothelium, smooth-muscle cells, and extracellular matrix. The most common features are medial hypertrophy, eccentric and concentric intimal fibrosis, recanalized thrombi appearing as fibrous webs, and plexiform lesions.

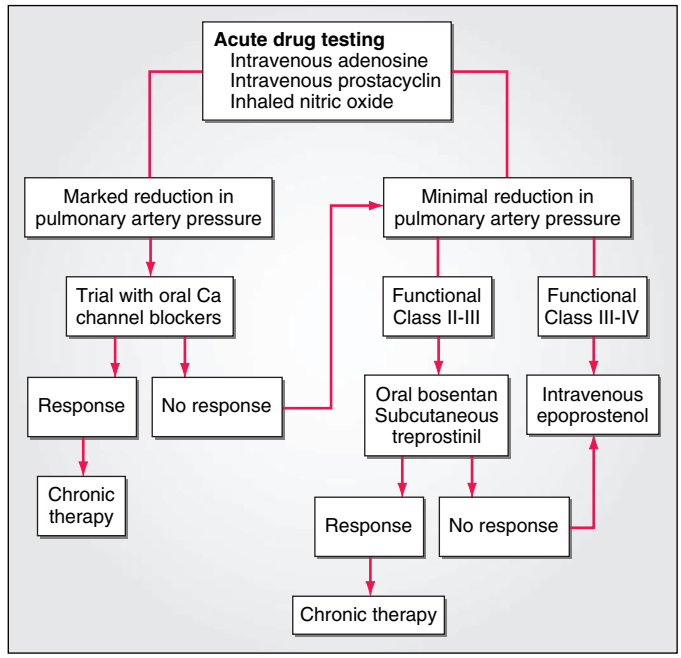

FIGURE 220-2 An algorithm for the selection of optimal drug treatment of a patient with pulmonary arterial hypertension. (*Adapted with permission from Rich.*)

Pathobiology There are likely several pathobiologic processes that result in pulmonary arterial hypertension as a final common pathway. These include inhibition of the voltage-regulated potassium channel producing vasoconstriction of the pulmonary artery smooth-muscle cells, reduced expression of nitric oxide synthase in the endothelium of the pulmonary arterial bed, increased expression of endothelin and basic fibroblast growth factor, and thrombin deposition related to a procoagulant state. The types of abnormalities that occur are likely influenced by the patient's genotype and exposure to risk factors that serve to trigger these processes.

TABLE 220-1 *Additional Diagnostic Tests to Evaluate the Suspected Cause of Pulmonary Hypertension*

Cause	*Diagnostic Test*
Collagen vascular disease	Serologic and immunogenetic studies
Congenital heart disease	Transesophageal echocardiography with contrast
Portal hypertension	Ultrasonography, computed tomography (CT)
Human immunodeficiency virus	HIV serologic test
Left ventricular diastolic dysfunction	Left ventricular end-diastolic pressure or left atrial pressure measurement
Mitral valve disease	Echocardiography with Doppler
Mediastinal fibrosis	CT, magnetic resonance imaging
Chronic obstructive lung disease	Pulmonary function tests
Obstructive sleep apnea	Sleep apnea study
Pulmonary fibrosis	High-resolution chest CT
Interstitial pneumonitis	Transbronchial or open-lung biopsy
Pulmonary thromboembolic disease	Perfusion lung scan, contrast-enhanced Spiral CT, pulmonary angiography
Sarcoidosis	Lung or lymph node biopsy

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension (PPH) is uncommon, with an estimated incidence of 2 cases per million. There is a strong female predominance, with most patients presenting in the fourth and fifth decades, although the age range is from infancy to >60 years.

GENETIC CONSIDERATIONS Familial PPH accounts for 12 to 20% of cases of PPH and is characterized by autosomal dominant inheritance, variable age of onset, and incomplete penetrance. The clinical and pathologic features of familial and sporadic PPH are identical. Heterozygous germline mutations that involve the gene coding the type II bone morphogenetic protein receptor (BMPR II), a member of the transforming growth factor β superfamily, have been found to underly many cases of familial PPH. This gene, which is located on chromosome 2q31, has been designated as the PPH I gene. An interruption in the BMP-mediated signaling pathway predisposes the cells within the small pulmonary arteries to proliferation rather than apoptosis. These observations support the concept that PPH is a result of abnormal proliferation of pulmonary vascular endothelial and smooth-muscle cells.

NATURAL HISTORY The natural history of PPH is uncertain because initially the disease can be asymptomatic. Because the predominant symptom is dyspnea, which can have an insidious onset, the disease is typically diagnosed late in its course. Prior to current therapies, a mean survival of 2 to 3 years from the time of diagnosis was reported. It appears that the survival of patients with pulmonary hypertension secondary to congenital heart disease is longer than for patients with PPH, while the survival of patients with pulmonary hypertension secondary to scleroderma is shorter. Functional class remains a strong predictor of survival, with patients who are in New York Heart Association (NYHA) functional class IV having a mean survival of <6 months. The cause of death is usually RV failure, which is manifest by progressive hypoxemia, tachycardia, hypotension, and edema.

TREATMENT

Because the pulmonary artery pressure in PPH increases dramatically with exercise, patients should be cautioned against participating in activities that demand increased physical stress. Digoxin may increase cardiac output and lower circulating levels of norepinephrine. Diuretic therapy relieves peripheral edema and may be useful in reducing RV volume overload in the presence of tricuspid regurgitation. Resting and exercise pulse oximetry should be obtained, as oxygen supplementation helps to alleviate dyspnea and RV ischemia in patients whose arterial oxygen saturation is reduced. Anticoagulant therapy is advocated for all patients with PPH since thrombin deposition occurs in the pulmonary circulation; thrombin can serve as a growth factor to promote the disease process. One retrospective study and one prospective study demonstrated that the anticoagulant warfarin increases survival of patients with PPH. The dose of warfarin is generally titrated to achieve an INR of two to three times control.

Calcium Channel Blockers Patients who have substantial reductions in pulmonary arterial pressure in response to short-acting vasodilators at the time of cardiac catheterization may be candidates for oral calcium channel blockers. Typically, patients require high doses (e.g., nifedipine, 240 mg/d, or amlodipine, 20 mg/d[1]). Patients who respond favorably usually have dramatic reductions in pulmonary artery pressure and pulmonary vascular resistance associated with improved symptoms, regression of RV hypertrophy, and improved survival with chronic therapy. However, <20% of patients respond to calcium channel blockers in the long term. These drugs can be particularly hazardous when given to patients who are unresponsive, as they can result in hypotension, hypoxemia, tachycardia, and worsening right heart failure.

[1]These agents have not been approved for the treatment of primary pulmonary hypertension by the U.S. Food and Drug Administration.

Prostacyclins *Epoprostenol* is the best characterized approved treatment of pulmonary arterial hypertension for patients who are NYHA functional class III or IV and unresponsive to other therapies. Clinical trials have demonstrated an improvement in symptoms, exercise tolerance, and survival even if no acute hemodynamic response to drug challenge occurs. Recent reports have documented sustained benefits for >10 years in some patients. The drug can only be administered intravenously and requires placement of a permanent central venous catheter and infusion through an ambulatory infusion pump system. It generally takes several months to titrate the dose gradually upwards to optimal clinical efficacy, which is usually between 25 and 50 ng/kg per min. Side effects include flushing, jaw pain, and diarrhea, which are generally tolerated by most patients. The major problem with this therapy is infection related to the venous catheter, which requires close monitoring and diligence on behalf of the patient.

Recently, *treprostinil* has been approved for patients with PPH who are NYHA functional classes II to IV and who are unresponsive to conventional therapy, defined as anticoagulation, diuretics, and calcium blockers. An analogue of epoprostenol, treprostinil has a longer half-life and is stable at room temperature, allowing it to be administered subcutaneously through a small infusion pump that was originally developed for insulin. Short-term clinical trials have demonstrated an increase in exercise capacity and a reduction of dyspnea. The major problem with this treatment has been local pain at the infusion site, which has caused patients to discontinue therapy.

Endothelin Receptor Antagonists The nonselective endothelin receptor antagonist *bosentan* was recently approved as an oral treatment of PPH for patients who are NYHA functional classes III and IV and who are unresponsive to conventional therapy. In randomized clinical trials, bosentan was shown to improve exercise tolerance as measured by an increase in 6-min walk distance, improve functional class, and extend time until clinical worsening versus placebo. Therapy is initiated at 62.5 mg bid for the first month and then increased to 125 mg bid thereafter. Because of the high frequency of abnormal hepatic function tests associated with drug use, primarily an increase in transaminases, it is recommended that liver function be monitored monthly throughout the duration of use. Bosentan is also contraindicated in patients who are currently on cyclosporine or glyburide. There are no data to support the use of bosentan for other forms of pulmonary hypertension.

Sildenafil There have been several case reports on the use of sildenafil (Viagra), an oral phosphodiesterase-5 inhibitor, in the treatment of pulmonary hypertension. Phosphodiesterase-5 is responsible for the hydrolysis of cyclic GMP in pulmonary vascular smooth muscles, the mediator through which nitric oxide lowers pulmonary artery pressure and inhibits pulmonary vascular growth. These reports suggest that oral sildenafil has a similar efficacy to inhaled nitric oxide. Large randomized clinical trials using sildenafil as a treatment of pulmonary hypertension are under consideration.

Lung Transplantation (See also Chap. 248) Lung transplantation is considered for patients who, while on epoprostenol, continue to manifest right heart failure. Acceptable results have been achieved with heart-lung, bilateral lung, and single lung transplant. The availability of donor organs often influences the choice of procedure. The recurrence of PPH has never been reported in a patient who has undergone lung transplantation.

CONDITIONS ASSOCIATED WITH PULMONARY HYPERTENSION

COLLAGEN VASCULAR DISEASE All of the collagen vascular diseases may be associated with pulmonary arterial hypertension. This complication occurs commonly with the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) and in scleroderma (Chap. 303), and less frequently in systemic lupus erythematosus (Chap. 300), Sjögrens syndrome (Chap. 304),

dermatomyositis, polymyositis (Chap. 306), and rheumatoid arthritis (Chap. 301). It is usual for these patients to have some element of coexistent interstitial pulmonary fibrosis even though it may not be apparent on chest x-ray, computed tomography, or pulmonary function tests. Consequently, these patients tend to have hypoxemia as an important clinical feature, along with the other classic findings of pulmonary hypertension.

Treatment for these patients is identical to that for patients with PPH (see above) but is less effective. It is rare for these patients to respond to calcium channel blockers. Bosentan, treprostinil, and epoprostenol have been effective in clinical trials. The treatment of the pulmonary hypertension, however, does not affect the natural history of the underlying collagen vascular disease.

CONGENITAL SYSTEMIC TO PULMONARY SHUNTS It is common for large post-tricuspid cardiac shunts (e.g., ventricular septal defect, patent ductus arteriosus) to produce severe pulmonary hypertension (Chap. 218), which, although less common, may also occur in pre-tricuspid shunts (e.g., atrial septal defect, anomalous pulmonary venous drainage). In patients with uncorrected shunts, the clinical features include those associated with right-to-left shunting such as hypoxemia and peripheral cyanosis, which worsen dramatically with exertion (Chap. 31). Pulmonary arterial hypertension may occur years or even decades after surgical correction of these lesions, in which case there will be no associated right-to-left shunting. These patients present similarly to patients with PPH but tend to have better long-term survival. This has been attributed to the more slowly progressive nature of the underlying vascular disease. The treatments are similar to those for PPH.

PORTAL HYPERTENSION Portal hypertension is associated with pulmonary arterial hypertension, but the mechanism remains unknown. The risk is not related to the severity of underlying liver disease. Patients with advanced cirrhosis can have the combined features of a high-output cardiac state in association with the features of pulmonary hypertension and RV failure. Thus, a normal cardiac output may actually reflect a marked impairment of RV function. The etiology of ascites and edema can be confusing in these patients since it can have both cardiac and hepatic causes. Venous congestion from right heart failure, however, is poorly tolerated by cirrhotic livers. Patients with mild pulmonary hypertension who have a favorable response to epoprostenol have undergone successful liver transplantation with improvement of the pulmonary vascular disease.

HIV INFECTION The mechanism by which HIV infection produces pulmonary hypertension remains unknown (Chap. 173). The evaluation and treatment are identical to those for PPH. Treatment of the HIV infection does not appear to affect the severity or natural history of the underlying pulmonary hypertension.

ANOREXIGENS A causal relationship has been established between exposure to several anorexigens, including aminorex and the fenfluramines, and the development of pulmonary arterial hypertension. Although the fenfluramines were removed from the world markets in 1997, there are still patients who were exposed prior to that time who are now developing pulmonary hypertension. While the clinical features are identical to those of PPH, the patients appear to be less responsive to medical treatments and have a poorer prognosis.

PULMONARY VENOOCCLUSIVE DISEASE Pulmonary venoocclusive disease is a rare and distinct pathologic entity found in $<10\%$ of patients who present with the diagnosis of unexplained pulmonary hypertension. Histologically it is manifest by widespread intimal proliferation and fibrosis of the intrapulmonary veins and venules, occasionally extending to the arteriolar bed. The pulmonary venous obstruction explains the increase in pulmonary capillary wedge pressure observed in patients with advanced disease. These patients may develop orthopnea that can mimic LV failure. The therapy of this condition is not established.

PULMONARY CAPILLARY HEMANGIOMATOSIS Pulmonary capillary hemangiomatosis is a very rare form of pulmonary hypertension. Histologically it is characterized by the presence of infiltrating thin-walled blood vessels throughout the pulmonary interstitium and walls of the pulmonary arteries and veins. The presenting symptoms are usually those of PPH but often with hemoptysis as a clinical feature. The diagnosis can be made with pulmonary angiography. The clinical course is usually one of progressive deterioration leading to severe pulmonary hypertension, right-sided heart failure, and death. There is no established therapy.

PULMONARY VENOUS HYPERTENSION

Pulmonary hypertension occurs as a result of increased resistance to pulmonary venous drainage. It is often associated with diastolic dysfunction of the left ventricle; diseases affecting the pericardium or mitral or aortic valves; or rare entities such as cor triatriatum, left atrial myxoma, extrinsic compression of the central pulmonary veins from fibrosing mediastinitis, and pulmonary venoocclusive disease. Pulmonary venous hypertension affects the pulmonary veins and venules, producing arterialization of the external elastic lamina, medial hypertrophy, and focal eccentric intimal fibrosis. Microcirculatory lesions include capillary congestion, focal alveolar edema, and dilatation of the interstitial lymphatics. Although these lesions are potentially reversible, regression may take years after the underlying cause is removed. In some patients pulmonary venous hypertension triggers reactive vasoconstriction in the pulmonary arterial bed and results in proliferative changes of the intima and media that can produce severe elevations in pulmonary artery pressure. Clinically it may be confusing and appear as if two separate disease processes are occurring simultaneously.

LEFT VENTRICULAR DIASTOLIC DYSFUNCTION Pulmonary hypertension as a result of LV diastolic failure is common but often unrecognized (Chap. 216). It can occur with or without LV systolic failure. The most common causes are hypertensive heart disease; coronary artery disease; or impaired LV compliance related to age, diabetes, and hypoxemia. Symptoms of orthopnea and paroxysmal nocturnal dyspnea are prominent. Many patients improve considerably if LV end-diastolic pressure is lowered.

MITRAL VALVE DISEASE Mitral stenosis and mitral regurgitation represent important causes of pulmonary hypertension (Chap. 219). These patients often have superimposed pulmonary vasoconstriction resulting in marked elevations in pulmonary artery pressures. An echocardiogram usually shows abnormalities such as thickened mitral valve leaflets with reduced mobility or severe mitral regurgitation documented by Doppler echocardiography (Chap. 211). At cardiac catheterization a pressure gradient between the pulmonary capillary wedge pressure and LV end-diastolic pressure is diagnostic of mitral stenosis.

In patients with mitral stenosis corrective surgery of the mitral valve or mitral balloon valvuloplasty predictably results in a reduction in pulmonary artery pressure and pulmonary vascular resistance. Patients with mitral regurgitation, however, may not have as dramatic a response from surgery due to persistent elevations in LV end-diastolic pressure.

PULMONARY HYPERTENSION ASSOCIATED WITH LUNG DISEASE AND HYPOXEMIA

The mechanism of hypoxic pulmonary vasoconstriction involves the inhibition of potassium currents and membrane depolarization of pulmonary vascular smooth muscle as a result of the change in membrane sulfhydryl redox status. Increased calcium entry into the vascular smooth-muscle cells mediates hypoxic pulmonary vasoconstriction. Pulmonary vascular remodeling in response to chronic hypoxia is also mediated by a reduction in nitric oxide production; an increase in endothelin 1; and increased expression of platelet-derived growth factors, vascular endothelial growth factor, and angiotensin II. Chronic hypoxia results in muscularization of the arterioles with minimal ef-

fects on the intima. When it occurs as an isolated entity, the changes produced are potentially reversible.

Although chronic hypoxia is an established cause of pulmonary hypertension, it rarely leads to an increase in the mean pulmonary artery pressure >40 mmHg. Polycythemia in response to the hypoxemia is a characteristic finding. Hypoxia may also occur in conjunction with other causes of pulmonary hypertension associated with more extensive vascular changes. Clinically, the hypoxia will tend to have an added adverse affect. Patients with chronic hypoxia who have a marked elevation in pulmonary pressure should be evaluated for other causes of the pulmonary hypertension.

CHRONIC OBSTRUCTIVE LUNG DISEASE Chronic obstructive lung disease (COLD) is a common cause of pulmonary hypertension in the advanced stages (Chap. 242). Pulmonary hypertension has been attributed to multiple factors, including hypoxic pulmonary vasoconstriction, acidemia, hypercapnia, the mechanical effects of high lung volume on pulmonary vessels, the loss of small vessels in the vascular bed, and regions of emphysematous lung destruction.

Although the elevation of pulmonary artery pressure associated with COLD tends to be mild, the presence of pulmonary hypertension confers a worse outcome. The only effective therapy is supplemental oxygen. Several large clinical trials have documented that continuous oxygen therapy relieves some of the pulmonary vasoconstriction, relieves chronic ischemia throughout the systemic and pulmonary vascular beds, and improves survival. Long-term oxygen therapy is indicated if the resting arterial P_{O_2} remains <55 mmHg.

INTERSTITIAL LUNG DISEASE Pulmonary hypertension from interstitial lung disease is often associated with obliteration of the pulmonary vascular bed by lung destruction and fibrosis (Chap. 243). In addition, hypoxemia and pulmonary vasculopathy can be contributory factors. A large number of patients have pulmonary fibrosis of unknown etiology. Interstitial lung disease is often associated with the collagen vascular diseases. Patients are commonly older than 50 years and report an insidious onset of progressive dyspnea and cough for months to years. A definitive diagnosis requires an open-lung biopsy to rule out other diseases such as bronchiolitis obliterans, nonspecific interstitial pneumonia, and hypersensitivity pneumonitis. Management of these disorders is discussed in Chap. 243. None of the medical treatments developed for pulmonary arterial hypertension have been shown to be effective in these patients.

SLEEP-DISORDERED BREATHING *Sleep apnea*, defined as repeated episodes of obstructive apnea and hypopnea during sleep together with daytime somnolence and altered cardiopulmonary function, is a common condition (Chap. 247). The incidence of pulmonary hypertension in the setting of obstructive sleep apnea appears to be <20% and is generally mild. Therapeutic strategies for patients with sleep apnea should be directed towards establishing normal nocturnal oxygenation and ventilation, abolishing snoring, eliminating disruption of sleep due to upper airway closure, and avoiding factors that tend to aggravate the condition such as alcohol, sedatives, and hypnotic agents. The most important advance in medical treatment has been positive airway pressure delivered through a face mask during sleep.

When mild pulmonary hypertension is associated with sleep apnea, the treatments directed towards the sleep apnea are often effective in reducing pulmonary arterial pressure. Some patients, however, will present with severe pulmonary hypertension in conjunction with sleep apnea, which may or may not be related. In these cases it is recommended that the patients be treated for sleep apnea for a minimum of 3 months before treating the pulmonary arterial hypertension as a separate entity.

ALVEOLAR HYPOVENTILATION Pulmonary hypertension can occur in patients with chronic hypoventilation and hypoxia secondary to thoracovertebral deformities. Symptoms are slowly progressive and related to hypoxemia (Chap. 246). In patients with advanced disease, intermittent positive-pressure breathing and supplemental oxygen have been used successfully.

Pulmonary hypertension secondary to hypoxemia has been reported in patients with neuromuscular disease as a result of generalized weakness of the respiratory muscles and in patients with diaphragmatic paralysis. Diaphragmatic paralysis is generally a result of trauma to the phrenic nerve. Patients with nontraumatic bilateral diaphragmatic paralysis may go unrecognized until they present with either respiratory failure or pulmonary hypertension.

PULMONARY HYPERTENSION DUE TO THROMBOEMBOLIC DISEASE

ACUTE PULMONARY THROMBOEMBOLISM See Chap. 244

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION Patients appropriately treated for acute pulmonary thromboembolism with intravenous heparin and chronic oral warfarin therapy rarely develop chronic pulmonary hypertension. However, there is a subset of patients with impaired fibrinolytic resolution of the thromboembolism, which leads to organization and incomplete recanalization and chronic obstruction of the pulmonary vascular bed. The entity of chronic thromboembolic pulmonary hypertension has been well characterized and often mimics PPH. In many patients, the initial pulmonary thromboembolism was undetected or untreated.

Diagnosis The physical examination is typical of pulmonary hypertension but may include bruits heard over areas of the lung, representing blood flow through vessels with partial occlusion. A perfusion lung scan or contrast-enhanced spiral computed tomography scan usually reveals underlying thromboemboli. However, pulmonary angiography is necessary to determine the precise location and proximal extent of the thromboemboli, and hence the potential for operability.

TREATMENT

Pulmonary thromboendarterectomy is an established surgical treatment in patients whose thrombi are accessible to surgical removal. The operative mortality is fairly high, at ~12% in experienced centers. Postoperative survivors who have a good result can expect to realize an improvement in functional class and exercise tolerance. Life-long anticoagulation using warfarin is mandatory. Thrombolytic therapy is rarely of help in patients with chronic thromboembolic pulmonary hypertension and may expose these patients to the increased risk of bleeding without potential benefit. Patients who are not surgical candidates have a poor outcome.

SICKLE CELL DISEASE Cardiovascular system abnormalities are prominent in the clinical spectrum of sickle cell disease, and pulmonary hypertension has been reported to occur in 20% of patients (Chap. 91). The pulmonary hypertension can usually be attributed to LV diastolic dysfunction. Although patients with sickle cell disease have an increased risk of thromboembolism, sickle cell disease rarely produces pulmonary arterial hypertension.

OTHER DISORDERS DIRECTLY AFFECTING PULMONARY VASCULATURE

SARCOIDOSIS Sarcoidosis can produce severe pulmonary hypertension as a result of chronic severe fibrocystic lung involvement (Chap. 309). In addition, direct cardiovascular involvement can coexist. Consequently, patients with sarcoidosis who present with progressive dyspnea and clinical features of pulmonary hypertension need a thorough evaluation. There is a subset of patients with sarcoidosis who present with severe pulmonary hypertension believed to be due to direct pulmonary vascular involvement. Many of these patients exhibit a favorable response to intravenous epoprostenol therapy.

SCHISTOSOMIASIS Although extremely rare in North America, schistosomiasis is the most common cause of pulmonary hypertension worldwide (Chap. 203). The development of pulmonary hypertension almost always occurs in the setting of hepatosplenic disease and portal hypertension. Schistosome ova can embolize from the liver to the lungs, where they result in an inflammatory pulmonary vascular re-

action and chronic changes. The diagnosis is confirmed by finding the parasite ova in the urine or stools of patients with symptoms, which can be difficult. The efficacy of therapies directed towards pulmonary hypertension in these patients is unknown.

221 CARDIOMYOPATHY AND MYOCARDITIS

Joshua Wynne, Eugene Braunwald

The cardiomyopathies are a group of diseases that affect the heart muscle itself and are not the result of hypertension or congenital or acquired valvular, coronary, or pericardial abnormalities. The diffuse myocardial fibrosis that accompanies multiple myocardial scars produced by extensive coronary artery disease can impair left ventricular function and is frequently referred to as *ischemic cardiomyopathy*. This colloquial use of the term should be avoided; the term *cardiomyopathy* should be restricted to a condition *primarily* involving the myocardium. When the cardiomyopathies are classified on an etiologic basis, two fundamental forms are recognized: (1) a primary type, consisting of heart muscle disease of unknown cause; and (2) a secondary type, consisting of myocardial disease of known cause or associated with a disease involving other organ systems (Table 221-1). (In the World Health Organization classification, the term *specific cardiomyopathy* is used to describe heart muscle diseases associated with certain systemic or cardiac disorders; examples include hypertensive and metabolic cardiomyopathy.) In many cases, however, it is not possible to arrive at a specific etiologic diagnosis, and thus it is often more desirable to classify the cardiomyopathies into one of three types (dilated, restrictive, hypertrophic) on the basis of differences in their pathophysiology and clinical presentation (Fig. 221-1; Tables 221-2 and 221-3).

TABLE 221-1 *Etiologic Classification of Cardiomyopathies*

PRIMARY MYOCARDIAL INVOLVEMENT
Idiopathic (D,R,H)
Familial (D,R,H)
Eosinophilic endomyocardial disease (R)
Endomyocardial fibrosis (R)
SECONDARY MYOCARDIAL INVOLVEMENT
Infective (D)
Viral myocarditis
Bacterial myocarditis
Fungal myocarditis
Protozoal myocarditis
Metazoal myocarditis
Spirochetal
Rickettsial
Metabolic (D)
Familial storage disease (D,R)
Glycogen storage disease
Mucopolysaccharidoses
Hemochromatosis
Fabry's disease
Deficiency (D)
Electrolytes
Nutritional
Connective tissue disorders (D)
Systemic lupus erythematosus
Polyarteritis nodosa
Rheumatoid arthritis
Progressive systemic sclerosis
Dermatomyositis
Infiltrations and granulomas (R,D)
Amyloidosis
Sarcoidosis
Malignancy
Neuromuscular (D)
Muscular dystrophy
Myotonic dystrophy
Friedreich's ataxia (H,D)
Sensitivity and toxic reactions (D)
Alcohol
Radiation
Drugs
Peripartum heart disease (D)

Note: The principal clinical manifestation(s) of each etiologic grouping is denoted by D (dilated), R (restrictive), or H (hypertrophic) cardiomyopathy.

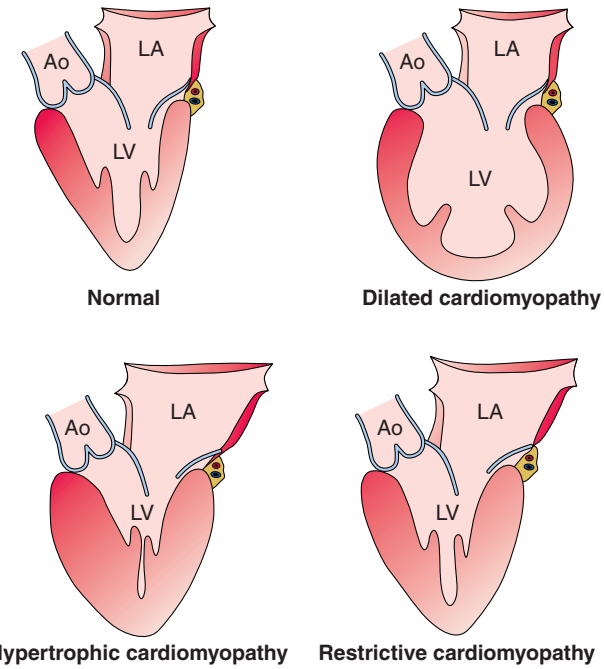

FIGURE 221-1 Drawing comparing the three broad classes of cardiomyopathies. Ao, aorta; LA, left atrium; LV, left ventricle. *(From BF Waller: J Am Soc Echocardiogr 1:4, 1988.)*

DILATED CARDIOMYOPATHY

About one in three cases of congestive heart failure (CHF) is due to dilated cardiomyopathy, with the remainder the consequence of coronary artery disease. Left and/or right ventricular systolic pump function is impaired, leading to progressive cardiac enlargement and hypertrophy, a process called *remodeling*. Symptoms of CHF typically appear only after remodeling has been ongoing for some time (months or even years). There is, however, no close correlation between the degree of contractile dysfunction and the severity of symptoms.

Although no cause is apparent in many cases, dilated cardiomyopathy is probably the end result of myocardial damage produced by

TABLE 221-2 *Clinical Classification of Cardiomyopathies*

1. Dilated: Left and/or right ventricular enlargement, impaired systolic function, congestive heart failure, arrhythmias, emboli
2. Restrictive: Endomyocardial scarring or myocardial infiltration resulting in restriction to left and/or right ventricular filling
3. Hypertrophic: Disproportionate left ventricular hypertrophy, typically involving septum more than free wall, with or without an intraventricular systolic pressure gradient; usually of a nondilated left ventricular cavity

a variety of toxic, metabolic, or infectious agents. Dilated cardiomyopathy may be the late sequel of acute viral myocarditis, possibly mediated through an immunologic mechanism. Although it may occur in any patient population, it is most commonly a disease of middle-aged men and is more common in African Americans than in whites. The prevalence of this condition is increasing. A reversible form of dilated cardiomyopathy may be found with alcohol abuse, pregnancy, thyroid disease, cocaine use, and chronic uncontrolled tachycardia. Obesity increases the risk of developing heart failure, as does sleep apnea. At least 20% (and perhaps as many as 40%) of patients have familial forms of the disease, with mutations of genes encoding cytoskeletal (such as the dystrophin and desmin genes), contractile, nuclear membrane (such as the lamin A/C gene), and other proteins. The disease is genetically heterogeneous but most commonly autosomal dominant in transmission; autosomal recessive, mitochondrial (especially in children), and X-linked inheritance is found as well.

TABLE 221-3 *Laboratory Evaluation of the Cardiomyopathies*

	Dilated	*Restrictive*	*Hypertrophic*
Chest roentgenogram	Moderate to marked cardiac silhouette enlargement Pulmonary venous hypertension	Mild cardiac silhouette enlargement	Mild to moderate cardiac silhouette enlargement
Electrocardiogram	ST-segment and T-wave abnormalities	Low voltage, conduction defects	ST-segment and T-wave abnormalities Left ventricular hypertrophy Abnormal Q waves
Echocardiogram	Left ventricular dilatation and dysfunction	Increased left ventricular wall thickness Normal or mildly reduced systolic function	Asymmetric septal hypertrophy (ASH) Systolic anterior motion (SAM) of the mitral valve
Radionuclide studies	Left ventricular dilatation and dysfunction (RVG)	Normal or mildly reduced systolic function (RVG)	Vigorous systolic function (RVG) Perfusion defect (^{201}Tl)
Cardiac catheterization	Left ventricular dilatation and dysfunction Elevated left- and often right-sided filling pressures Diminished cardiac output	Normal or mildly reduced systolic function Elevated left- and right-sided filling pressures	Vigorous systolic function Dynamic left ventricular outflow obstruction Elevated left- and right-sided filling pressures

Note: RVG, radionuclide ventriculogram; ^{201}Tl, thallium 201.

Right ventricular dysplasia is a unique familial cardiomyopathy marked by progressive replacement of the right ventricular wall with adipose tissue. Often associated with ventricular arrhythmias, the clinical course is variable, but sudden death is a constant threat. Catheter ablation of arrhythmia sites and insertion of an implantable cardioverter-defibrillator are often employed.

CLINICAL MANIFESTATIONS Symptoms of left- and right-sided congestive failure develop gradually in most patients (Chap. 216). Some patients have left ventricular dilatation for months or even years before becoming symptomatic. Although vague chest pain may be present, typical angina pectoris is unusual and suggests the presence of concomitant ischemic heart disease. Syncope due to arrhythmias and systemic embolism (often emanating from a ventricular thrombus) may occur.

PHYSICAL EXAMINATION Variable degrees of cardiac enlargement and findings of CHF are noted. In patients with advanced disease, the pulse pressure is narrow and the jugular venous pressure is elevated. Third and fourth heart sounds are common, and mitral or tricuspid regurgitation may occur.

LABORATORY EXAMINATIONS The chest roentgenogram demonstrates enlargement of the cardiac silhouette due to left ventricular dilatation, although generalized cardiomegaly is often seen. The lung fields may demonstrate evidence of pulmonary venous hypertension and interstitial or alveolar edema. The electrocardiogram often shows sinus tachycardia or atrial fibrillation, ventricular arrhythmias, left atrial abnormality, diffuse nonspecific ST-T-wave abnormalities, and sometimes intraventricular conduction defects and low voltage. Echocardiography and radionuclide ventriculography show left ventricular dilatation, with normal, minimally thickened, or thinned walls, and systolic dysfunction (reduced ejection fraction). The detection of elevated circulating levels of brain natriuretic peptide (Chaps. 32 and 216) may help clarify which patients with dyspnea of uncertain etiology actually have heart failure rather than pulmonary disease as the cause of their symptoms, and indentifies patients at increased risk of sudden death.

Cardiac catheterization and coronary angiography are often performed to exclude ischemic heart disease, and bedside hemodynamic monitoring may be helpful in the management of the acutely decompensated patient. Angiography reveals a dilated, diffusely hypokinetic left ventricle, often with some degree of mitral regurgitation. Transvenous endomyocardial biopsy is usually not necessary in idiopathic or familial dilated cardiomyopathy. However, it may be helpful in the recognition of secondary cardiomyopathies, such as amyloidosis and acute myocarditis.

TREATMENT

Most patients pursue an inexorably downhill course, and the majority, particularly those >55 years, die within 3 years of the onset of symptoms. African Americans are more likely to suffer progressive heart failure and death than Caucasians. Spontaneous improvement or stabilization occurs in about a quarter of patients. Death is due to either CHF or ventricular tachy- or bradyarrhythmia; sudden death is a constant threat. Systemic embolization is a concern, and patients should be considered for chronic anticoagulation. Standard therapy of heart failure with salt restriction, angiotensin-converting enzyme (ACE) inhibitors, diuretics, and digitalis produces symptomatic improvement (Chap. 216). An angiotensin II receptor blocker may be substituted in ACE-intolerant patients. Most patients should be treated with a β-adrenergic blocker. Spironolactone should be added for most patients with recent or current advanced heart failure. Some patients with dilated cardiomyopathy who have biopsy evidence of myocardial inflammation have been treated with immunosuppressive therapy, but long-term evidence of efficacy is lacking. Alcohol should be avoided because of its cardiac toxic effects, as should calcium channel blockers and nonsteroidal anti-inflammatory drugs. Antiarrhythmic agents are best avoided for fear of proarrhythmia, unless they are needed to treat symptomatic or serious arrhythmias. For the one in three patients with an intraventricular conduction delay (such as right or left bundle branch block), biventricular pacing (termed *resynchronization therapy*) improves symptoms, reduces hospitalizations, and perhaps reduces mortality. Insertion of an implantable cardioverter-defibrillator is useful in patients with symptomatic ventricular arrhythmias, and its use in other patients is evolving. In patients with advanced disease who are refractory to medical therapy, cardiac transplantation should be considered (Chap. 217).

ALCOHOLIC CARDIOMYOPATHY Individuals who consume large quantities of alcohol over many years may develop a clinical picture identical to idiopathic dilated cardiomyopathy. The risk of developing cardiomyopathy is partially genetically determined. Reducing or ceasing alcohol consumption before severe heart failure has developed may halt the progression or even reverse the course of this disease. Alcoholic pa-

tients with advanced heart failure have a poor prognosis, particularly if they continue to drink; fewer than one-quarter survive 3 years.

A second presentation of alcoholic cardiotoxicity may be found in individuals without overt heart failure and consists of recurrent supraventricular or ventricular tachyarrhythmias. Termed the *holiday heart syndrome*, it typically appears after a drinking binge; atrial fibrillation is seen most frequently, followed by atrial flutter and ventricular premature depolarizations.

PERIPARTUM CARDIOMYOPATHY (See also Chap. 6) Cardiac dilatation and CHF of unexplained cause may develop during the last trimester of pregnancy or within 6 months after delivery; most women develop symptoms in the month before or immediately after delivery. The patient who develops peripartum cardiomyopathy typically is multiparous, African American, and over the age of 30, although the disease may be found in a wide spectrum of patients. The symptoms, signs, and treatment are similar to those in patients with idiopathic dilated cardiomyopathy. The mortality rate is around 10 to 20%. The prognosis in these patients appears to be related to whether the heart size returns to normal after the first episode of CHF. If it does, subsequent pregnancies may sometimes be tolerated, albeit with an increased risk of recurrent heart failure; if the heart remains enlarged, however, further pregnancies frequently produce additional myocardial damage, ultimately leading to refractory CHF and death. Those who recover should be encouraged to avoid further pregnancies, particularly if cardiomegaly persists.

NEUROMUSCULAR DISEASE (See also Chap. 367) Cardiac involvement is common in many of the muscular dystrophies. In *Duchenne's progressive muscular dystrophy*, mutations in a gene that encodes a cardiac structural protein (*dystrophin*) lead to myocyte death. Myocardial involvement is most frequently indicated by a distinctive and unique electrocardiographic pattern consisting of tall R waves in right precordial leads with an R/S ratio >1.0, often associated with deep Q waves in the limb and lateral precordial leads. A variety of supraventricular and ventricular arrhythmias are frequently found. Rapidly progressive CHF may develop despite extended periods of apparent circulatory stability during which the only detectable abnormalities are in the electrocardiogram. *Myotonic dystrophy* is characterized by a variety of electrocardiographic abnormalities, especially disorders of impulse formation and conduction, but other overt clinical evidence of heart disease is uncommon. Because of these abnormalities, syncope and sudden death are major hazards; in appropriate patients, insertion of a permanent pacemaker may be effective. Involvement of the heart is very common in *Friedreich's ataxia* (manifested by abnormal electrocardiographic or echocardiographic findings), with as many as half the patients developing cardiac symptoms. The electrocardiogram most commonly demonstrates ST-segment and T-wave abnormalities. The echocardiogram may demonstrate left ventricular hypertrophy, with either symmetric or asymmetric hypertrophy of the left ventricular septum compared with the free wall. Although morphologically similar to some cases of hypertrophic cardiomyopathy, cellular disarray is lacking.

DRUGS A variety of pharmacologic agents may damage the myocardium acutely, producing a pattern of inflammation (myocarditis), or they may lead to chronic damage of the type seen with idiopathic dilated cardiomyopathy. Certain drugs produce only electrocardiographic abnormalities, while others may precipitate fulminant CHF and death.

The anthracycline derivatives, particularly doxorubicin (Adriamycin), are powerful antineoplastic agents that, when given in high doses (>550 mg/m^2 for doxorubicin), may produce fatal heart failure. The incidence of heart failure is related not only to the dose of the drug but also to the presence or absence of several risk factors (cardiac irradiation, age >70 years, underlying heart disease, hypertension, treatment with cyclophosphamide); at any dose of doxorubicin, patients with these risk factors have an eight- to tenfold greater frequency of developing heart failure than do patients lacking them. Radionuclide ventriculography and echocardiography, usually combined with exercise stress, may document preclinical deterioration of left ventricular function and allow appropriate dose adjustments. By monitoring left ventricular function, it is often possible to continue doxorubicin even in patients at high risk for developing heart failure. Efforts to modify the dose schedule by giving the drug more slowly, along with the selective use of potentially cardioprotective agents such as the iron-chelator dexrazoxone, have further reduced the risk of cardiotoxicity. Some patients with CHF, even those with severe depression of left ventricular function, have demonstrated recovery of cardiac function with aggressive management with ACE inhibitors and diuretics. In others, late asymptomatic contractile dysfunction may occur, even in those without initial cardiotoxicity.

High-dose *cyclophosphamide* may produce CHF acutely or within 2 weeks of administration; a characteristic histopathologic feature is myocardial edema and hemorrhagic necrosis. Electrocardiographic changes and arrhythmias may result from treatment with tricyclic antidepressants, the phenothiazines, emetine, lithium, and various aerosol propellants. *Cocaine abuse* is associated with a variety of life-threatening cardiac complications, including sudden death, myocarditis, dilated cardiomyopathy, and acute myocardial infarction (resulting from coronary spasm and/or thrombosis with or without underlying coronary artery stenosis). Nitrates, calcium channel blockers, and benzodiazepines have been used to treat cocaine-induced cardiotoxicities; β-adrenergic blockers should be avoided.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by left ventricular hypertrophy, typically of a nondilated chamber, without obvious cause such as hypertension or aortic stenosis. It is found in about 1 in 500 of the general population. Two features of HCM have attracted the greatest attention: (1) asymmetric left ventricular hypertrophy, often with preferential hypertrophy of the interventricular septum; and (2) a dynamic left ventricular outflow tract pressure gradient, related to a narrowing of the subaortic area as a consequence of the midsystolic apposition of the anterior mitral valve leaflet against the hypertrophied septum, i.e., systolic anterior motion (SAM) of the mitral valve. Initial studies of this disease emphasized the dynamic "obstructive" features, and it has been termed *idiopathic hypertrophic subaortic stenosis* and *hypertrophic obstructive cardiomyopathy*. It has become clear, however, that only about one-quarter of patients with HCM demonstrate an outflow tract pressure gradient. The ubiquitous pathophysiologic abnormality is not systolic but rather *diastolic* dysfunction (Chap. 215), characterized by increased stiffness of the hypertrophied muscle. This results in elevated diastolic filling pressures and is present despite a hyperdynamic left ventricle.

The pattern of hypertrophy is distinctive in HCM and differs from that seen in secondary hypertrophy (as in hypertension). Most patients have striking regional variations in the extent of hypertrophy in different portions of the left ventricle, and the majority demonstrate a ventricular septum whose thickness is disproportionately increased when compared with the free wall. Other patients may demonstrate disproportionate involvement of the apex or left ventricular free wall; 10% or more of patients have concentric involvement of the ventricle. A bizarre and disorganized arrangement of cardiac muscle cells in the septum occurs, with disorganization of the myofibrillar architecture, along with a variable degree of myocardial fibrosis and thickening of the small intramural coronary arteries. In some children, systolic compression of an intramyocardial segment of a coronary artery may lead to ischemia and death.

GENETIC CONSIDERATIONS About half of all patients with HCM have a positive family history compatible with autosomal-dominant transmission. More than 150 different mutations of 10 different genes that encode sarcomeric proteins have been identified. About 40% of these are associated with mutations of the cardiac β-myosin heavy chain gene on chromosome 14, with certain mutations associ-

ated with more malignant prognoses. About 15% have a mutation of the cardiac troponin T gene on chromosome 1, 20% a mutation of myosin-binding protein C (chromosome 11), and ~5% a mutation of the α-tropomyosin gene. The remainder of familial cases are due to mutations of other genes such as the gene for troponin I. Echocardiographic studies have confirmed that about one-third of the first-degree relatives of patients with familial HCM have evidence of the disease, although in many of these patients the extent of hypertrophy is mild, no outflow tract pressure gradient is present, and symptoms are not prominent. Since the hypertrophic characteristics may not be apparent in childhood and often appear first in adolescence, a single normal echocardiogram in a child does not exclude the presence of the disease. Many sporadic cases of HCM probably represent spontaneous mutations.

CLINICAL FEATURES The clinical course of HCM is highly variable. Many patients are asymptomatic or mildly symptomatic and may be relatives of patients with known disease. Unfortunately, the first clinical manifestation of the disease may be sudden death, frequently occurring in children and young adults, often during or after physical exertion. In symptomatic patients, the most common complaint is dyspnea, largely due to increased stiffness of the left ventricular walls, which impairs ventricular filling and leads to elevated left ventricular diastolic and left atrial pressures. Other symptoms include angina pectoris, fatigue, and syncope. Symptoms are not closely related to the presence or severity of an outflow pressure gradient. Most patients with gradients demonstrate a double or triple apical precordial impulse, a rapidly rising carotid arterial pulse, and a fourth heart sound. The hallmark of obstructive HCM is a systolic murmur, which is typically harsh, diamond-shaped, and usually begins well after the first heart sound, since ejection is unimpeded early in systole. The murmur is best heard at the lower left sternal border as well as at the apex, where it is often more holosystolic and blowing in quality, no doubt due to the mitral regurgitation that usually accompanies obstructive HCM.

HEMODYNAMICS In contrast to the obstruction produced by a fixed narrowed orifice, such as valvular aortic stenosis, the pressure gradient in HCM, when present, is dynamic and may change between examinations and even from beat to beat. Obstruction appears to result from further narrowing of an already small left ventricular outflow tract by SAM of the mitral valve against the hypertrophied septum. While SAM is occasionally found in a variety of conditions besides HCM, it is *always* found when obstruction is present in HCM. Three basic mechanisms are involved in the production and intensification of the dynamic pressure gradient: (1) increased left ventricular contractility, (2) decreased ventricular volume (preload), and (3) decreased aortic impedance and pressure (afterload). Interventions that increase myocardial contractility, such as exercise, sympathomimetic amines, and digitalis glycosides, and those that reduce ventricular volume, such as the Valsalva maneuver, sudden standing, nitroglycerin, amyl nitrite, or tachycardia, may all cause an increase in the gradient and the murmur. Conversely, elevation of arterial pressure by phenylephrine, squatting, sustained handgrip, augmentation of venous return by passive leg raising, and expansion of the blood volume all increase ventricular volume and ameliorate the gradient and murmur.

LABORATORY EVALUATION The *electrocardiogram* commonly shows left ventricular hypertrophy and widespread, deep, broad Q waves that suggest an old myocardial infarction. Many patients demonstrate arrhythmias, both atrial (supraventricular tachycardia or atrial fibrillation) and ventricular (ventricular tachycardia), during ambulatory (Holter) monitoring. *Chest roentgenography* may be normal, although a mild to moderate increase in the cardiac silhouette is common. The mainstay of the diagnosis of HCM is the *echocardiogram*, which demonstrates left ventricular hypertrophy, often with the septum 1.3 or more times the thickness of the high posterior left ventricular free wall. The septum may demonstrate an unusual "ground-glass" appearance, probably related to its abnormal cellular architecture and myocardial fibrosis. SAM of the mitral valve is found in patients with pressure gradients. The left ventricular cavity typically is small in HCM, with vigorous posterior wall motion but reduced septal excursion. A rare form of HCM, characterized by apical hypertrophy, is often associated with giant negative T waves on the electrocardiogram and a "spade-shaped" left ventricular cavity on angiography; it usually has a benign clinical course. *Radionuclide scintigraphy* with thallium 201 frequently reveals evidence of myocardial perfusion defects even in asymptomatic patients.

Although cardiac catheterization is not required to diagnose HCM, the two typical *hemodynamic* features are an elevated left ventricular diastolic pressure due to diminished left ventricular compliance and, when obstruction is present, a systolic pressure gradient between the body of the left ventricle and the subaortic region. When a gradient is not present, it can be induced in some patients by provocative maneuvers such as infusion of isoproterenol, inhalation of amyl nitrite, or the Valsalva maneuver.

Rx TREATMENT

Since sudden death often occurs during or just after physical exertion, competitive sports and probably strenuous activity should be proscribed. Dehydration should be avoided, and diuretics should be used with caution. β-Adrenergic blockers are often used and ameliorate angina pectoris and syncope in one-third to one-half of patients. Resting intraventricular pressure gradients are usually unchanged, although these drugs may limit the increase in the gradient that occurs during exercise. It does not appear that β-adrenergic blockers offer any protection against sudden death. Amiodarone appears to be effective in reducing the frequency of supraventricular as well as life-threatening ventricular arrhythmias, and anecdotal data suggest that it may reduce the risk of sudden death. Verapamil and diltiazem may reduce the stiffness of the ventricle, reduce the elevated diastolic pressures, increase exercise tolerance, and, in some instances, reduce the severity of outflow tract pressure gradients, although adverse side effects occur in about one-quarter of patients. Nifedipine should be avoided. Disopyramide has been used in some patients to reduce left ventricular contractility and the outflow pressure gradient.

If atrial fibrillation occurs, a strenuous effort should be made to restore and then maintain sinus rhythm. Dual-chamber permanent pacing with a short PR interval has been reported to improve symptoms and reduce the outflow gradient in some patients with severe symptoms, presumably by altering the pattern of ventricular depolarization and contraction, although much of the putative benefit has been attributed to a placebo effect. Infarction of the interventricular septum induced by ethanol injections into the septal artery has also been reported to reduce obstruction. A surgical myotomy/myectomy of the hypertrophied septum may result in lasting symptomatic improvement in about three-quarters of severely symptomatic patients with large pressure gradients who are unresponsive to medical management. Digitalis, diuretics, nitrates, vasodilators, and β-adrenergic agonists are best avoided if possible, particularly in patients with known left ventricular outflow tract pressure gradients. Even social alcohol ingestion may produce sufficient vasodilatation to exacerbate an outflow pressure gradient. First-degree relatives of patients with HCM should be screened by echocardiography. The insertion of an implantable cardioverter defibrillator should be considered in patients (Chap. 214) with a high-risk profile for sudden cardiac death (see below).

PROGNOSIS The natural history of HCM is variable, although many patients never exhibit any clinical manifestations. Atrial fibrillation is common late in the course of the disease; its onset often leads to an increase in symptoms in two out of three patients, due to loss of the atrial contribution to filling of the thickened ventricle. Infective endocarditis occurs in $<10\%$ of patients, but endocarditis prophylaxis is indicated, particularly in patients with resting obstruction and mitral regurgitation. Progression of HCM to left ventricular dilatation and dysfunction with wall thinning without an outflow pressure gradient

occurs in about 5 to 10% of patients. The major cause of mortality in HCM is sudden death, which may occur in asymptomatic patients or interrupt an otherwise stable course in symptomatic ones. The annual risk of dying from HCM is about 1% per year, similar to the normal adult population. Patients at higher risk of sudden death include those with a history of resuscitation from sudden cardiac death, ventricular tachycardia on ambulatory monitoring or at electrophysiologic testing, marked ventricular hypertrophy, (ventricular septal thickness >30 mm), syncope (especially in children), genetic mutations associated with an increased risk, an abnormal blood pressure response to exercise, and a family history of sudden death. There is no correlation between the risk of sudden death and the severity of symptoms, but there is an increased risk of death in patients with outflow gradients.

RESTRICTIVE CARDIOMYOPATHY

The hallmark of the restrictive cardiomyopathies is abnormal diastolic function (Chap. 215); the ventricular walls are excessively rigid and impede ventricular filling. Myocardial fibrosis, hypertrophy, or infiltration due to a variety of causes is usually responsible. The infiltrative diseases, which represent important causes for secondary restrictive cardiomyopathy, may also show some impairment of systolic function. Myocardial involvement with *amyloid* is a common cause of secondary restrictive cardiomyopathy, although restriction is also seen in hemochromatosis, glycogen deposition, endomyocardial fibrosis, sarcoidosis, Fabry's disease, the eosinophilias, and scleroderma; in the transplanted heart and following mediastinal irradiation; and in neoplastic infiltration and myocardial fibrosis of diverse causes. In many of these conditions, particularly those with substantial concomitant endocardial involvement, partial obliteration of the ventricular cavity by fibrous tissue and thrombus contributes to the abnormally increased resistance to ventricular filling. Thromboembolic complications ensue in about a third of patients.

The inability of the ventricle to fill limits cardiac output and raises filling pressure. Therefore, exercise intolerance and dyspnea are usually the most prominent symptoms. As a result of persistently elevated venous pressure, these patients commonly have dependent edema, ascites, and an enlarged, tender, and often pulsatile liver. The jugular venous pressure is elevated and does not fall normally, or it may rise with inspiration (Kussmaul's sign). The heart sounds may be distant, and third and fourth heart sounds are common. In contrast to constrictive pericarditis, which the restrictive cardiomyopathies resemble in many respects, the apex impulse is usually easily palpable, and mitral regurgitation is more common. The electrocardiogram often shows low-voltage, nonspecific ST-T-wave changes and various arrhythmias. Pericardial calcification on x-ray, which occurs in constrictive pericarditis, is absent. Echocardiography typically reveals symmetrically thickened left ventricular walls and normal or slightly reduced ventricular volumes and systolic function. Cardiac catheterization shows a decreased cardiac output, elevation of the right and left ventricular end-diastolic pressures, and a dip-and-plateau configuration of the diastolic portion of the ventricular pressure pulse resembling that seen in constrictive pericarditis.

Differentiation from constrictive pericarditis may be challenging (Chap. 222). This distinction is of importance because the latter condition is potentially curable by operation. Helpful in the differentiation of these two diseases are right ventricular transvenous endomyocardial biopsy (by revealing myocardial infiltration or fibrosis in restrictive cardiomyopathy) and computed tomography or magnetic resonance imaging (by demonstrating a thickened pericardium in constrictive pericarditis). Treatment is usually disappointing, except for hemochromatosis (where deferoxamine has been helpful in reducing myocardial iron content), and Fabry's disease (where infusion of galactose stimulates the activity of the deficient enzyme with attendant improvement in cardiac function). Chronic anticoagulation is often recommended to reduce the risk of embolization from the heart.

ENDOMYOCARDIAL FIBROSIS This is a progressive disease of unknown cause that occurs most commonly in children and young adults residing in tropical and subtropical Africa, particularly Uganda and Nigeria. Endomyocardial fibrosis is a frequent cause of heart failure in Africa, accounting for up to one-quarter of deaths due to heart disease. The condition is characterized by fibrous endocardial lesions of the inflow portion of the right or left ventricle (or both) and often involves the atrioventricular valves, producing valvular regurgitation. The apex of the ventricles may be obliterated by a mass of thrombus and fibrous tissue. In some ways this disease resembles eosinophilic endomyocardial disease (see below), although they occur in quite different geographic areas and age groups and generally are felt to be different diseases.

The clinical picture depends on which ventricle and atrioventricular valve show predominant involvement; left-sided involvement results in symptoms of pulmonary congestion, while predominant right-sided disease presents features of a restrictive cardiomyopathy. Medical treatment is often disappointing, and surgical excision of the fibrotic endocardium and replacement of the involved atrioventricular valve have led to substantial symptomatic improvement in some patients.

EOSINOPHILIC ENDOMYOCARDIAL DISEASE Also called *Loeffler's endocarditis* and *fibroplastic endocarditis*, this disease appears to be a subcategory of the hypereosinophilic syndrome in which the heart is predominantly involved, with cardiac damage the apparent result of the toxic effects of eosinophilic proteins. Typically, the endocardium of either or both ventricles thickens markedly, with involvement of the underlying myocardium. Large mural thrombi may develop in either ventricle, thereby compromising the size of the ventricular cavity and serving as a source of pulmonary and systemic emboli. Hepatosplenomegaly and localized eosinophilic infiltration of other organs are usually present. Management usually includes diuretics, afterload-reducing agents, and anticoagulation. The use of glucocorticoids and cytotoxic drugs (hydroxyurea in particular) appears to have improved survival substantially. Surgical treatment, as for endomyocardial fibrosis, may be helpful in selected patients.

DIFFERENTIAL DIAGNOSIS Involvement of the heart is the most frequent cause of death in *primary amyloidosis* (Chap. 310), while clinically significant cardiac involvement is uncommon in the secondary form. Focal deposits of amyloid in elderly patients (*senile cardiac amyloidosis*) are common and usually clinically insignificant. Aspiration of abdominal fat or biopsy of the myocardium or other organs permits the diagnosis to be made before death in over three-quarters of cases. The heart is firm, rubbery, and noncompliant, and four clinical presentations (alone or in combination) are seen: (1) diastolic dysfunction (restrictive cardiomyopathy), (2) systolic dysfunction, (3) arrhythmias and conduction disturbances, and (4) orthostatic hypotension. The two-dimensional echocardiogram may be helpful in making the diagnosis of amyloidosis and may show a thickened myocardial wall with a distinctive "speckled" appearance. Chemotherapy, often with alkylating agents, appears to have improved survival in specific cases, and heart transplantion (often combined with bone marrow transplantation, or liver or kidney transplantation for hereditary amyloidosis) may help selected patients, but the overall prognosis is poor, especially in the primary form with advanced cardiac involvement.

Hemochromatosis (Chap. 336) is often the result of multiple transfusions or a hemoglobinopathy; the familial (autosomal recessive) form should be suspected if cardiomyopathy occurs in the setting of diabetes mellitus, hepatic cirrhosis, and increased skin pigmentation. The diagnosis may be confirmed by endomyocardial biopsy. Phlebotomy may be of some benefit if employed early in the course of the disease. Continuous subcutaneous administration of deferoxamine may reduce body iron stores and result in clinical improvement.

Myocardial *sarcoidosis* (Chap. 309) is generally associated with other manifestations of systemic disease and may cause restrictive as well as congestive features, since cardiac infiltration by sarcoid granulomas results not only in increased stiffness of the myocardium but also in diminished systolic contractile function. A variety of arrhyth-

mias, including high-grade atrioventricular block, have been noted. A common cardiac manifestation of systemic sarcoidosis is right heart overload due to pulmonary artery hypertension as a result of parenchymal pulmonary involvement. Many patients are treated empirically with glucocorticoids. The *carcinoid syndrome* results in endocardial fibrosis and stenosis and/or regurgitation of the tricuspid and/or pulmonary valve (Chap. 219); morphologically similar lesions have been seen with the use of the anorexic agents fenfluramine and phentermine.

MYOCARDITIS

Myocarditis, i.e., cardiac inflammation, is most commonly the result of an infectious process. Myocarditis may also result from a hypersensitivity to drugs or may be caused by radiation, chemicals, or physical agents. In an unknown number of cases, acute myocarditis progresses to chronic dilated cardiomyopathy. While almost every infectious agent is capable of producing myocarditis (Table 221-1), clinically significant acute myocarditis in the United States is caused most commonly by viruses, especially coxsackievirus B. The clinical manifestations range from an asymptomatic state, with the presence of myocarditis inferred only by the finding of transient electrocardiographic ST-T-wave abnormalities, to a fulminant condition with arrhythmias, heart failure, and death. In some patients, myocarditis simulates acute myocardial infarction, with chest pain, electrocardiographic changes, and elevated serum levels of myocardial enzymes. Patients with myocarditis and pulmonary hypertension are at a particularly high risk of death.

The physical examination is often normal, although more severe cases may show a muffled first heart sound, along with a third heart sound and a murmur of mitral regurgitation. A pericardial friction rub may be audible in patients with associated pericarditis.

Though viral myocarditis is most often self-limited and without sequelae, severe involvement may recur, and it is likely that acute viral myocarditis occasionally progresses to a chronic form and to dilated cardiomyopathy. Patients with viral myocarditis often give a history of a preceding upper respiratory febrile illness or a flulike syndrome, and viral nasopharyngitis or tonsillitis may be evident clinically. The isolation of virus from the stool, pharyngeal washings, or other body fluids and changes in specific antibody titers are helpful clinically. Endomyocardial biopsy, carried out early in the illness, may show round-cell infiltration and necrosis of adjacent myocytes.

Exercise may be deleterious in patients with viral myocarditis, and strenuous activity should be proscribed until the electrocardiogram has returned to normal. Patients who develop CHF respond to the usual measures (ACE inhibitors, diuretics, and salt restriction), but they appear to be unusually sensitive to digitalis. Arrhythmias are common and are occasionally difficult to manage. Deaths attributed to heart failure, tachyarrhythmias, and heart block have been reported, and it seems prudent to monitor the electrocardiogram of patients with arrhythmias, especially during the acute illness. Patients with fulminant myocarditis may require mechanical cardiopulmonary support or cardiac transplantation, but the majority survive and many demonstrate substantial recovery of ventricular function.

HIV MYOCARDITIS (See also Chap. 173) Many HIV-infected patients have subclinical cardiac involvement, including pericardial effusion, right-sided chamber enlargement, and neoplastic involvement. Overt clinical involvement is seen in 10% of HIV patients, and the most common finding is left ventricular dysfunction that in some cases appears to be due to infiltration of the myocardium by the virus itself. In other patients, the heart is affected by any of the various opportunistic infections common in AIDS, such as toxoplasmosis, as well as by cardiac metastases in Kaposi's sarcoma. The clinical manifestations of cardiac involvement may be incorrectly attributed to concurrent noncardiac problems such as pneumonia. This is unfortunate, since the dilated cardiomyopathy of HIV infection may respond at least transiently to standard therapy with digitalis, diuretics, and ACE inhibitors.

BACTERIAL MYOCARDITIS Bacterial involvement of the heart is uncommon, but when it does occur, it is usually as a complication of endocarditis. Myocardial abscess formation may involve the valve rings and interventricular septum. *Diphtheritic myocarditis* develops in over one-quarter of the patients with diphtheria, is one of the most serious complications, and is the most common cause of death (Chap. 122). Cardiac damage is due to the liberation of a toxin that inhibits protein synthesis and leads to a dilated, flabby, hypocontractile heart; the conduction system is frequently involved as well. Cardiomegaly and severe CHF typically appear after the first week of illness. Prompt therapy with antitoxin is crucial; antibiotic therapy is also indicated but is of less urgency.

CHAGAS DISEASE Chagas disease, caused by the protozoan *Trypanosoma cruzi* and transmitted by an insect vector (Chap. 197), produces an extensive myocarditis that typically becomes evident years after the initial infection. It is one of the most common causes of heart disease encountered in Central and South America; in rural endemic areas 20 to 75% of the population may be affected. An increasing number of cases are found in the United States as patients migrate from endemic areas; in rare cases, it has been transmitted by transfusion and organ donation. Although only about 1% of infected individuals have an acute illness, which may include acute myocarditis, upwards of one-third develop chronic myocardial damage many years later. The chronic form is characterized by dilatation of several cardiac chambers, fibrosis and thinning of the ventricular wall, aneurysm formation (especially at the left ventricular apex), and mural thrombi. Chronic progressive heart failure is the rule and is associated with poor survival. The electrocardiogram is abnormal in most patients with cardiac involvement and typically shows right bundle branch block and left anterior hemiblock, which may progress to complete atrioventricular block. The *echocardiogram* may reveal a unique pattern of hypokinesis of the posterior left ventricular wall and relatively preserved septal motion. Ventricular arrhythmias are common and are seen especially during and after exertion; oral amiodarone appears to be particularly effective in treating ventricular tachyarrhythmias. The cause of death is either intractable CHF or an arrhythmia, with a minority of patients dying from embolic phenomena.

Rx TREATMENT

Therapy is directed toward amelioration of the CHF and arrhythmias; progressive conduction system disease and heart block may require implantation of a pacemaker. Anticoagulation (if feasible) may reduce the risk of thromboembolism. Medical therapy is often unsatisfactory or unavailable (especially in poor rural areas), however, and a more promising tactic in endemic areas has been the use of insecticides to eliminate the vector.

GIANT CELL MYOCARDITIS This rare myocarditis of unknown cause is characterized by rapidly fatal CHF and arrhythmia in young to middle-aged adults. At necropsy, the distinctive features include cardiac enlargement, ventricular thrombi, grossly visible serpiginous areas of myocardial necrosis in both ventricles, and microscopic evidence of giant cells within an extensive inflammatory infiltrate. The cause of giant cell myocarditis remains obscure, although it occurs in association with thymoma, systemic lupus erythematosus, and thyrotoxicosis. While treatment with immunosuppressive therapy may help some patients, cardiac transplantation is the treatment of choice.

LYME CARDITIS (See also Chap. 157) Lyme disease is caused by a tick-borne spirochete and is most common in the Northeast, upper Midwest, and Pacific Coastal regions of the United States during the summer months. About 10% of patients develop symptomatic cardiac involvement during the acute phase of the disease. Conduction abnormalities are the most common manifestations of involvement and may lead to syncope. Concomitant myopericarditis is not uncommon, and mild asymptomatic left ventricular dysfunction may occur. Intrave-

nous ceftriaxone or penicillin is used in all but the mildest forms of Lyme carditis, in which case oral amoxicillin or doxycycline is employed. Hospitalization with electrocardiographic monitoring is indicated in patients with second- or third-degree atrioventricular block. A temporary pacemaker may be needed for symptomatic heart block, but permanent pacing is rarely required. The utility of glucocorticoids in reversing heart block is uncertain, but they are often employed. Long-term cardiac manifestations of Lyme disease are uncommon.

222 PERICARDIAL DISEASE

Eugene Braunwald

NORMAL FUNCTIONS OF THE PERICARDIUM The visceral pericardium is a serous membrane that is separated by a small quantity (15 to 50 mL) of fluid, an ultrafiltrate of plasma from a fibrous sac, the parietal pericardium. The pericardium normally prevents sudden dilatation of the cardiac chambers during exercise and with hypervolemia. The pericardium also restricts the anatomic position of the heart, minimizes friction between the heart and surrounding structures, prevents displacement of the heart and kinking of the great vessels, and probably retards the spread of infections from the lungs and pleural cavities to the heart. Notwithstanding the foregoing, total absence of the pericardium does not produce obvious clinical disease. In partial left pericardial defects, the main pulmonary artery and left atrium may bulge through the defect; very rarely, herniation and subsequent strangulation of the left atrium may cause sudden death.

ACUTE PERICARDITIS

Acute pericarditis, by far the most common pathologic process involving the pericardium, may be classified both clinically and etiologically (Table 222-1). Pain, a pericardial friction rub, electrocardiographic changes, and pericardial effusion with cardiac tamponade and paradoxical pulse are cardinal manifestations of many forms of acute pericarditis.

Chest pain is an important but not invariable symptom in various forms of acute pericarditis (Chap. 12); it is usually present in the acute infectious types and in many of the forms presumed to be related to hypersensitivity or autoimmunity. Pain is often absent in a slowly developing tuberculous, postirradiation, neoplastic, or uremic pericarditis. The pain of pericarditis is often severe, retrosternal and left precordial, and referred to the back and the left trapezius ridge. Often the pain is pleuritic consequent to accompanying pleural inflammation, i.e., sharp and aggravated by inspiration, coughing, and changes in body position, but sometimes it is a steady, constricting pain that radiates into either arm or both arms and resembles that of myocardial ischemia; therefore, confusion with acute myocardial infarction (AMI) is common. Characteristically, however, pericardial pain may be relieved by sitting up and leaning forward and is intensified by lying supine. The differentiation of AMI from acute pericarditis becomes perplexing when, with acute pericarditis, serum biomarkers of myocardial damage such as creatine kinase and troponin rise, presumably because of concomitant involvement of the epicardium. However, these elevations, if they occur, are quite modest, given the extensive electrocardiographic ST-segment elevation in pericarditis.

The *pericardial friction rub,* the most important physical sign of acute pericarditis, may have up to three components per cardiac cycle and is high-pitched, scratching, and grating, as described in Chap. 209; it can sometimes be elicited only when firm pressure with the diaphragm of the stethoscope is applied to the chest wall at the left lower sternal border. It is heard most frequently during expiration with the patient in an upright and leaning forward position. The rub is often inconstant, and the loud to-and-fro leathery sound may disappear within a few hours, possibly to reappear the following day.

The *electrocardiogram* (ECG) in acute pericarditis without massive effusion usually displays changes secondary to acute subepicardial inflammation (see Fig. 210-16). There is widespread elevation of the ST segments, often with upward concavity, involving two or three standard limb leads and V_2 to V_6, with reciprocal depressions only in aVR and sometimes V_1. Usually there are no significant changes in QRS complexes, except for some reduction in voltage in patients with large pericardial effusions. After several days, the ST segments return to normal, and only then do the T waves become inverted. In contrast, in AMI, ST elevations are convex, and reciprocal depression is usually more prominent; QRS changes occur, particularly the development of Q waves, as well as notching and loss of R-wave amplitude; and T-wave inversions are usually seen within hours *before* the ST segments have become isoelectric. Sequential ECGs are useful in distinguishing acute pericarditis from AMI. In the latter, elevated ST segments return to normal within hours. Early repolarization is a normal variant and may also cause widespread ST-segment elevation, most prominent in left precordial leads. However, in this condition the T waves are usually tall and the ST/T ratio is <0.25, but this ratio is higher in acute pericarditis. Depression of the PR segment (below the TP segment) is also common and reflects atrial involvement.

PERICARDIAL EFFUSION In acute pericarditis, effusion is usually associated with pain and/or the above-mentioned ECG changes characteristic of pericarditis and an enlargement of the cardiac silhouette. Pericardial effusion is especially important clinically when it develops within a relatively short time, since it may lead to cardiac tamponade (see below). Differentiation from cardiac enlargement may be difficult on physical examination, but heart sounds tend to become faint with pericardial effusion; the friction rub may disappear, and the apex impulse may vanish, but sometimes it remains palpable, albeit medial to the left border of cardiac dullness. The base of the left lung may be compressed by pericardial fluid, producing Ewart's sign, a patch of dullness beneath the angle of the left scapula. The chest roentgenogram may show a "water bottle" configuration of the cardiac silhouette (Fig. 222-1) but may also be normal or almost so. Lucent pericardial fat lines may be seen deep within the cardiopericardial silhouette. Fluoroscopic examination may show the ventricular pulsations to be diminished.

Diagnosis *Echocardiography* (Chap. 211) is the most effective imaging technique available, since it is sensitive, specific, simple, non-

TABLE 222-1 Classification of Pericarditis

CLINICAL CLASSIFICATION

I. Acute pericarditis (<6 weeks)
  A. Fibrinous
  B. Effusive (serous or sanguineous)
II. Subacute pericarditis (6 weeks to 6 months)
  A. Effusive-constrictive
  B. Constrictive
III. Chronic pericarditis (>6 months)
  A. Constrictive
  B. Effusive
  C. Adhesive (nonconstrictive)

ETIOLOGIC CLASSIFICATION

I. Infectious pericarditis
  A. Viral (coxsackievirus A and B, echovirus, mumps, adenovirus, hepatitis, HIV)
  B. Pyogenic (pneumococcus, streptococcus, staphylococcus, *Neisseria, Legionella*)
  C. Tuberculous
  D. Fungal (histoplasmosis, coccidioidomycosis, *Candida,* blastomycosis)
  E. Other infections (syphilitic, protozoal, parasitic)
II. Noninfectious pericarditis
  A. Acute myocardial infarction
  B. Uremia
  C. Neoplasia
    1. Primary tumors (benign or malignant, mesothelioma)
    2. Tumors metastatic to pericardium (lung and breast cancer, lymphoma, leukemia)
  D. Myxedema
  E. Cholesterol
  F. Chylopericardium
  G. Trauma
    1. Penetrating chest wall
    2. Nonpenetrating
  H. Aortic dissection (with leakage into pericardial sac)
  I. Postirradiation
  J. Familial Mediterranean fever
  K. Familial pericarditis
    1. Mulibrey nanism[a]
  L. Acute idiopathic
  M. Whipple's disease
  N. Sarcoidosis
III. Pericarditis presumably related to hypersensitivity or autoimmunity
  A. Rheumatic fever
  B. Collagen vascular disease (SLE, rheumatoid arthritis, ankylosing spondylitis, scleroderma, acute rheumatic fever, Wegener's granulomatosis)
  C. Drug-induced (e.g., procainamide, hydralazine, phenytoin, isoniazide, minoxidil, anticoagulants, methysergide)
  D. Postcardiac injury
    1. Postmyocardial infarction (Dressler's syndrome)
    2. Postpericardiotomy
    3. Posttraumatic

[a] An autosomal recessive syndrome, characterized by growth failure, muscle hypotonia, hepatomegaly, ocular changes, enlarged cerebral ventricles, mental retardation, and chronic constrictive pericarditis.

invasive, may be performed at the bedside, and can identify accompanying cardiac tamponade (see below) (Fig. 222-2). The presence of pericardial fluid is recorded by two-dimensional transthoracic echocardiography as a relatively echo-free space between the posterior pericardium and left ventricular epicardium in patients with small effusions and as a space between the anterior right ventricle and the parietal pericardium just beneath the anterior chest wall in those with larger effusions. In the latter the heart may swing freely within the pericardial sac; when severe, the extent of this motion alternates and may be associated with electrical alternans. Echocardiography allows localization and estimation of the quantity of pericardial fluid. The diagnosis of pericardial fluid or thickening may be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI); these techniques may be superior to echocardiography in detecting loculated pericardial effusions and pericardial thickening.

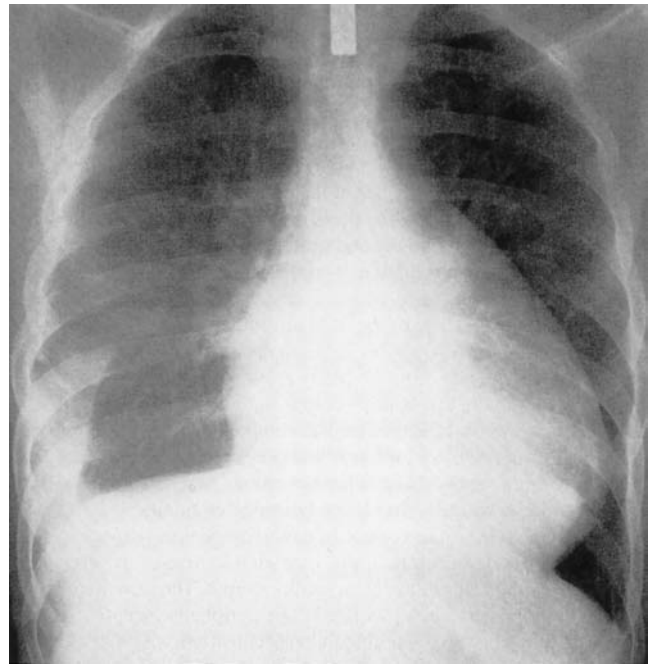

FIGURE 222-1 Chest radiogram from a patient with a pericardial effusion showing typical "water bottle" heart. There is also a right pleural effusion. *[From SS Kabbani, M LeWinter, in MH Crawford et al (eds): Cardiology. London, Mosby, 2001.]*

Pericardiocentesis When pericardial fluid is removed for diagnostic and/or therapeutic purposes, a needle attached to a properly grounded ECG lead is inserted into the pericardial space, usually through a subxiphoid approach, and, if possible, using echocardiographic control. Intrapericardial pressure should be measured before fluid is withdrawn. Pericardial effusion nearly always has the physical characteristics of an exudate. Bloody fluid is commonly due to tuberculosis or neoplasm but may also be found in the effusion of rheumatic fever, post-cardiac injury, and post-myocardial infarction (MI) and in uremic pericarditis. Transudative pericardial effusions may occur in heart failure.

CARDIAC TAMPONADE The accumulation of fluid in the pericardium in a quantity sufficient to cause serious obstruction to the inflow of blood

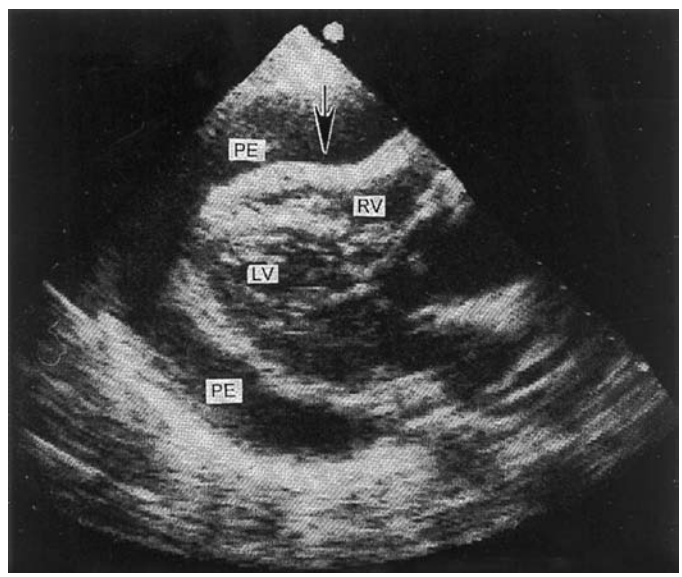

FIGURE 222-2 Large pericardial effusion (PE) with tamponade. Arrow indicates right ventricular (RV) collapse. LV, left ventricle. *(From LeWinter, with permission.)*

TABLE 222-2 *Features That Distinguish Cardiac Tamponade from Constrictive Pericarditis and Similar Clinical Disorders*

Characteristic	Tamponade	Constrictive Pericarditis	Restrictive Cardiomyopathy	RVMI
Clinical				
Pulsus paradoxus	Common	Usually absent	Rare	Rare
Jugular veins				
Prominent *y* descent	Absent	Usually present	Rare	Rare
Prominent *x* descent	Present	Usually present	Present	Rare
Kussmaul's sign	Absent	Present	Absent	Absent
Third heart sound	Absent	Absent	Rare	May be present
Pericardial knock	Absent	Often present	Absent	Absent
Electrocardiogram				
Low ECG voltage	May be present	May be present	May be present	Absent
Electrical alternans	May be present	Absent	Absent	Absent
Echocardiography				
Thickened pericardium	Absent	Present	Absent	Absent
Pericardial calcification	Absent	Often present	Absent	Absent
Pericardial effusion	Present	Absent	Absent	Absent
RV size	Usually small	Usually normal	Usually normal	Enlarged
Myocardial thickness	Normal	Normal	Usually increased	Normal
Right atrial collapse and RVDC	Present	Absent	Absent	Absent
Increased early filling, ↑ mitral flow velocity	Absent	Present	Present	May be present
Exaggerated respiratory variation in flow velocity	Present	Present	Absent	Absent
CT/MRI				
Thickened/calcific pericardium	Absent	Present	Absent	Absent
Cardiac catheterization				
Equalization of diastolic pressures	Usually present	Usually present	Usually absent	Absent or present
Cardiac biopsy helpful?	No	No	Sometimes	No

Abbreviations: RV, right ventricle; RVMI, right ventricular myocardial infarction; RVDC, right ventricular diastolic collapse; ECG, electrocardiograph.

to the ventricles results in cardiac tamponade. This complication may be fatal if it is not recognized and treated promptly. The three most common causes of tamponade are neoplastic disease, idiopathic pericarditis, and uremia. Tamponade may also result from bleeding into the pericardial space either following cardiac operations and trauma (including cardiac perforation during cardiac catheterization or insertion of pacemaker wires) or from tuberculosis and hemopericardium. The latter may occur when a patient with any form of acute pericarditis is treated with anticoagulants.

The three principal features of tamponade are elevation of intracardiac pressures, limitation of ventricular filling, and reduction of cardiac output. The quantity of fluid necessary to produce this critical state may be as small as 200 mL when the fluid develops rapidly or >2000 mL in slowly developing effusions when the pericardium has had the opportunity to stretch and adapt to an increasing volume. The volume of fluid required to produce tamponade also varies directly with the thickness of the ventricular myocardium and inversely with the thickness of the parietal pericardium.

Table 222-2 lists the features that distinguish cardiac tamponade from constrictive pericarditis. The classic findings of falling arterial pressure, rising venous pressure, and faint heart sounds usually occur only with severe, acute tamponade, as occurs with cardiac trauma or rupture. Tamponade may also develop more slowly, and under these circumstances the clinical manifestations may resemble those of heart failure, including dyspnea, orthopnea, hepatic engorgement, and jugular venous hypertension. A high index of suspicion for cardiac tamponade is required, since, in many instances, no obvious cause for pericardial disease is apparent. Tamponade should be considered in any patient with hypotension and elevation of jugular venous pressure with a prominent *x* descent and a diminutive or absent *y* descent. In contrast, in constrictive pericarditis, the *y* descent is prominent (Chap. 209). A positive Kussmaul sign (see below) is rare in cardiac tamponade, as is a pericardial knock. Their presence suggests that an organizing process and epicardial constriction are present in addition to effusion. A widening of the area of flatness to percussion across the anterior aspect of the chest wall, a paradoxical pulse (see below), hypotension, relatively clear lung fields, diminished pulsations of the cardiac silhouette on fluoroscopy, enlargement of the cardiac silhouette (especially in subacute or chronic tamponade), reduction in amplitude of the QRS complexes, and *electrical alternans* of the P, QRS, and T waves should raise the suspicion of cardiac tamponade.

Paradoxical Pulse This important clue to the presence of cardiac tamponade consists of *a greater than normal (10 mmHg) inspiratory decline in systolic arterial pressure*. When severe, it may be detected by palpating weakness or disappearance of the arterial pulse during inspiration, but usually sphygmomanometric measurement of systolic pressure during slow respiration is required.

Since both ventricles share a tight incompressible covering, i.e., the pericardial sac, the inspiratory enlargement of the right ventricle in cardiac tamponade compresses and reduces left ventricular volume; leftward bulging of the interventricular septum further reduces the left ventricular cavity as the right ventricle enlarges during inspiration. Thus, in cardiac tamponade the normal inspiratory augmentation of right ventricular volume causes an exaggerated reciprocal reduction in left ventricular volume. Also, respiratory distress increases the fluctuations in intrathoracic pressure, which exaggerates the mechanism just described. Right ventricular infarction (Chap. 228) may resemble cardiac tamponade with hypotension, elevated jugular venous pressure, an absent *y* descent in the jugular venous pulse, and occasionally pulsus paradoxus. The differences between these two conditions are shown in Table 222-2.

Paradoxical pulse occurs not only in cardiac tamponade but also in approximately one-third of patients with constrictive pericarditis. This physical finding is not pathognomonic of pericardial disease because it may be observed in some cases of hypovolemic shock, acute and chronic obstructive airways disease, and pulmonary embolus.

Low-pressure tamponade refers to mild tamponade in which the intrapericardial pressure is increased from its slightly subatmospheric levels to +5 to +10 mmHg; in some instances hypovolemia coexists. As a consequence, the central venous pressure is normal or only slightly elevated, while arterial pressure is unaffected and there is no paradoxical pulse. The patients are asymptomatic or complain of mild weakness and dyspnea. The diagnosis is aided by echocardiography, and both hemodynamic and clinical manifestations improve following pericardiocentesis.

Diagnosis Since immediate treatment of cardiac tamponade may be lifesaving, prompt measures to establish the diagnosis by echocardiography should be undertaken (Fig. 222-2). When pericardial effusion

causes tamponade, Doppler ultrasound shows that tricuspid and pulmonic valve flow velocities increase markedly during inspiration, while pulmonic vein, mitral, and aortic flow velocities diminish (Fig. 222-3). Often the right ventricular cavity is reduced in diameter, and there is late diastolic inward motion (collapse) of the right ventricular free wall and of the right atrium. Transesophageal echocardiography may be necessary to diagnose a loculated effusion or hemorrhage responsible for cardiac tamponade.

TREATMENT

Patients with acute pericarditis should be observed frequently for the development of an effusion; if a large effusion is present, the patient should be hospitalized and watched closely for signs of tamponade. In the presence of an effusion, arterial and venous pressures and heart rate should be monitored or followed carefully and serial echocardiograms obtained. If manifestations of tamponade appear, pericardiocentesis must be carried out at once, since relief of the intrapericardial pressure may be lifesaving. Intravenous saline may be administered as the patient is being readied. It is helpful, though not essential, to carry this out in the catheterization laboratory with hemodynamic and fluoroscopic monitoring. A small, multiholed catheter advanced over the needle inserted into the pericardial cavity may be left in place to allow draining of the pericardial space if fluid reaccumulates. When a *diagnostic* pericardiocentesis of a large effusion is carried out, an attempt should be made to remove as much fluid as possible. Surgical drainage through a limited (subxiphoid) thoracotomy may be required in recurrent tamponade, when it is necessary to remove loculated effusions, and/or when it is necessary to obtain tissue for diagnosis.

VIRAL OR IDIOPATHIC FORM OF ACUTE PERICARDITIS In some cases of this common disorder, an A or B coxsackievirus or the virus of influenza, echovirus, mumps, herpes simplex, chickenpox, adenovirus, or Epstein-Barr has been isolated from pericardial fluid and/or appropriate elevations in viral antibody titers have been noted. In many instances, acute pericarditis occurs in association with illnesses of known viral origin and, presumably, are caused by the same agent. Commonly, there is an antecedent infection of the respiratory tract, but in many patients such an association is not evident and viral isolation and serologic studies are negative. Most frequently, a viral causation cannot be established; the term *acute idiopathic pericarditis* is then appropriate. Pericardial effusion is a common cardiac manifestation of HIV; it is usually secondary to infection (often mycobacterial) or neoplasm—most frequently lymphoma or Kaposi's sarcoma. Approximately 80% are asymptomatic, while dyspnea or chest pain occur in the remainder. Pericardial effusion in full-blown AIDS is associated with a shortened survival (Chap. 173).

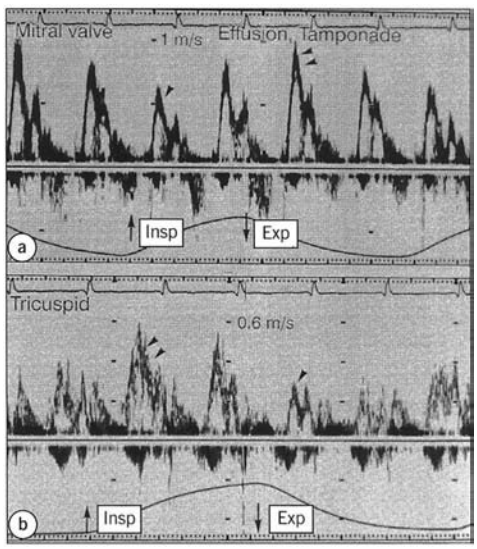

FIGURE 222-3 Doppler tracing of (*A*) mitral and (*B*) tricuspid inflow velocities in a patient with cardiac tamponade. Note the marked respiratory variation from inspiration (Insp) to (exp) expiration. *(From JJ Schultzman et al. Am J Cardiol 70:1353, 1992; with permission.)*

Acute pericarditis occurs at all ages but is more frequent in young adults and is often associated with pleural effusions and pneumonitis. The almost simultaneous development of fever and precordial pain, often 10 to 12 days after a presumed viral illness, constitutes an important feature in the differentiation of acute pericarditis from AMI, in which pain precedes fever. The constitutional symptoms are usually mild to moderate, and a pericardial friction rub is often audible. The disease ordinarily runs its course in a few days to 4 weeks, but one or more recurrences occur in about one-fourth of patients. Although accumulation of some pericardial fluid is common, tamponade is unusual, and constrictive pericarditis is a possible complication. The ST-segment alterations in the ECG usually disappear after 1 or more weeks, but the abnormal T waves may persist for several years and be a source of confusion in persons without a clear history of pericarditis. Pleuritis and pneumonitis frequently accompany pericarditis. Granulocytosis followed by lymphocytosis is common.

TREATMENT

There is no specific therapy, but bed rest and anti-inflammatory treatment with aspirin may be given. If this is ineffective, one of the nonsteroidal anti-inflammatory agents, such as indomethacin (25 to 75 mg qid), or a glucocorticoid (e.g., prednisone, 40 to 80 mg daily) usually suppresses the clinical manifestations of the acute illness and may be useful in patients in whom the purulent and tuberculous forms of pericarditis have been excluded. Anticoagulants should be avoided. After the patient has been asymptomatic and afebrile for about a week, the dose of the anti-inflammatory agent is gradually tapered. Colchicine may prevent recurrences, but when recurrences are multiple, frequent, disabling, and continue beyond 2 years, pericardiectomy may be effective in terminating the illness.

POST-CARDIAC INJURY SYNDROME Acute pericarditis may appear under a variety of circumstances that have one common feature: previous injury to the myocardium, with blood in the pericardial cavity. The syndrome may develop after a cardiac operation (postpericardiotomy syndrome); after cardiac trauma (Chap. 223), e.g., a stab wound, contusions after a nonpenetrating blow to the chest; or after perforation of the heart with a catheter. Rarely, it follows AMI.

The clinical picture mimics acute viral or idiopathic pericarditis. The principal symptom is the pain of acute pericarditis, which usually develops 1 to 4 weeks following the cardiac injury but sometimes appears only after an interval of months. Recurrences are common and may occur up to 2 years or more after the injury. Fever with temperature up to 40°C, pericarditis, pleuritis, and pneumonitis are the outstanding features, and the bout of illness usually subsides in 1 or 2 weeks. The pericarditis may be of the fibrinous variety or it may be a pericardial effusion, which is often serosanguineous, and may be accompanied by arthralgias, but rarely causes tamponade. Leukocytosis, an increased sedimentation rate, and electrocardiographic changes typical of acute pericarditis may also occur.

The mechanisms responsible for this syndrome have not been identified, but they are probably the result of a hypersensitivity reaction in which the antigen originates from injured myocardial tissue and/or pericardium; the suggested designation of *post-cardiac injury syndrome* for this group of disorders implies that they may have a common pathogenetic mechanism. Circulating autoantibodies to myocardium occur frequently, but their precise role has not been defined. Viral infection may also play an etiologic role, since antiviral antibodies are often elevated in patients who develop this syndrome following cardiac surgery.

Often no treatment is necessary aside from aspirin and analgesics. The management of pericardial effusion and tamponade has already been discussed. When the illness is followed by a series of disabling

recurrences, therapy with a nonsteroidal anti-inflammatory agent or a glucocorticoid is usually effective.

DIFFERENTIAL DIAGNOSIS Since there is no specific test for *acute idiopathic pericarditis*, the diagnosis is one of exclusion. Consequently, all other disorders that may be associated with acute fibrinous pericarditis must be considered. A common diagnostic error is mistaking acute viral or idiopathic pericarditis for AMI and vice versa. When acute fibrinous pericarditis is associated with AMI, it may be confused with acute viral or idiopathic pericarditis; this complication of infarction, described in Chap. 228, is characterized by fever, pain, and a friction rub in the first 4 days following the development of the infarct. ECG abnormalities (such as the appearance of Q waves, brief ST-segment elevations with reciprocal changes, and earlier T-wave changes in MI) and the extent of the elevations of myocardial enzymes are helpful in differentiating pericarditis from AMI.

Pericarditis secondary to post-cardiac injury is differentiated from acute idiopathic pericarditis chiefly by timing. If it occurs within a few weeks of an MI or a chest blow, it may be justified to conclude that the two are probably related. If the infarct has been silent or the chest blow forgotten, the relationship to the pericarditis may not be recognized.

It is important to distinguish *pericarditis due to collagen vascular disease* from acute idiopathic pericarditis. Most important in the differential diagnosis is the pericarditis due to systemic lupus erythematosus (SLE; Chap. 300) or drug-induced (procainamide or hydralazine) lupus. Pain is often present in pericarditis due to collagen vascular disease. Sometimes in SLE the pericarditis appears as an asymptomatic effusion and, rarely, tamponade develops. When pericarditis occurs in the absence of any obvious underlying disorder, the diagnosis may be made on discovery of LE cells or a rise in the titer of antinuclear antibodies. Acute pericarditis may complicate the viral, pyogenic, mycobacterial, and fungal infections that occur in AIDS. Acute pericarditis is an occasional complication of *rheumatoid arthritis*, *scleroderma*, and *polyarteritis nodosa*, and other evidence of these diseases is usually obvious. Asymptomatic pericardial effusion is also frequent in these disorders. It is important to question every patient with acute pericarditis about the ingestion of procainamide, hydralazine, isoniazid, cromolyn, and minoxidil, since these drugs can cause this syndrome.

The pericarditis of *acute rheumatic fever* is generally associated with evidence of severe pancarditis and with cardiac murmurs (Chap. 302). *Pyogenic (purulent) pericarditis* is usually secondary to cardiothoracic operations, immunosuppressive therapy, rupture of the esophagus into the pericardial sac, or rupture of a ring abscess in a patient with infective endocarditis and with septicemia complicating aseptic pericarditis. It is accompanied by fever, chills, septicemia, and evidence of infection elsewhere.

Uremic pericarditis (Chap. 261) occurs in up to one-third of patients with chronic uremia and is seen most frequently in patients undergoing chronic hemodialysis. It may be fibrinous and is generally associated with an effusion that may be sanguineous. A friction rub is common, but pain is usually absent. Treatment with an anti-inflammatory agent and intensification of hemodialysis is usually adequate. Pericardial instillation of glucocorticoids may be helpful. Occasionally, tamponade occurs and pericardiocentesis is required. When uremic pericarditis is recurrent or persistent, pericardiectomy may be necessary. Pericarditis due to *neoplastic diseases* results from extension or invasion of metastatic tumors (most commonly carcinoma of the lung and breast, malignant melanoma, lymphoma, and leukemia) to the pericardium; pain, atrial arrhythmias, and tamponade are complications that occur occasionally. *Mediastinal irradiation* for neoplasm may cause acute pericarditis and/or chronic constrictive pericarditis after eradication of the tumor. Unusual causes of acute pericarditis include syphilis, fungal infection (histoplasmosis, blastomycosis, aspergillosis, and candidiasis), and parasitic infestation (amebiasis, toxoplasmosis, echinococcosis, trichinosis).

CHRONIC PERICARDIAL EFFUSIONS Chronic pericardial effusions are sometimes encountered in patients without an antecedent history of acute pericarditis. They may cause few symptoms per se, and their presence may be detected by finding an enlarged cardiac silhouette on chest roentgenogram.

Tuberculosis This is a common cause of chronic pericardial effusion, although less so in the United States than in other parts of the world (Chap. 150). The clinical picture is that of a chronic, systemic illness in a patient with pericardial effusion. It is important to consider this condition in a middle-aged or elderly person with fever and enlargement of the cardiac silhouette of undetermined origin, with or without elevation of venous pressure. Weight loss, fever, and fatigability are sometimes observed. Inasmuch as treatment is quite effective, overlooking a tuberculous pericardial effusion may have serious consequences. If the etiology of chronic pericardial effusion remains obscure, a pericardial biopsy, preferably by a limited thoracotomy, should be performed. If definitive evidence is then still lacking but the specimen shows caseation necrosis, antituberculous chemotherapy is indicated. If the biopsy specimen shows a thickened pericardium, pericardiectomy should be carried out in order to prevent the development of constriction.

Other Causes *Myxedema* may be responsible for a pericardial effusion that is sometimes massive but rarely, if ever, causes cardiac tamponade. The cardiac silhouette is markedly enlarged, and an echocardiogram is necessary to distinguish cardiomegaly from pericardial effusion. The diagnosis of myxedema is frequently overlooked. It is important, therefore, to carry out appropriate tests for thyroid function (Chap. 320) as well as echocardiography in patients with an enlarged cardiac outline of undetermined origin. Myxedematous pericardial effusion responds to thyroid hormone replacement. *Cholesterol pericardial disease* is sometimes associated with myxedema. It is characterized by large pericardial effusions with a high cholesterol content, which may induce an inflammatory response and constrictive pericarditis.

Neoplasms, SLE, rheumatoid arthritis, mycotic infections, radiation therapy, pyogenic infections, severe chronic anemia, and chylopericardium may also cause chronic pericardial effusion and should be considered and specifically looked for in such patients.

Aspiration and analysis of the pericardial fluid are often helpful in diagnosis, especially in patients with chronic large effusions that are nonresponsive to nonsteroidal anti-inflammatory drugs. Fluid should be sent for hematocrit, cell count, protein, culture, and cytology. In infections the organism can often be identified by smear or culture and should lead to treatment with appropriate systemic antibiotics. Grossly sanguineous pericardial fluid results most commonly from a neoplasm, tuberculosis, uremia, or slow leakage from an aortic aneurysm. Pericardiocentesis may resolve large effusions, but pericardiectomy may be required with recurrence. Intrapericardial instillation of sclerosing agents or anti-neoplastc agents (e.g., bleomycin) may be used to prevent reaccumulation of fluid.

CHRONIC CONSTRICTIVE PERICARDITIS

This disorder results when the healing of an acute fibrinous or serofibrinous pericarditis or a chronic pericardial effusion is followed by obliteration of the pericardial cavity with the formation of granulation tissue. The latter gradually contracts and forms a firm scar, encasing the heart and interfering with filling of the ventricles. In some reports, a high percentage of cases has been of tuberculous origin, but in North America, tuberculosis is now an infrequent cause. Chronic constrictive pericarditis may also follow trauma, cardiac operation of any type, mediastinal irradiation, purulent infection, histoplasmosis, neoplastic disease (especially breast cancer, lung cancer, and lymphoma), acute viral or idiopathic pericarditis, rheumatoid arthritis, SLE, and chronic renal failure with uremia treated by chronic dialysis. In many patients the cause of the pericardial disease is undetermined, and in them an asymptomatic or forgotten bout of viral pericarditis, acute or idiopathic, may have been the inciting event. The heart may also be con-

stricted and compressed by malignant tumors or organized blood clot in the pericardial cavity.

The basic physiologic abnormality in symptomatic patients with chronic constrictive pericarditis, as in those with cardiac tamponade, is the inability of the ventricles to fill because of the limitations imposed by the rigid, thickened pericardium or the tense pericardial fluid. In constrictive pericarditis, ventricular filling is unimpeded during early diastole but is reduced abruptly when the elastic limit of the pericardium is reached, while in cardiac tamponade, ventricular filling is impeded throughout diastole. In chronic constrictive pericarditis, ventricular end-diastolic and stroke volumes are reduced and the end-diastolic pressures in both ventricles and the mean pressures in the atria, pulmonary veins, and systemic veins are all elevated to similar levels, i.e., within 5 mmHg of one another. The fibrotic process may extend into the myocardium and cause myocardial scarring, and venous congestion may then be due to the combined effects of the myocardial and pericardial lesions. Despite these hemodynamic changes, myocardial function may be normal or only slightly impaired.

In constrictive pericarditis, the central venous and right and left atrial pressure pulses display an M-shaped contour, with prominent *x* and *y* descents; the *y* descent, which is absent or diminished in cardiac tamponade, is the most prominent deflection in constrictive pericarditis and is interrupted by a rapid rise in pressure during early diastole, when ventricular filling is impeded by the constricting pericardium. These characteristic changes are transmitted to the jugular veins, where they may be recognized by inspection. In constrictive pericarditis, the ventricular pressure pulses in both ventricles exhibit characteristic "square root" signs during diastole (Fig. 222-4). These hemodynamic changes, although characteristic, are not pathognomonic of constrictive pericarditis but may also be observed in cardiomyopathies characterized by restriction of ventricular filling (Chap. 221).

CLINICAL AND LABORATORY FINDINGS (Table 222-2) Weakness, fatigue, weight gain, increased abdominal girth, abdominal discomfort, and edema are common. The patient often appears chronically ill with decreased skeletal muscle mass and a protuberant abdomen. Exertional dyspnea is common, and orthopnea may occur, although it is usually not severe. Acute left ventricular failure (acute pulmonary edema) is very uncommon. The cervical veins are distended and may remain so even after intensive diuretic treatment, and venous pressure may fail to decline during inspiration (Kussmaul's sign). The latter is frequent in chronic pericarditis but may also occur in tricuspid stenosis, right ventricular infarction, and restrictive cardiomyopathy. The pulse pressure is normal or reduced. In about one-third of the cases a paradoxical pulse can be detected. Congestive hepatomegaly is pronounced and may impair hepatic function; ascites is common and is usually more prominent than dependent edema. In about half of patients the heart is normal in size. The apical pulse is reduced and retracts in systole.

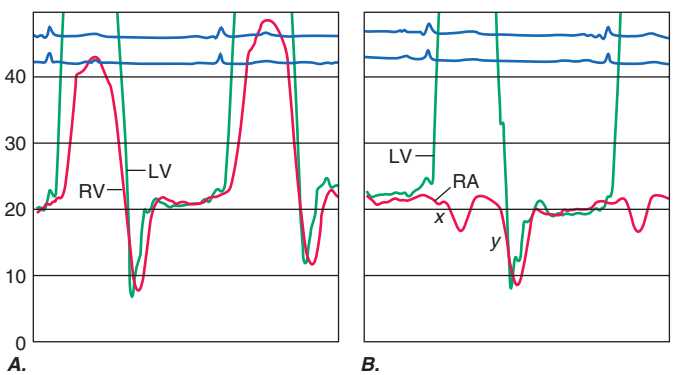

FIGURE 222-4 Pressure recording in a patient with constrictive pericarditis. *A*. Simultaneous right ventricular (RV) and left ventricular (LV) pressure tracings with equalization of diastolic pressure as well as "dip and plateau" morphology. *B*. Simultaneous right atrial (RA) and LV pressure with equalization of RA and LV diastolic pressure. Note the prominent *y* descent. *(From P Vaitkus et al: Circulation 93:834, 1996; with permission.)*

The heart sounds may be distant; an early third heart sound, i.e., a pericardial knock, occurring 0.09 to 0.12 s after aortic valve closure is often conspicuous. Protein-losing enteropathy is a rare complication.

The *ECG* frequently displays low voltage of the QRS complex and diffuse flattening or inversion of the T waves. Atrial fibrillation is present in about one-third of patients. The *chest roentgenogram* shows a normal or slightly enlarged heart, sometimes with pericardial calcification.

Inasmuch as the usual physical signs of cardiac disease (murmurs, cardiac enlargement) may be inconspicuous or absent in chronic constrictive pericarditis, hepatic enlargement and dysfunction associated with intractable ascites may lead to a mistaken diagnosis of cirrhosis of the liver. This error can be avoided if the neck veins are inspected carefully in patients with ascites and hepatomegaly. *Given a clinical picture resembling hepatic cirrhosis, but with the added feature of distended neck veins, careful search for calcification of the pericardium by chest roentgenography and CT or MRI should be carried out and may disclose this curable or remediable form of heart disease.*

The echocardiogram typically shows pericardial thickening, atrial enlargement, dilatation of the inferior vena cava and hepatic veins, and a sharp halt in ventricular filling in early diastole, with normal ventricular systolic function and flattening of the left ventricular posterior wall endocardium. There is a distinctive pattern of transvalvular flow velocity on Doppler echocardiography, with an exaggerated reduction in blood flow velocity in the pulmonary veins and across the mitral valve during inspiration, and the opposite occurring during expiration. Diastolic flow velocity in the vena cavae into the right atrium and across the tricuspid valve increases in an exaggerated manner during inspiration and declines during expiration. However, echocardiography cannot definitively exclude the diagnosis. MRI and CT scanning, especially the latter, are more accurate than echocardiography in establishing or excluding the presence of a thickened pericardium. Pericardial thickening and even pericardial calcification, however, are not synonymous with constrictive pericarditis since they may occur without seriously impairing ventricular filling.

DIFFERENTIAL DIAGNOSIS Like cor pulmonale (Chap. 216), chronic constrictive pericarditis may be associated with severe systemic venous hypertension but little pulmonary congestion; the heart is usually not enlarged, and a paradoxical pulse may be present. However, in cor pulmonale advanced parenchymal pulmonary disease is usually obvious and venous pressure *falls* during inspiration, i.e., Kussmaul's sign is negative. *Tricuspid stenosis* (Chap. 219) may also simulate chronic constrictive pericarditis; congestive hepatomegaly, splenomegaly, ascites, and venous distention may be equally prominent, and the manifestations of left-sided heart failure may be inconspicuous. However, in tricuspid stenosis, a characteristic murmur as well as mitral stenosis are usually present. In tricuspid stenosis, a paradoxical pulse and a steep, deep *y* descent in the jugular venous pulse do not occur, serving to differentiate it from chronic constrictive pericarditis.

Because constrictive pericarditis can be corrected surgically, it is important, though often difficult, to distinguish chronic constrictive pericarditis from restrictive cardiomyopathy (Chap. 221), which has a similar physiologic abnormality, i.e., restriction of ventricular filling. In many of these patients the ventricular wall is thickened on echocardiographic examination (Table 222-2). The features favoring the diagnosis of restrictive cardiomyopathy over chronic constrictive pericarditis include a well-defined apex beat, cardiac enlargement, and pronounced orthopnea with attacks of acute left ventricular failure, left ventricular hypertrophy, gallop sounds (in place of a pericardial knock), bundle branch block, and in some cases abnormal Q waves on the ECG. The echocardiogram in chronic constrictive pericarditis characteristically shows pericardial thickening, i.e., a distinct echo posterior to the left ventricular wall, and paradoxical septal motion.

The left ventricular wall moves sharply outward in early diastole on Doppler myocardial imaging. Marked respiratory variations in atrioventricular flow velocities on Doppler echocardiography are also characteristic of constrictive pericarditis but not restrictive cardiomyopathy (Fig. 222-4). The definitive diagnosis of restrictive cardiomyopathy, when it is due to an infiltrative disease such as amyloidosis, can often be established by endomyocardial biopsy. CT scanning and MRI are very useful in distinguishing between restrictive cardiomyopathy and chronic constrictive pericarditis. In the former, the ventricular walls are hypertrophied, while in the latter the pericardium is thickened and sometimes calcified.

When a patient has progressive, disabling, and unresponsive congestive failure and displays any of the features of constrictive heart disease, the most careful and detailed clinical and laboratory studies must be carried out in order to detect or exclude constrictive pericarditis, since the latter is usually curable.

Rx TREATMENT

Pericardial resection is the only definitive treatment of constrictive pericarditis, but dietary sodium restriction and diuretics are useful during preoperative preparation. The benefits derived from cardiac decortication are often striking, and the improvement, though slight at first, is usually progressive over a period of months. The risk of this operation depends on the extent of penetration of the myocardium by the calcific process, by the severity of myocardial atrophy, by the extent of secondary impairment of hepatic and/or renal function, and by the patient's general condition. Operative mortality is in the range of 5 to 15%; the patients with the most severe and/or advanced disease are at highest risk. Therefore, surgical treatment should be carried out relatively early in the course.

Many cases of constrictive pericarditis are of tuberculous origin. Antituberculous therapy during the phase of effusion may prevent the development of constriction, and such therapy should be carried out before and after operation if a tuberculous origin can be diagnosed or suspected (Chap. 150).

Subacute Effusive-Constrictive Pericarditis This form of pericardial disease is characterized by the combination of a tense effusion in the pericardial space and constriction of the heart by thickened pericardium. It shares a number of features both with chronic pericardial effusion producing cardiac compression and with pericardial constriction. It may be caused by tuberculosis, multiple attacks of acute idiopathic pericarditis, radiation, traumatic pericarditis, uremia, and scleroderma. The heart is generally enlarged, and a paradoxical pulse and a prominent *x* descent (without a prominent *y* descent) are present in the atrial and jugular venous pressure pulses. Following pericardiocentesis, the physiologic findings may change from those of cardiac tamponade to those of pericardial constriction, with a "square root" sign in the ventricular pressure pulse and a prominent *y* descent in the atrial and jugular venous pressure pulses. Furthermore, the intrapericardial pressure and the central venous pressure may decline, but not to normal. In many patients the condition progresses to the chronic constrictive form of the disease. Wide excision of both the visceral and parietal pericardium is usually effective.

OTHER DISORDERS OF THE PERICARDIUM

Pericardial cysts appear as rounded or lobulated deformities of the cardiac silhouette, most commonly at the right cardiophrenic angle. They do not cause symptoms, and their major clinical significance lies in the possibility of confusion with a tumor, ventricular aneurysm, or massive cardiomegaly. *Tumors* involving the pericardium are most commonly secondary to malignant neoplasms originating in or invading the mediastinum, including carcinoma of the bronchus and breast, lymphoma, and melanoma. The most common *primary* malignant tumor is the mesothelioma. The usual clinical picture of malignant pericardial tumor is an insidiously developing, often bloody, pericardial effusion. Surgical exploration is required to establish a definitive diagnosis and to carry out definitive or, more commonly, palliative treatment.

223 CARDIAC TUMORS, CARDIAC MANIFESTATIONS OF SYSTEMIC DISEASES, AND TRAUMATIC CARDIAC INJURY

Wilson S. Colucci, Daniel T. Price

TUMORS OF THE HEART

PRIMARY TUMORS

Primary tumors of the heart are rare. Approximately three-quarters are histologically benign, and the remainder, which in almost all cases are sarcomas, are malignant (Table 223-1). Because all cardiac tumors have the potential to cause life-threatening complications, and many are now curable by surgery, it is important that the diagnosis be made whenever possible.

CLINICAL PRESENTATION Cardiac tumors may present with a wide array of cardiac and noncardiac manifestations. The location and the size of the tumor are the major determinants of the specific signs and symptoms, many of which are present in more common forms of heart disease, such as chest pain, syncope, heart failure, murmurs, arrhythmias, conduction disturbances, and pericardial effusion with or without tamponade.

MYXOMA Myxomas are the most common type of primary cardiac tumor in all age groups, accounting for one-third to one-half of all cases at postmortem and for about three-quarters of the tumors treated surgically. They occur at all ages, most commonly in the third through sixth decades, with a female predilection. Although most myxomas are sporadic, some are familial with autosomal dominant transmission or are part of a syndrome that involves a complex of abnormalities including lentigines or pigmented nevi, primary nodular adrenal cortical disease with or without Cushing's syndrome, myxomatous mammary fibroadenomas, testicular tumors, and/or pituitary adenomas with gigantism or acromegaly. Patients with Carney complex have spotty skin pigmentation, myxomas, endocrine overactivity, and schwanno-

TABLE 223-1 *Relative Incidence of Primary Tumors of the Heart*

Type	Number	Percent
Benign	199	58.0
Myxoma	114	33.2
Rhabdomyoma	20	5.8
Fibroma	20	5.8
Hemangioma	17	5.0
Atrioventricular nodal	10	2.9
Granular cell	4	1.2
Lipoma	2	0.6
Paraganglioma	2	0.6
Myocytic hamartoma	2	0.6
Histiocytoid cardiomyopathy	2	0.6
Inflammatory psuedotumor	2	0.6
Other benign tumors	4	1.2
Malignant	144	42.0
Sarcoma	137	39.9
Lymphoma	7	2.1

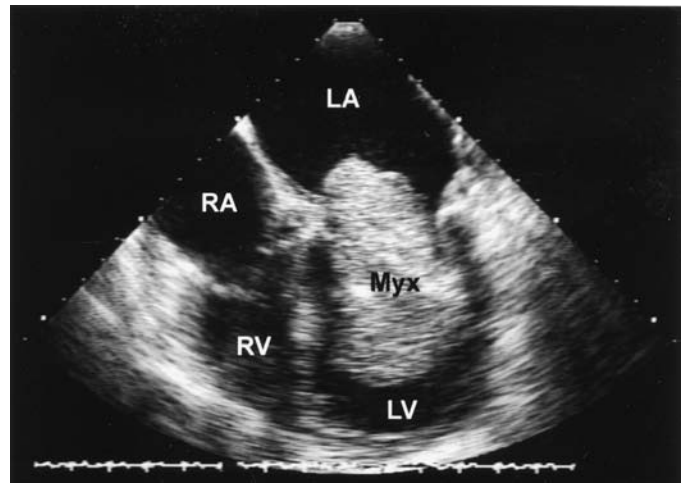

FIGURE 223-1 Transthoracic echocardiogram during diastole demonstrating a large myocardial mass, which is an atrial myxoma (Myx) that prolapses into the left ventricle (LV). LA, left atrium; RA, right atrium; RV, right ventricle. *(Courtesy of Dr. Rick Nishimura.)*

mas that are due to mutations of the gene encoding the protein kinase A type I-α regulatory subunit. Certain constellations of findings have been referred to as the *NAME* syndrome (nevi, atrial myxoma, myxoid neurofibroma, and ephelides) or the *LAMB* syndrome (lentigines, atrial myxoma, and blue nevi). Approximately 7% of cardiac myxomas are familial or part of the myxoma syndrome with the complex of abnormalities described above.

Pathologically, myxomas are gelatinous structures consisting of myxoma cells imbedded in a stroma rich in glycosaminoglycans. Most are pedunculated on a fibrovascular stalk and average 4 to 8 cm in diameter. Most are solitary and located in the atria, particularly the left, where they arise from the interatrial septum in the vicinity of the fossa ovalis. In contrast to sporadic tumors, familial or myxoma syndrome tumors tend to occur in younger individuals, be multiple or ventricular in location, and have more postoperative recurrences, probably reflecting their multicentric nature.

Myxomas commonly present with obstructive, embolic, or constitutional signs and symptoms. The most common clinical presentation mimics that of mitral valve disease—either stenosis due to tumor prolapse into the mitral orifice, or regurgitation due to tumor-induced valvular trauma. Ventricular myxomas may cause outflow obstruction similar to that caused by subaortic or subpulmonic stenosis. The symptoms and signs of myxoma may be of sudden onset or positional in nature, reflecting changes in tumor position due to gravity. An auscultatory finding, termed a "tumor plop," is a characteristic low-pitched sound that may be audible during early or mid-diastole and is thought to result from the tumor abruptly stopping as it strikes the ventricular wall. Myxomas may also present with peripheral or pulmonary emboli, or constitutional signs and symptoms including fever, weight loss, cachexia, malaise, arthralgias, rash, clubbing, Raynaud's phenomenon, hypergammaglobulinemia, anemia, polycythemia, leukocytosis, elevated erythrocyte sedimentation rate, thrombocytopenia, or thrombocytosis. Not surprisingly, myxomas are frequently misdiagnosed as endocarditis, collagen vascular disease, or noncardiac tumor.

Two-dimensional transthoracic or transesophageal echocardiography is useful in the diagnosis of cardiac myxoma and allows determination of the site of tumor attachment and tumor size, which are important considerations in the planning of surgical excision (Fig. 223-1). Computed tomography (CT) and particularly magnetic resonance imaging (MRI) may provide important information regarding size, shape, composition, and surface characteristics of the tumor. Because myxomas may be familial, echocardiographic screening of first-degree relatives is appropriate, particularly if the patient is young and has multiple tumors or evidence of myxoma syndrome. Although cardiac catheterization and angiography have previously been performed routinely before surgery, catheterization of the chamber from which the tumor arises carries the risk of tumor emboli. Catheterization is no longer considered mandatory when adequate noninvasive information is available and other cardiac diseases (e.g., coronary artery disease) are not considered likely.

TREATMENT

Surgical excision utilizing cardiopulmonary bypass is indicated and is generally curative. Myxomas recur in approximately 12 to 22% of familial cases and in about 1 to 2% of sporadic cases. Tumor recurrence is most likely due to multifocal lesions in the former and inadequate resection in the latter.

OTHER BENIGN TUMORS Cardiac *lipomas*, although relatively common, are usually incidental findings at postmortem examination. However, they may grow as large as 15 cm and may present with symptoms due to mechanical interference with cardiac function, arrhythmias, or conduction disturbances, or as an abnormality of the cardiac silhouette on chest x-ray. *Papillary fibroelastomas*, similarly, are relatively common findings on cardiac valves or the adjacent endothelium at postmortem, but seldom result in clinical symptoms. Occasionally, these growths may cause mechanical interference with valve function. *Rhabdomyomas* and *fibromas*, the most frequent tumors in infants and children, most commonly occur in the ventricles and therefore produce signs and symptoms by mechanical obstruction that may mimic valvular stenosis, congestive heart failure, restrictive or hypertrophic cardiomyopathy, and pericardial constriction. Rhabdomyomas are probably hamartomatous growths; are multiple in 90% of cases; and may be associated with tuberous sclerosis, adenoma sebaceum, and benign kidney tumors in approximately 30% of patients. Calcification of a cardiac tumor strongly suggests that it is a fibroma, although myxomas and sarcomas also may be calcified. *Hemangiomas* and *mesotheliomas* are generally small tumors, most often intramyocardial in location, and may cause atrioventricular (AV) conduction disturbances and even sudden death as a result of their prediliction for the region of the AV node. Other benign tumors arising from the heart include *teratoma*, *chemodectoma*, *neurilemoma*, *granular cell myoblastoma*, and *bronchogenic cysts*.

SARCOMA Almost all primary cardiac malignancies are sarcomas, which may be of several histologic types. In general, these tumors are characterized by a rapidly downhill course leading to the patient's death in weeks to months from the time of presentation as a result of hemodynamic compromise, local invasion, or distant metastases. Sar-

comas commonly involve the right side of the heart, and because of their rapid growth, invasion of the pericardial space and obstruction of the cardiac chambers or vena cavae are common. Sarcomas can also occur on the left side of the heart and may be mistaken for myxomas.

℞ TREATMENT

At the time of presentation these tumors have often spread too extensively for surgical excision. Although scattered reports exist of palliation with surgery, radiotherapy, and/or chemotherapy, the overall experience with cardiac sarcomas is poor. The one exception appears to be cardiac lymphosarcomas, which may respond to a combination of chemo- and radiotherapy.

TUMORS METASTATIC TO THE HEART

Tumors metastatic to the heart are much more common than primary tumors, and their incidence is likely to increase as the life expectancy of patients with various forms of malignant neoplasms is extended by more effective therapy. Although cardiac metastases occur in 1 to 20% of all tumor types, the relative incidence is especially high in malignant melanoma and, to a somewhat lesser extent, in leukemia and lymphoma. In absolute numbers, the most common primary originating sites of cardiac metastases are carcinoma of the breast and lung, reflecting the high incidence of these cancers. Cardiac metastases almost always occur in the setting of widespread primary disease, and most often either primary or metastatic disease exists elsewhere in the thoracic cavity. Nevertheless, a cardiac metastasis may occasionally be the initial presentation of a tumor elsewhere in the body.

Cardiac metastases reach the heart from the blood stream, the lymphatics, or by direct invasion. They generally are small, firm nodules. Diffuse infiltration may also occur, especially with sarcomas or hematologic neoplasms. The pericardium is most often involved, followed by myocardial involvement of any chamber, and, rarely, by involvement of the endocardium or cardiac valves.

Cardiac metastases result in clinical manifestations only about 10% of the time and rarely are the cause of death. In most instances the metastases are not the cause of the presenting clinical features but occur in the setting of a previously recognized malignant neoplasm. Although cardiac metastases may present with a large number of nonspecific signs and symptoms, the most common are dyspnea, signs of acute pericarditis, cardiac tamponade, a rapid increase in the cardiac silhouette on chest x-ray, new onset of ectopic tachyarrhythmia or AV block, and congestive heart failure. As with primary cardiac tumors, the clinical presentation is more closely related to the location and size of the tumor than to histologic type. Many of these signs and symptoms also occur with myocarditis, pericarditis, or cardiomyopathy resulting from radiotherapy or chemotherapy.

Electrocardiographic (ECG) findings are nonspecific. On chest x-ray the cardiac silhouette is most often normal but may reveal a pericardial effusion or bizarre contour. Echocardiography is useful for the diagnosis of pericardial effusion and the visualization of larger metastases. Computed tomography (CT), MRI, and radionuclide imaging with gallium or thallium may provide useful anatomic information. Angiography may delineate discrete lesions, and pericardiocentesis can allow a specific cytologic diagnosis.

℞ TREATMENT

Because most patients with cardiac metastases have widespread disease, therapy generally consists of treatment of the primary tumor. Symptomatic malignant effusions are treated by removal of fluid by pericardiocentesis, with or without concomitant instillation of a sclerosing agent (e.g., tetracycline), or placement of a pericardial window for drainage to the pleural space, to palliate symptoms, and to delay or prevent reaccumulation of the effusion.

CARDIAC EFFECTS OF CANCER THERAPY See Chap. 221

CARDIOVASCULAR MANIFESTATIONS OF SYSTEMIC DISEASES

DIABETES MELLITUS (See also Chap. 323)

There is an increased incidence of large-vessel atherosclerosis and myocardial infarction in patients with both insulin- and noninsulin-dependent diabetes mellitus. Coronary artery disease is the most common cause of death in adults with diabetes mellitus. Diabetes mellitus is an independent risk factor for coronary artery disease (Chap. 224), and the incidence of coronary artery disease is related to the duration of diabetes. In patients with diabetes mellitus, myocardial infarctions are not only more frequent but also tend to be larger in size and more likely to result in complications such as heart failure, shock, and death. Patients with diabetes mellitus are more likely to have an abnormal or absent pain response to myocardial ischemia, probably as a result of generalized autonomic nervous system dysfunction. Ambulatory ECG monitoring has shown that up to 90% of episodes of ischemia are silent in diabetic patients with coronary artery disease; the presentation of their ischemia may be exertional or episodic dyspnea, flash pulmonary edema, arrhythmias, heart block, or syncope. Since coronary artery disease is more common in patients with diabetes mellitus and often is not associated with typical anginal symptoms, the threshold for the diagnosis should be low, particularly when the duration of disease is long and concomitant risk factors for coronary artery disease (e.g., hypertension, smoking, hyperlipidemia) are present.

Patients with diabetes mellitus may also have myocardial dysfunction characteristic of a restrictive cardiomyopathy in the absence of large-vessel (epicardial) coronary artery disease, with abnormal relaxation of the myocardium, and evidenced clinically by elevated left ventricular filling pressures. Histologically, these patients have interstitial fibrosis with increased amounts of collagen, glycoprotein, triglycerides, and cholesterol in the myocardial interstitium. In some cases intimal thickening, hyaline deposition, and inflammatory changes have been observed in small intramural arteries. Patients with diabetes mellitus have an increased risk of developing clinical heart failure, even after correction for the presence of coronary artery disease, hypertension, and obesity, and it is likely that diabetic cardiomyopathy contributes to excessive cardiovascular morbidity and mortality in these patients. There is some evidence that insulin therapy results in an amelioration of the myocardial dysfunction.

MALNUTRITION AND VITAMIN DEFICIENCY MALNUTRITION

(See also Chap. 62)

In patients whose intake of protein, calories, or both is severely deficient, the heart may become thin, pale, and flabby with myofibrillar atrophy and interstitial edema. The systolic pressure and cardiac output are low, and the pulse pressure is narrow. Generalized edema is common and is due to a combination of factors, including reduced serum oncotic pressure and myocardial dysfunction. Such profound states of malnutrition, termed *marasmus* in the case of caloric deficiency and *kwashiorkor* in the case of relative protein deficiency, are most common in underdeveloped countries. However, significant nutritional heart disease may also occur in developed nations, particularly in patients with chronic diseases such as AIDS, in patients with anorexia nervosa, and in patients with severe cardiac failure in whom gastrointestinal hypoperfusion and venous congestion may lead to anorexia and malabsorption. Open-heart surgery poses increased risk in malnourished patients, and they may benefit from preoperative hyperalimentation.

THIAMINE DEFICIENCY (BERIBERI) (See also Chap. 61) In many cases, malnutrition is accompanied by thiamine deficiency, although this hypovitaminosis may also occur in the presence of an adequate protein and caloric intake, particularly in the Far East, where polished rice deficient in thiamine may be a major dietary component. In Western nations, the widespread use of thiamine-enriched flour limits the presence of deficiency primarily to alcoholics and food faddists. The meas-

urement of the thiamine-pyrophosphate effect (TPPE) can biochemically quantitate thiamine stores. An elevated TPPE, indicative of thiamine deficiency, has been found in 20 to 90% of patients with chronic heart failure. The deficiency appears to result from both reduced dietary intake and a diuretic-induced increase in the urinary excretion of thiamine. The acute administration of thiamine to these patients increases the left ventricular ejection fraction and the excretion of salt and water.

Clinically, there is usually evidence of generalized malnutrition, peripheral neuropathy, glossitis, and anemia. The characteristic cardiovascular syndrome is heart failure with increased cardiac output, tachycardia, and often elevated filling pressures in the left and right sides of the heart. The major cause of the high-output cardiac state is vasomotor depression, the precise mechanism of which is not understood but which leads to a reduced systemic vascular resistance. The cardiac examination reveals a wide pulse pressure, tachycardia, a third heart sound, and, frequently, an apical systolic murmur. The ECG may show decreased voltage, a prolonged QT interval, and T-wave abnormalities. The chest x-ray generally shows a large heart with signs of congestive heart failure. The response to thiamine is often dramatic, with an increase in systemic vascular resistance, decrease in cardiac output, clearing of pulmonary congestion, and a reduction in heart size often occurring in 12 to 48 h. Although the response to digitalis and diuretics may be poor before thiamine therapy, these agents may be important *after* thiamine is given, since the left ventricle may not be capable of dealing with the increased work load presented by the return of vascular tone.

VITAMIN B_6, B_{12}, AND FOLATE DEFICIENCY (See also Chap. 61) These vitamin cofactors in the metabolism of homocysteine probably contribute to the majority of cases of hyperhomocysteinemia in the general population. Hyperhomocysteinemia is associated with increased risk of atherosclerosis. Supplementation of these vitamins has reduced the incidence of hyperhomocysteinemia in the United States. The clinical benefit of normalizing elevated homocysteine levels, however, remains unproven.

OBESITY (See also Chap. 64)

Severe obesity, particularly when it occurs in an upper-body distribution, is associated with an increase in cardiovascular morbidity and mortality. Although obesity itself is not considered a disease, there is clearly an increased prevalence of hypertension, glucose intolerance, and atherosclerotic coronary artery disease in obese patients. In addition, these patients have a distinct abnormality of the cardiovascular system characterized by increases in total and central blood volumes, cardiac output, and left ventricular filling pressure. The elevated cardiac output appears to be required to support the metabolic needs of the excessive adipose tissue. Left ventricular filling pressure is often at the upper limits of normal and rises excessively with exercise. As a result of chronic volume overload, eccentric cardiac hypertrophy with cardiac dilatation and abnormal ventricular function may develop. Pathologically, there are left and, in some cases, right ventricular hypertrophy and generalized cardiac dilatation, which is not due simply to fatty infiltration of the myocardium. Although these patients may develop pulmonary congestion, peripheral edema, and exercise intolerance, the recognition of these findings may be difficult in massively obese patients.

Weight reduction is the most effective therapy and results in reduction in blood volume and in the return of cardiac output toward normal. However, rapid weight reduction may be dangerous, as cardiac arrhythmias and sudden death due to electrolyte imbalance have been described. Digitalis, sodium restriction, and diuretics may also be useful. This form of heart disease should be distinguished from the Pickwickian syndrome (Chap. 246), which may share several of the cardiovascular features of heart disease secondary to severe obesity but, in addition, frequently has components of central apnea, hypoxemia, pulmonary hypertension, and cor pulmonale.

THYROID DISEASE (See also Chap. 320)

Thyroid hormone exerts a major influence on the cardiovascular system by a number of direct and indirect mechanisms, and not surprisingly, cardiovascular effects are prominent in both hypo- and hyperthyroidism. Thyroid hormone causes increases in total-body metabolism and oxygen consumption that indirectly place an increased work load on the heart. In addition, although the exact mechanism has not been defined, thyroid hormone exerts direct inotropic, chronotropic, and dromotropic effects that are similar to those seen with adrenergic stimulation (e.g., tachycardia, increased cardiac output). Thyroid hormone increases the synthesis of myosin and of Na^+,K^+-ATPase, as well as the density of myocardial β-adrenergic receptors.

HYPERTHYROIDISM Cardiovascular presentations of hyperthyroidism include palpitations, systolic hypertension, fatigue, or, in patients with underlying heart disease, angina or heart failure. Sinus tachycardia is found in about 40% of patients and atrial fibrillation in about 15%. Other findings include a hyperdynamic precordium, a widened pulse pressure, an increase in the intensity of the first heart sound and the pulmonic component of the second heart sound, and a third heart sound. An increased incidence of mitral valve prolapse has been associated with hyperthyroidism, and in some cases there may be a midsystolic murmur heard best at the left sternal border with or without a systolic ejection click. A *Means-Lerman scratch* is a systolic scratchy sound, heard at the left second intercostal space during expiration; it is thought to result from the rubbing of the hyperdynamic pericardium against the pleura.

Elderly patients with hyperthyroidism, so-called apathetic hyperthyroidism, may present with only the cardiovascular manifestations of thyrotoxicosis, such as atrial fibrillation, which may be resistant to therapy until the hyperthyroidism is controlled. Angina pectoris and congestive heart failure are unusual unless there is coexistent underlying heart disease, and in many cases symptoms resolve with treatment of the hyperthyroidism.

HYPOTHYROIDISM Cardiac manifestations of hypothyroidism include a reduction in cardiac output, stroke volume, heart rate, blood pressure, and pulse pressure. In about one-third of patients there is a pericardial effusion which only rarely results in tamponade. Increased capillary permeability results in pleural and pericardial effusions. Other clinical signs include cardiomegaly, bradycardia, weak arterial pulses, and distant heart sounds. Although the signs and symptoms of myxedema may suggest the diagnosis of congestive heart failure, in the absence of other cardiac disease, myocardial failure is uncommon. The ECG generally shows sinus bradycardia and low voltage and may show prolongation of the QT interval, decreased P-wave voltage, prolonged AV conduction time, intraventricular conduction disturbances, and nonspecific ST-T wave abnormalities. Chest x-ray may show cardiomegaly, often with a "water bottle" configuration, pleural effusions, and, in some cases, evidence of congestive heart failure. Pathologically, the heart is pale, dilated, and flabby, often with myofibrillar swelling, loss of striations, and interstitial fibrosis.

Patients with hypothyroidism frequently have elevations of cholesterol and triglycerides, and severe atherosclerotic coronary artery disease. Before treatment with thyroid hormone, patients with hypothyroidism frequently do not have angina pectoris, presumably because of the low metabolic demands caused by their condition. However, angina and myocardial infarction may be precipitated during initiation of thyroid hormone replacement, especially in elderly patients with underlying heart disease. Therefore, replacement should be done with care, starting with low doses that are increased gradually.

MALIGNANT CARCINOID (See also Chap. 329)

These tumors elaborate a variety of vasoactive amines (e.g., serotonin), kinins, indoles, and other substances believed to be responsible for the

diarrhea, flushing, and labile blood pressure in these patients. The cardiac lesions due to gastrointestinal carcinoids are almost exclusively in the right side of the heart and occur only when there are hepatic metastases, suggesting that the substance responsible for the cardiac lesions is inactivated by passage through the liver and lungs. Similar lesions occur in the left side of the heart when there exists a right-to-left shunt or when the tumor is located in the lungs. These lesions are fibrous plaques on the endothelium of the cardiac chambers, valves, and great vessels. These plaques, which result in distortion of the cardiac valves, consist of smooth-muscle cells embedded in a stroma of acid mucopolysaccharide and collagen and presumably result from healing of endothelial injury.

The clinical syndrome is most often that of tricuspid regurgitation, pulmonic stenosis, or both. In some cases a high-output cardiac state may occur, presumably as a result of a decrease in systemic vascular resistance due to a vasoactive substance released by the tumor. Progression of the cardiac lesions does not appear to be affected by treatment with serotonin antagonists, and, in some severely symptomatic patients, valve replacement is indicated. Coronary artery spasm, presumably due to a circulating vasoactive substance, may occur in patients with carcinoid syndrome.

PHEOCHROMOCYTOMA (See also Chap. 322)

In addition to causing labile or sustained hypertension, the high circulating levels of catecholamines as a result of the pheochromocytoma may also cause direct myocardial injury. Focal myocardial necrosis and inflammatory cell infiltration are present in about 50% of patients who die with pheochromocytoma and may contribute to clinically significant left ventricular failure and pulmonary edema. In addition, hypertension results in left ventricular hypertrophy. Left ventricular function and congestive heart failure may resolve after removal of the tumor.

ACROMEGALY (See also Chap. 318)

The effect of excessive growth hormone on cardiac function results in congestive heart failure that may be due to high cardiac output, diastolic dysfunction due to ventricular hypertrophy (with increased left ventricular chamber size or wall thickness), or global systolic dysfunction. Hypertension occurs in up to one-third of patients and is characterized by suppression of the renin-aldosterone axis and increases in total body sodium and plasma volume. Cardiac disease occurs in about one-third of patients with acromegaly, and is associated with a doubling in the risk of death from heart disease.

RHEUMATOID ARTHRITIS AND THE COLLAGEN VASCULAR DISEASES

RHEUMATOID ARTHRITIS (See also Chap. 301) There may be inflammation of any or all anatomical parts of the heart in patients with rheumatoid arthritis. Pericarditis is the most common cause of clinically apparent disease and may be found by echocardiography in 10 to 50% of all patients with rheumatoid arthritis, particularly those with subcutaneous nodules. However, only a small fraction of these patients have clinical evidence of pericarditis, which usually follows a benign course but occasionally may progress to cardiac tamponade or constrictive pericarditis. The pericardial fluid is generally an exudate, with decreased concentrations of complement and glucose, and elevated cholesterol. Coronary arteritis with intimal inflammation and edema is present in about 20% of cases but only rarely results in angina pectoris or myocardial infarction. The cardiac valves, most often the mitral and aortic, may be involved by inflammation and granuloma formation that in some cases may cause clinically significant regurgitation due to valve deformity. Myocarditis rarely results in cardiac dysfunction.

Treatment is directed at the underlying rheumatoid arthritis and may include glucocorticoids. Pericardiectomy is usually required in cases of tamponade or persistent effusion.

SERONEGATIVE ARTHROPATHIES (See also Chap. 305) The seronegative arthropathies, ankylosing spondylitis, Reiter's syndrome, psoriatic arthritis, and the arthritides associated with ulcerative colitis and regional enteritis all may be accompanied by a pancarditis and proximal aortitis; the latter may result in aortic regurgitation and may extend into the anterior mitral valve ring and/or AV node. Conduction disturbances are common, occurring in up to one-third of patients; they are more common in patients with aortic valve disease and appear to be associated with the presence of the HLA-B27 antigen. Both aortic regurgitation and AV block are more common in patients with peripheral joint involvement and longstanding disease; treatment with aortic valve replacement and permanent pacemaker placement may be required. Up to one-fifth of patients with peripheral joint involvement and disease for more than 30 years have significant aortic regurgitation. Occasionally, aortic regurgitation precedes the onset of arthritis, and, therefore, the diagnosis of a seronegative arthritis should be considered in young males with isolated aortic regurgitation.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) (See also Chap. 300) Pericarditis is common, occurring in about two-thirds of patients, and generally follows a benign course, although rarely tamponade or constriction may result. The characteristic *endocardial lesions* of SLE, described by Libman and Sacks, consist of wartlike lesions most often located at the angles of the AV valves or on the ventricular surface of the mitral valve. Hemodynamically important valvular regurgitation is rare. Patients with the antiphospholipid syndrome have a higher incidence of cardiovascular abnormalities, including valvular disease (particularly regurgitant lesions), a variety of thrombotic disorders (venous and arterial thrombosis, thrombocytopenia, premature stroke), myocardial infarction, pulmonary hypertension, and cardiomyopathy. Myocarditis generally parallels the activity of the disease and, although common histologically, seldom results in clinical heart failure unless associated with hypertension. Although arteritis of large coronary arteries may rarely result in myocardial ischemia, there is also an increased frequency of coronary atherosclerosis that may be related to hypertension or glucocorticoid therapy.

TRAUMATIC CARDIAC INJURY

Traumatic cardiac damage may be due to either penetrating or nonpenetrating injuries. The most frequent cause of a *nonpenetrating injury* is the impact of the chest against the steering wheel of an automobile. The absence of external signs of thoracic trauma does not exclude serious injury of the heart. Although the most common injury is myocardial contusion, any structure of the heart may be affected by the trauma.

Myocardial contusions are often not immediately recognized in trauma patients due to focus on more obvious injuries. Myocardial contusion may cause arrhythmias, bundle branch block, or ECG abnormalities resembling those of infarction or pericarditis; hence, it is important to consider trauma as a cause of otherwise unexplained ECG changes. Serum creatine kinase (CK-MB) isoenzyme levels are increased in about 20% of patients, but false-positive elevations of MB may occur in the presence of massive injuries associated with large increases in total CK. Cardiac troponin levels may have a greater diagnostic value than CK-MB levels. Echocardiography can detect abnormal wall motion and the presence of pericardial effusion, in addition to aiding in diagnosis of other forms of cardiac trauma. Myocardial contusion may produce positive radionuclide scans and regional impairment of ventricular function, as occurs in myocardial infarction (Chap. 228). Pericardial effusion may occur weeks or even months after the accident. In these cases, the pericardial effusion is a manifestation of the postcardiac injury syndrome, which resembles the post-pericardiotomy syndrome (Chap. 222).

Rupture of the heart valves or the supporting structures leads to acute valvular incompetence. The presence of a loud heart murmur followed by the development of rapidly progressive heart failure after trauma heralds this diagnosis, which can be made by either transthoracic or transesophageal echocardiography.

The most serious consequence of nonpenetrating injury is myocardial rupture, leading to tamponade or intracardiac shunting. Although

it is generally immediately fatal, up to 40% of patients with cardiac rupture have been reported to survive long enough to reach a specialized trauma center. Hemopericardium may also follow tearing of a pericardial vessel or coronary artery.

Rupture of the aorta is a common consequence of nonpenetrating chest trauma. Indeed, rupture of the aorta at the isthmus or just above the aortic valve is the most common vascular deceleration injury. The clinical presentation is similar to that of aortic dissection (Chap. 231). The arterial pressure and pulse amplitude may be increased in the upper extremities and decreased in the lower extremities, and on chest x-ray there may be widening of the mediastinum. Occasionally, aortic rupture is limited by the aortic adventitia and results in a silent false aneurysm that may be discovered months or years after the injury.

Penetrating injuries of the heart, produced by bullets or stab wounds, usually result in immediate or very rapid death because of hemopericardium or massive hemorrhage. However, up to half of such patients may survive if they are resuscitated and/or survive long enough to reach a specialized trauma center. Perforation complicating the placement of an intravenous intracardiac catheter or pacemaker lead is another common cause of penetrating injuries to the heart and great vessels.

When great vessel rupture is due to a penetrating injury, there is usually a hemothorax and, less often, a hemopericardium. Hematoma formation may compress major vessels, and AV fistulae may form, sometimes resulting in high-output congestive heart failure.

Patients who suffer penetrating injuries of the heart should be carefully examined several weeks after the event to rule out a ventricular septal defect or mitral regurgitation that may have gone undetected at the time of emergency surgery. Sometimes the patient survives the acute incident and presents with a cardiac murmur and congestive heart failure. A left-to-right shunt due to traumatic ventricular septal defect, aortopulmonary artery fistula, or coronary AV fistula may be suspected and confirmed by cardiac catheterization and angiocardiography.

Rx TREATMENT

The treatment of an uncomplicated myocardial contusion, with or without myocardial infarction, is similar to that for a myocardial infarction, except that anticoagulation is contraindicated, and should include monitoring for the development of complications such as arrhythmia and cardiac rupture (Chap. 228). Acute myocardial failure resulting from the rupture of a valve usually requires operative correction. Immediate thoractomy should be carried out for most cases of penetrating injury, or if there is evidence of cardiac tamponade and/or shock regardless of the type of trauma. Pericardiocentesis may be helpful in patients with tamponade, but usually only as a temporizing maneuver on the way to the operating room. Pericardial hemorrhage often leads to constriction, which must be treated by decortication.

224 THE PATHOGENESIS OF ATHEROSCLEROSIS

Peter Libby

Atherosclerosis is the leading cause of death and disability in the developed world. Despite our familiarity with this disease, some of its fundamental characteristics remain poorly recognized and understood. Although many generalized or systemic risk factors predispose to its development, atherosclerosis affects various regions of the circulation preferentially and yields distinct clinical manifestations depending on the particular circulatory bed affected. Atherosclerosis of the coronary arteries commonly causes myocardial infarction (Chap. 228) and angina pectoris (Chap. 226). Atherosclerosis of the arteries supplying the central nervous system frequently provokes strokes and transient cerebral ischemia (Chap. 349). In the peripheral circulation, atherosclerosis causes intermittent claudication and gangrene and can jeopardize limb viability. Involvement of the splanchnic circulation can cause mesenteric ischemia. Atherosclerosis can affect the kidneys either directly (e.g., renal artery stenosis) or as a frequent site of atheroembolic disease (Chap. 231).

Even within a given arterial bed, atherosclerosis tends to occur focally, typically in certain predisposed regions. In the coronary circulation, for example, the proximal left anterior descending coronary artery exhibits a particular predilection for developing atherosclerotic occlusive disease. Likewise, atherosclerosis preferentially affects the proximal portions of the renal arteries and, in the extracranial circulation to the brain, the carotid bifurcation. Indeed, atherosclerotic lesions often form at branching points of arteries, regions of disturbed blood flow. Not all manifestations of atherosclerosis result from stenotic, occlusive disease. Ectasia and development of aneurysmal disease, for example, frequently occur in the aorta (Chap. 231). The mechanisms that underlie this discontinuous anatomic distribution of atherosclerosis remain uncertain.

Atherosclerosis manifests itself focally not only in space, as just described, but in time as well. Atherogenesis in humans typically occurs over a period of many years, usually many decades. Growth of atherosclerotic plaques probably does not occur in a smooth linear fashion, but rather discontinuously, with periods of relative quiescence punctuated by periods of rapid evolution. After a generally prolonged "silent" period, atherosclerosis may become clinically manifest. The clinical expressions of atherosclerosis may be *chronic*, as in the development of stable, effort-induced angina pectoris or of predictable and reproducible intermittent claudication. Alternatively, a much more dramatic *acute* clinical event such as myocardial infarction, a cerebrovascular accident, or sudden cardiac death may first herald the presence of atherosclerosis. Other individuals may never experience clinical manifestations of arterial disease despite the presence of widespread atherosclerosis demonstrated post mortem.

INITIATION OF ATHEROSCLEROSIS

FATTY STREAK FORMATION An integrated view of experimental results in animals and study of human atherosclerosis suggests that the "fatty

streak" represents the initial lesion of atherosclerosis. The formation of these early lesions of atherosclerosis most often seems to arise from focal increases in the content of lipoproteins within regions of the intima. This accumulation of lipoprotein particles may not result simply from an increased permeability, or "leakiness," of the overlying endothelium (Fig. 224-1). Rather, these lipoproteins may collect in the intima of arteries because they bind to constituents of the extracellular matrix, increasing the residence time of the lipid-rich particles within the arterial wall. Lipoproteins that accumulate in the extracellular space of the intima of arteries often associate with proteoglycan molecules of the arterial extracellular matrix, an interaction that may promote the retention of lipoprotein particles by binding them and slowing their egress from the intima.

Lipoprotein particles in the extracellular space of the intima, particularly those bound to matrix macromolecules, may undergo chemical modifications. Accumulating evidence supports a pathogenic role for such modifications of lipoproteins in atherogenesis. Two types of such alterations in lipoproteins bear particular interest in the context of understanding how risk factors actually promote atherogenesis: oxidation and nonenzymatic glycation.

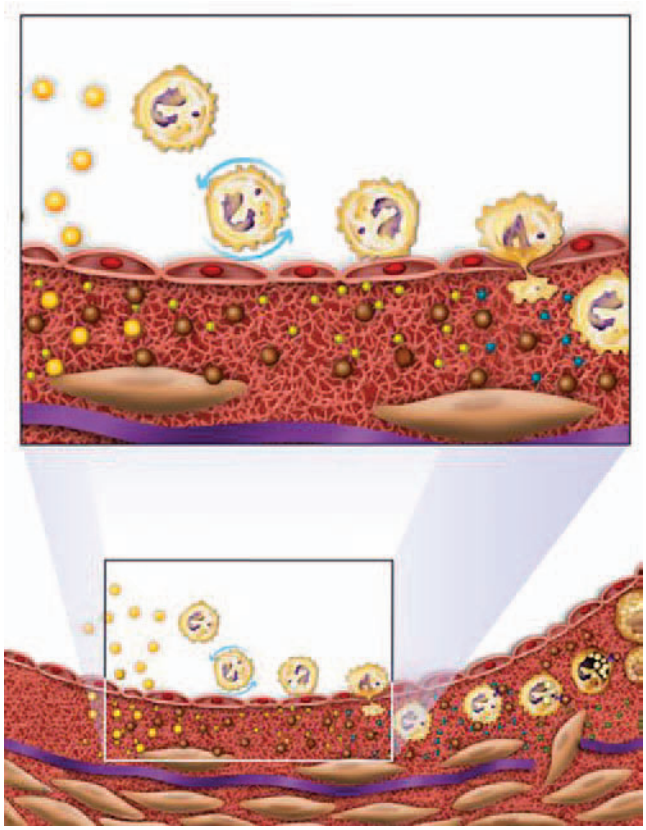

FIGURE 224-1 Cross-sectional view of an artery depicting steps in development of an atheroma, from left to right. The *upper panel* shows a detail of the boxed area below. The endothelial monolayer overlying the intima contacts blood. Hypercholesterolemia promotes accumulation of LDL particles (light spheres) in the intima. The lipoprotein particles often associate with constituents of the extracellular matrix, notably proteoglycans. Sequestration within the intima separates lipoproteins from some plasma antioxidants and favors oxidative modification. Such modified lipoprotein particles (darker spheres) may trigger a local inflammatory response responsible for signaling subsequent steps in lesion formation. The augmented expression of various adhesion molecules for leukocytes recruits monocytes to the site of a nascent arterial lesion.

Once adherent, some white blood cells will migrate into the intima. The directed migration of leukocytes probably depends on chemoattractant factors including modified lipoprotein particles themselves and chemoattractant cytokines depicted by the smaller spheres, such as the chemokine macrophage chemoattractant protein 1 produced by vascular wall cells in response to modified lipoproteins. Leukocytes in the evolving fatty streak can divide and exhibit augmented expression of receptors for modified lipoproteins (scavenger receptors). These mononuclear phagocytes ingest lipids and become foam cells, represented by a cytoplasm filled with lipid droplets. As the fatty streak evolves into a more complicated atherosclerotic lesion, smooth-muscle cells migrate from the media (*bottom of lower panel*), through the internal elastic membrane (*solid wavy line*), and accumulate within the expanding intima where they lay down extracellular matrix that forms the bulk of the advanced lesion (*bottom panel, right-hand side*).

Lipoprotein Oxidation Lipoproteins sequestered from plasma antioxidants in the extracellular space of the intima become susceptible to oxidative modification. Oxidatively modified low-density lipoprotein (LDL), rather than being a defined homogenous entity, actually comprises a variable and incompletely defined mixture. Both the lipid and protein moieties of these particles can participate in oxidative modification. Modifications of the lipids may include formation of hydroperoxides, lysophospholipids, oxysterols, and aldehydic breakdown products of fatty acids. Modifications of the apoprotein moieties may include breaks in the peptide backbone as well as derivatization of certain amino acid residues. A more recently recognized modification may result from local hypochlorous acid production by inflammatory cells within the plaque, giving rise to chlorinated species such as chlorotyrosyl moieties. Considerable evidence supports the presence of such oxidation products in atherosclerotic lesions.

Nonenzymatic Glycation In diabetic patients with sustained hyperglycemia, nonenzymatic glycation of apolipoproteins and other arterial proteins likely occurs that may alter their function and propensity to accelerate atherogenesis. A good deal of experimental work suggests that both oxidatively modified and glycated lipoproteins or their constituents can contribute to many of the subsequent cellular events of lesion development.

LEUKOCYTE RECRUITMENT After the accumulation of extracellular lipid, recruitment of leukocytes occurs as a second step in the formation of the fatty streak (Fig. 224-1). The white blood cell types typically found in the evolving atheroma include primarily cells of the mononuclear lineage: monocytes and lymphocytes. A number of adhesion molecules or receptors for leukocytes expressed on the surface of the arterial endothelial cell likely participate in the recruitment of leukocytes to the nascent fatty streak. Constituents of oxidatively modified LDL can augment expression of leukocyte adhesion molecules. This example illustrates how the accumulation of lipoproteins in the arterial intima may link mechanistically with leukocyte recruitment and subsequent events in lesion formation.

Laminar shear forces, such as those encountered in most regions of normal arteries, can also suppress the expression of leukocyte adhesion molecules. Sites of predilection for forming atherosclerotic lesions (e.g., branch points) often have disturbed laminar flow. Ordered laminar shear of normal blood flow augments the production of nitric oxide by endothelial cells. This molecule, in addition to its vasodilator properties, can act at the low levels constitutively produced by arterial endothelium as a local anti-inflammatory autacoid, for example, limiting local adhesion molecule expression. These examples indicate how hemodynamic forces may influence the cellular events that underlie atherosclerotic lesion initiation and provide a potential explanation for the focal distribution of atherosclerotic lesions at certain sites predetermined by altered flow patterns.

Once adherent to the surface of the arterial endothelial cell via interaction with adhesion receptors, the monocytes and lymphocytes penetrate the endothelial layer and take up residence in the intima. In addition to products of modified lipoproteins, cytokines (a class of protein mediators of inflammation) can regulate the expression of adhesion molecules involved in leukocyte recruitment. For example, the cytokines interleukin 1 (IL-1) or tumor necrosis factor α (TNF-α) induce or augment the expression of leukocyte adhesion molecules on endothelial cells. Because modified lipoproteins can induce cytokine release from vascular wall cells, this pathway may provide an additional link between accumulation and modification of lipoproteins and leukocyte recruitment. The directed migration of leukocytes into the arterial wall may also result from the actions of modified lipoprotein. For example, oxidized LDL may promote the chemotaxis of leukocytes. Also, oxidatively modified lipoproteins can elicit the production

by vascular wall cells of chemoattractant cytokines such as monocyte chemoattractant protein 1.

FOAM CELL FORMATION Once resident within the intima, the mononuclear phagocytes differentiate into macrophages and transform into lipid-laden foam cells. The conversion of mononuclear phagocytes into foam cells requires the uptake of lipoprotein particles by receptor-mediated endocytosis. One might suppose that the well-recognized "classical" receptor for LDL mediates this lipid uptake. Patients or animals lacking effective LDL receptors due to genetic alterations (e.g., familial hypercholesterolemia), however, have abundant arterial lesions and extraarterial xanthomata rich in macrophage-derived foam cells. Also, the exogenous cholesterol suppresses expression of the LDL receptor, such that under hypercholesterolemic conditions the level of this cell-surface receptor for LDL decreases. Candidates for alternative receptors that can mediate lipid-loading of foam cells include a growing number of macrophage "scavenger" receptors, which preferentially endocytose modified lipoproteins, and other receptors for oxidized LDL or β-VLDL (very low density lipoprotein), a type of lipoprotein commonly encountered in certain hypercholesterolemic states (Chap. 335). By ingesting lipids from the extracellular space, the mononuclear phagocytes bearing such scavenger receptors may remove lipoproteins from the developing lesion. Some lipid-loaded macrophages may leave the artery wall, functioning to clear lipid from the artery. Lipid accumulation, and hence propensity to form atheroma, ensues if the amount of lipid entering the artery wall exceeds that exported by mononuclear phagocytes or other pathways. Macrophages may thus play a vital role in the dynamic economy of lipid accumulation in the arterial wall during atherogenesis. Some lipid-laden foam cells within the expanding intimal lesion perish. Some foam cells may die as a result of programmed cell death known as *apoptosis*. This death of mononuclear phagocytes results in formation of the lipid-rich center, often called the *necrotic core*, of more complicated atherosclerotic plaques.

Macrophages taking up modified lipoproteins, much like intrinsic vascular wall cells, may elaborate cytokines and growth factors that can further signal some of the cellular events in lesion complication. A number of growth factors or cytokines elaborated by mononuclear phagocytes can stimulate smooth-muscle cell proliferation and production of extracellular matrix, which accumulates in atherosclerotic plaques. Cytokines found in the plaque, including IL-1 or TNF-α, can induce local production of growth factors such as forms of platelet-derived growth factor (PDGF), fibroblast growth factor, and others that may contribute to plaque evolution and complication. Other cytokines, notably interferon γ (IFN-γ) derived from activated T cells within lesions, can inhibit smooth-muscle proliferation and synthesis of interstitial forms of collagen. These examples illustrate how atherogenesis likely depends on a complex balance between mediators that can promote lesion formation and other pathways that can mitigate the atherogenic process.

FACTORS THAT MODULATE INHIBITION OF ATHEROMA

Elaboration of small molecules by activated mononuclear phagocytes and vascular wall cells in the evolving lesion may also modulate atherogenesis. Notably, reactive oxygen species can modulate growth of smooth-muscle cells, activate inflammatory gene expression via the nuclear factor kappa B (NFκB) transcriptional control system, and annihilate NO radicals, decreasing the effect of this endogenous vasodilator. However, the macrophage in the lesion may be activated to express the inducible form of the enzyme that can synthesize NO, known as inducible NO synthase. This high-capacity form of the enzyme can produce relatively large, potentially cytotoxic amounts of NO radicals. While at the low concentrations of NO produced by the constitutive NO synthase in endothelial cells, this radical may produce beneficial effects; when overproduced by activated phagocytes, however, it may prove deleterious.

Export by phagocytes may constitute one response to local lipid overload in the evolving lesion. Another mechanism, reverse cholesterol transport mediated by high-density lipoproteins (HDL), may provide an independent pathway for lipid removal from atheroma. This transfer of cholesterol from the cell to the HDL particle involves specialized cell surface molecules such as the ATP binding cassette transporter (ABCA1) (the gene mutated in Tangier disease, a condition characterized by very low HDL levels) and a family of scavenger receptors (the "B" family). Such "reverse cholesterol transport" explains part of HDL's antiatherogenic action.

Although clear evidence supports lipoprotein disorders as predisposing factors for atheroma formation, other etiologies may contribute to or modulate atherogenesis (see Table 225-1). For example, hypertension constitutes an independent risk factor for coronary events. Male gender and the postmenopausal state also augment the risk of developing coronary artery disease. Premenopausal women have increased HDL levels compared to age-matched men. However, a favorable lipoprotein pattern only partially accounts for the protection against atherosclerosis conferred by the premenopausal state. Although laboratory studies suggest that estrogens have direct beneficial effects on the arterial wall, clinical trials have not shown that estrogen replacement therapy prevents recurrent myocardial infarction in postmenopausal women. Indeed, treatment with a combination of estrogen and progesterone appears to augment cardiovascular events in women with or without prior myocardial infarction.

Diabetes mellitus aggravates atherogenesis. In addition to the well-known microvascular complications of diabetes (Chap. 323), macrovascular disease such as atherosclerosis causes a great deal of excess mortality in the diabetic population. Diabetes-associated dyslipidemias strongly promote atherogenesis. In particular, the constellation of insulin resistance, high triglycerides, and low HDL, often in association with the central adiposity and hypertension frequently seen in type 2 diabetic patients, seems to accelerate atherogenesis potently. As noted above, hyperglycemia may promote the nonenzymatic glycation of LDL. LDL modified in this manner, like oxidatively modified LDL, may signal many of the initial events in atherogenesis. Triglyceride-rich lipoprotein particles, often elevated in poorly controlled diabetic patients, also accentuate atherogenesis.

Lp(a) (often pronounced "lipoprotein little a" to distinguish it from apolipoprotein AI and others found in HDL) provides a potential link between hemostasis and blood lipids. The Lp(a) particle consists of an apoprotein (a) molecule bound by a sulfhydryl link to the apolipoprotein B moiety of an LDL particle. Apoprotein (a) has homology with plasminogen and may inhibit fibrinolysis by competing with plasminogen. Other risk factors for atherosclerosis related to blood clotting include elevated levels of fibrinogen or of the inhibitor of fibrinolysis, plasminogen-activator inhibitor 1 (PAI-1). Another nonlipid risk factor for coronary events, elevated levels of *homocysteine*, may act by promoting thrombosis, although the pathophysiology of this association is uncertain at present. Although individuals with marked elevations of Lp(a) or homocysteine do appear to have heightened risk of coronary thrombosis, in the population at large these factors show a much weaker correlation with vascular events than LDL, HDL, or the global inflammatory marker C-reactive protein (CRP).

The relationship between *tobacco use* and atherosclerosis also remains poorly understood. The rapid reduction in risk for cardiac events after cessation of cigarette smoking implies that tobacco may promote thrombosis or some other determinant of plaque stability as well as contribute to the evolution of the atherosclerotic lesion itself. For example, tobacco smokers have elevated fibrinogen levels, a variable associated with increased atherosclerosis and acute cardiovascular events.

INFLAMMATION In other situations, antecedent inflammatory states may predispose toward atherosclerosis. For example, *Kawasaki disease* in childhood may promote development of vascular lesions in the arteries of adults. Infectious agents continue to be proposed as instigators or potentiators of atherogenesis. However, in humans, an atherogenic role

for viral or microbial pathogens (e.g., Herpesviridiae, including cytomegalovirus, or *Chlamydia*) remains speculative. In some patients, immune or autoimmune reactions may contribute to atherogenesis. In the particular example of the accelerated form of coronary arteriopathy that plagues heart transplant recipients, immunologic factors may contribute importantly to the pathogenesis.

Known monogenic defects in lipoprotein metabolism account for only a fraction of the familial risk for coronary artery disease. Thus, other as yet undefined and perhaps multiple genetic factors may contribute to coronary risk. Mechanisms of disease susceptibility involving the arterial wall might account for some of the genetic predisposition to atherosclerosis unexplained by lipoprotein disorders. Application of molecular genetic techniques may identify new polymorphisms linked to coronary risk and may eventually shed light on new pathophysiologic mechanisms. For example, some data suggest a link between certain alleles of the genes encoding angiotensin-converting enzyme, the cytokine lymphotoxin, or PAI-1 with increased risk of myocardial infarction. Application of genomic technologies may aid identification of "modifier" genes that modulate individual responses to established risk factors. Large studies currently in progress should clarify these and other potential genetic factors that influence atherosclerosis.

ATHEROMA EVOLUTION AND COMPLICATIONS

INVOLVEMENT OF ARTERIAL SMOOTH-MUSCLE CELLS Although the fatty streak commonly precedes the development of a more advanced atherosclerotic plaque, not all fatty streaks progress to form complex atheromas. Why do some fatty streaks progress to fibrous lesions while others do not? By what mechanisms do fatty streaks evolve into more complex lesions? While accumulation of lipid-laden macrophages is the hallmark of the fatty streaks, accumulation of fibrous tissue typifies the more advanced atherosclerotic lesion. The smooth-muscle cell synthesizes the bulk of the extracellular matrix of the complex atherosclerotic lesion. Hence, arrival of smooth-muscle cells and their elaboration of extracellular matrix probably provides a critical transition, yielding a fibrofatty lesion in place of a simple accumulation of macrophage-derived foam cells.

Recent research has provided insight into the mechanisms that may trigger migration and proliferation of smooth-muscle cells into and within the evolving intimal lesion and signal the accumulation of extracellular matrix. Cytokines and growth factors elicited by modified lipoproteins or other agents from both vascular wall cells and infiltrating leukocytes can modulate functions of the smooth-muscle cell (Fig. 224-1). For example, PDGF elaborated by activated endothelial cells can stimulate the migration of smooth-muscle cells. In this manner, smooth-muscle cells resident in the tunica media may migrate into the intima. Various growth factors produced locally can stimulate the proliferation of both resident smooth-muscle cells in the intima and those that have migrated from the media. Transforming growth factor β (TGF-β), among other mediators, potently stimulates interstitial collagen production by smooth-muscle cells. These mediators may arise not only from neighboring vascular cells or leukocytes (a "paracrine" pathway) but also, in some instances, from the same cell that responds to the factor (an "autocrine" pathway). Together, these alterations in smooth-muscle cells, signaled by these mediators acting at short distances, can hasten transformation of the fatty streak into a more fibrous smooth-muscle cell and extracellular matrix-rich lesion.

BLOOD COAGULATION In addition to locally produced mediators, atherogenic risk factor signals related to blood coagulation and thrombosis likely contribute to atheroma evolution and complication. Current evidence suggests that fatty streak formation begins underneath a morphologically intact endothelium. In advanced fatty streaks, however, microscopic breaches in endothelial integrity may occur. Microthrombi rich in platelets can form at such sites of limited endothelial denudation, due to exposure of the highly thrombogenic extracellular matrix of underlying basement membrane. Activated platelets release numerous factors that can promote the fibrotic response. In addition to PDGF and TGF-β, low-molecular-weight mediators such as serotonin can also alter smooth-muscle function. Most of these microthrombi probably resolve without clinical manifestation by a process of local fibrinolysis, resorption, and endothelial repair.

MICROVESSELS As atherosclerotic lesions advance, abundant plexi of microvessels develop in connection with the artery's vasa vasorum. These newly developing microvascular networks may contribute to lesion complication in several ways. These blood vessels provide an abundant surface area for leukocyte trafficking and may serve as the portal of entry and exit of white blood cells from the established atheroma. The plaques' microvessels may also furnish foci for intraplaque hemorrhage. Like the neovessels in the diabetic retina, microvessels of the plaque may be friable and prone to rupture and produce focal hemorrhage. Such a vascular leak leads to thrombosis in situ and thrombin generation from prothrombin. In addition to its role in blood coagulation, thrombin can modulate many aspects of vascular cell function including stimulation of proliferation and cytokine release from smooth-muscle cells and production of growth factors such as PDGF from endothelial cells. Atherosclerotic plaques often contain fibrin and hemosiderin, indicating episodes of intraplaque hemorrhage as an element in plaque complication.

As they advance, atherosclerotic plaques also accumulate *calcium*. Proteins that are usually associated with bone also occur in atherosclerotic lesions. For example, osteocalcin, osteopontin, and bone morphogenetic proteins localize in atherosclerotic plaques. In fact, mineralization of the atherosclerotic plaque recapitulates many aspects of bone formation.

PLAQUE EVOLUTION Traditionally, atherosclerosis research has focused much attention on proliferation of smooth-muscle cells, yet these cells actually replicate rather slowly in complicated atherosclerotic lesions. Estimates of the rate of smooth-muscle cell division in such lesions at a given time show a replicative rate below 1%. Such observations do not exclude bursts of proliferative activity at certain junctures in the history of an atheroma, perhaps in association with local thrombin generation due to microvascular hemorrhage or formation of a microthrombus at a site of localized endothelial denudation, as discussed above. On the other hand, cell death has been recognized as a component of atherogenesis since the time of Virchow in the mid-nineteenth century. Indeed, complex atheroma often have a primarily fibrous character lacking the hypercellular appearance of less advanced lesions and actually exhibiting a paucity of smooth-muscle cells. This relative lack of smooth-muscle cells in advanced atheroma may result from the ultimate predominance of cytostatic mediators such as TGF-β or IFN-γ, which can inhibit smooth-muscle cell proliferation. Also, smooth-muscle cells as well as macrophages in advanced atherosclerotic lesions can undergo programmed cell death, or apoptosis. Some of the same cytokines that activate atherogenic functions of vascular wall cells can also trigger apoptosis in these cells.

Thus, during the evolution of the atherosclerotic plaque, a complex balance between entry and egress of lipoproteins and leukocytes, cell proliferation and cell death, extracellular matrix production and remodeling, as well as calcification and neovascularization contribute to lesion formation. Multiple and often competing signals trigger these various cellular events. Increasingly, we appreciate links between atherogenic risk factors and the altered behavior of intrinsic vascular wall cells and infiltrating leukocytes that underlie the complex pathogenesis of these lesions.

CLINICAL SYNDROMES OF ATHEROSCLEROSIS

Atherosclerotic lesions occur ubiquitously in Western societies. Most atheroma produce no symptoms, and many never cause clinical manifestations. Numerous patients with diffuse atherosclerosis may succumb to unrelated illnesses without ever having experienced a clinically significant manifestation of atherosclerosis. What accounts for this variability in the clinical expression of atherosclerotic disease?

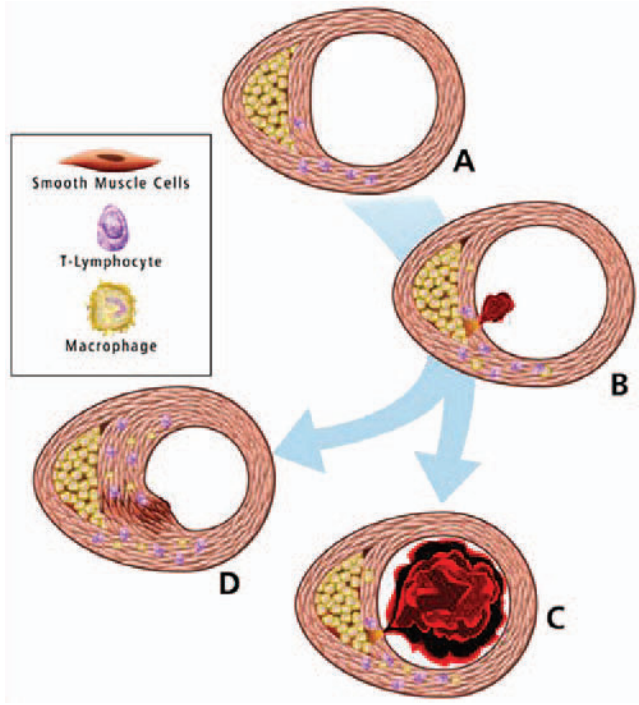

FIGURE 224-2 Plaque rupture, thrombosis, and healing. *A.* Arterial remodeling during atherogenesis. During the initial part of the life history of an atheroma, growth is often outward, preserving the caliber of lumen. This phenomenon of "compensatory enlargement" accounts in part for the tendency of coronary arteriography to underestimate the degree of atherosclerosis. *B.* Rupture of the plaque's fibrous cap causes thrombosis. Physical disruption of the atherosclerotic plaque commonly causes arterial thrombosis by allowing blood coagulant factors to contact thrombogenic collagen found in the arterial extracellular matrix and tissue factor produced by macrophage-derived foam cells in the lipid core of lesions. In this manner, sites of plaque rupture form the nidus for thrombi. The normal artery wall possesses several fibrinolytic or antithrombotic mechanisms that tend to resist thrombosis and lyse clots that begin to form in situ. Such antithrombotic or thrombolytic molecules include thrombomodulin, tissue and urokinase-type plasminogen activators, heparan sulfate proteoglycans, prostacyclin, and nitric oxide. *C.* When the clot overwhelms the endogenous fibrinolytic mechanisms, it may propagate and lead to arterial occlusion. The consequences of this occlusion depend on the degree of existing collateral vessels. In a patient with chronic multivessel, occlusive coronary artery disease, collateral channels have often formed. In such circumstances, even a total arterial occlusion may not lead to myocardial infarction, or it may produce an unexpectedly modest or a non-ST segment elevation infarct because of collateral flow. In the patient with less advanced disease and without substantial stenotic lesions to provide a stimulus to collateral vessel formation, sudden plaque rupture and arterial occlusion commonly produces ST-segment elevation infarction. These are the types of patients who may present with myocardial infarction or sudden death as a first manifestation of coronary atherosclerosis. In some cases, the thrombus may lyse or organize into a mural thrombus without occluding the vessel. Such instances may be clinically silent. *D.* The subsequent thrombin-induced fibrosis and healing causes a fibroproliferative response that can lead to a more fibrous lesion, one that can produce an eccentric plaque that causes a hemodynamically significant stenosis. In this way, a nonocclusive mural thrombus, even if clinically silent or causing unstable angina rather than infarction, can provoke a healing response that can promote lesion fibrosis and luminal encroachment. Such a sequence of events may convert a "vulnerable" atheroma with a thin fibrous cap prone to rupture into a more "stable" fibrous plaque with a reinforced cap. Angioplasty of unstable coronary lesions may "stabilize" the lesions by a similar mechanism, producing a wound followed by healing.

Arterial remodeling during atheroma formation (Fig. 224-2*A*) represents a frequently overlooked but clinically important feature of lesion evolution. During the initial phases of atheroma development, the plaque usually grows outward, in an abluminal direction. Vessels affected by atherogenesis tend to increase in diameter, a phenomenon known as *compensatory enlargement*, a type of vascular remodeling. The growing atheroma does not encroach upon the arterial lumen until the burden of atherosclerotic plaque exceeds approximately 40% of the area encompassed by the internal elastic lamina. Thus, during much of its life history, an atheroma will not cause stenosis that can limit tissue perfusion.

Flow-limiting stenoses commonly form later in the history of the plaque. Many such plaques cause stable syndromes such as demand-induced angina pectoris or intermittent claudication in the extremities. In the coronary and other circulations, even occlusion due to atheroma does not invariably lead to infarction. The hypoxic stimulus of repeated bouts of ischemia characteristically induces formation of collateral vessels in the myocardium, mitigating the consequences of an acute occlusion of an epicardial coronary artery. On the other hand, we now appreciate that many lesions that cause acute or unstable atherosclerotic syndromes, particularly in the coronary circulation, may arise from atherosclerotic plaques that do not produce a flow-limiting stenosis. Such lesions may produce only minimal luminal irregularities on traditional angiograms and often do not meet the traditional criteria for "significance" by arteriography. Instability of such nonocclusive stenoses may explain the frequency of myocardial infarction as an initial manifestation of coronary artery disease (in at least a third of cases) in patients who report no prior history of angina pectoris, a syndrome usually caused by flow-limiting stenoses.

PLAQUE INSTABILITY AND RUPTURE Pathologic studies afford considerable insight into the microanatomic substrate underlying the "instability" of plaques that are not critically stenotic. A superficial erosion of the endothelium or a frank plaque rupture or fissure usually produces the thrombus that causes episodes of unstable angina pectoris or the occlusive and relatively persistent thrombus that causes acute myocardial infarction (Fig. 224-2*B*). In the case of carotid atheroma, a deeper ulceration that provides a nidus for formation of platelet thrombi may underlie the unstable syndromes that cause transient ischemic attacks.

Rupture of the plaque's fibrous cap (Fig. 224-2*C*) permits contact between coagulation factors in the blood with highly thrombogenic tissue factor expressed by macrophage foam cells in the plaque's lipid-rich core. If the ensuing thrombus is nonocclusive or transient, the episode of plaque disruption may not cause symptoms or may result in ischemic symptoms such as rest angina. Occlusive thrombi that endure will often cause acute myocardial infarction, particularly in the absence of a well-developed collateral circulation supplying the affected territory. Repetitive episodes of plaque disruption and healing provide one likely mechanism of transition of the fatty streak to a more complex fibrous lesion (Fig. 224-2*D*). The healing process in arteries, as in skin wounds, involves the laying down of new extracellular matrix and fibrosis.

Not all atheroma exhibit the same propensity to rupture. Pathologic studies of culprit lesions that have caused acute myocardial infarction reveal several characteristic features. Plaques that have proved vulnerable tend to have thin fibrous caps, relatively large lipid cores, and a high content of macrophages. Morphometric studies of such culprit lesions show that macrophages and T lymphocytes predominate at the site of plaque rupture. On the other hand, sites of plaque rupture contain relatively few smooth-muscle cells. The cells that concentrate at sites of plaque rupture bear markers of inflammatory activation. The presence of the transplantation, or histocompatibility, antigen HLA-DR provides one convenient gauge of the degree of inflammation in cells in atheroma. Resting cells in normal arteries seldom express this transplantation antigen. However, macrophages and smooth-muscle cells at sites of human coronary artery plaque disruption do bear this inducible cell-surface marker. Therefore, the presence of HLA-DR-positive macrophages and T cells indicates an ongoing inflammatory response at sites of plaque rupture.

Inflammatory mediators may actually regulate processes that govern the integrity of the plaque's fibrous cap and hence its propensity to rupture. For example, the T cell–derived cytokine IFN-γ, found in atherosclerotic plaques and required to induce the HLA-DR present at sites of rupture, can inhibit growth and collagen synthesis of smooth-muscle cells. Cytokines derived from activated macrophages such as TNF-α or IL-1 in addition to T cell–derived IFN-γ can elicit the ex-

pression of genes that encode proteolytic enzymes that can degrade the extracellular matrix of the plaque's fibrous cap. Thus, inflammatory mediators can impair collagen synthesis required for maintenance and repair of the fibrous cap and trigger degradation of extracellular matrix macromolecules, processes that weaken the plaque's fibrous cap and enhance its vulnerability to rupture. In contrast to vulnerable plaques, those with a dense extracellular matrix and relatively thick fibrous cap without substantial tissue factor-rich lipid cores seem generally resistant to rupture and unlikely to provoke thrombosis.

CONCLUSION

We now appreciate that features of the biology of the atheromatous plaque in addition to its degree of luminal encroachment influence the clinical manifestations of this disease. This enhanced understanding of plaque biology provides insight into the diverse ways in which atherosclerosis can present clinically and why the disease may remain silent or stable for prolonged periods, punctuated by acute complications at certain times. Increased understanding of atherogenesis provides new insight into the ways in which current therapies may improve outcomes and also suggests new targets for future intervention.

225 PREVENTION AND TREATMENT OF ATHEROSCLEROSIS

Peter Libby

Atherosclerosis remains the major cause of death and premature disability in developed societies. Moreover, current predictions estimate that by the year 2020 cardiovascular diseases, notably atherosclerosis, will become the leading global cause of total disease burden, defined as the years subtracted from healthy life by disability or premature death. Substantial success has been achieved in recent years in reducing morbidity and mortality due to acute coronary events. However, the treatment of the underlying disease process, atherosclerosis, and preventing its acute complications presents an enormous challenge and opportunity simultaneously.

THE CONCEPT OF ATHEROSCLEROTIC RISK FACTORS

During the first half of the twentieth century, animal experiments and clinical observation linked certain variables, such as hypercholesterolemia, to the risk of atherosclerotic events. The systematic study of risk factors in humans, however, began approximately mid-century. The prospective, community-based Framingham Heart Study provided rigorous support for the concept that hypercholesterolemia, hypertension, and other factors correlated with cardiovascular risk. Similar observational studies performed in the United States and abroad provided independent support for the concept of "risk factors" for cardiovascular disease. Numerous data suggested a link between dietary habits and cardiovascular risk based upon population surveys.

From a practical viewpoint, the cardiovascular risk factors that have emerged from such studies fall into two categories: those modifiable by lifestyle and/or pharmacotherapy and those that are essentially unmodifiable. The weight of evidence supporting various risk factors differs. For example, hypercholesterolemia and hypertension certainly predict coronary risk, but other so-called nontraditional risk factors, such as levels of homocysteine, lipoprotein (a) [Lp(a)], or infection, remain controversial. One must further distinguish factors that actually participate in atherogenesis from those that may merely serve as markers of risk without direct involvement in pathogenesis. Table 225-1 lists the risk factors recognized by the current National Cholesterol Education Project Adult Treatment Panel III (ATP III). The sections below will consider some of these risk factors and approaches to their modification.

LIPID DISORDERS Abnormalities in plasma lipoproteins and derangements in lipid metabolism rank as the most firmly established and best understood risk factors for atherosclerosis. Chap. 335 describes the lipoprotein classes and provides a detailed discussion of lipoprotein metabolism. Chap. 224 considers the mechanisms by which lipoproteins may influence atherogenesis. Therefore, this section will focus on preventive aspects of the treatment of lipid disorders.

TABLE 225-1 Major Risk Factors (Exclusive of LDL Cholesterol) That Modify LDL Goals

Cigarette smoking
Hypertension (BP ≥ 140/90 mmHg or on antihypertensive medication)
Low HDL cholesterol[a] [<1.0 mmol/L (<40 mg/dL)]
Diabetes mellitus
Family history of premature CHD
CHD in male first-degree relative <55 years
CHD in female first-degree relative <65 years
Age (men ≥45 years; women ≥55 years)
Lifestyle risk factors
Obesity (BMI ≥ 30 kg/m^2)
Physical inactivity
Atherogenic diet
Emerging risk factors
Lipoprotein(a)
Homocysteine
Prothrombotic factors
Proinflammatory factors
Impaired fasting glucose
Subclinical atherogenesis

[a] HDL cholesterol ≥1.6 mmol/L (≥60 mg/dL) counts as a "negative" risk factor; its presence removes one risk factor from the total count.
Note: LDL, low-density lipoprotein; BP, blood pressure; HDL, high-density lipoprotein; CHD, coronary heart disease; BMI, body-mass index.
Source: Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 285:2486, 2001.

Current ATP III guidelines recommend cholesterol screening in all adults >20 years. The screen should include a fasting lipid profile [total cholesterol, triglycerides, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol] repeated every 5 years. The ATP III guidelines strive to match the intensity of treatment to an individual's risk. A quantitative estimate of risk places individuals in one of three treatment strata (Table 225-2). The first step in applying these guidelines is to count an individual's risk factors (Table 225-1). Individuals with fewer than two risk factors fall into the lowest treatment intensity stratum [LDL goal <4.1 mmol/L (< 160 mg/dL)]. In those with two or more of these risk factors, the next step involves a simple calculation of an estimate of the 10-year risk of developing coronary heart disease (CHD) (Table 225-1); (see also *http://www.nhlbi.nih.gov/guidelines/cholesterol/* for the algorithm and a downloadable risk calculator). Those with a 10-year risk ≤ 20% fall into the intermediate stratum [LDL goal <3.4 mmol/L (< 130 mg/

dL)]. Those with a calculated 10-year CHD risk of > 20%, any evidence of established atherosclerosis, or diabetes (now considered a CHD risk-equivalent) fall into the most intensive treatment group [LDL goal <2.6 mmol/L (< 100 mg/dL)]. The first maneuver to achieve the LDL goal involves therapeutic lifestyle changes (TLC), including specific diet and exercise recommendations established by the guidelines. According to ATP III criteria, those with LDL levels exceeding goal for their risk group by >0.8 mmol/L (> 30 mg/dL) merit consideration for drug therapy. In patients with triglycerides >2.6 mmol/L (>200 mg/dL), ATP III guidelines specify a secondary goal for therapy, "non-HDL cholesterol" (simply the HDL cholesterol level subtracted from the total cholesterol). Cutpoints for therapeutic decision for non-HDL cholesterol are 0.8 mmol/L (30 mg/dL) more than those for LDL. A robust body of clinical trial evidence now supports the effectiveness of aggressive management of dyslipidemia. Addition of drug therapy to dietary and other nonpharmacologic measures reduces cardiovascular risk in patients with established coronary atherosclerosis and in individuals who have not previously suffered CHD events as well (Fig. 225-1). As guidelines inevitably lag the emerging clinical trial evidence base, the practitioner may elect to exercise clinical judgement in making therapeutic decisions in individual patients.

TABLE 225-2 *LDL Cholesterol Goals and Cutpoints for Therapeutic Lifestyle Changes (TLC) and Drug Therapy in Different Risk Categories*

Risk Category	LDL Goal, mmol/L (mg/dL)	LDL Level at which to Initiate TLC, mmol/L (mg/dL)	LDL Level at which to Consider Drug Therapy, mmol/L (mg/dL)
CHD or CHD risk equivalents[a] (10-year risk >20%)	<2.6 (<100)	≥2.6 (≥100)	≥3.4 (≥130) [drug optional between 2.6 and 3.3 (100 and 129)]
2+ Risk factors (10-year risk ≤20%)	<3.4 (<130)	≥3.4 (≥130)	10-Year risk 10–20%: ≥3.4 (≥130) 10-Year risk 10%: ≥4.1 (≥160)
0–2 Risk factors	<4.1 (<160)	≥4.1 (≥160)	≥4.9 (≥190) [drug optional between 4.1 and 4.9 (160 and 189)]

[a] Diabetes mellitus is a CHD risk equivalent.
Note: LDL, low-density lipoprotein; CHD, coronary heart disease.

Lipid-lowering therapies do not appear to exert their beneficial effect on cardiovascular events by causing a marked "regression" of obstructive coronary lesions. Angiographically monitored studies of lipid lowering have shown at best a modest reduction in coronary artery stenoses over the duration of study. Yet these same studies consistently show substantial decreases in coronary events. These results suggest that the beneficial mechanism of lipid lowering does not require a substantial reduction in the fixed stenoses. Rather, the benefit may derive from "stabilization" of atherosclerotic lesions without decreased stenosis. Such stabilization of atherosclerotic lesions and the attendant decrease in coronary events may result from the egress of lipids or by favorably influencing aspects of the biology of atherogenesis discussed in Chap. 224. In addition, as sizeable lesions may protrude abluminally rather than into the lumen, shrinkage of such plaques might not be apparent on angiograms.

The benefit of LDL lowering by HMG-CoA reductase inhibitor (statin) therapy on cardiovascular events seems to require 6 to 24 months of treatment. Improvement of vasomotor responses to endothelial-dependent vasodilators occurs much more rapidly, requiring ≤6 months. Thus, HMG-CoA reductase inhibitors may act by two or more mechanisms on the arteries of hypercholesterolemic individuals. The relatively rapid improvement in endothelial-dependent vasomotion may reflect enhanced production or reduced destruction of the endogenous vasodilator nitric oxide at the level of the arterial endothelium. Reduction in the thrombotic complications of atherosclerosis, such as myocardial infarction or unstable angina, probably requires more prolonged treatment to effect removal of lipid from deeper within the atheroma, yielding improvements in the biology underlying plaque destabilization described in Chap. 224. In addition to their potent beneficial effects on the lipid profile, statins may have direct actions on the biology of the atheroma independent of lipid lowering.

In addition to statins, clinical trials have shown reductions in CHD events in certain populations with drugs that affect the lipoprotein profile, including fibric acid derivatives and nicotinic acid. New classes of lipid-lowering medications, including cholesterol absorption inhibitors, may prove useful adjuncts to current therapies; however, clinical trial evidence demonstrating benefits for CHD outcomes are not yet available.

Current understanding of the mechanism by which elevated LDL levels promote atherogenesis relates to oxidative modification of these particles within the artery wall, promoting formation of macrophage-derived foam cells and providing a stimulus for inflammation (Chap. 224). These concepts stimulated interest in the possibility that antioxidants, either dietary or pharmacologic, might reduce CHD events. Both experimental and observational clinical studies supported this notion. However, rigorous and well-controlled clinical trials have consistently shown that antioxidant vitamin therapy does *not* improve CHD outcomes. Therefore, the current evidence base does *not* support the use of antioxidant vitamins for this indication.

HYPERTENSION (See also Chap. 230) A wealth of epidemiologic data support a relationship between hypertension and atherosclerotic risk, and extensive clinical trial evidence has established that pharmacologic treatment of hypertension can reduce the risk of stroke and heart failure. More recent studies also show a reduction in CHD risk by antihypertensive therapy, particularly interruption of the renin-angiotensin system.

DIABETES MELLITUS, INSULIN RESISTANCE, AND THE METABOLIC SYNDROME (See also Chap. 323) Diabetes mellitus is a CHD risk equivalent; most patients with diabetes mellitus die of atherosclerosis and its complications. Aging and rampant obesity in the U.S. population underlie a current epidemic of type 2 (non-insulin-dependent) diabetes mellitus. The abnormal lipoprotein profile associated with insulin resistance, known as *diabetic dyslipidemia*, accounts for part of the elevated cardiovascular risk in patients with type 2 diabetes. While diabetic patients often have LDL cholesterol levels near average, the LDL particles tend to be smaller and denser and thus more atherogenic (Chap. 335). Other features of diabetic dyslipidemia include low HDL and elevated triglyceride levels. Hypertension also frequently accompanies

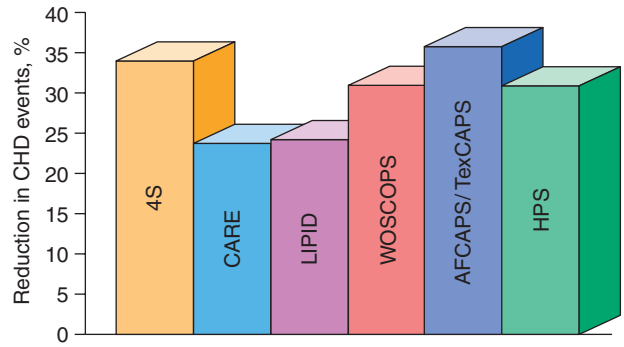

FIGURE 225-1 Lipid lowering reduces coronary events, as reflected on this graph showing the reduction percentages for onset of the acute coronary syndromes achieved by participants in six major clinical studies. 4S, Scandinavian Simvastatin Survival Study (patients with coronary heart disease and elevated cholesterol); CARE, Cholesterol and Recurrent Events (patients with coronary heart disease and average cholesterol); LIPID, Long-Term Intervention with Pravastatin in Ischemic Disease (patients with coronary heart disease and average cholesterol); WOSCOPS, West of Scotland Coronary Prevention Study (normal patients with elevated cholesterol); AFCAPS/TexCAPS, Air Force Coronary Atherosclerosis Prevention Study/Texas Coronary Atherosclerosis Prevention Study (normal patients with average cholesterol); HPS, Heart Protection Study (patients with coronary heart disease, or at high risk, with a wide range of cholesterol).

obesity, insulin resistance, and dyslipidemia. Indeed, the ATP III guidelines now recognize this cluster of risk factors and provide criteria for diagnosis of the "metabolic syndrome" (Table 225-3).

Therapeutic objectives for intervention in these patients include addressing the underlying causes, including obesity and low physical activity, by initiating TLC. The ATP III guidelines provide an explicit step-by-step plan for implementing TLC. Treatment of the component risk factors should accompany TLC. Establishing that strict glycemic control reduces the risk of macrovascular complications of diabetes has proved much more elusive than the established beneficial effects on microvascular complications such as retinopathy or renal disease. In the absence of clear-cut evidence that tight glycemic control reduces coronary risk in diabetic patients, attention to other aspects of risk in this patient population assumes even greater importance. In this regard, multiple clinical trials have demonstrated unequivocal benefit of HMG-CoA reductase inhibitor therapy in diabetic patients over all ranges of LDL cholesterol levels. The Veterans Affairs HDL Intervention Trial showed that gemfibrozil, a fibric acid derivative, reduced CHD and stroke in a population of men, many of whom had features of the metabolic syndrome. Diabetic populations appear to derive particular benefit from antihypertensive strategies that block the action of angiotensin II. Thus, the antihypertensive regimen for patients with the metabolic syndrome should include angiotensin-converting enzyme inhibitors or angiotensin receptor blockers when possible. Most of these individuals will require more than one antihypertensive agent to achieve the current American Diabetes Association blood pressure goal of 130/85 mmHg.

MALE GENDER/POSTMENOPAUSAL STATE Decades of observational studies have verified excess coronary risk in men compared with premenopausal women. After menopause, however, coronary risk accelerates in women. At least part of the apparent protection against CHD in premenopausal women derives from their relatively higher HDL levels compared with those of men. After menopause, HDL values fall in concert with increased coronary risk. Estrogen therapy lowers LDL cholesterol and raises HDL cholesterol, changes that should decrease coronary risk.

Multiple observational and experimental studies suggested that estrogen therapy (ET) might reduce coronary risk. However, several recent clinical trials have failed to demonstrate a net benefit of estrogen when combined with progestin on CHD outcomes. In the Heart and Estrogen/Progestin Replacement Study, postmenopausal female survivors of acute myocardial infarction were randomized to an estrogen/progestin combination or to placebo. This study showed no overall reduction in recurrent coronary events in the active treatment arm. Indeed, early in the 5-year course of this trial, there was a trend toward an actual increase in vascular events in the treated women. Extended follow-up of this cohort did not disclose an accrual of benefit in the treatment group. The Women's Health Initiative (WHI) study arm using a similar ET plus progesterone regimen was halted because of a small but significant hazard of cardiovascular events, stroke, and breast cancer. The excess cardiovascular events may result from an increase in thromboembolism (Chap. 327).

These clinical trials do not exclude a potential CHD benefit of estrogen alone or selective estrogen receptor modulator regimens; the estrogen *without progestin* arm of the WHI continues and should prove informative in this regard. Physicians should work with women to provide information and help weigh the small but evident CHD risk of estrogen/progestin vs. the benefits on postmenopausal symptoms and osteoporosis, taking personal preferences into account. The current disappointment surrounding estrogen/progestin therapy as a means of reducing cardiovascular risk highlights the need for redoubled attention to known modifiable risk factors in women. In the recent clinical trials with HMG-CoA reductase inhibitors, women, when included, have derived benefits at least commensurate with those seen in men.

TABLE 225-3 *Clinical Identification of the Metabolic Syndrome—Any Three Risk Factors*

Risk Factor	Defining Level
Abdominal obesity[a]	
Men (waist circumference)[b]	>102 cm (>40 in.)
Women	>88 cm (>35 in.)
Triglycerides	>1.7 mmol/L (>150 mg/dL)
HDL cholesterol	
Men	<1.0 mmol/L (<40 mg/dL)
Women	<1.3 mmol/L (<50 mg/dL)
Blood pressure	≥130/≥85 mmHg
Fasting glucose	>6.1 mmol/L (>110 mg/dL)

[a] Overweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body-mass index (BMI). Therefore, the simple measure of waist circumference is recommended to identify the BMI component of the metabolic syndrome.

[b] Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased, e.g., 94–102 cm (37–39 in.). Such patients may have a strong genetic contribution to insulin resistance. They should benefit from lifestyle changes, similarly to men with categorical increases in waist circumference.

DYSREGULATED COAGULATION OR FIBRINOLYSIS Thrombosis ultimately causes the gravest complications of atherosclerosis. The propensity to form thrombi and/or to lyse clots once they form clearly influences the manifestations of atherosclerosis. Thrombosis provoked by atheroma rupture and subsequent healing may promote plaque growth (Chap. 224). Certain individual characteristics can influence thrombosis or fibrinolysis and have received attention as potential coronary risk factors. For example, fibrinogen levels correlate with coronary risk and provide information regarding coronary risk independent of the lipoprotein profile. Elevated fibrinogen levels might promote a thrombotic diathesis. Alternatively, fibrinogen, an acute-phase reactant, may serve as a marker of inflammation rather than directly participating in the pathogenesis of coronary events.

The stability of an arterial thrombus depends on the balance between fibrinolytic factors, such as plasmin, and inhibitors of the fibrinolytic system, such as plasminogen activator inhibitor (PAI) 1. However, the levels of tissue plasminogen activator and PAI-1 in plasma have not proven to add information beyond the lipid profile to assessment of cardiovascular risk. Lp(a) (Chap. 335) may modulate fibrinolysis, and although individuals with elevated Lp(a) levels have increased CHD risk, Lp(a) levels do not potently predict risk in the population at large.

Aspirin reduces CHD events in several contexts. Chap. 226 discusses aspirin therapy in stable ischemic heart disease, Chap. 227 reviews recommendations for aspirin treatment in acute coronary syndromes, and Chap. 349 describes aspirin's role in preventing recurrent ischemic stroke. In primary prevention, pooled trial data show that low-dose aspirin treatment (81 mg qd to 325 mg qod) can reduce risk of first myocardial infarction in men. Individuals with CHD risk factors, and especially men > 45 years old, should take aspirin in the absence of contraindications.

HOMOCYSTEINE A large body of literature suggests a relationship between hyperhomocysteinemia and coronary events. Several mutations in the enzymes involved in homocysteine accumulation correlate with thrombosis and, in some studies, coronary risk. Prospective studies have not shown a robust utility of hyperhomocysteinemia in CHD risk stratification, and there are no clinical trial data showing that intervention to lower homocysteine levels reduces CHD events. Fortification of the U.S. diet with folic acid to reduce neural tube defects has lowered homocysteine levels in the population at large. Measurement of homocysteine levels should be reserved for individuals with atherosclerosis at a young age or out of proportion to established risk factors. Physicians who advise consumption of supplements containing folic acid should consider that this treatment might mask pernicious anemia.

INFLAMMATION/INFECTION An accumulation of clinical evidence shows that markers of inflammation correlate with coronary risk. For example, variations of plasma levels of C-reactive protein (CRP), as mea-

sured by a high-sensitivity assay, can prospectively predict risk of myocardial infarction. CRP levels also correlate with outcome of patients with acute coronary syndromes. In contrast to several other novel risk factors, CRP adds predictive information to that derived from established risk factors such as cholesterol (Fig. 225-2). Elevated levels of the acute-phase reactant CRP may merely reflect ongoing inflammation rather than a direct etiologic role for CRP in coronary artery disease. Elevations in acute-phase reactants such as fibrinogen or CRP could reflect overall atherosclerotic burden and/or extravascular inflammation that could potentiate atherosclerosis or its complications. In all likelihood, both factors contribute to elevation of inflammatory markers in patients at risk for coronary events. Indeed, lipid-lowering therapy may reduce coronary events in part by reducing the inflammatory aspects of the pathogenesis of atherosclerosis.

One source of inflammatory stimulus could arise from infectious agents. Interest has resurged in the possibility that infections may cause or contribute to atherosclerosis. A spate of recent publications has furnished evidence that supports a role of *Chlamydia pneumoniae*, cytomegalovirus, or other infectious agents in atherosclerosis and restenosis following coronary intervention. Some microorganisms exist in human atherosclerotic plaques. However, prospective and well-controlled seroepidemiologic studies show little or no association between infection with various agents and atherosclerosis. At present no sufficiently powered clinical trial supports the use of antibiotics to reduce CHD risk.

LIFESTYLE MODIFICATION The prevention of atherosclerosis presents a long-term challenge to all health care professionals and for public health policy as well. Both individual practitioners and organizations providing health care should strive to help patients optimize their risk factor profile long before atherosclerotic disease becomes manifest. The care plan for all patients seen by internists should include measures to assess and minimize cardiovascular risk. Physicians must counsel patients regarding the health risks of tobacco use and provide guidance regarding smoking cessation. Likewise, physicians should advise all patients about prudent dietary and exercise habits for maintaining ideal body weight. The recent National Institutes of Health Consensus Panel on Physical Activity and Cardiovascular Health established a goal of accumulating at least 30 min of moderate-intensity physical activity on a daily basis. Obesity, particularly the male pattern of centripetal or visceral fat accumulation, can contribute to the elements of the metabolic syndrome (Table 225-3). Physicians should encourage their patients to take responsibility for behavior related to modifiable risk factors for development of premature atherosclerotic disease. Conscientious counseling and patient education may forestall the need for pharmacologic measures intended to reduce coronary risk.

ISSUES IN RISK ASSESSMENT A growing panel of markers of coronary risk presents a perplexing array to the practitioner. Markers measured in peripheral blood include size fractions of LDL particles and concentrations of homocysteine, Lp(a), fibrinogen, CRP, and PAI-1 among others. In general, such specialized tests add little to the information available from a careful history and physical examination combined with measurement of a plasma lipoprotein profile and fasting blood sugar. The high-sensitivity CRP measurement may well prove an exception in view of its robustness in risk prediction, its ease of reproducible and standardized measurement, its relative stability in individuals over time, and, most importantly, its ability to add to the risk information disclosed by standard measurements such as the lipid profile. Given the utility of high-sensitivity CRP measurement in predicting a gamut of important cardiovascular outcomes, this simple blood test may prove useful in the future in guiding therapy, particularly in primary prevention. Current guidelines, however, recommend the use of this test only in individuals with intermediate risk of a CHD event (10–20%, 10-year risk).

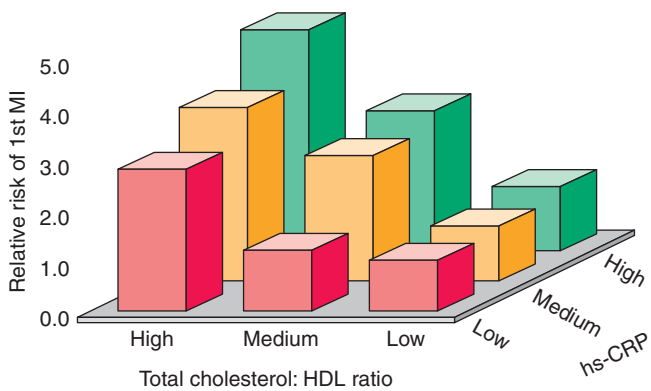

FIGURE 225-2 Measurement of C-reactive protein (CRP) level adds predictive value to TC:HDL ratio in determining risk of first MI among apparently healthy men. TC, total cholesterol; HDL, high-density lipoprotein; MI, myocardial infarction; hs-CRP, high-sensitivity measurement of CRP. *(Adapted from PM Ridker et al: Circulation 97:2007, 1998).*

Similar concerns pertain to the use of specialized radiographic estimations of coronary artery calcification. Accumulating information indicates that the amount of calcium determined by such techniques as electron beam computed tomography correlates with coronary risk. However, the utility of using such estimates of coronary artery calcium content as a guide to therapy remains unproven, particularly in asymptomatic individuals. Inappropriate use of such imaging modalities might promote excessive invasive diagnostic and therapeutic procedures. Widespread application of such modalities for screening should await proof that clinical benefit derives from their application.

THE CHALLENGE OF IMPLEMENTATION: CHANGING PHYSICIAN AND PATIENT BEHAVIOR

Despite declining age-adjusted rates of coronary death, cardiovascular mortality is on the rise due to the aging of the population overall. There is a powerful global trend toward increased atherosclerotic disease. Enormous challenges remain regarding translation of the current evidence base into practice. We must learn how to help individuals adopt a healthy lifestyle and learn to deploy our increasingly powerful pharmacologic tools most economically and effectively. The obstacles to implementation of current evidence-based prevention and treatment of atherosclerosis include economics, education, physician awareness, and patient adherence to recommended regimens. Future goals in the field of treatment of atherosclerosis should include application of the current knowledge regarding risk-factor management and, when appropriate, drug therapy.

226 ISCHEMIC HEART DISEASE

Andrew P. Selwyn, Eugene Braunwald

Ischemia refers to a lack of oxygen due to inadequate perfusion of the myocardium, which causes an imbalance between oxygen supply and demand. The most common cause of myocardial ischemia is obstructive atherosclerotic disease of epicardial coronary arteries.

EPIDEMIOLOGY Ischemic heart disease (IHD) causes more deaths and disability and incurs greater economic costs than any other illness in the developed world. IHD is the most common, serious, chronic, life-threatening illness in the United States, where >12 million persons have IHD, >6 millon have angina pectoris, and >7 million have sustained a myocardial infarction. A high-fat and energy-rich diet, smoking, and a sedentary life-style are associated with the emergence of IHD (Chap. 225). In the United States and western Europe, it is growing amongst the poor rather than the rich (who are adopting more healthful life-styles), while primary prevention has delayed the disease to later in life in all socioeconomic groups. Obesity, insulin resistance, and type 2 diabetes mellitus are increasing and are powerful risk factors for IHD. With urbanization in the developing world, the prevalence of risk factors for IHD is increasing rapidly in these regions. Large increases in IHD throughout the world are projected, and IHD is likely to become the most common cause of death worldwide by 2020.

PATHOPHYSIOLOGY Although the large epicardial coronary arteries are capable of constriction and relaxation, in healthy persons they serve as conduits and are referred to as *conductance vessels*, while the intramyocardial arterioles normally exhibit changes in tone and are therefore referred to as *resistance vessels*. Abnormal constriction of the conductance vessels can cause severe ischemia in Prinzmetal's angina (Chap. 227). Abnormal constriction or failure of normal dilation of the coronary resistance vessels can also cause ischemia. When it causes angina this condition is referred to as *microvascular angina*.

The normal coronary circulation is dominated and controlled by the heart's requirements for oxygen. This need is met by the ability of the coronary vascular bed to vary its resistance (and therefore blood flow) considerably while the myocardium extracts a high and relatively fixed percentage of oxygen. Normally, intramyocardial resistance vessels demonstrate an immense capacity for dilation. For example, the changing oxygen needs of the heart with exercise and emotional stress affect coronary vascular resistance and in this manner regulate the supply of oxygen and substrate to the myocardium (*metabolic regulation*). The coronary resistance vessels also adapt to physiologic alterations in blood pressure in order to maintain coronary blood flow at levels appropriate to myocardial needs (*autoregulation*).

By reducing the lumen of the coronary arteries, atherosclerosis limits appropriate increases in perfusion when the demand for flow is augmented, as occurs during exertion or excitement. When the luminal reduction is severe, myocardial perfusion in the basal state is reduced. Coronary blood flow can also be limited by spasm, arterial thrombi, and, rarely, coronary emboli as well as by ostial narrowing due to luetic aortitis. Congenital abnormalities, such as origin of the left anterior descending coronary artery from the pulmonary artery, may cause myocardial ischemia and infarction in infancy, but this cause is very rare in adults. Myocardial ischemia can also occur if myocardial oxygen demands are markedly increased, and when coronary blood flow may be limited, as occurs in severe left ventricular hypertrophy due to aortic stenosis. The latter can present with angina that is indistinguishable from that caused by coronary atherosclerosis (Chap. 219). A reduction in the oxygen-carrying capacity of the blood, as in extremely severe anemia or in the presence of carboxyhemoglobin, rarely causes myocardial ischemia by itself but it may lower the threshold for ischemia in patients with moderate coronary obstruction. Not infrequently, two or more causes of ischemia coexist, such as an increase in oxygen demand due to left ventricular hypertrophy secondary to hypertension and a reduction in oxygen supply secondary to coronary atherosclerosis and anemia.

CORONARY ATHEROSCLEROSIS Epicardial coronary arteries are the major site of atherosclerotic disease. The major risk factors for atherosclerosis [high plasma low-density lipoprotein (LDL), low plasma high-density lipoprotein (HDL), cigarette smoking, hypertension, and diabetes mellitus (Chaps. 224 and 225)] disturb the normal functions of the vascular endothelium. These functions include local control of vascular tone, maintenance of an anticoagulant surface, and defense against inflammatory cells. The loss of these defenses leads to inappropriate constriction, luminal clot formation, and abnormal interactions with blood monocytes and platelets. The latter results in the subintimal collections of fat, smooth-muscle cells, fibroblasts, and intercellular matrix (i.e., atherosclerotic plaques), which develop at irregular rates in different segments of the epicardial coronary tree and lead eventually to segmental reductions in cross-sectional area. When a stenosis reduces the cross-sectional area by ~75%, a full range of increases in flow to meet increased myocardial demand is not possible. When the luminal area is reduced by ≳80%, blood flow at rest may be reduced, and further minor decreases in the stenotic orifice can reduce coronary flow dramatically and cause myocardial ischemia.

Segmental atherosclerotic narrowing of epicardial coronary arteries is caused most commonly by the formation of a plaque, which is subject to fissuring, erosion, hemorrhage, and thrombosis. Any of these events can temporarily worsen the obstruction, reduce coronary blood flow, and cause clinical manifestations of myocardial ischemia, as described below. The location of the obstruction influences the quantity of myocardium rendered ischemic and determines the severity of the clinical manifestations. Thus, critical obstructions in vessels such as the left main coronary artery or the proximal left anterior descending coronary artery are particularly hazardous. Severe coronary narrowing and myocardial ischemia are frequently accompanied by the development of collateral vessels, especially when the narrowing develops gradually. When well developed, such vessels can, by themselves, provide sufficient blood flow to sustain the viability of the myocardium at rest but not during conditions of increased demand.

Once stenosis of a proximal epicardial artery has reduced the cross-sectional area by ≳70%, the distal resistance vessels (when they function normally) dilate to reduce vascular resistance and maintain coronary blood flow. A pressure gradient develops across the proximal stenosis, and poststenotic pressure falls. When the resistance vessels are maximally dilated, myocardial blood flow becomes dependent on the pressure in the coronary artery distal to the obstruction. In these circumstances ischemia, manifest clinically by angina or electrocardiographically by ST-segment depression, can be precipitated by increases in myocardial oxygen demands caused by physical activity, emotional stress, and/or tachycardia. Changes in the caliber of the stenosed coronary artery due to physiologic vasomotion, loss of endothelial control of dilation, pathologic spasm (Prinzmetal's angina), or small platelet plugs can also upset the critical balance between oxygen supply and demand and thus precipitate myocardial ischemia.

EFFECTS OF ISCHEMIA During episodes of inadequate perfusion caused by coronary atherosclerosis, myocardial tissue oxygen tension falls and may cause transient disturbances of the mechanical, biochemical, and electrical functions of the myocardium. The abrupt development of severe ischemia, as occurs with total or subtotal coronary occlusion, is associated with almost instantaneous failure of normal muscle contraction and relaxation. The relatively poor perfusion of the subendocardium causes more intense ischemia of this portion of the wall. Ischemia of large portions of the ventricle causes transient left ventricular failure, and if the papillary muscles are involved, mitral regurgitation can complicate this event. When ischemia is transient, it may be associated with angina pectoris; when it is prolonged, it can lead to myocardial necrosis and scarring with or without the clinical picture of acute myocardial infarction (Chap. 228). Coronary atherosclerosis is a focal process that usually causes nonuniform ischemia.

Regional disturbances of ventricular contractility cause segmental akinesis or, in severe cases, bulging (dyskinesia), which can greatly reduce myocardial pump function.

A wide range of abnormalities in cell metabolism, function, and structure underlie these mechanical disturbances during ischemia. The normal myocardium metabolizes fatty acids and glucose to carbon dioxide and water. With severe oxygen deprivation, fatty acids cannot be oxidized, and glucose is broken down to lactate; intracellular pH is reduced, as are the myocardial stores of high-energy phosphates, i.e., ATP and creatine phosphate. Impaired cell membrane function leads to the leakage of potassium and the uptake of sodium by myocytes. The severity and duration of the imbalance between myocardial oxygen supply and demand determine whether the damage is reversible ($\lesssim$20 min for total occlusion in the absence of collaterals) or whether it is permanent, with subsequent myocardial necrosis (>20 min).

Ischemia also causes characteristic changes in the electrocardiogram (ECG) such as repolarization abnormalities, as evidenced by inversion of T waves and, when more severe, by displacement of ST segments (Chap. 210). Transient ST-segment depression often reflects subendocardial ischemia, while ST-segment elevation is thought to be caused by more severe transmural ischemia. Another important consequence of myocardial ischemia is electrical instability, which may lead to ventricular tachycardia or ventricular fibrillation (Chap. 214). Most patients who die suddenly from IHD do so as a result of ischemia-induced ventricular tachyarrhythmias (Chap. 256).

ASYMPTOMATIC VERSUS SYMPTOMATIC IHD Postmortem studies on accident victims and military casualties in western countries have shown that coronary atherosclerosis often begins to develop prior to age 20 and is widespread even among adults who were asymptomatic during life. Exercise stress tests in asymptomatic persons may show evidence of silent myocardial ischemia, i.e., exercise-induced ECG changes not accompanied by angina pectoris; coronary angiographic studies of such persons may reveal coronary artery obstruction (Chap. 212)]. Postmortem examination of patients with such obstruction without a history of clinical manifestations of myocardial ischemia often shows macroscopic scars secondary to myocardial infarction in regions supplied by diseased coronary arteries. According to population studies, ~25% of patients who survive acute myocardial infarction may not reach medical attention, and these patients carry the same adverse prognosis as those who present with the classic clinical syndrome (Chap. 228). Sudden death may be unheralded and is a common presenting manifestation of IHD (Chap. 256). Patients with IHD can also present with cardiomegaly and heart failure secondary to ischemic damage of the left ventricular myocardium that may have caused no symptoms prior to the development of heart failure; this condition is referred to as *ischemic cardiomyopathy*. In contrast to the asymptomatic phase of IHD, the symptomatic phase is characterized by chest discomfort due to either angina pectoris or acute myocardial infarction (Chap. 228). Having entered the symptomatic phase, the patient may exhibit a stable or progressive course, revert to the asymptomatic stage, or suddenly die.

STABLE ANGINA PECTORIS

This episodic clinical syndrome is due to transient myocardial ischemia. Various diseases that cause myocardial ischemia as well as the numerous forms of discomfort with which it may be confused are discussed in Chap. 12. Males constitute ~70% of all patients with angina pectoris and an even greater fraction of those <50 years.

HISTORY The typical patient with angina is a man >50 years or a woman >60 years who complains of chest discomfort, usually described as heaviness, pressure, squeezing, smothering, or choking and only rarely as frank pain. When the patient is asked to localize the sensation, he or she will typically press on the sternum, sometimes with a clenched fist, to indicate a squeezing, central, substernal discomfort (Levine's sign). Angina is usually crescendo-decrescendo in nature, typically lasts 2 to 5 min, and can radiate to the left shoulder and to both arms, especially to the ulnar surfaces of the forearm and hand. It can also arise in or radiate to the back, interscapular region, root of the neck, jaw, teeth, and epigastrium. Angina is rarely localized below the umbilicus or above the mandible.

Although episodes of angina are typically caused by exertion (e.g., exercise, hurrying, or sexual activity) or emotion (e.g., stress, anger, fright, or frustration) and are relieved by rest, they may also occur at rest [see "Unstable Angina Pectoris," (Chap. 227)] and at night while the patient is recumbent (angina decubitus). The patient may be awakened at night distressed by typical chest discomfort and dyspnea. Nocturnal angina may be due to episodic tachycardia or to the expansion of the intrathoracic blood volume that occurs with recumbency; the latter causes an increase in cardiac size and myocardial oxygen demand that lead to ischemia and transient left ventricular failure.

The threshold for the development of angina pectoris may vary by time of day and emotional state. Many patients report a fixed threshold for angina, which occurs predictably at a certain level of activity, such as climbing two flights of stairs at a normal pace. In these patients coronary stenosis and myocardial oxygen supply are fixed and ischemia is precipitated by an increase in myocardial oxygen demand. In other patients the threshold for angina may vary considerably within any given day and from day to day. In such patients variations in myocardial oxygen supply, most likely due to changes in coronary vascular tone, may play an important role. A patient may report symptoms upon minor exertion in the morning (a short walk or shaving) yet by midday may be capable of much greater effort without symptoms. Angina may also be precipitated by unfamiliar tasks, a heavy meal, exposure to cold, or a combination. Exertional angina is typically relieved by rest in 1 to 5 min and even more rapidly by rest and sublingual nitroglycerin (see below). Indeed, the diagnosis of angina should be suspect if it does not respond to the combination of these two measures. The severity of angina can be expressed by the Canadian Cardiac Society functional classification (Table 226-1).

Sharp, fleeting chest pain or prolonged, dull aches localized to the left submammary area are rarely due to myocardial ischemia. However, angina pectoris may be atypical in location and not strictly related to provoking factors. In addition, this symptom may exacerbate and remit over days, weeks, or months. Its occurrence can be seasonal, being more frequent in the winter in temperate climates. Anginal "equivalents" are symptoms of myocardial ischemia other than angina. These include dyspnea, fatigue, and faintness and are more common in the elderly and in diabetic patients.

TABLE 226-1 *Grading of Angina Pectoris According to CCS Classification*

Class	Description of Stage
I	"Ordinary physical activity does not cause . . . angina," such as walking or climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
II	"Slight limitation of ordinary activity." Angina occurs on walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals; in cold, in wind, or under emotional stress; or only during the few hours after awakening. Angina occurs on walking >2 blocks on the level and climbing >1 flight of ordinary stairs at a normal pace and under normal conditions.
III	"Marked limitations of ordinary physical activity." Angina occurs on walking 1 to 2 blocks on the level and climbing 1 flight of stairs under normal conditions and at a normal pace.
IV	"Inability to carry on any physical activity without discomfort—anginal symptoms may be present at rest."

Systematic questioning of the patient with suspected IHD is important to uncover the features of an unstable syndrome associated with increased risk, such as angina occurring at rest or awakening the patient from sleep. Since coronary atherosclerosis is often accompanied by similar diseases in other arteries, the patient with angina should be questioned and examined for peripheral arterial disease (intermittent claudication, Chap. 232), stroke, or transient ischemic attacks (Chap. 349). It is also important to uncover a family history of premature IHD (<45 years in first-degree male relatives and <55 in female relatives) and the presence of diabetes mellitus, hyperlipidemia, hypertension, cigarette smoking, and other risk factors for coronary atherosclerosis (Chap. 224). The history of typical angina pectoris establishes the diagnosis of IHD until proven otherwise. In patients with atypical angina (Chap. 12), the coexistence of advanced age, male gender, the postmenopausal state, and risk factors for atherosclerosis increase the likelihood of important coronary disease.

PHYSICAL EXAMINATION This is often normal in patients with stable angina, but it may reveal evidence of atherosclerotic disease at other sites, such as an abdominal aortic aneurysm, carotid arterial bruits, and diminished arterial pulse in the lower extremities, or of risk factors for atherosclerosis, such as xanthelasma and xanthomas (Chap. 224). Examination of the fundi may reveal increased light reflexes and arteriovenous nicking as evidence of hypertension. There may also be signs of anemia, thyroid disease, and nicotine stains on the fingertips from cigarette smoking. Palpation may reveal cardiac enlargement and abnormal contraction of the cardiac impulse (left ventricular akinesia or dyskinesia). Auscultation can uncover arterial bruits, a third and/or fourth heart sound, and, if acute ischemia or previous infarction has impaired papillary muscle function, an apical systolic murmur due to mitral regurgitation. These auscultatory signs are best appreciated with the patient in the left decubitus position. Aortic stenosis, aortic regurgitation (Chap. 219), pulmonary hypertension (Chap. 220), and hypertrophic cardiomyopathy (Chap. 221) must be excluded, since these disorders may cause angina in the absence of coronary atherosclerosis. Examination during an anginal attack is useful, since ischemia can cause transient left ventricular failure with the appearance of a third and/or fourth heart sound, a dyskinetic cardiac apex, mitral regurgitation, and even pulmonary edema. Tenderness of the chest wall or reproduction of the pain with palpation of the chest discomfort makes it unlikely that it is caused by angina.

LABORATORY EXAMINATION Although the diagnosis of IHD can be made with confidence from the clinical examination, a number of simple laboratory tests can be helpful. The urine should be examined for evidence of diabetes mellitus and renal disease (including microalbuminuria) since these conditions accelerate atherosclerosis. Similarly, examination of the blood should include measurements of lipids (cholesterol—total, LDL, HDL—and triglycerides), glucose, creatinine, hematocrit, and, if indicated based on the physical examination, thyroid function. A chest x-ray is important, since it may show the consequences of IHD, i.e., cardiac enlargement, ventricular aneurysm, or signs of heart failure. These signs can support the diagnosis of IHD and are important in assessing the degree of cardiac damage.

ELECTROCARDIOGRAM A 12-lead ECG recorded at rest is normal in about half the patients with typical angina pectoris, but there may be signs of an old myocardial infarction (Chap. 210). Although repolarization abnormalities, i.e., ST-segment and T-wave changes as well as left ventricular hypertrophy and intraventricular conduction disturbances, are suggestive of IHD, they are nonspecific, since they can also occur in pericardial, myocardial, and valvular heart disease or, in the case of the former, transiently with anxiety, changes in posture, drugs, or esophageal disease. Typical ST-segment and T-wave changes that accompany episodes of angina pectoris and disappear thereafter are more specific.

STRESS TESTING ■ Electrocardiographic The most widely used test for both the diagnosis of IHD and estimating the prognosis involves recording the 12-lead ECG before, during, and after exercise, usually on a treadmill. The test consists of a standardized incremental increase in external workload while the symptoms, ECG, and arm blood pressure are monitored. Performance is usually symptom-limited, and the test is discontinued upon evidence of chest discomfort, severe shortness of breath, dizziness, severe fatigue, ST-segment depression > 0.2 mV (2 mm), a fall in systolic blood pressure >10 mmHg, or the development of a ventricular tachyarrhythmia. This test seeks to discover any limitation in exercise performance, to detect typical ECG signs of myocardial ischemia, and to establish their relationship to chest discomfort. The ischemic ST-segment response is generally defined as flat depression of the ST segment >0.1 mV below baseline (i.e., the PR segment) and lasting longer than 0.08 s (Fig. 226-1). Upsloping or junctional ST-segment changes are not considered characteristic of ischemia and do not constitute a positive test. Although T-wave abnormalities, conduction disturbances, and ventricular arrhythmias that develop during exercise should be noted, they are also not diagnostic. Negative exercise tests in which the target heart rate (85% of maximal heart rate for age and sex) is not achieved are considered to be nondiagnostic.

When interpreting ECG stress tests, the probability that coronary artery disease (CAD) exists in the patient or population under study (i.e., pretest probability) should be considered (Fig. 2-2). Overall, false-positive or false-negative results occur in one-third of cases. However, a positive result on exercise indicates that the likelihood of CAD is 98% in males >50 years with a history of typical angina pectoris and who develop chest discomfort during the test. The likelihood decreases if the patient has atypical or no chest pain by history and/or during the test. The incidence of false-positive tests is significantly increased in patients with low probabilities of IHD, such as asymptomatic men under the age of 40 or in premenopausal women with no risk factors for premature atherosclerosis. It is also increased in patients taking cardioactive drugs, such as digitalis and quinidine, or in those with intraventricular conduction disturbances, resting ST-segment and T-wave abnormalities, ventricular hypertrophy, or abnormal serum potassium levels. Obstructive disease limited to the circumflex coronary artery may result in a false-negative stress test since the posterior portion of the heart which this vessel supplies is not well represented on the surface 12-lead ECG. Since the overall sensitivity of exercise stress electrocardiography is only ~75%, a negative result does not exclude CAD, although it makes the likelihood of three-vessel or left main CAD extremely unlikely.

FIGURE 226-1 Lead V_4 at rest (*top*) and after 4½ min of exercise (*bottom*). There is 3 mm (0.3 mV) of horizontal ST-segment depression, indicating a positive test for ischemia. *[Modified from BR Chaitman, in E Braunwald et al (eds): Heart Disease, 6th ed, Philadelphia, Saunders, 2001.]*

The physician should be present throughout the exercise test, and it is important to measure total duration of exercise, the times to the onset of ischemic ST-segment change and chest discomfort, the external work performed (generally expressed as the stage of exercise), and the internal cardiac work performed, i.e., by the heart rate–blood pressure product. The depth of the ST-segment depression and the time needed for recovery of these ECG changes are also important. Because the risks of exercise testing are small but real—estimated at one fatality and two nonfatal complications per 10,000 tests—equipment for resuscitation should be available. Modified (heart rate–limited rather than symptom-limited) exercise tests can be performed safely in patients as early as 6 days after uncomplicated myocardial infarction. Contraindications to exercise stress testing include rest angina within 48 h, unstable rhythm, severe aortic stenosis, acute myocarditis, uncontrolled heart failure, and active infective endocarditis.

The normal response to graded exercise includes progressive increases in heart rate and blood pressure. Failure of the blood pressure to increase or an actual decrease with signs of ischemia during the test is an important adverse prognostic sign, since it may reflect ischemia-induced global left ventricular dysfunction. The development of angina and/or severe (>0.2 mV) ST-segment depression at a low workload, i.e., before completion of stage II of the Bruce protocol, and/or ST-segment depression that persists for >5 min after the termination of exercise increases the specificity of the test and suggests severe IHD and a high risk of future adverse events.

Cardiac Imaging (See also Chap. 211) When the resting ECG is abnormal (e.g., Wolff-Parkinson-White syndrome, >1 mm of resting ST-segment depression, left bundle branch block, paced ventricular rhythm), information gained from an exercise test can be enhanced by stress myocardial perfusion imaging after the intravenous administration of thallium 201 or technetium 99m sestamibi during exercise (or a pharmacologic) stress; the imaging is carried out both immediately after cessation of exercise to detect regional ischemia and 4 h later to confirm reversible ischemia and regions of persistent absent uptake that signify infarction.

A sizable fraction of patients who need noninvasive stress testing to identify myocardial ischemia and increased risk of coronary events cannot exercise because of peripheral vascular or musculoskeletal disease, exertional dyspnea, or deconditioning. In these circumstances intravenous dipyridamole or adenosine can be used in place of exercise. The development of a transient perfusion defect with a tracer such as radioactive thallium or technetium 99m sestamibi is used to detect myocardial ischemia. Ambulatory monitoring of the ECG can assess myocardial ischemia as episodes of ST-segment depression. These techniques are sensitive and capable of identifying patients with ischemia who are at increased risk of coronary events.

Two-dimensional echocardiography can assess both global and regional wall motion abnormalities of the left ventricle due to myocardial infarction or persistent ischemia. Stress (exercise or dobutamine) echocardiography may cause the emergence of regions of akinesis or dyskinesis not present at rest. Stress echocardiography, like stress myocardial perfusion imaging, is more sensitive than exercise electrocardiography in the diagnosis of IHD. The relative advantages of stress echocardiography and stress radionuclide perfusion imaging in the diagnosis of IHD are shown in Table 226-2.

Echocardiography or radionuclide angiography should be carried out to assess left ventricular function in patients with chronic stable angina and in patients with a history of a prior myocardial infarction, pathologic Q waves, or clinical evidence of heart failure.

CORONARY ARTERIOGRAPHY (See also Chap. 212) This diagnostic method outlines the lumina of the coronary arteries and can be used to detect or exclude serious coronary obstruction. However, coronary arteriography provides no information regarding the arterial wall, and severe atherosclerosis that does not encroach on the lumen may go undetected.

Indications Coronary arteriography is indicated in (1) patients with chronic stable angina pectoris who are severely symptomatic despite medical therapy and who are being considered for revascularization, i.e., a percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG); (2) patients with troublesome symptoms that present diagnostic difficulties in whom there is need to confirm or rule out the diagnosis of IHD; (3) patients with known or possible angina pectoris who have survived cardiac arrest; (4) patients with angina or evidence of ischemia on noninvasive testing with clinical or laboratory evidence of ventricular dysfunction; and (5) patients judged to be at high risk of sustaining coronary events based on signs of severe ischemia on noninvasive testing, regardless of the presence or severity of symptoms (see below).

Examples of other indications include:

1. Patients with chest discomfort suggestive of angina pectoris but a negative or nondiagnostic stress test who require a definitive diagnosis for guiding medical management, alleviating psychological stress, career or family planning, or insurance purposes.
2. Patients who have been admitted repeatedly to the hospital for suspected acute coronary syndromes (acute myocardial infarction or unstable angina) but in whom this diagnosis has not been established and in whom the presence or absence of CAD should be determined.
3. Patients with careers that involve the safety of others (e.g., pilots, fire fighters, police) who have questionable symptoms, suspicious or positive noninvasive tests, and in whom there are reasonable doubts about the state of the coronary arteries.
4. Patients with aortic stenosis or hypertrophic cardiomyopathy and angina in whom the chest pain could be due to IHD.
5. Male patients >45 and females > 55 years who are to undergo a cardiac operation, such as valve replacement or repair, and who may or may not have clinical evidence of myocardial ischemia.
6. Patients who are at high risk after myocardial infarction because of the recurrence of angina or the presence of heart failure, frequent ventricular premature contractions, or signs of ischemia on the stress test.
7. Patients with angina pectoris, regardless of severity, in whom noninvasive testing indicates a high risk of coronary events.
8. Patients in whom coronary spasm or another nonatherosclerotic cause of myocardial ischemia (e.g., coronary artery anomaly, Kawasaki's disease) is suspected.

PROGNOSIS The principal prognostic indicators in patients known to have IHD are age, the functional state of the left ventricle, the location(s) and severity of coronary artery narrowing, and the severity or activity of myocardial ischemia. Angina pectoris of recent onset, unstable angina (Chap. 227), early post-myocardial infarction angina, angina that is unresponsive or poorly responsive to medical therapy or is accompanied by symptoms of congestive heart failure all indicate an increased risk for adverse coronary events. The same is true for the

TABLE 226-2 Comparative Advantages of Stress Echocardiography and Stress Radionuclide Perfusion Imaging in Diagnosis of CAD

Advantages of stress echocardiography
1. Higher specificity
2. Versatility—more extensive evaluation of cardiac anatomy and function
3. Greater convenience/efficacy/availability
4. Lower cost

Advantages of stress perfusion imaging
1. Higher technical success rate
2. Higher sensitivity—especially for single vessel coronary disease involving the left circumflex
3. Better accuracy in evaluating possible ischemia when multiple resting LV wall motion abnormalities are present
4. More extensive published data base—especially in evaluation of prognosis

Note: CAD, coronary artery disease; LV, left ventricular.
Source: From Gibbons RJ et al, 1999, with permission.

physical signs of heart failure, episodes of pulmonary edema, transient third heart sounds, or mitral regurgitation, and for echocardiographic or radioisotopic (or roentgenographic) evidence of cardiac enlargement and reduced (<0.40) ejection fraction. Most importantly, any of the following signs during noninvasive testing indicate a high risk for coronary events: inability to exercise for 6 minutes, i.e., stage II (Bruce protocol) of the exercise test; a strongly positive exercise test showing onset of myocardial ischemia at low workloads (≥0.1 mV ST-segment depression before completion of stage II; ≥0.2 mV ST depression at any stage; ST depression for >5 min following the cessation of exercise; a decline in systolic pressure >10 mmHg during exercise; the development of ventricular tachyarrhythmias during exercise); the development of large or multiple perfusion defects or increased lung uptake during stress radioisotope perfusion imaging; and a decrease in left ventricular ejection fraction during exercise on radionuclide ventriculography or during stress echocardiography. Conversely, patients who can complete stage III of the Bruce exercise protocol and have a normal stress perfusion scan or negative stress echocardiographic evaluation are at very low risk of future coronary events.

On cardiac catheterization, elevations of left ventricular end-diastolic pressure and ventricular volume and reduced ejection fraction are the most important signs of left ventricular dysfunction and are associated with a poor prognosis. Patients with chest discomfort but normal left ventricular function and normal coronary arteries have an excellent prognosis. In patients with normal left ventricular function and mild angina but with critical stenoses (≥70% luminal diameter) of one, two, or three epicardial coronary arteries, the 5-year mortality rates are approximately 2, 8, and 11%, respectively. Obstructive lesions of the left anterior descending coronary artery proximal to the origin of the first septal artery are associated with a greater risk than are lesions of the right or left circumflex coronary artery, since the former vessel usually perfuses a greater quantity of myocardium. Stenosis (>50% luminal diameter) of the left main coronary artery is associated with a mortality rate of about 15% per year. The segmental atherosclerotic plaques in epicardial arteries with fissuring or filling defects indicates increased risk. These lesions go through phases of inflammatory cellular activity, degeneration, endothelial instability, abnormal vasomotion, platelet aggregation, and fissuring or hemorrhage. These factors can temporarily worsen the stenosis and cause abnormal reactivity of the vessel wall, thus exacerbating the manifestations of ischemia. The recent onset of symptoms, the development of severe ischemia during stress testing (see above), and unstable angina pectoris (Chap. 227) all reflect episodes of rapid progression in coronary lesions.

With any degree of obstructive CAD, mortality is greatly increased when left ventricular function is impaired; conversely, at any level of left ventricular function, the prognosis is influenced importantly by the quantity of myocardium perfused by critically obstructed vessels. Therefore, it is useful to collect all the evidence substantiating past myocardial damage (evidence of myocardial infarction on ECG, echocardiography, radioisotope imagine, or left ventriculography), residual left ventricular function (ejection fraction and wall motion), and risk of future damage from coronary events (extent of coronary disease and severity of ischemia defined by noninvasive stress testing). The larger the quantity of established myocardial necrosis, the less the heart is able to withstand additional damage and the poorer the prognosis. All the above signs of past damage plus the risk of future damage should be considered indicators of risk.

The plasma level of C-reactive protein is an indicator of inflammation and risk of future adverse coronary events in populations with atherosclerosis (Chap. 225). Similarly, electron beam computed tomography to measure coronary calcification and ultrasound measures of carotid intimal thickening can be used for the same purpose. The presence of other risk factors for coronary atherosclerosis [advanced age (>75 years), diabetes, morbid obesity, accompanying peripheral and/or cerebrovascular disease, previous myocardial infarction] worsen the prognosis of angina.

TREATMENT

Each patient must be evaluated individually with respect to his or her expectations and goals, control of symptoms, and prevention of adverse clinical outcomes such as myocardial infarction and premature death. The degree of disability as well as the physical and emotional stress that precipitate angina must be carefully recorded in order to set treatment goals. The management plan should include the following components: (1) explanation and reassurance, (2) identification and treatment of aggravating conditions, (3) adaptation of activity, (4) treatment of risk factors that will decrease the occurrence of adverse coronary outcomes, (5) drug therapy for angina, and (6) consideration of mechanical revascularization (Table 226-3).

Explanation and Reassurance Patients with IHD need to understand their condition as best they can and to realize that a long and useful life is possible even though they suffer from angina pectoris or have experienced and recovered from an acute myocardial infarction. Offering case histories of persons in public life who have lived with coronary disease as well as results of national studies showing improved outcomes can be of great value when encouraging patients to resume or maintain activity and return to their occupation. A planned program of rehabilitation can encourage patients to lose weight, improve exercise tolerance, and control risk factors with more confidence.

Identification and Treatment of Aggravating Conditions A number of conditions may either increase oxygen demand or decrease oxygen supply to the myocardium and may precipitate or exacerbate angina in patients with IHD. Aortic valve disease and hypertrophic cardiomyopathy may cause or contribute to angina and should be excluded or treated. Obesity, hypertension, and hyperthyroidism should be treated aggressively in order to reduce the frequency and severity of anginal episodes. Decreased myocardial oxygen supply may be due to reduced oxygenation of the arterial blood (e.g., in pulmonary disease or, when carboxyhemoglobin is present, due to cigarette or cigar smoking) or decreased oxygen-carrying capacity (e.g., in anemia). Correction of these abnormalities, if present, may reduce or even eliminate angina pectoris.

Adaptation of Activity Myocardial ischemia is caused by a discrepancy between the demand of the heart muscle for oxygen and the ability of the coronary circulation to meet this demand. Most patients can be helped to understand this concept and utilize it in the rational programming of activity. Many tasks that ordinarily evoke angina may be accomplished without symptoms simply by reducing the speed at which they are performed. Patients must appreciate the diurnal variation in their tolerance of certain activities and should reduce their energy requirements in the morning, immediately after meals, and in cold or inclement weather.

It may be necessary to recommend a change in employment or residence to avoid physical stress. However, with the exception of manual laborers, most patients with IHD can continue to function merely by allowing more time to complete each task. In some patients, anger and frustration may be the most important factors precipitating myocardial ischemia. If these cannot be avoided, training in stress management may be useful. A treadmill exercise test to determine the approximate heart rate at which ischemic ECG changes or symptoms develop may be helpful in the development of a specific exercise program.

Physical conditioning usually improves the exercise tolerance of patients with angina and exerts substantial psychological benefits. It may also improve the chances of surviving a myocardial infarction. A regular program of isotonic exercise within the limits of each patient's threshold for the development of angina pectoris and that does not exceed 80% of the heart rate associated with ischemia on exercise testing should be strongly encouraged.

TABLE 226-3 *Guidelines for the Treatment of Chronic Stable Angina*

Treatment of Symptoms

Class I[a]
1. Aspirin
2. β-blockers—particularly with a prior history of MI
3. Calcium antagonists as initial therapy
   a. If β-blockers are contraindicated
   b. With β-blockers to control symptom
   c. When β-blockers are stopped due to side effects
4. Sublingual nitroglycerin (tablets or spray) for relief of symptoms
5. Lipid lowering; LDL <2.6 mmol/L (100 mg/dL)
6. Health-promoting behaviors including smoking cessation, treatment of obesity, low-fat diet, supervised exercise program

Class IIa[b]
1. Clopidogrel when aspirin is contraindicated
2. Long-acting nondihydropyridine calcium antagonists (not short-acting) instead of β-blockers as initial therapy
3. Add long-acting nitrates and β-blockers or calcium antagonists for symptoms as needed

Class III[d]
1. Dypiridamole
2. Chelation therapy

Treatment of Risk Factors to Improve Outcomes

Class I
1. Smoking cessation
2. Treatment of dyslipidemia; LDL ≤2.6 mmol/L (100 mg/dL)
3. Angiotensin-converting enzyme inhibitor
4. Treatment of hypertension
5. Ideal weight and supervised exercise program
6. Low-fat diet
7. Treatment of diabetes using ADA National Guidelines

Class IIb[c]
1. Folate therapy for elevated homocysteine
2. Interventions directed at psychosocial stress

Class III
1. Hormone replacement therapy in postmenopausal women
2. Vitamins E and C
3. Treatment of depression
4. Chelation therapy
5. Herbal remedies and acupuncture

Treatment Using Revascularization

Class I
1. Coronary artery bypass surgery (CABG) for significant left main disease
2. CABG for 3-vessel coronary disease and reduced (≤50%) left ventricular function
3. CABG for 2-vessel CAD including LAD disease and reduced LV function
4. CABG for 3-vessel CAD plus high risk for percutaneous coronary intervention (PCI), abnormal (high risk) stress test, or diabetes
5. CABG in patients with prior CABG or PCI, recurrent restenosis, and high risk on noninvasive testing
6. PCI for 1- to 3-vessel CAD, normal LV function, no diabetes, lesions suitable (low risk) for PCI
7. PCI or CABG for failed medical therapy and acceptable risk with either modality

Class IIa
1. Repeat CABG for multiple vein graft stenoses, particularly including the LAD
2. PCI for simple focal vein graft stenosis
3. PCI or CABG for 1- or 2-vessel disease and moderate ischemia on noninvasive testing, including disease of the LAD

Class IIb
1. PCI instead of CABG in 2- or 3-vessel CAD (including the LAD) with controlled diabetes and lesions suitable (low risk) for PCI
2. PCI for technically suitable left main disease when CABG is not possible
3. PCI instead of CABG in 1- to 3-vessel CAD when each lesion is suitable (low risk) but the patient exhibits reduced LV function, treated diabetes, history of malignant arrhythmia, survived sudden death

Class III
1. PCI in left main disease or 3-vessel CAD with diabetes or poor LV function in patients who are candidates for CABG surgery
2. PCI or CABG in patients with mild symptoms, no evidence of ischemia in noninvasive testing, and not yet given an adequate trial of medical therapy
3. Baseline coronary stenoses (≤ 60%) and no signs of ischemia on noninvasive testing

Follow-up—Monitoring Disease, Testing, and Therapies

Class I
1. Chest x-ray with new evidence of congestive heart failure (CHF)
2. LV function testing for new evidence of CHF or MI
3. Echocardiogram for worsening of valvular disease
4. Treadmill testing for any change in clinical state
5. Stress imaging for any change in clinical state if the ECG cannot be interpreted or patient cannot exercise
6. Stress imaging for patients with prior revascularization and any change in clinical state
7. Coronary angiography in patients with obvious change in clinical state and limitations in daily activity despite medical therapy

Class IIb
1. Repeat annual treadmill exercise testing in patients with no change in clinical state, who can exercise, have no ECG abnormalities at rest, with an estimated morality of ≤ 1% per year

Class III
1. Echo or nuclear stress imaging for LV function and ischemia with no change in symptoms, normal ECG, no MI, and no CHF
2. Repeat treadmill stress test in ≤ 3 years in stable patients with estimated annual mortality ≤1% on an initial evaluation shown by:
   a. Low-risk Duke treadmill score
   b. Negative imaging study
   c. Normal LV function and no obstructive CAD
3. Stress imaging if stable, can exercise, normal resting ECG
4. Repeat coronary arteriogram with no change in clinical state, exercise testing, or stress imaging or insignificant CAD on initial examination

[a] Class I, therapies supported by evidence of efficacy.
[b] Class IIa, weight of evidence in favor of a therapy.
[c] Class IIb, evidence of efficacy less well established.
[d] Class III, therapies that are not useful and can be harmful.

Note: MI, myocardial infarction; LDL, low-density lipoprotein; ADA, American Diabetes Association; CAD, coronary artery disease; LAD, left anterior descending (coronary artery); LV, left ventricular; ECG, electrocardiogram.

Treatment of Risk Factors A *family history* of premature IHD is an important indicator of increased risk and should trigger a search for treatable risk factors such as hyperlipidemia, hypertension, and diabetes. *Obesity* impairs the treatment of other risk factors and increases the risk of adverse coronary events. In addition, obesity is often accompanied by three other risk factors—diabetes mellitus, hypertension, and hyperlipidemia. The treatment of obesity and these accompanying risk factors is an important component of any management plan. A diet low in saturated fatty acids and a caloric intake to achieve optimal body weight is a cornerstone in the management of chronic IHD. Small controlled trials have shown that the combination of a 10% fat vegetarian diet, aerobic exercise, stress management training, smoking cessation, and psychosocial support can reduce the progression of coronary obstructive lesions, reduce angina, and result in fewer coronary events.

Cigarette smoking accelerates coronary atherosclerosis in both sexes and at all ages and increases the risk of thrombosis, plaque instability, myocardial infarction, and death (Chap. 225). Also, by increasing myocardial oxygen needs and reducing oxygen supply, it aggravates angina. Smoking cessation studies have demonstrated important benefits with a significant decline in the occurrence of these adverse outcomes. The physician's message must be clear and strong and supported by programs that achieve and monitor abstinence (Chap. 375). *Hypertension* (Chap. 230) is associated with increased risk of adverse clinical events from coronary atherosclerosis as well as stroke. In addition, the left ventricular hypertrophy that results from sustained

TABLE 226-4 *Drugs Commonly Used for Angina Pectoris*

Drug	Usual Dose	Side Effects	Contraindications
NITRATES			
Sublingual NTG	0.3–0.6 mg	Flushing, headache	Intolerance of side effects
Isosorbide dinitrate SR			
Oral	10–60 mg q8h	Flushing, headache, tolerance after 24 h	As above, worsening ischemia on withdrawal
Sublingual	2.5–10 mgq4–6h		
Transdermal NTG patch	0.4–1.2 mg/h for 12–14 h	Flushing, headache, tolerance after 24 h	As above, worsening ischemia on withdrawal
Isosorbide-5-monitrate			
Oral	20–30 mg bid	Flushing, headache, tolerance after 24 h	As above, worsening ischemia on withdrawal
Oral SR	60–240 mg once daily		
BETA BLOCKERS			
Propranolol	20–80 mg qid	Depression, constipation, impotence, bronchospasm, heart failure, bradycardia	Asthma, AV conduction block, heart failure
Metoprolol	25–200 mg bid	As above	As above
Atenolol	50–150 mg once daily	As above	As above
CALCIUM CHANNEL BLOCKING DRUGS			
Nifedipine XL	30–90 mg daily	Hypotension, flushing, edema, worsening angina	Hypotension, intolerance of side effects
Diltiazem SR	60–120 mg bid	Constipation, AV conduction block, worsening heart failure	AV conduction block, impaired LV function, bradycardia
Verapamil SR	180–240 mg daily	Constipation, AV conduction block, worsening heart failure	AV conduction delay, impaired LV function, bradycardia
Amlodipine	5–10 mg daily	Edema	Intolerance of side effects

Note: NTG, nitroglycerin; SR, slow release; XL, slow release preparation.

hypertension aggravates ischemia. There is evidence that long-term, effective treatment of hypertension can decrease the occurrence of adverse coronary events. *Diabetes mellitus* (Chap. 323) accelerates coronary and peripheral atherosclerosis and is frequently associated with dyslipidemias and increases in the risk of angina, myocardial infarction, and sudden coronary death. Strict control of the dyslipidemia and hypertension that are frequently found in diabetic patients is essential, as described below.

Dyslipidemia The treatment of dyslipidemia is central when aiming for long-term relief from angina, reduced need for revascularization, and reduction in myocardial infarction and death. Epidemiologic observations, angiographic trials, and controlled trials have shown that (1) men >45 years and women >55 years with two risk factors (family history of premature IHD, cigarette smoking, hypertension), diabetes mellitus, or evidence of atherosclerotic disease should have a total cholesterol ≤ 5.17 mmol/L (≤200 mg/dL), LDL ≤ 2.58 mmol/L (≤100 mg/dL), and HDL ≥ 1.03 mmol/L (≥40 mg/dL). The control of lipids can be achieved by the combination of a diet low in saturated fatty acids, exercise, and weight loss. Frequently, HMG-CoA reductase inhibitors (statins) are required and can lower LDL cholesterol (25 to 50%), raise HDL cholesterol (5 to 9%), and lower triglycerides (5 to 30%). Niacin or fibrates can be used to raise HDL cholesterol and lower triglycerides (Chaps. 225 and 335). Controlled trials with lipid-regulating regimens have shown equal proportional benefit for men, women, the elderly, diabetics, and even smokers.

Risk Reduction in Women with IHD The incidence of clinical IHD in premenopausal women is very low. However, following the menopause, the atherogenic risk factors increase (e.g., increased LDL, reduced HDL) and the rate of clinical coronary events accelerates to the levels observed in men. Women have not given up cigarette smoking as effectively as have men. Diabetes mellitus, which is more common in women, greatly increases the occurrence of clinical IHD and amplifies the deleterious effects of hypertension, hyperlipidemia, and smoking. Cardiac catheterization and coronary revascularization are often applied more sparingly in women and at a later, and more severe, stage of the disease than in men. When cholesterol lowering, beta blockers after myocardial infarction, and coronary artery bypass grafting (CABG) are applied in the appropriate patient groups, women enjoy the same benefits of improved outcome as do men.

Compliance with regard to the health-promoting behaviors listed above is generally very poor, and the conscientious physician must not underestimate the major effort required to meet this challenge. Fewer than one-half of patients in the United States discharged from the hospital with proven coronary disease receive treatment for dyslipidemia. Given the proof that treating dyslipidemia brings major benefits, physicians need to secure treatment pathways, monitor compliance, and follow up.

Drug Therapy The commonly used drugs for the treatment of angina pectoris are summarized in Table 226-4.

NITRATES This valuable class of drugs in the management of angina pectoris acts by causing systemic venodilation, thereby reducing myocardial wall tension and oxygen requirements, and by dilating the epicardial coronary vessels and increasing blood flow in collateral vessels. The nitrates likely bind to guanylate cyclase in vascular smooth-muscle cells, oxidize sulfhydryl groups, and are converted to *S*-nitrosothiols. This leads to an increase in cyclic guanosine monophosphate, which causes relaxation of vascular smooth muscle. The absorption of these agents is most rapid and complete through the mucous membranes. For this reason, nitroglycerin is most commonly administered sublingually in tablets of 0.4 or 0.6 mg. Patients with angina should be instructed to take the medication both to relieve angina and also approximately 5 min before stress that is likely to induce an episode. The value of this prophylactic use of the drug cannot be overemphasized.

A pulsating feeling in the head or headache is the most common side effect of nitroglycerin and fortunately is only rarely disturbing at the doses usually required to relieve or prevent angina. Postural dizziness has also been reported. Nitroglycerin deteriorates with exposure to air, moisture, and sunlight, so that if the drug neither relieves discomfort nor produces a slight sensation of burning at the sublingual site of absorption, the preparation may be inactive and a fresh supply should be obtained. If relief is not achieved by rest and within 2 or 3 min after nitroglycerin, a second or third dose may be given at 5-min intervals. If discomfort continues despite treatment, the patient should consult a physician or report promptly to a hospital emergency room for evaluation of possible unstable angina or acute myocardial infarction (Chap. 228).

Nitrates improve exercise tolerance in patients with chronic angina and relieve ischemia in patients with unstable angina as well as in patients with Prinzmetal's variant angina (Chap. 227). A diary of angina and nitroglycerin use may be valuable for detecting changes in the frequency, severity, or threshold for discomfort that may signify the development of unstable angina pectoris and/or herald an impending myocardial infarction.

Long-Acting Nitrates None of the long-acting nitrates is as effective as sublingual nitroglycerin for the acute relief of angina. These prepara-

tions can be swallowed, chewed, or administered as a patch or paste by the transdermal route. They can provide effective plasma levels for up to 24 h, but the therapeutic response is highly variable. Different preparations and/or administration during the daytime should be tried only to prevent discomfort while avoiding side effects such as headache and dizziness. Individual dose titration is important in order to prevent side effects. Useful preparations include isosorbide dinitrate (10 to 60 mg orally bid or tid), nitroglycerin ointment (0.5 to 2.0 in. qid), or sustained-release transdermal patches (5 to 25 mg/d). Tolerance with loss of efficacy develops with 12 to 24 h of continuous exposure to all of the long-acting nitrates due to depletion of sulfhydryl groups, decreased benefit through increased generation of oxygen free radicals, and to counterregulatory alterations in intravascular fluid balance with fluid retention. In order to minimize the effects of tolerance, the minimum effective dose should be used and a minimum of 8 h each day kept free of the drug so as to restore any useful response(s).

β-ADRENERGIC BLOCKERS These drugs represent an important component of the pharmacologic treatment of angina pectoris. They reduce myocardial oxygen demand by inhibiting the increases in heart rate, arterial pressure, and myocardial contractility caused by adrenergic activation. Beta blockade reduces these variables most strikingly during exercise while causing only small reductions at rest. Long-acting beta-blocking drugs (e.g., atenolol, 50 to 100 mg/d, or nadolol, 40 to 80 mg/d) offer the advantage of once-a-day dosage (Table 226-4). The therapeutic aims include relief of angina and ischemia. These drugs can also reduce mortality and reinfarction in patients after myocardial infarction and are moderately effective antihypertensive agents. Relative contraindications include asthma and reversible airway obstruction in patients with chronic lung disease, atrioventricular conduction disturbances, severe bradycardia, Raynaud's phenomenon, and a history of mental depression. Side effects include fatigue, reduced exercise tolerance, nightmares, impotence, cold extremities, intermittent claudication, bradycardia (sometimes severe), impaired atrioventricular conduction, left ventricular failure, bronchial asthma, worsening claudication, and intensification of the hypoglycemia produced by oral hypoglycemic agents and insulin. Reducing the dose or even discontinuation may be necessary if these side effects develop and persist. Since sudden discontinuation can intensify ischemia, the doses should be tapered over 2 weeks.

Beta blockers with relative β_1-receptor specificity, such as metoprolol and atenolol, may be preferable in patients with mild bronchial obstruction, insulin-requiring diabetes mellitus, or intermittent claudication.

CALCIUM ANTAGONISTS Slow-release nifedipine (30 to 90 mg once daily), verapamil (80 to 120 mg tid), diltiazem (30 to 90 mg qid), amlodipine (2.5 to 10 mg daily), and other calcium antagonists are coronary vasodilators that produce variable and dose-dependent reductions in myocardial oxygen demand, contractility, and arterial pressure. These combined pharmacologic effects are advantageous and make these agents as effective as beta blockers in the treatment of angina pectoris. They are indicated when beta blockers are contraindicated, poorly tolerated, or ineffective. Verapamil and diltiazem may produce symptomatic disturbances in cardiac conduction and bradyarrhythmias.They also exert negative inotropic actions and are more likely to aggravate left ventricular failure, particularly when used in patients with left ventricular dysfunction, especially if they are also receiving beta blockers. Although useful effects are usually achieved when calcium antagonists are combined with beta blockers and nitrates, careful individual titrations of the doses are essential with these combinations. Variant (Prinzmetal's) angina responds particularly well to calcium antagonists, supplemented when necessary by nitrates (Chap. 227). Nifedipine as well as other calcium antagonists are formulated as long-acting preparations, including diltiazem (60 to 120 mg twice daily) and verapamil (180 to 240 mg once daily).

Verapamil should not ordinarily be combined with beta blockers because of the combined effects on heart rate and contractility. Diltiazem can be combined with beta blockers with caution in patients with normal ventricular function and no conduction disturbances. Amlodipine and beta blockers have complementary actions on coronary blood supply and myocardial oxygen demands. While the former decreases blood pressure and dilates coronary arteries, the latter slows heart rate and decreases contractility. Amlodipine and the other second-generation dihydropyridine calcium antagonists (nicardipine, isradipine, long-acting nifedipine, and felodipine) are potent vasodilators and useful in the simultaneous treatment of angina and hypertension. Short-acting dihydropyridines should be avoided because of the risk of precipitating infarction, particularly in the absence of beta blockers.

CHOICE BETWEEN BETA BLOCKERS AND CALCIUM ANTAGONISTS FOR INITIAL THERAPY Since beta blockers have been shown to improve life expectancy following acute myocardial infarction (Chap. 228) while calcium antagonists have not, the former may also be preferable in patients with chronic IHD. However, calcium antagonists are indicated in patients with the following: (1) inadequate responsiveness to the combination of beta blockers and nitrates; many such patients do well with a combination of a beta blocker and a dihydropyridine calcium antagonist; (2) adverse reactions to beta blockers such as depression, sexual disturbances, and fatigue; (3) angina and a history of asthma or chronic obstructive pulmonary disease; (4) sick-sinus syndrome or significant atrioventricular conduction disturbances; (5) Prinzmetal's angina; or (6) symptomatic peripheral arterial disease.

ANTIPLATELET DRUGS Aspirin is an irreversible inhibitor of platelet cyclooxygenase activity and thereby interferes with platelet activation. Chronic administration of 75 to 325 mg orally per day has been shown to reduce coronary events in asymptomatic adult men, patients with chronic stable angina, and patients with or who have survived unstable angina and myocardial infarction. Administration of this drug should be considered in all patients with IHD in the absence of gastrointestinal bleeding, allergy, or dyspepsia. Clopidogrel (300 mg loading and 75 mg/d) is an oral agent that blocks ADP receptor–mediated platelet aggregation. It provides the same benefits as aspirin, if not better, particularly if aspirin causes the side effects listed above. Clopidogrel with aspirin can improve coronary outcomes when given to patients for 1 year after an episode of unstable angina but with some increase in the risk of bleeding (Chap. 227). This increased risk is improved when the dose of aspirin is reduced.

Other Therapies The angiotensin-converting enzyme inhibitors have become widely used in the treatment of survivors of myocardial infarction, patients with hypertension or chronic IHD including angina pectoris, and those at high risk of vascular disease, such as diabetes. A large clinical trial (the Heart Outcomes Prevention Evaluation Study) has shown that up to 10 mg/d of ramipril can result in the reduction of major adverse events (death, myocardial infarction, and stroke), angina, and the need for revascularization in a group of high-risk patients with atherosclerotic cardiovascular disease (including chronic IHD) and normal left ventricular function. →***The dosing and side effects of these agents are discussed in Chaps. 216, 228, and 230.***

Enhanced external counterpulsation utilizes pneumatic cuffs on the lower extremities to provide diastolic augmentation and systolic unloading of blood pressure in order to decrease cardiac work and oxygen consumption while enhancing coronary blood flow. Recent trials have shown that regular application improves angina, exercise capacity, and regional myocardial perfusion.

In summary, a regimen of diet, exercise, smoking cessation, together with treatment of hypertension and dyslipidemia and use of aspirin and beta blockers form a treatment plan that reduces angina, the need for revascularization, myocardial infarction, and coronary death. ACE inhibitors should be used in patients with angina, particularly those with hypertension and/or diabetes.

ANGINA AND HEART FAILURE Transient left ventricular failure with angina can be controlled by the use of nitrates. For patients with established congestive heart failure the increased left ventricular wall tension raises myocardial oxygen demand. Treatment of congestive heart failure with an angiotensin-converting enzyme inhibitor, diuretic, and digitalis (Chap. 216) reduces heart size, wall tension, and myocardial oxygen demand, which, in turn, helps to control angina and ischemia. If the symptoms and signs of heart failure are controlled, every effort should be made to cautiously use beta blockers not only for angina but because trials in heart failure have shown significant improvement in survival. Nocturnal angina can often be relieved by the treatment of heart failure. Nitrates are useful and can simultaneously improve the disturbed hemodynamics of congestive heart failure by vasodilatation, thereby reducing preload, and relieve angina by preventing or reversing myocardial ischemia. The combination of congestive heart failure and angina in patients with IHD usually indicates a poor prognosis and warrants serious consideration of cardiac catheterization and coronary revascularization.

CORONARY REVASCULARIZATION

While the basic management of patients with IHD is medical, as described above, many patients are improved by coronary revascularization procedures. These interventions should be employed in conjunction with but do not replace the continuing need to modify risk factors and medical therapy.

PERCUTANEOUS CORONARY INTERVENTION (See also Chap. 229 and Table 226-5) PCI, most commonly percutaneous transluminal coronary angioplasty with stenting, is widely used to achieve revascularization of the myocardium in patients with symptomatic IHD and suitable stenoses of epicardial coronary arteries. Whereas patients with stenosis of the left main coronary artery and those with three-vessel IHD (especially with diabetes and/or impaired left ventricular function) who require revascularization are best treated with CABG, PCI is widely employed in patients with symptoms and evidence of ischemia due to stenoses of one or two vessels, and even in selected patients with three-vessel disease, and may offer many advantages over surgery.

Indications and Patient Selection The most common clinical indication for PCI is angina pectoris, despite medical therapy, accompanied by evidence of ischemia during a stress test. PCI is more effective than medical therapy for the relief of angina. Whereas PCI improves outcomes in patients with unstable angina and myocardial infarction, the value of this procedure in reducing the occurrence of coronary death and myocardial infarction in patients with chronic stable angina has not been established. PCI can be used to treat stenoses in native coronary arteries as well as in bypass grafts in patients who have recurrent angina following CABG. This is an important indication when the technical difficulties and the increased mortality that accompanies reoperation are considered. PCI has also been carried out in patients with recent total occlusion (within 3 months) of a coronary artery and angina; in this group the primary success rate is slightly decreased.

TABLE 226-5 *Comparison of Revascularization Procedures in Multivessel Disease*

Procedure	*Advantages*	*Disadvantages*
Percutaneous coronary intervention (PCI)	Less invasive Shorter hospital stay Lower initial cost Easily repeated Effective in relieving symptoms	Restenosis High incidence of incomplete revascularization Unknown effect on outcomes in patients with severe left ventricular dysfunction Limited to specific anatomic subsets Poor outcome in diabetics with 2- or 3-vessel coronary disease
Coronary artery bypass grafting (CABG)	Effective in relieving symptoms Improved survival in certain subsets Ability to achieve complete revascularization	Cost Increased risk of a repeat procedure due to late graft closure Morbidity and mortality of major surgery

Source: Modified from DP Faxon, in GA Beller (ed), *Chronic Ischemic Heart Disease,* in E Braunwald (series ed), *Atlas of Heart Diseases,* Philadelphia, Current Medicine, 1995.

Risks When coronary stenoses are discrete and symmetric, two and even three vessels can be dilated in sequence. However, case selection is essential in order to avoid a prohibitive risk of complications, which are usually due to dissection or thrombosis with vessel occlusion, uncontrolled ischemia, and ventricular failure. Oral aspirin, clopidogrel, and intravenous heparin are given to reduce coronary thrombus formation. In unstable angina and when intracoronary thrombus is seen, the use of specific platelet glycoprotein receptor (GpIIb/IIIa) antagonists further reduces thrombotic complications and increases success. In experienced hands, the overall mortality rate is $<0.5\%$, the need for emergency coronary surgery $<1\%$, and the occurrence of clinical myocardial infarction $<2\%$. Minor complications occur in 5 to 10% of patients and include occlusion of a branch of a coronary artery, myocardial infarction manifest only by release of CK-MB into the circulation, and complications of arterial catheterization. Left main coronary artery stenosis is generally regarded as a contraindication to PCI; such patients should be treated with CABG.

Efficacy Primary success, i.e., adequate dilation (an increase in luminal diameter $>20\%$ to a residual diameter obstruction $<50\%$) with relief of angina, is achieved in $>95\%$ of cases. Recurrent stenosis of the dilated vessels occurs in $\sim 20\%$ of cases within 6 months of PCI with base metal stents, and angina will recur within 6 months in 10% of cases. Restenosis is more common in patients with diabetes mellitus, arteries with small caliber, incomplete dilation of the stenosis, occluded vessels, obstructed vein grafts, dilation of the left anterior descending coronary artery, and stenoses containing thrombi. It is usual clinical practice to administer aspirin for months after the procedure. Although aspirin and the antiplatelet drug clopidogrel may help prevent acute coronary thrombosis during and shortly following PCI with stenting, there is no evidence that these medications reduce the incidence of restenosis. Controlled trials have shown that the catheter-based local delivery of beta irradiation can significantly reduce the recurrence of in-stent restenosis. In diseased vein grafts procedural success has been improved by the use of capture devices or filters that prevent embolization, ischemia, and infarction. Moreover, the use of stents that locally deliver antiproliferative drugs such as rapamycin can reduce restenosis to near zero within the stent and 3 to 7% at the edges. These significant advances are extending the use of PCI.

Successful PCI produces effective relief of angina in $>95\%$ of cases and has been shown to be more effective than medical therapy for up to 2 years. More than one-half of patients with symptomatic IHD who require revascularization can be treated initially by PCI. Successful PCI is less invasive and expensive than CABG, usually requires only 1 to 2 days in the hospital, and permits considerable savings in the initial cost of care. Successful PCI also allows earlier return to work and the resumption of an active life. However, this economic benefit is reduced over time because of the greater need for follow-up and for repeat procedures. Clinical trials in patients after PCI have shown improvements in outcome with statin treatment.

CORONARY ARTERY BYPASS GRAFTING (See Table 226-5) Anastomosis of one or both of the internal mammary arteries or a radial artery to the coronary artery distal to the obstructive lesion is carried out. For additional obstructions that cannot be bypassed by an artery, a section of a vein (usually the saphenous) is used to form a connection between the aorta and the coronary artery distal to the obstructive lesion.

Although some indications for CABG are controversial, certain areas of agreement exist:

1. The operation is relatively safe, with mortality rates <1% in patients without serious comorbid disease and normal left ventricular function, and when the procedure is performed by an experienced surgical team.
2. Intraoperative and postoperative mortality increase with the severity of ventricular dysfunction, comorbidities, age >80 years, and lack of surgical experience. The effectiveness and risk of CABG vary widely depending on case selection and the skill and experience of the surgical team.
3. Occlusion of *venous* grafts is observed in 10 to 20% of patients during the first postoperative year and in approximately 2% per year during 5- to 7-year follow-up and 4% per year thereafter. Long-term patency rates are considerably higher for internal mammary and radial artery implantations than saphenous vein grafts. In patients with left anterior descending coronary artery obstruction, survival is better when coronary bypass involves the internal mammary artery rather than a saphenous vein. Graft patency and outcomes are improved by meticulous treatment of risk factors, particularly dyslipidemia.
4. Angina is abolished or greatly reduced in ~90% of patients following complete revascularization. Although this is usually associated with graft patency and restoration of blood flow, the pain may also have been alleviated as a result of infarction of the ischemic segment or a placebo effect. Within 3 years, angina recurs in about one-fourth of patients but is rarely severe.
5. Survival may be improved by operation in patients with stenosis of the left main coronary artery as well as in patients with three- or two-vessel disease with significant obstruction of the proximal left anterior descending coronary artery. The survival benefit is greater in patients with abnormal left ventricular function (ejection fraction < 50%). Survival *may* also be improved in the following patients: (1) with obstructive CAD who have survived sudden cardiac death or sustained ventricular tachycardia; (2) who have undergone previous CABG and who have multiple saphenous vein graft stenoses, especially of a graft supplying the left anterior descending coronary artery; and (3) with recurrent stenosis following PCI, and high-risk criteria on noninvasive testing.
6. Minimally invasive CABG through a small thoracotomy and/or off-pump surgery can reduce morbidity and shorten convalescence in suitable patients.

Indications for CABG are usually based on the severity of symptoms, coronary anatomy, and ventricular function. The ideal candidate is male, <80 years of age, has no other complicating disease, has troublesome or disabling angina that is not adequately controlled by medical therapy or does not tolerate medical therapy and wishes to lead a more active life, and has severe stenoses of two or three epicardial coronary arteries with objective evidence of myocardial ischemia as a cause of the chest discomfort. Great symptomatic benefit can be anticipated in such patients. Congestive heart failure and/or left ventricular dysfunction, advanced age (>80 years), reoperation, urgent need for surgery, and the presence of diabetes mellitus are all associated with a higher perioperative mortality.

Left ventricular dysfunction can be due to noncontractile segments that are viable (hibernating myocardium). These can be detected by using radionuclide scans of myocardial perfusion and metabolism, positron emission tomography, or delayed scanning with thallium-201 or by improvement of regional functional impairment, provoked by low-dose dobutamine. In such patients, revascularization can return function and improve survival.

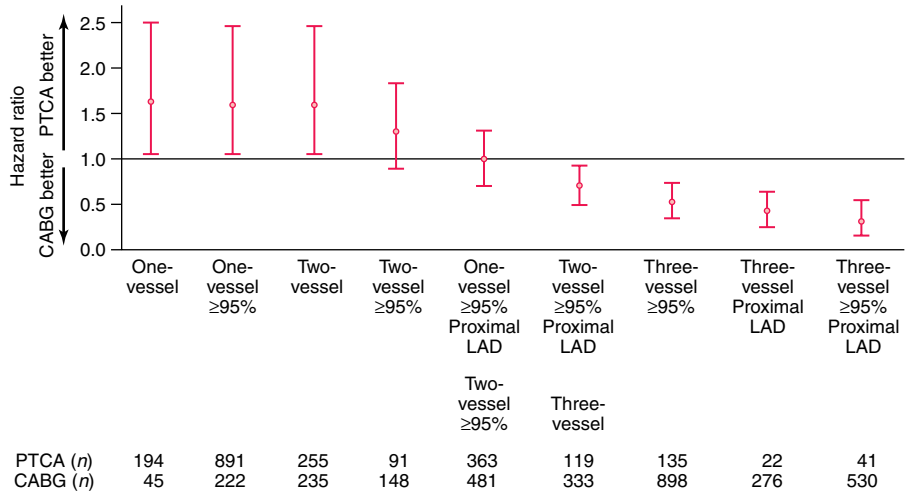

FIGURE 226-2 Results from the Duke database comparing percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass grafting (CABG). The preferred method of therapy depends on the extent and severity of coronary disease. PTCA seems to be superior in patients with less extensive disease, whereas CABG is more advantageous for patients with more extensive coronary disease. LAD, left anterior descending [*Modified from RH Jones et al. J Thorac Cardiovasc Surg III: 1013, 1996; with permission.*]

The Choice between PCI and CABG (Table 226-5; Fig. 226-2) A number of randomized clinical trials have compared PCI and CABG in patients with multivessel CAD who were suitable technically for both procedures. The redevelopment of angina requiring repeat coronary angiography and repeat revascularization due to restenosis was higher in the PCI groups. (This disadvantage of PCI may be abolished by the use of drug-eluting stents.) However, the occurrence of death or myocardial infarction has been found to be similar between both groups for up to 5 years. In patients with diabetes mellitus as well as obstruction of two or more coronary arteries, CABG results in significantly better outcomes and survival and should be the revascularization technique of choice.

Based on these trials and observational studies, it is now recommended that patients with an unacceptable level of angina despite optimal medical management be considered for coronary revascularization. Patients with single- or two-vessel disease with normal left ventricular function and anatomically suitable lesions are ordinarily advised to undergo PCI (Chap. 229). Patients with three-vessel disease (or two-vessel disease that includes the proximal left desending coronary artery) and impaired global left ventricular function (left ventricular ejection fraction < 50%) or diabetes mellitus or those with left main coronary artery disease or other lesions unsuitable for catheter-based procedures should be considered for CABG as the initial method of revascularization (Table 226-3, Table 226-5, and Fig. 226-2).

ASYMPTOMATIC (SILENT) ISCHEMIA

Obstructive CAD, acute myocardial infarction, and transient myocardial ischemia are frequently asymptomatic. During continuous ambulatory ECG monitoring, the majority of ambulatory patients with typical chronic stable angina are found to have objective evidence of myocardial ischemia (ST-segment depression) during episodes of chest discomfort while they are active outside the hospital, but many of these patients have more frequent episodes of asymptomatic ischemia. In addition, there is a large (but as yet unknown) number of totally asymptomatic persons with severe coronary atherosclerosis who exhibit ST-segment changes during activity. Some of these patients exhibit higher thresholds to electrically induced pain, others show higher endorphin levels, and still others may be diabetics with autonomic dysfunction.

Frequent episodes of ischemia (symptomatic and asymptomatic) during daily life appear to be associated with an increased likelihood of adverse coronary events (death and myocardial infarction). In addition, patients with asymptomatic ischemia after suffering a myocardial infarction are at greater risk for a second coronary event. The

widespread use of exercise ECG during routine examinations has also identified some of these heretofore unrecognized patients with asymptomatic CAD. Longitudinal studies have demonstrated an increased incidence of coronary events in asymptomatic patients with positive exercise tests.

TREATMENT

The management of patients with asymptomatic ischemia must be individualized. Thus, the physician should consider the following: (1) the degree of positivity of the stress test, particularly the stage of exercise at which ECG signs of ischemia appear, the magnitude and number of the perfusion defect(s) on thallium scintigraphy, and the change in left ventricular ejection fraction which occurs on radionuclide ventriculography or echocardiography during ischemia and/or during exercise; (2) the ECG leads showing a positive response, with changes in the anterior precordial leads indicating a less favorable prognosis than changes in the inferior leads; and (3) the patient's age, occupation, and general medical condition. Most would agree that an asymptomatic 45-year-old commercial airline pilot with 0.4-mV ST-segment depression in leads V_1 to V_4 during mild exercise should undergo coronary arteriography, whereas the asymptomatic, sedentary 75-year-old retiree with 0.1-mV ST-segment depression in leads II and III during maximal activity need not. However, there is no consensus about the appropriate procedure in the large majority of patients for whom the situation is less extreme. Asymptomatic patients with silent ischemia, three-vessel CAD, and impaired left ventricular function may be considered appropriate candidates for CABG.

The treatment of risk factors, particularly lipid lowering as described above, and the use of aspirin and beta blockers have been shown to reduce events and improve outcomes in asymptomatic as well as symptomatic patients with ischemia and proven CAD. While the incidence of asymptomatic ischemia can be reduced by treatment with beta blockers, calcium channel antagonists, and long-acting nitrates, it is not clear whether this is necessary or desirable in patients who have not suffered a myocardial infarction. However, there is evidence that β-adrenoceptor blockade begun 7 to 35 days after acute myocardial infarction improves survival (Chap. 228).

227 UNSTABLE ANGINA AND NON-ST-ELEVATION MYOCARDIAL INFARCTION

Christopher P. Cannon, Eugene Braunwald

Patients with ischemic heart disease fall into two large groups: patients with stable angina secondary to chronic coronary artery disease (Chap. 226) and patients with acute coronary syndromes (ACS). The latter group, in turn, is composed of patients with acute myocardial infarction (MI) with ST-segment elevation on their presenting electrocardiogram (STEMI; Chap. 228) and those with unstable angina (UA) and non-ST-segment elevation MI (UA/NSTEMI; Fig. 228-1). Every year in the United States, ~1.4 million patients are admitted to hospitals with UA/NSTEMI as compared with 400,000 patients with acute STEMI.

DEFINITION The diagnosis of UA is based largely on the clinical presentation. *Stable* angina pectoris is characterized by chest or arm discomfort that is rarely described as pain, but that is reproducibly associated with physical exertion or stress and is relieved within 5 to 10 min by rest and/or sublingual nitroglycerin (Chaps. 12 and 226). UA is defined as angina pectoris or equivalent ischemic discomfort with at least one of three features: (1) it occurs at rest (or with minimal exertion) usually lasting > 10 min, (2) it is severe and of new onset (i.e., within the prior 4 to 6 weeks), and/or (3) it occurs with a crescendo pattern (i.e., distinctly more severe, prolonged, or frequent than previously). The diagnosis of NSTEMI is established if a patient with the clinical features of UA develops evidence of myocardial necrosis, as reflected in elevated cardiac biomarkers.

PATHOPHYSIOLOGY UA/NSTEMI can be caused by a reduction in oxygen supply and/or by an increase in myocardial oxygen demand (e.g., by tachycardia or severe anemia) superimposed on a coronary obstruction. Four pathophysiologic processes that may contribute to the development of UA have been identified: (1) plaque rupture or erosion with superimposed nonocclusive thrombus, believed to be the most common cause; (2) dynamic obstruction [e.g., coronary spasm, as in Prinzmetal's variant angina (p. 1448)]; (3) progressive mechanical obstruction [e.g., rapidly advancing coronary atherosclerosis or restenosis following percutaneous coronary intervention (PCI)]; and (4) secondary UA related to increased myocardial oxygen demand and/or decreased supply (e.g., anemia). More than one of these processes may be involved in many patients.

Among patients with UA/NSTEMI studied at angiography, ~5% have left main stenosis, 15% have three-vessel coronary artery disease, 30% have two-vessel disease, 40% have single-vessel disease, and 10% have no critical coronary stenosis; some of the latter have Prinzmetal's variant angina (see below). The "culprit lesion" on angiography may show an eccentric stenosis with scalloped or overhanging edges and a narrow neck. Angioscopy may reveal "white" (platelet-rich) thrombi, as opposed to "red" thrombi, more often seen in patients with acute STEMI.

CLINICAL PRESENTATION ■ History and Physical Examination The clinical hallmark of UA/NSTEMI is chest pain, typically located in the substernal region or sometimes in the epigastrium, that frequently radiates to the neck, left shoulder, and left arm (Chap. 12). This discomfort is usually severe enough to be considered painful. Anginal "equivalents" such as dyspnea and epigastric discomfort may also occur. The examination resembles that in patients with stable angina (Chap. 226) and may be unremarkable. If the patient has a large area of myocardial ischemia or a large NSTEMI, the physical findings can include dia-

phoresis, pale cool skin, sinus tachycardia, a third and/or fourth heart sound, basilar rales, and sometimes hypotension, resembling the findings of large STEMI.

Electrocardiogram In UA, ST-segment depression, transient ST-segment elevation, and/or T-wave inversion occur in 30 to 50% of patients, depending on the severity of the clinical presentation. In patients with the clinical features of UA, the presence of new ST-segment deviation, even of only 0.05 mV, is an important predictor of adverse outcome. T-wave changes are sensitive for ischemia but are less specific, unless they are new, deep T-wave inversions (≥0.3 mV).

Cardiac Biomarkers Patients with UA who have elevated biomarkers of necrosis, such as CK-MB and troponin (a much more specific marker of myocardial necrosis), are at increased risk for death or recurrent MI. Elevated levels of these markers distinguish patients with NSTEMI from those with UA. There is a direct relationship between the degree of troponin elevation and mortality. However, in patients *without* a clear clinical history of myocardial ischemia, minor troponin elevations have been reported and can be caused by congestive heart failure, myocarditis, or pulmonary embolism or may be false-positive readings. Thus, in patients with an *unclear* history, small troponin elevations may not be diagnostic of an ACS.

DIAGNOSTIC EVALUATION (See also Chap. 12) Approximately 6 to 7 million persons per year in the United States present to hospital emergency departments (EDs) with a complaint of chest pain or other symptoms suggestive of ACS. A diagnosis of an ACS is established in 20 to 25% of such patients. The first step in evaluating patients with possible UA/NSTEMI is to determine the *likelihood* that coronary artery disease is the cause of the presenting symptoms. The 2002 American College of Cardiology/American Heart Association (ACC/AHA) Guidelines include, among the factors associated with a high likelihood of ACS, a clinical history typical of ischemic discomfort, a history of established coronary artery disease by angiography, prior MI, congestive heart failure, new electrocardiographic (ECG) changes, or elevated cardiac biomarkers. Factors associated with an intermediate likelihood of ACS in patients with the clinical features of this condition are: age >70 years, male gender, diabetes mellitus, known peripheral arterial or cerebrovascular disease, and old ECG abnormalities.

Diagnostic Pathways There are four major diagnostic tools used in the diagnosis of UA/NSTEMI in the ED—the clinical history, the ECG, cardiac markers, and stress testing. The goals are to: (1) recognize or exclude MI (using cardiac markers), (2) evaluate for rest ischemia (chest pain at rest, serial or continuous ECGs), and (3) evaluate for significant coronary artery disease (using provocative stress testing). Typical pathways begin with assessment of the likelihood that the presenting symptoms are due to ischemia. Patients with a low likelihood of ischemia are usually managed with an ED-based critical pathway (which in some institutions is carried out in a "chest pain unit" (Fig. 227-1). Evaluation of such patients includes clinical monitoring for recurrent ischemic discomfort, serial ECGs, and cardiac markers, typically performed at baseline and at 4 to 6 h and 12 h after presentation. If new elevations in cardiac markers (currently CK-MB and troponin) or ECG changes are noted, the patient is admitted to the hospital. If the patient remains pain free and the markers are negative, the patient may go on to stress testing. This may be performed as early as 6 h after presentation in the ED or chest pain center, or on an outpatient basis within 72 h. For most patients, standard treadmill ECG stress testing is used, but for patients with fixed abnormalities on the ECG (e.g., left bundle branch block), perfusion or echocardiographic imaging is used. For patients who cannot walk, pharmacologic stress is used. By demonstrating normal myocardial perfusion, sestamibi or thallium imaging (Chap. 211) can reduce unnecessary hospitalizations by excluding acute ischemia.

RISK STRATIFICATION AND PROGNOSIS Patients with documented UA/NSTEMI exhibit a wide spectrum of early (30 day) risk, ranging from ~2 to 10%, and of new or recurrent infarction of 3 to 10%. Assessment of "global risk" can be accomplished by clinical risk scoring systems

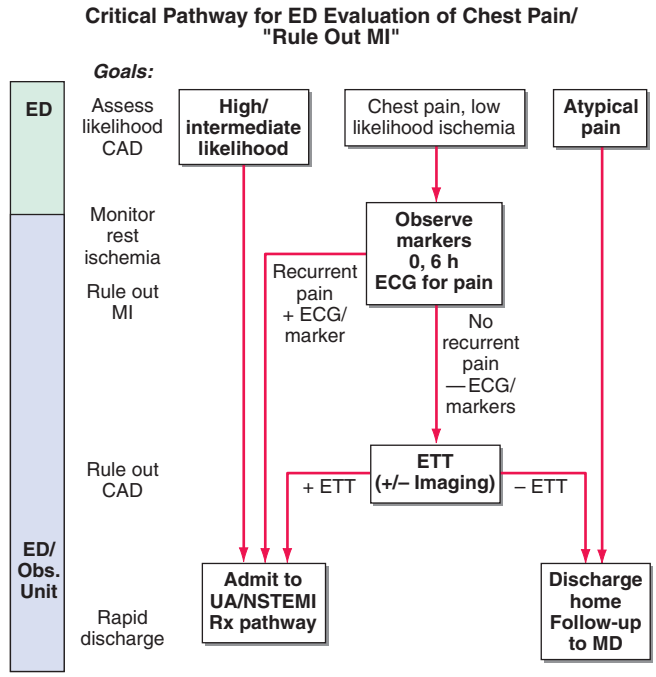

FIGURE 227-1 Diagnostic evaluation of patients presenting with suspected UA/NSTEMI. The first step is to assess the likelihood of coronary artery disease. Patients at high or intermediate likelihood are admitted to the hospital. Those with clearly atypical chest pain are discharged home. Patients with a *low* likelihood of ischemia enter the pathway and are observed in a monitored bed in the emergency department (ED) or observation unit over a period of 6 h and 12-lead electrocardiograms are performed if the patient has recurrent chest discomfort. A panel of cardiac markers (e.g., troponin and CK-MB) are drawn at baseline and 6 h later. If the patient develops recurrent pain, has ST-segment or T-wave changes, or had positive cardiac markers, he/she is admitted to the hospital and treated for UA/NSTEMI. If the patient has negative markers and no recurrence of pain, he/she is sent for exercise treadmill testing, with imaging reserved for patients with abnormal baseline electrocardiograms (e.g., left bundle branch block or left ventricular hypertrophy). If positive, the patient is admitted; if negative, the patient is discharged home with follow-up to his/her primary physician. (CAD, coronary artery disease; ECG,electrocardiogram; E.D., emergency department; ETT, exercise tolerance test; MI, myocardial infarction; OBS, observation unit.) [*Adapted from CP Cannon, E Braunwald, in E Braunwald et al (eds): Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed. Philadelphia, Saunders, 2001.*]

such as that used in the Thrombolysis in Myocardial Ischemia Trial (TIMI), which includes seven independent risk factors: age ≥ 65 years, three or more risk factors for coronary artery disease, documented coronary artery disease at catheterization, development of UA/NSTEMI while on aspirin, more than two episodes of angina within the preceeding 24 h, ST deviation ≥ 0.5 mm, and an elevated cardiac marker (Fig. 227-2).

Early risk assessment (especially using troponin, ST-segment changes, and/or a global risk scoring system) is useful both in predicting the risk of recurrent cardiac events and in identifying those patients who would derive the greatest benefit from the newer and more potent antithrombotic therapies, such as low-molecular-weight heparin (LMWH) and glycoprotein (GP)IIb/IIIa inhibitors, and from an early invasive strategy. For example, in the TACTICS-TIMI 18 Trial, an early invasive strategy conferred a 40% reduction in recurrent cardiac events in patients with a positive troponin level, whereas no benefit was observed in those with a negative troponin level.

Among other cardiac biomarkers under intensive investigation are C-reactive protein, B-type natriuretic peptide, and CD-40 ligand, all of which correlate independently with increased mortality and recurrent cardiac events in patients presenting with UA/NSTEMI. Multimarker strategies are now gaining favor both to define the pathophysiologic mechanisms underlying a given patient's presentation more fully and to stratify the patient's risk further.

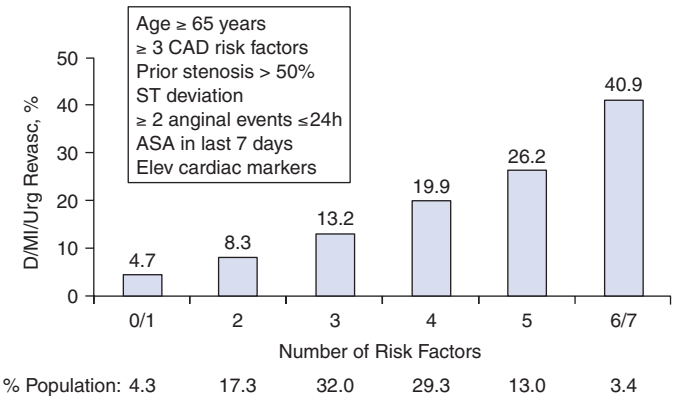

FIGURE 227-2 The TIMI Risk Score for UA/NSTEMI, a simple but comprehensive clinical risk stratification score to identify increasing risk of death, myocardial infarction, or urgent revascularization to day 14. (*Adapted from Antman et al.*)

TREATMENT

Medical Treatment Patients with UA/NSTEMI should be placed at bed rest with continuous ECG monitoring for ST-segment deviation and cardiac rhythm. Ambulation is permitted if the patient shows no recurrence of ischemia (discomfort or ECG changes) and does not develop a biomarker of necrosis for 12 to 24 h. Medical therapy involves simultaneous anti-ischemic treatment and antithrombotic treatment.

Anti-Ischemic Treatment (Table 227-1) In order to provide relief and prevention of recurrence of chest pain, initial treatment should include nitrates and beta blockers.

NITRATES Nitrates should first be given sublingually or by buccal spray (0.3 to 0.6 mg) if the patient is experiencing ischemic pain. If pain persists after three doses given 5 min apart, intravenous nitroglycerin (5 to 10 μg/min using nonabsorbing tubing) is recommended. The rate of the infusion may be increased by 10 μg/min every 3 to 5 min until symptoms are relieved or systolic arterial pressure falls to <90 mmHg. Topical or oral nitrates (Chap. 226) can be used once the pain has resolved, or they may replace intravenous nitroglycerin when the

TABLE 227-1 *Drugs Commonly Used in Intensive Medical Management of Patients with Unstable Angina and Non-ST Elevation MI*

Drug Category	Clinical Condition	When to Avoid[a]	Dosage
Nitrates	Symptoms are not fully relieved with three sublingual nitroglycerin tablets and initiation of beta-blocker therapy	Hypotension	5–10 μg/min by continuous infusion Titrated up to 75–100 μg/min until relief of symptoms or limiting side effects (headache or hypotension with a systolic blood pressure <90 mmHg or more than 30% below starting mean arterial pressure levels if significant hypertension is present) Topical, oral, or buccal nitrates are acceptable alternatives for patients without ongoing or refractory symptoms
Beta blockers[b]	Unstable angina	PR interval (ECG) >0.24 s 2° or 3° atrioventricular block Heart rate <60 beats/min Blood pressure <90 mmHg Shock Left ventricular failure with congestive heart failure Severe reactive airway disease	Metoprolol[c] 5-mg increments by slow (over 1–2 min IV administration Repeated every 5 min for a total initial dose of 15 mg Followed in 1–2 h by 25–50 mg by mouth every 6 h If a very conservative regimen is desired, initial doses can be reduced to 1–2 mg Esmolol[c] Starting maintenance dose of 0.1 mg/kg per min IV Titration in increments of 0.05 mg/kg per min every 10–15 min as tolerated by blood pressure until the desired therapeutic response has been obtained, limiting symptoms develop, or a dose of 0.20 mg/kg per min is reached Optional loading dose of 0.5 mg/kg may be given by slow IV administration (2–5 min) for more rapid onset of action
Calcium channel blockers	Patients whose symptoms are not relieved by adequate doses of nitrates and beta blockers or in patients unable to tolerate adequate doses of one or both of these agents or in patients with variant angina	Pulmonary edema Evidence of left ventricular dysfunction (for diltiazem or verapamil)	Dependent on specific agent
Morphine sulfate	Patients whose symptoms are not relieved after three serial sublingual nitroglycerin tablets or whose symptoms recur with adequate anti-ischemic therapy	Hypotension Respiratory depression Confusion Obtundation	2–5 mg IV dose May be repeated every 5–30 min as needed to relieve symptoms and maintain patient comfort

[a] Allergy or prior intolerance is a contraindication for all categories of drugs listed in this chart.
[b] Choice of the specific agent is not as important as ensuring that appropriate candidates receive this therapy. If there are concerns about patient intolerance owing to existing pulmonary disease, especially asthma, left ventricular dysfunction, or risk of hypotension or severe bradycardia, initial selection should favor a short-acting agent, such as propranolol or metoprolol or the ultra-short-acting agent esmolol. Mild wheezing or a history of chronic obstructive pulmonary disease should prompt a trial of a short-acting agent at a reduced dose (e.g., 2.5 mg IV metoprolol, 12.5 mg oral metoprolol, or 25 μg/kg per min esmolol as initial doses) rather than complete avoidance of beta-blocker therapy.
[c] Metoprolol and esmolol are two of several beta blockers that may be employed.
Note: Some of the recommendations in this guide suggest the use of agents for purposes or in doses other than those specified by the U.S. Food and Drug Adminstration. Such recommendations are made after consideration of concerns regarding nonapproved indications. Where made such recommendations are based on more recent clinical trials or expert consensus.
IV, intravenous; aPTT, activated partial thromboplastin time; ECG, electrocardiogram; 2°, second-degree, 3°, third-degree.

patient has been pain free for 12 to 24 h. The only absolute contraindications to the use of nitrates are hypotension or the use of sildenafil (Viagra) or other drugs in that class within the previous 24 h.

***β*-ADRENERGIC BLOCKADE** These agents are the other mainstay of anti-ischemic treatment. Intravenous beta blockade followed by oral beta blockade targeted to a heart rate of 50 to 60 beats/min is recommended. Heart rate–slowing calcium channel blockers, e.g., verapamil or diltiazem, are recommended in patients who have persistent or recurrent symptoms after treatment with full-dose nitrates and beta blockers and in patients with contraindications to beta blockade. Additional medical therapy includes angiotensin-converting enzyme (ACE) inhibition and HMG-CoA reductase inhibitors (statins) for long-term secondary prevention.

If pain persists despite intravenous nitroglycerin and beta blockade, morphine sulfate, 1 to 5 mg intravenously, can be administered every 5 to 30 min as needed.

Antithrombotic Therapy (Table 227-2) This is the other main component of treatment for UA/NSTEMI. Initial treatment should begin with the platelet cyclooxygenase inhibitor aspirin (Fig. 227-3). The thienopyridine clopidogrel, which blocks the platelet adenosine receptor (in combination with aspirin), was shown in the CURE trial to confer a 20% relative reduction in cardiovascular death, MI, or stroke compared with aspirin alone in both low- and high-risk patients with UA/NSTEMI, but to be associated with a moderate (absolute 1%) increase in serious bleeding, which is more marked in patients who undergo coronary artery bypass grafting. Pretreatment with clopidogrel has also been shown to reduce adverse outcomes associated with and following PCI (Chap. 229). Continued benefit of long-term (~1 year) treatment with the combination of clopidogrel and aspirin has been observed both in patients treated conservatively and in those who underwent a PCI. This combination is recommended for all patients with UA/NSTEMI who are not at excessive risk for bleeding.

Unfractionated heparin (UFH) or LMWH should be added to aspirin and clopidogrel. Based on several randomized trials showing the superiority of the LMWH enoxaparin to UFH in reducing recurrent cardiac events, the 2002 ACC/AHA UA/NSTEMI guidelines favor enoxaparin as the preferred antithrombin. Direct thrombin inhibitors and factor Xa inhibitors are being studied as replacements for heparin.

Intravenous GP IIb/IIIa inhibitors have also been shown to be beneficial in treating UA/NSTEMI (Fig. 227-3). For "upstream" management of high-risk patients in whom an invasive management is intended (i.e., initiating therapy when the patient first presents to the hospital), the small molecule inhibitors eptifibatide and tirofiban show benefit, while the monoclonal antibody abciximab appears not to be effective in patients treated conservatively, (i.e., in those not undergoing coronary angiography or PCI). However, abciximab has been shown to be beneficial in patients with UA/NSTEMI undergoing PCI. As with all antithrombotic agents, bleeding is the most important adverse effect of these drugs. Thus, patients with a history of bleeding must be screened carefully and given fewer antithrombotic agents.

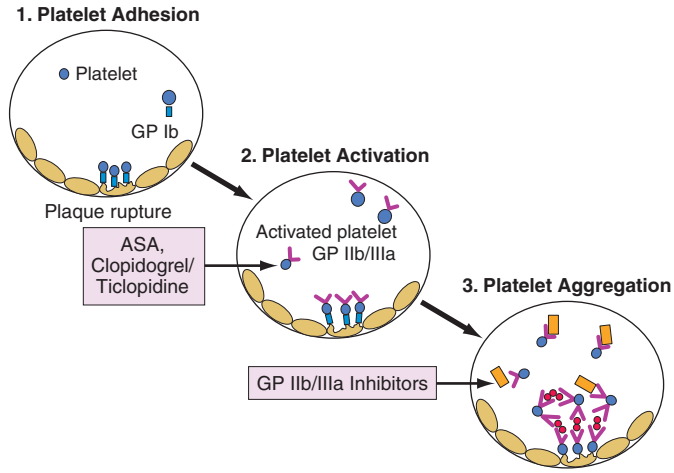

FIGURE 227-3 Platelets initiate thrombosis at the site of a ruptured plaque: *platelet adhesion* occurs via: (1) the GP 1b receptor in conjunction with von Willebrand factor. This is followed by *platelet activation* (2), which leads to a shape change in the platelet, degranulation of the alpha and dense granules, and expression of glycoprotein IIb/IIIa receptors on the platelet surface with activation of the receptor, such that it can bind fibrinogen. The final step is *platelet aggregation* (3), in which fibrinogen (or von Willebrand factor) binds to the activated GP IIb/IIIa receptors. Aspirin (ASA) and clopidogrel act to decrease platelet activation, whereas the glycoprotein IIb/IIIa inhibitors inhibit the final step of platelet aggregation. [*From CP Cannon, E Braunwald, in E Braunwald et al (eds): Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed. Philadelphia, Saunders, 2001.*]

INVASIVE VERSUS CONSERVATIVE STRATEGY Multiple clinical trials have shown the benefit of an early invasive strategy in high-risk patients, i.e., patients with multiple clinical risk factors, ST-segment deviation, and/or positive biomarkers (Table 227-3). In this strategy, following treatment with anti-ischemic and antithrombotic agents, coronary arteriography is carried out within ~48 h of admission, followed by coronary revascularization (PCI or coronary artery bypass grafting), depending on the coronary anatomy.

Such a strategy is quite cost-effective in high-risk patients. In low-risk patients, the outcomes from an invasive strategy are similar to those obtained from a conservative strategy, which consists of anti-

TABLE 227-2 *Clinical Use of Antithrombotic Therapy*

ORAL ANTIPLATELET THERAPY	
Aspirin	Initial dose of 162–325 mg nonenteric formulation followed by 75–160 mg/d of an enteric or a nonenteric formulation
Clopidogrel (Plavix)	Loading dose of 300 mg followed by 75 mg/d
HEPARINS[a]	
Dalteparin (Fragmin)	120 IU/kg SC every 12 h (maximum 10,000 IU twice daily)
Enoxaparin (Lovenox)	1 mg/kg SC every 12 h; the first dose may be preceded by a 30-mg IV bolus
Heparin (UFH)	Bolus 60–70 U/kg (maximum 5000 U) IV followed by infusion of 12–15 U/kg per h (initial maximum 1000 U/h) titrated to a PTT 1.5–2.5 times control
INTRAVENOUS ANTIPLATELET THERAPY	
Abciximab (ReoPro)	0.25 mg/kg bolus followed by infusion of 0.125 μg/kg per min (maximum 10 μg/min) for 12 to 24 h
Eptifibatide (Integrilin)	180 μg/kg bolus followed by infusion of 2.0 μg/kg per min for 72 to 96 h
Tirofiban (Aggrastat)	0.4 μg/kg per min for 30 min followed by infusion of 0.1 μg/kg per min for 48 to 96 h

[a] Other LMWH exist beyond those listed.

TABLE 227-3 *Class I Recommendations for Use of an Early Invasive Strategy*[a]

Class I (level of evidence: A) indications
Recurrent angina at rest/low-level activity despite Rx
Elevated TnT or TnI
New ST-segment depression
Rec. angina/ischemia with CHF symptoms, rales, MR
Positive stress test
EF < 0.40
Decreased BP
Sustained VT
PCI < 6 mos, prior CABG

[a] Any one of the high-risk indicators.
Abbreviations: TnT, troponin T; TnI, troponin I; CHF, congestive heart failure; MR, mitral regurgitation; EF, ejection fraction; BP, blood pressure; VT, ventricular tachycardia; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting.

ischemic and antithrombotic therapy followed by "watchful waiting," in which coronary arteriography is carried out only if rest pain or ST-segment changes recur or there is evidence of ischemia on a stress test.

LONG-TERM MANAGEMENT The time of hospital discharge is a "teachable moment" for the patient, when the physician can review and optimize the medical regimen. Risk factor modification is key, and the physician should discuss with the patient the importance of smoking cessation, achieving optimal weight, daily exercise, following an appropriate diet, blood pressure control, tight control of hyperglycemia (for diabetic patients), and lipid management, as recommended for patients with chronic stable angina (Chap. 225).

There is evidence of benefit with long-term therapy with five classes of drugs that are directed at different components of the atherothrombotic process. Beta blockers are appropriate anti-ischemic therapy and may help decrease triggers for MI. Statins and ACE inhibitors are recommended for long-term plaque stabilization. Antiplatelet therapy, now recommended to be the combination of aspirin and clopidogrel for at least 9 to 12 months, with aspirin continued thereafter, prevents or reduces the severity of any thrombosis that would occur if a plaque does rupture. Thus, a multifactorial approach to long-term medical therapy is directed at preventing the various components of atherothrombosis.

PRINZMETAL'S VARIANT ANGINA

In 1959, Prinzmetal et al. described a syndrome of ischemic pain that occurs at rest but not usually with exertion and is associated with transient ST-segment elevation. This syndrome is due to focal spasm of an epicardial coronary artery, leading to severe myocardial ischemia. Although it is frequently thought that the spasm occurs in arteries without stenosis, many Prinzmetal patients have spasm adjacent to atheromatous plaques. The exact cause of the spasm is not well defined, but it may be related to hypercontractility of vascular smooth muscle due to vasoconstrictor mitogens, leukotrienes, or serotonin. In some patients it is a manifestation of a vasospastic disorder and is associated with migraine, Raynaud's phenomenon, or aspirin-induced asthma.

CLINICAL AND ANGIOGRAPHIC MANIFESTATIONS Patients with variant angina are younger and have fewer coronary risk factors (with the exception of cigarette smoking) than patients with UA secondary to coronary atherosclerosis. The anginal discomfort is often extremely severe and has usually not progressed from a period of chronic stable angina. Cardiac examination is usually normal in the absence of ischemia.

The clinical diagnosis of variant angina is made with the detection of transient ST-segment *elevation* with rest pain. Many patients also exhibit multiple episodes of asymptomatic ST-segment elevation (*silent ischemia*). Small elevations of CK-MB may occur in patients with prolonged attacks of variant angina. Exercise testing in patients with variant angina is of limited value because the patients can demonstrate ST elevation, depression, or no ST changes.

Coronary angiography demonstrates transient coronary spasm as the diagnostic hallmark of Prinzmetal's angina. Significant proximal coronary stenosis of at least one major vessel occurs in the majority of patients, and in them spasm usually occurs within 1 cm of the obstruction. Focal spasm is most common in the right coronary artery, and it may occur at one or more sites in one artery or in multiple arteries simultaneously. Ergonovine, acetylcholine, other vasoconstrictor medications, and hyperventilation have been used to provoke and demonstrate focal coronary stenosis to establish the diagnosis. Hyperventilation has also been used to provoke rest angina, ST-segment elevation, and spasm on coronary arteriography.

TREATMENT

Nitrates and calcium channel blockers are the main treatments for patients with variant angina. Sublingual or intravenous nitroglycerin often abolishes episodes of variant angina promptly, and long-acting nitrates are useful in preventing recurrences. Calcium antagonists are extremely effective in preventing the coronary artery spasm of variant angina, and they should be prescribed in maximally tolerated doses. Similar efficacy rates have been noted among the various types of calcium antagonists. Prazosin, a selective α-adrenoreceptor blocker, has also been found to be of value in some patients, while aspirin may actually increase the severity of ischemic episodes. The response to beta blockers is variable. Coronary revascularization may be helpful in patients with variant angina who also have discrete, proximal fixed obstructive lesions.

PROGNOSIS Many patients with Prinzmetal's angina pass through an acute, active phase, with frequent episodes of angina and cardiac events during the first 6 months after presentation. Long-term survival at 5 years is excellent (~90 to 95%). Patients with no or mild fixed coronary obstruction tend to experience a more benign course than do patients with associated severe obstructive lesions. Nonfatal MI occurs in up to 20% of patients by 5 years. Patients with variant angina who develop serious arrhythmias during spontaneous episodes of pain are at a higher risk for sudden death. In most patients who survive an infarction or the initial 3- to 6-month period of frequent episodes, the condition stabilizes and there is a tendency for symptoms and cardiac events to diminish with time.

228 ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Elliott M. Antman, Eugene Braunwald

Acute myocardial infarction (AMI) is one of the most common diagnoses in hospitalized patients in industrialized countries. In the United States, approximately 650,000 patients experience a new AMI and 450,000 experience a recurrent AMI each year. The early (30-day) mortality rate from AMI is ~30%, with more than half of these deaths occurring before the stricken individual reaches the hospital. Although the mortality rate after admission for AMI has declined by ~30% over the past two decades, approximately 1 of every 25 patients who survives the initial hospitalization dies in the first year after AMI. Survival is markedly reduced in elderly patients (over age 75).

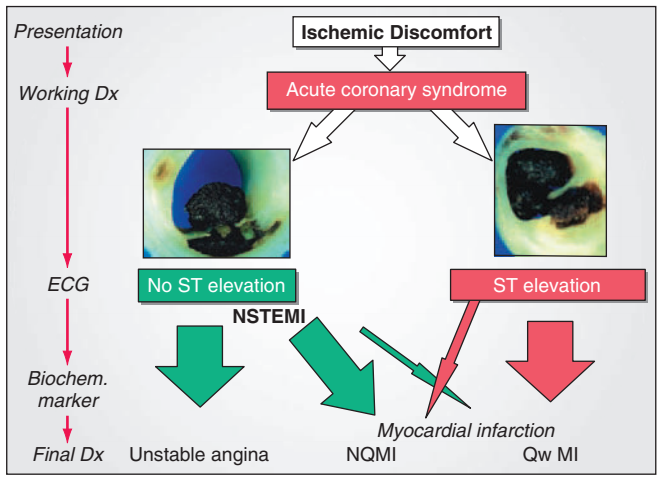

FIGURE 228-1 Acute coronary syndromes. Following disruption of a vulnerable plaque, patients experience ischemic discomfort resulting from a reduction of flow through the affected epicardial coronary artery. The flow reduction may be caused by a completely occlusive thrombus (right) or subtotally occlusive thrombus (left). Patients with ischemic discomfort may present with or without ST-segment elevation. Of patients with ST-segment elevation, the majority (*large red arrow*) ultimately develop a Q-wave MI (QwMI), while a minority (*small red arrow*) develop a non-Q-wave MI (NQMI). Patients who present without ST-segment elevation are suffering from either unstable angina or a non-ST-segment elevation MI (NSTEMI) (*large green arrows*), a distinction that is ultimately made on the presence or absence of a serum cardiac marker such as CKMB or a cardiac troponin detected in the blood. The majority presenting with NSTEMI ultimately develop a NQMI on the ECG; a minority develop a QwMI *(small green arrow)*. (*Adapted from CW Hamm et al: Lancet 358:1533, 2001, and MJ Davies: Heart 83:361, 2000; with permission from the BMJ Publishing Group.*)

When patients with acute ischemic discomfort are first seen, the working diagnosis is that they are suffering from an acute coronary syndrome (Fig. 228-1). The 12-lead electrocardiogram (ECG) is at the center of the decision pathway for management since it permits distinction of those patients presenting with ST-segment elevation from those presenting without ST-segment elevation. Serum cardiac biomarkers are obtained to distinguish unstable angina from non-ST-segment MI (NSTEMI) (Chap. 227) and to assess the magnitude of an ST-segment elevation MI (STEMI).

PATHOPHYSIOLOGY: ROLE OF ACUTE PLAQUE RUPTURE

STEMI generally occurs when coronary blood flow decreases abruptly after a thrombotic occlusion of a coronary artery previously affected by atherosclerosis. Slowly developing, high-grade coronary artery stenoses do not usually precipitate STEMI because of the development of a rich collateral network over time. Instead, STEMI occurs when a coronary artery thrombus develops rapidly at a site of vascular injury. This injury is produced or facilitated by factors such as cigarette smoking, hypertension, and lipid accumulation. In most cases, infarction occurs when an atherosclerotic plaque fissures, ruptures, or ulcerates and when conditions (local or systemic) favor thrombogenesis, so that a mural thrombus forms at the site of rupture and leads to coronary artery occlusion. Histologic studies indicate that the coronary plaques prone to rupture are those with a rich lipid core and a thin fibrous cap (Chap. 224). After an initial platelet monolayer forms at the site of the ruptured plaque, various agonists (collagen, ADP, epinephrine, serotonin) promote platelet activation. After agonist stimulation of platelets, there are production and release of thromboxane A_2 (a potent local vasoconstrictor), further platelet activation, and potential resistance to thrombolysis.

In addition to the generation of thromboxane A_2, activation of platelets by agonists promotes a conformational change in the glycoprotein IIb/IIIa receptor (Chap. 101). Once converted to its functional state, this receptor develops a high affinity for amino acid sequences on soluble adhesive proteins (i.e., integrins) such as von Willebrand factor (vWF) and fibrinogen. Since vWF and fibrinogen are multivalent molecules, they can bind to two different platelets simultaneously, resulting in platelet cross-linking and aggregation.

The coagulation cascade is activated on exposure of tissue factor in damaged endothelial cells at the site of the ruptured plaque. Factors VII and X are activated, ultimately leading to the conversion of prothrombin to thrombin, which then converts fibrinogen to fibrin (Chap. 102). Fluid-phase and clot-bound thrombin participate in an autoamplification reaction that leads to further activation of the coagulation cascade. The culprit coronary artery eventually becomes occluded by a thrombus containing platelet aggregates and fibrin strands.

In rare cases, STEMI may be due to coronary artery occlusion caused by coronary emboli, congenital abnormalities, coronary spasm, and a wide variety of systemic—particularly inflammatory—diseases. The amount of myocardial damage caused by coronary occlusion depends on (1) the territory supplied by the affected vessel, (2) whether or not the vessel becomes totally occluded, (3) the duration of coronary occlusion, (4) the quantity of blood supplied by collateral vessels to the affected tissue, (5) the demand for oxygen of the myocardium whose blood supply has been suddenly limited, (6) native factors that can produce early spontaneous lysis of the occlusive thrombus, and (7) the adequacy of myocardial perfusion in the infarct zone when flow is restored in the occluded epicardial coronary artery.

Patients at increased risk of developing STEMI include those with multiple coronary risk factors (Chap. 224) and those with unstable angina or Prinzmetal's variant angina (Chap. 227). Less common underlying medical conditions predisposing patients to STEMI include hypercoagulability, collagen vascular disease, cocaine abuse, and intracardiac thrombi or masses that can produce coronary emboli.

CLINICAL PRESENTATION

In up to one-half of cases, a precipitating factor appears to be present before STEMI, such as vigorous physical exercise, emotional stress, or a medical or surgical illness. Although STEMI may commence at any time of the day or night, circadian variations have been reported such that clusters are seen in the morning within a few hours of awakening.

Pain is the most common presenting complaint in patients with STEMI. The pain is deep and visceral; adjectives commonly used to describe it are *heavy*, *squeezing*, and *crushing*, although occasionally it is described as stabbing or burning (Chap. 12). It is similar in character to the discomfort of angina pectoris (Chap. 226) but is usually more severe and lasts longer. Typically the pain involves the central portion of the chest and/or the epigastrium, and on occasion it radiates to the arms. Less common sites of radiation include the abdomen, back, lower jaw, and neck. The frequent location of the pain beneath the xiphoid and patients' denial that they may be suffering a heart attack are chiefly responsible for the common mistaken impression of indigestion. The pain of STEMI may radiate as high as the occipital area but not below the umbilicus. It is often accompanied by weakness, sweating, nausea, vomiting, anxiety, and a sense of impending doom. The pain may commence when the patient is at rest, but when it begins during a period of exertion, it does not usually subside with cessation of activity, in contrast to angina pectoris.

The pain of STEMI can simulate pain from acute pericarditis (Chap. 222), pulmonary embolism (Chap. 244), acute aortic dissection (Chap. 231), costochondritis, and gastrointestinal disorders. These conditions should therefore be considered in the differential diagnosis. Radiation of discomfort to the trapezius is not seen in patients with STEMI and may be a useful distinguishing feature that suggests pericarditis is the correct diagnosis. However, *pain is not uniformly present in patients with STEMI*. The proportion of painless STEMIs is greater in patients with diabetes mellitus, and it increases with age. In the elderly, STEMI may present as sudden-onset breathlessness, which may progress to pulmonary edema. Other less common presentations, with or without pain, include sudden loss of consciousness, a confusional state, a sensation of profound weakness, the appearance

of an arrhythmia, evidence of peripheral embolism, or merely an unexplained drop in arterial pressure.

PHYSICAL FINDINGS Most patients are anxious and restless, attempting unsuccessfully to relieve the pain by moving about in bed, altering their position, and stretching. Pallor associated with perspiration and coolness of the extremities occurs commonly. The combination of substernal chest pain persisting for >30 min and diaphoresis strongly suggests STEMI. Although many patients have a normal pulse rate and blood pressure within the first hour of STEMI, about one-fourth of patients with anterior infarction have manifestations of sympathetic nervous system hyperactivity (tachycardia and/or hypertension), and up to one-half with inferior infarction show evidence of parasympathetic hyperactivity (bradycardia and/or hypotension).

The precordium is usually quiet, and the apical impulse may be difficult to palpate. In patients with anterior wall infarction, an abnormal systolic pulsation caused by dyskinetic bulging of infarcted myocardium may develop in the periapical area within the first days of the illness and then may resolve. Other physical signs of ventricular dysfunction include fourth (S_4) and third (S_3) heart sounds, decreased intensity of the first heart sound, and paradoxical splitting of the second heart sound (Chap. 209). A transient midsystolic or late systolic apical systolic murmur due to dysfunction of the mitral valve apparatus may be present. A pericardial friction rub is heard in many patients with transmural STEMI at some time in the course of the disease, if they are examined frequently. The carotid pulse is often decreased in volume, reflecting reduced stroke volume. Temperature elevations up to 38°C may be observed during the first week after STEMI. The arterial pressure is variable; in most patients with transmural infarction, systolic pressure declines by approximately 10 to 15 mmHg from the preinfarction state.

LABORATORY FINDINGS

Myocardial infarction (MI) progresses through the following temporal stages: (1) acute (first few hours to 7 days), (2) healing (7 to 28 days), and (3) healed (≥29 days). When evaluating the results of diagnostic tests for STEMI, the temporal phase of the infarction process must be considered. The laboratory tests of value in confirming the diagnosis may be divided into four groups: (1) ECG, (2) serum cardiac biomarkers, (3) cardiac imaging, and (4) nonspecific indexes of tissue necrosis and inflammation.

ELECTROCARDIOGRAM The electrocardiographic manifestations of STEMI are described in Chap. 210. During the initial stage of the acute phase of MI, total occlusion of an epicardial artery produces ST-segment elevation. Most patients initially presenting with ST-segment elevation evolve Q waves on the ECG and are ultimately diagnosed as having sustained a Q-wave MI (Fig. 228-1). A small proportion may sustain only a non-Q-wave MI. When the obstructing thrombus is not totally occlusive, obstruction is transient, or if a rich collateral network is present, no ST-segment elevation is seen. Such patients are initially considered to be experiencing either unstable angina or NSTEMI (Chap. 227). Among patients presenting *without* ST-segment elevation, if a serum cardiac biomarker of necrosis (see below) is detected and no Q wave develops, the diagnosis of non-Q-wave MI is ultimately made (Fig. 228-1). A minority of patients who present initially without ST-segment elevation may develop a Q-wave MI. Previously it was believed that transmural MI is present if the ECG demonstrates Q waves or loss of R waves, and nontransmural MI may be present if the ECG shows only transient ST-segment and T-wave changes. However, electrocardiographic-pathologic correlations are far from perfect; therefore a more rational nomenclature for designating electrocardiographic infarction is now commonly in use, with the terms *Q-wave MI* and *non-Q-wave MI* replacing the terms *transmural MI* and *nontransmural MI*, respectively (Fig. 228-1).

SERUM CARDIAC BIOMARKERS Certain proteins, called serum cardiac markers, are released into the blood in large quantities from necrotic heart muscle after STEMI. The rate of liberation of specific proteins differs depending on their intracellular location and molecular weight and the local blood and lymphatic flow. The temporal pattern of protein release is of diagnostic importance, but contemporary urgent reperfusion strategies necessitate making a decision (based largely on a combination of clinical and ECG findings) before the results of blood tests have returned from the central laboratory. Rapid whole-blood bedside assays for serum cardiac markers are now available and may facilitate management decisions, particularly in patients with nondiagnostic ECGs.

Creatine phosphokinase (CK) rises within 4 to 8 h and generally returns to normal by 48 to 72 h (Fig. 228-2). An important drawback of total CK measurement is its lack of specificity for STEMI, as CK may be elevated with skeletal muscle trauma. A two- to threefold elevation of total CK may follow an intramuscular injection, for example. This ambiguity may lead to the erroneous diagnosis of STEMI in a patient who has been given an intramuscular injection of a narcotic for chest pain of noncardiac origin. Other potential sources of total CK elevation are (1) skeletal muscular diseases, including muscular dystrophy, myopathies, and polymyositis; (2) electrical cardioversion; (3) hypothyroidism; (4) stroke; (5) surgery; and (6) skeletal muscle damage secondary to trauma, convulsions, and prolonged immobilization.

The MB isoenzyme of CK has the advantage over total CK that it is not present in significant concentrations in extracardiac tissue and therefore is considerably more specific. However, cardiac surgery, myocarditis, and electrical cardioversion often result in elevated serum levels of the MB isoenzyme. A ratio (relative index) of CKMB mass: CK activity ≥2.5 suggests but is not diagnostic of a myocardial rather than a skeletal muscle source for the CKMB elevation. This ratio is less useful when levels of total CK are high owing to skeletal muscle injury or when the total CK level is within the normal range but CKMB is elevated.

Cardiac-specific troponin T (cTnT) and *cardiac-specific troponin I* (cTnI) have amino acid sequences different from those of the skeletal muscle forms of these proteins. These differences permitted the development of quantitative assays for cTnT and cTnI with highly specific monoclonal antibodies. Since cTnT and cTnI are not normally detectable in the blood of healthy individuals but may increase after

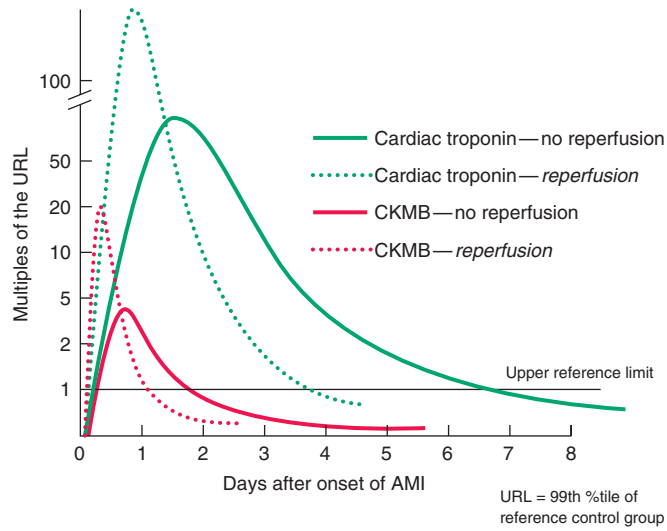

FIGURE 228-2 Typical cardiac biomarkers that are used to evaluate patients with STEMI include the MB isoenzyme of CK (CKMB) and cardiac-specific troponins. The black horizontal line depicts the upper reference limit (URL) for the cardiac biomarker in the clinical chemistry laboratory. The kinetics of release of CKMB and cardiac troponin in patients who do not undergo reperfusion are shown in the solid green and red curves as multiples of the URL. When patients with STEMI undergo reperfusion, as depicted in the dashed green and red curves, the cardiac biomarkers are detected sooner, rise to a higher peak value, but decline more rapidly, resulting in a smaller area under the curve and limitation of infarct size. (*Adapted from JS Alpert et al: J Am Coll Cardiol 36:959, 2000, and AH Wu et al: Clin Chem 45:1104, 1999.*)

STEMI to levels >20 times higher than the upper reference limit, the noise level of the assay), the measurement of cTnT or cTnI is of considerable diagnostic usefulness, and they are now the preferred biochemical markers for MI (Fig. 228-2). The cardiac troponins are particularly valuable when there is clinical suspicion of either skeletal muscle injury or a small MI that may be below the detection limit for CK and CKMB measurements. Levels of cTnI and cTnT may remain elevated for 7 to 10 days after STEMI.

Myoglobin is released into the blood within only a few hours of the onset of STEMI. Although myoglobin is one of the first serum cardiac markers that rises above the normal range after STEMI, it lacks cardiac specificity, and it is rapidly excreted in the urine, so that blood levels return to the normal range within 24 h of the onset of infarction.

Many hospitals are using cTnT or cTnI rather than CKMB as the routine serum cardiac marker for diagnosis of STEMI, although any of these analytes remains clinically acceptable. It is *not* cost-effective to measure both a cardiac-specific troponin and CKMB at all time points in every patient. However, in view of the prolonged elevation of cardiac-specific troponins (>1 week), episodes of recurrent ischemic discomfort and suspected recurrent MI are more readily diagnosed with a serum cardiac marker that remains elevated in the blood more briefly, such as CKMB or myoglobin.

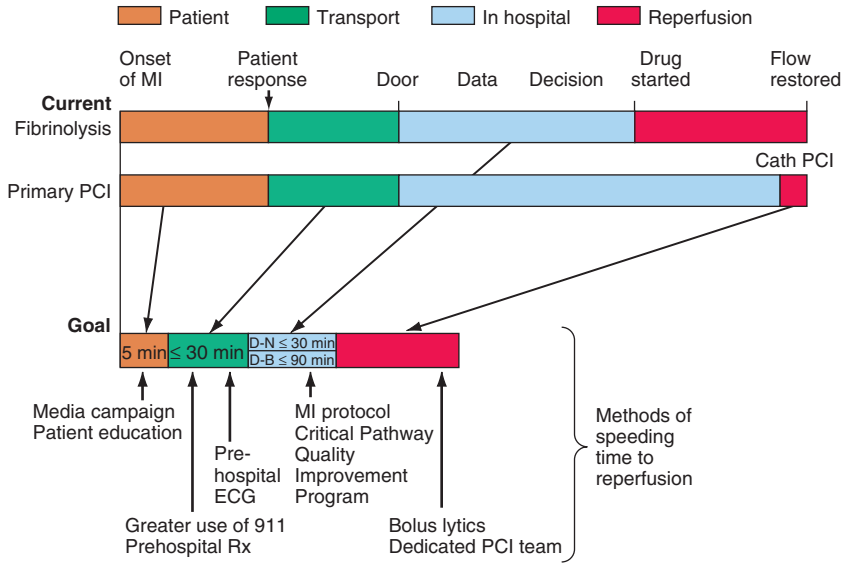

FIGURE 228-3 Major components of time delay between onset of symptoms from STEMI and restoration of flow in the infarct-related artery. Plotted sequentially from left to right are shown the times for patients to recognize symptoms and seek medical attention, transportation to the hospital, in-hospital decision-making, implementation of reperfusion strategy, and restoration of flow once the reperfusion strategy has been initiated. The time to initiate fibrinolytic therapy is the "door-to-needle" (D-N) time; this is followed by the period of time required for pharmacologic restoration of flow. More time is required to move the patient to the catheterization laboratory for a percutaneous coronary interventional (PCI) procedure, referred to as the "door-to-balloon" (D-B) time, but restoration of flow in the epicardial infarct-related artery occurs promptly after PCI. At the bottom are shown a variety of methods for speeding the time to reperfusion along with the goals for the time intervals for the various components of the time delay. (*Adapted from CP Cannon et al: J Thromb Thrombol 1:27, 1994.*)

While it has long been recognized that the total quantity of protein released correlates with the size of the infarct, the peak protein concentration correlates only weakly with infarct size. Recanalization of a coronary artery occlusion (either spontaneously or by mechanical or pharmacologic means) in the early hours of STEMI causes earlier and higher peaking (at about 8 to 12 h after reperfusion) of serum cardiac markers (Fig. 228-2).

For the purposes of confirming the diagnosis of MI, serum cardiac markers should be measured on admission, 6 to 9 h after admission, and 12 to 24 h after admission if the diagnosis remains uncertain.

The *nonspecific reaction* to myocardial injury is associated with polymorphonuclear leukocytosis, which appears within a few hours after the onset of pain and persists for 3 to 7 days; the white blood cell count often reaches levels of 12,000 to 15,000/μL. The erythrocyte sedimentation rate rises more slowly than the white blood cell count, peaking during the first week and sometimes remaining elevated for 1 or 2 weeks.

CARDIAC IMAGING Abnormalities of wall motion on *two-dimensional echocardiography* (Chap. 211) are almost universally present. Although acute STEMI cannot be distinguished from an old myocardial scar or from acute severe ischemia by echocardiography, the ease and safety of the procedure make its use appealing as a screening tool. In the emergency department setting, early detection of the presence or absence of wall motion abnormalities by echocardiography can aid in management decisions, such as whether the patient should receive reperfusion therapy [e.g., fibrinolysis or a percutaneous coronary intervention (PCI)]. Echocardiographic estimation of left ventricular (LV) function is useful prognostically; detection of reduced function serves as an indication for therapy with an angiotensin-converting enzyme (ACE) inhibitor (see "Angiotensin-Converting Enzyme Inhibitors," below). Echocardiography may also identify the presence of right ventricular (RV) infarction, ventricular aneurysm, pericardial effusion, and LV thrombus. In addition, Doppler echocardiography is useful in the detection and quantitation of a ventricular septal defect and mitral regurgitation, two serious complications of STEMI (see below).

Several *radionuclide imaging techniques* (Chap. 211) are available for evaluating patients with suspected STEMI. However, these imaging modalities are used less often than echocardiography because they are more cumbersome and lack sensitivity and specificity in many clinical circumstances. Myocardial perfusion imaging with ^{201}Tl or ^{99m}Tc-sestamibi, which are distributed in proportion to myocardial blood flow and concentrated by viable myocardium (Chap. 226), reveal a defect ("cold spot") in most patients during the first few hours after development of a transmural infarct. However, although perfusion scanning is extremely sensitive, it cannot distinguish acute infarcts from chronic scars and thus is not specific for the diagnosis of *acute* MI. Radionuclide ventriculography, carried out with ^{99m}Tc-labeled red blood cells, frequently demonstrates wall motion disorders and reduction in the ventricular ejection fraction in patients with STEMI. While of value in assessing the hemodynamic consequences of infarction and in aiding in the diagnosis of RV infarction when the RV ejection fraction is depressed, this technique is nonspecific, as many cardiac abnormalities other than MI alter the radionuclide ventriculogram.

INITIAL MANAGEMENT

PREHOSPITAL CARE The prognosis in STEMI is largely related to the occurrence of two general classes of complications: (1) electrical complications (arrhythmias) and (2) mechanical complications ("pump failure"). Most out-of-hospital deaths from STEMI are due to the sudden development of ventricular fibrillation. The vast majority of deaths due to ventricular fibrillation occur within the first 24 h of the onset of symptoms, and, of these, over half occur in the first hour. Therefore, the major elements of prehospital care of patients with suspected STEMI include (1) recognition of symptoms by the patient and prompt seeking of medical attention; (2) rapid deployment of an emergency medical team capable of performing resuscitative maneuvers, including defibrillation; (3) expeditious transportation of the patient to a hospital facility that is continuously staffed by physicians and nurses skilled in managing arrhythmias and providing advanced cardiac life support; and (4) expeditious implementation of reperfusion therapy (Fig. 228-3). The biggest delay usually occurs not during transportation to the hospital but rather between the onset of pain and the pa-

tient's decision to call for help. This delay can best be reduced by education of the public by health care professionals concerning the significance of chest pain and the importance of seeking early medical attention. Increasingly, monitoring and treatment are carried out by trained personnel in the ambulance, further shortening the time between the onset of the infarction and appropriate treatment. General guidelines for initiation of fibrinolysis in the prehospital setting include the ability to transmit 12-lead ECGs to confirm the diagnosis, the presence of paramedics in the ambulance, training of paramedics in the interpretation of ECGs and management of STEMI, and online medical command and control that can authorize the initiation of treatment in the field.

MANAGEMENT IN THE EMERGENCY DEPARTMENT In the emergency department, the goals for the management of patients with suspected STEMI include control of cardiac pain, rapid identification of patients who are candidates for urgent reperfusion therapy, triage of lower-risk patients to the appropriate location in the hospital, and avoidance of inappropriate discharge of patients with STEMI. Many aspects of the treatment of STEMI are initiated in the emergency department and then continued during the in-hospital phase of management.

Aspirin is essential in the management of patients with suspected STEMI and is effective across the entire spectrum of acute coronary syndromes (Fig. 228-1). Rapid inhibition of cyclooxygenase in platelets followed by a reduction of thromboxane A_2 levels is achieved by buccal absorption of a chewed 160- to 325-mg tablet in the emergency department. This measure should be followed by daily oral administration of aspirin in a dose of 75 to 162 mg.

In patients whose arterial oxygen saturation is normal as estimated by pulse oximetry or measured by an arterial blood gas specimen, supplemental oxygen is of limited if any clinical benefit and therefore is not cost-effective. However, when hypoxemia is present, oxygen should be administered by nasal prongs or face mask (2 to 4 L/min) for the first 6 to 12 h after infarction; the patient should then be reassessed to determine if there is a continued need for such treatment.

Control of Pain Sublingual *nitroglycerin* can be given safely to most patients with STEMI. Up to three doses of 0.4 mg should be administered at about 5-min intervals. In addition to diminishing or abolishing chest discomfort, nitroglycerin may be capable of both decreasing myocardial oxygen demand (by lowering preload) and increasing myocardial oxygen supply (by dilating infarct-related coronary vessels or collateral vessels). In patients whose initially favorable response to sublingual nitroglycerin is followed by the return of chest pain, particularly if accompanied by other evidence of ongoing ischemia such as further ST-segment or T-wave shifts, the use of intravenous nitroglycerin should be considered. Therapy with nitrates should be avoided in patients who present with low systolic arterial pressure (<90 mmHg) or in whom there is clinical suspicion of RV infarction (inferior infarction on ECG, elevated jugular venous pressure, clear lungs, and hypotension). Nitrates should not be administered to patients who have taken the phosphodiesterase-5 inhibitor sildenafil for erectile dysfunction within the preceding 24 h since it may potentiate the hypotensive effects of nitrates. An idiosyncratic reaction to nitrates, consisting of sudden marked hypotension, sometimes occurs but can usually be reversed promptly by the rapid administration of intravenous atropine.

Morphine is a very effective analgesic for the pain associated with STEMI. However, it may reduce sympathetically mediated arteriolar and venous constriction, and the resulting venous pooling may reduce cardiac output and arterial pressure. These hemodynamic disturbances usually respond promptly to elevation of the legs, but in some patients volume expansion with intravenous saline is required. The patient may experience diaphoresis and nausea, but these events usually pass and are replaced by a feeling of well-being associated with the relief of pain. Morphine also has a vagotonic effect and may cause bradycardia or advanced degrees of heart block, particularly in patients with posteroinferior infarction. These side effects usually respond to atropine (0.5 mg intravenously). Morphine is routinely administered by repetitive (every 5 min) intravenous injection of small doses (2 to 4 mg) rather than by the subcutaneous administration of a larger quantity, because absorption may be unpredictable by the latter route.

Intravenous *beta blockers* are also useful in the control of the pain of STEMI. These drugs control pain effectively in some patients, presumably by diminishing myocardial oxygen demand and hence ischemia. More important, there is evidence that intravenous beta blockers reduce in-hospital mortality, particularly in high-risk patients (see "Beta-Adrenoceptor Blockers," below). A commonly employed regimen is metoprolol, 5 mg every 2 to 5 min for a total of three doses, provided the patient has a heart rate > 60 beats per minute (bpm), systolic pressure > 100 mmHg, a PR interval < 0.24 s, and rales that are no higher than 10 cm up from the diaphragm. Fifteen minutes after the last intravenous dose, an oral regimen is initiated of 50 mg every 6 h for 48 h, followed by 100 mg every 12 h.

Unlike beta blockers, calcium antagonists are of little value in the acute setting, and there is evidence that short-acting dihydropyridines may be associated with an increased mortality risk.

Management Strategies The primary tool for screening patients and making triage decisions is the initial 12-lead ECG. When ST-segment elevation of at least 2 mm in two contiguous precordial leads and 1 mm in two limb leads is present, a patient should be considered a candidate for *reperfusion therapy* (Fig. 228-4). The process of selecting patients for fibrinolysis versus primary PCI (angioplasty, or stenting; Chap. 229) is discussed below. In the absence of ST-segment elevation, fibrinolysis is not helpful, and evidence exists suggesting that it may be harmful.

Limitation of Infarct Size The quantity of myocardium that becomes necrotic as a consequence of a coronary artery occlusion is determined by factors other than just the site of occlusion. While the central zone of the infarct contains necrotic tissue that is irretrievably lost, the fate of the surrounding ischemic myocardium may be improved by timely restoration of coronary perfusion, reduction of myocardial oxygen demands, prevention of the accumulation of noxious metabolites, and blunting of the impact of mediators of reperfusion injury (e.g., calcium overload and oxygen-derived free radicals). Up to one-third of patients with STEMI may achieve *spontaneous* reperfusion of the infarct-related coronary artery within 24 h and experience improved healing of infarcted tissue. Reperfusion either pharmacologically (by fibrinolysis)

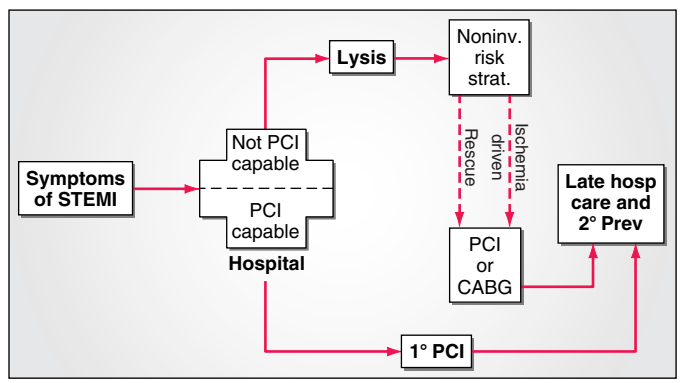

FIGURE 228-4 Reperfusion strategies for STEMI. Following the onset of symptoms of STEMI, the patient is transported to the hospital where reperfusion options are assessed. If the hospital is not capable of performing percutaneous coronary intervention (PCI), the patient is treated with fibrinolytic therapy; if the hospital is capable of performing PCI, reperfusion is implemented in the form of primary PCI. Patients who receive fibrinolytic therapy should undergo noninvasive risk stratification (Noninv. Risk Strat.). Patients with continued chest pain or failure to resolve ST-segment elevation by about 90 min should be referred for rescue PCI; if spontaneous recurrent ischemia or provoked ischemia is detected on noninvasive testing later in the hospital, patients should be referred for PCI or coronary artery bypass graft (CABG) surgery. All patients should receive therapies for secondary prevention of STEMI. (*Adapted from PW Armstrong, D Collen, EM Antman: Circulation 107:2533, 2003, with permission.*)

or by PCI accelerates the occluded infarct-related artery in those patients in whom spontaneous thrombolysis ultimately would have occurred and also greatly increases the number of patients in whom restoration of flow in the infarct-related artery is accomplished. Timely restoration of flow in the epicardial infarct–related artery combined with improved perfusion of the downstream zone of infarcted myocardium results in a limitation of infarct size. Protection of the ischemic myocardium by the maintenance of an optimal balance between myocardial oxygen supply and demand through pain control, treatment of congestive heart failure (CHF), and minimization of tachycardia and hypertension extends the "window" of time for the salvage of myocardium by reperfusion strategies.

Glucocorticoids and nonsteroidal anti-inflammatory agents, with the exception of aspirin, should be avoided in the setting of STEMI. They can impair infarct healing and increase the risk of myocardial rupture, and their use may result in a larger infarct scar. In addition, they can increase coronary vascular resistance, thereby potentially reducing flow to ischemic myocardium.

Primary Percutaneous Coronary Intervention (See also Chap. 229) PCI, usually angioplasty and/or stenting without preceding fibrinolysis, referred to as *primary PCI*, is effective in restoring perfusion in STEMI when carried out on an emergency basis in the first few hours of MI. It has the advantage of being applicable to patients who have contraindications to fibrinolytic therapy but otherwise are considered appropriate candidates for reperfusion. It appears to be more effective than fibrinolysis in opening occluded coronary arteries and, *when performed by experienced operators [≥75 PCI cases (not necessarily primary) per year] in dedicated medical centers (≥36 primary PCI cases per year)*, is associated with better short-term and long-term clinical outcomes. Compared with fibrinolysis, primary PCI is generally preferred when the diagnosis is in doubt, cardiogenic shock is present (especially in patients <75 years), bleeding risk is increased, or symptoms have been present for at least 2 to 3 h when the clot is more mature and less easily lysed by fibrinolytic drugs. However, PCI is expensive in terms of personnel and facilities, and its applicability is limited by its availability, around the clock, in only a minority of hospitals.

Fibrinolysis If no contraindications are present (see below), fibrinolytic therapy should ideally be initiated within 30 min of presentation (i.e., door-to-needle time ≤30 min). The principal goal of fibrinolysis is prompt restoration of full coronary arterial patency. The fibrinolytic agents tissue plasminogen activator (tPA), streptokinase, tenecteplase (TNK), and reteplase (rPA) have been approved by the U.S. Food and Drug Administration for intravenous use in the setting of STEMI. These drugs all act by promoting the conversion of plasminogen to plasmin, which subsequently lyses fibrin thrombi. Although considerable emphasis was first placed on a distinction between more fibrin-specific agents, such as tPA, and non-fibrin-specific agents, such as streptokinase, it is now recognized that these differences are only relative, as some degree of systemic fibrinolysis occurs with tPA. TNK and rPA are referred to as *bolus fibrinolytics* since their administration does not require a prolonged intravenous infusion.

When assessed angiographically, flow in the culprit coronary artery is described by a simple qualitative scale called the ***t**hrombolysis **i**n **m**yocardial **i**nfarction **(TIMI)** grading system*: grade 0 indicates complete occlusion of the infarct-related artery; grade 1 indicates some penetration of the contrast material beyond the point of obstruction but without perfusion of the distal coronary bed; grade 2 indicates perfusion of the entire infarct vessel into the distal bed but with flow that is delayed compared with that of a normal artery; and grade 3 indicates full perfusion of the infarct vessel with normal flow. Early reports frequently lumped TIMI grades 2 and 3 under the general category of *patency*, but it is now recognized that grade 3 flow is the goal of reperfusion therapy, because full perfusion of the infarct-related coronary artery yields far better results in terms of limiting infarct size, maintenance of LV function, and reduction of both short- and long-term mortality rates. Relatively new methods of angiographic assessment of the efficacy of fibrinolysis include counting the number of frames on the cine film required for dye to flow from the origin of the infarct-related artery to a landmark in the distal vascular bed (*TIMI frame count*) and determining the rate of entry and exit of contrast dye from the microvasculature in the myocardial infarct zone (*TIMI myocardial perfusion grade*).

Fibrinolytic therapy can reduce the relative risk of in-hospital death by up to 50% when administered within the first hour of the onset of symptoms of STEMI, and much of this benefit is maintained for at least 10 years. Appropriately used fibrinolytic therapy appears to reduce infarct size, limit LV dysfunction, and reduce the incidence of serious complications such as septal rupture, cardiogenic shock, and malignant ventricular arrhythmias. Since myocardium can be salvaged only before it has been irreversibly injured, the timing of reperfusion therapy, by fibrinolysis or a catheter-based approach, is of extreme importance in achieving maximum benefit. While the upper time limit depends on specific factors in individual patients, it is clear that "every minute counts" and that patients treated within 1 to 3 h of the onset of symptoms generally benefit most. Although reduction of the mortality rate is more modest, the therapy remains of benefit for many patients seen 3 to 6 h after the onset of infarction, and some benefit appears to be possible up to 12 h, especially if chest discomfort is still present and ST segments remain elevated in ECG leads that do not yet demonstrate new Q waves. Compared with PCI for STEMI (primary PCI), fibrinolysis is generally the preferred reperfusion strategy for patients presenting in the first hour of symptoms, if there are logistical concerns about transportation of the patient to a suitable PCI center (experienced operator and team with a track record for a "door-to-balloon" time of < 2 h), or there is an anticipated delay of at least 1 h between the time that fibrinolysis could be started versus implementation of PCI. Although patients <75 years achieve a greater relative reduction in the mortality rate with fibrinolytic therapy than do older patients, the higher *absolute* mortality rate (15 to 25%) in the latter results in similar absolute reductions in the mortality rates for both age groups.

tPA and the other relatively fibrin-specific plasminogen activators rPA and TNK are more effective than streptokinase at restoring full perfusion—i.e., TIMI grade 3 coronary flow—and have a small edge in improving survival as well. The current recommended regimen of tPA consists of a 15-mg bolus followed by 50 mg intravenously over the first 30 min, followed by 35 mg over the next 60 min. Streptokinase is administered as 1.5 million units (MU) intravenously over 1 h. rPA is administered in a double-bolus regimen consisting of a 10-MU bolus given over 2 to 3 min followed by a second 10-MU bolus 30 min later. TNK is given as a single weight-based intravenous bolus of 0.53 mg/kg over 10 s. In addition to the fibrinolytic agents discussed above, pharmacologic reperfusion typically involves adjunctive antiplatelet and antithrombotic drugs, as discussed subsequently.

Alternative pharmacologic regimens for reperfusion combine an intravenous glycoprotein IIb/IIIa inhibitor with a reduced dose of a fibrinolytic agent. Compared with fibrinolytic agents that involve a prolonged infusion (e.g., tPA) such combination reperfusion regimens facilitate the rate and extent of fibrinolysis by inhibiting platelet aggregation, weakening the clot structure, and allowing penetration of the thrombolytic agent deeper into the clot. However, combination reperfusion regimens have similar efficacy as compared with bolus fibrinolytics (e.g., rPA) and are associated with an increased risk of bleeding, especially in patients >75 years. Therefore, combination reperfusion regimens have not been approved for use but remain under active investigation to determine if they are helpful for preparing patients who are referred promptly for PCI—an experimental strategy called *facilitated PCI*.

CONTRAINDICATIONS AND COMPLICATIONS Clear contraindications to the use of fibrinolytic agents include a history of cerebrovascular hemorrhage at any time, a nonhemorrhagic stroke or other cerebrovascular event within the past year, marked hypertension (a reliably determined systolic arterial pressure > 180 mmHg and/or a diastolic pressure > 110

mmHg) at any time during the acute presentation, suspicion of aortic dissection, and active internal bleeding (excluding menses). While advanced age is associated with an increase in hemorrhagic complications, the benefit of fibrinolytic therapy in the elderly appears to justify its use if no other contraindications are present and the amount of myocardium in jeopardy appears to be substantial.

Relative contraindications to fibrinolytic therapy, which require assessment of the risk:benefit ratio, include current use of anticoagulants (international normalized ratio ≥2), a recent (<2 weeks) invasive or surgical procedure or prolonged (>10 min) cardiopulmonary resuscitation, known bleeding diathesis, pregnancy, a hemorrhagic ophthalmic condition (e.g., hemorrhagic diabetic retinopathy), active peptic ulcer disease, and a history of severe hypertension that is currently adequately controlled. Because of the risk of an allergic reaction, patients should not receive streptokinase if that agent had been received within the preceding 5 days to 2 years.

Allergic reactions to streptokinase occur in ~2% of patients who receive it. While a minor degree of hypotension occurs in 4 to 10% of patients given this agent, marked hypotension occurs, although rarely, in association with severe allergic reactions.

Hemorrhage is the most frequent and potentially the most serious complication. Because bleeding episodes that require transfusion are more common when patients require invasive procedures, unnecessary venous or arterial interventions should be avoided in patients receiving thrombolytic agents. Hemorrhagic stroke is the most serious complication and occurs in ~0.5 to 0.9% of patients being treated with these agents. This rate increases with advancing age, with patients >70 years experiencing roughly twice the rate of intracranial hemorrhage as those <65 years. Large-scale intervention trials have suggested that the rate of intracranial hemorrhage with tPA or rPA is slightly higher than with streptokinase.

Cardiac catheterization and coronary angiography should be carried out after fibrinolytic therapy if there is evidence of either (1) failure of reperfusion (persistent chest pain and ST-segment elevation >90 min), in which case a *rescue PCI* should be considered; or (2) coronary artery reocclusion (reelevation of ST segments and/or recurrent chest pain) or the development of recurrent ischemia (such as recurrent angina in the early hospital course or a positive exercise stress test before discharge), in which case an *elective PCI* should be considered. The potential benefits of routine angiography after PCI even in asymptomatic patients following administration of fibrinolytic therapy are controversial, but such an approach may have merit given the numerous technological advances that have occurred in the catheterization laboratory and the increasing number of skilled interventionalists. Coronary artery bypass surgery should be reserved for patients whose coronary anatomy is unsuited to angioplasty but in whom revascularization appears to be advisable because of extensive jeopardized myocardium or recurrent ischemia.

HOSPITAL PHASE MANAGEMENT

CORONARY CARE UNITS These units are routinely equipped with a system that permits continuous monitoring of the cardiac rhythm of each patient and hemodynamic monitoring in selected patients. Defibrillators, respirators, noninvasive transthoracic pacemakers, and facilities for introducing pacing catheters and flow-directed balloon-tipped catheters are also usually available. Equally important is the organization of a highly trained team of nurses who can recognize arrhythmias; adjust the dosage of antiarrhythmic, vasoactive, and anticoagulant drugs; and perform cardiac resuscitation, including electroshock, when necessary.

Patients should be admitted to a coronary care unit early in their illness when it is expected that they will derive benefit from the sophisticated and expensive care provided. The availability of electrocardiographic monitoring and trained personnel outside the coronary care unit has made it possible to admit lower-risk patients (e.g., those not hemodynamically compromised and without active arrhythmias) to "intermediate care units."

The duration of stay in the coronary care unit is dictated by the ongoing need for intensive care. If STEMI has been ruled out (ideally within 8 to 12 h) and symptoms are controlled with oral therapy, patients may be transferred out of the coronary care unit. Also, patients who have a confirmed STEMI but who are considered to be at low risk (no prior infarction and no persistent chest discomfort, CHF, hypotension, or cardiac arrhythmias) may be safely transferred out of the coronary care unit within 24 h.

Activity Factors that increase the work of the heart during the initial hours of infarction may increase the size of the infarct. Therefore, patients with STEMI should be kept at bed rest for the first 12 h. However, in the absence of complications, patients should be encouraged, under supervision, to resume an upright posture by dangling their feet over the side of the bed and sitting in a chair within the first 24 h. This practice is psychologically beneficial and usually results in a reduction in the pulmonary capillary wedge pressure. In the absence of hypotension and other complications, by the second or third day patients typically are ambulating in their room with increasing duration and frequency, and they may shower or stand at the sink to bathe. By day 3 after infarction, patients should be increasing their ambulation progressively to a goal of 185 m (600 ft) at least three times a day.

Diet Because of the risk of emesis and aspiration soon after MI, patients should receive either nothing or only clear liquids by mouth for the first 4 to 12 h. The typical coronary care unit diet should provide ≤30% of total calories as fat and have a cholesterol content of ≤300 mg/d. Complex carbohydrates should make up 50 to 55% of total calories. Portions should not be unusually large, and the menu should be enriched with foods that are high in potassium, magnesium, and fiber but low in sodium. Diabetes mellitus and hypertriglyceridemia are managed by restriction of concentrated sweets in the diet.

Bowels Bed rest and the effect of the narcotics used for the relief of pain often lead to constipation. A bedside commode rather than a bedpan, a diet rich in bulk, and the routine use of a stool softener such as dioctyl sodium sulfosuccinate (200 mg/d) are recommended. If the patient remains constipated despite these measures, a laxative can be prescribed. Contrary to prior belief, it is safe to perform a gentle rectal examination on patients with STEMI.

Sedation Many patients require sedation during hospitalization to withstand the period of enforced inactivity with tranquillity. Diazepam (5 mg), oxazepam (15 to 30 mg), or lorazepam (0.5 to 2 mg), given three or four times daily, is usually effective. An additional dose of any of the above medications may be given at night to ensure adequate sleep. Attention to this problem is especially important during the first few days in the coronary care unit, where the atmosphere of 24-h vigilance may interfere with the patient's sleep. However, sedation is no substitute for reassuring, quiet surroundings. Many drugs used in the coronary care unit, such as atropine, H_2 blockers, and narcotics, can produce delirium, particularly in the elderly. This effect should not be confused with agitation, and it is wise to conduct a thorough review of the patient's medications before arbitrarily prescribing additional doses of anxiolytics.

PHARMACOTHERAPY

ANTITHROMBOTIC AGENTS The use of antiplatelet and antithrombin therapy during the initial phase of STEMI is based on extensive laboratory and clinical evidence that thrombosis plays an important role in the pathogenesis of this condition. The primary goal of treatment with antiplatelet and antithrombin agents is to establish and maintain patency of the infarct-related artery. A secondary goal is to reduce the patient's tendency to thrombosis and thus the likelihood of mural thrombus formation or deep venous thrombosis, either of which could result in pulmonary embolization. The degree to which antiplatelet and antithrombin therapy achieves these goals partly determines how effectively it reduces the risk of mortality from STEMI.

As noted previously (see "Management in the Emergency Department," above), aspirin is the standard antiplatelet agent for patients

with STEMI. The most compelling evidence for the benefits of antiplatelet therapy (mainly with aspirin) in STEMI is found in the comprehensive overview by the Antiplatelet Trialists' Collaboration. Data from nearly 20,000 patients with MI enrolled in 15 randomized trials were pooled and revealed a relative reduction of 27% in the mortality rate, from 14.2% in control patients to 10.4% in patients receiving antiplatelet agents.

The glycoprotein IIb/IIIa receptor is the focus of intense investigation (Chaps. 101 and 103). Glycoprotein inhibitors appear useful for preventing thrombotic complications in patients with STEMI undergoing PCI.

The standard antithrombin agent used in clinical practice is unfractionated heparin (UFH). Despite numerous clinical trials, the precise role of heparin in patients treated with fibrinolytic agents remains uncertain. The available data fail to show any convincing benefit of UFH with respect to either coronary arterial patency or mortality rate when UFH is added to a regimen of aspirin and a non-fibrin-specific thrombolytic agent such as streptokinase. Although not conclusively proven, it appears that the immediate administration of intravenous UFH, in addition to a regimen of aspirin and relatively fibrin-specific fibrinolytic agents (tPA, rPA, or TNK), helps to facilitate thrombolysis and to establish and maintain patency of the infarct-related artery. This effect is achieved at the cost of a small increased risk of bleeding. The recommended dose of UFH is an initial bolus of 60 U/kg (maximum 4000 U) followed by an initial infusion of 12 U/kg per hour (maximum 1000 U/h). The activated partial thromboplastin time during maintenance therapy should be 1.5 to 2 times the control value.

An alternative to UFH for anticoagulation of patients with STEMI that is being used with increased frequency in patients with unstable angina/NSTEMI (Chap. 227) are the low-molecular-weight heparin (LMWH) preparations, which are formed by enzymatic or chemical depolymerization to produce saccharide chains of varying length but with a mean molecular weight of about 5000 Da. The risks and benefits of LMWHs for management of patients with STEMI are under investigation.

Patients with an anterior location of the infarction, severe LV dysfunction, CHF, a history of embolism, two-dimensional echocardiographic evidence of mural thrombus, or atrial fibrillation are at increased risk of systemic or pulmonary thromboembolism. Such individuals should receive full therapeutic levels of antithrombin therapy (UFH or LMWHs) while hospitalized, followed by at least 3 months of warfarin therapy.

BETA-ADRENOCEPTOR BLOCKERS The benefits of beta blockers in patients with STEMI can be divided into those that occur immediately when the drug is given acutely and those that accrue over the long term when the drug is given for secondary prevention after an infarction. Acute intravenous beta blockade improves the myocardial oxygen supply-demand relationship, decreases pain, reduces infarct size, and decreases the incidence of serious ventricular arrhythmias. An overview of the data from 27,000 patients enrolled in nine randomized trials in the prethrombolytic era indicates that intravenous followed by oral beta blockade is associated with a 15% relative reduction in mortality, nonfatal reinfarction, and nonfatal cardiac arrest. In patients who undergo fibrinolysis soon after the onset of chest pain, no incremental reduction in mortality rate is seen with beta blockers, but recurrent ischemia and reinfarction are reduced.

Thus, beta blocker therapy after STEMI is useful for most patients (including those treated with an ACE inhibitor) except those in whom it is specifically contraindicated (patients with heart failure or severely compromised LV function, heart block, orthostatic hypotension, or a history of asthma) and perhaps those whose excellent long-term prognosis (defined as an expected mortality rate of $<1\%$ per year) markedly diminishes any potential benefit (patients <55 years with normal ventricular function, no complex ventricular ectopy, and no angina).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS ACE inhibitors reduce the mortality rate after STEMI, and the mortality benefits are additive to those achieved with aspirin and beta blockers. The maximum benefit is seen in high-risk patients (those who are elderly or who have an anterior infarction, a prior infarction, and/or globally depressed LV function), but evidence suggests that a short-term benefit occurs when ACE inhibitors are prescribed unselectively to all hemodynamically stable patients with STEMI (i.e., those with a systolic pressure >100 mmHg). The mechanism involves a reduction in ventricular remodeling after infarction (see "Ventricular Dysfunction," below) with a subsequent reduction in the risk of CHF. The rate of recurrent infarction may also be lower in patients treated chronically with ACE inhibitors after infarction.

ACE inhibitors should be prescribed within 24 h to all patients with STEMI. Before hospital discharge, LV function should be assessed with an imaging study. ACE inhibitors should be continued indefinitely in patients who have clinically evident CHF, in patients in whom an imaging study shows a reduction in global LV function or a large regional wall motion abnormality, or in those who are hypertensive. The use of angiotensin receptor blockers (ARBs) has not been as thoroughly explored as ACE inhibitors in STEMI patients. However, clinical experience in the management of patients with heart failure as well as data from clinical trials in STEMI patients suggest that ARBs may be useful in patients with depressed LV function or with clinical heart failure who are intolerant of an ACE inhibitor.

OTHER AGENTS Although the actual impact on the mortality rate is slight (three to four lives saved per 1000 patients treated), *nitrates* (intravenous or oral) may be useful in the relief of pain associated with STEMI. Favorable effects on the ischemic process and ventricular remodeling (see below) previously led many physicians to routinely use *intravenous nitroglycerin* (5 to 10 μg/min initial dose and up to 200 μg/min as long as hemodynamic stability is maintained) for the first 24 to 48 h after the onset of infarction. However, the benefits of routine use of intravenous nitroglycerin are less in the contemporary era where beta-adrenoceptor blockers and ACE inhibitors are routinely prescribed for patients with STEMI.

Results of multiple trials of different calcium antagonists have failed to establish a role for these agents in the treatment of most patients with STEMI, in contrast to the more consistent data that exist for other drugs (e.g., beta blockers, aspirin, fibrinolytic agents). The routine use of calcium antagonists cannot be recommended. Strict control of blood glucose in diabetic patients with STEMI has been shown to reduce the mortality rate. Serum magnesium should be measured in all patients on admission, and any demonstrated deficits should be corrected to minimize the risk of arrhythmias.

COMPLICATIONS AND THEIR MANAGEMENT

VENTRICULAR DYSFUNCTION After STEMI, the left ventricle undergoes a series of changes in shape, size, and thickness in both the infarcted and noninfarcted segments. This process is referred to as *ventricular remodeling* and generally precedes the development of clinically evident CHF in the months to years after infarction. Soon after STEMI, the left ventricle begins to dilate. Acutely, this results from expansion of the infarct, i.e., slippage of muscle bundles, disruption of normal myocardial cells, and tissue loss within the necrotic zone, resulting in disproportionate thinning and elongation of the infarct zone. Later, lengthening of the noninfarcted segments occurs as well. The overall chamber enlargement that occurs is related to the size and location of the infarct, with greater dilation following infarction of the apex of the left ventricle and causing more marked hemodynamic impairment, more frequent heart failure, and a poorer prognosis. Progressive dilation and its clinical consequences may be ameliorated by therapy with ACE inhibitors and other vasodilators (e.g., nitrates). In patients with an ejection fraction $<40\%$, regardless of whether or not heart failure is present, ACE inhibitors should be prescribed.

HEMODYNAMIC ASSESSMENT Pump failure is now the primary cause of in-hospital death from STEMI. The extent of ischemic necrosis correlates well with the degree of pump failure and with mortality, both early (within 10 days of infarction) and later. The most common clinical signs are pulmonary rales and S_3 and S_4 gallop sounds. Pulmonary congestion is also frequently seen on the chest roentgenogram. Ele-

vated LV filling pressure and elevated pulmonary artery pressure are the characteristic hemodynamic findings, but these findings may result from a reduction of ventricular compliance (diastolic failure) and/or a reduction of stroke volume with secondary cardiac dilation (systolic failure) (Chap. 215).

A classification originally proposed by Killip divides patients into four groups: class I, no signs of pulmonary or venous congestion; class II, moderate heart failure as evidenced by rales at the lung bases, S_3 gallop, tachypnea, or signs of failure of the right side of the heart, including venous and hepatic congestion; class III, severe heart failure, pulmonary edema; and class IV, shock with systolic pressure $<$ 90 mmHg and evidence of peripheral vasoconstriction, peripheral cyanosis, mental confusion, and oliguria. When this classification was established in 1967, the expected hospital mortality rate of patients in these classes was as follows: class I, 0 to 5%; class II, 10 to 20%; class III, 35 to 45%; and class IV, 85 to 95%. With advances in management, the mortality rate in each class has fallen, perhaps by as much as one-third to one-half.

Hemodynamic evidence of abnormal LV function appears when contraction is seriously impaired in 20 to 25% of the left ventricle. Infarction of $\geq$40% of the left ventricle usually results in cardiogenic shock (Chap. 255). Positioning of a balloon flotation catheter in the pulmonary artery permits monitoring of LV filling pressure; this technique is useful in patients who exhibit hypotension and/or clinical evidence of CHF. Cardiac output can also be determined with a pulmonary artery catheter. With the addition of intraarterial pressure monitoring, systemic vascular resistance can be calculated as a guide to adjusting vasopressor and vasodilator therapy. Some patients with STEMI have markedly elevated LV filling pressures ($>$22 mmHg) and normal cardiac indexes [$>$2.6 and $>$3.6 L/(min/m^2)], while others have relatively low LV filling pressures ($<$15 mmHg) and reduced cardiac indexes. The former patients usually benefit from diuresis, while the latter may respond to volume expansion by means of intravenous administration of colloid-containing solutions.

Hypovolemia This is an easily corrected condition that may contribute to the hypotension and vascular collapse associated with STEMI in some patients. It may be secondary to previous diuretic use, to reduced fluid intake during the early stages of the illness, and/or to vomiting associated with pain or medications. Consequently, hypovolemia should be identified and corrected in patients with STEMI and hypotension before more vigorous forms of therapy are begun. Central venous pressure reflects RV rather than LV filling pressure and is an inadequate guide for adjustment of blood volume, since LV function is almost always affected much more adversely than RV function in patients with STEMI. The optimal LV filling or pulmonary artery wedge pressure may vary considerably among patients. Each patient's ideal level (generally ~20 mmHg) is reached by cautious fluid administration during careful monitoring of oxygenation and cardiac output. Eventually, the cardiac output level plateaus, and further increases in LV filling pressure only increase congestive symptoms and decrease systemic oxygenation without raising arterial pressure.

TREATMENT

The management of CHF in association with STEMI is similar to that of acute heart failure secondary to other forms of heart disease (avoidance of hypoxemia, diuresis, afterload reduction, inotropic support) (Chap. 216), except that the benefits of digitalis administration to patients with STEMI are unimpressive. By contrast, diuretic agents are extremely effective, as they diminish pulmonary congestion in the presence of systolic and/or diastolic heart failure (Chap. 255). LV filling pressure falls and orthopnea and dyspnea improve after the intravenous administration of furosemide or other loop diuretics. These drugs should be used with caution, however, as they can result in a massive diuresis with associated decreases in plasma volume, cardiac output, systemic blood pressure, and hence coronary perfusion. Nitrates in various forms may be used to decrease preload and congestive symptoms. Oral isosorbide dinitrate, topical nitroglycerin ointment, or intravenous nitroglycerin all have the advantage over a diuretic of lowering preload through venodilation without decreasing the total plasma volume. In addition, nitrates may improve ventricular compliance if ischemia is present, as ischemia causes an elevation of LV filling pressure. Vasodilators must be used with caution to prevent serious hypotension. As noted earlier, ACE inhibitors are an ideal class of drugs for management of ventricular dysfunction after STEMI, especially for the long term.

CARDIOGENIC SHOCK Efforts to reduce infarct size and prompt treatment of ongoing ischemia and other complications of MI appear to have reduced the incidence of cardiogenic shock from 20% to about 7%. Only 10% of patients with this condition present with it on admission, while 90% develop it during hospitalization. Typically, patients who develop cardiogenic shock have severe multivessel coronary artery disease with evidence of "piecemeal" necrosis extending outward from the original infarct zone. →***The evaluation and management of cardiogenic shock and severe power failure after STEMI are discussed in detail in Chap. 255.***

RIGHT VENTRICULAR INFARCTION Approximately one-third of patients with inferoposterior infarction demonstrate at least a minor degree of RV necrosis. An occasional patient with inferoposterior LV infarction also has extensive RV infarction, and rare patients present with infarction limited primarily to the right ventricle. Clinically significant RV infarction causes signs of severe RV failure [jugular venous distention, Kussmaul's sign (Chap. 209), hepatomegaly] with or without hypotension. ST-segment elevations of right-sided precordial ECG leads, particularly lead V_4R, are frequently present in the first 24 h in patients with RV infarction. Two-dimensional echocardiography is helpful in determining the degree of RV dysfunction. Catheterization of the right side of the heart often reveals a distinctive hemodynamic pattern resembling cardiac tamponade or constrictive pericarditis (steep right atrial "y" descent and an early diastolic dip and plateau in RV waveforms) (Chap. 222). Therapy consists of volume expansion to maintain adequate RV preload and efforts to improve LV performance with attendant reduction in pulmonary capillary wedge and pulmonary arterial pressures.

ARRHYTHMIAS (See also Chaps. 213 and 214) The incidence of arrhythmias after STEMI is higher in patients seen early after the onset of symptoms. The mechanisms responsible for infarction-related arrhythmias include autonomic nervous system imbalance, electrolyte disturbances, ischemia, and slowed conduction in zones of ischemic myocardium. An arrhythmia can usually be managed successfully if trained personnel and appropriate equipment are available when it develops. Since most deaths from arrhythmia occur during the first few hours after infarction, the effectiveness of treatment relates directly to the speed with which patients come under medical observation. The prompt management of arrhythmias constitutes a significant advance in the treatment of STEMI.

Ventricular Premature Beats Infrequent, sporadic ventricular premature depolarizations occur in almost all patients with STEMI and do not require therapy. Whereas in the past, frequent, multifocal, or early diastolic ventricular extrasystoles (so-called warning arrhythmias) were routinely treated with antiarrhythmic drugs to reduce the risk of development of ventricular tachycardia and ventricular fibrillation, pharmacologic therapy is now reserved for patients with sustained ventricular arrhythmias. Prophylactic antiarrhythmic therapy (either intravenous lidocaine early or oral agents later) is contraindicated for ventricular premature beats in the absence of clinically important ventricular tachyarrhythmias, as such therapy may actually increase the mortality rate. Beta-adrenoceptor blocking agents are effective in abolishing ventricular ectopic activity in patients with STEMI and in the prevention of ventricular fibrillation. As described above (see "Beta-Adrenoceptor Blockers"), they should be used routinely in patients without contraindications. In addition, hypokalemia and hypomagnesemia are risk factors for ventricular fibrillation in patients with

STEMI; the serum potassium concentration should be adjusted to approximately 4.5 mmol/L and magnesium to about 2.0 mmol/L.

Ventricular Tachycardia and Fibrillation Within the first 24 h of STEMI, ventricular tachycardia and fibrillation can occur without prior warning arrhythmias. The occurrence of ventricular fibrillation can be reduced by prophylactic administration of intravenous lidocaine. However, prophylactic use of lidocaine has not been shown to reduce overall mortality from STEMI. In fact, in addition to causing possible noncardiac complications, lidocaine may predispose to an excess risk of bradycardia and asystole. For these reasons, and with earlier treatment of active ischemia, more frequent use of beta-blocking agents, and the nearly universal success of electrical cardioversion or defibrillation, routine prophylactic antiarrhythmic drug therapy *is no longer recommended*. It should be reserved for patients who cannot reach a hospital or for those treated in hospitals that lack the constant presence in the coronary care unit of a physician or nurse trained in the recognition and treatment of ventricular fibrillation.

Sustained ventricular tachycardia that is well tolerated hemodynamically should be treated with an intravenous regimen of amiodarone (bolus of 150 mg over 10 min, followed by infusion of 1.0 mg/min for 6 h and then 0.5 mg/min); or procainamide (bolus of 15 mg/kg over 20 to 30 min; infusion of 1 to 4 mg/min); if it does not stop promptly, electroversion should be used (Chap. 214). An unsynchronized discharge of 200 to 300 J (defibrillation) is used immediately in patients with ventricular fibrillation or when ventricular tachycardia causes hemodynamic deterioration. Ventricular tachycardia or fibrillation that is refractory to electroshock may be more responsive after the patient is treated with epinephrine (1 mg intravenously or 10 mL of a 1:10,000 solution via the intracardiac route), bretylium (a 5-mg/kg bolus), or amiodarone (a 75- to 150-mg bolus).

Ventricular arrhythmias, including the unusual form of ventricular tachycardia known as *torsades de pointes* (Chap. 214), may occur in patients with STEMI as a consequence of other concurrent problems (such as hypoxia, hypokalemia, or other electrolyte disturbances) or of the toxic effects of an agent being administered to the patient (such as digoxin or quinidine). A search for such secondary causes should always be undertaken.

Although the in-hospital mortality rate is increased, the long-term survival is good in patients who survive to hospital discharge after *primary* ventricular fibrillation, i.e., ventricular fibrillation that is a primary response to acute ischemia and is not associated with predisposing factors such as CHF, shock, bundle branch block, or ventricular aneurysm. This result is in sharp contrast to the poor prognosis for patients who develop ventricular fibrillation *secondary* to severe pump failure. For patients who develop ventricular tachycardia or ventricular fibrillation late in their hospital course (i.e., after the first 48 h), the mortality rate is increased both in-hospital and during long-term follow-up. Such patients should be considered for electrophysiologic study and implantation of a cardioverter/defibrillator (Fig. 228-5) (Chap. 214).

Accelerated Idioventricular Rhythm Accelerated idioventricular rhythm (AIVR, "slow ventricular tachycardia"), a ventricular rhythm with a rate of 60 to 100 bpm, occurs in 25% of patients with STEMI. It often occurs transiently during fibrinolytic therapy at the time of reperfusion. The rate of AIVR is usually similar to that of the sinus rhythm that precedes and follows it, and this similarity of rate plus the relatively minor hemodynamic effects make this rhythm more difficult to detect except by electrocardiographic monitoring. For the most part, AIVR is benign and does not presage the development of classic ventricular tachycardia. Most episodes of AIVR do not require treatment if the patient is monitored carefully, as degeneration into a more serious arrhythmia is rare, and, if it occurs, AIVR can generally be treated readily with a drug that increases the sinus rate (atropine).

Supraventricular Arrhythmias Sinus tachycardia is the most common supraventricular arrhythmia. If it occurs secondary to another cause (such as anemia, fever, heart failure, or a metabolic derangement), the primary problem should be treated first. However, if it appears to be due to sympathetic overstimulation (e.g., as part of a hyperdynamic state), then treatment with a beta blocker is indicated. Other common arrhythmias in this group are atrial flutter and atrial fibrillation, which are often secondary to LV failure. Digoxin is usually the treatment of choice for supraventricular arrhythmias if heart failure is present. If heart failure is absent, beta blockers, verapamil, or diltiazem are suitable alternatives for controlling the ventricular rate, as they may also help to control ischemia. If the abnormal rhythm persists for >2 h with a ventricular rate >120 bpm or if tachycardia induces heart failure, shock, or ischemia (as manifested by recurrent pain or ECG changes), a synchronized electroshock (100 to 200 J) should be used.

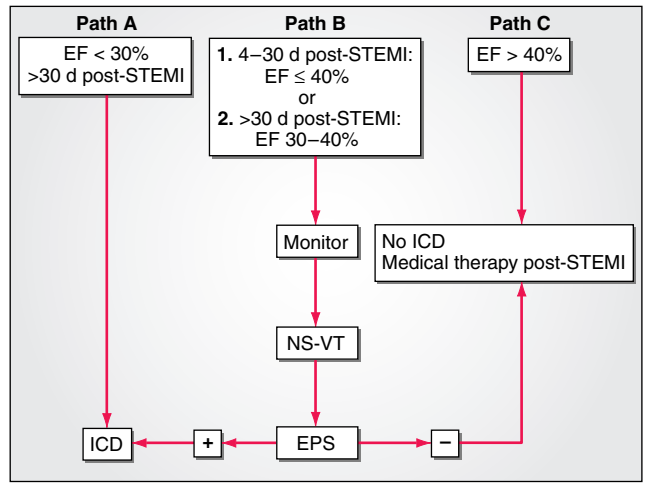

FIGURE 228-5 Algorithm for assessment of need for electrophysiologic study and implantation of a cardioverter/defibrillator. The appropriate management path is selected based upon the timing of and measurement of left ventricular ejection fraction (table at top of figure). In path A, patients with markedly depressed left ventricular function at least 1 month post-STEMI are referred for insertion of an implantable cardioverter/defibrillator (ICD). Path B illustrates the management of patients in an intermediate-risk category who require further evaluation with an electrophysiology study (EPS). If the EPS reveals inducible ventricular tachycardia/ventricular fibrillation, an ICD is implanted; if the EPS is negative, no ICD is implanted and the patient receives medical therapy post-STEMI. Path C illustrates the management of patients with preserved left ventricular function who do not receive an ICD and are treated with medical therapy post-STEMI. (*Adapted from EM Antman et al: ACC/AHA guidelines for the management of patients with ST elevation myocardial infarction. Circulation and JACC, 2004, in press; with permission.*)

Accelerated junctional rhythms have diverse causes but may occur in patients with inferoposterior infarction. Digitalis excess must be ruled out. In some patients with severely compromised LV function, the loss of appropriately timed atrial systole results in a marked decrease in cardiac output. Right atrial or coronary sinus pacing is indicated in such instances.

Sinus Bradycardia Treatment of sinus bradycardia is indicated if hemodynamic compromise results from the slow heart rate. Atropine is the most useful drug for increasing heart rate and should be given intravenously in doses of 0.5 mg initially. If the rate remains <50 to 60 bpm, additional doses of 0.2 mg, up to a total of 2.0 mg, may be given. Persistent bradycardia (<40 bpm) despite atropine may be treated with electrical pacing. Isoproterenol should be avoided.

Atrioventricular and Intraventricular Conduction Disturbances (See also Chap. 213) Both the in-hospital mortality rate and the post-discharge mortality rate of patients who have complete atrioventricular (AV) block in association with anterior infarction are markedly higher than those of patients who develop AV block with inferior infarction. This difference is related to the fact that heart block in inferior infarction is commonly a result of increased vagal tone and/or the release of adenosine and therefore is transient. In anterior wall infarction, heart block is usually related to ischemic malfunction of the conduction system, which is commonly associated with extensive myocardial necrosis.

Temporary electrical pacing provides an effective means of increasing the heart rate of patients with bradycardia due to AV block. However, acceleration of the heart rate may have only a limited impact on prognosis in patients with anterior wall infarction and complete heart block in whom the large size of the infarct is the major factor determining outcome. It should be carried out if it improves hemodynamics, however. Pacing does appear to be beneficial in patients with inferoposterior infarction who have complete heart block associated with heart failure, hypotension, marked bradycardia, or significant ventricular ectopic activity. A subgroup of these patients, those with RV infarction, often respond poorly to ventricular pacing because of the loss of the atrial contribution to ventricular filling. In such patients, dual-chamber AV sequential pacing may be required.

External noninvasive pacing electrodes should be positioned in a "demand" mode for patients with sinus bradycardia (rate $<$ 50 bpm) that is unresponsive to drug therapy, Mobitz II second-degree AV block, third-degree heart block, or bilateral bundle branch block (e.g., right bundle branch block plus left anterior fascicular block). Retrospective studies suggest that permanent pacing may reduce the long-term risk of sudden death due to bradyarrhythmias in the rare patient who develops combined persistent bifascicular and transient third-degree heart block during the acute phase of MI.

OTHER COMPLICATIONS ■ Recurrent Chest Discomfort Recurrent angina develops in ~25% of patients hospitalized for STEMI. This percentage is even higher in patients who undergo successful thrombolysis. Since recurrent or persistent ischemia often heralds extension of the original infarct or reinfarction in a new myocardial zone and is associated with a doubling of risk after STEMI, patients with these symptoms should be referred for prompt coronary arteriography and mechanical revascularization. Repeat administration of a fibrinolytic agent is an alternative to early mechanical revascularization.

Pericarditis (See also Chap. 222) Pericardial friction rubs and/or pericardial pain are frequently encountered in patients with transmural STEMI. This complication can usually be managed with aspirin (650 mg qid). It is important to diagnose the chest pain of pericarditis accurately, since failure to recognize it may lead to the erroneous diagnosis of recurrent ischemic pain and/or infarct extension, with resulting inappropriate use of anticoagulants, nitrates, beta blockers, or coronary arteriography. When it occurs, complaints of pain radiating to either trapezius muscle is helpful since such a pattern of discomfort is typical of pericarditis but rarely occurs with ischemic discomfort. Anticoagulants potentially could cause tamponade in the presence of acute pericarditis (as manifested by either pain or persistent rub) and therefore should not be used unless there is a compelling indication.

Thromboembolism Clinically apparent thromboembolism complicates STEMI in ~10% of cases, but embolic lesions are found in 20% of patients in necropsy series, suggesting that thromboembolism is often clinically silent. Thromboembolism is considered to be an important contributing cause of death in 25% of patients with STEMI who die after admission to the hospital. Arterial emboli originate from LV mural thrombi, while most pulmonary emboli arise in the leg veins.

Thromboembolism typically occurs in association with large infarcts (especially anterior), CHF, and a LV thrombus detected by echocardiography. The incidence of arterial embolism from a clot originating in the ventricle at the site of an infarction is small but real. Two-dimensional echocardiography reveals LV thrombi in about one-third of patients with anterior wall infarction but in few patients with inferior or posterior infarction. Arterial embolism often presents as a major complication, such as hemiparesis when the cerebral circulation is involved or hypertension if the renal circulation is compromised. When a thrombus has been clearly demonstrated by echocardiographic or other techniques or when a large area of regional wall motion abnormality is seen even in the absence of a detectable mural thrombus, systemic anticoagulation should be undertaken (in the absence of contraindications), as the incidence of embolic complications appears to be markedly lowered by such therapy. The appropriate duration of therapy is unknown, but 3 to 6 months is probably prudent.

Left Ventricular Aneurysm The term *ventricular aneurysm* is usually used to describe *dyskinesis* or local expansile paradoxical wall motion. Normally functioning myocardial fibers must shorten more if stroke volume and cardiac output are to be maintained in patients with ventricular aneurysm; if they cannot, overall ventricular function is impaired. True aneurysms are composed of scar tissue and neither predispose to nor are associated with cardiac rupture.

The complications of LV aneurysm do not usually occur for weeks to months after STEMI; they include CHF, arterial embolism, and ventricular arrhythmias. Apical aneurysms are the most common and the most easily detected by clinical examination. The physical finding of greatest value is a double, diffuse, or displaced apical impulse. Ventricular aneurysms are readily detected by two-dimensional echocardiography, which may also reveal a mural thrombus in an aneurysm.

Rarely, myocardial rupture may be contained by a local area of pericardium, along with organizing thrombus and hematoma. Over time, this *pseudoaneurysm* enlarges, maintaining communication with the LV cavity through a narrow neck. Because a pseudoaneurysm often ruptures spontaneously, it should be surgically repaired if recognized.

POSTINFARCTION RISK STRATIFICATION AND MANAGEMENT

Many clinical factors have been identified that are associated with an increase in cardiovascular risk after initial recovery from STEMI. Some of the most important factors include persistent ischemia (spontaneous or provoked), depressed LV ejection fraction ($<$40%), rales above the lung bases on physical examination or congestion on chest radiograph, and symptomatic ventricular arrhythmias. Other features associated with increased risk include a history of previous MI, age $>$75, diabetes mellitus, prolonged sinus tachycardia, hypotension, ST-segment changes at rest without angina ("silent ischemia"), an abnormal signal-averaged ECG, nonpatency of the infarct-related coronary artery (if angiography is undertaken), and persistent advanced heart block or a new intraventricular conduction abnormality on the ECG. Therapy must be individualized on the basis of the relative importance of the risk(s) present.

The goal of preventing reinfarction and death after recovery from STEMI has led to strategies to evaluate risk after infarction. In stable patients, submaximal exercise stress testing may be carried out before hospital discharge to detect residual ischemia and ventricular ectopy and to provide the patient with a guideline for exercise in the early recovery period. Alternatively, or in addition, a maximal (symptom-limited) exercise stress test may be carried out 4 to 6 weeks after infarction. Evaluation of LV function is usually warranted as well. Recognition of a depressed LV ejection fraction by echocardiography or radionuclide ventriculography identifies patients who should receive ACE inhibitors (see "Angiotensin-Converting Enzyme Inhibitors," above). Patients in whom angina is induced at relatively low workloads, those who have a large reversible defect on perfusion imaging or a depressed ejection fraction, those with demonstrable ischemia, and those in whom exercise provokes symptomatic ventricular arrhythmias should be considered at high risk for recurrent MI or death from arrhythmia (Fig. 228-5). Cardiac catheterization with coronary angiography and/or invasive electrophysiologic evaluation is advised.

Exercise tests also aid in formulating an individualized exercise prescription, which can be much more vigorous in patients who tolerate exercise without any of the above-mentioned adverse signs. Additionally, predischarge stress testing may provide an important psychological benefit, building the patient's confidence by demonstrating a reasonable exercise tolerance. Furthermore, particularly when no arrhythmias or signs of ischemia are identified, the patient benefits by the physician's reassurance that objective evidence suggests no immediate jeopardy.

In many hospitals a cardiac rehabilitation program with progressive exercise is initiated in the hospital and continued after discharge. Ideally, such programs should include an educational component that informs patients about their disease and its risk factors.

The usual duration of hospitalization for an uncomplicated STEMI is about 5 days. The remainder of the convalescent phase may be accomplished at home. During the first 1 to 2 weeks, the patient should be encouraged to increase activity by walking about the house and outdoors in good weather. Normal sexual activity may be resumed during this period. After 2 weeks, the physician must regulate the patient's activity on the basis of exercise tolerance. Most patients will be able to return to work within 2 to 4 weeks.

SECONDARY PREVENTION

Various secondary preventive measures are at least partly responsible for the improvement in the long-term mortality and morbidity rates after STEMI. Long-term treatment with an antiplatelet agent (usually aspirin) after STEMI is associated with a 25% reduction in the risk of recurrent infarction, stroke, or cardiovascular mortality (36 fewer events for every 1000 patients treated). In addition, in patients taking aspirin chronically, STEMIs tend to be smaller and are more likely to be non-Q-wave in nature. An alternative antiplatelet agent that may be used for secondary prevention in patients intolerant of aspirin is the ADP receptor antagonist clopidogrel (75 mg orally daily). ACE inhibitors should be used indefinitely by patients with clinically evident heart failure, a moderate decrease in global ejection fraction, or a large regional wall motion abnormality to prevent late ventricular remodeling and recurrent ischemic events.

The chronic routine use of oral beta-adrenoceptor blockers for at least 2 years after STEMI is supported by well-conducted, placebo-controlled trials that have convincingly demonstrated reductions in the rates of total mortality, sudden death, and, in some instances, reinfarction. In contrast, calcium antagonists are not recommended for routine secondary prevention.

Evidence suggests that warfarin lowers the risk of late mortality and the incidence of reinfarction after STEMI. Most physicians prescribe aspirin routinely for all patients without contraindications and add warfarin for patients at increased risk of embolism (see "Thromboembolism," above). Several studies suggest that in patients <75 years a low dose of aspirin (75 to 81 mg/d) in combination with warfarin administered to achieve an INR > 2.0 is more effective than aspirin alone for preventing recurrent MI and embolic cerebrovascular accident. However, there is an increased risk of bleeding and a high rate of discontinuation of warfarin that has limited clinical acceptance of combination antithrombotic therapy. Combination antiplatelet therapy with aspirin and clopidogrel has been established as an important treatment strategy for reducing the risk of death and recurrent ischemic events in the year following presentation with unstable angina/NSTEMI. Trials are underway to assess whether such combined antiplatelet therapy is also effective and safe in patients recovering from STEMI.

Finally, risk factors for *atherosclerosis* (Chap. 224) should be discussed with the patient, and, when possible, favorably modified. In particular, efforts should be made to ensure the cessation of smoking and the control of hypertension and hyperlipidemia [the target low-density lipoprotein level is <2.6 mmol/L (<100 mg/dL)]. In addition, regular physical exercise and reduction of emotional stress should be encouraged. Hormone replacement therapy prevention of coronary events should not be given de novo to postmenopausal women after STEMI. Postmenopausal women already taking estrogen plus progestin at the time of STEMI may continue that therapy.

229 PERCUTANEOUS CORONARY REVASCULARIZATION

Donald S. Baim

While bypass surgery was once the only means of coronary revascularization, in 1977 Andreas Gruntzig introduced a form of catheter-based coronary revascularization that he termed *percutaneous transluminal coronary angioplasty (PTCA)*. Given the limitations of his early equipment, fewer than 1000 PTCA procedures were performed worldwide each year. By the mid-1980s, progressive improvements in the balloon angioplasty equipment led to improved results, expanded indications for use, and explosive growth in the numbers of PTCA procedures; the annual number of PTCA procedures ($\sim$300,000) then roughly matched the number of surgical bypass operations. During the 1990s, a number of newer devices (including stents and atherectomy devices) were introduced that further improved the acute success, safety, and long-term durability and allowed the number of percutaneous coronary revascularizations (PCRs), or percutaneous coronary interventions (PCIs), to grow further (from 800,000 to 1 million procedures annually), more than double the annual number of coronary bypass operations ($\sim$400,000). This dominant role of catheter-based intervention in the treatment of coronary artery disease has led to creation of a separate area within the field of cardiovascular diseases known as *interventional cardiology*, with incremental fellowship requirements and Board certification based on training, ongoing experience (75 procedures per year), and a written examination.

All catheter-based coronary interventions are derivatives of diagnostic cardiac catheterization (Chap. 212), in which catheters are introduced into the arterial circulation by needle puncture, advanced into the heart under fluoroscopic guidance, and used for pressure measurements or injections of radiopaque liquid contrast agents. Interventional procedures differ in that the catheter placed into the ostium of the narrowed coronary artery has a slightly larger lumen diameter to allow passage of a flexible, steerable guidewire (diameter <0.5 mm) down the coronary artery lumen, through the narrowing, and into the vessel beyond. This guidewire then serves as the rail over which angioplasty balloons or other therapeutic devices are advanced and used to enlarge the narrowed segment of coronary artery (Fig. 229-1). Because PCR is performed with local anesthesia and requires only a short (1-day) hospitalization, its use in suitable patients can greatly decrease recovery time and expense compared to coronary bypass surgery. While not all types of coronary narrowing are well suited to catheter-based intervention, PCR is the treatment of choice for roughly 70% of patients with symptomatic single-vessel disease and roughly 20% of patients with symptomatic three-vessel disease. Selection of suitable cases for PCR versus bypass surgery takes into account the anatomic restrictions of PCR (in dealing with diffuse disease, bifurcation lesions, etc.). Both patient and physician need to be aware that while catheter-based in-

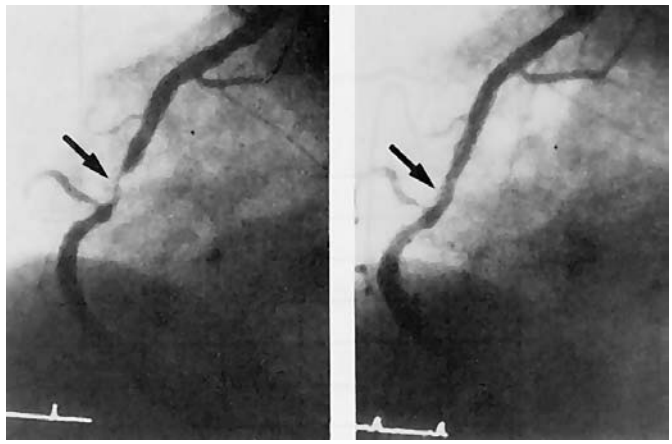

FIGURE 229-1 Focal discrete stenosis of the mid-right coronary angioplasty in a patient with unstable angina, shown before (*left panel*) and after (*right panel*) inflation of the PTCA balloon catheter. The lesion is typical of the straightforward lesion anatomy treated by early (pre-1985) coronary angioplasty.

tervention is done under anesthesia and has a lower elective mortality rate than bypass surgery (0.4 to 1.0%, compared to a rate of 1 to 3%), it is still an invasive procedure whose risks and benefits need to be weighed carefully for each individual patient. To decide which patients should undergo revascularization (rather than continued medical management), and to select which patients should undergo catheter-based rather than surgical revascularization, a detailed understanding of both clinical and coronary angiographic factors, as well as the applicability of various interventional techniques, is required.

INDICATIONS

The fundamental indication for PCR is the presence of one or more coronary stenoses that are approachable by catheter-based techniques and are thought to be responsible for a clinical syndrome that warrants revascularization. Moreover, the risks and benefits of revascularization by PCR for the individual patient should compare favorably with those of surgery. In patients with significant narrowing of a single coronary artery, the main benefit of revascularization lies in relief of anginal symptoms rather than in increasing their already good prognosis with medical therapy. By contrast, for the patient with significant left main stenosis or multivessel disease, revascularization may both relieve angina *and* improve long-term survival. For most patients with multivessel coronary disease, the current choice is surgical rather than catheter-based revascularization, particularly when one or more vessels supplying significant areas of viable myocardium are not well suited to PCR due to unfavorable anatomic features. In patients for whom either PCR or bypass surgery is a possible treatment for multivessel coronary artery disease, randomized trials have suggested that the two procedures are essentially equivalent in terms of in-hospital and 3- to 5-year mortality rates, except for patients with diabetes mellitus and multivessel coronary artery disease where surgical treatment appears to offer improved 5- to 7-year survival compared to PCR. However, patients who undergo PCR are more likely to need a second revascularization procedure (generally repeat PCR to treat restenosis) to maintain an equivalent level of symptom relief at 5 years. Repeat procedures will thus be needed in 50% of patients undergoing PTCA and in 20% of patients undergoing stenting, compared to 7 to 10% for patients undergoing bypass surgery, for multivessel disease.

The current clinical indications for PCR cover the spectrum of ischemic heart disease, from patients with unstable angina or acute infarction to patients with silent ischemia, as summarized in the recent ACC/AHA guidelines. One clear indication is *moderately severe, chronic, stable angina*, which persists despite medical antianginal therapy (Chap. 226). Occasionally, PCR is offered to patients with objective evidence of ischemia on noninvasive testing (i.e., an abnormal exercise test) and suitable coronary lesions, even though they have comparatively mild anginal symptoms. At the other extreme, many patients undergo PCR for more pressing indications, including unstable angina or acute myocardial infarction (MI) (with or without prior thrombolytic therapy). An aggressive approach to the treatment of unstable angina is now favored. It involves initial stabilization with beta blockers, nitrates, heparin, and antiplatelet agents (aspirin and frequently a platelet glycoprotein IIb/IIIa receptor blocker), followed by prompt diagnostic catheterization and same-procedure PCR of the culprit blockage. This approach offers the patient a more rapid return to work, fewer readmissions and late revascularizations, and potentially a reduction in late events compared to more prolonged initial trials of medical stabilization before proceeding with invasive evaluation and treatment.

In the early 1980s the introduction of intravenous fibrinolytic agents to reopen the occluded infarct-related vessel represented a major advance in the treatment of acute MI (Chap. 228). While use of immediate PCR would be expected to improve the results of fibrinolytic therapy further (by treating the underlying atherosclerotic stenosis), randomized trials showed that routine PCR after thrombolytic administration had no benefit compared to "watchful waiting," reserving PCR for patients who exhibited spontaneous or exercise-induced ischemia. In contrast, there is now strong evidence that *primary* or direct PCR (that is, PCR used instead of fibrinolytic therapy) can reduce the in-hospital mortality rate (from roughly 7 to 4%) when performed promptly by a skilled operator (Fig. 229-2). Another advantage of PCR is that it can be performed even in acute MI patients who have relative contraindications to fibrinolytic therapy (advanced age, hypertension, prior stroke, recent surgery, etc.).

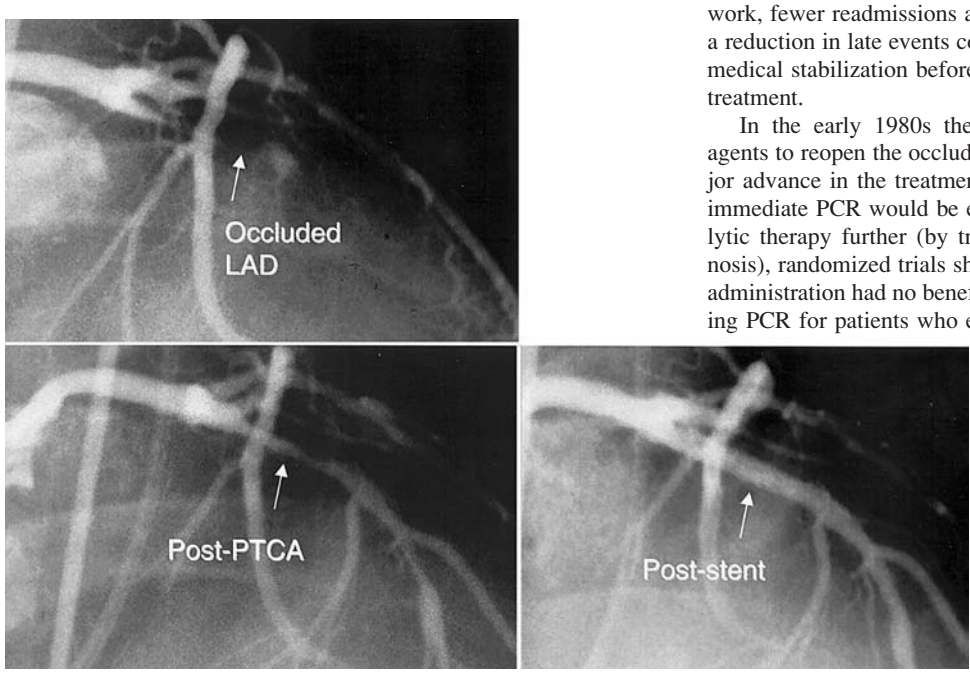

FIGURE 229-2 Left coronary angiogram in a patient with acute anterior myocardial infarction and cardiogenic shock shows occlusion of the proximal left anterior descending coronary artery (*top panel, arrow*) with only faint filling beyond the obstructing thrombus. After initial PTCA (*lower left panel*), there is restored antegrade flow with residual stenosis. After stent placement (*lower right panel*), there is no residual stenosis and brisk flow. This improvement was associated with reversal of shock hemodynamics, including normalization of severe lactic acidosis.

As the clinical indications for PCR have broadened, so have its anatomic capabilities. Largely through the introduction of newer interventional devices

such as stents, PCR has advanced well beyond the treatment of proximal, discrete, subtotal, concentric, noncalcified lesions. Calcified, complex, or diffuse disease lesions respond well to coronary stent placement, sometimes after pretreatment with rotational atherectomy. Even totally occluded coronary arteries (particularly ones that have been occluded for <6 months) can be crossed and dilated effectively, although the success rate remains lower than for subtotal lesions (60% versus 90% for subtotal stenotic lesions). In addition to lesions in the native coronary tree, obstructions in the saphenous vein (Fig. 229-3) or internal mammary artery bypass grafts can also be dilated successfully to treat postbypass angina. If multiple lesions are responsible for the clinical syndrome, they generally can be dilated during a single procedure. When the severity of some individual lesions is unclear based on prior stress testing and angiography, special guidewires can be used to measure their physiologic severity during maximal coronary flow induced by adenosine infusion.

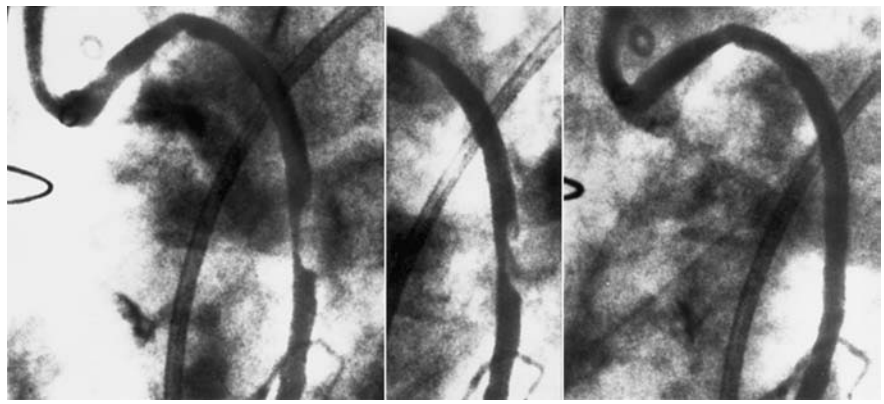

FIGURE 229-3 Stent placement in a diseased saphenous vein graft. *Left*: Severe eccentric stenosis in an 8-year-old saphenous vein graft to the left anterior descending coronary artery. *Middle*: After balloon angioplasty, the lumen remains stenotic due to elastic recoil of the vessel wall and disruption (dissection) of the plaque. *Right*: After placement of a coronary stent, both recoil and dissection have been overcome, providing a large smooth lumen.

NONBALLOON TECHNIQUES

While conventional balloon angioplasty (PTCA) offered anatomic versatility and acceptable short- and long-term results, it was limited when used to approach certain anatomic lesion types (e.g., calcified eccentric, ostial, thrombus-containing, or bifurcation lesions). It was also plagued by the problems of intimal dissection (which led to abrupt closure of the dilated segment in 3% of cases, requiring emergency bypass surgery) and restenosis of 30 to 40% of the dilated segments within 6 months of initially successful treatment. These problems motivated the development of a number of newer, nonballoon techniques that entered routine clinical practice during the early 1990s. These include atherectomy and stent placement, the latter of which now dominates current PCR (see below). In parallel, improvements in adjunctive pharmacotherapy (especially thienopyridines and platelet glycoprotein IIb/IIIa receptor blockers) has helped produce significant improvements in the success, safety, and long-term results. While most newer PCR procedures have higher in-hospital cost than conventional balloon angioplasty, much of this incremental cost can be recouped by the reduction in acute complications and the treatment of subsequent restenosis.

STENTS These are metallic scaffolds that are inserted into a diseased vessel segment in their collapsed form and are then deployed by balloon inflation or self-expansion (after removal of an external constraining membrane) (Fig. 229-4). They overcome two of the principal limitations of balloon dilatation—local dissection of the plaque and the tendency for elastic recoil of the vessel wall—allowing stents consistently to establish a normal-appearing vessel lumen. Since 1994, when the first two balloon-expandable stent designs were approved by the U.S. Food and Drug Administration (FDA), a number of second- and third-generation stent designs have been developed that offer easier delivery of a wider variety of sizes and lengths, into tortuous or distal lesions. Other refinements in stent design include optional membranous coverings (to seal aneurysms or perforations) and drug-eluting coatings (to suppress stent thrombosis and in-stent proliferation).

In the early experience, metallic stents proved prone to thrombotic occlusion, either acute (<24 h) or subacute (1 to 14 days with a peak at 6 days), requiring an aggressive anticoagulation regimen (aspirin, dipyridamole, and warfarin) to reduce such thromboses to ~3%. This aggressive anticoagulant regimen prolonged hospitalization and increased the incidence of local vascular complications at the femoral arterial entry site. Many of these thrombotic complications were the result of incomplete stent expansion, and greater attention to full initial deployment allowed even more favorable thrombosis rates (<1%), with only antiplatelet drugs (aspirin plus the platelet ADP-receptor blockers, ticlopidine or clopidogrel). This rapid evolution in devices, concomitant medications, and indications has led to the dominance of stent placement in catheter-based coronary revascularization, with placement of one or more stents in 85% of all procedures.

In addition to controlling complications related to abrupt vessel closure, the fact that stenting provides a large acute luminal area compared to PTCA alone has reduced the incidence of subsequent restenosis (e.g., angiographic restenosis rates of 20% versus 33%, and clinical restenosis rates of 10% versus 16 to 20%). When in-stent restenosis does occur, it is the consequence of excessive neointimal hyperplasia within the stent (Fig. 229-5). This can be treated by balloon dilatation, followed by catheter-delivered local β or γ radiation to suppress subsequent neointimal regrowth. Since such radiation treatment also inhibits endothelialization, placement of new stents at the time of radiation should be avoided or they should be protected by prolonging antiplatelet therapy to 9 to 12 months. More recent research has demonstrated that stents can be coated to elute antiproliferative agents such as rapamycin or taxol that inhibit excessive proliferation. Local release of these agents has further decreased angiographic restenosis rates (to <10%) and clinical restenosis rates (to roughly 5%)—benefits that have broadened the use of stents and PCR following their release in early 2003.

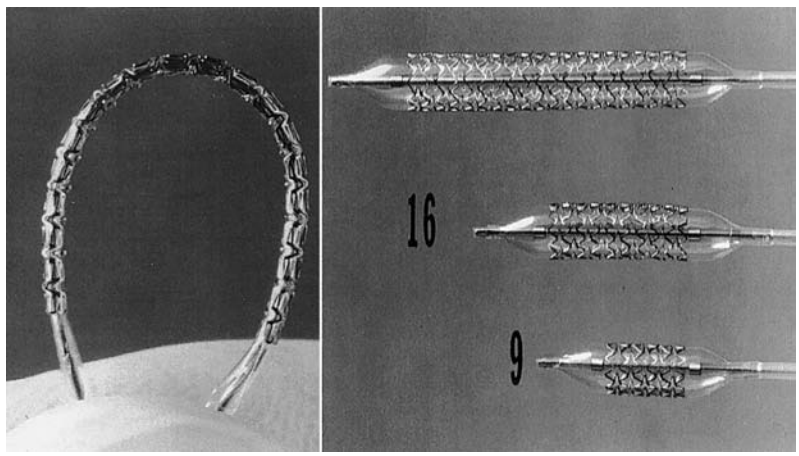

FIGURE 229-4 Second-generation stent. *Left*: The flexibility typical of second-generation stents is shown in bending the collapsed stent on its delivery balloon. *Right*: The same stent design is shown in its balloon-expanded configuration, in some of the available lengths [32 mm (*top*), 16 mm, and 9 mm]. The availability of a variety of second-generation stents since 1997 has helped make stent placement a part of more than 85% of all PCRs.

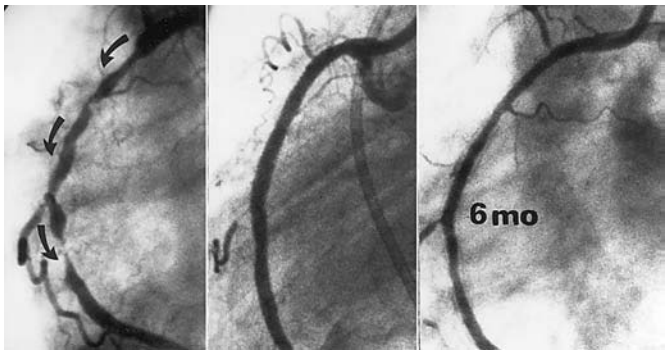

FIGURE 229-5 Short- and long-term results in a long lesion in the right coronary artery. *Left*: A long (~50 mm) area of disease (*arrows*) is present in the right coronary artery. *Middle*: Contrast injection after placement of two long second-generation stents (25 and 35 mm long) shows excellent patency throughout the proximal- and mid-portions of the vessel. *Right*: Follow-up angiogram 6 months after stent placement shows mild lumen reduction throughout the stented segment due to neointimal hyperplasia within the stent (note the separation between the stent shadows and the contrast-filled lumen). Mild degrees of proliferative narrowing are benign and common within stents (particularly long stents such as this one). Had the degree of lumen reduction been greater and associated with recurrent symptoms or an abnormal exercise test, however, re-intervention would have been performed, possibly followed by local radiation delivery (brachytherapy) to inhibit excessive subsequent tissue regrowth. Use of a drug-eluting stent would have virtually eliminated this in-stent neointimal hyperplasia.

ATHERECTOMY Whereas both balloon angioplasty and stent placement enlarge the coronary lumen by displacing plaque, atherectomy catheters enlarge the lumen by removing plaque mass from the treated lesion. Several mechanical atherectomy devices were developed in the 1990s, including directional, rotational, extraction, and laser atherectomy. Although each has certain applications, the greater technical difficulty and procedural complication profile of atherectomy compared to stenting has relegated these devices to niche roles in current PCR. Suction thrombectomy devices may be useful when large intracoronary thrombi are present (e.g., acute MI), and embolic protection devices (distal filters or occlusion/aspiration devices) may be useful adjuncts during the treatment of saphenous vein graft or other lesions prone to the liberation of debris that may compromise the distal myocardial microcirculation.

RESULTS

The success rate for PCR—defined as leaving a residual diameter stenosis <50% (<30% when a stent has been used), without producing an associated complication—now exceeds 97%. Failures may result from inability to cross the target lesion with the guidewire or balloon catheter, particularly when that target lesion is a chronic total occlusion, or failure to dilate a rigid calcified stenosis (now treated by rotational atherectomy). Before the advent of stents, some local dissection was present in virtually all successful balloon dilatation procedures, and more extensive dissection led to abrupt closure of the dilated segment soon after withdrawal of the balloon catheter, necessitating emergency bypass surgery in approximately 3% of cases. In the stent era, however, the incidence of emergency bypass surgery is now <0.3%. The main remaining hazards of PCR are thrombosis and vessel perforation, each of which is well below 1%.

Since PCR causes local endothelial injury and leaves metallic foreign bodies (stents) in the vessel lumen, platelet activation and thrombosis are expected potential complications. All PCRs are thus performed under systemic anticoagulation (heparin, 7000 to 10,000 units, or a direct-acting thrombin inhibitor), to maintain an activated clotting time of 250 to 300, and antiplatelet therapy (aspirin, 325 mg/d starting at least 24 h before PCR and continued for at least 3 to 6 months after the procedure). If a coronary stent has been placed, aspirin is supplemented by a blocker of the platelet ADP receptor, clopidogrel, to reduce the likelihood of stent thrombosis. Intravenous antiplatelet agents (blockers of the platelet glycoprotein IIb/IIIa receptors) may reduce further the incidence of ischemic complications (especially postprocedural elevation of cardiac enzymes). They are used prophylactically in what are perceived to be high-risk interventions or provisionally in interventions that have left behind an imperfect mechanical result (e.g., a nonstented distal dissection).

Perforation of a coronary artery was an extremely rare complication of conventional balloon angioplasty but may occur in up to 1% of patients undergoing more aggressive atherectomy procedures. Even small perforations of the distal vessel by the angioplasty guidewire may lead to significant hemopericardium requiring urgent pericardiocentesis in the setting of intense anticoagulant and antiplatelet therapy. Finally, catheter-based interventions are subject to all of the complications of diagnostic catheterization, including adverse reactions to iodinated contrast agents and groin hematoma. For most patients, however, catheter-based coronary revascularization offers a safe and effective alternative to surgical revascularization.

FOLLOW-UP

After successful PCR of all "culprit" lesions, marked improvement or complete resolution of the presenting ischemic syndrome should be evident. In approximately 20% of patients, however, evidence of recurrent ischemia develops within 6 months, reflecting restenosis of the dilated segment in response to the local injury of PCR. When recurrent ischemia develops later than 6 months after PCR, it tends to reflect progression of disease at another site, rather than restenosis of a previous treatment site. Whether due to restenosis or disease progression, most post-PCR ischemia can be treated by repeat PCR, so that only about 10% of patients require bypass surgery during the 5 years after a successful procedure. Since all post-PCR patients have provided evidence of severe obstructive coronary atherosclerosis requiring revascularization, an aggressive program to reduce atherosclerotic risk factors and thereby slow the pace of development of new lesions should be part of any post-PCR regimen. This should include control of hypertension, hyperlipidemia, and smoking cessation (Chap. 226).

SUMMARY

Over the past 25 years, the development of new techniques (such as stent placement), new drug regimens, and refinements in practice driven by "evidence-based" medicine, catheter-based revascularization (PCR) has developed from a procedural curiosity to what is now the dominant form of coronary revascularization. As short- and long-term results have improved and the number of procedures has continued to grow, the pace of development continues to accelerate.

230 HYPERTENSIVE VASCULAR DISEASE

Naomi D.L. Fisher, Gordon H. Williams

An elevated arterial pressure is probably the most important public health problem in developed countries. It is common, asymptomatic, readily detectable, usually easily treatable, and often leads to lethal complications if left untreated. As a result of extensive educational programs in the late 1960s and 1970s by both private and government agencies, the number of undiagnosed and/or untreated patients was reduced significantly by the late 1980s to a level of ~25%, with a concomitant decline in cardiovascular mortality. Unfortunately, by the mid-1990s, this beneficial trend began to wane. The number of undiagnosed patients with hypertension increased to nearly 33%, the decline in cardiovascular mortality flattened, and the number of individuals with chronic diseases with untreated or poorly treated hypertension increased. For example, the prevalence of end-stage renal disease per million population increased from <100 in 1982 to >250 in 1995, and the prevalence of congestive heart failure from ages 55 to 75 more than doubled between 1976 to 1980 and 1988 to 1991. Thus, although our understanding of the pathophysiology of elevated arterial pressure has increased, in 90 to 95% of cases the etiology (and thus potentially the means of prevention or cure) is still largely unknown. As a consequence, in most cases the hypertension is treated nonspecifically, resulting in a large number of minor side effects and a relatively high (50 to 60%) noncompliance rate.

PREVALENCE The prevalence of hypertension depends on both the racial composition of the population studied and the criteria used to define the condition. In a white suburban population like that in the Framingham Study, nearly one-fifth of individuals have blood pressures >160/95 mmHg, while almost one-half have pressures >140/90 mmHg. An even higher prevalence has been documented in the nonwhite population. In females the prevalence is closely related to age, with a substantial increase occurring after age 50. This increase is presumably related to the hormonal changes of menopause, although the mechanism is unclear. Thus, the ratio of hypertension frequency in women versus men increases from 0.6 to 0.7 at age 30 to 1.1 to 1.2 at age 65.

The prevalence of various forms of secondary hypertension depends on the nature of the population studied and on how extensive the evaluation is. There are no available data to define the frequency of secondary hypertension in the general population, although in middle-aged males it has been reported to be 6%. On the other hand, in referral centers where patients undergo an extensive evaluation, it has been reported to be as high as 35%. The various forms of hypertension are outlined in Table 230-1, and their relative frequencies are given in Table 230-2.

ESSENTIAL HYPERTENSION

Patients with arterial hypertension and no definable cause are said to have *primary*, *essential*, or *idiopathic hypertension*. Undoubtedly, the primary difficulty in uncovering the responsible mechanisms in these patients is attributable to the variety of systems that are involved in the regulation of arterial pressure: peripheral and/or central adrenergic, renal, hormonal, and vascular. In addition, these systems are interrelated in a complex fashion, with input from multiple genes (see below). Several abnormalities have been described in patients with essential hypertension, often with a claim that one or more of them are primarily responsible for the hypertension. While it is still uncertain whether these individual abnormalities are primary or secondary, varying expressions of a single disease process, or reflective of separate disease entities, the accumulating data increasingly support the latter hypothesis. Therefore, just as pneumonia is caused by a variety of infectious agents, even though the clinical picture observed may be similar, so essential hypertension likely has a number of distinct causes. Thus, the distinction between primary and secondary hypertension has become blurred, and the approach to both the diagnosis and therapy of hypertensive patients has been modified. For example, when a group of patients with essential hypertension is separated into a distinct subset (e.g., low-renin essential hypertension), the patients have not been reclassified as having a form of secondary hypertension but rather remain in the essential hypertensive group. In this chapter, individuals in whom a specific structural organ or gene defect is responsible for hypertension are defined as having a *secondary* form of hypertension. In contrast, individuals in whom generalized or functional abnormalities may be the cause of hypertension, even if the abnormalities are discrete, are defined as having *essential* hypertension.

ENVIRONMENT A number of environmental factors have been implicated in the development of hypertension, including salt intake, obesity, occupation, alcohol intake, family size, and crowding. These factors have all been assumed to be important in the increase in blood pressure with age in more affluent societies, in contrast to the decline in blood pressure with age in less affluent groups.

SALT SENSITIVITY The environmental factor that has received the greatest attention is salt intake. Even this factor illustrates the heterogeneous nature of the essential hypertensive population, in that the blood pressure is particularly responsive to the level of sodium intake in only ~60% of hypertensives. The cause of this special sensitivity to salt

TABLE 230-1 Classification of Arterial Hypertension

SYSTOLIC HYPERTENSION WITH WIDE PULSE PRESSURE

I. Decreased compliance of aorta (arteriosclerosis)
II. Increased stroke volume
  A. Aortic regurgitation
  B. Thyrotoxicosis
  C. Hyperkinetic heart syndrome
  D. Fever
  E. Arteriovenous fistula
  F. Patent ductus arteriosus

SYSTOLIC AND DIASTOLIC HYPERTENSION (INCREASED PERIPHERAL VASCULAR RESISTANCE)

I. Renal
  A. Chronic pyelonephritis
  B. Acute and chronic glomerulonephritis
  C. Polycystic renal disease
  D. Renovascular stenosis or renal infarction
  E. Most other severe renal diseases (arteriolar nephrosclerosis, diabetic nephropathy, etc.)
  F. Renin-producing tumors
II. Endocrine
  A. Oral contraceptives
  B. Adrenocortical hyperfunction
    1. Cushing's disease and syndrome
    2. Primary hyperaldosteronism
    3. Congenital or hereditary adrenogenital syndromes (17α-hydroxylase and 11β-hydroxylase defects)
  C. Pheochromocytoma
  D. Myxedema
  E. Acromegaly
III. Neurogenic
  A. Psychogenic
  B. Diencephalic syndrome
  C. Familial dysautonomia (Riley-Day)
  D. Polyneuritis (acute porphyria, lead poisoning)
  E. Increased intracranial pressure (acute)
  F. Spinal cord section (acute)
IV. Miscellaneous
  A. Coarctation of aorta
  B. Increased intravascular volume (excessive transfusion, polycythemia vera)
  C. Polyarteritis nodosa
  D. Hypercalcemia
  E. Medications, e.g., glucocorticoids, cyclosporine
V. Unknown etiology
  A. Essential hypertension (>90% of all cases of hypertension)
  B. Toxemia of pregnancy
  C. Acute intermittent porphyria

TABLE 230-2 *Prevalence of Various Forms of Hypertension in the General Population and in Specialized Referral Clinics*[a]

Diagnosis	General Population, %	Specialty Clinic, %
Essential hypertension	92–94	65–85
Renal hypertension:		
Parenchymal	2–3	4–5
Renovascular	1–2	4–16
Endocrine hypertension:		
Primary aldosteronism	0.3	0.5–12
Cushing's syndrome	<0.1	0.2
Pheochromocytoma	<0.1	0.2
Oral contraceptive–induced	0.5–1	1–2
Miscellaneous	0.2	1

[a] Estimates based on a number of reports in the literature.

varies, with primary aldosteronism, bilateral renal artery stenosis, renal parenchymal disease, and low-renin essential hypertension accounting for about half the patients. In the remainder, the pathophysiology is still uncertain, but postulated contributing factors include chloride intake, calcium intake, a generalized cellular membrane defect, insulin resistance, and "nonmodulation" (see below).

ROLE OF RENIN Renin is an enzyme secreted by the juxtaglomerular cells of the kidney and linked with aldosterone in a negative feedback loop (Chap. 321). While a variety of factors can modify its rate of secretion, the primary determinant is the volume status of the individual, particularly as related to changes in dietary sodium intake. The end product of the action of renin on its substrate is the generation of the peptide angiotensin II. The response of target tissues to this peptide is uniquely determined by the prior dietary electrolyte intake. For example, sodium intake normally modulates adrenal and renal vascular responses to angiotensin II. With sodium restriction, adrenal responses are enhanced and the renal vascular responses reduced. Sodium loading has the opposite effect. The range of plasma renin activities observed in hypertensive subjects is broader than in normotensive individuals. In consequence, some hypertensive patients have been defined as having *low-renin* and others as having *high-renin* essential hypertension.

Low-Renin Essential Hypertension Approximately 20% of patients who by all other criteria have essential hypertension have suppressed plasma renin activity. Low-renin essential hypertension describes a widely recognized classification validated by clinical features, including salt-sensitivity of blood pressure and diuretic responsiveness. This situation is more common in individuals of African descent than in white patients, and in diabetics and the elderly. Though these patients are not hypokalemic, they have been reported to have expanded extracellular fluid volumes, and one unproven suggestion is that they have sodium retention and renin suppression due to excessive production of an unidentified mineralocorticoid. There are data to suggest that the low-renin state confers a beneficial natural history compared to that in patients with normal- or high-renin hypertension.

Nonmodulating Essential Hypertension Another subset of hypertensive patients who are also salt-sensitive has a reduced adrenal response to sodium restriction. In these individuals, sodium intake does not modulate either adrenal or renal vascular responses to angiotensin II. Hypertensives in this subset have been termed *nonmodulators* because of the absence of the sodium-mediated modulation of target tissue responses to angiotensin II. These individuals make up 25 to 30% of the hypertensive population, have plasma renin activity levels that are normal to high if measured when the patient is on a low-salt diet, and have hypertension that is salt-sensitive because of a defect in the kidney's ability to excrete sodium appropriately. They also are more insulin-resistant than other hypertensive patients, and the pathophysiologic characteristics can be corrected by the administration of an angiotensin-converting enzyme (ACE) inhibitor. Nonmodulation is much more frequent among males and postmenopausal females. Furthermore, the nonmodulation characteristic appears to be genetically determined (associated with a certain allele of the angiotensinogen gene). Thus, nonmodulators are probably the most completely characterized intermediate phenotype in the hypertensive population.

High-Renin Essential Hypertension Approximately 15% of patients with essential hypertension have plasma renin activity levels above the normal range. It has been suggested that plasma renin plays an important role in the pathogenesis of the elevated arterial pressure in these patients. However, most studies have found that saralasin (a substance that, like losartan, acts as a competitive antagonist of angiotensin II) significantly reduces blood pressure in fewer than half of these patients. This finding has led some investigators to postulate that the elevated renin levels and blood pressure may both be secondary to an increase in adrenergic system activity. It has been proposed that in patients with angiotensin-dependent high-renin hypertension whose arterial pressures are lowered by an angiotensin II antagonist, the mechanism responsible for the increase in renin and, therefore, for the hypertension is the nonmodulating defect.

SODIUM ION VERSUS CHLORIDE OR CALCIUM Most studies assessing the role of salt in the hypertensive process have assumed that it is the sodium ion that is important. However, some investigators have suggested that the chloride ion may be equally important. This suggestion is based on the observation that feeding chloride-free sodium salts to salt-sensitive hypertensive animals fails to increase arterial pressure. Calcium has also been implicated in the pathogenesis of some forms of essential hypertension. A low-calcium intake has been associated with an increase in blood pressure in epidemiologic studies; an increase in leukocyte cytosolic calcium levels has been reported in some hypertensives. Finally, calcium entry blockers are effective antihypertensive agents. Several studies have reported a potential link between the salt-sensitive forms of hypertension and calcium. It has been postulated that salt loading in combination with a defect in the kidney's ability to excrete salt may lead to a secondary increase in circulating natriuretic factors. One of these factors, the so-called digitalis-like natriuretic factor, inhibits ouabain-sensitive Na^+,K^+-ATPase and thereby leads to intracellular calcium accumulation and a hyperreactive vascular smooth muscle.

CELL MEMBRANE DEFECT Another postulated explanation for salt-sensitive hypertension is a generalized cell membrane defect. This hypothesis derives most of its data from studies on circulating blood elements, particularly red blood cells, in which abnormalities in the transport of sodium across the cell membrane have been documented. Since both increases and decreases in the activity of different transport systems have been reported, it is likely that some abnormalities are primary and some are secondary. It has been assumed that an abnormality in sodium transport reflects an undefined alteration in the cell membrane and that this defect occurs in many, perhaps all, cells of the body, particularly the vascular smooth-muscle cells. The defect leads to an abnormal accumulation of calcium in vascular smooth muscle, resulting in a heightened vascular responsiveness to vasoconstrictor agents. This defect has been proposed to be present in 35 to 50% of essential hypertensive persons on the basis of studies using red cells. Other studies suggest that the abnormality in red cell sodium transport is not fixed but can be modified by environmental factors.

The common final pathway in all these hypotheses is an increase in cytosolic calcium resulting in increased vascular reactivity. However, as described above, several mechanisms might produce this calcium accumulation.

INSULIN RESISTANCE Insulin resistance and/or hyperinsulinemia have been suggested as being responsible for the increased arterial pressure in some patients with hypertension. This feature is now widely recognized as part of syndrome X, or the metabolic syndrome (Chap. 225), marked also by central obesity, dyslipidemia (especially elevated triglycerides), and high blood pressure. While it is clear that a substantial fraction of the hypertensive population has insulin resistance

and hyperinsulinemia, it is less certain that this is more than an association. Insulin resistance is common in patients with diabetes mellitus type 2 and in obesity; both of these conditions are more common in hypertensive than in normotensive subjects. However, several studies have found that hyperinsulinemia and insulin resistance are present even in lean hypertensive patients without type 2 diabetes, suggesting that this relationship is more than a coincidence. As noted earlier, these individuals seem to be concentrated in the nonmodulation phenotype.

Hyperinsulinemia can increase arterial pressure by one or more of four mechanisms. An underlying assumption in each case is that some, but not all, of the target tissues of insulin are resistant to its effects. Specifically, tissues involved in glucose homeostasis are resistant (thereby producing the hyperinsulinemia), while tissues involved in the hypertensive process are not. First, hyperinsulinemia produces renal sodium retention (at least acutely) and increases sympathetic activity. Either or both of these effects could lead to an increase in arterial pressure. Another mechanism is vascular smooth-muscle hypertrophy secondary to the mitogenic action of insulin. Third, insulin also modifies ion transport across the cell membrane, thereby potentially increasing the cytosolic calcium levels of insulin-sensitive vascular or renal tissues. This mechanism would increase arterial pressure for reasons similar to those described above for the membrane-defect hypothesis. Finally, insulin resistance may be a marker for another pathologic process, e.g., nonmodulation, which could be the primary mechanism increasing blood pressure. It is important to point out, however, that the role of insulin in controlling arterial pressure is only vaguely understood, and, therefore, its potential as a pathogenic factor in hypertension remains unclear.

Few of the features of hypertension discussed above remain constant in a given patient. Some may be a reflection of the current metabolic and hormonal status of the patient rather than a permanent feature of the disease process. For example, at one point a patient might have insulin resistance secondary to obesity, which could lead to sodium retention, intravascular volume expansion, and renin suppression. This patient would be labeled as having "low-renin essential hypertension." If the patient lost weight, however, the salt-retaining tendency would be reversed. If the blood pressure did not normalize, the patient might then have "normal- or high-renin essential hypertension." Thus, the features reviewed above should not be considered mutually exclusive or permanent characteristics in a given patient with hypertension.

GENETIC CONSIDERATIONS Hypertension is one of the most common complex genetic disorders, with genetic heritability averaging ~30%. Data supporting this view emerge from animal studies as well as in population studies in humans. One approach has been to assess the correlation of blood pressure in families (familial aggregation). From these studies, the minimum size of the genetic factor can be expressed by a correlation coefficient of ~0.2. However, the variation in the size of the genetic factor in different studies reemphasizes the probably heterogeneous nature of the essential hypertensive population. In addition, most studies support the concept that the inheritance is probably multifactorial or that a number of different genetic defects each have an elevated blood pressure as one of their phenotypic expressions.

However, genes responsible for three distinct but rare monogenic hypertensive syndromes have been identified, two of which are inherited in a dominant fashion. Patients with *glucocorticoid-remediable hypertension* (GRA) have characteristically early-onset hypertension with increased frequency of strokes and evidence of hyperaldosteronism. Plasma aldosterone concentrates are high, plasma renin activity is low, and hypokalemia is frequent. A chimeric gene containing the promoter of the 11β-hydroxylase gene and the coding sequence for the aldosterone synthase gene has been identified in these patients, resulting in the ectopic production of aldosterone, which is corticotropin-dependent. The second dominant form is also a rare familial syndrome in which patients also *appear* to have elevated aldosterone activity, with suppressed plasma renin activity and hypokalemia. In these patients, however, plasma aldosterone is normal. Mutations in the epithelial amiloride-sensitive sodium channel located in the collecting cortical tubule are responsible. The third monogenic syndrome is also a low-renin state, termed the *syndrome of apparent mineralocorticoid excess* (AME), caused by a defect in renal 11β-hydroxysteroid dehydrogenase. In these patients, the protective conversion of cortisol to the inactive cortisone does not occur, and local cortisol binds to the renal mineralocorticoid receptor.

In addition to these monogenic syndromes, susceptibility genes have now been reported which have as one of their consequences an increased arterial pressure (see below and Chap. 321). The most promising of these is the gene for renin substrate, angiotensinogen, in which a substitution of threonine for methionine at codon 235 has been associated with hypertension. Also, in patients with low-renin essential hypertension, an association with the G460W polymorphism of the α-adducin gene has been demonstrated. One of the hints of the genetic heritability of the low-renin state has emerged from studies revealing the familial aggregation of low-renin hypertension.

More than 50 genes have been examined in association studies with hypertension, and the number is constantly growing. As can be seen in Table 230-3, most studies of likely genes have failed to document linkage or consistent association with hypertension. However, uncertainty exists as to the validity of these negative conclusions. A positive relationship between hypertension and a gene could be obscured by the high probability of a false-negative result because of the heterogeneity of the hypertensive population. Thus, intermediate phenotypes in the hypertensive population need to be identified to differentiate patients into more homogeneous subgroups; the role of a specific candidate gene can then be more readily assessed. Such an approach is illustrated in Table 230-4.

TABLE 230-3 *Genesis Hypothesized to be Involved in Essential Hypertension*

Gene	Statistical Approach[a]	
	Linkage +/−	Association +/−
Renin-angiotensin-aldosterone system/sodium-volume		
Angiotensin-converting enzyme	0/1	12/14
Angiotensinogen	3/4	12/9
Aldosterone synthase	1/1	5/7
α-Adducin	0/1	5/3
AT1 receptor		4/6
Atrial natriuretic peptide		2/5
Human natriuretic peptide receptor (A)		1/1
Human natriuretic peptide receptor (B)		1/2
Renin	3/2	2/2
Adrenergic		
β_2-Adrenergic receptor		3/4
β_3-Adrenergic receptor		3/1
Dopamine D_2 receptor		2/0

TABLE 230-4 *Role of Intermediate Phenotypes in Genetic Analysis*

	Phenotype	
Gene	Intermediate	Distant
Converting enzyme Angiotensinogen	Angiotensin II effect on kidney	Increases BP Increases BP
Aldo synthase	Increases 18-OH cortisol	Increases BP
Kallikrein	Decreases urine kallikrein	Increases BP
Na^+/H^+ exchanger	Increases Na/Li CTT	Increases BP
α-adducin	Low-renin hypertension	Increases BP
11 HSD_2	↑Cortisol/cortisone	Increases BP
ENaC	↓Renin, ↓aldosterone, ↓K^+	Increases BP

Note: BP, blood pressure; OH, hydroxy; CTT, countertransport; HSD, hydroxy steroid-dehydrogenase; eNac, epithelial sodium channel.

FACTORS THAT MODIFY THE COURSE OF ESSENTIAL HYPERTENSION Age, race, sex, smoking, alcohol intake, serum cholesterol, glucose intolerance, and weight all may alter the prognosis of this disease. The younger the patient when hypertension is first noted, the greater is the reduction in life expectancy if the hypertension is left untreated. In the United States, urban blacks have about twice the prevalence of hypertension as whites and more than four times the hypertension-induced morbidity rate. At all ages and in both white and nonwhite populations, females with hypertension fare better than males up to the age of 65, and the prevalence of hypertension in premenopausal females is substantially less than that in age-matched males or postmenopausal women. Yet, compared with their normotensive counterparts, females with hypertension run the same relative risk of a morbid cardiovascular event as do males. Accelerated atherosclerosis is an invariable companion of hypertension. Thus, it is not surprising that independent risk factors associated with the development of atherosclerosis, such as an elevated serum cholesterol, glucose intolerance, and/or cigarette smoking, significantly enhance the effect of hypertension on mortality rate regardless of age, sex, or race (Chap. 224). There is also no question that a positive correlation exists between obesity and arterial pressure. A gain in weight is associated with an increased frequency of hypertension in persons with previously normal blood pressure, and weight loss in obese persons with hypertension lowers their arterial pressure and, if they are being treated for hypertension, the intensity of therapy required to keep them normotensive. Whether these changes are mediated by changes in insulin resistance is unknown.

NATURAL HISTORY Because essential hypertension is a heterogeneous disorder, variables other than the arterial pressure modify its course. Thus, the probability of developing a morbid cardiovascular event with a given arterial pressure may vary as much as 20-fold depending on whether associated risk factors are present (Table 230-5). Although exceptions have been reported, most untreated adults with hypertension will develop further increases in arterial pressure with time. Furthermore, it has been demonstrated from both actuarial data and experience in the era prior to effective therapy that untreated hypertension is associated with a shortening of life by 10 to 20 years, usually related to an acceleration of the atherosclerotic process, with the rate of acceleration in part related to the severity of the hypertension. Even individuals who have relatively mild disease—i.e., without evidence of end-organ damage—that is left untreated for 7 to 10 years have a high risk of developing significant complications. Nearly 30% will exhibit atherosclerotic complications, and >50% will have end-organ damage related to the hypertension itself, such as cardiomegaly, congestive heart failure, retinopathy, a cerebrovascular accident, and/or renal insufficiency. Thus, even in its mild forms, hypertension is a progressive and lethal disease if left untreated.

SECONDARY HYPERTENSION

As noted earlier, in only a small minority of patients with elevated arterial pressure can a specific cause be identified. Yet these patients should not be ignored for at least two reasons: (1) correction of the cause may cure their hypertension, and (2) these secondary forms of the disease may provide insight into the etiology of essential hypertension. Nearly all the secondary forms of hypertension are related to an alteration in hormone secretion and/or renal function and are discussed in detail in other chapters.

TABLE 230-5 *Risk Factors for An Adverse Prognosis in Hypertension*

Black race
Youth
Male sex
Persistent diastolic pressure >115 mmHg
Smoking
Diabetes mellitus
Hypercholesterolemia
Obesity
Excess alcohol intake
Evidence of end organ damage
1. Cardiac
   a. Cardiac enlargement
   b. Electrocardiographic signs of ischemia or left ventricular strain
   c. Myocardial infarction
   d. Congestive heart failure
2. Eyes
   a. Retinal exudates and hemorrhages
   b. Papilledema
3. Renal: impaired renal function
4. Nervous system: cerebrovascular accident

RENAL HYPERTENSION (See also Chap. 267) Hypertension produced by renal disease is the result of either (1) an alteration in renal secretion of vasoactive materials resulting in a systemic or local change in arteriolar tone, or (2) a derangement in the renal handling of sodium and fluids leading to volume expansion. The main subdivisions of renal hypertension are renovascular hypertension, including preeclampsia and eclampsia, and renal parenchymal hypertension. A simple explanation for *renal vascular hypertension* is that decreased perfusion of renal tissue due to stenosis of a main or branch renal artery activates the renin-angiotensin system, described in Chap. 321. Circulating angiotensin II elevates arterial pressure by directly causing vasoconstriction, by stimulating aldosterone secretion with resulting sodium retention, and/or by stimulating the adrenergic nervous system. In practice, only about one-half of patients with renovascular hypertension have an absolute elevation in renin activity in peripheral plasma, although when renin measurements are referenced against an index of sodium balance, a much higher fraction have inappropriately high values.

Activation of the renin-angiotensin system has also been offered as an explanation for the hypertension in both acute and chronic *renal parenchymal disease*. In this formulation, the only difference between renovascular and renal parenchymal hypertension is that the decreased perfusion of renal tissue in the latter case results from inflammatory and fibrotic changes involving multiple small intrarenal vessels. There are enough differences between the two conditions, however, to suggest that other mechanisms are active in renal parenchymal disease. Specifically, (1) peripheral plasma renin activity is elevated far less frequently in renal parenchymal than in renovascular hypertension; (2) cardiac output is said to be normal in renal parenchymal hypertension (unless uremia and anemia are present) but slightly elevated in renovascular hypertension; (3) circulatory responses to tilting and to the Valsalva maneuver are exaggerated in the latter condition; and (4) blood volume tends to be high in patients with severe renal parenchymal disease and low in patients with severe unilateral renovascular hypertension. Alternative explanations for the hypertension in renal parenchymal disease include the possibilities that the damaged kidneys (1) produce an unidentified vasopressor substance other than renin, (2) fail to produce a necessary humoral vasodilator substance (perhaps prostaglandin or bradykinin), (3) fail to inactivate circulating vasopressor substances, and/or (4) are ineffective in disposing of sodium. In the last case, the retained sodium would be responsible for the hypertension as outlined earlier.

Although all of these explanations, including participation of the renin-angiotensin system, probably have some validity in individual patients, the hypothesis involving sodium retention is particularly attractive. It is supported by the observation that those patients with chronic pyelonephritis or polycystic renal disease who are salt wasters do not develop hypertension and by the observation that removal of salt and water by dialysis or diuretics is effective in controlling arterial pressure in most patients with renal parenchymal disease.

A rare form of renal hypertension results from the excess secretion of renin by juxtaglomerular cell tumors or nephroblastomas. The initial presentation is similar to that of hyperaldosteronism, with hypertension, hypokalemia, and overproduction of aldosterone. However, in contrast to primary aldosteronism, peripheral renin activity is *elevated instead of subnormal*. This disease can be distinguished from other forms of secondary aldosteronism by the presence of normal renal function and unilateral increases in renal vein renin concentration without a renal artery lesion.

ENDOCRINE HYPERTENSION ■ Adrenal Hypertension Hypertension is a feature of a variety of adrenal cortical abnormalities. In *primary aldosteronism* (Chap. 321), there is a clear relationship between the aldosterone-induced sodium retention and the hypertension. Normal individuals given aldosterone develop hypertension only if they also ingest sodium. Since aldosterone causes sodium retention by stimulating renal tubular exchange of sodium for potassium, hypokalemia is a prominent feature in most patients with primary aldosteronism, and, therefore, the measurement of serum potassium provides a simple screening test. The effect of sodium retention and volume expansion in chronically suppressing plasma renin activity is critical for the definitive diagnosis. In most clinical situations, plasma renin activity and plasma or urinary aldosterone levels parallel each other, but in patients with primary aldosteronism, aldosterone levels are high and relatively fixed because of autonomous aldosterone secretion, whereas plasma renin activity levels are suppressed and respond sluggishly to sodium depletion. Primary aldosteronism may be secondary to either a tumor or bilateral adrenal hyperplasia. It is important to distinguish between these two conditions preoperatively, since the hypertension in the latter case is usually not modified by operation.

The sodium-retaining effect of large amounts of glucocorticoids (perhaps resulting in part from saturation of the 11β-hydroxysteroid hydrogenase enzyme system in the kidney by the increased concentration of cortisol) also offers an explanation for the hypertension in severe cases of Cushing's syndrome (Chap. 321). Moreover, increased production of mineralocorticoids has also been documented in some patients with Cushing's syndrome. However, the hypertension in many cases of Cushing's syndrome does not seem volume-dependent, leading investigators to speculate that it may be secondary to glucocorticoid-induced production of renin substrate (angiotensin-mediated hypertension). In the forms of the adrenogenital syndrome due to C-11 or C-17 hydroxylase deficiency (Chap. 321), deoxycorticosterone accounts for the sodium retention and the resulting hypertension, which is accompanied by suppression of plasma renin activity.

In patients with pheochromocytoma (Chap. 322), increased secretion of epinephrine and norepinephrine by a tumor (most often located in the adrenal medulla) causes excessive stimulation of adrenergic receptors, which results in peripheral vasoconstriction and cardiac stimulation. This diagnosis is confirmed by demonstrating increased urinary excretion of epinephrine and norepinephrine and/or their metabolites.

Acromegaly (See also Chap. 318) Hypertension, coronary atherosclerosis, and cardiac hypertrophy are frequent complications of this condition.

Hypercalcemia (See also Chap. 331) The hypertension that occurs in up to one-third of patients with hyperparathyroidism ordinarily can be attributed to renal parenchymal damage due to nephrolithiasis and nephrocalcinosis. However, increased calcium levels can also have a direct vasoconstrictive effect. In some cases, the hypertension disappears when the hypercalcemia is corrected. Thus, paradoxically, the increased serum calcium level in hyperparathyroidism raises blood pressure, while epidemiologic studies suggest that a high calcium intake lowers blood pressure. To confuse the issue further, calcium entry–blocking agents are effective antihypertensive agents. Additional studies are needed to resolve these seemingly conflicting observations.

COARCTATION OF THE AORTA (See also Chap. 218) The hypertension associated with coarctation may be caused by the constriction itself or perhaps by the changes in the renal circulation, which result in an unusual form of renal arterial hypertension. The diagnosis of coarctation is usually evident from physical examination and routine x-ray findings.

EFFECTS OF HYPERTENSION

Patients with hypertension die prematurely; the most common cause of death is heart disease, with stroke and renal failure also frequent, particularly in patients with significant retinopathy.

EFFECTS ON THE HEART Cardiac compensation for the excessive workload imposed by increased systemic pressure is at first sustained by concentric left ventricular hypertrophy, characterized by an increase in wall thickness. Ultimately, the function of this chamber deteriorates, the cavity dilates, and the symptoms and signs of heart failure appear (Chap. 215). Angina pectoris may also occur because of the combination of accelerated coronary arterial disease and increased myocardial oxygen requirements as a consequence of the increased myocardial mass (Chap. 226). On physical examination, the heart is enlarged and has a prominent left ventricular impulse. The sound of aortic closure is accentuated, and there may be a faint murmur of aortic regurgitation. Presystolic (atrial, fourth) heart sounds appear frequently in hypertensive heart disease, and a protodiastolic (ventricular, third) heart sound or summation gallop rhythm may be present. Electrocardiographic changes of left ventricular hypertrophy (Chap. 210) may occur, but the electrocardiogram substantially underestimates the frequency of cardiac hypertrophy compared with that observed with the echocardiogram. Evidence of ischemia or infarction may be observed late in the disease. Most deaths due to hypertension result from myocardial infarction or congestive heart failure. Recent data suggest that some of the myocardial damage may be mediated by aldosterone in the presence of a normal/high salt intake rather than just the increased blood pressure or an increase in angiotensin II levels per se.

NEUROLOGIC EFFECTS The neurologic effects of long-standing hypertension may be divided into retinal and central nervous system changes. Because the retina is the only tissue in which the arteries and arterioles can be examined directly, repeated ophthalmoscopic examination provides the opportunity to observe the progress of the vascular effects of hypertension. The Keith-Wagener-Barker classification of the *retinal changes* in hypertension has provided a simple and excellent means for serial evaluation of hypertensive patients (see Fig. 25-1).

Central nervous system dysfunction also occurs frequently in patients with hypertension. Occipital headaches, most often occurring in the morning, are among the most prominent early symptoms of hypertension. Dizziness, light-headedness, vertigo, tinnitus, and dimmed vision or syncope may also be observed, but the more serious manifestations are due to vascular occlusion, hemorrhage, or encephalopathy (Chap. 349). The pathogeneses of the former two disorders are quite different. *Cerebral infarction* is secondary to the increased atherosclerosis observed in hypertensive patients, whereas *cerebral hemorrhage* is the result of both the elevated arterial pressure and the development of cerebral vascular microaneurysms (Charcot-Bouchard aneurysms). Only age and arterial pressure are known to influence the development of the microaneurysms. Thus, it is not surprising that arterial pressure shows a better association with cerebral hemorrhage than with either cerebral or myocardial infarction.

Hypertensive encephalopathy (see p. 1480) consists of the following symptom complex: severe hypertension, disordered consciousness,

increased intracranial pressure, retinopathy with papilledema, and seizures. The pathogenesis is uncertain but is probably not related to arteriolar spasm or cerebral edema. Focal neurologic signs are infrequent and, if present, suggest that infarction, hemorrhage, or transient ischemic attacks are more likely diagnoses. Although some investigators have suggested that prompt lowering of arterial pressure in these patients may adversely affect cerebral blood flow, most studies indicate that this is not the case.

EFFECTS ON THE KIDNEY (See also Chap. 267) Arteriosclerotic lesions of the afferent and efferent arterioles and the glomerular capillary tufts are the most common renal vascular lesions in hypertension and result in a decreased glomerular filtration rate and tubular dysfunction. Proteinuria and microscopic hematuria occur because of glomerular lesions, and ~10% of the deaths caused by hypertension result from renal failure. Blood loss in hypertension occurs not only from renal lesions; epistaxis, hemoptysis, and metrorrhagia also occur frequently in these patients.

APPROACH TO THE PATIENT

DEFINITION Since there is no dividing line between normal and high blood pressure, arbitrary levels have been established to define persons who have an increased risk of developing a morbid cardiovascular event and/or will benefit from medical therapy. These should be based upon not only the level of diastolic pressure but also systolic pressure, age, sex, race, and concomitant diseases. For example, patients with a diastolic pressure >90 mmHg have a significant reduction in morbidity and mortality rate if they receive adequate therapy. These, then, are patients who have hypertension and who should be considered for treatment.

The level of *systolic* pressure is very important in assessing the influence of arterial pressure on cardiovascular morbidity. Data increasingly suggest that it may be more important than diastolic pressure, especially in those over the age of 50. For example, males with normal diastolic pressures (<82 mmHg) but elevated systolic pressures (>158 mmHg) have a cardiovascular mortality rate 2.5 times higher than individuals who have similar diastolic pressures but whose systolic pressures clearly are normal (<130 mmHg). A reduction in mortality and morbidity with treatment, specifically in the elderly, has been documented in these patients. This beneficial effect results mainly from a reduction in strokes and occurs in women as well. Other significant demographic factors that modify the influence of blood pressure on the frequency of morbid cardiovascular events are age, race, and sex, with young black males being most adversely affected by hypertension.

When hypertension is suspected, blood pressure should be measured at least twice during two separate examinations after the initial screening. In adults, a *diastolic* pressure <85 mmHg is considered to be normal; one between 85 and 89 mmHg is high normal; one of 90 to 99 mmHg represents stage 1 or mild hypertension; one of 100 to 109 mmHg represents stage 2 or moderate hypertension; and one of ≥110 mmHg represents stage 3 or severe hypertension. A *systolic* pressure <130 mmHg indicates normal blood pressure; one between 130 and 139 mmHg indicates high normal; one between 140 and 159 mmHg indicates stage 1 or mild hypertension; one between 160 and 179 mmHg indicates stage 2 or moderate hypertension; and one ≥180 mmHg indicates stage 3 or severe hypertension. Isolated systolic hypertension, common among the elderly, is defined by systolic pressure ≥140 mmHg together with a normal diastolic pressure. *White coat hypertension* describes a significant percentage of individuals whose blood pressure, measured in the office by a professional, is persistently higher than when measured at home or under casual circumstances. Current estimates are that 10 to 20% of patients declared hypertensive in their doctors' offices are normotensive outside it; this diagnosis is relatively more common among the elderly and pregnant women. Increasing use of ambulatory blood pressure monitoring (ABPM) may provide additional useful information in patients who are difficult to classify. These devices measure blood pressure over a 12- or 24-h period as patients perform normal activities and during sleep. However, normal values for this procedure and its usefulness in relation to therapeutic outcomes are not currently known. A useful classification of hypertension derived from the 2003 European Society of Hypertension Guidelines is shown in Table 230-6. Of note, the Seventh US Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) published a new classification in 2003 which limited normal blood pressure to <120 mmHg systolic and <80 mmHg diastolic, and added a new category of "prehypertension" defined by systolic pressure between 120 and 139 or diastolic blood pressure between 80 and 89 mm. Prevention strategies are recommended for this population.

Arterial pressure fluctuates in most persons, whether they are normotensive or hypertensive. Patients who are classified as having *labile hypertension* are those who sometimes, but not always, have arterial pressures in the hypertensive range. These patients are often considered to have borderline hypertension. Sustained hypertension can become accelerated or enter a malignant phase (p. 1480), although that is unusual in treated patients. *Accelerated hypertension* is defined as a significant recent increase over previous hypertensive levels associated with evidence of vascular damage on funduscopic examination but without papilledema.

PATIENT EVALUATION In evaluating patients with hypertension, the initial history, physical examination, and laboratory tests should be directed at (1) uncovering correctable secondary forms of hypertension (see below), (2) establishing a pretreatment baseline, (3) assessing factors that may influence the type of therapy or be changed adversely by therapy, (4) determining if target organ damage is present, and (5) determining whether other risk factors for the development of arteriosclerotic cardiovascular disease are present (Table 230-5).

Symptoms and Signs Most patients with hypertension have no specific symptoms referable to their blood pressure elevation and are identified only in the course of a physical examination. When symptoms do bring the patient to the physician, they fall into three categories. They are related to (1) the elevated pressure itself, (2) the hypertensive vascular disease, and (3) the underlying disease, in the case of secondary hypertension. Though popularly considered a symptom of elevated arterial pressure, headache is characteristic of only severe hypertension; most commonly such headaches are localized to the occipital region and are present when the patient awakens in the morning but subside spontaneously after several hours. Other complaints that may be related to elevated blood pressure include dizziness, palpitations, easy fatigability, and

TABLE 230-6 Classification of Blood Pressure for Adults ≥18 Years Old

Category	Systolic Pressure, mmHg	Diastolic Pressure, mmHg
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Hypertension[a]		
Stage 1 (mild)	140–159	90–99
Stage 2 (moderate)	160–179	100–109
Stage 3 (severe)	≥180	≥110
Isolated systolic hypertension	≥140	<90

[a] Based on the average of ≥2 readings taken at each of two or more visits after an initial screening.

Note: Classification of blood pressure for adults aged 18 years and older not taking antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status.

impotence. Complaints referable to vascular disease include epistaxis, hematuria, blurring of vision owing to retinal changes, episodes of weakness or dizziness due to transient cerebral ischemia, angina pectoris, and dyspnea due to cardiac failure. Pain due to dissection of the aorta or to a leaking aneurysm is a rare presenting symptom.

Examples of symptoms related to the underlying disease in secondary hypertension are polyuria, polydipsia, and muscle weakness secondary to hypokalemia in patients with primary aldosteronism or weight gain, and emotional lability in patients with Cushing's syndrome. The patient with a pheochromocytoma may present with episodic headaches, palpitations, diaphoresis, and postural dizziness.

History A strong family history of hypertension, along with the reported finding of intermittent pressure elevation in the past, favors the diagnosis of essential hypertension. Secondary hypertension often develops before the age of 35 years or after 55. A history of repeated urinary tract infections suggests chronic pyelonephritis, although this condition may occur in the absence of symptoms. A history of weight gain is compatible with Cushing's syndrome, and one of weight loss is compatible with pheochromocytoma. A number of aspects of the history aid in determining whether vascular disease has progressed to a dangerous stage. These include angina pectoris and symptoms of cerebrovascular insufficiency, congestive heart failure, and/or peripheral vascular insufficiency. Other risk factors that should be asked about include cigarette smoking, diabetes mellitus, lipid disorders, and a family history of early deaths due to cardiovascular disease. Finally, aspects of the patient's lifestyle that could contribute to the hypertension or affect its treatment should be assessed, including diet, physical activity, family status, work, and educational level.

Physical Examination The physical examination starts with the patient's general appearance. For instance, are the round face and truncal obesity of Cushing's syndrome present? Is muscular development in the upper extremities out of proportion to that in the lower extremities, suggesting coarctation of the aorta? The next step is to compare the blood pressures and pulses in the two upper extremities and in the supine and standing positions (for at least 2 min). A rise in diastolic pressure when the patient goes from the supine to the standing position is most compatible with essential hypertension; a fall, in the absence of antihypertensive medications, suggests secondary forms of hypertension. Funduscopic findings provide one of the best indications of the duration of hypertension and of prognosis. A useful guide is the Keith-Wagener-Barker classification of funduscopic changes, in which classification from normal through grade IV retinopathy is based upon the presence of arteriolar light reflex, arteriovenous crossing defects, hemmorhages and exudates; the specific changes in each fundus should be recorded and a grade assigned (see Fig. 25-8). Palpation and auscultation of the carotid arteries for evidence of stenosis or occlusion should be carried out. In examination of the heart and lungs, evidence of left ventricular hypertrophy and cardiac decompensation should be sought. Is there a left ventricular lift? Are third and fourth heart sounds present? Are there pulmonary rales? A third heart sound and pulmonary rales are unusual in uncomplicated hypertension. Their presence suggests ventricular dysfunction. Chest examination also includes a search for extracardiac murmurs and palpable collateral vessels that may result from coarctation of the aorta.

The most important part of the abdominal examination is auscultation for bruits originating in stenotic renal arteries. Bruits due to renal arterial narrowing nearly always have a diastolic component or may be continuous and are best heard just to the right or left of the midline above the umbilicus or in the flanks. The abdomen should also be palpated for an abdominal aneurysm and for the enlarged kidneys of polycystic renal disease. The femoral pulses should be felt, and, if they are decreased and/or delayed in comparison with the radial pulse, the blood pressure in the lower extremities must be measured. Even if the femoral pulse is normal to palpation, arterial pressure in the lower extremities should be recorded at least once in patients in whom hypertension is discovered before the age of 30 years.

Laboratory Investigation The *basic* laboratory studies that should be performed in all patients are described in Table 230-7. Renal status is evaluated by assessing the presence of protein, blood, and glucose in the urine and measuring serum creatinine and/or blood urea nitrogen. Microscopic examination of the urine is also helpful. The serum potassium level should be measured both as a screen for mineralocorticoid-induced hypertension and to provide a baseline before diuretic therapy is begun. A blood glucose determination is helpful both because diabetes mellitus may be associated with accelerated arteriosclerosis, renal vascular disease, and diabetic nephropathy in patients with hypertension and because primary aldosteronism, Cushing's syndrome, and pheochromocytoma may all be associated with hyperglycemia. The possibility of hypercalcemia may also be investigated. Serum cholesterol, high-density lipoprotein cholesterol, and triglyceride levels identify other factors that predispose to the development of arteriosclerosis.

An electrocardiogram should be obtained in all cases. The echocardiogram is more sensitive than either the electrocardiogram or physical examination in determining whether cardiac hypertrophy is present and may be a useful addition to the *baseline* evaluation of a hypertensive patient, particularly as left ventricular hypertrophy is an independent cardiovascular risk factor and its presence indicates the need for vigorous antihypertensive therapy. Because of the cost of an echocardiogram and the uncertainty as to whether the resultant information would modify therapy, it is unclear that routine *follow-up* echocardiograms during therapy are justified. The chest roentgenogram may also be helpful by providing the opportunity to identify aortic dilation or elongation and the rib notching that occurs in coarctation of the aorta.

Most patients do not require ABPM, but readings are useful in diagnosing white coat hypertension and also in evaluating refractory hypertension, circadian patterns of blood pressure, and relation

TABLE 230-7 Laboratory Tests for Evalution of Hypertension

BASIC TESTS FOR INITIAL EVALUATION

1. Always included
   a. Urine for protein, blood, and glucose
   b. Microscopic urinalysis
   c. Hematocrit
   d. Serum potassium
   e. Serum creatinine and/or blood urea nitrogen
   f. Fasting glucose
   g. Total cholesterol
   h. Electrocardiogram
2. Usually included, depending on cost and other factors
   a. Thyroid-stimulating hormone
   b. White blood cell count
   c. HDL and LDL cholesterol and triglycerides
   d. Serum calcium and phosphate
   e. Chest x-ray; limited echocardiogram

SPECIAL STUDIES TO SCREEN FOR SECONDARY HYPERTENSION

1. Renovascular disease: angiotensin-converting enzyme inhibitor radionuclide renal scan, renal duplex Doppler flow studies, and MRI angiography
2. Pheochromocytoma: 24-h urine assay for creatinine, metanephrines, and catecholamines
3. Cushing's syndrome: overnight dexamethasone suppression test or 24-h urine cortisol and creatinine
4. Primary aldosteronism: plasma aldosterone: renin activity ratio

Note: HDL, high-density lipoprotein; LDL, low-density lipoprotein; MRI, magnetic resonance imaging.

of blood pressure to symptoms like dizziness and visual changes. ABPM readings are good predictors of future cardiovascular events. Mean 24-h systolic pressure ≥135 mmHg has been associated with a nearly double cardiovascular risk. When the normal nocturnal decline in blood pressure ("dipping") is absent, readings correlate well with the prevalence and extent of target organ damage in hypertensive individuals.

DIAGNOSIS OF SECONDARY HYPERTENSION The abrupt onset of severe hypertension and/or the onset of hypertension of any severity in a patient under the age of 35 or over the age of 55 should lead to laboratory tests to exclude renovascular hypertension and pheochromocytoma, and the finding on physical examination of bilateral upper abdominal masses consistent with polycystic renal disease should lead to the performance of an abdominal ultrasound. An elevated creatinine or blood urea nitrogen level, associated with proteinuria and hematuria, should prompt a detailed workup for renal insufficiency (Chap. 259). A familial history of hypertension, particularly with early age of onset, should spark consideration of a genetic form. Special studies for secondary hypertension are also indicated if there is therapeutic failure with the initial drug program. The specific diagnostic measures depend on the most likely causes of secondary hypertension.

Pheochromocytoma (See also Chap. 322) A history of headaches, palpitations, anxiety attacks, unusual sweating, hyperglycemia, and weight loss should also lead to tests to exclude pheochromocytoma. The easiest and best screening procedure for pheochromocytoma is the measurement of catecholamines and their metabolites in a 24-h urine sample collected while the patient is hypertensive. Measurement of plasma catecholamine levels may also be useful, while the assay of plasma-free metanephrines holds promise for heightened sensitivity. These tests may be indicated even in patients who do not have episodic hypertension, since over half the patients with pheochromocytoma have fixed hypertension. Provocative tests are seldom, if ever, indicated, although occasionally a suppressive test may be useful.

Cushing's Syndrome (See also Chap. 321) A 24-h urine test for cortisol and creatinine or the administration of 1 mg of dexamethasone at bedtime, followed by the measurement of plasma cortisol at 7 to 10 A.M., is the best test to screen for the presence of Cushing's syndrome. A urine cortisol level of <2750 nmol (100 μg) or suppression of the plasma cortisol level to <140 nmol/L (5 μg/dL) effectively rules out Cushing's syndrome.

Renovascular Hypertension (See also Chap. 267) The presence of an abdominal bruit should lead to a workup for renovascular hypertension. Suspicion for this form of hypertension should also be especially high in patients with deterioration of renal function after institution of ACE inhibitor therapy or in older patients with atherosclerotic disease. Over the past decades the standard approach to screen for renovascular hypertension has progressed from the rapid-sequence intravenous pyelogram to one of three noninvasive techniques: the captopril-enhanced radionuclide renal scan (the preferred choice), a duplex Doppler flow study, or magnetic resonance (MR) angiography with gadolinium enhancements. Perhaps the most sensitive and specific screening test, the spiral computed tomography (CT) scan, which gives a three-dimensional view, also requires giving an intravenous contrast agent.

The definitive test for surgically correctable renal disease is the combination of a renal angiogram and renal vein renin determinations. The renal arteriogram both establishes the presence of a renal arterial lesion and aids in the determination of whether the lesion is due to atherosclerosis or to one of the fibrous or fibromuscular dysplasias. It does not, however, prove that the lesion is responsible for the hypertension, nor does it permit prediction of the chances of surgical cure. It must be noted that (1) renal artery stenosis is a frequent finding by angiography and at postmortem in normotensive individuals, and (2) essential hypertension is a common condition and may occur in combination with renal arterial stenosis that is not responsible for the hypertension. Bilateral renal vein catheterization for measurement of plasma renin activity is therefore used to assess the functional significance of any lesion noted on arteriography. When one kidney is ischemic and the other is normal, all the renin released comes from the involved kidney. In the most straightforward situation, the ischemic kidney has a significantly higher venous plasma renin activity than the normal kidney, by a factor of ≥1.5. Moreover, the renal venous blood draining the uninvolved kidney exhibits levels similar to those in the inferior vena cava below the entrance of the renal veins.

Significant benefit from operative correction may be anticipated in at least 80% of patients with the findings described above if care is taken to prepare the patient properly before renal vein blood sampling, i.e., by discontinuing renin-suppressing drugs, such as beta blockers, for at least 10 days; restricting the patient to a low-sodium intake for 4 days; and/or giving a converting-enzyme inhibitor for 24 h. When obstructing lesions in the *branches* of the renal arteries are demonstrated by arteriography, an attempt to obtain blood samples from the *main branches* of the renal vein should be made in an effort to identify a localized intrarenal arterial lesion responsible for the hypertension.

Primary Aldosteronism (See also Chap. 321) These patients usually exhibit hypokalemia. Diuretic therapy often complicates the picture when the hypokalemia is first observed and needs to be assessed. Given the presence of hypokalemia, the relation between plasma renin activity and the aldosterone level becomes the key to the diagnosis of primary aldosteronism. The aldosterone concentration or excretion rate is high and plasma renin activity is low in primary aldosteronism, and these levels are relatively unaffected by changes in sodium balance. Thus, the aldosterone:renin ratio is high. A critical part of the evaluation after primary aldosteronism has been established is to determine whether disease is unilateral or bilateral, because surgical removal of the lesion usually reduces arterial pressure only in patients with unilateral disease.

Rx TREATMENT

INDICATIONS FOR THERAPY Patients with a diastolic pressure repeatedly >90 mmHg or systolic pressure >140 mmHg should be treated unless specific contraindications exist. Patients with isolated *systolic* hypertension (levels >160 mmHg with diastolic pressure <89 mmHg) should also be treated if they are over age 65 (Fig. 230-1). Patients with labile hypertension or isolated systolic hypertension who are not treated should have regular follow-up examinations at 6-month intervals because of the frequent development of progressive and/or sustained hypertension. Finally, patients with atherosclerotic vascular disease or diabetes mellitus and diastolic blood pressures between 85 and 90 mmHg should also receive antihypertensive therapy (Fig. 230-2).

Appropriate therapy for patients with white coat hypertension is debated, largely because the ultimate risk of cardiovascular events in these patients is still unknown. Some believe that subjects whose blood pressure is susceptible to apprehension and anxiety in the doctor's office are likely to have elevations during other periods of stress in their lives. Others hold white coat hypertension to be a tightly circumscribed phenomenon. In either case, these individuals would clearly benefit from life-style modifications to reduce progression to sustained hypertension. At present, there are insufficient data to warrant treatment with antihypertensive therapy unless other risk factors are present.

What should the blood pressure goal be? Previously it was assumed that 140/90 mmHg was the desired level. This still seems reasonable for nondiabetic patients since the Hypertension Optimal Treatment (HOT) study did not detect a significant difference in cardiovascular risk between nondiabetic patients treated to goal diastolic blood pressures of 90 versus 80 mmHg. However, in patients with

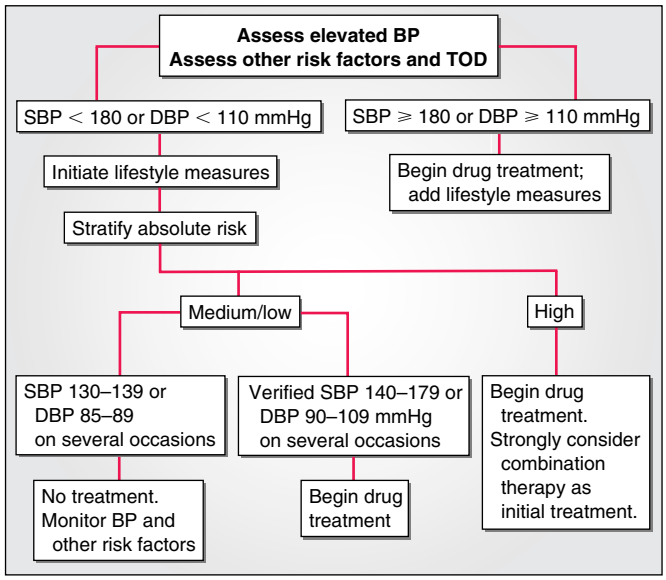

FIGURE 230-1 Initiation of treatment in patients with hypertension. See Table 230-11 for listing of classes of agents to use initially. In the initial evaluation, patients are stratified for cardiovascular risk using: level of blood pressure; the presence of risk factors—smoking, obesity, male gender, etc.—which vary from 0 factors (low risk) to three or more factors (high risk equivalent to having diabetes mellitus), target organ damage (TOD, i.e., clinical cardiovascular or renal disease) or diabetes (both high risk if present regardless of other risk factors). SBP, systolic blood pressure; DBP, diastolic blood pressure

diabetes this is not the case. In the U.K. Prospective Diabetes Study (UKPDS), patients reaching a blood pressure of 144/82 mmHg had a substantially lower risk compared to those with a blood pressure of 154/87 mmHg. The HOT study investigators documented a similar finding in their diabetic subset. Importantly, these studies have failed to document the existence of a "J" or "U" curve, indicating no increased risk of excessive blood pressure reduction. Thus, it is reasonable to target a blood pressure well within the normal range for diabetic patients, at most 130/85 mmHg. Newer studies may force this recommended goal even lower (see "Diabetes Mellitus," below). While not definitively proven, it seems prudent to use the same goal in patients with target organ damage, and in young and middle-aged patients, depending on what other cardiovascular risk factors are present. For elderly individuals, a goal of 140/90 mmHg is appropriate. Importantly, how aggressive one should be in achieving these blood pressure goals depends on the number and severity of other risk factors present.

Probably fewer than one-third of hypertensive patients in the United States are being treated effectively. Only a small number of these failures are related to drug unresponsiveness. Most are related to (1) failure to detect hypertension, (2) failure to institute effective treatment of an asymptomatic hypertensive patient, and (3) failure of the asymptomatic hypertensive patient to adhere to therapy. To help with the latter problem, patients must be educated to continue treatment once an effective regimen has been identified. Side effects and inconveniences of treatment must be minimized or counteracted in order to obtain the patient's continued cooperation.

The identification of an operable form of secondary hypertension does not automatically mean that surgical treatment is indicated. The decision depends on the age and general health of the patient, the natural history of the lesion, and the response of the arterial pressure to drug therapy. In patients with renovascular hypertension, the feasibility of renal angioplasty, the advantages of surgical repair versus nephrectomy, and the degree of overall renal functional impairment must be considered. Age and general health are important in patients with renovascular hypertension due to arteriosclerosis, because there is no evidence that repair of the stenosis increases life expectancy in the elderly patient with other evidence of vascular disease. Knowledge of the natural history of the disease is especially important when making a decision in the case of a young patient with renal artery stenosis due to fibrous dysplasia. If the arteriographic appearance suggests that the stenosis is due to intimal or subadventitial fibroplasia, the lesion may be expected to progress, and operation or angioplasty is required. Medial fibroplasia, on the other hand, often remains stable, and operation or angioplasty may not be necessary if pressure can be controlled by drug therapy.

The decision regarding operation should also be considered carefully in patients with primary aldosteronism when neither abdominal CT nor bilateral adrenal venous sampling for aldosterone demonstrates a tumor, because such patients may prove to have multinodular hyperplasia. In that case, bilateral adrenalectomy would be required to eliminate the aldosterone excess, and, even then, hypertension would usually persist. If hypokalemia can be controlled by an aldosterone receptor antagonist, e.g., spironolactone, or other drug therapy and arterial pressure lowered with antihypertensive agents, then it is reasonable to withhold operative treatment.

GENERAL MEASURES Nondrug therapeutic intervention is probably indicated in all patients with sustained hypertension and probably in most with labile hypertension. The general measures employed include (1) relief of stress, (2) dietary management, (3) regular aerobic exercise, (4) weight reduction (if needed), and (5) control of other risk factors contributing to the development of arteriosclerosis. Though it

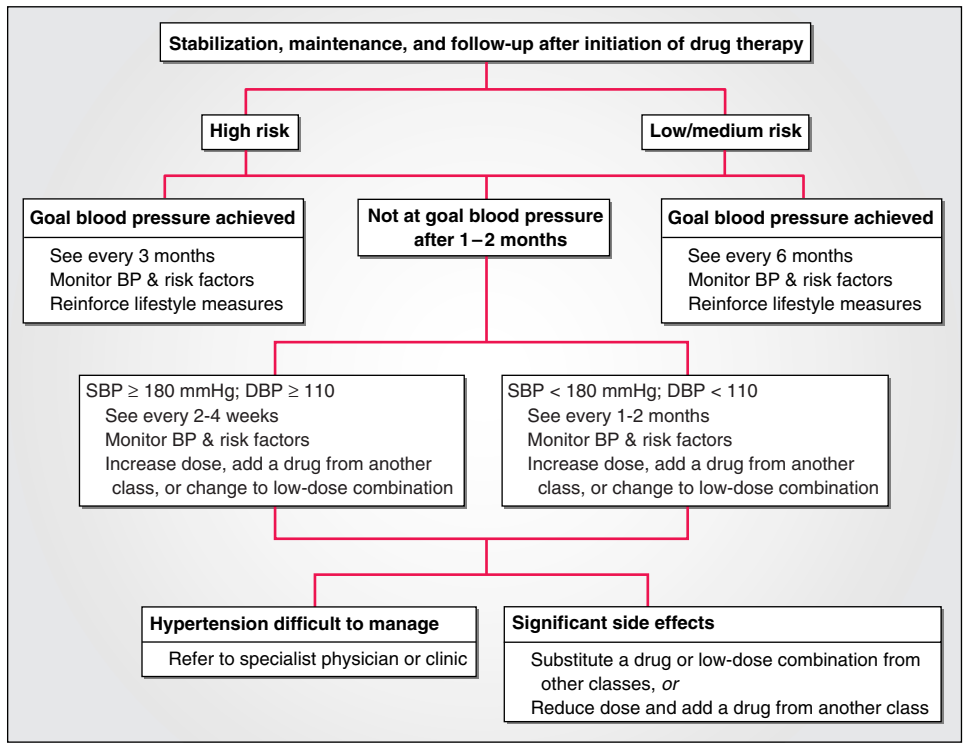

FIGURE 230-2 Approach to the hypertensive patient after initiating antihypertensive drug treatment. See Fig. 230-1 for initial steps and definition of risk and Table 230-11 for initial choice of agents.

is usually impossible to extricate the hypertensive patient from all internal and external stresses, he or she should be advised to avoid unnecessary tensions. In rare instances, it may be appropriate to recommend a change of job or of life-style. It has been suggested that relaxation techniques may also lower arterial pressure.

Dietary management has three aspects:

1. Because of the documented efficacy of sodium restriction and volume contraction in lowering blood pressure, patients previously were instructed to curtail sodium intake drastically. Some investigators have suggested that this is not necessary. They base their conclusion on two observations: (1) In many patients the blood pressure is not sensitive to the level of sodium intake, and (2) diuretics provide another method of decreasing body sodium stores in individuals whose blood pressure is sodium-sensitive. However, meta-analyses of previous diet studies have documented a 5-mmHg reduction in systolic pressure and a 2.6-mmHg reduction in diastolic pressure when sodium intake is reduced by ~75 meq/d. In addition, several reports have documented that, while mild sodium restriction has little if any direct action on blood pressure, it significantly potentiates the efficacy of nearly all antihypertensive agents. Thus, by making it possible to control blood pressure with lower doses of drugs, sodium restriction leads to a reduction in side effects. In addition, it is quite clear that some hypertensive patients are salt-sensitive (p. 1463), and the level of sodium intake does influence the blood pressure. Thus, since there is no apparent risk to mild sodium restriction, the most practical approach is to advise mild dietary sodium restriction (up to 5 g NaCl per day), which can be achieved by eliminating all additions of salt to food that is prepared normally. Some studies have also reported a lowering of arterial pressure related to an *increase* in potassium and/or calcium intake. For example, in one meta-analysis, dietary potassium supplements of 50 to 120 meq/d reduced blood pressure by about the same amount as salt restriction (by 6 mmHg systolic and 3.4 mmHg diastolic). While the advisability of these forms of dietary alteration is still controversial, the fact that a moderately high calcium intake (1.5 g elemental calcium daily) probably also reduces the extent of age-related osteoporosis, combined with the results of the potassium supplementation studies, indicate that they are probably useful adjuncts. A particularly useful approach is the DASH (Dietary Approaches to Stop Hypertension) diet, which uses natural foods that are high in potassium and low in saturated and total fat, emphasizing fruits, vegetables, and low-fat dairy products. This diet significantly lowered blood pressure in borderline and stage 1 hypertensive subjects (11.4/5.5 mm Hg)(see Table 230-6 for definitions). The sequel DASH-sodium trial found that coupling the DASH diet with moderate sodium restriction led to greater falls in pressure than dietary manipulation alone, although the gain was modest. While salt restriction has been shown to lower blood pressure, no study has yet examined whether cardiovascular outcomes are reduced.

2. Caloric restriction should be urged for hypertensive patients who are overweight. Some obese patients will show a significant reduction in blood pressure simply as a consequence of weight loss. In the Trial of Antihypertensive Interventions and Management (TAIM) study, weight reduction (average 4.4 kg over 6 months) lowered blood pressure by 2.5 mmHg.

3. A restriction in the intake of cholesterol and saturated fats is recommended, as this diet modification may diminish the incidence of arteriosclerotic complications. Reducing alcohol intake to <15 mL daily is also beneficial. Regular exercise is indicated within the limits of the patient's cardiovascular status. Not only is exercise helpful in controlling weight, but there is also evidence that physical conditioning itself may lower arterial pressure. Isotonic exercises (jogging, swimming) are better than isometric exercises (weight lifting) since the latter, if anything, raises arterial pressure. The dietary management outlined above is aimed at the control of other risk factors. Probably the most significant additional step that could be taken in this area would be to convince the smoker to give up cigarettes.

DRUG THERAPY FOR HYPERTENSION (Table 230-8) To make rational use of antihypertensive drugs, the sites and mechanisms of their action must be understood. In general, there are seven classes of drugs: diuretics, ACE inhibitors, angiotensin receptor antagonists, calcium channel antagonists; antiadrenergic agents, vasodilators, and mineralocorticoid receptor antagonists.

Diuretics (See also Chap. 216) The thiazides are the most frequently used and most extensively investigated members of this group, and their early effect is related to sodium diuresis and volume depletion. A reduction in peripheral vascular resistance has also been reported by some workers to be important in the long term. Traditionally, thiazide diuretics have formed the cornerstone of most therapeutic programs designed to lower arterial pressure, and they are usually effective within 3 to 4 days. Furthermore, they have been shown to reduce mortality and morbidity in long-term trials. Resistance to their routine use arose primarily because of their adverse metabolic effects, which include hypokalemia due to renal potassium loss, hyperuricemia due to uric acid retention, carbohydrate intolerance, and hyperlipidemia. These effects are minimized if the dose is kept below the equivalent of 25 mg/d of hydrochlorothiazide. The more potent loop-acting diuretics furosemide and bumetanide have also been shown to be antihypertensive but have been used less extensively for this indication, primarily because of their shorter duration of action. Triamterene and amiloride also impede sodium reabsorption, although triamterene has little intrinsic antihypertensive effect. Their major disadvantage is that they can produce hyperkalemia, particularly in patients with impaired renal function. Any of the potassium-sparing diuretics can also be given along with thiazide diuretics to minimize renal potassium loss.

ACE Inhibitors Drugs in this group inhibit the enzyme converting angiotensin I into angiotensin II—ACE. These agents are an increasingly popular choice for initial therapy. They are useful because they not only inhibit the generation of a potent vasoconstrictor (angiotensin II) but also retard the degradation of a potent vasodilator (bradykinin), alter prostaglandin production, and can modify the activity of the adrenergic nervous system. They are especially useful in renal or renovascular hypertension and in diabetic patients, as well as in accelerated and malignant hypertension. They are also as effective in mild, uncomplicated hypertension as beta blockers and thiazides—and have fewer side effects, particularly ones that adversely affect the patient's quality of life, such as fatigue, impotence, and forgetfulness. Ten ACE inhibitors are currently available in the United States. As a group they can cause the adverse effects of cough in 5 to 10% of patients, hyperkalemia in patients with renal insufficiency, and the idiosyncratic reaction of angioedema.

Usually, diuretics are stopped 2 to 3 days before administration of an ACE inhibitor is begun and are added back later if needed. These drugs should be used with caution when the renin system is activated (e.g., by severe heart failure, prior diuretic therapy, or substantial salt restriction) to avoid profound hypotension. In patients with bilateral renal artery stenosis, rapid deterioration of renal function may occur.

It is now well-established than activation of the renin-angiotensin system is responsible for detrimental effects on the cardiovascular and renal systems, and that blockade with ACE inhibitors is effective against these end-organ changes, even in patients without hypertension. The HOPE (Heart Outcomes Prevention Evaluation) trial demonstrated a significant reduction in the rates of death, myocardial infarction, and stroke in a broad range of high-risk patients given ramipril.

Angiotensin Receptor Antagonists (ARBs) These drugs are the most selective blockers of the renin-angiotensin system currently available. They have effects similar to those of ACE inhibitors. However, instead of blocking the production of angiotensin II, they competitively inhibit its binding to the angiotensin II AT_1 receptor subtype. It is not yet known what the long-term effects, in any, will be from exposure of the angiotensin II receptors to chronic increased circulating concentrations of angiotensin II. The utility, efficacy, and tolerability of ARBs are similar to those of the ACE inhibitors, but they appear to cause

TABLE 230-8 *Drugs Used in Treatment of Hypertension—Listed According to Site of Action*

Site of Action	Drug	Dosage	Indications	Contraindications/Cautions	Frequent or Peculiar Side Effects
DIURETICS					
Renal tubule	Thiazides: e.g., hydrochlorothiazide	Depends on specific drug Oral: 12.5–25 mg daily	Mild hypertension; as adjunct in treatment of moderate to severe hypertension	Diabetes mellitus, hyperuricemia, primary aldosteronism	Potassium depletion, hyperglycemia, hyperuricemia, hypercholesterolemia, dermatitis, purpura, depression, hypercalcemia
	Loop-acting: e.g., furosemide	Oral: 20–80 mg 2 or 3 times a day	Mild hypertension; as adjunct in severe or malignant hypertension, particularly with renal failure	Hyperuricemia, primary aldosteronism	Potassium depletion, hyperuricemia, hyperglycemia, hypocalcemia, blood dyscrasias, rash, nausea, vomiting, diarrhea
	Potassium-sparing:		Hypertension due to hypermineralocorticoidism; as adjunct to thiazide therapy		
	Spironolactone	Oral: 25 mg 2 to 4 times daily		Renal failure	Hyperkalemia, diarrhea, gynecomastia, menstrual irregularities
	Triamterene	Oral: 25–100 mg daily			Hyperkalemia, nausea, vomiting, leg cramps, nephrolithiasis, GI disturbances
	Amiloride	Oral: 5–10 mg daily			
ANTIADRENERGIC AGENTS					
Central	Clonidine	Oral: 0.05–0.6 mg twice daily	Mild to moderate hypertension, renal disease with hypertension		Postural hypotension, drowsiness, dry mouth, rebound hypertension after abrupt withdrawal, insomnia
	Guanabenz	Oral: 4–16 mg twice daily			
	Guanfacine	Oral: 1–3 mg daily			
	Methyldopa (also acts by blocking sympathetic nerves)	Oral: 250–1000 mg twice daily IV: 250–1000 mg every 4–6 h (tolerance may develop)	Mild to moderate hypertension (oral), malignant hypertension (IV)	Pheochromocytoma, active hepatic disease (IV), during MAO inhibitor administration	Postural hypotension, sedation, fatigue, diarrhea, impaired ejaculation, fever, gynecomastia, lactation, positive Coombs' tests (occasionally associated with hemolysis), chronic hepatitis, acute ulcerative colitis, lupus-like syndrome
Autonomic ganglia	Trimethaphan	IV: 1–6 mg/min	Severe or malignant hypertension	Severe coronary artery disease, cerebrovascular insufficiency, diabetes mellitus (on hypoglycemic therapy), glaucoma, prostatism	Postural hypotension, visual symptoms, dry mouth, constipation, urinary retention, impotence
Nerve endings	Guanethidine	Oral: 10–150 mg daily	Moderate to severe hypertension	Pheochromocytoma, severe coronary artery disease, cerebrovascular insufficiency, during MAO inhibitor administration	Postural hypotension, bradycardia, dry mouth, diarrhea, impaired ejaculation, fluid retention, asthma
	Guanadrel	Oral: 5–50 mg twice daily			
α Receptors	Phentolamine	IV: 1–5 mg bolus	Suspected or proved pheochromocytoma	Severe coronary artery disease	Tachycardia, weakness, dizziness, flushing
	Phenoxybenzamine	Oral: 10–50 mg once or twice daily (tolerance may develop)	Proved pheochromocytoma		Postural hypotension, tachycardia, miosis, nasal congestion, dry mouth
	Prazosin	Oral: 1–10 mg twice daily	Mild to moderate hypertension	Use with caution in the elderly	Sudden syncope, headache, sedation, dizziness, tachycardia, anticholinergic effect, fluid retention
	Terazosin	Oral: 1–20 mg daily			
	Doxazosin	Oral: 1–16 mg daily			
β Receptors	Propranolol	Oral: 10–120 mg 2 to 4 times daily	Mild to moderate hypertension (especially with evidence of hyperdynamic circulation); as adjunct to hydralazine therapy	Congestive heart failure, asthma, diabetes mellitus (on hypoglycemic therapy), during MAO inhibitor administration, COPD, sick sinus syndrome, 2d or 3d degree heart block	Dizziness, depression, bronchospasm, nausea, vomiting, diarrhea, constipation, heart failure, fatigue, Raynaud's phenomenon, hallucinations, hypertriglyceridemia, hypercholesterolemia, psoriasis; sudden withdrawal may precipitate angina or myocardial injury in patients with heart disease
	Metoprolol	Oral: 25–150 mg twice daily			
	Nadolol	Oral: 20–120 mg daily			
	Atenolol	Oral: 25–100 mg daily			
	Timolol	Oral: 5–15 mg twice daily			

(continued)

TABLE 230-8 *Drugs Used in Treatment of Hypertension—Listed According to Site of Action—(Continued)*

Site of Action	Drug	Dosage	Indications	Contraindications/Cautions	Frequent or Peculiar Side Effects
	Betaxolol	Oral: 10–20 mg daily			
	Carteolol	Oral: 2.5–10 mg daily			
	Pindolol	Oral: 5–30 mg twice daily			Less resting bradycardia than other beta blockers
	Acebutolol	Oral: 200–600 mg twice daily			
α/β Receptors	Labetalol	Oral: 100–600 mg twice daily IV: 2 mg/min			Similar to beta blockers with more postural effects
	Carvediol	Oral: 12.5–50 mg daily or in divided doses			
VASODILATORS					
Vascular smooth muscle	Hydralazine	Oral: 10–75 mg 4 times daily IV or IM: 10–50 mg every 6 h (tolerance may develop)	As adjunct in treatment of moderate to severe hypertension (oral), malignant hypertension (IV or IM), renal disease with hypertension	Lupus erythematosus, severe coronary artery disease	Headache, tachycardia, angina pectoris, anorexia, nausea, vomiting, diarrhea, lupus-like syndrome, rash, fluid retention
	Minoxidil	Oral: 2.5–40 mg twice daily	Severe hypertension	Severe coronary artery disease	Tachycardia, aggravates angina, marked fluid retention, hair growth on face and body, coarsening of facial features, possible pericardial effusions
	Diazoxide	IV: 1–3 mg/kg up to 150 mg rapidly	Severe or malignant hypertension	Diabetes mellitus, hyperuricemia, congestive heart failure	Hyperglycemia, hyperuricemia, sodium retention
	Nitroprusside	IV: 0.5–8 (μg/kg)/min	Malignant hypertension		Apprehension, weakness, diaphoresis, nausea, vomiting, muscle twitching, cyanide toxicity
ANGIOTENSIN-CONVERTING ENZYME INHIBITORS					
Converting enzyme	Captopril	Oral: 12.5–75 mg twice daily	Mild to severe hypertension, renal artery stenosis	Renal failure (reduction of dose), bilateral renal artery stenosis, pregnancy	Leukopenia, pancytopenia, hypotension, cough, angioedema, urticarial rash, fever, loss of taste, acute renal failure in bilateral renal artery stenosis, hyperkalemia
	Benazepril	Oral: 5–40 mg daily			Same as captopril, but little evidence for leukopenia, but perhaps increased frequency of cough and angioedema. All can be given once daily, but side effects are reduced if one-half dose is given twice daily. Fosinopril is excreted more in bile than the others.
	Enalapril	Oral: 2.5–40 mg daily			
	Enalaprilat	IV: 0.625–1.25 mg over 5 min every 6–8 h			
	Fosinopril	Oral: 10–40 mg daily			
	Lisinopril	Oral: 5–40 mg daily			
	Quinapril	Oral: 5–80 mg daily			
	Ramipril	Oral: 1.25–20 mg daily			
	Trandolapril	Oral: 1–4 mg daily			
ANGIOTENSIN RECEPTOR ANTAGONISTS					
	Losartan	Oral: 25–50 mg once or twice daily	Mild to severe hypertension, renal artery stenosis	Pregnancy, bilateral renal artery stenosis	Hypotension, acute renal failure in bilateral renal artery stenosis, hyperkalemia
	Valsartan	Oral: 80–320 mg			
	Irbesartan	Oral: 150–300 mg daily			

(continued)

TABLE 230-8—*(Continued)*

Site of Action	Drug	Dosage	Indications	Contraindications/Cautions	Frequent or Peculiar Side Effects
CALCIUM CHANNEL ANTAGONISTS					
Vascular smooth muscle	Dihydropyridines:				
	Nifedipine XL	Oral: 30–90 mg daily	Mild to moderate hypertension	Heart failure, 2d or 3d degree heart block	Tachycardia, flushing, gastrointestinal disturbances, hyperkalemia, edema, headache
	Amlodipine	Oral: 2.5–10 mg daily			
	Felodipine XL	Oral: 5–10 mg daily			
	Isradipine	Oral: 2.5–10 mg daily			
	Nicardipine	Oral: 20–40 mg 3 times daily			
	Benzothiazepines:				
	Diltiazem	Oral: 30–90 mg 4 times daily or as CD form 180–300 mg daily	Mild to moderate hypertension	Heart failure, 2d or 3d degree heart block	Same as amlodipine, except no tachycardia or edema, but can cause heart block, constipation, and liver dysfunction
	Phenylalkylamine:				
	Verapamil	Oral: 30–120 mg 4 times daily or as SR form 120–480 mg daily	Mild to moderate hypertension	Heart failure, 2d or 3d degree heart block	
MINERALOCORTICOID RECEPTOR ANTAGONISTS					
Renal tubule	Spironolactone	Oral: 25–50 mg 2 to 4 times daily	Hypertension due to hypermineralocorticoidism; as adjunct to thiazide therapy	Renal failure	Hyperkalemia, diarrhea, menstrual irregularities, gynecomastia
	Eplerenone	50–100 mg daily	Hypertension due to hypermineralocorticoidism; as adjunct to thiazide therapy	Renal failure, diabetic nephropathy	Hyperkalemia, no antiandrogenic or progesterone side effects

Note: MAO, monoamine oxidase; COPD, chronic obstructive pulmonary disease; XL, CD, SR are long-acting or sustained-release formulations.

fewer side effects. Specifically, they do not cause excessive cough or angioedema. There appears to be variation within the class in terms of antihypertensive efficacy. No studies are available to allow comparison of efficacy between ACE inhibitors and ARBs, and their joint use, while already in clinical practice, awaits more substantiating data.

A number of large-scale prospective studies are under way to investigate the effects of ARBs on mortality and morbidity in patients with cardiovascular disease. The Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study has shown that losartan-based antihypertensive treatment was superior to atenolol in reducing cardiovascular mortality and morbidity, especially stroke and regression of left ventricular hypertrophy (Table 230-9). Three studies have demonstrated that irbesartan and losartan significantly reduce the progression on diabetic nephropathy in patients with type 2 diabetes mellitus.

Calcium Channel Antagonists There are three subclasses of calcium channel antagonists: the phenylalkylamine derivatives (e.g., verapamil), the benzothiazepines (e.g., diltiazem), and the dihydropyridines (e.g., amlodipine). To date, there is only one therapeutic agent in each of the first two classes but a number of agents in the third class. All three subclasses modify calcium entry into cells by interacting with specific binding sites on the α_1 subunit of the L-type voltage-dependent calcium channel. Thus, since there are other calcium channels (e.g., the T and N types), the actions of these drugs only partially modify total calcium transport into cells. The relative specificity of each agent stems from the fact that each class has a unique binding site on the α_1 subunit, and these sites are variably expressed in different tissues. Thus, while agents from all three subclasses cause vasodilation, usually only the dihydropyridines produce reflex tachycardia. Diltiazem and verapamil can both slow atrioventricular conduction—a feature not observed with the dihydropyridines. While calcium channel antagonists are also useful in angina pectoris (Chap. 226), because of their negative inotropic actions, they should be used with caution in hypertensive patients with heart failure.

Considerable controversy has surrounded the use of calcium channel antagonists in the treatment of hypertension. In part the controversy was secondary to the inadequacy of the data and the confusion between the use of short-acting agents (e.g., nifedipine) and long-acting agents. Several facts have helped partially to resolve this controversy. First has been the general recognition that despite its previously frequent use as an antihypertensive agent, short-acting nifedipine rarely, if ever, should be used to treat hypertension, since it has been reported to increase the incidence of acute coronary events. Second, the results of the SYST-EUR (Systolic Hypertension in Europe) trial documented, in patients over the age of 60 with isolated systolic hypertension, that a long-acting dihydropyridine calcium channel antagonist reduced cardiovascular morbidity and mortality to an extent equivalent to that previously reported for diuretics and beta blockers. The effect was greater among diabetics. Thus, long-acting calcium channel antagonists are often used as first-line hypertension therapy.

Antiadrenergic Agents ■ ***β-ADRENERGIC RECEPTOR BLOCKERS*** (See also Chap. 226) A number of effective β-adrenergic receptor blocking agents are available that block sympathetic effects on the heart and are most effective in reducing cardiac output and in lowering arterial pressure when there is increased cardiac sympathetic nerve activity. These agents are also often used as first-line therapy. In addition, they block the adrenergic nerve–mediated release of renin from the renal juxtaglomerular cells. This action may be an important component of their blood pressure–lowering action. β-Adrenergic blockers are particularly useful when employed in conjunction with vasodilators, which tend to evoke a reflex increase in heart rate, and with diuretics, the administration of which often results in an elevation of circulating renin activity. In practice, beta blockers appear to be effective even when there is no evidence of increased sympathetic tone, with about one-half or more of all hypertensive patients showing a fall in pressure. Furthermore, like diuretics, they have been shown to reduce morbidity and mortality in long-term clinical trials. However, these agents can precipitate congestive heart failure and asthma in susceptible individuals, and they must be used with caution in diabetic patients receiving

TABLE 230-9 *Randomized Clinical Trials in Hypertension*

Trial Reference	Patient Number and Characteristics	Trial Arms	Endpoints	Results	Conclusion
SYST-EUR, JA Staessen et al, Lancet 350: 757, 1997	4695, >60 years old 2 years' follow-up	Nitrendipine/ enalapril or HTZ Placebo	Primary: Death, all cardiovascular events, strokes	Active treatment reduced total stroke rate 42% ($p = .003$); nonfatal stroke decreased 44% ($p = .007$). All fatal and nonfatal cardiac endpoints declined 26% ($p = .03$). Cardiovascular mortality decreased 27% ($p = .07$).	Among elderly patients with isolated systolic hypertension, nitrendipine reduced cardiovascular complications; treatment of 1000 patients for 5 years with this regimen may prevent 29 strokes and/or 53 major cardiovascular endpoints
SYST-EUR, J Tuomilehto et al, N Engl J Med 341:372, 1999	4695 (diabetic = 492) >60 years old 2 years' follow-up	Nitrendipine/enalapril or HTZ Placebo	Primary: Death, all cardiovascular events, strokes	In diabetics total mortality reduced 55%; mortality from cardiovascular disease by 76%; all cardiovascular events combined by 69%; nonfatal stroke by 73% Reductions in mortality and all cardiovascular events were significantly larger among diabetic than nondiabetic patients ($p = .04$ to $.01$).	Calcium channel antagonist significantly reduces cardiovascular morbidity and mortality in elder hypertensive patients; the effect is greater in diabetic than nondiabetic subjects
CAPPP Trial, L Hansson et al, Lancet 353: 611, 1999	10,985, age 25–66, diastolic BP ≥ 100 mmHg 2–3 years' follow-up	Captopril Diuretics/beta blocker	Primary: Composite of fatal and nonfatal myocardial infarction, stroke, and other cardiovascular deaths	Primary endpoint relative risk 1.05, $p = .52$; Cardiovascular mortality was lower with captopril, relative risk (RR) 0.77, $p = .092$ Fatal and nonfatal stroke was more common with captopril, RR 1.25, $p = .044$	Captopril and conventional treatment did not differ in preventing cardiovascular morbidity and mortality
HOT Study, Hansson et al, Lancet 351: 1755, 1998	18,790, 50–80 years with diastolic BP 100–115 mmHg 3–4 years' follow-up	Felodipine plus four other agents to reduce diastolic BP to 90 mmHg or 85 mmHg or 80 mmHg	Major cardiovascular events	Lowest cardiovascular mortality occurred at 86.5 mmHg; further reduction below these BPs was safe but no further reduction in risk; in patients with diabetes, a 51% reduction in cardiovascular events in target group = 80 mmHg compared with target group = 90 mmHg (p for trend = .006)	Intensive lowering of BP was associated with a low rate of cardiovascular events down to a diastolic BP of 82.6 mmHg
DASH Trial, LJ Appel et al, N Engl J Med 336:1117, 1997	459 with diastolic blood pressure 80–95 mmHg; 8 wks. Sodium intake and body weight were maintained constant.	Diet rich in fruits and vegetables Diet rich in fruits, vegetables, and low-fat dairy products Control (average U.S. diet)	Blood pressure	Combination diet reduced systolic and diastolic BP by 5.5 and 3.0 mmHg more than the control diet ($p < .001$); the fruit and vegetable diet had an intermediate effect	A diet rich in fruits, vegetables, and low-fat dairy food can substantially lower BP
FG Messerli et al, JAMA 279: 1903, 1998	Meta-analysis of efficacy of beta blockers vs. diuretics as first-line therapy for elderly patients (>60 years) with hypertension Approximate mean of 5 years' follow-up	Diuretics, 8 trials Beta blockers, 2 trials	Cerebrovascular events, coronary heart disease, stroke mortality, cardiovascular mortality, all-cause mortality	Diuretics significantly reduced cerebrovascular events odds ratio (0.61), coronary heart disease odds ratio (0.74), stroke mortality odds ratio (0.67), cardiovascular mortality odds ratio (0.75), and all-cause mortality odds ratio (0.86); beta blockers significantly reduced only cerebrovascular events odds ratio (0.74)	In elderly patients with hypertension, first-line diuretics reduced morbidity and mortality better than beta blockers

(continued)

TABLE 230-9—*(Continued)*

Trial Reference	Patient Number and Characteristics	Trial Arms	Endpoints	Results	Conclusion
HOPE, S Yusuf et al, 2000	9297 high-risk patients (≥55 years old) with vascular disease or diabetes plus one other cardiovascular risk factor	Ramipril vs. placebo for a mean of 5 years	Primary: Composite of myocardial infarction, stroke, or death from cardiovascular causes	Ramipril significantly reduced the rates of death from cardiovascular causes (RR 0.74), MI (RR 0.80), stroke (RR 0.68), cardiac arrest (RR 0.62), heart failure (RR 0.77), and complications related to diabetes (RR 0.84).	Ramipril significantly reduced the rates of death, MI, and stroke in high-risk patients not known to have a low ejection fraction or heart failure.
LIFE, B Dahlof et al, Lancet 359: 995, 2002	9193, age 55–80, with essential hypertension and LVH by ECG	Once daily losartan-based or atenolol-based antihypertensive treatment for at least 4 years and until 1040 patients had primary cardiovascular event	Primary cardiovascular event (death, MI, or stroke)	BP fell by 30.2/16.6 (SD 18.5/10.1) and 29.1/16.8 mmHg (19.2/10.1) in the losartan vs. atenolol groups The primary composite endpoint occurred in 508 losartan and 588 atenolol patients (RR 0.87) New-onset diabetes was less frequent with losartan	Losartan prevented more cardiovascular morbidity and death than atenolol for similar reduction in BP
ALLHAT, ALLHAT Collaborative Research Group, 2002	42,419 high-risk hypertensives ≥ 55 years	Chlorthalidone vs. lisinopril vs. amlodipine vs. doxazosin	Fatal coronary heart disease and nonfatal MI	Doxazosin arm stopped after 3 years because of increased rate of heart failure	No difference in primary endpoints or in all-cause mortality between ACE inhibition, calcium channel blockade, and diuretics

Note: HTZ, hydrochlorothiazine; BP, blood pressure; MI, myocardial infarction; LVH, left ventricular hypertrophy; ECG, electrocardiogram.

hypoglycemic therapy because they inhibit the usual sympathetic responses to hypoglycemia.

Cardioselective beta-blocking agents (so-called beta$_1$ blockers, e.g., metoprolol, atenolol) have been developed and may be superior to nonselective beta blockers such as propranolol and timolol in patients with bronchospasm. Nadolol, a nonselective beta blocker, unlike other drugs of this class, is excreted unchanged in the urine and has a half-life of 14 to 20 h; only one dose a day is required. Atenolol also usually needs to be given only once a day. Pindolol and acebutolol are nonselective beta blockers that have partial agonist activity and, therefore, produce less bradycardia. Labetalol exerts both α- and β-adrenergic blocking actions. Thus, it lowers arterial pressure not only by the same complex actions as do beta blockers but also directly by reducing systemic vascular resistance. Usually it has a more rapid onset of action but produces more postural symptoms and sexual dysfunction than the other beta blockers. It is usually not used as first-line therapy as there is no mortality study in which it has been tested.

Centrally acting agents include clonidine and methyldopa. These drugs and their metabolites stimulate α_2 receptors in the vasomotor centers of the brain, thereby reducing sympathetic outflow and arterial pressure. Usually a fall in cardiac output and heart rate also occurs. Since the baroreceptor reflex is intact, postural symptoms are absent. However, rebound hypertension may occur rarely when clonidine is stopped. This effect is probably secondary to an increase in norepinephrine release, which is inhibited by these agents owing to their agonist effect on presynaptic α receptors. They are usually not used as first-line therapy.

***α*-ADRENERGIC RECEPTOR BLOCKERS** These agents are also not usually used as first-line therapy. Phentolamine and phenoxybenzamine block the action of norepinephrine at α-adrenergic receptor sites. These two compounds block both presynaptic (α_2) and postsynaptic (α_1) α receptors, and the former action accounts for the tolerance that develops. Prazosin, terazosin, and doxazosin are more effective because they selectively block only *postsynaptic* α receptors, i.e., α_1 receptors. Thus, presynaptic α activity remains, suppressing norepinephrine release, and tolerance occurs only infrequently. Accordingly, these three agents can produce substantial hypotension following the first dose. Their use has decreased with a report of their association with an increase in cardiovascular events. The doxazosin arm of the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was terminated prematurely because of a significant increase in the risk of congestive heart failure.

Vasodilators These agents are usually not used for initial therapy. Hydralazine is the most versatile of the drugs that cause direct relaxation of vascular smooth muscle; it acts mainly on arterial resistance. Unfortunately, the effect of hydralazine on peripheral resistance is partly negated by a reflex increase in sympathetic discharge that raises heart rate and cardiac output, limiting the usefulness of hydralazine, especially in patients with severe coronary artery disease. Minoxidil is even more potent than hydralazine but unfortunately produces significant hypertrichosis and fluid retention and, therefore, is mainly limited to patients with severe hypertension and renal insufficiency.

Diazoxide is restricted in its application to acute situations. It begins to act immediately to lower blood pressure, and its effects may last for several hours. Nitroprusside given intravenously also acts as a direct vasodilator, with onset and offset of actions that are almost immediate. Nitroglycerin is a third direct-acting vasodilator useful as an intravenous agent. These latter three drugs are useful only for the treatment of hypertensive emergencies (Table 230-10).

Mineralocorticoid Receptor Antagonists In addition to its classic hormonal effects on the kidney causing sodium retention and potassium excretion, aldosterone is now recognized as a paracrine hormone that can act locally not only in the kidneys but also in the heart and blood vessels, contributing to fibrosis and hypertrophy. Aldosterone antagonists are emerging as agents that may counter these detrimental ef-

TABLE 230-10 *Therapeutic Agents Used to Treat Malignant Hypertension*

Drug	Route	Starting Dose	Time Course of Action			Oral Preparation Available
			Onset	Peak	Duration	
IMMEDIATE ONSET						
Nitroprusside	Continuous IV	0.25 μg/kg per min	<1 min	1–2 min	2–5 min	No
Nitroglycerin	Continuous IV	5 μg/min	1–5 min	2–6 min	3–10 min	No
Diazoxide	IV bolus	50 mg q5–10min up to 600 mg	1–5 min	2–4 min	4–12 h	No
Fenoldopan	Continuous IV	0.1–0.3 μg/kg per min	<5 min	5–10 min	30 min	No
Esmolol	Continuous IV	250–500 μg/min × 1 min; then 50–100 μg/kg per min × 4 min	1–2 min	2–3 min	10–20 min	No
DELAYED ONSET						
Enalaprilat	IV	1.25 mg q6h	10–15 min	3–4 h	6–24 h	Yes
Hydralazine	IV, IM	5–10 mg q20min × 3	10–20 min	20–40 min	4–12 h	Yes
Labetalol	IV	20–80 mg q10min up to 300 mg	5 min	20–30 min	3–6 h	Yes
Nicardipine	IV	5–15 mg/h	5–10 min	20–40 min	1–4 h	Yes

fects of aldosterone, including but not limited to hypertension. Spironolactone causes renal sodium loss by blocking the effect of mineralocorticoids, and it was initially employed as more effective management in hypertensive patients whose mineralocorticoid levels are excessive, such as patients with primary or secondary aldosteronism. However, the Randomized Aldactone Evaluation Study (RALES) clinical trial in heart failure using low doses of spironolactone achieved a 30% reduction in mortality, suggesting that an aldosterone receptor antagonist may be beneficial even when aldosterone levels are relatively normal (Chap. 216). Eplerenone is a new, selective mineralocorticoid receptor antagonist without clinically significant androgen receptor blocking or progesterone receptor stimulating activities, which translates into absence of gynecomastia and impotence in men and of menstrual irregularity in women. Both agents, like ACE inhibitors and angiotensin II receptor antagonists, can increase potassium levels significantly in patients with renal insufficiency. Initial close monitoring of serum potassium levels in patients with compromised renal function is, therefore, advised.

APPROACH TO DRUG THERAPY The aim of drug therapy is to use the agents described, alone or in combination, to return arterial pressure to normal levels with minimal side effects. Ideally, one would choose a therapeutic program that specifically corrects the underlying defect resulting in the elevated blood pressure, e.g., treatment with spironolactone or eplerenone for patients with primary aldosteronism. As our knowledge of the mechanisms underlying the hypertension in individual patients increases, more specific drug programs will become available. Such programs presumably will result in normalization of blood pressure with fewer side effects. In the absence of this information, an empirical approach is used, which takes into consideration efficacy, safety, impact on the quality of life, compliance, ease of administration, and cost. When used in combination, drugs are chosen for their different sites of action. Three major trials of anti-hypertensive agents have been reported recently. The mammoth ALLHAT trial resulted in no difference in either combined fatal coronary heart disease or nonfatal myocardial infarction between patients started on treatment with an ACE inhibitor, diuretic, or calcium channel blocker. In an Australian randomized trial of >6000 elderly hypertensives, in contrast, treatment with ACE inhibitors resulted in fewer cardiovascular events than treatment with diuretic agents, despite similar reductions of blood pressure. Guidelines for the initiation of antihypertensive therapy should be based upon two criteria: level of systolic and diastolic blood pressure and the total level of cardiovascular risk.

Since many effective antihypertensive agents are available, a number of useful therapeutic regimens have been developed. There are two major authoritative groups that have published treatment guidelines in 2003: The US Joint National Committee (JNC) and the European Society of Hypertension (ESH) and the European Society of Cardiology (ESC). In the absence of specific therapy, their approaches are similar in many respects, relying heavily on the results of randomized clinical trials (Table 230-9), except for which drugs should be used to initiate therapy. JNC7 recommends starting with diuretics because mortality trials have demonstrated a positive effect of treatment with these agents. The ESH/ESC guidelines recommend initiating therapy with any of five classes of agents (Table 230-11), or with a combination; recent study results from ALLHAT have made it advisable to remove alpha blockade from this list (see below). The different rec-

TABLE 230-11 *Guidelines for Selecting Initial Drug Treatment of Hypertension*

Class of Drug	Compelling Indications	Possible Indications	Compelling Contraindications	Possible Contraindications
Diuretics	Heart failure Elderly patients Systolic hypertension	Diabetes	Gout	Dyslipidemia Sexually active males
β-Blockers	Angina After myocardial infarct Tachyarrhythmias	Heart failure Pregnancy Diabetes	Asthma and COPD Heart block[a]	Dyslipidemia Athletes and physically active patients Peripheral vascular disease
ACE inhibitors	Heart failure Left ventricular dysfunction After myocardial infarct Diabetic nephropathy		Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Calcium antagonists	Angina Elderly patients Systolic hypertension	Peripheral vascular disease	Heart block[b]	Congestive heart failure[c]
Angiotensin II antagonists	ACE inhibitor cough	Heart failure	Pregnancy Bilateral renal artery stenosis Hyperkalemia	

[a] Grade 2 or 3 atrioventricular block.
[b] Grade 2 or 3 atrioventricular block with verapamil or diltiazem.
[c] Verapamil or diltiazem.

Note: COPD, chronic obstructive pulmonary disease; ACE, angiotensin-converting enzyme.
Source: Adapted with permission from 1999 WHO.

ommendations, in part, reflect the fact that European committees reviewed more recent data from mortality clinical trials that, in one case, documented reductions in morbidity and mortality with a long-acting calcium channel antagonist versus placebo similar to previous reports for diuretics and beta blockers; in another case, ACE inhibitors were shown to be as effective as beta blockers and diuretics in reducing mortality. Practically, it has become less important which agent is chosen as "initial therapy" since the majority of hypertensive patients will require more than one agent to reach goal blood pressure.

There are several critical caveats common to both the JNC 7 and ESH/ESC approaches:

1. Start with an agent that may also treat and/or not harm a coexisting condition.
2. Start with an agent that the patient is likely to tolerate best; long-term compliance is related to tolerability and efficacy of the first agent used.
3. For low- or medium-risk patients, start with a low dose of an agent and, if blood pressure is not controlled, increase only moderately.
4. Add an additional agent from a different, complementary class if blood pressure is not controlled with a moderate dose of the first agent.
5. Use a diuretic when two agents are used, in nearly all cases.
6. Use thiazide diuretics only at low doses, i.e., ≤25 mg/d of hydrochlorothiazide or its equivalent, unless some pressing reason exists.
7. For medium- to high-risk patients, strongly consider low-dose combination therapy as initial therapy:
   a. A diuretic with a beta blocker, ACE inhibitor, or angiotensin II antagonist;
   b. A calcium channel blocker with an ACE inhibitor or a beta blocker.

If therapy with low doses of two drugs does not achieve blood pressure control, the primary agent should be increased to full dose, e.g., 20 mg of enalapril or 360 mg of diltiazem. If the blood pressure is still not controlled, then a detailed search for a secondary cause of hypertension, as outlined above, is indicated, with lower levels of suspicion in diabetics and the elderly. If none is found, then a dietary assessment will often reveal a high sodium intake. With reduction in salt intake to ≤5 g/d, blood pressure is often controlled. If the blood pressure is still not controlled, a third agent should be added. Caution should be used with the addition of an ACE inhibitor, as administration of such an agent to a patient who is already taking a diuretic occasionally may lead to profound hypotension.

If the blood pressure is controlled, then a stepwise reduction in the dose and/or withdrawal of some of the agents should be carried out to determine the minimal therapeutic program that will maintain the blood pressure at ≤140/90 mmHg. Fewer than 5% of patients will still be hypertensive at this point. For these, one first should consider the reasons for therapeutic failure, as shown in Table 230-12. If none can be identified, then one of the other agents listed in Table 230-11 should be added. If blood pressure is still not controlled, then consideration should be given to an alternate class as listed in Table 230-8. If blood pressure is controlled, previous drugs are withdrawn sequentially to determine the minimal therapeutic program that will maintain a normal blood pressure.

TABLE 230-12 *Reasons for Poor Therapeutic Response in Patients with Hypertension*

Inadequate patient compliance
Volume expansion
Caused by excessive sodium intake
Caused by nondiuretic antihypertensive agent
Caused by renal damage
Excessive weight gain
Inadequate doses
Drug antagonism
Cold remedies
Sympathomimetics
Oral contraceptives (estrogens)
Adrenal steroids
Secondary forms of hypertension

While the recommendations outlined above are satisfactory for a large majority of patients, it is important to use a flexible approach, because individual patients may respond differently to individual drugs and drug combinations. For those patients requiring multiple drugs, once the appropriate combination has been found, the use of a single formulation with the appropriate combination of drugs may simplify the regimen and thereby increase compliance. Every effort should be made to reduce the number of times each day the patients must interrupt their schedules for the medication. Pharmacologic treatment of essential hypertension is usually lifelong, and since most patients are asymptomatic, compliance with a complex regimen may be a serious problem, particularly if the therapeutic regimen has a negative impact on the quality of the patient's life. Finally, it is uncertain what level of arterial pressure should be accepted as representing adequate control. It is clear that reducing diastolic blood pressure to <90 mmHg is appropriate and reduces morbidity and/or mortality.

SPECIAL CONSIDERATIONS Five groups of patients with hypertension require special consideration because of associated conditions: those with renal disease, coronary artery disease, or diabetes mellitus; women of reproductive age; and the elderly. These groups are considered in the following sections.

Renal Disease Reduction of arterial pressure in hypertensive patients with impaired renal function is often accompanied initially by an increase in serum creatinine. This change does not represent further structural renal damage and should not deter the physician from continuing the therapy, since achievement of blood pressure control may eventually reduce the value toward normal. However, if serum creatinine increases in a patient treated with an ACE inhibitor, care needs to be exercised, because these patients may have bilateral renal artery disease. Their renal function will continue to deteriorate as long as the ACE inhibitor is given. Thus, ACE inhibitors should be used cautiously in patients with impaired renal function, and renal function should be assessed frequently (every 4 to 5 days) for the first 3 weeks. While these drugs are contraindicated in patients with bilateral renal artery stenosis, together with angiotensin receptor blockers they are the drugs of choice in patients with unilateral renal artery stenosis and a normally functioning contralateral kidney and probably also in patients with chronic renal failure with or without diabetes mellitus.

Coronary Artery Disease Beta blockers, important in reducing mortality after myocardial infarction and in the treatment of angina, are useful antihypertensive agents in patients with coronary artery disease. ACE inhibitors are useful in these patients as well, especially those with hypertension and left ventricular dysfunction.

Diabetes Mellitus The diabetic patient with hypertension is particularly challenging to treat because multiple agents are usually needed to achieve goal blood pressure and because many of the agents used to lower blood pressure can affect glucose metabolism adversely. ACE inhibitors or angiotensin receptor blockers should be first-line therapy in hypertensive individuals with type 2 diabetes. They have no known adverse effects on glucose or lipid metabolism and minimize the development of diabetic nephropathy by reducing renal vascular resistance and renal perfusion pressure—the primary factor underlying renal deterioration in these patients (Chap. 323). Meta-analyses of clinical studies have demonstrated that setting a lower blood pressure goal in diabetic patients is ideal to prevent progression of end-organ disease, with current recommendations shifting from 130/85 mmHg downward to 130/80. The average hypertensive diabetic patient will require at least three medications to achieve appropriate control.

Women of Reproductive Age ■ *ORAL CONTRACEPTIVES* Several years ago, a common cause of endocrine hypertension was the use of estrogen-containing oral contraceptives. However, more recent studies have

suggested that this is no longer true, probably owing to the lower estrogen content of modern oral contraceptives. In patients receiving these agents who do become hypertensive, the mechanism is likely to be activation of the renin-angiotensin-aldosterone system. The estrogen component of oral contraceptive agents stimulates the hepatic synthesis of the renin substrate angiotensinogen, which in turn favors the increased production of angiotensin II and secondary aldosteronism. However, only a small number of women taking oral contraceptives actually have an increase in arterial pressure to a level >140/90mmHg, and in about half of these, the hypertension will remit within 6 months of stopping the drug. Why some women taking oral contraceptives develop hypertension and others do not is unclear but may be related to (1) increased vascular sensitivity to angiotensin II, (2) the presence of mild renal disease, (3) familial factors (>50% have a positive family history for hypertension), (4) age (hypertension is significantly more prevalent in women over age 35), (5) the estrogen content of the contraceptive, and/or (6) obesity. Indeed, some investigators have suggested that oral contraceptives simply unmask women with essential hypertension.

PREGNANCY (See also Chap. 6) The patient who is pregnant and hypertensive or who develops hypertension during pregnancy (pregnancy-induced hypertension, preeclampsia, eclampsia) is particularly difficult to treat. Because it is uncertain whether autoregulation of uterine blood flow occurs, lowering blood pressure in the pregnant hypertensive patient may result in reduced placental and fetal perfusion. Thus, a conservative approach to lowering blood pressure is usually indicated. In the second and third trimesters, antihypertensive agents are often not indicated unless the diastolic pressure exceeds 95 mmHg. In general, severe salt restriction and/or diuretics are not used because of the associated increase in fetal wastage. Beta blockers need to be used cautiously for similar reasons. Methyldopa and hydralazine, and to a lesser extent calcium channel antagonists, are the antihypertensive agents used most often, because they have no known adverse effects on the fetus. Little is known about the safety of other antihypertensive agents in pregnancy, except that nitroprusside, ACE inhibitors, and angiotensin receptor blockers may cause adverse effects on the fetus and are contraindicated.

Elderly Patients Hypertensive patients who are over age 65, and particularly those over age 75, offer substantial challenges to the physician. Several studies have reported that healthy elderly patients, whether male or female, who are treated with relatively modest doses of antihypertensive agents show a substantial reduction in strokes and stroke-related deaths. This is true whether the patient has systolic and diastolic hypertension or isolated systolic hypertension. What is not clear from these studies is how broadly the results can be extrapolated, since the studies were performed in healthy elderly patients, while many such patients have other diseases. Thus, in the elderly hypertensive patient, individualization of therapy is warranted.

MALIGNANT HYPERTENSION

In addition to marked blood pressure elevation (usually diastolic blood pressure > 130 mmHg) in association with papilledema and retinal hemorrhages and exudates, the full-blown medical emergency of malignant hypertension may include manifestations of hypertensive encephalopathy, such as severe headache, vomiting, visual disturbances (including transient blindness), transient paralyses, convulsions, stupor, and coma. These manifestations have been attributed to spasm of cerebral vessels and to cerebral edema. In some patients who have died, multiple small thrombi have been found in the cerebral vessels. Cardiac decompensation and rapidly declining renal function are other critical features of malignant hypertension. Oliguria may, in fact, be the presenting feature. The vascular lesion characteristic of malignant hypertension is fibrinoid necrosis of the walls of small arteries and arterioles, and this development can be reversed by effective antihypertensive therapy.

The pathogenesis of malignant hypertension is unknown. However, at least two independent processes—dilation of cerebral arteries and generalized arteriolar fibrinoid necrosis—contribute to the associated signs and symptoms. The cerebral arteries dilate because the normal autoregulation of cerebral blood flow decompensates as a result of the markedly elevated arterial pressure. Cerebral blood flow therefore is excessive, producing the encephalopathy associated with malignant hypertension. Many patients also show evidence of a microangiopathic hemolytic anemia; this secondary phenomenon could contribute to the deterioration of renal function. Most patients also have elevated levels of peripheral plasma renin activity and increased aldosterone production, and these effects may be involved in causing vascular damage.

Perhaps <1% of hypertensive patients develop the malignant phase, which can occur in the course of both essential and secondary hypertension. Rarely, it is the first recognized manifestation of hypertension, and it is unusual for it to occur in patients under treatment. The average age at diagnosis is 40, and men are affected more often than women. Prior to the availability of effective therapy, the life expectancy after diagnosis of malignant hypertension was <2 years, with most deaths being due to renal failure, cerebral hemorrhage, or congestive heart failure. With the advent of effective antihypertensive therapy, at least half the patients survive for >5 years.

℞ TREATMENT

Malignant hypertension is a medical emergency that requires immediate therapy. However, it needs to be distinguished from severe hypertension, in which overly aggressive therapy could result in a potentially hazardous reduction in myocardial and cerebral perfusion. The initial aims of therapy should be (1) correction of medical complications, and (2) reduction of diastolic pressure by one-third, but not to a level <95 mmHg. The drugs available for treatment of malignant hypertension can be divided into two groups on the basis of time of onset of action (Table 230-10). If the patient has hypertensive encephalopathy or pulmonary edema, and if arterial pressure must be reduced rapidly, then one from the immediate-acting group should be used, but they are not satisfactory for long-term management.

Furosemide is an important adjunct to the therapy just discussed. Given either orally or intravenously, it serves to maintain sodium diuresis in the face of a falling arterial pressure and thus will speed recovery from encephalopathy and congestive heart failure as well as maintain the sensitivity to the primary antihypertensive drug. Digitalis (Chap. 216) may also be indicated if there is evidence of cardiac decompensation.

In patients with malignant hypertension in whom the existence of pheochromocytoma is suspected, urine should be collected for measurement of the products of catecholamine metabolism, and drugs that might release additional catecholamines, such as methyldopa, reserpine, and guanethidine, must be avoided. The parenteral drug of choice in these patients is phentolamine, administered with care to avoid a precipitous reduction in arterial pressure.

231 DISEASES OF THE AORTA

Victor J. Dzau, Mark A. Creager

The aorta is the conduit through which the blood ejected from the left ventricle is delivered to the systemic arterial bed. In adults, its diameter is approximately 3 cm at the origin, 2.5 cm in the descending portion in the thorax, and 1.8 to 2 cm in the abdomen. The aortic wall consists of a thin intima composed of endothelium, subendothelial connective tissue, and an internal elastic lamina; a thick tunica media composed of smooth-muscle cells and extracellular matrix; and an adventitia composed primarily of connective tissue enclosing the vasa vasorum and nervi vascularis. In addition to its conduit function, the viscoelastic and compliant properties of the aorta also subserve a buffering function. The aorta is distended during systole to enable a portion of the stroke volume to be stored, and it recoils during diastole so that blood continues to flow to the periphery. Because of its continuous exposure to high pulsatile pressure and shear stress, the aorta is particularly prone to injury and disease resulting from mechanical trauma (Table 231-1). The aorta is also more prone to rupture than any other vessel, especially with the development of aneurysmal dilatation, since its wall tension, as governed by Laplace's law (i.e., proportional to the product of pressure and radius), would be increased.

AORTIC ANEURYSM

An *aneurysm* is defined as a pathologic dilatation of a segment of a blood vessel. A *true aneurysm* involves all three layers of the vessel wall and is distinguished from a *pseudoaneurysm*, in which the intimal and medial layers are disrupted and the dilatation is lined by adventitia only and sometimes by perivascular clot. Aneurysms may also be classified according to their gross appearance. A *fusiform aneurysm* affects the entire circumference of a segment of the vessel, resulting in a diffusely dilated lesion. In contrast, a *saccular aneurysm* involves only a portion of the circumference, resulting in an outpouching of the vessel wall. Aortic aneurysms are also classified according to location, i.e., abdominal versus thoracic. Aneurysms of the descending thoracic aorta are usually contiguous with infradiaphragmatic aneurysms and are referred to as *thoracoabdominal aortic aneurysms*.

TABLE 231-1 Diseases of the Aorta: Etiology and Associated Factors

Aortic aneurysm	Aortic occlusion
Atherosclerosis	Atherosclerosis

Mycotic infection	Rheumatic aortitis
Rheumatic aortitis	Takayasu's arteritis
Trauma	Giant cell arteritis
Aortic dissection	
Cystic medial necrosis	
Systemic hypertension	
Atherosclerosis	
Takayasu's arteritis	
Giant cell arteritis	

ETIOLOGY The most common pathologic condition associated with aortic aneurysm is *atherosclerosis*. It is controversial whether atherosclerosis itself actually causes aortic aneurysms or whether atherosclerosis develops as a secondary event in the dilated aorta. Causality is implied by studies that have shown that many patients with aortic aneurysms have coexisting risk factors for atherosclerosis (Chap. 224), particularly cigarette smoking, as well as atherosclerosis in other blood vessels. Seventy-five percent of atherosclerotic aneurysms are located in the distal abdominal aorta, below the renal arteries.

Cystic medial necrosis is the term used to describe the degeneration of collagen and elastic fibers in the tunica media of the aorta, as well as the loss of medial cells that are replaced by multiple clefts of mucoid material. Cystic medial necrosis characteristically affects the proximal aorta, results in circumferential weakness and dilatation, and leads to development of fusiform aneurysms involving the ascending aorta and the sinuses of Valsalva. This condition is particularly prevalent in patients with Marfan syndrome and Ehlers-Danlos syndrome type IV (Chap. 342) but also occurs in pregnant women, in patients with hypertension, and in those with valvular heart disease. Sometimes it appears as an isolated condition in patients without any other apparent disease. Familial clusterings of aortic aneurysms occur in 20% of patients, suggesting a hereditary basis of the disease. Mutations of the genes encoding fibrillin-1 and type III procollagen have been implicated in some cases. Linkage analysis has identified loci on chromosomes 5q13-14 and 11q23.3-q24 in several families, although the specific culprit genes have not been described. *Syphilis* (Chap. 153) is a relatively uncommon cause of aortic aneurysm. Syphilitic periaortitis and mesoaortitis damage elastic fibers, resulting in thickening and weakening of the aortic wall. Approximately 90% of syphilitic aneurysms are located in the ascending aorta or aortic arch. *Tuberculous aneurysms* (Chap. 150) typically affect the thoracic aorta and result from direct extension of infection from hilar lymph nodes or contiguous abscesses or from bacterial seeding. Loss of aortic wall elasticity results from granulomatous destruction of the medial layer. A *mycotic aneurysm* is a rare condition that develops as a result of staphylococcal, streptococcal, or salmonella infections of the aorta, usually at an atherosclerotic plaque. These aneurysms are usually saccular. Blood cultures are often positive and reveal the nature of the infecting agent.

Vasculitides associated with aortic aneurysm include Takayasu's arteritis and giant cell arteritis, which may cause aneurysms of the aortic arch and descending thoracic aorta. Spondyloarthropathies such as ankylosing spondylitis, rheumatoid arthritis, psoriatic arthritis, relapsing polychondritis and Reiter's syndrome are associated with dilatation of the ascending aorta. Behçet's disease (Chap. 307) causes thoracic and abdominal aortic aneurysms. *Traumatic aneurysms* may develop after penetrating or nonpenetrating chest trauma and most commonly affect the descending thoracic aorta just beyond the site of insertion of the ligamentum arteriosum. *Congenital aortic aneurysms* may be primary or associated with anomalies such as a bicuspid aortic valve or aortic coarctation.

THORACIC AORTIC ANEURYSMS The clinical manifestations and natural history of thoracic aortic aneurysms depend on their location. Cystic medial necrosis is the most common cause of ascending aortic aneu-

rysms, whereas atherosclerosis is the condition most frequently associated with aneurysms of the aortic arch and descending thoracic aorta. The average growth rate of thoracic aneurysms is 0.1 to 0.4 cm per year. The risk of rupture is related to the size of the aneurysm and the presence of symptoms; it increases substantially for ascending aortic aneurysms >6 cm and descending thoracic aneurysms >7 cm. Most thoracic aortic aneurysms are asymptomatic. However, compression or erosion of adjacent tissue by aneurysms may cause symptoms such as chest pain, shortness of breath, cough, hoarseness, or dysphagia. Aneurysmal dilatation of the ascending aorta may cause congestive heart failure as a consequence of aortic regurgitation; and compression of the superior vena cava may produce congestion of the head, neck, and upper extremities.

A chest x-ray may be the first test to suggest the diagnosis of a thoracic aortic aneurysm (Fig. 231-1). Findings include widening of the mediastinal shadow and displacement or compression of the trachea or left mainstem bronchus. Two-dimensional echocardiography, and particularly transesophageal echocardiography, can be used to assess the proximal ascending aorta and descending thoracic aorta. Both contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) are sensitive and specific tests for assessment of aneurysms of the thoracic aorta. In asymptomatic patients whose aneurysms are too small to justify surgery, noninvasive testing with either contrast-enhanced CT or MRI should be performed at least every 6 to 12 months to monitor expansion. Contrast aortography is frequently required preoperatively to assess the length of the aneurysm and involvement of branch vessels (Fig. 231-2).

Patients with thoracic aortic aneurysms, and particularly patients with Marfan syndrome who have evidence of aortic root dilatation, should receive long-term beta-blocker therapy. Additional medical therapy should be given, as necessary, to control hypertension. Operative repair with placement of a prosthetic graft is indicated in patients with symptomatic thoracic aortic aneurysms, and in those in whom the aortic diameter is >6 cm or has increased by >1 cm per year. In patients with Marfan syndrome, thoracic aortic aneurysms >5 cm should be considered for surgery.

ABDOMINAL AORTIC ANEURYSMS Abdominal aortic aneurysms occur more frequently in males than in females, and the incidence increases with age. Abdominal aortic aneurysms may affect 1 to 2% of men older than 50 years. At least 90% of all abdominal aortic aneurysms >4.0 cm are affected by atherosclerosis, and most of these aneurysms are below the level of the renal arteries. Prognosis is related to both the size of the aneurysm and the severity of coexisting coronary artery and cerebrovascular disease. The risk of rupture increases with the size of the aneurysm. The 5-year risk of rupture for aneurysms <5 cm is 1 to 2%, whereas it is 20 to 40% for aneurysms >5 cm in diameter. The formation of mural thrombi within the aneurysm may predispose to peripheral embolization.

An abdominal aortic aneurysm commonly produces no symptoms. It is usually detected on routine examination as a palpable, pulsatile, and nontender mass, or it is an incidental finding during an abdominal x-ray or ultrasound performed for other reasons. However, as abdominal aortic aneurysms expand, they may become painful. Some patients complain of strong pulsations in the abdomen; others experience pain in the chest, lower back, or scrotum. Aneurysmal pain is usually a harbinger of rupture and represents a medical emergency. More often, acute rupture occurs without any prior warning, and this complication is always life-threatening. Rarely, there is leakage of the aneurysm with severe pain and tenderness. Acute pain and hypotension occur with rupture of the aneurysm, which requires emergency operation.

Abdominal radiography may demonstrate the calcified outline of the aneurysm. However, about 25% of aneurysms are not calcified and cannot be visualized by plain x-ray. An abdominal ultrasound can delineate the transverse and longitudinal dimensions of an abdominal aortic aneurysm and may detect mural thrombus. Abdominal ultrasound is useful for serial documentation of aneurysm size and can be used to screen patients at risk for developing aortic aneurysm, such as those with affected siblings, peripheral atherosclerosis, or peripheral artery aneurysms. In one larger study, ultrasound screening of men aged 65 to 74 years was associated with a risk reduction in aneurysm-related death by 42%. CT with contrast and MRI are accurate, noninvasive tests to determine the location and size of abdominal aortic aneurysms (Fig. 231-3). Contrast aortography is used for the evaluation of patients with aneurysms before surgery, but the procedure carries a small risk of complications, such as bleeding, allergic reactions, and atheroembolism. This technique is useful in documenting the length of the aneurysm, especially its upper and lower limits, and the extent of associated atherosclerotic vascular disease. However, since the presence of mural clots may reduce the luminal size, aortography may underestimate the diameter of an aneurysm.

FIGURE 231-2 An aortogram demonstrating a large fusiform aneurysm of the descending thoracic aorta.

FIGURE 231-3 A computed tomographic angiogram (CTA) depicting a fusiform abdominal aortic aneurysm that has been treated with a bifurcated stent graft.

TREATMENT

Operative repair of the aneurysm and insertion of a prosthetic graft is indicated for abdominal aortic aneurysms of any size that are expanding rapidly or are associated with symptoms. For asymptomatic aneurysms, operation is indicated if the diameter is >5.5 cm. Operation may be recommended in patients with aneurysm diameters of 4 to 5 cm, except for patients with exceptionally high operative risk. However, in recent randomized trials of patients with abdominal aortic aneurysms <5.5 cm, there was no difference in the long-term (5- to 8-year) mortality rate between those followed with ultrasound surveillance and those undergoing elective aneurysm repair. Thus, serial noninvasive follow-up of smaller aneurysms (<5 cm) is an alternative to immediate surgery. Percutaneous placement of endovascular stent grafts (Fig. 231-3) for treatment of infrarenal abdominal aortic aneurysms is currently available for selected patients, and initial reports have been favorable.

In surgical candidates, careful preoperative cardiac and general medical evaluations (followed by appropriate therapy of complicating conditions) are essential. Preexisting coronary artery disease, congestive heart failure, pulmonary disease, diabetes, and advanced age add to the risk of surgery. Perioperative management should include the placement of a Swan-Ganz catheter and arterial line to monitor and optimize left ventricular filling pressure, cardiac output, and arterial pressure, especially during clamping and unclamping of the aorta, as well as during the immediate postoperative period. With careful preoperative cardiac evaluation and postoperative care, the operative mortality rate approximates 1 to 2%. After acute rupture, the mortality rate of emergent operation generally exceeds 50%.

AORTIC DISSECTION

Aortic dissection is caused by a circumferential or, less frequently, transverse tear of the intima. It often occurs along the right lateral wall of the ascending aorta where the hydraulic shear stress is high. Another common site is the descending thoracic aorta just below the ligamentum arteriosum. The initiating event is either a primary intimal tear with secondary dissection into the media or a medial hemorrhage that dissects into and disrupts the intima. The pulsatile aortic flow then dissects along the elastic lamellar plates of the aorta and creates a false lumen. The dissection usually propagates distally down the descending aorta and into its major branches, but it may also propagate proximally. In some cases, a secondary distal intimal disruption occurs, resulting in the reentry of blood from the false to the true lumen.

There are at least two important pathologic and radiologic variants: intramural hematoma without an intimal flap and penetrating atherosclerotic ulcer. The clinical picture and therapeutic management of intramural hematoma are similar to those for classic aortic dissection. By contrast, penetrating ulcers are usually localized and are not associated with extensive propagation. They are primarily found in the mid and distal portions of the descending thoracic aorta and are associated with extensive atherosclerotic disease. The ulcer can erode beyond the intimal border, leading to medial hematoma, and may progress to false aneurysm formation or rupture.

DeBakey and coworkers initially classified aortic dissections as type I, in which an intimal tear occurs in the ascending aorta but which involves the descending aorta as well; type II, in which the dissection is limited to the ascending aorta; and type III, in which the intimal tear is located in the descending area with distal propagation of the dissection (Fig. 231-4). Another classification (Stanford) is that of type A, in which the dissection involves the ascending aorta (proximal dissection), and type B, in which it is limited to the descending aorta (distal dissection). From a management standpoint, classification into type A or B is more practical and useful, since DeBakey types I and II are managed in a similar manner.

The factors that predispose to aortic dissection include systemic hypertension, a coexisting condition in 70% of patients, and cystic medial necrosis. Aortic dissection is the major cause of morbidity and mortality in patients with Marfan syndrome (Chap. 342) and similarly may affect patients with Ehlers-Danlos syndrome. The incidence is

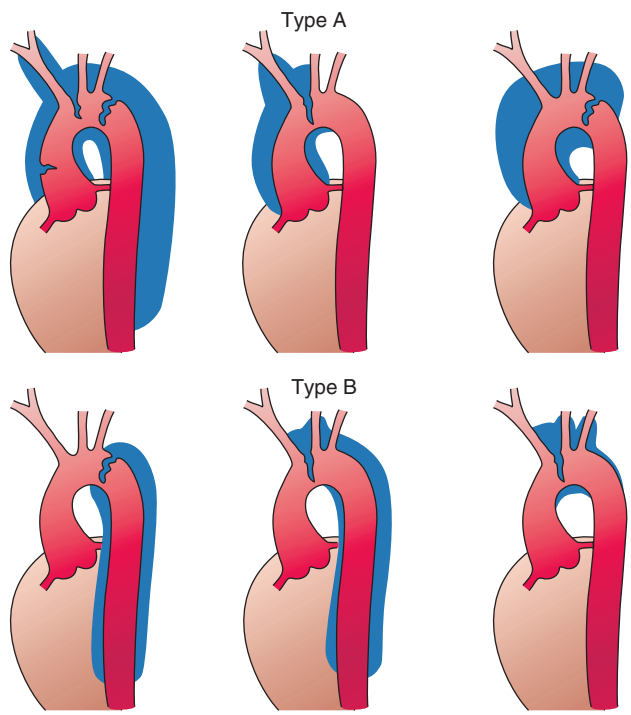

FIGURE 231-4 Classification of aortic dissections. Stanford classification: Type A dissections (*top panels*) involve the ascending aorta independent of site of tear and distal extension; type B dissections (*bottom panels*) involve transverse and/or descending aorta without involvement of the ascending aorta. DeBakey classification: Type I dissection involves ascending to descending aorta (*top left*); type II dissection is limited to ascending or transverse aorta, without descending aorta (*top center + top right*); type III dissection involves descending aorta only (*bottom left*). *[From DC Miller, in RM Doroghazi, EE Slater (eds): Aortic Dissection. New York, McGraw-Hill, 1983, with permission.]*

also increased in patients with inflammatory aortitis (i.e., Takayasu's arteritis, giant cell arteritis), congenital aortic valve anomalies (e.g., bicuspid valve), in those with coarctation of the aorta, and in otherwise normal women during the third trimester of pregnancy.

CLINICAL MANIFESTATIONS The peak incidence is in the sixth and seventh decades. Men are more affected than women by a ratio of 2:1. The presentations of aortic dissection and its variants are the consequences of intimal tear, dissecting hematoma, occlusion of involved arteries, and compression of adjacent tissues. Acute aortic dissection presents with the sudden onset of pain (Chap. 12), which is often described as very severe and tearing and is associated with diaphoresis. The pain may be localized to the front or back of the chest, often the interscapular region, and typically migrates with propagation of the dissection. Other symptoms include syncope, dyspnea, and weakness. Physical findings may include hypertension or hypotension, loss of pulses, aortic regurgitation, pulmonary edema, and neurologic findings due to carotid artery obstruction (hemiplegia, hemianesthesia) or spinal cord ischemia (paraplegia). Bowel ischemia, hematuria, and myocardial ischemia have all been observed. These clinical manifestations reflect complications resulting from the dissection occluding the major arteries. Furthermore, clinical manifestations may result from the compression of adjacent structures (e.g., superior cervical ganglia, superior vena cava, bronchus, esophagus) by the expanding dissection causing aneurysmal dilatation, and include Horner's syndrome, superior vena caval syndrome, hoarseness, dysphagia, and airway compromise. Hemopericardium and cardiac tamponade may complicate a type A lesion with retrograde dissection. Acute aortic regurgitation is an important and common (>50%) complication of proximal dissection. It is the outcome of either a circumferential tear that widens the aortic root or a disruption of the annulus by dissecting hematoma that tears a leaflet(s) or displaces it below the line of closure. Signs of aortic regurgitation include bounding pulses, a wide pulse pressure, a diastolic murmur often radiating along the right sternal border, and evidence of congestive heart failure. The clinical manifestation depends on the severity of the regurgitation.

In dissections involving the ascending aorta, the chest x-ray often reveals a widened superior mediastinum. A pleural effusion (usually left-sided) may also be present. This effusion is typically serosanguineous and not indicative of rupture unless accompanied by hypotension and falling hematocrit. In dissections of the descending thoracic aorta, a widened mediastinum may also be observed on chest x-ray. In addition, the descending aorta may appear to be wider than the ascending portion. An electrocardiogram that shows no evidence of myocardial ischemia is helpful in distinguishing aortic dissection from myocardial infarction. Rarely, the dissection involves the right or left coronary ostium and causes acute myocardial infarction. The diagnosis of aortic dissection can be established by aortography or by the use of noninvasive techniques such as echocardiography, CT, or MRI. Aortography may be used to document the diagnosis; to identify the entry point, the intimal flap, and the false and true lumina; and to establish the extent of dissection into the major arteries. Coronary angiography may be performed concomitantly in high-risk patients in the evaluation and preparation for surgery. The sensitivity of aortography is 70% for visualizing an intimal flap, 56% for the site of intimal tear, and 87% for false lumen. It is unable to recognize intramural hemorrhage. Transthoracic echocardiography can be performed simply and rapidly and has an overall sensitivity of 60 to 85%. For diagnosing proximal ascending aortic dissections, its sensitivity exceeds 80%; it is less useful for detecting dissection of the arch and descending thoracic aorta. Transesophageal echocardiography requires greater skill and patient cooperation but is very accurate in identifying dissections of the ascending and descending thoracic aorta, but not the arch, achieving 98% sensitivity and approximately 90% specificity. Echocardiography also provides important information regarding the presence and severity of aortic regurgitation and pericardial effusion. CT and MRI are both highly accurate in identifying the intimal flap and the extent of the dissection; each has a sensitivity and specificity >90%. They are useful in recognizing intramural hemorrhage and penetrating ulcers. MRI can also detect blood flow, which may be useful in characterizing antegrade versus retrograde dissection. Transesophageal echocardiography, CT, and MRI are the diagnostic procedures of choice over contrast aortography. Their relative utility depends on the availability and expertise in individual institutions as well as on the hemodynamic stability of the patient, with CT and MRI obviously less suitable for unstable patients.

TREATMENT

Medical therapy should be initiated as soon as the diagnosis is considered. The patient should be admitted to an intensive care unit for monitoring hemodynamics and urine output. Unless hypotension is present, therapy should be aimed at reducing cardiac contractility and systemic arterial pressure, and thereby shear stress. For acute dissection, unless contraindicated, β-adrenergic blockers should be administered parenterally, using intravenous propranolol, metoprolol, or the short-acting esmolol to achieve a heart rate of approximately 60 beats/min. This should be accompanied by sodium nitroprusside infusion to lower systolic blood pressure to ≤120 mmHg. Labetalol (Chap. 230), a drug with both β- and α-adrenergic blocking properties, is also used as a parenteral agent in the acute therapy of dissection.

The calcium channel antagonists, verapamil and diltiazem, may be used intravenously if nitroprusside or labetalol cannot be employed. The addition of a parenteral angiotensin-converting enzyme (ACE) inhibitor, such as enalaprilat, to a β-adrenergic blocker may also be considered. Isolated use of direct vasodilators, such as diazoxide and hydralazine, is contraindicated because these agents can increase hydraulic shear and may propagate dissection.

Emergent or urgent surgical correction is the preferred treatment for ascending aortic dissections (type A) and complicated type B dissections including those characterized by propagation, compromise of major aortic branches, impending rupture, or continued pain. Surgery involves excision of the intimal flap, obliteration of the false lumen, and placement of an interposition graft. A composite valve-graft conduit is used if the aortic valve is disrupted. The overall in-hospital mortality rate after surgical treatment of patients with aortic dissection is reported to be 15 to 25%. The major causes of perioperative mortality and morbidity include myocardial infarction, paraplegia, renal failure, tamponade, hemorrhage, and sepsis. Reports of the use of endoluminal stent grafts in selected patients with type B dissection are encouraging. Other transcatheter techniques, such as fenestration of the intimal flaps and stenting of narrowed branch vessels to increase flow to compromised organs, are also under investigation. For uncomplicated and stable distal dissection (type B), medical therapy is the preferred treatment. The in-hospital mortality rate of medically treated patients with type B dissection is 10 to 20%. Long-term therapy for patients with aortic dissection (with or without surgery) consists of the control of hypertension and reduction of cardiac contractility with the use of beta blockers plus other antihypertensive agents such as ACE inhibitors or calcium antagonists. Patients with chronic type B dissection should be followed on an outpatient basis every 6 to 12 months by contrast-enhanced CT or MRI to detect propagation or expansion. Patients with Marfan syndrome are at high risk for postdissection complications. The long-term prognosis for patients with treated dissections is generally good with careful follow-up; the 10-year survival rate is approximately 60%.

AORTIC OCCLUSION

CHRONIC ATHEROSCLEROTIC OCCLUSIVE DISEASE Atherosclerosis may affect the thoracic and abdominal aorta. Occlusive aortic disease caused by atherosclerosis is usually confined to the distal abdominal aorta below the renal arteries. Frequently the disease extends to the iliac arteries (Chap. 232). Claudication characteristically involves the lower back, buttocks, and thighs and may be associated with impotence in males

(Leriche syndrome). The severity of the symptoms depends on the adequacy of collaterals. With sufficient collateral blood flow, a complete occlusion of the abdominal aorta may occur without the development of ischemic symptoms. The physical findings include absence of femoral and other distal pulses bilaterally and the detection of an audible bruit over the abdomen (usually at or below the umbilicus) and the common femoral arteries. Atrophic skin, loss of hair, and coolness of the lower extremities are usually observed. In advanced ischemia, rubor on dependency and pallor on elevation can be seen.

The diagnosis is usually established by the physical examination and noninvasive testing, including leg pressure measurements, Doppler velocity analysis, pulse volume recordings, and duplex ultrasonography. The anatomy may be defined by MRI, CT or conventional aortography before revascularization. Operative treatment is indicated in patients with debilitating symptoms and/or with the development of leg ischemia.

ACUTE OCCLUSION Acute occlusion in the distal abdominal aorta represents a medical emergency because it threatens the viability of the lower extremities. It usually results from an occlusive embolus that almost always originates from the heart. Rarely, acute occlusion may occur as the result of in situ thrombosis in a preexisting severely narrowed segment of the aorta or plaque rupture and hemorrhage into such an area.

The clinical picture is one of acute ischemia of the lower extremities. Severe rest pain, coolness, and pallor of the lower extremities and the absence of distal pulses bilaterally are the usual manifestations. Diagnosis should be established rapidly by aortography. Emergency thrombectomy or revascularization is indicated.

AORTITIS

Aortitis frequently affects the thoracic aorta and may result in aneurysmal dilatation and aortic regurgitation; it occasionally obstructs branch vessels of the aorta.

SYPHILITIC AORTITIS This late manifestation of luetic infection (Chap. 153) usually affects the proximal ascending aorta, particularly the aortic root, resulting in aortic dilatation and aneurysm formation. Syphilitic aortitis may occasionally involve the aortic arch or the descending aorta. The aneurysms may be saccular or fusiform and are usually asymptomatic, but compression of and erosion into adjacent structures may result in symptoms; rupture may also occur.

The initial lesion is an obliterative endarteritis of the vasa vasorum, especially in the adventitia. This is an inflammatory response to the invasion of the adventitia by the spirochetes. Destruction of the aortic media occurs as the spirochetes spread into this layer, usually via the lymphatics accompanying the vasa vasorum. Destruction of collagen and elastic tissues leads to dilation of the aorta, scar formation, and calcification. These changes account for the characteristic radiographic appearance of a calcified ascending aortic aneurysm.

The disease typically presents as an incidental chest radiographic finding 15 to 30 years after initial infection. Symptoms may result from aortic regurgitation, narrowing of coronary ostia due to syphilitic aortitis, compression of adjacent structures (e.g., esophagus), or rupture. Diagnosis is established by a positive serologic test, i.e., rapid plasmin reagin (RPR) or fluorescent treponemal antibody. Treatment includes penicillin and surgical excision and repair.

RHEUMATIC AORTITIS Rheumatoid arthritis (Chap. 301), ankylosing spondylitis (Chap. 305), psoriatic arthritis (Chap. 305), Reiter's syndrome (Chap. 305), relapsing polychondritis, and inflammatory bowel disorders may all be associated with aortitis involving the ascending aorta. The inflammatory lesions usually involve the ascending aorta and may extend to the sinuses of Valsalva, the mitral valve leaflets, and adjacent myocardium. The clinical manifestations are aneurysm, aortic regurgitation, and involvement of the cardiac conduction system.

TAKAYASU'S ARTERITIS This inflammatory disease often affects the ascending aorta and aortic arch causing obstruction of the aorta and its major arteries. Takayasu's arteritis is also termed *pulseless disease* because of the frequent occlusion of the large arteries originating from the aorta. It may also involve the descending thoracic and abdominal aorta and occlude large branches such as the renal arteries. Aortic aneurysms may also occur. The pathology is a panarteritis, characterized by mononuclear cells and occasionally giant cells, with marked intimal hyperplasia, medial and adventitial thickening, and, in chronic form, fibrotic occlusion. The disease is most prevalent in young females of Asian descent but does occur in women of other geographic and ethnic origins and also in young men. During the acute stage, fever, malaise, weight loss, and other systemic symptoms may be evident. An elevation of the erythrocyte sedimentation rate is common. The chronic stages of the disease present with symptoms related to large artery occlusion, such as upper extremity claudication, cerebral ischemia, and syncope. The chronic disease is intermittently active. Since the process is progressive and there is no definitive therapy, the prognosis is usually poor. Glucocorticoids and immunosuppressive agents have been reported to be effective in some patients during the acute phase. Occasionally, anticoagulation prevents thrombosis and complete occlusion of a large artery. Surgical bypass or endovascular intervention of a critically stenotic artery may be necessary.

GIANT CELL ARTERITIS (See also Chap. 306) This vasculitis occurs in older individuals and affects women more often than men. Primarily large and medium-sized arteries are affected. The pathology is that of focal granulomatous lesions involving the entire arterial wall. It may be associated with polymyalgia rheumatica. Obstruction of medium-sized arteries (e.g., temporal and ophthalmic arteries) and of major branches of the aorta and the development of aortitis and aortic regurgitation are some of the complications of the disease. High-dose glucocorticoid therapy may be effective when given early.

232 VASCULAR DISEASES OF THE EXTREMITIES

Mark A. Creager, Victor J. Dzau

ARTERIAL DISORDERS

PERIPHERAL ARTERIAL DISEASE Atherosclerosis is the leading cause of occlusive arterial disease of the extremities in patients over 40 years old; the highest incidence occurs in the sixth and seventh decades of life. As in patients with atherosclerosis of the coronary and cerebral vasculature, there is an increased prevalence of peripheral atherosclerotic disease in individuals with diabetes mellitus, hypercholesterolemia, hypertension, or hyperhomocysteinemia and in cigarette smokers.

Pathology (See also Chap. 224) Segmental lesions causing stenosis or occlusion are usually localized in large and medium-sized vessels. The pathology of the lesions includes atherosclerotic plaques with calcium deposition, thinning of the media, patchy destruction of muscle and elastic fibers, fragmentation of the internal elastic lamina, and thrombi composed of platelets and fibrin. The primary sites of involvement are the abdominal aorta and iliac arteries (30% of symptomatic patients), the femoral and popliteal arteries (80 to 90% of patients), and the more distal vessels, including the tibial and peroneal arteries (40 to 50% of patients). Atherosclerotic lesions occur preferentially at arterial branch points, sites of increased turbulence, altered shear stress, and intimal injury. Involvement of the distal vasculature is most common in elderly individuals and patients with diabetes mellitus.

Clinical Evaluation Fewer than 50% of patients with peripheral arterial disease (PAD) are symptomatic, though many have a slow or impaired gait. The most common *symptom* is intermittent claudication, which is defined as a pain, ache, cramp, numbness, or a sense of fatigue in the muscles; it occurs during exercise and is relieved by rest. The site of claudication is distal to the location of the occlusive lesion. For example, buttock, hip, and thigh discomfort occur in patients with aortoiliac disease (Leriche syndrome), whereas calf claudication develops in patients with femoral-popliteal disease. Symptoms are far more common in the lower than in the upper extremities because of the higher incidence of obstructive lesions in the former region. In patients with severe arterial occlusive disease, critical limb ischemia may develop. Patients will complain of rest pain or a feeling of cold or numbness in the foot and toes. Frequently, these symptoms occur at night when the legs are horizontal and improve when the legs are in a dependent position. With severe ischemia, rest pain may be persistent.

Important *physical findings* of PAD include decreased or absent pulses distal to the obstruction, the presence of bruits over the narrowed artery, and muscle atrophy. With more severe disease, hair loss, thickened nails, smooth and shiny skin, reduced skin temperature, and pallor or cyanosis are frequent physical signs. In addition, ulcers or gangrene may occur. Elevation of the legs and repeated flexing of the calf muscles produce pallor of the soles of the feet, whereas rubor, secondary to reactive hyperemia, may develop when the legs are dependent. The time required for rubor to develop or for the veins in the foot to fill when the patient's legs are transferred from an elevated to a dependent position is related to the severity of the ischemia and the presence of collateral vessels. Patients with severe ischemia may develop peripheral edema because they keep their legs in a dependent position much of the time. Ischemic neuritis can result in numbness and hyporeflexia.

Noninvasive Testing The history and physical examination are usually sufficient to establish the diagnosis of PAD. An objective assessment of the severity of disease is obtained by noninvasive techniques. These include digital pulse volume recordings, Doppler flow velocity waveform analysis, duplex ultrasonography (which combines B-mode imaging and pulse-wave Doppler examination), segmental pressure measurements, transcutaneous oximetry, stress testing (usually using a treadmill), and tests of reactive hyperemia. In the presence of significant PAD, the volume displacement in the leg is decreased with each pulse, and the Doppler velocity contour becomes progressively flatter. Duplex ultrasonography is often useful in detecting stenotic lesions in native arteries and bypass grafts.

Arterial pressure can be recorded noninvasively along the legs by serial placement of sphygmomanometric cuffs and use of a Doppler device to auscultate or record blood flow. Normally, systolic blood pressure in the legs and arms is similar. Indeed, ankle pressure may be slightly higher than arm pressure due to pulse-wave reflection. In the presence of hemodynamically significant stenoses, the systolic blood pressure in the leg is decreased. Thus, if one were to obtain a ratio of the ankle and brachial artery pressures (termed the *ankle:brachial index*, or ABI), it would be ≥ 1.0 in normal individuals and < 1.0 in patients with peripheral arterial disease. A ratio of < 0.5 is consistent with severe ischemia.

Treadmill testing allows the physician to assess functional limitations objectively. Decline of the ankle-brachial systolic pressure ratio immediately after exercise may provide further support for the diagnosis of PAD in patients with equivocal symptoms and findings on examination. Exercise testing also allows simultaneous evaluation for the presence of coronary artery disease.

Magnetic resonance angiography and conventional contrast angiography should not be used for routine diagnostic testing but are performed prior to potential revascularization. Either test is useful in defining the anatomy to assist operative planning and is also indicated if nonsurgical interventions are being considered, such as percutaneous transluminal angioplasty (PTA) or thrombolysis. Studies have suggested that magnetic resonance angiography has diagnostic accuracy comparable to that of contrast angiography.

Prognosis The natural history of patients with PAD is influenced primarily by the extent of coexisting coronary artery and cerebral vascular disease. Studies using coronary angiography have estimated that approximately one-half of patients with symptomatic PAD also have significant coronary artery disease. Life-table analysis has indicated that patients with claudication have a 70% 5-year and a 50% 10-year survival rate. Most deaths are either sudden or secondary to myocardial infarction. The likelihood of symptomatic progression of PAD appears less than the chance of succumbing to coronary artery disease. Approximately 75% of nondiabetic patients who present with mild to moderate claudication remain symptomatically stable or improve. Deterioration is likely to occur in the remainder, with approximately 5% of the group ultimately undergoing amputation. The prognosis is worse in patients who continue to smoke cigarettes or who have diabetes mellitus.

TREATMENT

Therapeutic options include supportive measures, pharmacologic treatment, nonoperative interventions, and surgery. Supportive measures include meticulous care of the feet, which should be kept clean and protected against excessive drying with moisturizing creams. Well-fitting and protective shoes are advised to reduce trauma. Sandals and shoes made of synthetic materials that do not "breathe" should be avoided. Elastic support hose should be avoided, as they reduce blood flow to the skin. In patients with ischemia at rest, shock blocks under the head of the bed together with a canopy over the feet may improve perfusion pressure and ameliorate some of the rest pain.

Treatment of associated factors that contribute to the development of atherosclerosis should be initiated. The importance of discontinuing cigarette smoking cannot be overemphasized. The physician must assume a major role in this life-style modification. It is important to

control blood pressure in hypertensive patients but to avoid hypotensive levels. Treatment of hypercholesterolemia is advocated, although reduction in cholesterol levels has not been shown unequivocally to reverse peripheral atherosclerotic lesions. However, it has been shown to prevent or to slow progression of the disease and to improve survival in patients with atherosclerosis. Patients with claudication should also be encouraged to exercise regularly and at progressively more strenuous levels. Supervised exercise training programs may improve muscle efficiency and prolong walking distance. Patients also should be advised to walk for 30 to 45 min daily, stopping at the onset of claudication and resting until the symptoms resolve before resuming ambulation.

Pharmacologic Management This form of treatment of patients with PAD has not been as successful as the medical treatment of coronary artery disease (Chap. 226). In particular, vasodilators as a class have not proved to be beneficial. During exercise, peripheral vasodilation occurs distal to sites of significant arterial stenoses. As a result, perfusion pressure falls, often to levels less than that generated in the interstitial tissue by the exercising muscle. Drugs such as α-adrenergic blocking agents, calcium channel antagonists, papaverine, and other vasodilators have not been shown to be effective in patients with PAD. Pentoxifylline, a substituted xanthine derivative, has been reported to decrease blood viscosity and to increase red cell flexibility, thereby increasing blood flow to the microcirculation and enhancing tissue oxygenation. Several placebo-controlled studies have found that pentoxifylline increased the duration of exercise in patients with claudication, but its efficacy has not been confirmed in all clinical trials.

Cilostazol, a phosphodiesterase inhibitor with vasodilator and antiplatelet properties, has been reported to increase claudication distance in multiple trials. Several studies have suggested that long-term parenteral administration of vasodilator prostaglandins decreases pain and facilitates healing of ulcers in patients with severe limb ischemia. Clinical trials with angiogenic growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) are proceeding. One placebo-controlled trial reported that intraarterial administration of recombinant bFGF modestly increased walking time in patients with claudication. Intramuscular gene transfer of DNA encoding VEGF or bFGF may promote collateral blood vessel growth in patients with critical limb ischemia, but evidence documenting clinical efficacy is not available and awaits the outcome of ongoing trials.

Platelet inhibitors, particularly aspirin, reduce the risk of adverse cardiovascular events in patients with peripheral atherosclerosis. Clopidogrel, a drug that inhibits platelet aggregation via its effect on ADP-dependent platelet-fibrinogen binding, appears to be more effective than aspirin in reducing cardiovascular morbidity and mortality in patients with PAD. The anticoagulants heparin and warfarin have not been shown to be effective in patients with chronic PAD but may be useful in acute arterial obstruction secondary to thrombosis or systemic embolism. Similarly, thrombolytic intervention using drugs such as streptokinase, urokinase, or recombinant tissue plasminogen activator (tPA) (alteplase) may have a role in the treatment of acute thrombotic arterial occlusion but is not effective in patients with chronic arterial occlusion secondary to atherosclerosis.

Revascularization Revascularization procedures, including nonoperative as well as operative interventions, are usually reserved for patients with progressive, severe, or disabling symptoms and ischemia at rest, as well as for individuals who must be symptom-free because of their occupation. Angiography should be performed mainly in patients who are being considered for a revascularization procedure. Nonoperative interventions include PTA, stent placement, and atherectomy (Chap. 229). PTA of the iliac artery is associated with a higher success rate than PTA of the femoral and popliteal arteries. Approximately 90 to 95% of iliac PTAs are initially successful, and the 3-year patency rate is >75%. Patency rates may be higher if a stent is placed in the iliac artery. The initial success rate for femoral-popliteal PTA is approximately 80%, with a 60% 3-year patency rate. Patency rates are influenced by the severity of pretreatment stenoses; the prognosis of total occlusive lesions is worse than that of nonocclusive stenotic lesions.

Several operative procedures are available for treating patients with aortoiliac and femoral-popliteal artery disease. The preferred operative procedure depends on the location and extent of the obstruction(s) and general medical condition of the patient. Operative procedures for aortoiliac disease include aortobifemoral bypass, axillofemoral bypass, femoral-femoral bypass, and aortoiliac endarterectomy. The most frequently used procedure is the aortobifemoral bypass using knitted Dacron grafts. Immediate graft patency approaches 99%, and 5- and 10-year graft patency in survivors is >90 and 80%, respectively. Operative complications include myocardial infarction and stroke, infection of the graft, peripheral embolization, and sexual dysfunction from interruption of autonomic nerves in the pelvis. Operative mortality ranges from 1 to 3%, mostly due to ischemic heart disease.

Operative therapy for femoral-popliteal artery disease includes in situ and reverse autogenous saphenous vein bypass grafts, placement of polytetrafluoroethylene (PTFE) or other synthetic grafts, and thromboendarterectomy. Operative mortality ranges from 1 to 3%. The long-term patency rate depends on the type of graft used, the location of the distal anastomosis, and the patency of runoff vessels beyond the anastomosis. Patency rates of femoral-popliteal saphenous vein bypass grafts at 1 year approach 90% and at 5 years, 70 to 80%. Five-year patency rates of infrapopliteal saphenous vein bypass grafts are 60 to 70%. In contrast, 5-year patency rates of infrapopliteal PTFE grafts are <30%. Lumbar sympathectomy alone or as an adjunct to aortofemoral reconstruction has fallen into disfavor.

Preoperative cardiac risk assessment may identify individuals especially likely to experience an adverse cardiac event during the perioperative period. Patients with angina, prior myocardial infarction, ventricular ectopy, heart failure, or diabetes are among those at increased risk. Noninvasive tests, such as treadmill testing (if feasible), dipyridamole or adenosine radionuclide myocardial perfusion imaging, dobutamine echocardiography, and ambulatory ischemia monitoring permit further stratification of patient risk (Chap. 229). Patients with abnormal test results require close supervision and adjunctive management with anti-ischemic medications. β-Adrenergic blockers reduce the risk of postoperative cardiovascular complications. It is not known whether coronary angiography and coronary arterial revascularization reduce overall perioperative mortality in high-risk patients undergoing peripheral vascular surgery, but cardiac catheterization should be considered in patients suspected of having left main or three-vessel coronary artery disease.

FIBROMUSCULAR DYSPLASIA This is a hyperplastic disorder affecting medium-sized and small arteries. It occurs predominantly in females and usually involves renal and carotid arteries but can affect extremity vessels such as the iliac and subclavian arteries. The histologic classification includes intimal, medial, and periadventitial dysplasia. Medial dysplasia is the most common type and is characterized by hyperplasia of the media with or without fibrosis of the elastic membrane. It is identified angiographically by a "string of beads" appearance caused by thickened fibromuscular ridges contiguous with thin, less involved portions of the arterial wall. When limb vessels are involved, clinical manifestations are similar to those for atherosclerosis, including claudication and rest pain. PTA and surgical reconstruction have been beneficial in patients with debilitating symptoms or threatened limbs.

THROMBOANGIITIS OBLITERANS Thromboangiitis obliterans (Buerger's disease) is an inflammatory occlusive vascular disorder involving small and medium-sized arteries and veins in the distal upper and lower extremities. Cerebral, visceral, and coronary vessels may also be affected. This disorder develops most frequently in men under age 40. The prevalence is higher in Asians and individuals of eastern European descent. While the cause of thromboangiitis obliterans is not

known, there is a definite relationship to cigarette smoking in patients with this disorder.

In the initial stages of thromboangiitis obliterans, polymorphonuclear leukocytes infiltrate the walls of the small and medium-sized arteries and veins. The internal elastic lamina is preserved, and thrombus may develop in the vascular lumen. As the disease progresses, mononuclear cells, fibroblasts, and giant cells replace the neutrophils. Later stages are characterized by perivascular fibrosis and recanalization.

The clinical features of thromboangiitis obliterans often include a triad of claudication of the affected extremity, Raynaud's phenomenon (p. 1489), and migratory superficial vein thrombophlebitis. Claudication is usually confined to the calves and feet or the forearms and hands, because this disorder primarily affects distal vessels. In the presence of severe digital ischemia, trophic nail changes, painful ulcerations, and gangrene may develop at the tips of the fingers or toes. The physical examination shows normal brachial and popliteal pulses but reduced or absent radial, ulnar, and/or tibial pulses. Arteriography is helpful in making the diagnosis. Smooth, tapering segmental lesions in the distal vessels are characteristic, as are collateral vessels at sites of vascular occlusion. Proximal atherosclerotic disease is usually absent. The diagnosis can be confirmed by excisional biopsy and pathologic examination of an involved vessel.

There is no specific treatment except abstention from tobacco. The prognosis is worse in individuals who continue to smoke, but results are discouraging even in those who do stop smoking. Arterial bypass of the larger vessels may be used in selected instances, as well as local debridement, depending on the symptoms and severity of ischemia. Antibiotics may be useful; anticoagulants and glucocorticoids are not helpful. If these measures fail, amputation may be required.

VASCULITIS Other vasculitides may affect the arteries supplying the upper and lower extremities. →***Takayasu's arteritis and giant cell (temporal) arteritis are discussed in Chap. 306.***

ACUTE ARTERIAL OCCLUSION This results in the sudden cessation of blood flow to an extremity. The severity of ischemia and the viability of the extremity depend on the location and extent of the occlusion and the presence and subsequent development of collateral blood vessels. There are two principal causes of acute arterial occlusion: embolism and thrombus in situ.

The most common sources of arterial emboli are the heart, aorta, and large arteries. Cardiac disorders that cause thromboembolism include atrial fibrillation, both chronic and paroxysmal; acute myocardial infarction; ventricular aneurysm; cardiomyopathy; infectious and marantic endocarditis; prosthetic heart valves; and atrial myxoma. Emboli to the distal vessels may also originate from proximal sites of atherosclerosis and aneurysms of the aorta and large vessels. Less frequently, an arterial occlusion results paradoxically from a venous thrombus that has entered the systemic circulation via a patent foramen ovale or other septal defect. Arterial emboli tend to lodge at vessel bifurcations because the vessel caliber decreases at these sites; in the lower extremities, emboli lodge most frequently in the femoral artery, followed by the iliac artery, aorta, and popliteal and tibioperoneal arteries.

Acute arterial thrombosis in situ occurs most frequently in atherosclerotic vessels at the site of an atherosclerotic plaque or aneurysm and in arterial bypass grafts. Trauma to an artery may also result in the formation of an acute arterial thrombus. Arterial occlusion may complicate arterial punctures and placement of catheters. Less frequent causes include the thoracic outlet compression syndrome, which causes subclavian artery occlusion, and entrapment of the popliteal artery by abnormal placement of the medial head of the gastrocnemius muscle. Polycythemia and hypercoagulable disorders (Chaps. 95 and 103) are also associated with acute arterial thrombosis.

Clinical Features The symptoms of an acute arterial occlusion depend on the location, duration, and severity of the obstruction. Often, severe pain, paresthesia, numbness, and coldness develop in the involved extremity within 1 h. Paralysis may occur with severe and persistent ischemia. Physical findings include loss of pulses distal to the occlusion, cyanosis or pallor, mottling, decreased skin temperature, muscle stiffening, loss of sensation, weakness, and/or absent deep tendon reflexes. If acute arterial occlusion occurs in the presence of an adequate collateral circulation, as is often the case in acute graft occlusion, the symptoms and findings may be less impressive. In this situation, the patient complains about an abrupt decrease in the distance walked before claudication occurs or of modest pain and paresthesia. Pallor and coolness are evident, but sensory and motor functions are generally preserved. The diagnosis of acute arterial occlusion is usually apparent from the clinical presentation. Arteriography is useful for confirming the diagnosis and demonstrating the location and extent of occlusion.

℞ TREATMENT

Once the diagnosis is made, the patient should be anticoagulated with intravenous heparin to prevent propagation of the clot. In cases of severe ischemia of recent onset, and particularly when limb viability is jeopardized, immediate intervention to ensure reperfusion is indicated. Endovascular or surgical thromboembolectomy or arterial bypass procedures are used to restore blood flow to the ischemic extremity promptly, particularly when a large proximal vessel is occluded.

Intraarterial thrombolytic therapy is effective when acute arterial occlusion is caused by a thrombus in an atherosclerotic vessel or arterial bypass graft. Thrombolytic therapy may also be indicated when the patient's overall condition contraindicates surgical intervention or when smaller distal vessels are occluded, thus preventing surgical access. One approach for administering intraarterial urokinase is to give 240,000 IU/h for 4 h, followed by 120,000 IU/h for a maximum of 48 h. Intraarterial recombinant tPA may be administered at infusion rates of 1 mg/h or 0.05 mg/kg per hour. Meticulous observation for hemorrhagic complications is required during intraarterial thrombolytic therapy.

If the limb is not in jeopardy, a more conservative approach that includes observation and administration of anticoagulants may be taken. Anticoagulation prevents recurrent embolism and reduces the likelihood of thrombus propagation. It can be initiated with intravenous heparin and followed by oral warfarin. Recommended dosages are the same as those used for deep vein thrombosis (see below). Emboli resulting from infectious endocarditis, the presence of prosthetic heart valves, or atrial myxoma often require surgical intervention to remove the cause.

ATHEROEMBOLISM Atheroembolism constitutes a subset of acute arterial occlusion. In this condition, multiple small deposits of fibrin, platelet, and cholesterol debris embolize from proximal atherosclerotic lesions or aneurysmal sites. Large protruding aortic atheromas are a source of emboli that may lead to stroke and renal insufficiency as well as limb ischemia. Atheroembolism may occur after intraarterial procedures. Since the emboli tend to lodge in the small vessels of the muscle and skin and may not occlude the large vessels, distal pulses usually remain palpable. Patients complain of acute pain and tenderness at the site of embolization. Digital vascular occlusion may result in ischemia and the "blue toe" syndrome; digital necrosis and gangrene may develop (Fig. 232-1). Localized areas of tenderness, pallor, and livedo reticularis (see below) occur at sites of emboli. Skin or muscle biopsy may demonstrate cholesterol crystals.

Ischemia resulting from atheroemboli is notoriously difficult to treat. Usually neither surgical revascularization procedures nor thrombolytic therapy is helpful because of the multiplicity, composition, and distal location of the emboli. Some evidence suggests that platelet inhibitors prevent atheroembolism. Surgical intervention to remove or bypass the atherosclerotic vessel or aneurysm that causes the recurrent atheroemboli may be necessary.

THORACIC OUTLET COMPRESSION SYNDROME This is a symptom complex resulting from compression of the neurovascular bundle (artery, vein,

FIGURE 232-1 Atheroembolism causing cyanotic discoloration and impending necrosis of the toes (blue toe syndrome).

or nerves) at the thoracic outlet as it courses through the neck and shoulder. Cervical ribs, abnormalities of the scalenus anticus muscle, proximity of the clavicle to the first rib, or abnormal insertion of the pectoralis minor muscle may compress the subclavian artery and brachial plexus as these structures pass from the thorax to the arm. Patients may develop shoulder and arm pain, weakness, paresthesia, claudication, Raynaud's phenomenon, and even ischemic tissue loss and gangrene. Examination is often normal unless provocative maneuvers are performed. Occasionally, distal pulses are decreased or absent and digital cyanosis and ischemia may be evident. Tenderness may be present in the supraclavicular fossa. Abducting the affected arm by 90° and externally rotating the shoulder may precipitate symptoms. Several additional maneuvers are used to confirm the diagnosis of vascular compression and to suggest the location of the abnormality. These include the scalene maneuver (extension of the neck and rotation of the head to the side of the symptoms), the costoclavicular maneuver (posterior rotation of shoulders), and the hyperabduction maneuver (raising the arm 180°), which may cause subclavian bruits and loss of pulses in the arm. A chest x-ray will indicate the presence of cervical ribs. The electromyogram will be abnormal if the brachial plexus is involved.

℞ TREATMENT

Most patients can be managed conservatively. They should be advised to avoid the positions that cause symptoms. Many patients benefit from shoulder girdle exercises. Surgical procedures such as removal of the first rib or resection of the scalenus anticus muscle are necessary occasionally for relief of symptoms or treatment of ischemia.

ARTERIOVENOUS FISTULA Abnormal communications between an artery and a vein, bypassing the capillary bed, may be congenital or acquired. Congenital arteriovenous fistulas are the result of persistent embryonic vessels that fail to differentiate into arteries and veins; they may be associated with birthmarks, can be located in almost any organ of the body, and frequently occur in the extremities. Acquired arteriovenous fistulas are either created to provide vascular access for hemodialysis or occur as a result of a penetrating injury such as a gunshot or knife wound or as complications of arterial catheterization or surgical dissection. An infrequent cause of arteriovenous fistula is rupture of an arterial aneurysm into a vein.

The clinical features depend on the location and size of the fistula. Frequently, a pulsatile mass is palpable, and a thrill and bruit lasting throughout systole and diastole are present over the fistula. With long-standing fistulas, clinical manifestations of chronic venous insufficiency, including peripheral edema, large, tortuous varicose veins, and stasis pigmentation become apparent because of the high venous pressure. Evidence of ischemia may occur in the distal portion of the extremity. Skin temperature is higher over the arteriovenous fistula. Large arteriovenous fistulas may result in an increased cardiac output with consequent cardiomegaly and high-output heart failure (Chap. 216).

Diagnosis The diagnosis is often evident from the physical examination. Compression of a large arteriovenous fistula may cause reflex slowing of the heart rate (Nicoladoni-Branham sign). Arteriography can confirm the diagnosis and is useful in demonstrating the site and size of the arteriovenous fistula.

℞ TREATMENT

Management of arteriovenous fistulas may involve surgery, radiotherapy, or embolization. Congenital arteriovenous fistulas are often difficult to treat because the communications may be numerous and extensive, and new ones frequently develop after ligation of the most obvious ones. Many of these lesions are best treated conservatively using elastic support hose to reduce the consequences of venous hypertension. Occasionally, embolization with autologous material, such as fat or muscle, or with hemostatic agents, such as gelatin sponges or silicon spheres, is used to obliterate the fistula. Acquired arteriovenous fistulas are usually amenable to surgical treatment that involves division or excision of the fistula. Occasionally, autogenous or synthetic grafting is necessary to reestablish continuity of the artery and vein.

RAYNAUD'S PHENOMENON Raynaud's phenomenon is characterized by episodic digital ischemia, manifested clinically by the sequential development of digital blanching, cyanosis, and rubor of the fingers or toes following cold exposure and subsequent rewarming. Emotional stress may also precipitate Raynaud's phenomenon. The color changes are usually well demarcated and are confined to the fingers or toes. Typically, one or more digits will appear white when the patient is exposed to a cold environment or touches a cold object. The blanching, or pallor, represents the ischemic phase of the phenomenon and results from vasospasm of digital arteries. During the ischemic phase, capillaries and venules dilate, and cyanosis results from the deoxygenated blood that is present in these vessels. A sensation of cold or numbness or paresthesia of the digits often accompanies the phases of pallor and cyanosis.

With rewarming, the digital vasospasm resolves, and blood flow into the dilated arterioles and capillaries increases dramatically. This "reactive hyperemia" imparts a bright red color to the digits. In addition to rubor and warmth, patients often experience a throbbing, painful sensation during the hyperemic phase. Although the triphasic color response is typical of Raynaud's phenomenon, some patients may develop only pallor and cyanosis; others may experience only cyanosis.

Pathophysiology Raynaud originally proposed that cold-induced episodic digital ischemia was secondary to exaggerated reflex sympathetic vasoconstriction. This theory is supported by the fact that α-adrenergic blocking drugs as well as sympathectomy decrease the frequency and severity of Raynaud's phenomenon in some patients. An alternative hypothesis is that the digital vascular responsiveness to cold or to normal sympathetic stimuli is enhanced. It is also possible that normal reflex sympathetic vasoconstriction is superimposed on local digital vascular disease or that there is enhanced adrenergic neuroeffector activity.

Raynaud's phenomenon is broadly separated into two categories: the idiopathic variety, termed *Raynaud's disease*, and the secondary variety, which is associated with other disease states or known causes of vasospasm (Table 232-1).

Raynaud's Disease This appellation is applied when the secondary causes of Raynaud's phenomenon have been excluded. Over 50% of patients with Raynaud's phenomenon have Raynaud's disease. Women are affected about five times more often than men, and the age of presentation is usually between 20 and 40 years. The fingers

TABLE 232-1 Classification of Raynaud's Phenomenon

Primary or idiopathic Raynaud's phenomenon: Raynaud's disease
Secondary Raynaud's phenomenon
Collagen vascular diseases: scleroderma, systemic lupus erythematosus, rheumatoid arthritis, dermatomyositis, polymyositis
Arterial occlusive diseases: atherosclerosis of the extremities, thromboangiitis obliterans, acute arterial occlusion, thoracic outlet syndrome
Pulmonary hypertension
Neurologic disorders: intervertebral disk disease, syringomyelia, spinal cord tumors, stroke, poliomyelitis, carpal tunnel syndrome
Blood dyscrasias: cold agglutinins, cryoglobulinemia, cryofibrinogenemia, myeloproliferative disorders, Waldenström's macroglobulinemia
Trauma: vibration injury, hammer hand syndrome, electric shock, cold injury, typing, piano playing
Drugs: ergot derivatives, methysergide, β-adrenergic receptor blockers, bleomycin, vinblastine, cisplatin

are involved more frequently than the toes. Initial episodes may involve only one or two fingertips, but subsequent attacks may involve the entire finger and may include all the fingers. The toes are affected in 40% of patients. Although vasospasm of the toes usually occurs in patients with symptoms in the fingers, it may happen alone. Rarely, the earlobes and the tip of the nose are involved. Raynaud's phenomenon occurs frequently in patients who also have migraine headaches or variant angina. These associations suggest that there may be a common predisposing cause for the vasospasm.

Results of physical examination are often entirely normal; the radial, ulnar, and pedal pulses are normal. The fingers and toes may be cool between attacks and may perspire excessively. Thickening and tightening of the digital subcutaneous tissue (*sclerodactyly*) develop in 10% of patients. Angiography of the digits for diagnostic purposes is not indicated.

In general, patients with Raynaud's disease appear to have the milder forms of Raynaud's phenomenon. Fewer than 1% of these patients lose a part of a digit. After the diagnosis is made, the disease improves spontaneously in approximately 15% of patients and progresses in about 30%.

Secondary Causes of Raynaud's Phenomenon Raynaud's phenomenon occurs in 80 to 90% of patients with systemic sclerosis (scleroderma) and is the presenting symptom in 30% (Chap. 303). It may be the only symptom of scleroderma for many years. Abnormalities of the digital vessels may contribute to the development of Raynaud's phenomenon in this disorder. Ischemic fingertip ulcers may develop and progress to gangrene and autoamputation. About 20% of patients with systemic lupus erythematosus (SLE) have Raynaud's phenomenon (Chap. 300). Occasionally, persistent digital ischemia develops and may result in ulcers or gangrene. In most severe cases, the small vessels are occluded by a proliferative endarteritis. Raynaud's phenomenon occurs in about 30% of patients with dermatomyositis or polymyositis (Chap. 369). It frequently develops in patients with rheumatoid arthritis and may be related to the intimal proliferation that occurs in the digital arteries.

Atherosclerosis of the extremities is a frequent cause of Raynaud's phenomenon in men over age 50. Thromboangiitis obliterans is an uncommon cause of Raynaud's phenomenon but should be considered in young men, particularly in those who are cigarette smokers. The development of cold-induced pallor in these disorders may be confined to one or two digits of the involved extremity. Occasionally, Raynaud's phenomenon may follow acute occlusion of large and medium-sized arteries by a thrombus or embolus. Embolization of atheroembolic debris may cause digital ischemia. The latter situation often involves one or two digits and should not be confused with Raynaud's phenomenon. In patients with the thoracic outlet syndrome, Raynaud's phenomenon may result from diminished intravascular pressure, stimulation of sympathetic fibers in the brachial plexus, or a combination of both. Raynaud's phenomenon occurs in patients with primary pulmonary hypertension (Chap. 220); this is more than coincidental and may reflect a neurohumoral abnormality that affects both the pulmonary and digital circulations.

A variety of blood dyscrasias may be associated with Raynaud's phenomenon. Cold-induced precipitation of plasma proteins, hyperviscosity, and aggregation of red cells and platelets may occur in patients with cold agglutinins, cryoglobulinemia, or cryofibrinogenemia. Hyperviscosity syndromes that accompany myeloproliferative disorders and Waldenström's macroglobulinemia should also be considered in the initial evaluation of patients with Raynaud's phenomenon.

Raynaud's phenomenon occurs often in patients whose vocations require the use of vibrating hand tools, such as chain saws or jackhammers. The frequency of Raynaud's phenomenon also seems to be increased in pianists and keyboard operators. Electric shock injury to the hands or frostbite may lead to the later development of Raynaud's phenomenon.

Several drugs have been causally implicated in Raynaud's phenomenon. These include ergot preparations; methysergide; β-adrenergic receptor antagonists; and the chemotherapeutic agents bleomycin, vinblastine, and cisplatin.

Rx TREATMENT

Most patients with Raynaud's phenomenon experience only mild and infrequent episodes. These patients need reassurance and should be instructed to dress warmly and avoid unnecessary cold exposure. In addition to gloves and mittens, patients should protect the trunk, head, and feet with warm clothing to prevent cold-induced reflex vasoconstriction. Tobacco use is contraindicated.

Drug treatment should be reserved for the severe cases. The calcium channel antagonists, especially nifedipine and diltiazem, decrease the frequency and severity of Raynaud's phenomenon. Adrenergic blocking agents, such as reserpine, have been shown to increase nutritional blood flow to the fingers. The postsynaptic α_1-adrenergic antagonist prazosin has been used with favorable responses. Doxazosin and terazosin may also be effective. Other sympatholytic agents, such as methyldopa, guanethidine, and phenoxybenzamine, may be useful in some patients. Surgical sympathectomy is helpful in some patients who are unresponsive to medical therapy, but benefit is often transient.

ACROCYANOSIS In this condition, there is arterial vasoconstriction and secondary dilation of the capillaries and venules with resulting persistent cyanosis of the hands and, less frequently, the feet. Cyanosis may be intensified by exposure to a cold environment. Women are affected much more frequently than men, and the age of onset is usually <30 years. Generally, patients are asymptomatic but seek medical attention because of the discoloration. Examination reveals normal pulses, peripheral cyanosis, and moist palms. Trophic skin changes and ulcerations do *not* occur. The disorder can be distinguished from Raynaud's phenomenon because it is persistent and not episodic, the discoloration extends proximally from the digits, and blanching does not occur. Ischemia secondary to arterial occlusive disease can usually be excluded by the presence of normal pulses. Central cyanosis and decreased arterial oxygen saturation are not present. Patients should be reassured and advised to dress warmly and avoid cold exposure. Pharmacologic intervention is not indicated.

LIVEDO RETICULARIS In this condition, localized areas of the extremities develop a mottled or netlike appearance of reddish to blue discoloration. The mottled appearance may be more prominent following cold exposure. The idiopathic form of this disorder occurs equally in men and women, and the most common age of onset is in the third decade. Patients with the idiopathic form are usually asymptomatic and seek attention for cosmetic reasons. Livedo reticularis can also occur following atheroembolism (see above). Rarely, skin ulcerations develop. Patients should be reassured and advised to avoid cold environments. No drug treatment is indicated.

PERNIO (CHILBLAINS) This is a vasculitic disorder associated with exposure to cold; acute forms have been described. Raised erythematous lesions develop on the lower part of the legs and feet in cold weather. These are associated with pruritus and a burning sensation, and they may blister and ulcerate. Pathologic examination demonstrates angiitis characterized by intimal proliferation and perivascular infiltration of mononuclear and polymorphonuclear leukocytes. Giant cells may be present in the subcutaneous tissue. Patients should avoid exposure to cold, and ulcers should be kept clean and protected with sterile dressings. Sympatholytic drugs may be effective in some patients.

ERYTHROMELALGIA (ERYTHERMALGIA) This disorder is characterized by burning pain and erythema of the extremities. The feet are involved more frequently than the hands, and males are affected more frequently than females. Erythromelalgia may occur at any age but is most common in middle age. It may be primary or secondary to myeloproliferative disorders such as polycythemia vera and essential thrombocytosis, or it may occur as an adverse effect of drugs such as nifedipine or bromocriptine. Patients complain of burning in the extremities that is precipitated by exposure to a warm environment and aggravated by a dependent position. The symptoms are relieved by exposing the affected area to cool air or water or by elevation. Erythromelalgia can be distinguished from ischemia secondary to peripheral arterial disorders and peripheral neuropathy because the peripheral pulses are present and the neurologic examination is normal. There is no specific treatment; aspirin may produce relief in patients with erythromelalgia secondary to myeloproliferative disease. Treatment of associated disorders in secondary erythromelalgia may be helpful.

FROSTBITE In this condition, tissue damage results from severe environmental cold exposure or from direct contact with a very cold object. Tissue injury results from both freezing and vasoconstriction. Frostbite usually affects the distal aspects of the extremities or exposed parts of the face, such as the ears, nose, chin, and cheeks. Superficial frostbite involves the skin and subcutaneous tissue. Patients experience pain or paresthesia, and the skin appears white and waxy. After rewarming, there is cyanosis and erythema, wheal-and-flare formation, edema, and superficial blisters. Deep frostbite involves muscle, nerves, and deeper blood vessels. It may result in edema of the hand or foot, vesicles and bullae, tissue necrosis, and gangrene.

Initial treatment is rewarming, performed in an environment where reexposure to freezing conditions will not occur. Rewarming is accomplished by immersion of the affected part in a water bath at temperatures of 40 to 44°C (104 to 111°F). Massage, application of ice water, and extreme heat are contraindicated. The injured area should be cleansed with soap or antiseptic and sterile dressings applied. Analgesics are often required during rewarming. Antibiotics are used if there is evidence of infection. The efficacy of sympathetic blocking drugs is not established. Following recovery, the affected extremity may exhibit increased sensitivity to cold.

DISORDERS OF THE VEINS AND LYMPHATICS

VENOUS DISORDERS

Veins in the extremities can be broadly classified as either superficial or deep. In the lower extremity, the superficial venous system includes the greater and lesser saphenous veins and their tributaries. The deep veins of the leg accompany the major arteries. Perforating veins connect the superficial and deep systems at multiple locations. Bicuspid valves are present throughout the venous system to direct the flow of venous blood centrally.

VENOUS THROMBOSIS The presence of thrombus within a superficial or deep vein and the accompanying inflammatory response in the vessel wall is termed *venous thrombosis* or *thrombophlebitis*. Initially, the thrombus is composed principally of platelets and fibrin. Red cells become interspersed with fibrin, and the thrombus tends to propagate in the direction of blood flow. The inflammatory response in the vessel wall may be minimal or characterized by granulocyte infiltration, loss of endothelium, and edema.

TABLE 232-2 Conditions Associated with an Increased Risk for Development of Venous Thrombosis

Surgery
Orthopedic, thoracic, abdominal, and genitourinary procedures
Neoplasms
Pancreas, lung, ovary, testes, urinary tract, breast, stomach
Trauma
Fractures of spine, pelvis, femur, or tibia; spinal cord injuries
Immobilization
Acute myocardial infarction, congestive heart failure, stroke, postoperative convalescence
Pregnancy
Estrogen use (for replacement or contraception)
Hypercoagulable states
Resistance to activated protein C; deficiencies of antithrombin III, protein C, or protein S; antiphospholipid antibodies; myeloproliferative diseases; dysfibrinogenemia; disseminated intravascular coagulation
Venulitis
Thromboangiitis obliterans, Behçet's disease, homocysteinuria
Previous deep vein thrombosis

The factors that predispose to venous thrombosis were initially described by Virchow in 1856 and include stasis, vascular damage, and hypercoagulability. Accordingly, a variety of clinical situations are associated with increased risk of venous thrombosis (Table 232-2). Venous thrombosis may occur in >50% of patients having orthopedic surgical procedures, particularly those involving the hip or knee, and in 10 to 40% of patients who undergo abdominal or thoracic operations. The prevalence of venous thrombosis is particularly high in patients with cancer of the pancreas, lungs, genitourinary tract, stomach, and breast. Approximately 10 to 20% of patients with idiopathic deep vein thrombosis have or develop clinically overt cancer; there is no consensus on whether these individuals should be subjected to intensive diagnostic workup to search for occult malignancy.

The risk of thrombosis is increased following trauma, such as fractures of the spine, pelvis, femur, and tibia. Immobilization, regardless of the underlying disease, is a major predisposing cause of venous thrombosis. This fact may account for the relatively high incidence in patients with acute myocardial infarction or congestive heart failure. The incidence of venous thrombosis is increased during pregnancy, particularly in the third trimester and in the first month postpartum, and in individuals who use oral contraceptives or receive postmenopausal hormone replacement therapy. A variety of clinical disorders that produce systemic hypercoagulability, including resistance to activated protein C (factor V Leiden); prothrombin G20210A gene mutation; antithrombin III, protein C, and protein S deficiencies; antiphospholipid syndrome; hyperhomocysteinemia; SLE; myeloproliferative diseases; dysfibrinogenemia; and disseminated intravascular coagulation, are associated with venous thrombosis. Venulitis occurring in thromboangiitis obliterans, Behçet's disease, and homocysteinuria may also cause venous thrombosis.

DEEP VENOUS THROMBOSIS (DVT) The most important consequences of this disorder are pulmonary embolism (Chap. 244) and the syndrome of chronic venous insufficiency. DVT of the iliac, femoral, or popliteal veins is suggested by unilateral leg swelling, warmth, and erythema. Tenderness may be present along the course of the involved veins, and a cord may be palpable. There may be increased tissue turgor, distention of superficial veins, and the appearance of prominent venous collaterals. In some patients, deoxygenated hemoglobin in stagnant veins imparts a cyanotic hue to the limb, a condition called *phlegmasia cerulea dolens*. In markedly edematous legs, the interstitial tissue pressure may exceed the capillary perfusion pressure, causing pallor, a condition designated *phlegmasia alba dolens*.

The diagnosis of DVT of the calf is often difficult to make at the bedside. This is so because only one of multiple veins may be involved, allowing adequate venous return through the remaining patent

vessels. The most common complaint is calf pain. Examination may reveal posterior calf tenderness, warmth, increased tissue turgor or modest swelling, and, rarely, a cord. Increased resistance or pain during dorsiflexion of the foot (Homans' sign) is an unreliable diagnostic sign.

DVT occurs less frequently in the upper extremity than in the lower extremity, but the incidence is increasing because of greater utilization of indwelling central venous catheters. The clinical features and complications are similar to those described for the leg.

Diagnosis D-Dimer, a degradation product of cross-linked fibrin, is often elevated in patients with venous thrombosis. It is a sensitive, but not specific, test for venous thrombosis. The noninvasive test used most often to diagnose DVT is duplex venous ultrasonography (B-mode, i.e., two-dimensional, imaging, and pulse-wave Doppler interrogation). By imaging the deep veins, thrombus can be detected either by direct visualization or by inference when the vein does not collapse on compressive maneuvers. The Doppler ultrasound measures the velocity of blood flow in veins. This velocity is normally affected by respiration and by manual compression of the foot or calf. Flow abnormalities occur when deep venous obstruction is present. The sensitivity of duplex venous ultrasonography approaches 95% for proximal DVT and 75% for symptomatic calf vein thrombosis.

Magnetic resonance imaging (MRI) is another noninvasive means to detect DVT. Its diagnostic accuracy for assessing proximal DVT is similar to that of duplex ultrasonography. It is useful in patients with suspected thrombosis of the superior and inferior venae cavae or pelvic veins.

DVT can also be diagnosed by venography. Contrast medium is injected into a superficial vein of the foot and directed to the deep system by the application of tourniquets. The presence of a filling defect or absence of filling of the deep veins is required to make the diagnosis.

DVT must be differentiated from a variety of disorders that cause unilateral leg pain or swelling, including muscle rupture, trauma, or hemorrhage; a ruptured popliteal cyst; and lymphedema. It may be difficult to distinguish swelling caused by the postphlebitic syndrome from that due to acute recurrent DVT. Leg pain may also result from nerve compression, arthritis, tendinitis, fractures, and arterial occlusive disorders. A careful history and physical examination can usually determine the cause of these symptoms.

℞ TREATMENT

Anticoagulants (See also Chap. 244) Prevention of pulmonary embolism is the most important reason for treating patients with DVT, since in the early stages the thrombus may be loose and poorly adherent to the vessel wall. Patients should be placed in bed, and the affected extremity should be elevated above the level of the heart until the edema and tenderness subside. Anticoagulants prevent thrombus propagation and allow the endogenous lytic system to operate. Initial therapy should include either unfractionated heparin or low-molecular-weight heparin. Unfractionated heparin should be administered intravenously as an initial bolus of 7500 to 10,000 IU, followed by a continuous infusion of 1000 to 1500 IU/h. The rate of the heparin infusion should be adjusted so that the activated partial thromboplastin time (aPTT) is approximately twice the control value. Subcutaneous injection of heparin has been used as an alternative form of therapy. In $<5\%$ of patients, heparin therapy may cause thrombocytopenia (heparin-induced thrombocytopenia, HIT). Infrequently, these patients develop arterial thrombosis and ischemia.

Low-molecular-weight (4000 to 6000 Da) heparins are as effective as or better than conventional, unfractionated heparin in preventing extension or recurrence of venous thrombosis. Depending on the specific preparation, low-molecular-weight heparin is administered subcutaneously, in fixed doses, once or twice daily; for example, the dose of enoxaparin is 1 mg/kg subcutaneously bid. The incidence of thrombocytopenia is less with low-molecular-weight heparin than with conventional preparations. A direct thrombin inhibitor, such as lepirudin or argatroban, may be used as initial anticoagulant therapy for patients in whom heparin is contraindicated because of HIT. Warfarin is administered during the first week of treatment with heparin and may be started as early as the first day of heparin treatment if the aPTT is therapeutic. It is important to overlap heparin treatment with oral anticoagulant therapy for at least 4 to 5 days because the full anticoagulant effect of warfarin is delayed. The dose of warfarin should be adjusted to maintain the prothrombin time at an international normalized ratio (INR) of 2.0 to 3.0.

Anticoagulant treatment is indicated for patients with proximal DVT, since pulmonary embolism may occur in $\sim 50\%$ of untreated individuals. The use of anticoagulants for isolated DVT of the calf is controversial. However, approximately 20 to 30% of calf thrombi propagate to the thigh, thereby increasing the risk of pulmonary embolism. The overall incidence of pulmonary embolism in patients presenting initially with deep calf vein thrombosis is 5 to 20%. Also, isolated calf vein thrombosis has been identified as a cause of embolic stroke via a patent foramen ovale.

Therefore, patients with calf vein thrombosis should either receive anticoagulants or be followed with serial noninvasive tests to determine whether proximal propagation has occurred. Anticoagulant treatment should be continued for at least 3 to 6 months for patients with acute idiopathic DVT and for those with a temporary risk factor for venous thrombosis to decrease the chance of recurrence. In a recent study of patients with idiopathic venous thromboembolism, long-term management with low-intensity warfarin using a targeted INR of 1.5 to 2.0, following at least 3 months of therapy with full-dose anticoagulation, reduced the risk of recurrent DVT and pulmonary embolism. The duration of treatment is indefinite for patients with recurrent DVT and for those in whom associated causes, such as malignancy or hypercoagulability, have not been eliminated. If treatment with anticoagulants is contraindicated because of a bleeding diathesis or risk of hemorrhage, protection from pulmonary embolism can be achieved by mechanically interrupting the flow of blood through the inferior vena cava. Inferior vena cava plication generally has been replaced by percutaneous insertion of a filter.

Thrombolytics Thrombolytic drugs such as streptokinase, urokinase, and tPA may also be used, but there is no evidence that thrombolytic therapy is more effective than anticoagulants in preventing pulmonary embolism. However, early administration of thrombolytic drugs may accelerate clot lysis, preserve venous valves, and decrease the potential for developing postphlebitic syndrome.

Prophylaxis Prophylaxis should be considered in clinical situations where the risk of DVT is high. Low-dose unfractionated heparin (5000 units 2 h prior to surgery and then 5000 units every 8 to 12 h postoperatively), warfarin, and external pneumatic compression are all useful. Low-dose heparin reduces the risk of DVT associated with thoracic and abdominal surgery and with prolonged bed rest. Low-molecular-weight heparins have been shown to prevent DVT in patients undergoing general or orthopedic surgery and in acutely ill medical patients. They are said to be more effective than conventional heparin and to cause an equal or lower incidence of bleeding. Danaparoid, a low-molecular-weight heparinoid, may be used for prophylaxis in patients undergoing hip surgery. Fondaparinux, a synthetic pentasaccharide capable of catalysing antithrombin-mediated inhibition of factor Xa, may be used for prophylaxis in patients undergoing major orthopedic surgery. Warfarin in a dose that yields a prothrombin time equivalent to an INR of 2.0 to 3.0 is effective in preventing DVT associated with bone fractures and orthopedic surgery. Warfarin is started the night before surgery and continued throughout the convalescent period. External pneumatic compression devices applied to the legs are used to prevent DVT when even low doses of heparin or warfarin might cause serious bleeding, as during neurosurgery or transurethral resection of the prostate.

SUPERFICIAL VEIN THROMBOSIS Thrombosis of the greater or lesser saphenous veins or their tributaries—i.e., superficial vein thrombosis—does not result in pulmonary embolism. It is associated with intravenous catheters and infusions, occurs in varicose veins, and may develop in association with DVT. Migrating superficial vein thrombosis is often a marker for a carcinoma and may also occur in patients with vasculitides, such as thromboangiitis obliterans. The clinical features of superficial vein thrombosis are easily distinguished from those of DVT. Patients complain of pain localized to the site of the thrombus. Examination reveals a reddened, warm, and tender cord extending along a superficial vein. The surrounding area may be red and edematous.

TREATMENT

Treatment is primarily supportive. Initially, patients can be placed at bed rest with leg elevation and application of warm compresses. Nonsteroidal anti-inflammatory drugs may provide analgesia but may also obscure clinical evidence of thrombus propagation. If a thrombosis of the greater saphenous vein develops in the thigh and extends toward the saphenofemoral vein junction, it is reasonable to consider anticoagulant therapy to prevent extension of the thrombus into the deep system and a possible pulmonary embolism.

VARICOSE VEINS Varicose veins are dilated, tortuous superficial veins that result from defective structure and function of the valves of the saphenous veins, from intrinsic weakness of the vein wall, from high intraluminal pressure, or, rarely, from arteriovenous fistulas. Varicose veins can be categorized as primary or secondary. Primary varicose veins originate in the superficial system and occur two to three times as frequently in women as in men. Approximately half of patients have a family history of varicose veins. Secondary varicose veins result from deep venous insufficiency and incompetent perforating veins or from deep venous occlusion causing enlargement of superficial veins that are serving as collaterals.

Patients with venous varicosities are often concerned about the cosmetic appearance of their legs. Symptoms consist of a dull ache or pressure sensation in the legs after prolonged standing; it is relieved with leg elevation. The legs feel heavy, and mild ankle edema develops occasionally. Extensive venous varicosities may cause skin ulcerations near the ankle. Superficial venous thrombosis may be a recurring problem, and, rarely, a varicosity ruptures and bleeds. Visual inspection of the legs in the dependent position usually confirms the presence of varicose veins.

Varicose veins can usually be treated with conservative measures. Symptoms often decrease when the legs are elevated periodically, when prolonged standing is avoided, and when elastic support hose are worn. External compression stockings provide a counterbalance to the hydrostatic pressure in the veins. Small symptomatic varicose veins can be treated with sclerotherapy, in which a sclerosing solution is injected into the involved varicose vein and a compression bandage is applied. Surgical therapy usually involves extensive ligation and stripping of the greater and lesser saphenous veins and should be reserved for patients who are very symptomatic, suffer recurrent superficial vein thrombosis, and/or develop skin ulceration. Surgical therapy may also be indicated for cosmetic reasons.

CHRONIC VENOUS INSUFFICIENCY Chronic venous insufficiency may result from DVT and/or valvular incompetence. Following DVT, the delicate valve leaflets become thickened and contracted so that they cannot prevent retrograde flow of blood; the vein becomes rigid and thick-walled. Although most veins recanalize after an episode of thrombosis, the large proximal veins may remain occluded. Secondary incompetence develops in distal valves because high pressures distend the vein and separate the leaflets. Primary deep venous valvular dysfunction may also occur without previous thrombosis. Patients with venous insufficiency often complain of a dull ache in the leg that worsens with prolonged standing and resolves with leg elevation. Examination demonstrates increased leg circumference, edema, and superficial varicose veins. Erythema, dermatitis, and hyperpigmentation develop along the distal aspect of the leg, and skin ulceration may occur near the medial and lateral malleoli. Cellulitis may be a recurring problem. Patients should be advised to avoid prolonged standing or sitting; frequent leg elevation is helpful. Graduated compression stockings should be worn during the day. These efforts should be intensified if skin ulcers develop. Ulcers should be treated with applications of wet to dry dressings and, occasionally, dilute topical antibiotic solutions. Commercially available dressings comprising antiseptic solutions and compressive bandages may be applied and should be changed weekly until healing occurs. Recurrent ulceration and severe edema may be treated by surgical interruption of incompetent communicating veins. Rarely, surgical valvuloplasty and bypass of venous occlusions are employed.

LYMPHATIC DISORDERS

Lymphatic capillaries are blind-ended tubes formed by a single layer of endothelial cells. The absent or widely fenestrated basement membrane of lymphatic capillaries allows access to interstitial proteins and particles. Lymphatic capillaries merge to form larger vessels that contain smooth muscle and are capable of vasomotion. Small and medium-sized lymphatic vessels empty into progressively larger channels, most of which drain into the thoracic duct. The lymphatic circulation is involved in the absorption of interstitial fluid and in the response to infection.

LYMPHEDEMA Lymphedema may be categorized as primary or secondary (Table 232-3). The prevalence of primary lymphedema is approximately 1 per 10,000 individuals. Primary lymphedema may be secondary to agenesis, hypoplasia, or obstruction of the lymphatic vessels. It may be associated with Turner syndrome, Klinefelter syndrome, Noonan syndrome, the yellow nail syndrome, the intestinal lymphangiectasia syndrome, and lymphangiomyomatosis. Women are affected more frequently than men. There are three clinical subtypes: congenital lymphedema, which appears shortly after birth; lymphedema praecox, which has its onset at the time of puberty; and lymphedema tarda, which usually begins after age 35. Familial forms of congenital lymphedema (Milroy's disease) and lymphedema praecox (Meige's disease) may be inherited in an autosomal dominant manner with variable penetrance; autosomal or sex-linked recessive forms are less common.

Secondary lymphedema is an acquired condition resulting from damage to or obstruction of previously normal lymphatic channels (Table 232-3). Recurrent episodes of bacterial lymphangitis, usually caused by streptococci, are a very common cause of lymphedema. The most common cause of secondary lymphedema worldwide is filariasis (Chap. 202). Tumors, such as prostate cancer and lymphoma, can also obstruct lymphatic vessels. Both surgery and radiation therapy for breast carcinoma may cause lymphedema of the upper extremity. Less common causes include tuberculosis, contact dermatitis, lymphogranuloma venereum, rheumatoid arthritis, pregnancy, and self-induced or factitious lymphedema following application of tourniquets.

Lymphedema is generally a painless condition, but patients may experience a chronic dull, heavy sensation in the leg, and most often

TABLE 232-3 Causes of Lymphedema

Radiation therapy

they are concerned about the appearance of the leg. Lymphedema of the lower extremity, initially involving the foot, gradually progresses up the leg so that the entire limb becomes edematous. In the early stages, the edema is soft and pits easily with pressure. In the chronic stages, the limb has a woody texture, and the tissues become indurated and fibrotic. At this point the edema may no longer be pitting. The limb loses its normal contour, and the toes appear square. Lymphedema should be distinguished from other disorders that cause unilateral leg swelling, such as DVT and chronic venous insufficiency. In the latter condition, the edema is softer, and there is often evidence of a stasis dermatitis, hyperpigmentation, and superficial venous varicosities.

The evaluation of patients with lymphedema should include diagnostic studies to clarify the cause. Abdominal and pelvic ultrasound and computed tomography can be used to detect obstructing lesions such as neoplasms. MRI may reveal edema in the epifascial compartment and identify lymph nodes and enlarged lymphatic channels. Lymphoscintigraphy and lymphangiography are rarely indicated, but either can be used to confirm the diagnosis or to differentiate primary from secondary lymphedema. Lymphoscintigraphy involves the injection of radioactively labeled technetium-containing colloid into the distal subcutaneous tissue of the affected extremity. In lymphangiography, contrast material is injected into a distal lymphatic vessel that has been isolated and cannulated. In primary lymphedema, lymphatic channels are absent, hypoplastic, or ectatic. In secondary lymphedema, lymphatic channels are usually dilated, and it may be possible to determine the level of obstruction.

TREATMENT

Patients with lymphedema of the lower extremities must be instructed to take meticulous care of their feet to prevent recurrent lymphangitis. Skin hygiene is important, and emollients can be used to prevent drying. Prophylactic antibiotics are often helpful, and fungal infection should be treated aggressively. Patients should be encouraged to participate in physical activity; frequent leg elevation can reduce the amount of edema. Physical therapy, including massage to facilitate lymphatic drainage, may be helpful. Patients can be fitted with graduated compression hose to reduce the amount of lymphedema that develops with upright posture. Occasionally, intermittent pneumatic compression devices can be applied at home to facilitate reduction of the edema. Diuretics are contraindicated and may cause depletion of intravascular volume and metabolic abnormalities. Microsurgical lymphatico-venous anastomotic procedures have been performed to rechannel lymph flow from obstructed lymphatic vessels into the venous system.

233 APPROACH TO THE PATIENT WITH DISEASE OF THE RESPIRATORY SYSTEM

Jeffrey M. Drazen, Steven E. Weinberger

Patients with disease of the respiratory system generally present because of symptoms, an abnormality on a chest radiograph, or both. These findings often lead to a set of diagnostic possibilities; the differential diagnosis is then refined on the basis of additional information gleaned from physical examination, pulmonary function testing, additional imaging studies, and bronchoscopic examination. This chapter will consider the approach to the patient based on the major patterns of presentation, focusing on the history, the physical examination, and the chest radiograph. →***For further discussion of pulmonary function testing, see Chap. 234, and of other diagnostic studies, see Chap. 235.***

CLINICAL PRESENTATION

HISTORY Dyspnea (shortness of breath) and cough are common presenting symptoms for patients with respiratory system disease. Less common symptoms include hemoptysis (the coughing up of blood) and chest pain, often with a pleuritic quality.

Dyspnea (See also Chap. 29) When evaluating a patient with shortness of breath, one should first determine the time course over which the symptom has become manifest. Patients who were well previously and developed *acute* shortness of breath (over a period of hours to days) can have acute disease affecting the airways (an acute attack of asthma), the pulmonary parenchyma (acute pulmonary edema or an acute infectious process such as a bacterial pneumonia), the pleural space (a pneumothorax), or the pulmonary vasculature (a pulmonary embolus). A *subacute* presentation (over days to weeks) can suggest an exacerbation of preexisting airways disease (asthma or chronic bronchitis), an indolent parenchymal infection (*Pneumocystis carinii* pneumonia in a patient with AIDS, mycobacterial or fungal pneumonia), a noninfectious inflammatory process that proceeds at a relatively slow pace (Wegener's granulomatosis, eosinophilic pneumonia, bronchiolitis obliterans with organizing pneumonia, and many others), neuromuscular disease (Guillain-Barré syndrome, myasthenia gravis), pleural disease (pleural effusion from a variety of possible causes), or chronic cardiac disease (congestive heart failure). A *chronic* presentation (over months to years) often indicates chronic obstructive lung disease, chronic interstitial lung disease, or chronic cardiac disease. Chronic diseases of airways (not only chronic obstructive lung disease but also asthma) are characterized by exacerbations and remissions. Patients often have periods when they are severely limited by shortness of breath, but these may be interspersed with periods in which symptoms are minimal or absent. In contrast, many of the diseases of pulmonary parenchyma are characterized by a slow but inexorable progression.

Other Respiratory Symptoms *Cough* (Chap. 30) may indicate the presence of lung disease, but cough per se is not useful for the differential diagnosis. The presence of sputum accompanying the cough often suggests airway disease and may be seen in asthma, chronic bronchitis, or bronchiectasis.

Hemoptysis (Chap. 30) can originate from disease of the airways, the pulmonary parenchyma, or the vasculature. Diseases of the airways can be inflammatory (acute or chronic bronchitis, bronchiectasis, or cystic fibrosis) or neoplastic (bronchogenic carcinoma or bronchial carcinoid tumors). Parenchymal diseases causing hemoptysis may be either localized (pneumonia, lung abscess, tuberculosis, or infection with *Aspergillus*) or diffuse (Goodpasture's syndrome, idiopathic pulmonary hemosiderosis). Vascular diseases potentially associated with hemoptysis include pulmonary thromboembolic disease and pulmonary arteriovenous malformations.

Chest pain (Chap. 12) caused by diseases of the respiratory system usually originates from involvement of the parietal pleura. As a result, the pain is accentuated by respiratory motion and is often referred to as *pleuritic*. Common examples include primary pleural disorders, such as neoplasm or inflammatory disorders involving the pleura, or pulmonary parenchymal disorders that extend to the pleural surface, such as pneumonia or pulmonary infarction.

Additional Historic Information Information about risk factors for lung disease should be explicitly explored to assure a complete basis of historic data. A history of current and past smoking, especially of cigarettes, should be sought from all patients. The smoking history should include the number of years of smoking, the intensity (i.e., number of packs per day), and, if the patient no longer smokes, the interval since smoking cessation. The risk of lung cancer falls progressively in the decade following discontinuation of smoking, and loss of lung function above the expected age-related decline ceases with the discontinuation of smoking. Even though chronic obstructive lung disease and neoplasia are the two most important respiratory complications of smoking, other respiratory disorders (e.g., spontaneous pneumothorax, respiratory bronchiolitis–interstitial lung disease, eosinophilic granuloma of the lung, and pulmonary hemorrhage with Goodpasture's syndrome) are also associated with smoking. A history of significant secondhand (passive) exposure to smoke, whether in the home or at the workplace, should also be sought as it may be a risk factor for neoplasia or an exacerbating factor for airways disease.

The patient may have been exposed to other inhaled agents associated with lung disease, which act either via direct toxicity or through immune mechanisms (Chaps. 237 and 238). Such exposures can be either occupational or avocational, indicating the importance of detailed occupational and personal histories, the latter stressing exposures related to hobbies or the home environment. Important agents include the inorganic dusts associated with pneumoconiosis (especially asbestos and silica dusts) and organic antigens associated with hypersensitivity pneumonitis (especially antigens from molds and animal proteins). Asthma, which is more common in women than men, is often exacerbated by exposure to environmental allergens (dust mites, pet dander, or cockroach allergens in the home or allergens in the outdoor environment such as pollen and ragweed) or may be caused by occupational exposures (diisocyanates). Exposure to particular infectious agents can be suggested by contacts with individuals with known respiratory infections (especially tuberculosis) or by residence in an area with endemic pathogens (histoplasmosis, coccidioidomycosis, blastomycosis).

A history of coexisting nonrespiratory disease or of risk factors for or previous treatment of such diseases should be sought, as they may predispose a patient to both infectious and noninfectious respiratory system complications. Common examples include systemic rheumatic diseases that are associated with pleural or parenchymal lung disease (Chap. 301), metastatic neoplastic disease in the lung, or impaired host defense mechanisms and secondary infection, which occur in the case of hematologic and lymph node malignancies. Risk factors for AIDS should be sought, as the lungs are not only the most common site of AIDS-defining infection but can also be involved by noninfectious complications of AIDS (Chap. 173). Treatment of nonrespiratory dis-

TABLE 233-1 *Typical Chest Examination Findings in Selected Clinical Conditions*

Condition	Percussion	Fremitus	Breath Sounds	Voice Transmission	Adventitious Sounds
Normal	Resonant	Normal	Vesicular (at lung bases)	Normal	Absent
Consolidation or atelectasis (with patent airway)	Dull	Increased	Bronchial	Bronchophony, whispered pectoriloquy, egophony	Crackles
Consolidation or atelectasis (with blocked airway)	Dull	Decreased	Decreased	Decreased	Absent
Asthma	Resonant	Normal	Vesicular	Normal	Wheezing
Interstitial lung disease	Resonant	Normal	Vesicular	Normal	Crackles
Emphysema	Hyperresonant	Decreased	Decreased	Decreased	Absent or wheezing
Pneumothorax	Hyperresonant	Decreased	Decreased	Decreased	Absent
Pleural effusion	Dull	Decreased	Decreased[a]	Decreased[a]	Absent or pleural friction rub

ease can be associated with respiratory complications, either because of effects on host defense mechanisms (immunosuppressive agents, cancer chemotherapy) with resulting infection or because of direct effects on the pulmonary parenchyma (cancer chemotherapy, radiation therapy, or treatment with other agents, such as amiodarone) or on the airways (β-blocking agents causing airflow obstruction, angiotensin-converting enzyme inhibitors causing cough) (Chap. 237).

Family history is important for evaluating diseases that have a genetic component. These include disorders such as cystic fibrosis, α_1-antitrypsin deficiency, pulmonary hypertension, pulmonary fibrosis, and asthma.

PHYSICAL EXAMINATION The general principles of inspection, palpation, percussion, and auscultation apply to the examination of the respiratory system. However, the physical examination should be directed not only toward ascertaining abnormalities of the lungs and thorax but also toward recognizing other findings that may reflect underlying lung disease.

On *inspection*, the rate and pattern of breathing as well as the depth and symmetry of lung expansion are observed. Breathing that is unusually rapid, labored, or associated with the use of accessory muscles of respiration generally indicates either augmented respiratory demands or an increased work of breathing. Asymmetric expansion of the chest is usually due to an asymmetric process affecting the lungs, such as endobronchial obstruction of a large airway, unilateral parenchymal or pleural disease, or unilateral phrenic nerve paralysis. Visible abnormalities of the thoracic cage include kyphoscoliosis and ankylosing spondylitis, either of which can alter compliance of the thorax, increase the work of breathing, and cause dyspnea.

On *palpation*, the symmetry of lung expansion can be assessed, generally confirming the findings observed by inspection. Vibration produced by spoken sounds is transmitted to the chest wall and is assessed by the presence or absence and symmetry of tactile fremitus. Transmission of vibration is decreased or absent if pleural liquid is interposed between the lung and the chest wall or if an endobronchial obstruction alters sound transmission. In contrast, transmitted vibration may increase over an area of underlying pulmonary consolidation. Palpation may also reveal focal tenderness, as seen with costochondritis or rib fracture.

The relative resonance or dullness of the tissue underlying the chest wall is assessed by *percussion*. The normal sound of underlying air-containing lung is resonant. In contrast, consolidated lung or a pleural effusion sounds dull, while emphysema or air in the pleural space results in a hyperresonant percussion note.

On *auscultation* of the lungs, the examiner listens for both the quality and intensity of the breath sounds and for the presence of extra, or adventitious, sounds. Normal breath sounds heard through the stethoscope at the periphery of the lung are described as *vesicular breath sounds*, in which inspiration is louder and longer than expiration. If sound transmission is impaired by endobronchial obstruction or by air or liquid in the pleural space, breath sounds are diminished in intensity or absent. When sound transmission is improved through consolidated lung, the resulting *bronchial breath sounds* have a more tubular quality and a more pronounced expiratory phase. Sound transmission can also be assessed by listening to spoken or whispered sounds; when these are transmitted through consolidated lung, *bronchophony* and *whispered pectoriloquy*, respectively, are present. The sound of a spoken E becomes more like an A, though with a nasal or bleating quality, a finding that is termed *egophony*.

The primary adventitious (abnormal) sounds that can be heard include crackles (rales), wheezes, and rhonchi. *Crackles* are the discontinuous, typically inspiratory, sound created when alveoli and small airways open and close with respiration. They are often associated with interstitial lung disease, microatelectasis, or filling of alveoli by liquid. *Wheezes*, which are generally more prominent during expiration than inspiration, reflect the oscillation of airway walls that occurs when there is airflow limitation, as may be produced by bronchospasm, airway edema or collapse, or intraluminal obstruction by neoplasm or secretions. *Rhonchi* is the term applied to the sounds created when there is free liquid in the airway lumen; the viscous interaction between the free liquid and the moving air creates a low-pitched vibratory sound. Other adventitious sounds include pleural friction rubs and stridor. The gritty sound of a *pleural friction rub* indicates inflamed pleural surfaces rubbing against each other, often during both inspiratory and expiratory phases of the respiratory cycle. *Stridor*, which occurs primarily during inspiration, represents flow through a narrowed upper airway, as occurs in an infant with croup.

A summary of the patterns of physical findings on pulmonary examination in common types of respiratory system disease is shown in Table 233-1.

A meticulous *general physical examination* is mandatory in patients with disorders of the respiratory system. Enlarged lymph nodes in the cervical and supraclavicular regions should be sought. Disturbances of mentation or even coma can occur in patients with acute carbon dioxide retention and hypoxemia. Telltale stains on the fingers point to heavy cigarette smoking; infected teeth and gums may occur in patients with aspiration pneumonitis and lung abscess.

Clubbing of the digits can be found in lung cancer, interstitial lung disease, and chronic infections in the thorax, such as bronchiectasis, lung abscess, and empyema. Clubbing can also be seen with congenital heart disease associated with right-to-left shunting and with a variety of chronic inflammatory or infectious diseases, such as inflammatory bowel disease and endocarditis. A number of systemic diseases, such as systemic lupus erythematosus, scleroderma, and rheumatoid arthritis, may be associated with pulmonary complications, even though their primary clinical manifestations and physical findings are not primarily related to the lungs. Conversely, other diseases that most commonly affect the respiratory system, such as sarcoidosis, can have findings on physical examination not related to the respiratory system, including ocular findings (uveitis, conjunctival granulomas) and skin findings (erythema nodosum, cutaneous granulomas).

FIGURE 233-1 Posteroanterior (PA) chest radiograph of a patient with diffuse interstitial lung disease due to idiopathic pulmonary fibrosis. (*From Weinberger, with permission.*)

CHEST RADIOGRAPHY

Chest radiography is often the initial diagnostic study performed to evaluate patients with respiratory symptoms, but it can also provide the initial evidence of disease in patients who are free of symptoms. Perhaps the most common example of the latter situation is the finding of one or more nodules or masses when the radiograph is performed for a reason other than evaluation of respiratory symptoms.

A number of diagnostic possibilities are often suggested by the radiographic pattern (Figs. 233-1 and 233-2). A localized region of opacification involving the pulmonary parenchyma can be described as a nodule (usually <3 cm in diameter), a mass (usually ≥3 cm in diameter), or an infiltrate. Diffuse disease with increased opacification is usually characterized as having an alveolar, an interstitial, or a nodular pattern. In contrast, increased radiolucency can be localized, as seen with a cyst or bulla, or generalized, as occurs with emphysema. The chest radiograph is also particularly useful for the detection of pleural disease, especially if manifested by the presence of air or liquid in the pleural space. An abnormal appearance of the hila and/or the mediastinum can suggest a mass or enlargement of lymph nodes.

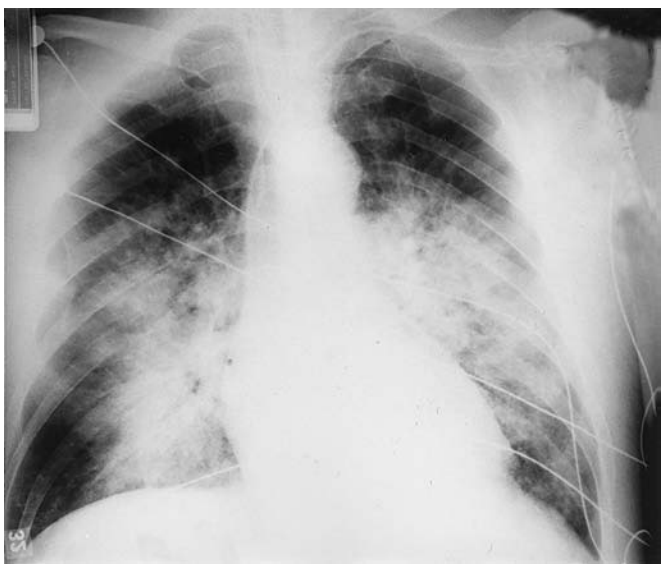

FIGURE 233-2 Anteroposterior (AP) chest radiograph demonstrating a diffuse alveolar filling pattern due to the acute respiratory distress syndrome (ARDS).

A summary of representative diagnoses suggested by these common radiographic patterns is presented in Table 233-2.

ADDITIONAL DIAGNOSTIC EVALUATION Further information for clarification of radiographic abnormalities is frequently obtained with computed tomographic scanning of the chest (see Figs. 235-1, -2; 243-1, -2; 251-3). This technique is more sensitive than plain radiography in detecting subtle abnormalities and can suggest specific diagnoses based on the pattern of abnormality. ***→For further discussion of the use of other imaging studies, including magnetic resonance imaging, scintigraphic studies, ultrasound, and angiography, see Chap. 235.***

Alteration in the function of the lungs as a result of respiratory system disease is assessed objectively by pulmonary function tests, and effects on gas exchange are evaluated by measurement of arterial blood gases or by oximetry (Chap. 234). As part of pulmonary function testing, quantitation of forced expiratory flow assesses the presence of obstructive physiology, which is consistent with diseases affecting the structure or function of the airways, such as asthma and chronic obstructive lung disease. Measurement of lung volumes assesses the presence of restrictive disorders, seen with diseases of the pulmonary parenchyma or respiratory pump and with space-occupying processes within the pleura.

Bronchoscopy is useful in some settings for visualizing abnormalities of the airways and for obtaining a variety of samples from either the airway or the pulmonary parenchyma (Chap. 235).

INTEGRATION OF THE PRESENTING CLINICAL PATTERN AND DIAGNOSTIC STUDIES

Patients with respiratory symptoms but a normal chest radiograph most commonly have diseases affecting the airways, such as asthma or chronic obstructive pulmonary disease. However, the latter diagnosis

TABLE 233-2 *Major Respiratory Diagnoses with Common Chest Radiographic Patterns*

Solitary circumscribed density—nodule (<3 cm) or mass (≥3 cm)
Primary or metastatic neoplasm
Localized infection (bacterial abscess, mycobacterial or fungal infection)
Wegener's granulomatosis (one or several nodules)
Rheumatoid nodule (one or several nodules)
Vascular malformation
Bronchogenic cyst
Localized opacification (infiltrate)
Pneumonia (bacterial, atypical, mycobacterial, or fungal infection)
Neoplasm
Radiation pneumonitis
Bronchiolitis obliterans with organizing pneumonia
Bronchocentric granulomatosis
Pulmonary infarction
Diffuse interstitial disease
Idiopathic pulmonary fibrosis
Pulmonary fibrosis with systemic rheumatic disease
Sarcoidosis
Drug-induced lung disease
Pneumoconiosis
Hypersensitivity pneumonitis
Infection (*Pneumocystis*, viral pneumonia)
Eosinophilic granuloma
Diffuse alveolar disease
Cardiogenic pulmonary edema
Acute respiratory distress syndrome
Diffuse alveolar hemorrhage
Infection (*Pneumocystis*, viral or bacterial pneumonia)
Sarcoidosis
Diffuse nodular disease
Metastatic neoplasm
Hematogenous spread of infection (bacterial, mycobacterial, fungal)
Pneumoconiosis
Eosinophilic granuloma

is also commonly associated with radiographic abnormalities, such as diaphragmatic flattening and attenuation of vascular markings. Other disorders of the respiratory system for which the chest radiograph is normal include disorders of the respiratory pump (either the chest wall or the neuromuscular apparatus controlling the chest wall) or pulmonary circulation and occasionally interstitial lung disease. Chest examination and pulmonary function tests are generally helpful in sorting out these diagnostic possibilities. Obstructive diseases associated with a normal or relatively normal chest radiograph are often characterized by findings on physical examination and pulmonary function testing that are typical for these conditions. Similarly, diseases of the respiratory pump or interstitial diseases may also be suggested by findings on physical examination or by particular patterns of restrictive disease seen on pulmonary function testing.

When respiratory symptoms are accompanied by radiographic abnormalities, diseases of the pulmonary parenchyma or the pleura are usually present. Either diffuse or localized parenchymal lung disease is generally visualized well on the radiograph, and both air and liquid in the pleural space (pneumothorax and pleural effusion, respectively) are usually readily detected by radiography.

Radiographic findings in the absence of respiratory symptoms often indicate localized disease affecting the airways or the pulmonary parenchyma. One or more nodules or masses can suggest intrathoracic malignancy, but they can also be the manifestation of a current or previous infectious process. Patients with diffuse parenchymal lung disease on radiographic examination may be free of symptoms, as is sometimes the case with pulmonary sarcoidosis.

234 DISTURBANCES OF RESPIRATORY FUNCTION

Steven E. Weinberger, Jeffrey M. Drazen

The respiratory system includes the lungs, the central nervous system (CNS), the chest wall (with the diaphragm and intercostal muscles), and the pulmonary circulation. The CNS controls the activity of the muscles of the chest wall, which constitute the pump of the respiratory system. Because these components of the respiratory system act in concert to achieve gas exchange, malfunction of an individual component or alteration of the relationships among components can lead to disturbances in function. In this chapter we consider three major aspects of disturbed respiratory function: (1) disturbances in ventilatory function, (2) disturbances in the pulmonary circulation, and (3) disturbances in gas exchange. →***For further discussion of disorders relating to CNS control of ventilation, see Chap. 246.***

DISTURBANCES IN VENTILATORY FUNCTION

Ventilation is the process whereby the lungs replenish the gas in the alveoli. Measurements of ventilatory function in common diagnostic use consist of quantification of the gas volume contained in the lungs under certain circumstances and the rate at which gas can be expelled from the lungs. The two measurements of lung volume commonly used for respiratory diagnosis are (1) total lung capacity (TLC), the volume of gas contained in the lungs after a maximal inspiration; and (2) residual volume (RV), the volume of gas remaining in the lungs at the end of a maximal expiration. The volume of gas that is exhaled from the lungs in going from TLC to RV is the *vital capacity* (VC) (Fig. 234-1).

Common clinical measurements of airflow are obtained from maneuvers in which the subject inspires to TLC and then forcibly exhales to RV. Three measurements are commonly made from a recording of forced exhaled volume versus time—i.e., a *spirogram*: (1) the volume of gas exhaled during the first second of expiration [forced expiratory volume (FEV) in 1 s, or FEV_1], (2) the total volume exhaled [forced vital capacity (FVC)], and (3) the average expiratory flow rate during the middle 50% of the VC [forced expiratory flow (FEF) between 25 and 75% of the VC, or $FEF_{25-75\%}$, also called the maximal midexpiratory flow rate (MMFR)] (Fig. 234-2).

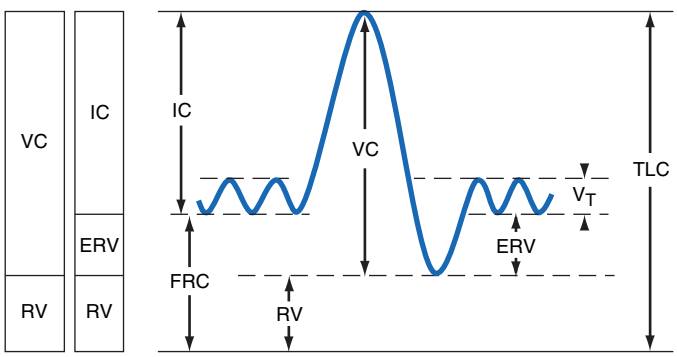

FIGURE 234-1 Lung volumes, shown by block diagrams *(left)* and by a spirographic tracing *(right)*. TLC, total lung capacity; VC, vital capacity; RV, residual volume; IC, inspiratory capacity; ERV, expiratory reserve volume; FRC, functional residual capacity; V_T, tidal volume. *(From Weinberger, with permission.)*

PHYSIOLOGIC FEATURES

The lungs are elastic structures, containing collagen and elastic fibers that resist expansion. For normal lungs to contain air, they must be distended either by a positive internal pressure—i.e., by a pressure in

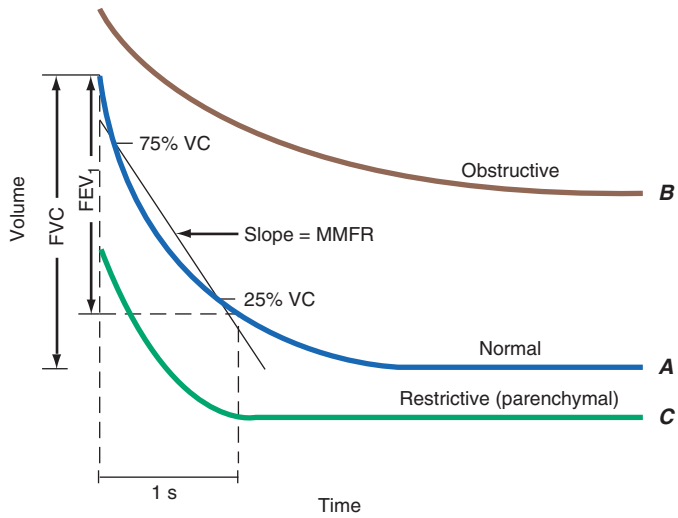

FIGURE 234-2 Spirographic tracings of forced expiration, comparing a normal tracing *(A)* and tracings in obstructive *(B)* and parenchymal restrictive *(C)* disease. Calculations of FVC, FEV_1, and $FEF_{25-75\%}$ are shown only for the normal tracing. Since there is no measure of absolute starting volume with spirometry, the curves are artificially positioned to show the relative starting lung volumes in the different conditions.

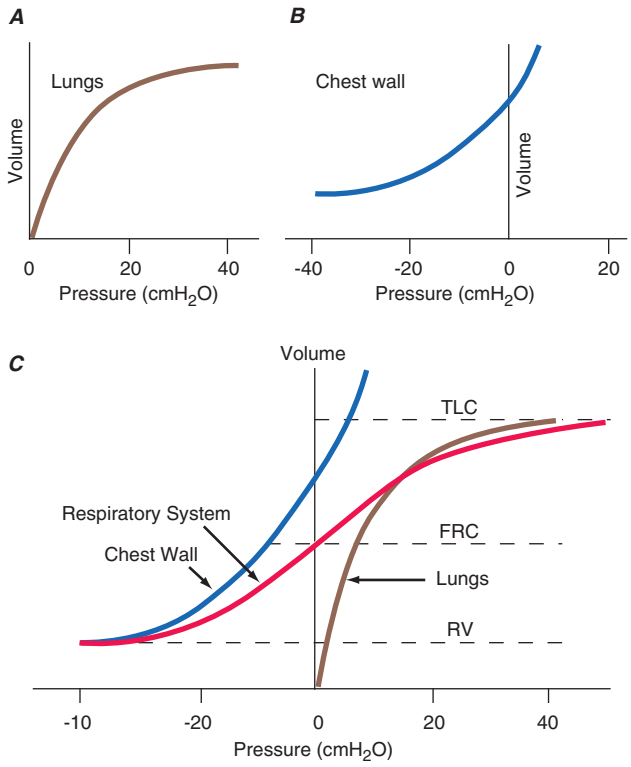

FIGURE 234-3 *A*. Pressure-volume curve of the lungs. *B*. Pressure-volume curve of the chest wall. *C*. RV, residual volume; FRC, functional residual capacity; TLC, total lung capacity. *(From Weinberger, with permission.)*

the airways and alveolar spaces—or by a negative external pressure—i.e., by a pressure outside the lung. The relationship between the volume of gas contained in the lungs and the distending pressure (the *transpulmonary pressure*, or P_{TP}, defined as alveolar pressure minus pleural pressure) is described by the pressure-volume curve of the lungs (Fig. 234-3*A*).

The chest wall is also an elastic structure, with properties similar to those of an expandable and compressible spring. The relationship between the volume enclosed by the chest wall and the distending pressure for the chest wall is described by the pressure-volume curve of the chest wall (Fig. 234-3*B*). For the chest wall to assume a volume different from its resting volume, the internal or external pressures acting on it must be altered.

At functional residual capacity (FRC), defined as the volume of gas in the lungs at the end of a normal exhalation, the lungs are partially inflated, so their elastic recoil exerts a force tending to empty the lungs. At the same time, chest wall volume is such that its elastic recoil promotes outward expansion. FRC occurs at the lung volume at which the tendency of the lungs to contract is opposed by the equal and opposite tendency of the chest wall to expand (Fig. 234-3*C*).

For the lungs and the chest wall to achieve a volume other than the resting volume (FRC), either the pressures acting on them must be changed passively—e.g., by a mechanical ventilator that delivers positive pressure to the airways and alveoli—or the respiratory muscles must actively oppose the tendency of the lungs and the chest wall to return to FRC. During inhalation to volumes above FRC, the inspiratory muscles actively overcome the tendency of the respiratory system to decrease volume back to FRC. During active exhalation to volumes below FRC, expiratory muscle activity must overcome the tendency of the respiratory system to increase volume back to FRC.

At TLC, the maximal force applied by the inspiratory muscles to expand the lungs is opposed mainly by the inward recoil of the lungs. As a consequence, the major determinants of TLC are the stiffness of the lungs and inspiratory muscle strength. If the lungs become stiffer—i.e., less compliant—TLC is decreased. If the lungs become less stiff (more compliant), TLC is increased. If the inspiratory muscles are significantly weakened, they are less able to overcome the inward elastic recoil of the lungs, and TLC is lowered.

At RV, the force exerted by the expiratory muscles to decrease lung volume further is balanced by the outward recoil of the chest wall, which becomes extremely stiff at low lung volumes. Two factors influence the volume of gas contained in the lungs at RV. The first is the ability of the subject to exert a prolonged expiratory effort, which is related to muscle strength and the ability to overcome sensory stimuli from the chest wall. The second is the ability of the lungs to empty to a small volume. In normal lungs, as P_{TP} is lowered, lung volume decreases. In lungs with diseased airways, as P_{TP} is lowered, flow limitation or airway closure may limit the amount of gas that can be expired. Consequently, either weak expiratory muscles or intrinsic airways disease can result in an elevation in measured RV.

Dynamic measurements of ventilatory function are made by having the subject inhale to TLC and then perform a forced expiration to RV. If a subject performs a series of such expiratory maneuvers using increasing muscular intensity, expiratory flow rates will increase until a certain level of effort is reached. Beyond this level, additional effort at any given lung volume will not increase the forced expiratory flow rate; this phenomenon is known as the *effort independence* of forced expiratory flow. The physiologic mechanisms determining the flow rates during this effort-independent phase of forced expiratory flow have been shown to be the elastic recoil of the lung, the airflow resistance of the airways between the alveolar zone and the physical site of flow limitation, and the airway wall compliance up to the site of flow limitation. Physical processes that decrease elastic recoil, increase airflow resistance, or increase airway wall compliance decrease the flow rate that can be achieved at any given lung volume. Conversely, processes that increase elastic recoil, decrease resistance, or stiffen airway walls increase the flow rate that can be achieved at any given lung volume.

MEASUREMENT OF VENTILATORY FUNCTION

Ventilatory function is measured under static conditions for determination of lung volumes and under dynamic conditions for determination of forced expiratory flow rates. VC, expiratory reserve volume (ERV), and inspiratory capacity (IC) (Fig. 234-1) are measured by having the patient breathe into and out of a spirometer, a device capable of measuring expired or inspired gas volume while plotting volume as a function of time. Other volumes—specifically, RV, FRC, and TLC —cannot be measured in this way because they include the volume of gas present in the lungs even after a maximal expiration. Two techniques are commonly used to measure these volumes: helium dilution and body plethysmography. In the helium dilution method, the subject repeatedly breathes in and out from a reservoir with a known volume of gas containing a trace amount of helium. The helium is diluted by the gas previously present in the lungs and very little is absorbed into the pulmonary circulation. From knowledge of the reservoir volume and the initial and final helium concentrations, the volume of gas present in the lungs can be calculated. The helium dilution method may underestimate the volume of gas in the lungs if there are slowly communicating airspaces, such as bullae. In this situation, lung volumes can be measured more accurately with a body plethysmograph, a sealed box in which the patient sits while panting against a closed mouthpiece. Because there is no airflow into or out of the plethysmograph, the pressure changes in the thorax during panting cause compression and rarefaction of gas in the lungs and simultaneous rarefaction and compression of gas in the plethysmograph. By measuring the pressure changes in the plethysmograph and at the mouthpiece, the volume of gas in the thorax can be calculated using Boyle's law.

Lung volumes and measurements made during forced expiration are interpreted by comparing the values measured with the values expected given the age, height, sex, and weight of the patient (Appendix

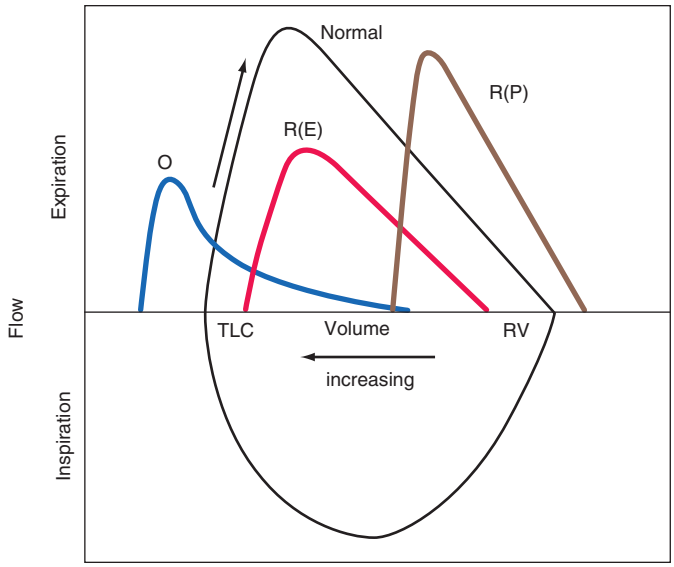

FIGURE 234-4 Flow-volume curves in different conditions: O, obstructive disease; R(P), parenchymal restrictive disease; R(E), extraparenchymal restrictive disease with limitation in inspiration and expiration. Forced expiration is plotted in all conditions; forced inspiration is shown only for the normal curve. TLC, total lung capacity; RV, residual volume. By convention, lung volume increases to the left on the abscissa. The arrow alongside the normal curve indicates the direction of expiration from TLC to RV.

Table C-4). Regression curves have been constructed on the basis of data obtained from large numbers of normal, nonsmoking individuals without evidence of lung disease. Predicted values for a given patient can then be obtained by using the patient's age and height in the appropriate regression equation; different equations are used depending on the patient's race and sex. Because there is some variability among normal individuals, values between 80 and 120% of the predicted value have traditionally been considered normal. Increasingly, calculated percentiles are used in determining normality. Specifically, values of individual measurements falling below the fifth percentile are considered to be below normal.

The normal value for the ratio FEV_1/FVC is approximately 0.75 to 0.80, although this value does fall somewhat with advancing age. The $FEF_{25-75\%}$ is often considered a more sensitive measurement of early airflow obstruction, particularly in small airways. However, this measurement must be interpreted cautiously in patients with abnormally small lungs (low TLC and VC). These patients exhale less air during forced expiration, and the $FEF_{25-75\%}$ may appear abnormal relative to the usual predicted value, even though it is normal relative to the size of the patient's lungs.

It is also a common practice to plot expiratory flow rates against lung volume (rather than against time); the close linkage of flow rates to lung volumes produces a typical *flow-volume curve* (Fig. 234-4). In addition, the spirometric values mentioned above can be calculated from the flow-volume curve. Commonly, flow rates during a maximal inspiratory effort performed as rapidly as possible are plotted as well, making the flow-volume curve into a *flow-volume loop*. At TLC, before expiratory flow starts, the flow rate is zero; once forced expiration has begun, a high peak flow rate is rapidly achieved. As expiration continues and lung volume approaches RV, the flow rate falls progressively, in a nearly linear fashion as a function of lung volume for a person with normal lung function. During maximal inspiration from RV to TLC, inspiratory flow is most rapid at the midpoint of inspiration, so the inspiratory portion of the loop is U-shaped or saddle-shaped. The flow rates achieved during maximal expiration can be analyzed quantitatively by comparing the flow rates at specified lung volumes with the predicted values, or qualitatively by analyzing the shape of the descending limb of the expiratory curve.

Assessing the strength of respiratory muscles is an additional part of the overall evaluation of some patients with respiratory dysfunction. When a patient exhales completely to RV and then tries to inspire maximally against an occluded airway, the pressure that can be generated is called the *maximal inspiratory pressure* (MIP). On the other hand, when a patient inhales to TLC and then tries to expire maximally against an occluded airway, the pressure generated is called the *maximal expiratory pressure* (MEP). In the proper clinical setting, these studies may provide useful information regarding the cause of abnormal lung volumes and the possibility that respiratory muscle weakness may be causally related to the lung volume abnormalities.

PATTERNS OF ABNORMAL FUNCTION

The two major patterns of abnormal ventilatory function, as measured by static lung volumes and spirometry, are restrictive and obstructive patterns. In the *obstructive pattern*, the hallmark is a decrease in expiratory flow rates. With fully established disease, the ratio FEV_1/FVC is decreased, as is the $FEF_{25-75\%}$ (Fig. 234-2, line *B*). The expiratory portion of the flow-volume loop demonstrates decreased flow rates for any given lung volume. Nonuniform emptying of airways is reflected by a coved (scooped) configuration of the descending part of the expiratory curve (Fig. 234-4). With early obstructive disease, which originates in the small airways, FEV_1/FVC may be normal; the only abnormalities noted on routine testing of pulmonary function may be a depression in $FEF_{25-75\%}$ and an abnormal, i.e., coved, configuration in the terminal portion of the forced expiratory flow-volume curve.

In *obstructive* disease, the TLC is normal or increased. When helium equilibration tests are used to measure lung volumes, the measured volume may be less than the actual volume if helium was not well distributed to all regions of the lung. Residual volume is elevated as a result of airway closure during expiration, and the ratio RV/TLC is increased. VC is frequently decreased in obstructive disease because of the striking elevations in RV with only minor changes in TLC.

The hallmark of a *restrictive pattern* is a decrease in lung volumes, primarily TLC and VC. Disorders resulting in a restrictive pattern can be broadly divided into two subgroups, depending on the location of the pathology: pulmonary parenchymal and extraparenchymal. In pulmonary parenchymal disease, RV is also generally decreased, and forced expiratory flow rates are preserved. In fact, when FEV_1 is considered as a percentage of the FVC, the flow rates are often supranormal, i.e., disproportionately high relative to the size of the lungs (Fig. 234-2, line *C*). The flow-volume curve may graphically demonstrate this disproportionate relationship between flow rates and lung volumes, since the expiratory portion of the curve appears relatively tall (preserved flow rates) but narrow (decreased lung volumes), as shown in Fig. 234-4.

With extraparenchymal disease, dysfunction can be predominantly in inspiration or in both inspiration and expiration (Table 234-1). In the extraparenchymal pattern characterized by *inspiratory dysfunction*, caused by either inspiratory muscle weakness or a stiff chest wall, inadequate distending forces are exerted on an otherwise nor-

TABLE 234-1 *Alterations in Ventilatory Function*

	TLC	RV	VC	FEV_1/FVC	MIP	MEP
Obstructive	N to ↑	↑	↓	↓[a]	N	N
Restrictive

[a] Can have inspiratory and expiratory limitation (see text).

mal lung. As a result, TLC values are less than predicted, RV is often not significantly affected, and expiratory flow rates are preserved. If inspiratory muscle weakness is the cause of this pattern, then MIP is decreased. In the extraparenchymal pattern characterized by *inspiratory and expiratory dysfunction*, the ability to expire to a normal RV is also limited, because of either expiratory muscle weakness or a deformed chest wall that is abnormally rigid at volumes below FRC. Consequently, RV is often elevated, unlike the pattern observed in the other restrictive subcategories. The ratio FEV_1/FVC is variable and depends on expiratory muscle strength. If expiratory muscle strength is significantly decreased, then MEP is decreased, the ability to expire rapidly is impaired, and FEV_1/FVC may be decreased even though there is no airflow obstruction. If expiratory muscle strength is normal but the chest wall is abnormally stiff below FRC, then FEV_1/FVC is normal or increased.

CLINICAL CORRELATIONS

Table 234-1 summarizes the typical patterns of altered ventilatory function as indicated by pulmonary function testing. This information can then be useful in diagnosis, as outlined in Table 234-2.

DISTURBANCES IN THE PULMONARY CIRCULATION

PHYSIOLOGIC FEATURES

The pulmonary vasculature must handle the entire output of the right ventricle, approximately 5 L/min in a normal adult at rest. The comparatively thin-walled vessels of the pulmonary arterial system provide relatively little resistance to flow and are capable of handling this large volume of blood at perfusion pressures that are low compared with those of the systemic circulation. The normal mean pulmonary artery pressure is 15 mmHg, as compared to approximately 95 mmHg for the normal mean aortic pressure. Regional blood flow in the lung is dependent on vascular geometry and on hydrostatic forces. In an upright person, perfusion is least at the apex of the lung and greatest at the base. When cardiac output increases, as occurs during exercise, the pulmonary vasculature is capable of recruiting previously unperfused vessels and distending underperfused vessels, thus responding to the increase in flow with a decrease in pulmonary vascular resistance. In consequence, the increase in mean pulmonary arterial pressure (PAP), even with a three- to fourfold increase in cardiac output, is small.

METHODS OF MEASUREMENT

Assessment of circulatory function in the pulmonary vasculature depends on measuring pulmonary vascular pressures and cardiac output. Clinically, these measurements are commonly made in intensive care units capable of invasive monitoring and in cardiac catheterization laboratories. With a flow-directed pulmonary arterial (Swan-Ganz) catheter, PAP and pulmonary capillary wedge pressure can be measured directly, and cardiac output can be obtained by the thermodilution method. Pulmonary vascular resistance (PVR) can then be calculated according to the equation

$$PVR = 80(PAP - PCW)/CO$$

where PVR = pulmonary vascular resistance (dyn·s/cm^5); PAP = mean pulmonary arterial pressure (mmHg); PCW = pulmonary capillary wedge pressure (mmHg); and CO = cardiac output (L/min).

The normal value for pulmonary vascular resistance is approximately 50 to 150 dyn·s/cm^5.

MECHANISMS OF ABNORMAL FUNCTION (See also Chap. 220)

PVR may increase by a variety of mechanisms. Pulmonary arterial and arteriolar vasoconstriction is a prominent response to alveolar hypoxia. PVR also increases if intraluminal thrombi or proliferation of smooth muscle in vessel walls diminishes the luminal cross-sectional area. If small pulmonary vessels are destroyed, either by scarring or by loss of alveolar walls, the total cross-sectional area of the pulmonary vascular bed diminishes, and PVR increases. When PVR is elevated, either PAP rises to maintain normal cardiac output or cardiac output falls if PAP does not increase.

CLINICAL CORRELATIONS

Disturbances in the function of the pulmonary vasculature as a result of primary cardiac disease, either congenital heart disease or conditions that elevate left atrial pressure, such as mitral stenosis, are beyond the scope of this chapter and are discussed in Chaps. 218 and 219, respectively. Instead, the focus will be on the pulmonary vasculature as its function is affected by diseases primarily involving the respiratory system, including the pulmonary vessels themselves.

All diseases of the respiratory system causing hypoxemia are potentially capable of increasing PVR, since alveolar hypoxia is a very potent stimulus for pulmonary vasoconstriction. The more prolonged and intense the hypoxic stimulus, the more likely it is that a significant increase in PVR producing pulmonary hypertension will result. In practice, patients with hypoxemia caused by chronic obstructive lung disease, interstitial lung disease, chest wall disease, and the obesity hypoventilation–sleep apnea syndrome are particularly prone to developing pulmonary hypertension. If there are additional structural changes in the pulmonary vasculature secondary to the underlying process, these will increase the likelihood of developing pulmonary hypertension.

With diseases directly affecting the pulmonary vessels, a decrease in the cross-sectional area of the pulmonary vascular bed is primarily responsible for increased PVR, while hypoxemia generally plays a lesser role. In the case of recurrent pulmonary emboli, parts of the pulmonary arterial system are occluded by intraluminal thrombi originating in the systemic venous system. With primary pulmonary hypertension (Chap. 220) or with pulmonary vascular disease secondary to scleroderma, the small pulmonary arteries and arterioles are affected by a generalized obliterative process that narrows and occludes these vessels. PVR increases, and significant pulmonary hypertension often results.

DISTURBANCES IN GAS EXCHANGE

PHYSIOLOGIC FEATURES

The primary functions of the respiratory system are to remove the appropriate amount of CO_2 from blood entering the pulmonary circulation and to provide adequate O_2 to blood leaving the pulmonary circulation. For these functions to be carried out properly, there must be adequate provision of fresh air to the alveoli for delivery of O_2 and removal of CO_2 (ventilation), adequate circulation of blood through the pulmonary vasculature (perfusion), adequate movement of gas between alveoli and pulmonary capillaries (diffusion), and appropriate contact between alveolar gas and pulmonary capillary blood (ventilation-perfusion matching).

A normal individual at rest inspires approximately 12 to 16 times per minute, each breath having a tidal volume of approximately 500 mL. A portion (approximately 30%) of the fresh air inspired with each breath does not reach the alveoli but remains in the conducting airways of the lung. This component of each breath, which is not generally available for gas exchange, is called the *anatomic dead space component*. The remaining 70% reaches the alveolar zone, mixes rapidly with the gas already there, and can participate in gas exchange. In this example, the total ventilation each minute is approximately 7 L, composed of 2 L/min of dead space ventilation and 5 L/min of alveolar ventilation. In certain diseases, some alveoli are ventilated but not perfused, so that some ventilation in addition to the anatomic dead space component is wasted. If total dead space ventilation is increased but total minute ventilation is unchanged, then alveolar ventilation must fall correspondingly.

Gas exchange is dependent on alveolar ventilation rather than total minute ventilation, as outlined below. The partial pressure of CO_2 in arterial blood (Pa_{CO_2}) is directly proportional to the amount of CO_2 produced per minute ($\dot{V}_{CO_2}$) and inversely proportional to alveolar ventilation ($\dot{V}A$), according to the relationship

$$Pa_{CO_2} = 0.863 \times \dot{V}_{CO_2}/\dot{V}A$$

where $\dot{V}_{CO_2}$ is expressed in mL/min, $\dot{V}A$ in L/min, and Pa_{CO_2} in mmHg. At fixed $\dot{V}_{CO_2}$, when alveolar ventilation increases, Pa_{CO_2} falls, and when alveolar ventilation decreases, Pa_{CO_2} rises. Maintaining a normal level of O_2 in the alveoli (and consequently in arterial blood) also depends on provision of adequate alveolar ventilation to replenish alveolar O_2. This principle will become more apparent from consideration of the alveolar gas equation below.

DIFFUSION OF O_2 AND CO_2 Both O_2 and CO_2 diffuse readily down their respective concentration gradients through the alveolar wall and pulmonary capillary endothelium. Under normal circumstances, this process is rapid, and equilibration of both gases is complete within one-third of the transit time of erythrocytes through the pulmonary capillary bed. Even in disease states in which diffusion of gases is impaired, the impairment is unlikely to be severe enough to prevent equilibration of CO_2 and O_2. Consequently, a diffusion abnormality rarely results in arterial hypoxemia at rest. If erythrocyte transit time in the pulmonary circulation is shortened, as occurs with exercise, and diffusion is impaired, then diffusion limitation may contribute to hypoxemia. Exercise testing can often demonstrate such physiologically significant abnormalities due to impaired diffusion. Even though diffusion limitation rarely makes a clinically significant contribution to resting hypoxemia, clinical measurements of what is known as *diffusing capacity* (see below) can be a useful measure of the integrity of the alveolar-capillary membrane.

VENTILATION-PERFUSION MATCHING In addition to the absolute levels of alveolar ventilation and perfusion, gas exchange depends critically on the proper matching of ventilation and perfusion. The spectrum of possible ventilation-perfusion ($\dot{V}/\dot{Q}$) ratios in an alveolar-capillary unit ranges from zero, in which ventilation is totally absent and the unit behaves as a shunt, to infinity, in which perfusion is totally absent and the unit behaves as dead space. The P_{O_2} and P_{CO_2} of blood leaving each alveolar-capillary unit depend on the gas tension (of blood and air) entering that unit and on the particular $\dot{V}/\dot{Q}$ ratio of the unit. At one extreme, when an alveolar-capillary unit has a $\dot{V}/\dot{Q}$ ratio of 0 and behaves as a shunt, blood leaving the unit has the composition of mixed venous blood entering the pulmonary capillaries, i.e., $P\bar{v}_{O_2} \approx$ 40 mmHg and $P\bar{v}_{CO_2} \approx$ 46 mmHg. At the other extreme, when an alveolar-capillary unit has a high $\dot{V}/\dot{Q}$ ratio, it behaves almost like dead space, and the small amount of blood leaving the unit has partial pressures of O_2 and CO_2 ($P_{O_2} \approx$ 150 mmHg, $P_{CO_2} \approx$ 0 mmHg while breathing room air) approaching the composition of inspired gas.

In the ideal situation, all alveolar-capillary units have equal matching of ventilation and perfusion, i.e., a ratio of approximately 1 when each is expressed in L/min. However, even in the normal individual, some $\dot{V}/\dot{Q}$ mismatching is present, since there is normally a gradient of blood flow from the apices to the bases of the lungs. There is a similar gradient of ventilation from the apices to the bases, but it is less marked than the perfusion gradient. As a result, ventilation-perfusion ratios are higher at the lung apices than at the lung bases. Therefore, blood coming from the apices has a higher P_{O_2} and lower P_{CO_2} than blood coming from the bases. The net P_{O_2} and P_{CO_2} of the blood mixture coming from all areas of the lung is a flow-weighted average of the individual components, which reflects both the relative amount of blood from each unit and the O_2 and CO_2 *content* of the blood coming from each unit. Because of the sigmoid shape of the oxyhemoglobin dissociation curve (see Fig. 91-2), it is important to distinguish between the partial pressure and the content of O_2 in blood. Hemoglobin is almost fully (~90%) saturated at a P_{O_2} of 60 mmHg, and little additional O_2 is carried by hemoglobin even with a substantial elevation of P_{O_2} above 60 mmHg. On the other hand, significant O_2 desaturation of hemoglobin occurs once P_{O_2} falls below 60 mmHg and onto the steep descending limb of the curve. As a result, blood coming from regions of the lung with a high $\dot{V}/\dot{Q}$ ratio and a high P_{O_2} has only a small elevation in O_2 content and cannot compensate for blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio and a low P_{O_2}, which has a significantly decreased O_2 content. Although $\dot{V}/\dot{Q}$ mismatching can influence P_{CO_2}, this effect is less marked and is often overcome by an increase in overall minute ventilation.

MEASUREMENT OF GAS EXCHANGE

ARTERIAL BLOOD GASES The most commonly used measures of gas exchange are the partial pressures of O_2 and CO_2 in arterial blood, i.e., Pa_{O_2} and Pa_{CO_2}, respectively. These partial pressures do not measure directly the quantity of O_2 and CO_2 in blood but rather the driving pressure for the gas in blood. The actual quantity or content of a gas in blood also depends on the solubility of the gas in plasma and the ability of any component of blood to react with or bind the gas of interest. Since hemoglobin is capable of binding large amounts of O_2, oxygenated hemoglobin is the primary form in which O_2 is transported in blood. The actual content of O_2 in blood therefore depends both on the hemoglobin concentration and on the Pa_{O_2}. The Pa_{O_2} determines what percentage of hemoglobin is saturated with O_2, based on the position on the oxyhemoglobin dissociation curve. Oxygen content in normal blood (at 37°C, pH 7.4) can be determined by adding the amount of O_2 dissolved in plasma to the amount bound to hemoglobin, according to the equation

$$O_2 \text{ content} = 1.34 \times [\text{hemoglobin}] \times \text{saturation} + 0.0031 \times P_{O_2}$$

since each gram of hemoglobin is capable of carrying 1.34 mL O_2 when fully saturated, and the amount of O_2 that can be dissolved in plasma is proportional to the P_{O_2}, with 0.0031 mL O_2 dissolved per deciliter of blood per mmHg P_{O_2}. In arterial blood, the amount of O_2 transported dissolved in plasma (approximately 0.3 mL O_2 per deciliter of blood) is trivial compared with the amount bound to hemoglobin (approximately 20 mL O_2 per deciliter of blood).

Most commonly, P_{O_2} is the measurement used to assess the effect of respiratory disease on the oxygenation of arterial blood. Direct measurement of O_2 saturation in arterial blood by oximetry is also important in selected clinical conditions. For example, in patients with carbon monoxide intoxication, carbon monoxide preferentially displaces O_2 from hemoglobin, essentially making a portion of hemoglobin unavailable for binding to O_2. In this circumstance, carbon monoxide saturation is high and O_2 saturation is low, even though the driving pressure for O_2 to bind to hemoglobin, reflected by P_{O_2}, is normal. Measurement of O_2 saturation is also important for the determination of O_2 content when mixed venous blood is sampled from a pulmonary arterial catheter to calculate cardiac output by the Fick technique. In mixed venous blood, the P_{O_2} is normally about 40 mmHg, but small changes in P_{O_2} may reflect relatively large changes in O_2 saturation.

A useful calculation in the assessment of oxygenation is the alve-

olar-arterial O_2 difference ($PA_{O_2} - Pa_{O_2}$), commonly called the *alveolar-arterial O_2* gradient (or A − a gradient). This calculation takes into account the fact that alveolar and, hence, arterial P_{O_2} can be expected to change depending on the level of alveolar ventilation, reflected by the arterial P_{CO_2}. When a patient hyperventilates and has a low P_{CO_2} in arterial blood and alveolar gas, alveolar and arterial P_{O_2} will rise; conversely, hypoventilation and a high P_{CO_2} are accompanied by a decrease in alveolar and arterial P_{O_2}. These changes in arterial P_{O_2} are independent of abnormalities in O_2 transfer at the alveolar-capillary level and reflect only the dependence of alveolar P_{O_2} on the level of alveolar ventilation.

In order to determine the alveolar-arterial O_2 difference, the alveolar P_{O_2} (PA_{O_2}) must first be calculated. The equation most commonly used for this purpose, a simplified form of the alveolar gas equation, is

$$PA_{O_2} = FI_{O_2} \times (P_B - P_{H_2O}) - Pa_{CO_2}/R$$

where FI_{O_2} = fractional concentration of inspired O_2 (≈0.21 when breathing room air); P_B = barometric pressure (approximately 760 mmHg at sea level); P_{H_2O} = water vapor pressure (47 mmHg when air is fully saturated at 37°C); and R = respiratory quotient (the ratio of CO_2 production to O_2 consumption, usually assumed to be 0.8). If the preceding values are substituted into the equation for the patient breathing air at sea level, the equation becomes

$$PA_{O_2} = 150 - 1.25 \times Pa_{CO_2}$$

The alveolar-arterial O_2 difference can then be calculated by subtracting measured Pa_{O_2} from calculated PA_{O_2}. In a healthy young person breathing room air, the $PA_{O_2} - Pa_{O_2}$ is normally less than 15 mmHg; this value increases with age and may be as high as 30 mmHg in elderly patients.

The adequacy of CO_2 elimination is measured by the partial pressure of CO_2 in arterial blood, i.e., Pa_{CO_2}. A more complete understanding of the mechanisms and chronicity of abnormal levels of P_{CO_2} also requires measurement of pH and/or bicarbonate (HCO_3^-), since P_{CO_2} and the patient's acid-base status are so closely intertwined (Chap. 42).

PULSE OXIMETRY Because measurement of Pa_{O_2} requires arterial puncture, it is not ideal either for office use or for routine or frequent measurement in the inpatient setting. Additionally, because it provides intermittent rather than continuous data about the patient's oxygenation, it is not ideal for close monitoring of unstable patients. Pulse oximetry, an alternative method for assessing oxygenation, is readily available in many clinical settings. Using a probe usually clipped over a patient's finger, the pulse oximeter calculates oxygen saturation (rather than Pa_{O_2}) based on measurements of absorption of two wavelengths of light by hemoglobin in pulsatile, cutaneous arterial blood. Because of differential absorption of the two wavelengths of light by oxygenated and nonoxygenated hemoglobin, the percentage of hemoglobin that is saturated with oxygen, i.e., the Sa_{O_2}, can be calculated and displayed instantaneously.

Although the pulse oximeter has been a major advance in the noninvasive, continuous monitoring of oxygenation, there are several issues and potential problems concerning its use. First, the clinician must be aware of the relationship between oxygen saturation and tension as shown by the oxyhemoglobin dissociation curve (see Fig. 91-2). Because the curve becomes relatively flat above an arterial P_{O_2} of 60 mmHg (corresponding to Sa_{O_2} = 90%), the oximeter is relatively insensitive to changes in Pa_{O_2} above this level. In addition, the position of the curve and therefore the specific relationship between Pa_{O_2} and Sa_{O_2} may change depending on factors such as temperature, pH, and the erythrocyte concentration of 2,3-diphosphoglycerate. Second, when cutaneous perfusion is decreased, e.g., owing to low cardiac output or the use of vasoconstrictors, the signal from the oximeter may be less reliable or even unobtainable. Third, other forms of hemoglobin, such as carboxyhemoglobin and methemoglobin, are not distinguishable from oxyhemoglobin when only two wavelengths of light are used. The Sa_{O_2} values reported by the pulse oximeter are not reliable in the presence of significant amounts of either of these forms of hemoglobin. In contrast, the device used to measure oxygen saturation in samples of arterial blood, called the CO-oximeter, uses at least four wavelengths of light and is capable of distinguishing oxyhemoglobin, deoxygenated hemoglobin, carboxyhemoglobin, and methemoglobin. Finally, the clinician must remember that the often-used goal of $Sa_{O_2} \geq 90\%$ does not indicate anything about CO_2 elimination and therefore does not ensure a clinically acceptable P_{CO_2}.

DIFFUSING CAPACITY The ability of gas to diffuse across the alveolar-capillary membrane is ordinarily assessed by the diffusing capacity of the lung for carbon monoxide (DL_{CO}). In this test, a small concentration of carbon monoxide (0.3%) is inhaled, usually in a single breath that is held for approximately 10 s. The carbon monoxide is diluted by the gas already present in the alveoli and is also taken up by hemoglobin as the erythrocytes course through the pulmonary capillary system. The concentration of carbon monoxide in exhaled gas is measured, and DL_{CO} is calculated as the quantity of carbon monoxide absorbed per minute per mmHg pressure gradient from the alveoli to the pulmonary capillaries. The value obtained for DL_{CO} depends on the alveolar-capillary surface area available for gas exchange and on the pulmonary capillary blood volume. In addition, the thickness of the alveolar-capillary membrane, the degree of $\dot{V}/\dot{Q}$ mismatching, and the patient's hemoglobin level will affect the measurement. Because of this effect of hemoglobin levels on DL_{CO}, the measured DL_{CO} is frequently corrected to take the patient's hemoglobin level into account. The value for DL_{CO}, ideally corrected for hemoglobin, can then be compared with a predicted value, based either on age, height, and gender or on the alveolar volume (V_A) at which the value was obtained. Alternatively, the DL_{CO} can be divided by V_A and the resulting value for DL_{CO}/V_A compared with a predicted value.

APPROACH TO THE PATIENT

ARTERIAL BLOOD GASES Hypoxemia is a common manifestation of a variety of diseases affecting the lungs or other parts of the respiratory system. The broad clinical problem of hypoxemia is often best characterized according to the underlying mechanism. The four basic, and not mutually exclusive, mechanisms of hypoxemia are (1) a decrease in inspired P_{O_2}, (2) hypoventilation, (3) shunting, and (4) $\dot{V}/\dot{Q}$ mismatching. Hypoxemia due to decreased diffusion occurs only under selected clinical circumstances and is not usually included among the general categories of hypoxemia. Determining the underlying mechanism for hypoxemia depends on measurement of the Pa_{CO_2}, calculation of $PA_{O_2} - Pa_{O_2}$, and knowledge of the response to supplemental O_2. A flowchart summarizing the approach to the hypoxemic patient is given in Fig. 234-5. →***See also Chap. 31.***

A decrease in the inspired P_{O_2} and hypoventilation both cause hypoxemia by lowering PA_{O_2} and therefore Pa_{O_2}. In each case, gas exchange at the alveolar-capillary level occurs normally, and $PA_{O_2} - Pa_{O_2}$ is not elevated. Hypoxemia due to decreased inspired P_{O_2} can be diagnosed from knowledge of the clinical situation. Inspired P_{O_2} is lowered either because the patient is at a high altitude, where barometric pressure is low, or, much less commonly, because the patient is breathing a gas mixture containing less than 21% O_2. The hallmark of hypoventilation as a cause of hypoxemia is an elevation in Pa_{CO_2}. This is associated with an increase in PA_{CO_2} and a fall in PA_{O_2}. When hypoxemia is due purely to a low inspired P_{O_2} or to alveolar hypoventilation, $PA_{O_2} - Pa_{O_2}$ is normal. If $PA_{O_2} - Pa_{O_2}$ and Pa_{CO_2} are both elevated, then an additional mechanism, such as $\dot{V}/\dot{Q}$ mismatching or shunting, is contributing to hypoxemia.

Shunting is a cause of hypoxemia when desaturated blood effectively bypasses oxygenation at the alveolar-capillary level. This situation occurs either because a structural problem allows desaturated blood to bypass the normal site of gas exchange or because

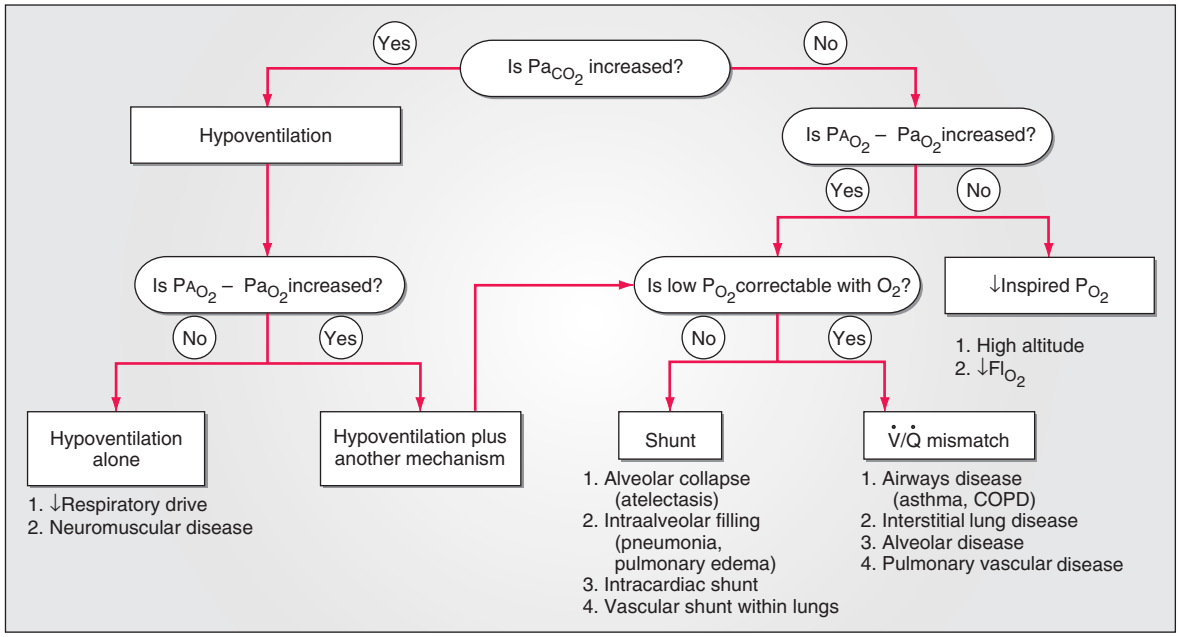

FIGURE 234-5 Flow diagram outlining the diagnostic approach to the patient with hypoxemia (Pa_{O_2} < 80 mmHg). $PA_{O_2} - Pa_{O_2}$ is usually < 15 mmHg for subjects ≤30 years old and increases by ~3 mmHg per decade after age 30. COPD, chronic obstructive pulmonary disease.

perfused alveoli are not ventilated. Shunting is associated with an elevation in the $PA_{O_2} - Pa_{O_2}$ value. When shunting is an important contributing factor to hypoxemia, the lowered Pa_{O_2} is relatively refractory to improvement by supplemental O_2.

Finally, the largest clinical category of hypoxemia is $\dot{V}/\dot{Q}$ mismatching. With $\dot{V}/\dot{Q}$ mismatching, regions with low $\dot{V}/\dot{Q}$ ratios contribute blood with a low P_{O_2} and a low O_2 content. Corresponding regions with high $\dot{V}/\dot{Q}$ ratios contribute blood with a high P_{O_2}. However, because blood is already almost fully saturated at a normal P_{O_2}, elevation of the P_{O_2} to a high value does not significantly increase O_2 saturation or content and therefore cannot compensate for the reduction of O_2 saturation and content in blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio. When $\dot{V}/\dot{Q}$ mismatch is the primary cause of hypoxemia, $PA_{O_2} - Pa_{O_2}$ is elevated, and P_{CO_2} generally is normal. Supplemental O_2 corrects the hypoxemia by raising the P_{O_2} in blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio; this response distinguishes hypoxemia due to $\dot{V}/\dot{Q}$ mismatching from that due to true shunt.

The essential mechanism underlying all cases of hypercapnia is alveolar ventilation that is inadequate for the amount of CO_2 produced. It is conceptually useful to characterize CO_2 retention further, based on a more detailed examination of the potential contributing factors. These include (1) increased CO_2 production; (2) decreased ventilatory drive ("won't breathe"); (3) malfunction of the respiratory pump or increased airways resistance, which makes it more difficult to sustain adequate ventilation ("can't breathe"); and (4) inefficiency of gas exchange (increased dead space or $\dot{V}/\dot{Q}$ mismatch) necessitating a compensatory increase in overall minute ventilation. In practice, more than one of these mechanisms is commonly responsible for hypercapnia, since increased minute ventilation is capable of compensating for increased CO_2 production and for inefficiencies of gas exchange.

DIFFUSING CAPACITY Although abnormalities in diffusion are rarely responsible for hypoxemia, clinical measurement of diffusing capacity is frequently used to assess the functional integrity of the alveolar-capillary membrane, which includes the pulmonary capillary bed. Diseases that affect solely the airways generally do not lower DL_{CO}, whereas diseases that affect the alveolar walls or the pulmonary capillary bed will have an effect on DL_{CO}. Even though DL_{CO} is a useful marker for assessing whether disease affecting the alveolar-capillary bed is present, an abnormal DL_{CO} does not necessarily imply that diffusion limitation is responsible for hypoxemia in a particular patient.

CLINICAL CORRELATIONS

Useful clinical correlations can be made with the mechanisms underlying hypoxemia (Fig. 234-5). A lowered inspired P_{O_2} contributes to hypoxemia if either the patient is at high altitude or the concentration of inspired O_2 is less than 21%. The latter problem occurs if a patient receiving anesthesia or ventilatory support is inadvertently given a gas mixture to breathe containing less than 21% O_2 or if O_2 is consumed from the ambient gas, as can occur during smoke inhalation from a fire. The primary feature of hypoventilation as a cause of hypoxemia is an elevation in arterial P_{CO_2}. →***For further discussion of the clinical correlations with hypoventilation, see Chap. 246.***

Shunting as a cause of hypoxemia can reflect transfer of blood from the right to the left side of the heart without passage through the pulmonary circulation, as occurs with an intracardiac shunt. This problem is most common in the setting of cyanotic congenital heart disease, when an interatrial or interventricular septal defect is associated with pulmonary hypertension so that shunting is in the right-to-left rather than the left-to-right direction. Shunting of blood through the pulmonary parenchyma is most frequently due to disease causing absence of ventilation to perfused alveoli. This can occur if the alveoli are atelectatic or if they are filled with fluid, as in pulmonary edema (both cardiogenic and noncardiogenic), or with extensive intraalveolar exudation of fluid due to pneumonia. Less commonly, vascular anomalies with arteriovenous shunting in the lung can cause hypoxemia. These anomalies can be hereditary, as found with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome), or acquired, as in pulmonary vascular malformations secondary to hepatic cirrhosis, which are similar to the commonly recognized cutaneous vascular malformations ("spider hemangiomas").

Ventilation-perfusion mismatch is the most common cause of hypoxemia clinically. Most of the processes affecting either the airways or the pulmonary parenchyma are distributed unevenly throughout the lungs and do not necessarily affect ventilation and perfusion equally. Some areas of lung may have good perfusion and poor ventilation, whereas others may have poor perfusion and relatively good ventilation. Important examples of airways diseases in which $\dot{V}/\dot{Q}$ mismatch causes hypoxemia are asthma and chronic obstructive lung disease.

Parenchymal lung diseases causing $\dot{V}/\dot{Q}$ mismatch and hypoxemia include interstitial lung disease and pneumonia.

Clinically important alterations in CO_2 elimination range from excessive ventilation and hypocapnia to inadequate CO_2 elimination and hypercapnia. →***For further discussion of these clinical problems, see Chap. 246.***

DIFFUSING CAPACITY Measurement of DL_{CO} may be useful for assessing disease affecting the alveolar-capillary bed or the pulmonary vasculature. In practice, three main categories of disease are associated with lowered DL_{CO}: interstitial lung disease, emphysema, and pulmonary vascular disease. With interstitial lung disease, scarring of alveolar-capillary units diminishes the area of the alveolar-capillary bed as well as pulmonary blood volume. With emphysema, alveolar walls are destroyed, so the surface area of the alveolar-capillary bed is again diminished. In patients with disease causing a decrease in the cross-sectional area and volume of the pulmonary vascular bed, such as recurrent pulmonary emboli or primary pulmonary hypertension, DL_{CO} is commonly diminished.

Diffusing capacity may be elevated if pulmonary blood volume is increased, as may be seen in congestive heart failure. However, once interstitial and alveolar edema ensue, the net DL_{CO} depends on the opposing influences of increased pulmonary capillary blood volume elevating DL_{CO} and pulmonary edema decreasing it. Finding an elevated DL_{CO} may be useful in the diagnosis of alveolar hemorrhage, as in Goodpasture's syndrome. Hemoglobin contained in erythrocytes in the alveolar lumen is capable of binding carbon monoxide, so the exhaled carbon monoxide concentration is diminished and the measured DL_{CO} is increased.

235 DIAGNOSTIC PROCEDURES IN RESPIRATORY DISEASE

Steven E. Weinberger, Jeffrey M. Drazen

The diagnostic modalities available for assessing the patient with suspected or known respiratory system disease include imaging studies and techniques for acquiring biologic specimens, some of which involve direct visualization of part of the respiratory system. →***Methods used to characterize the functional changes developing as a result of disease, including pulmonary function tests and measurements of gas exchange, are discussed in Chap. 234.***

IMAGING STUDIES

ROUTINE RADIOGRAPHY Routine chest radiography, which generally includes both posteroanterior and lateral views, is an integral part of the diagnostic evaluation of diseases involving the pulmonary parenchyma, the pleura, and, to a lesser extent, the airways and the mediastinum (see Figs. 233-1 and 233-2). Lateral decubitus views are often useful for determining whether pleural abnormalities represent freely flowing fluid, whereas apical lordotic views can often visualize disease at the lung apices better than the standard posteroanterior view. Portable equipment, which is often used for acutely ill patients who either cannot be transported to a radiology suite or cannot stand up for posteroanterior and lateral views, generally yields just a single radiograph taken in the anteroposterior direction. →***Common radiographic patterns and their clinical correlates are reviewed in Chap. 233.***

COMPUTED TOMOGRAPHY Computed tomography (CT) offers several advantages over routine chest radiography (Figs. 235-1, -2; 243-1, -2; 251-3). First, the use of cross-sectional images often makes it possible to distinguish between densities that would be superimposed on plain radiographs. Second, CT is far better than routine radiographic studies at characterizing tissue density, distinguishing subtle differences in density between adjacent structures, and providing accurate size assessment of lesions. As a result, CT is particularly valuable in assessing hilar and mediastinal disease (which is often poorly characterized by plain radiography), in identifying and characterizing disease adjacent to the chest wall or spine (including pleural disease), and in identifying areas of fat density or calcification in pulmonary nodules (Fig. 235-1). Its utility in the assessment of mediastinal disease has made CT an important tool in the staging of lung cancer (Chap. 75), as an assessment of tumor involvement of mediastinal lymph nodes is critical to proper staging. With the additional use of contrast material, CT also makes it possible to distinguish vascular from nonvascular structures, which is particularly important in distinguishing lymph nodes and masses from vascular structures.

Helical CT scanning allows the collection of continuous data over a larger volume of lung during a single breath-holding maneuver than is possible with conventional CT. With CT angiography, in which intravenous contrast is administered and images are acquired rapidly by helical scanning, pulmonary emboli can be detected in segmental and larger pulmonary arteries. With high-resolution CT (HRCT), the thickness of individual cross-sectional images is approximately 1 to 2 mm, rather than the usual 7 to 10 mm, and the images are reconstructed using high-spatial-resolution algorithms. The detail that can be seen on HRCT scans allows better recognition of subtle parenchymal and airway disease, such as bronchiectasis, emphysema, and diffuse parenchymal disease (Fig. 235-2). Certain nearly pathognomonic patterns have now been recognized for many of the interstitial lung diseases, such as lymphangitic carcinoma, idiopathic pulmonary fibrosis, sarcoidosis, and eosinophilic granuloma; however, it is not yet

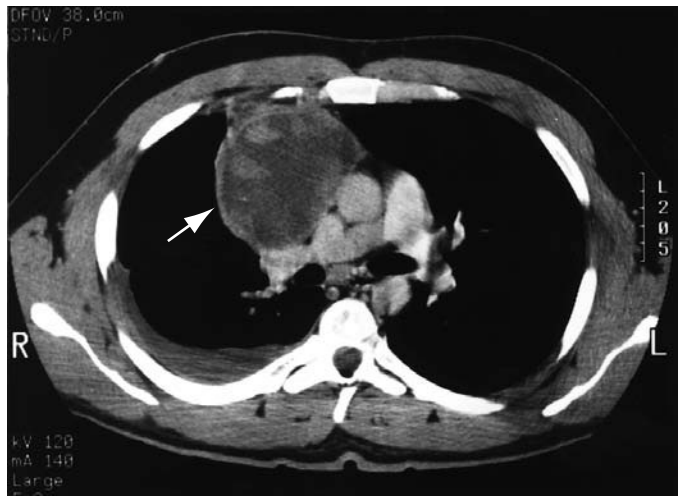

FIGURE 235-1 CT scan demonstrating a mediastinal mass of heterogeneous density (*arrow*). CT is superior to plain radiography for the detection of abnormal mediastinal densities and the distinction of masses from adjacent vascular structures.

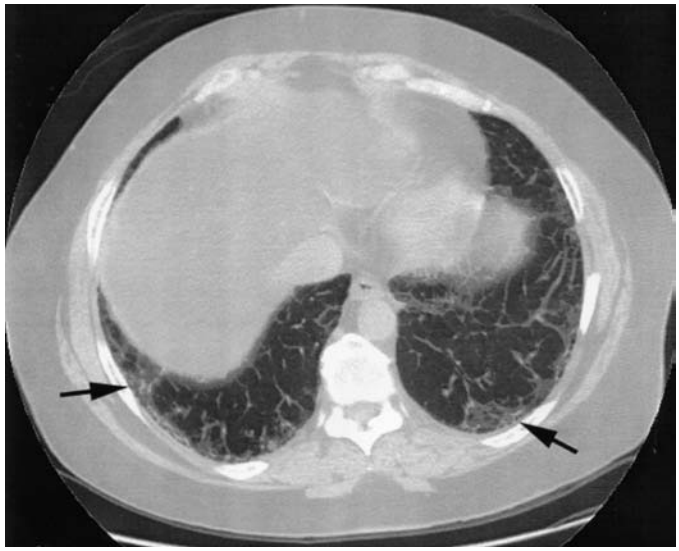

FIGURE 235-2 High-resolution CT scan from a patient with idiopathic pulmonary fibrosis. There are scattered reticular densities (arrows point to examples) that are especially prominent at the periphery of the lungs. This particular cross-section is from the base of the lungs, where the findings in idiopathic pulmonary fibrosis tend to be most marked.

clear in what settings these patterns obviate the need for obtaining lung tissue.

Recent advances in computer processing of the data acquired by helical scanning have allowed images to be presented in novel ways. For example, images may be displayed in views and planes other than the traditional cross-sectional view, and sophisticated three-dimensional reconstructions produce images (called *virtual bronchoscopy*) that mimic those seen by direct visualization through a bronchoscope.

MAGNETIC RESONANCE IMAGING The role of magnetic resonance (MR) imaging in the evaluation of respiratory system disease is less well defined than that of CT. Because MR generally provides a less detailed view of the pulmonary parenchyma as well as poorer spatial resolution, its usefulness in the evaluation of parenchymal lung disease is limited at present. However, MR images can be reconstructed in sagittal and coronal as well as transverse planes, so that the technique is well suited for imaging abnormalities near the lung apex, the spine, and the thoracoabdominal junction. MR images are dependent on tissue characteristics other than tissue density, unlike CT scanning. Therefore, in selected circumstances, MR images can better suggest the nature of abnormal tissue than can density-determined CT images. Finally, MR can be used to evaluate cardiac and vascular pathology within the thorax and to distinguish vascular from nonvascular structures without the need for contrast. Flowing blood does not produce a signal on MR imaging, so vessels appear as hollow tubular structures. This feature can be useful in determining whether abnormal hilar or mediastinal densities are vascular in origin and in defining aortic lesions such as aneurysms or dissection. In addition, gadolinium can be used as an intravascular contrast agent for MR angiography.

SCINTIGRAPHIC IMAGING Radioactive isotopes, administered by either intravenous or inhaled routes, allow the lungs to be imaged with a gamma camera. The most common use of such imaging is ventilation-perfusion lung scanning performed for evaluation of pulmonary embolism. When injected intravenously, albumin macroaggregates labeled with technetium 99m become lodged in pulmonary capillaries; therefore, the distribution of the trapped radioisotope follows the distribution of blood flow. When inhaled, radiolabeled xenon gas can be used to demonstrate the distribution of ventilation. For example, pulmonary thromboembolism usually produces one or more regions of ventilation-perfusion mismatch—that is, regions in which there is a defect in perfusion that follows the distribution of a vessel and that is not accompanied by a corresponding defect in ventilation (Chap. 244). Another common use of such radioisotope scans is in a patient with impaired lung function who is being considered for lung resection. The distribution of the isotope(s) can be used to assess the regional distribution of blood flow and ventilation, allowing the physician to estimate the level of postoperative lung function.

POSITRON EMISSION TOMOGRAPHIC SCANNING Positron emission tomographic (PET) scanning is increasingly being used to identify malignant lesions in the lung based on their increased uptake and metabolism of glucose. The technique involves injection of a radiolabeled glucose analogue, ^{18}F-fluoro-2-deoxyglucose (FDG), which is taken up by metabolically active malignant cells. However, FDG is trapped within the cell following phosphorylation, and the unstable fluorine 18 decays by emission of positrons, which can be detected by a specialized PET camera or by a gamma camera that has been adapted for imaging of positron-emitting radionuclides. This technique has been used in the evaluation of solitary pulmonary nodules and as an aid to staging lung cancer, through identification of mediastinal lymph node involvement by malignancy.

PULMONARY ANGIOGRAPHY The pulmonary arterial system can be visualized by pulmonary angiography, in which radiopaque contrast medium is injected through a catheter previously threaded into the pulmonary artery. When performed in cases of pulmonary embolism, pulmonary angiography demonstrates the consequences of an intravascular clot—either a defect in the lumen of a vessel (a "filling defect") or an abrupt termination ("cutoff") of the vessel. Other, less common indications for pulmonary angiography include visualization of a suspected pulmonary arteriovenous malformation and assessment of pulmonary arterial invasion by a neoplasm. However, with advances in CT scanning, traditional pulmonary angiography is increasingly being replaced by CT angiography. The latter allows rapid acquisition of images with a less invasive procedure, since the radiocontrast material is injected intravenously rather than into a pulmonary artery.

ULTRASOUND Because ultrasound energy is rapidly dissipated in air, ultrasound imaging is not useful for evaluation of the pulmonary parenchyma. However, it is helpful in the detection and localization of pleural abnormalities and is often used as a guide to placement of a needle for sampling of pleural liquid (i.e., for thoracentesis).

TECHNIQUES FOR OBTAINING BIOLOGIC SPECIMENS

COLLECTION OF SPUTUM Sputum can be collected either by spontaneous expectoration or after inhalation of an irritating aerosol, such as hypertonic saline. The latter method, called *sputum induction*, is commonly used to obtain sputum for diagnostic studies, either because sputum is not spontaneously being produced or because of an expected higher yield of certain types of findings. Knowledge of the appearance and quality of the sputum specimen obtained is especially important when one is interested in Gram's staining and culture. Because sputum consists mainly of secretions from the tracheobronchial tree rather than the upper airway, the finding of alveolar macrophages and other inflammatory cells is consistent with a lower respiratory tract origin of the sample, whereas the presence of squamous epithelial cells in a "sputum" sample indicates contamination by secretions from the upper airways.

Besides processing for routine bacterial pathogens by Gram's staining and culture, sputum can be processed for a variety of other pathogens, including staining and culture for mycobacteria or fungi, culture for viruses, and staining for *Pneumocystis carinii*. In the specific case of sputum obtained for evaluation of *P. carinii* pneumonia in a patient infected with HIV, for example, sputum should be collected by induction, rather than spontaneous expectoration, and an immunofluorescent stain should be used to detect the organisms. Cytologic staining of sputum for malignant cells, using the traditional Papanicolaou method, allows noninvasive evaluation for suspected lung cancer. Traditional stains and cultures are now also being supplemented in some

cases by immunologic techniques and by molecular biologic methods, including the use of polymerase chain reaction amplification and DNA probes.

PERCUTANEOUS NEEDLE ASPIRATION A needle can be inserted through the chest wall into a pulmonary lesion for the purpose of aspirating material for analysis by cytologic or microbiologic techniques. The procedure is usually carried out under CT guidance, which assists in the positioning of the needle and assures that it is localized in the lesion. Although the potential risks of this procedure include intrapulmonary bleeding and creation of a pneumothorax with collapse of the underlying lung, the low risk of complication in experienced hands is usually worth the information obtained. However, a limitation of the technique is sampling error due to the small amount of material obtained. Thus, findings other than a specific cytologic or microbiologic diagnosis are of limited clinical value.

THORACENTESIS Sampling of pleural liquid by thoracentesis is commonly performed for diagnostic purposes or, in the case of a large effusion, for palliation of dyspnea. Diagnostic sampling, either by blind needle aspiration or after localization by ultrasound, allows the collection of liquid for microbiologic and cytologic studies. Analysis of the fluid obtained for its cellular composition and chemical constituents, including glucose, protein, and lactate dehydrogenase, allows the effusion to be classified as either exudative or transudative (Chap. 245).

BRONCHOSCOPY Bronchoscopy is the process of direct visualization of the tracheobronchial tree. Although bronchoscopy is now performed almost exclusively with flexible fiberoptic instruments, rigid bronchoscopy, generally performed in an operating room on a patient under general anesthesia, still has a role in selected circumstances, primarily because of a larger suction channel and the fact that the patient can be ventilated through the bronchoscope channel. These situations include the retrieval of a foreign body and the suctioning of a massive hemorrhage, for which the small suction channel of the bronchoscope may be insufficient.

Flexible Fiberoptic Bronchoscopy This is an outpatient procedure that is usually performed in an awake but sedated patient. The bronchoscope is passed through either the mouth or the nose, between the vocal cords, and into the trachea. The ability to flex the scope makes it possible to visualize virtually all airways to the level of subsegmental bronchi. The bronchoscopist is able to identify endobronchial pathology, including tumors, granulomas, bronchitis, foreign bodies, and sites of bleeding. Samples from airway lesions can be taken by several methods, including washing, brushing, and biopsy. Washing involves instillation of sterile saline through a channel of the bronchoscope and onto the surface of a lesion. A portion of the liquid is collected by suctioning through the bronchoscope, and the recovered material can be analyzed for cells (cytology) or organisms (by standard stains and cultures). Brushing or biopsy of the surface of the lesion, using a small brush or biopsy forceps at the end of a long cable inserted through a channel of the bronchoscope, allows recovery of cellular material or tissue for analysis by standard cytologic and histopathologic methods.

The bronchoscope can be used to sample material not only from the regions that can be directly visualized (i.e., the airways) but also from the more distal pulmonary parenchyma. With the bronchoscope wedged into a subsegmental airway, aliquots of sterile saline can be instilled through the scope, allowing sampling of cells and organisms even from alveolar spaces. This procedure, called *bronchoalveolar lavage*, has been particularly useful for the recovery of organisms such as *P. carinii* in patients with HIV infection.

Brushing and biopsy of the distal lung parenchyma can also be performed with the same instruments that are used for endobronchial sampling. These instruments can be passed through the scope into small airways, where they penetrate the airway wall, allowing biopsy of peribronchial alveolar tissue. This procedure, called *transbronchial biopsy*, is used when there is either relatively diffuse disease or a localized lesion of adequate size. With the aid of fluoroscopic imaging, the bronchoscopist is able to determine not only whether and when the instrument is in the area of abnormality, but also the proximity of the instrument to the pleural surface. If the forceps are too close to the pleural surface, there is a risk of violating the visceral pleura and creating a pneumothorax; the other potential complication of transbronchial biopsy is pulmonary hemorrhage. The incidence of these complications is less than several percent.

Another procedure involves use of a hollow-bore needle passed through the bronchoscope for sampling of tissue adjacent to the trachea or a large bronchus. The needle is passed through the airway wall, and cellular material can be aspirated from mass lesions or enlarged lymph nodes, generally in a search for malignant cells. This procedure can facilitate the staging of lung cancer by identifying mediastinal lymph node involvement and in some cases obviates the need for a more invasive procedure. Other new techniques that are not yet widely available include fluorescence bronchoscopy (to detect early endobronchial malignancy) and endobronchial ultrasound (to identify and localize mediastinal pathology).

The bronchoscope may provide the opportunity for treatment as well as diagnosis. For example, an aspirated foreign body may be retrieved with an instrument passed through the scope, and bleeding may be controlled with a balloon catheter similarly introduced. Newer interventional techniques performed through a bronchoscope include methods for achieving and maintaining patency of airways that are partially or completely occluded, especially by tumors. These techniques include laser therapy, cryotherapy, electrocautery, and stent placement.

VIDEO-ASSISTED THORACIC SURGERY Recent advances in video technology have allowed the development of thoracoscopy, or video-assisted thoracic surgery (VATS), for the diagnosis and management of pleural as well as parenchymal lung disease. This procedure involves the passage of a rigid scope with a distal lens through a trocar inserted into the pleura. A high-quality image is shown on a monitor screen, allowing the operator to manipulate instruments passed into the pleural space through separate small intercostal incisions. With these instruments, the operator can biopsy lesions of the pleura under direct vision. In addition, this procedure is now used commonly to biopsy peripheral lung tissue or to remove peripheral nodules, for both diagnostic and therapeutic purposes. Because this procedure is much less invasive than the traditional thoracotomy performed for lung biopsy, it has largely supplanted "open lung biopsy."

THORACOTOMY Although frequently replaced by VATS, thoracotomy remains an option for the diagnostic sampling of lung tissue. It provides the largest amount of material, and it can be used to biopsy and/or excise lesions that are too deep or too close to vital structures for removal by VATS. The choice between VATS and thoracotomy needs to be made on a case-by-case basis, and the relative indications for each are still evolving as more experience is being gained with VATS.

MEDIASTINOSCOPY AND MEDIASTINOTOMY Tissue biopsy is often critical for the diagnosis of mediastinal masses or enlarged mediastinal lymph nodes. Although CT and PET scanning are useful for determining the size and nature of mediastinal lymph nodes as part of the staging of lung cancer, confirmation that enlarged lymph nodes are actually involved with tumor generally requires biopsy and histopathologic examination. The two major procedures used to obtain specimens from masses or nodes in the mediastinum are mediastinoscopy (via a suprasternal approach) and mediastinotomy (via a parasternal approach). Both procedures are performed under general anesthesia by a qualified surgeon. In the case of suprasternal mediastinoscopy, a rigid mediastinoscope is inserted at the suprasternal notch and passed into the mediastinum along a pathway just anterior to the trachea. Tissue can be obtained with biopsy forceps passed through the scope, sampling masses or nodes that are in a paratracheal or pretracheal position. Left paratracheal and aortopulmonary lymph nodes are not accessible by this route and thus are commonly sampled by parasternal mediasti-

notomy (the Chamberlain procedure). This approach involves either a right or left parasternal incision and dissection directly down to a mass or node that requires biopsy.

236 ASTHMA

E. R. McFadden, Jr.

Asthma is defined as a chronic inflammatory disease of airways that is characterized by increased responsiveness of the tracheobronchial tree to a multiplicity of stimuli. It is manifested physiologically by a widespread narrowing of the air passages, which may be relieved spontaneously or as a result of therapy, and clinically by paroxysms of dyspnea, cough, and wheezing. Asthma is an episodic disease, with acute exacerbations interspersed with symptom-free periods. Typically, most attacks are short-lived, lasting minutes to hours, and clinically the patient seems to recover completely after an attack. However, there can be a phase in which the patient experiences some degree of airway obstruction daily. This phase can be mild, with or without superimposed severe episodes, or much more serious, with severe obstruction persisting for days or weeks; the latter condition is known as *status asthmaticus*. In unusual circumstances, acute episodes can cause death.

PREVALENCE AND ETIOLOGY Asthma is a very common disease with immense social impact. The prevalence of asthma is rising in many parts of the world, but it is unclear whether this is due to an actual increase in incidence or merely to the fact that the size of the overall population is growing. It is estimated that 4 to 5% of the population of the United States is affected. Data from the Centers for Disease Control and Prevention suggest that 10 to 11 million persons had acute attacks in 1998, which resulted in 13.9 million outpatient visits, 2 million requests for urgent care, and 423,000 hospitalizations, with a total cost >$6 billion. The impact of the disease appears to fall more heavily on minorities and inner-city African-American and Hispanic persons.

Bronchial asthma occurs at all ages but predominantly in early life. About one-half of cases develop before age 10, and another third occur before age 40. In childhood, there is a 2:1 male/female preponderance, but the sex ratio equalizes by age 30. From an etiologic standpoint, asthma is a heterogeneous disease and genetic (atopic) and environmental factors, such as viruses, occupational exposures, and allergens, contribute to its initiation and continuance.

Atopy is the single largest risk factor for the development of asthma. *Allergic asthma* is often associated with a personal and/or family history of allergic diseases such as rhinitis, urticaria, and eczema; with positive wheal-and-flare skin reactions to intradermal injection of extracts of airborne antigens; with increased levels of IgE in the serum; and/or with a positive response to provocation tests involving the inhalation of specific antigen.

A significant fraction of patients with asthma present with no personal or family history of allergy, with negative skin tests, and with normal serum levels of IgE, and therefore have disease that cannot be classified on the basis of currently defined immunologic mechanisms. These patients are said to have *idiosyncratic asthma* or *nonatopic asthma*. Many patients have disease that does not fit clearly into either of the preceding categories but instead falls into a mixed group with features of each. In general, asthma that has its onset in early life tends to have a strong allergic component, whereas asthma that develops late tends to be nonallergic or to have a mixed etiology.

PATHOGENESIS (See also Chap. 298) Asthma results from a state of persistent subacute inflammation of the airways. Even in asymptomatic patients, the airways can be edematous and infiltrated with eosinophils, neutrophils, and lymphocytes, with or without an increase in the collagen content of the epithelial basement membrane. Overall, there is a generalized increase in cellularity associated with an elevated capillary density. There may also be glandular hypertrophy and denudation of the epithelium. These changes may persist despite treatment and often do not relate to the severity of the disease.

The physiologic and clinical features of asthma derive from an interaction among the resident and infiltrating inflammatory cells in the airway surface epithelium, inflammatory mediators, and cytokines. The cells thought to play important parts in the inflammatory response are mast cells, eosinophils, lymphocytes, and airway epithelial cells. The roles of neutrophils, macrophages, and other cellular constituents of the airways are less well defined. Each of the major cell types can contribute mediators and cytokines to initiate and amplify both acute inflammation and the long-term pathologic changes described (Fig. 236-1). The mediators released produce an intense, immediate inflammatory reaction involving bronchoconstriction, vascular congestion, edema formation, increased mucus production, and impaired mucociliary transport. This intense local event can then be followed by a more chronic one. Other elaborated chemotactic factors (eosinophil and neutrophil chemotactic factors of anaphylaxis and leukotriene B_4) also bring eosinophils, platelets, and polymorphonuclear leukocytes to the site of the reaction. The airway epithelium is both the target of, and a contributor to, the inflammatory cascade. This tissue both amplifies bronchoconstriction and promotes vasodilatation through the release of the compounds shown in Fig. 236-2.

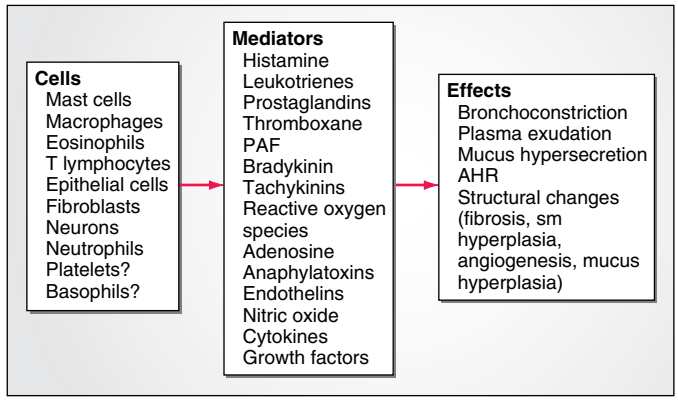

FIGURE 236-1 Cellular sources of inflammatory mediators and their physiologic effects. PAF, platelet-activating factor; AHR, antihyaluronidase reaction. [*From PJ Barnes, in E Middleton et al (eds): Allergy Principles and Practice, 5th ed. St. Louis, Mosby, 1998, with permission.*]

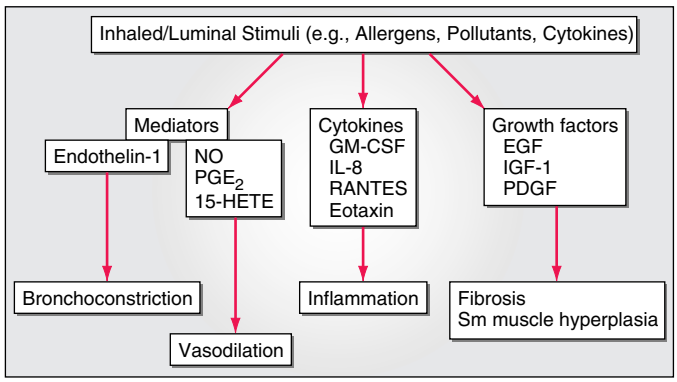

FIGURE 236-2 Inflammatory mediators derived from epithelial sources. [*From PJ Barnes, in E Middleton et al (eds): Allergy Principles and Practice, 5th ed. St. Louis, Mosby, 1998, with permission.*]

The eosinophil appears to play an important part in the infiltrative component. Interleukin (IL) 5 stimulates the release of these cells into the circulation and extends their survival. Once activated, these cells are a rich source of leukotrienes, and the granular proteins released (major basic protein and eosinophilic cationic protein) and oxygen-derived free radicals are capable of destroying the airway epithelium, which then is sloughed into the bronchial lumen in the form of Creola bodies. Besides resulting in a loss of barrier and secretory function, such damage elicits the production of chemotactic cytokines, leading to further inflammation. In theory, it can also expose sensory nerve endings, thus initiating neurogenic inflammatory pathways. That, in turn, could convert a primary local event into a generalized reaction via a reflex mechanism. Although an important element in inflammation, the role that the eosinophil plays in establishing and maintaining airway hyperresponsiveness is undergoing reevaluation. Studies using antibodies against IL-5 show a disassociation between the inflammatory and physiologic events following an antigen challenge and blood and sputum eosinophilia. The cytokine network possibly involved in asthma is shown in Fig. 236-3.

T lymphocytes also appear to be important in the inflammatory response. Activated T_H2 cells are present in increased numbers in asthmatic airways and produce cytokines such as IL-4 that initiate humoral (IgE) immune responses. They also elaborate IL-5 with its effect on eosinophils. Data are accumulating that asthma may be related to an imbalance between T_H1 and T_H2 immune responses, but firm conclusions are not yet available.

GENETIC CONSIDERATIONS Although there is little doubt that asthma has a strong familial component, the identification of the genetic mechanisms underlying the illness has proven difficult for such fundamental reasons as a lack of uniform agreement on the definition of the disease, the inability to define a single phenotype, non-Mendelian modes of inheritance, and an incomplete understanding of how environmental factors modify genetic expression. Screening families for candidate genes has identified multiple chromosomal regions that relate to atopy, elevated IgE levels, and airway hyperresponsiveness. Evidence for genetic linkage of high total serum IgE levels and atopy has been observed on chromosomes 5q, 11q, and 12q in a number of populations scattered throughout the world. Regions of the genome demonstrating evidence for linkage to bronchial hyperreactivity also typically show evidence for linkage to elevated total serum IgE levels. Excellent candidate genes exist for specific abnormalities in asthma within the regions that were identified in the linkage studies. For example, chromosome 5q contains cytokine clusters including IL-4, IL-5, IL-9, and IL-13. Other regions on chromosome 5q also contain the β-adrenergic receptors and the glucocorticoid receptors. Chromosome 6p contains regions that are important in antigen presentation and mediation of the inflammatory response. Chromosome 12q contains two genes that could influence atopy and airway hyperresponsiveness, including nitric oxide synthase.

STIMULI THAT INCITE ASTHMA The stimuli that incite acute episodes of asthma can be grouped into seven major categories: allergenic, pharmacologic, environmental, occupational, infectious, exercise-related, and emotional.

Allergens Allergic asthma is dependent on an IgE response controlled by T and B lymphocytes and activated by the interaction of antigen with mast cell–bound IgE molecules. The airway epithelium and submucosa contain dendritic cells that capture and process antigen. After taking up an immunogen, these cells migrate to the local lymph nodes where they present the material to T cell receptors. In the appropriate genetic setting, the interaction of antigen with a naïve T cell T_HO in the presence of IL-4 leads to the differentiation of the cell to a T_H2 subset. This process not only helps facilitate the inflammation of asthma but also causes B lymphocytes to switch their antibody production from IgG and IgM to IgE.

Once synthesized and released by B cells, IgE circulates in the blood until it attaches to high-affinity receptors on mast cells and low-affinity receptors on basophils. Most of the allergens that provoke asthma are airborne, and to induce a state of sensitivity they must be reasonably abundant for considerable periods of time. Once sensitization has occurred, however, the patient can exhibit exquisite responsivity, so that minute amounts of the offending agent can produce significant exacerbations of the disease. Immune mechanisms appear to be causally related to the development of asthma in 25 to 35% of all cases and to be contributory in perhaps another third. Higher prev-

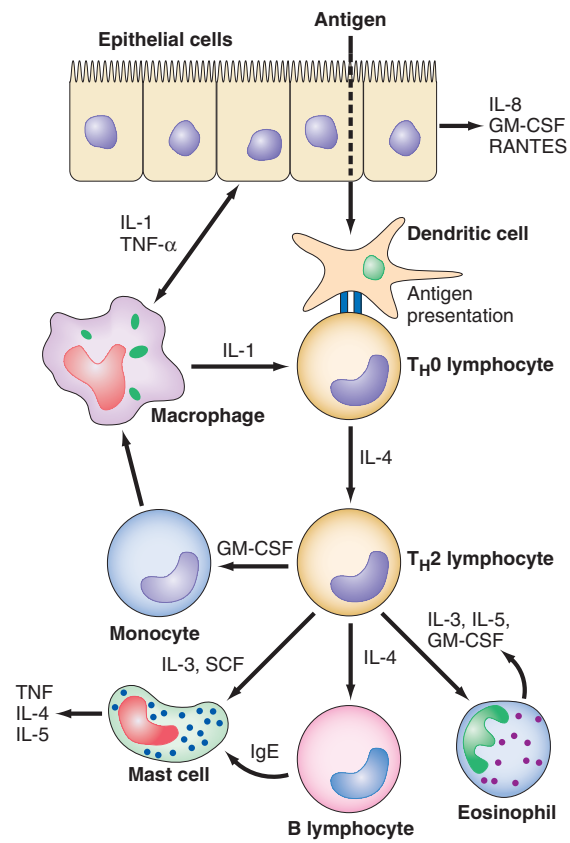

FIGURE 236-3 Cytokine network in allergic asthma. IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; RANTES, regulated on activation, T cell expressed and secreted; TNF, tumor necrosis factor; SCS, stem cell factor. [*From PJ Barnes, in E Middleton et al (eds): Allergy Principles and Practice, 5th ed. St. Louis, Mosby, 1998, with permission.*]

alences have been suggested, but it is difficult to know how to interpret the data because of confounding factors. Allergic asthma is frequently seasonal, and it is most often observed in children and young adults. A nonseasonal form may result from allergy to feathers, animal danders, dust mites, molds, and other environmental antigens that are present continuously. Exposure to antigen typically produces an immediate response in which airway obstruction develops in minutes and then resolves. In 30 to 50% of patients, a second wave of bronchoconstriction, the so-called late reaction, develops 6 to 10 h later. In a minority, only a late reaction occurs. It was formerly thought that the late reaction was essential to the development of the increase in airway reactivity that follows antigen exposure. This is now known not to be the case.

The mechanism by which an inhaled allergen provokes an acute episode of asthma depends in part on antigen-antibody interactions on the surface of pulmonary mast cells, with the subsequent generation and release of the mediators of immediate hypersensitivity. Current hypotheses hold that very small antigenic particles penetrate the lung's defenses and come in contact with mast cells that interdigitate with the epithelium at the luminal surface of the central airways. The subsequent elaboration of mediators and cytokines then produces the sequence outlined above.

Pharmacologic Stimuli The drugs most commonly associated with the induction of acute episodes of asthma are aspirin, coloring agents such as tartrazine, β-adrenergic antagonists, and sulfiting agents. It is important to recognize drug-induced bronchial narrowing because its presence is often associated with great morbidity. Furthermore, death sometimes has followed the ingestion of aspirin (or other nonsteroidal anti-inflammatory agents) or β-adrenergic antagonists. The typical aspirin-sensitive respiratory syndrome primarily affects adults, although the condition may occur in childhood. This problem usually begins with perennial vasomotor rhinitis that is followed by a hyperplastic rhinosinusitis with nasal polyps. Progressive asthma then appears. On exposure to even very small quantities of aspirin, affected individuals typically develop ocular and nasal congestion and acute, often severe episodes of airways obstruction.

The prevalence of aspirin sensitivity in patients with asthma varies from study to study, but many authorities feel that 10% is a reasonable figure. There is a great deal of cross-reactivity between aspirin and other nonsteroidal anti-inflammatory compounds that inhibit prostaglandin G/H synthase 1 (cyclooxygenase type 1). Indomethacin, fenoprofen, naproxen, zomepirac sodium, ibuprofen, mefenamic acid, and phenylbutazone are particularly important in this regard. However, acetaminophen, sodium salicylate, choline salicylate, salicylamide, and propoxyphene are well tolerated. The exact frequency of cross-reactivity to tartrazine and other dyes in aspirin-sensitive individuals with asthma is also controversial; again, 10% is the commonly accepted figure. This peculiar complication of aspirin-sensitive asthma is particularly insidious, however, in that tartrazine and other potentially troublesome dyes are widely present in the environment and may be unknowingly ingested by sensitive patients.

Patients with aspirin sensitivity can be desensitized by daily administration of the drug. After this form of therapy, cross-tolerance also develops to other nonsteroidal anti-inflammatory agents. The mechanism by which aspirin and other such drugs produce bronchospasm appears to be a chronic overexcretion of cysteinyl leukotrienes, which activate mast cells. The adverse reaction to aspirin can be inhibited with the use of leukotriene synthesis blockers or receptor antagonists.

β-Adrenergic antagonists regularly obstruct the airways in individuals with asthma as well as in others with heightened airway reactivity and should be avoided by such individuals. Even the selective beta_1 agents have this propensity, particularly at higher doses. In fact, the local use of beta_1 blockers in the eye for the treatment of glaucoma has been associated with worsening asthma.

Sulfiting agents, such as potassium metabisulfite, potassium and sodium bisulfite, sodium sulfite, and sulfur dioxide, which are widely used in the food and pharmaceutical industries as sanitizing and preserving agents, can also produce acute airway obstruction in sensitive individuals. Exposure usually follows ingestion of food or beverages containing these compounds, e.g., salads, fresh fruit, potatoes, shellfish, and wine. Exacerbation of asthma has been reported after the use of sulfite-containing topical ophthalmic solutions, intravenous glucocorticoids, and some inhalational bronchodilator solutions. The incidence and mechanism of action of this phenomenon are unknown. When suspected, the diagnosis can be confirmed by either oral or inhalational provocations.

Environment and Air Pollution (See also Chap. 238) Environmental causes of asthma are usually related to climatic conditions that promote the concentration of atmospheric pollutants and antigens. These conditions tend to develop in heavily industrial or densely populated urban areas and are frequently associated with thermal inversions or other situations creating stagnant air masses. In these circumstances, although the general population can develop respiratory symptoms, patients with asthma and other respiratory diseases tend to be more severely affected. The air pollutants known to have this effect are ozone, nitrogen dioxide, and sulfur dioxide. All produce greater effects during periods of high ventilation. In some regions of North America, seasonal concentrations of airborne antigens such as pollen can rise high enough to result in epidemics of asthma admissions to hospitals and an increase in the death rate. These events may be ameliorated by treating patients prophylactically with anti-inflammatory drugs before the allergy season begins.

Occupational Factors (See also Chap. 238) Occupation-related asthma is a significant health problem, and acute and chronic airway obstruction have been reported to follow exposure to a large number of compounds used in many types of industrial processes. In general, the agents can be classified into high-molecular-weight compounds, which are believed to induce asthma through immunologic mechanisms, and low-molecular-weight agents, which serve as haptines or can release bronchoconstrictor substances. High-molecular-weight compounds of importance are *wood and vegetable dusts* (e.g., those of oak, grain, flour, castor bean, green coffee bean, mako, gum acacia, karay, gum, and tragacanth), *pharmaceutical agents* (e.g., antibiotics, piperazine, and cimetidine), *biologic enzymes* (e.g., laundry detergents, pancreatic enzymes, and *Bacillus subtilis*), and *animal and insect dusts, serums, and secretions* (e.g., laboratory animals, chickens, crabs, prawns, oysters, flys, bees, and moths). Troublesome low-molecular-weight compounds are *metal salts* (e.g., platinum, chrome, vanadium, and nickel) and *industrial chemicals and plastics* (e.g., toluene diisocyanate, phthalic acid anhydride, trimellitic anhydride, persulfates, ethylenediamine, *p*-phenylenediamine, western red cedar, azidrocarbonamide, and various dyes). Formaldehyde and urea formaldehyde also fall into this group. It is important to recognize that exposure to sensitizing chemicals, particularly those used in paints, solvents, and plastics, can also occur during leisure or non-work-related activities.

If the occupational agent causes an immediate or dual immunologic reaction, the history is similar to that which occurs with exposure to other antigens. Often, however, patients will give a characteristic cyclic history. They are well when they arrive at work, and symptoms develop toward the end of the shift, progress after the work site is left, and then regress. Absence from work during weekends or vacations brings about remission. Frequently, there are similar symptoms in fellow employees.

Infections Respiratory infections are the most common of the stimuli that evoke acute exacerbations of asthma. Respiratory viruses and not bacteria or allergy to microorganisms are the major etiologic factors. In young children, the most important infectious agents are respiratory syncytial virus and parainfluenza virus. In older children and adults, rhinovirus and influenza virus predominate as pathogens. Simple colonization of the tracheobronchial tree is insufficient to evoke acute episodes of bronchospasm, and attacks of asthma occur only when

symptoms of an ongoing respiratory tract infection are, or have been, present. Viral infections can actively and chronically destabilize asthma, and they are perhaps the only stimuli that can produce constant symptoms for weeks. The mechanism by which viruses induce exacerbations of asthma may be related to the production of T cell–derived cytokines that potentiate the infiltration of inflammatory cells into already susceptible airways.

Exercise Exercise is a very common precipitant of acute episodes of asthma. This stimulus differs from other naturally occurring provocations, such as antigens, viral infections, and air pollutants, in that it does not evoke any long-term sequelae, nor does it increase airway reactivity. Typically the attacks follow exertion and do not occur during it. The critical variables that determine the severity of the postexertional airway obstruction are the levels of ventilation achieved and the temperature and humidity of the inspired air. The higher the ventilation and the lower the heat content of the air, the greater the response. For the same inspired air conditions, running produces a more severe attack of asthma than walking because of its greater ventilatory cost. Conversely, for a given task, the inhalation of cold air markedly enhances the response, while warm, humid air blunts or abolishes it. Consequently, activities such as ice hockey, cross-country skiing, and ice skating (high ventilations of cold air) are more provocative than is swimming in an indoor, heated pool (relatively low ventilation of humid air). The mechanism by which exercise produces obstruction may be related to a thermally produced hyperemia and capillary leakage in the airway wall.

Emotional Stress Psychological factors can worsen or ameliorate asthma. Changes in airway caliber seem to be mediated through modification of vagal efferent activity, but endorphins may also play a role. The extent to which psychological factors participate in the induction and/or continuation of any given acute exacerbation is not established but probably varies from patient to patient and in the same patient from episode to episode.

PATHOLOGY In a patient who has died of acute asthma, the most striking feature of the lungs at necropsy is their gross overdistention and failure to collapse when the pleural cavities are opened. When the lungs are cut, numerous gelatinous plugs of exudate are found in most of the bronchial branches down to the terminal bronchioles. Histologic examination shows hypertrophy of the bronchial smooth muscle, hyperplasia of mucosal and submucosal vessels, mucosal edema, denudation of the surface epithelium, pronounced thickening of the basement membrane, and eosinophilic infiltrates in the bronchial wall. There is an absence of any of the well-recognized forms of destructive emphysema.

PATHOPHYSIOLOGY The pathophysiologic hallmark of asthma is a reduction in airway diameter brought about by contraction of smooth muscle, vascular congestion, edema of the bronchial wall, and thick, tenacious secretions. The net result is an increase in airway resistance, a decrease in forced expiratory volumes and flow rates, hyperinflation of the lungs and thorax, increased work of breathing, alterations in respiratory muscle function, changes in elastic recoil, abnormal distribution of both ventilation and pulmonary blood flow with mismatched ratios, and altered arterial blood gas concentrations. Thus, although asthma is considered to be primarily a disease of airways, virtually all aspects of pulmonary function are compromised during an acute attack. In addition, in very symptomatic patients there frequently is electrocardiographic evidence of right ventricular hypertrophy and pulmonary hypertension. When a patient presents for therapy, the 1-s forced expiratory volume (FEV_1) or peak expiratory flow rate (PEFR) is typically $<40\%$ of predicted. In keeping with the alterations in mechanics, the associated air trapping is substantial. In acutely ill patients, residual volume frequently approaches 400% of normal, while functional residual capacity doubles.

Hypoxia is a universal finding during acute exacerbations, but frank ventilatory failure is relatively uncommon, being observed in 10 to 15% of patients presenting for therapy. Most individuals with asthma have hypocapnia and a respiratory alkalosis. In acutely ill patients, the finding of a normal arterial carbon dioxide tension tends to be associated with quite severe levels of obstruction. Consequently, when found in a symptomatic individual, it should be viewed as representing impending respiratory failure, and the patient should be treated accordingly. Equally, the presence of metabolic acidosis in the setting of acute asthma signifies severe obstruction. Cyanosis is a very late sign. Trying to judge the state of an acutely ill patient's ventilatory status on clinical grounds alone can be extremely hazardous, and clinical indicators should not be relied on with any confidence. Therefore, in patients with suspected alveolar hypoventilation, arterial blood gas tensions must be measured.

CLINICAL FEATURES The symptoms of asthma consist of a triad of dyspnea, cough, and wheezing, the last often being regarded as the sine qua non. In its most typical form, all three symptoms coexist. At the onset of an attack, patients experience a sense of constriction in the chest, often with a nonproductive cough. Respiration becomes audibly harsh; wheezing in both phases of respiration becomes prominent; expiration becomes prolonged; and patients frequently have tachypnea, tachycardia, and mild systolic hypertension. The lungs rapidly become overinflated, and the anteroposterior diameter of the thorax increases. If the attack is severe or prolonged, there may be a loss of adventitial breath sounds, and wheezing becomes very high pitched. Furthermore, the accessory muscles become visibly active, and a paradoxical pulse often develops. These two signs are extremely valuable in indicating the severity of the obstruction. In the presence of either, pulmonary function tends to be significantly more impaired than in their absence. It is important to note that the development of a paradoxical pulse depends on the generation of large negative intrathoracic pressures. Thus, if the patient's breathing is shallow, this sign and/or the use of accessory muscles could be absent even though obstruction is quite severe. The other signs and symptoms of asthma only imperfectly reflect the physiologic alterations that are present. Indeed, if the disappearance of subjective complaints or even of wheezing is used as the end point at which therapy for an acute attack is terminated, an enormous reservoir of residual disease will be missed.

The end of an episode is frequently marked by a cough that produces thick, stringy mucus, which often takes the form of casts of the distal airways (Curschmann's spirals) and, when examined microscopically, often shows eosinophils and Charcot-Leyden crystals. In extreme situations, wheezing may lessen markedly or even disappear, cough may become extremely ineffective, and the patient may begin a gasping type of respiratory pattern. These findings imply extensive mucus plugging and impending suffocation. Ventilatory assistance by mechanical means may be required. Atelectasis due to inspissated secretions occasionally occurs with asthmatic attacks. Spontaneous pneumothorax and/or pneumomediastinum occur but are rare.

Less typically, a patient with asthma may complain of intermittent episodes of nonproductive cough or exertional dyspnea. Unlike other individuals with asthma, when these patients are examined during symptomatic periods, they tend to have normal breath sounds but may wheeze after repeated forced exhalations and/or may show ventilatory impairments when tested in the laboratory. In the absence of both these signs, a bronchoprovocation test may be required to make the diagnosis.

DIFFERENTIAL DIAGNOSIS The differentiation of asthma from other diseases associated with dyspnea and wheezing is usually not difficult, particularly if the patient is seen during an acute episode. The physical findings and symptoms listed above and the history of periodic attacks are quite characteristic. A personal or family history of allergic diseases such as eczema, rhinitis, or urticaria is valuable contributory evidence. An extremely common feature of asthma is nocturnal awakening with dyspnea and/or wheezing. In fact, this phenomenon is so prevalent that its absence raises doubt about the diagnosis.

Upper airway obstruction by tumor or *laryngeal edema* can occa-

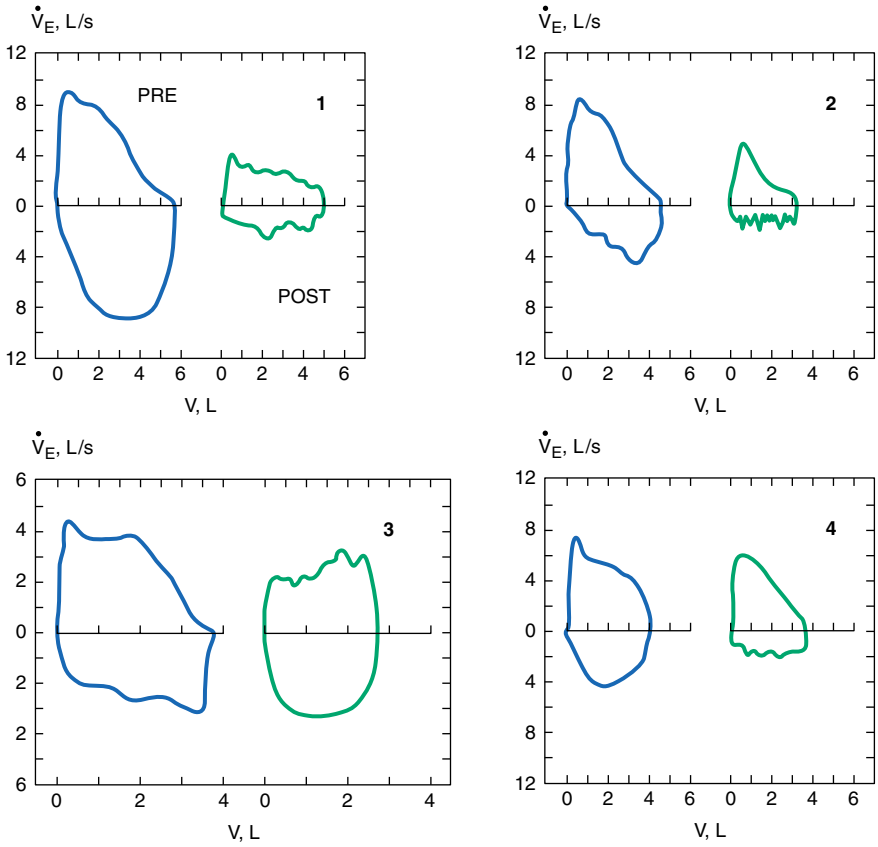

FIGURE 236-4 Representative examples of glottic dysfunction in four patients. The left-hand panels show normal flow-volume curves (blue). The right-hand panels (green) represent the development of glottic dysfunction after exercise challenges (green). Note the variable waveforms that can exist. When the patients' attacks ended, the post provocation flow-volume curves returned to normal. $\dot{V}_E$, ventilation; L/s, liters/second; V, L, lung volume in liters.

sionally be confused with asthma. Typically, a patient with such a condition will present with stridor, and the harsh respiratory sounds can be localized to the area of the trachea. Representative flow–volume curves are shown in Fig. 236-4. Diffuse wheezing throughout both lung fields is usually absent. However, differentiation can sometimes be difficult, and indirect laryngoscopy or bronchoscopy may be required. Asthma-like symptoms have been described in patients with glottic dysfunction. These individuals narrow their glottis during inspiration and expiration, producing episodic attacks of severe airway obstruction. Occasionally, carbon dioxide retention develops. However, unlike in asthma, the arterial oxygen tension is well preserved, and the alveolar-arterial gradient for oxygen narrows during the episode, instead of widening as with lower airway obstruction. To establish the diagnosis of glottic dysfunction, the glottis should be examined when the patient is symptomatic. Normal findings at such a time exclude the diagnosis; normal findings during asymptomatic periods do not.

Persistent wheezing localized to one area of the chest in association with paroxysms of coughing indicates *endobronchial disease* such as foreign-body aspiration, a neoplasm, or bronchial stenosis.

The signs and symptoms of *acute left ventricular failure* occasionally mimic asthma, but the findings of moist basilar rales, gallop rhythms, blood-tinged sputum, and other signs of heart failure (Chap. 216) allow the appropriate diagnosis to be reached.

Recurrent episodes of bronchospasm can occur with *carcinoid tumors* (Chap. 329), *recurrent pulmonary emboli* (Chap. 244), and *chronic bronchitis* (Chap. 242). In chronic bronchitis there are no true symptom-free periods, and one can usually obtain a history of chronic cough and sputum production as a background on which acute attacks of wheezing are superimposed. Recurrent emboli can be very difficult to separate from asthma. Frequently, patients with this condition present with episodes of breathlessness, particularly on exertion, and they sometimes wheeze. Lung scans may not be diagnostic because of the ventilation-perfusion abnormalities characteristic of asthma, and pulmonary angiography may be necessary to establish the correct diagnosis.

Eosinophilic pneumonias (Chap. 237) are often associated with asthmatic symptoms, as are various chemical pneumonias and exposures to insecticides and cholinergic drugs. Bronchospasm is occasionally a manifestation of *systemic vasculitis* with pulmonary involvement.

DIAGNOSIS The diagnosis of asthma is established by demonstrating reversible airway obstruction. *Reversibility* is traditionally defined as a ≥15% increase in FEV_1 after two puffs of a β-adrenergic agonist. When the spirometry results are normal at presentation, the diagnosis can be made by showing heightened airway responsiveness to challenges with histamine, methacholine, or isocapnic hyperventilation of cold air. Once the diagnosis is confirmed, the course of the illness and the effectiveness of therapy can be followed by measuring PEFRs at home and/or the FEV_1 in the office or laboratory. Positive wheal-and-flare reactions to skin tests can be demonstrated to various allergens, but such findings do not necessarily correlate with the intrapulmonary events. Sputum and blood eosinophilia and measurement of serum IgE levels are also helpful but are not specific for asthma. Chest roentgenograms showing hyperinflation are also nondiagnostic.

℞ TREATMENT

Elimination of the causative agent(s) from the environment of an allergic individual with asthma is the most successful means available for treating this condition (for details on avoidance, see Chap. 298). Desensitization or immunotherapy with extracts of the suspected allergens has enjoyed widespread favor, but controlled studies are limited and have not proved to be highly effective.

DRUG TREATMENT The available agents for treating asthma can be divided into two general categories: drugs that inhibit smooth-muscle contraction, i.e., the so-called "quick relief medications" (β-adrenergic agonists, methylxanthines, and anticholinergics) and agents that prevent and/or reverse inflammation, i.e., the "long-term control medications" (glucocorticoids, long-acting β_2-agonists, combined medications, mast cell–stabilizing agents, leukotriene modifiers, and methylxanthines (Table 236-1).

Quick Relief Medications ■ *ADRENERGIC STIMULANTS* The drugs in this category consist of the catecholamines, resorcinols, and saligenins. These agents produce airway dilation through stimulation of β-adrenergic receptors and activation of G proteins with the resultant formation of cyclic adenosine monophosphate (AMP). They also decrease release of mediators and improve mucociliary transport. The catecholamines (epinephrine, isoproterenol, and isoetharine) are short-acting (30 to 90 min) and are effective only when administered by inhalational or parenteral routes. Their use has been superceded by the longer acting selective β_2-agonists terbutaline, fenoterol (a resorsinol), and albuterol (a saligenin). The resorsinols and saligenins are highly selective for the respiratory tract and are virtually devoid of significant cardiac effects except at high doses.

Their major side effect is tremor. They are active by all routes of administration and are relatively long-lasting (4 to 6 h). Inhalation is the preferred route because it allows maximal bronchodilation with fewer side effects. In treating episodes of severe asthma, intravenous administration offers no advantages over the inhaled route.

Very long lasting compounds (salmeterol and formoterol) are available and provide sustained effects for 9 to 12 h (Table 236-1). They are particularly helpful for conditions such as nocturnal and exercise-induced asthma. Salmeterol is not recommended for the treatment of acute episodes because of its relatively slow onset of action (~30 min), nor is it intended as a rescue drug for breakthrough symptoms. In addition, its long half-life means that administration of extra doses can cause cumulative side effects. The limits to the use of formoterol are not yet fully established. These compounds are now thought of as long-term controller medications by some, presumably because of their anti-inflammatory activities. The clinical significance of this aspect of their pharmacology has yet to be completely elucidated.

TABLE 236-1 *Usual Dosages for Long-Term-Control Medications*

Medication	Dosage Form	Adult Dose
Inhaled glucocorticoids	*(See Table 236-2)*	
Systemic glucocorticoids	*(Applies to all three formulations)*	
Methylprednisolone	2-, 4-, 8-, 16-, 32-mg tablets	7.5–60 mg daily in a single dose in A.M. or qod as needed for control
Prednisolone	5-mg tablets, 5 mg/5 mL, 15 mg/5 mL	Short-course "burst" to achieve control: 40–60 mg/d as single or 2 divided doses for 3–10 days
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/mL, 5 mg/5 mL	
Long-acting inhaled β_2-agonists *(Should not be used for symptom relief or for exacerbations. Use with inhaled glucocorticoids.)*		
Salmeterol	MDI 21 μg/puff	2 puffs q 12 h
	DPI 50 μg/blister	1 blister q 12 h
Formoterol	DPI 12 μg/single-use capsule	1 capsule q 12 h
Combined medication		
Fluticasone/salmeterol	DPI 100, 250, or 500 μg/50 μg	1 inhalation bid; dose depends on severity of asthma
Cromolyn and Nedocromil		
Cromolyn	MDI 1 mg/puff	2–4 puffs tid-qid
	Nebulizer 20 mg/ampule	1 ampule tid-qid
Nedocromil	MDI 1.75 mg/puff	2–4 puffs bid-qid
Leukotriene modifiers		
Montelukast	4- or 5-mg chewable tablet, 10-mg tablet	10 mg qhs
Zafirlukast	10- or 20-mg tablet	40 mg daily (20-mg tablet bid)
Zileuton	300- or 600-mg tablet	2400 mg daily (given tablets qid)
Methylxanthines *[Serum monitoring is important (serum concentration of 5–15 μg/mL at steady state)].*		
Theophylline	Liquids, sustained-release tablets, and capsules	Starting dose 10 mg/kg per day up to 300 mg max; usual max, 800 mg/d

Note: MDI, metered-dose inhaler; DPI, daily permissible intake.

METHYLXANTHINES Theophylline and its various salts are medium-potency bronchodilators with questionable anti-inflammatory properties. The therapeutic plasma concentrations of theophylline lie between 5 and 15 μg/mL. The dose required to achieve the desired level varies widely from patient to patient owing to differences in the metabolism of the drug. Clearance falls with age and the concurrent use of erythromycin and other macrolide antibiotics, the quinolone antibiotics, and troleandomycin, allopurinol, cimetidine, and propranolol. It rises with use of cigarettes, marijuana, phenobarbital, phenytoin, or any other drug that is capable of inducing hepatic microsomal enzymes.

For maintenance therapy, long-acting theophylline compounds are available and are usually given once or twice daily. The dose is adjusted on the basis of the clinical response with the aid of serum theophylline measurements. Single-dose administration in the evening reduces nocturnal symptoms and helps keep the patient complaint-free during the day. However, the methylxanthines can disrupt sleep architecture. They are now considered second-line therapy, and as such they are rarely used in acute situations and infrequently in chronic ones. There is minimal evidence for additional benefit when used with optimal doses of β-adrenergics. There are some data that the methylxanthines can decrease inflammation, but as with the long-acting β_2-agonists, the effect is not large and its clinical impact is undefined. Nonetheless, some authorities now place these compounds in the "controller" class (Fig. 236-1). The most common side effects are nervousness, nausea, vomiting, anorexia, and headache. At plasma levels >30 μg/mL there is a risk of seizures and cardiac arrhythmias.

ANTICHOLINERGICS Anticholinergic drugs such as ipratropium bromide have been found to be both effective and free of untoward effects. They may be of particular benefit for patients with coexistent heart disease, in whom the use of methylxanthines and β-adrenergic stimulants may be dangerous. The major disadvantages of the anticholinergics are that they are slow to act (60 to 90 min may be required before peak bronchodilation is achieved) and they are of only modest potency.

Long-Term Controller Medications (Table 236-1) ■ *GLUCOCORTICOIDS* Glucocorticoids are the most potent and most effective anti-inflammatory medications available. Systemic or oral steroids are most beneficial in acute illness, when severe airway obstruction is not resolving or is worsening despite intense optimal bronchodilator therapy, and in chronic disease, when there has been failure of a previously optimal regimen with frequent recurrences of symptoms of increasing severity. Inhaled glucocorticoids are used in the long-term control of asthma.

Glucocorticoids are not bronchodilators, and the correct dose to use in acute situations is a matter of debate. In the United States, the recommended starting dose is 120 to 180 mg of methylprednisolone intravenously every 6 h. Since intravenous and oral administration produce the same effects, prednisone, 60 mg every 6 h, can be substituted. Clinical impressions suggest that smaller quantities may work as effectively, but there are no confirmatory data. In the United Kingdom and elsewhere, acute asthma both in and out of hospital is frequently treated with doses of prednisolone ranging from 30 to 40 mg given once daily. It should be emphasized that the effects of steroids in acute asthma are not immediate and may not be seen for ≥6 h after the initial administration. Consequently, it is mandatory to continue vigorous bronchodilator therapy during this interval.

Some believe that glucocorticoids should be given to all acutely ill patients upon presentation because of their long delay to peak effect. While there is some merit to this argument, glucocorticoids are often not necessary; the symptoms of ~80% of patients seen in emergency departments resolve rapidly with only inhaled β-agonists. Those who need steroids can be rapidly identified by monitoring their PEFR. Irrespective of the regimen chosen, it is important to appreciate that rapid tapering of glucocorticoids frequently results in recurrent obstruction. Most authorities recommend reducing the dose by one-half every third to fifth day, over 10 to 12 days, after an acute episode. Beyond this point, the drug can be abruptly stopped. In situations in which it appears that continued steroid therapy is needed, an alternate-day schedule should be instituted to minimize side effects. This is particularly important in children, since continuous glucocorticoid administration interrupts growth. Long-acting preparations such as dexamethasone should not be used in this approach, for they defeat the purpose of alternate-day schedules by causing prolonged suppression of the pituitary-adrenal axis. The availability of inhaled agents has all but eliminated the need for this form of therapy. The usual doses of

TABLE 236-2 *Comparative Daily Doses for Inhaled Steroids*

Drug	How Supplied	Dose Range		
		Low	Medium	High
Beclomethasone		168–540 μg	504–840 μg	>840 μg
	42 μg/puff	4–12 puffs	10–12 puffs	>20 puffs
	84 μg/puff	2–6 puffs	6–10 puffs	>10 puffs
Budesonide		200–400 μg	400–600 μg	>600 μg
	200 μg/dose	1–2 inhalations	2–3 inhalations	>3 inhalations
Flunisolide		500–1000 μg	1000–2000 μg	>2000 μg
	250 μg/dose	2–4 puffs	4–8 puffs	>8 puffs
Fluticasone		88–264 μg	264–660 μg	>660 μg
	MDI: 44,110, 220 μg/puff	2–6 puffs (44 μg) 2 puffs (110 μg)	2–6 puffs (110 μg)	>6 puffs (110 μg)
	DPI: 50,100, 250 μg/puff	2–6 inhalations (50 μg)	3–6 inhalations (100 μg)	>6 inhalations (100 μg)
Triamcinolone		400–1000 μg	1000–2000 μg	>2000 μg
	100 μg/puff	4–10 puffs	10–20 puffs	>20 puffs

Note: MDI, metered-dose inhaler; DPI, daily permissible intake.

oral glucocorticoids for nonemergent episodes of asthma are summarized in Table 236-1.

Inhaled Glucocorticoids These drugs are indicated in patients with persistent symptoms. The agents currently available in the United States and their comparative doses are presented in Table 236-2. These drugs share the ability to control inflammation, facilitate the long-term prevention of symptoms, reduce the need for oral glucocorticoids, minimize acute occurrences, and prevent hospitalizations.

There is no fixed dose of inhaled steroid that works for all patients. Requirements are dictated by the response of the individual and wax and wane in concert with progression of the disease. Generally, the worse the patient's condition, the more inhaled steroid is needed to gain control. Once achieved, however, remission can often be maintained with quantities as low as one or two puffs/day. Inhaled steroids can take up to a week or more to produce improvements; consequently, in rapidly deteriorating situations, it is best to prescribe oral preparations and initiate inhaled drugs as the dose of the former is reduced. In less emergent circumstances, the quantity of inhaled drug can be increased up to 2 to 2.5 times the recommended starting doses. The side effects increase in proportion to the dose-time product. In addition to thrush and dysphonia, the increased systemic absorption that accompanies larger doses of inhaled steroids has been reported to produce adrenal suppression, cataract formation, decreased growth in children, interference with bone metabolism, and purpura. As is the case with oral agents, suppression of inflammation, per se, cannot be relied upon to provide optimal results. It is essential to continue adrenergic or methylxanthine bronchodilators if the patient's disease is unstable. The combination of a long acting β-agonist and inhaled steroid seems particularly efficacious in patients with mild to moderate disease.

COMBINED MEDICATIONS The combination of an inhaled steroid and a long-acting β_2 agonist is gaining popularity. The only such combination available in the United States at present is fluticasone and salmeterol. Other combinations are being tested but are not yet available. There is little question that combinations of agents add a significant degree of convenience in the care of chronic asthma. They tend to work best in patients with milder disease. It has been suggested that the combination provides better pharmacologic activity than the individual drugs given alone.

MAST CELL–STABILIZING AGENTS Cromolyn sodium and nedocromil sodium do not influence airway tone. Their major therapeutic effect is to inhibit the degranulation of mast cells, thereby preventing the release of the chemical mediators of anaphylaxis.

Cromolyn sodium and nedocromil sodium, like the inhaled steroids, improve lung function, reduce symptoms, and lower airway reactivity in persons with asthma. They are most effective in atopic patients who have either seasonal disease or perennial airway stimulation. A therapeutic trial of two puffs four times daily for 4 to 6 weeks is frequently necessary before the beneficial effects of the drug appear. Unlike steroids, nedocromil and cromolyn sodium, when given prophylactically, block the acute obstructive effects of exposure to antigen, industrial chemicals, exercise, or cold air. With antigen, the late response is also abolished. Therefore, a patient who has intermittent exposure to either antigenic or nonantigenic stimuli that provoke acute episodes of asthma need not use these drugs continuously but instead can obtain protection by taking the drug only 15 to 20 min before contact with the precipitant.

LEUKOTRIENE MODIFIERS As mentioned earlier, the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4) produce many of the critical elements of asthma, and drugs have been developed that either reduce the synthesis of all of the leukotrienes by inhibiting 5-lipoxygenase (5-LO), the enzyme involved in their production, or competitively antagonize the principal moiety (LTD_4). Zileuton is the only 5-LO synthesis inhibitor that is available in the United States. It is a modest bronchodilator that reduces asthma morbidity, provides protection against exercise-induced asthma, and diminishes nocturnal symptoms, but it has limited effectiveness against allergens. Hepatic enzyme levels can be elevated after its use, and there are significant interactions with other drugs metabolized in the liver. The LTD_4 receptor antagonists (zafirlukast and montelukast) have therapeutic and toxicologic profiles similar to that of zileuton but are long acting and permit twice- to once-daily dose schedules.

This class of drugs does not appear to be uniformly effective in all patients with asthma. Although precise figures are lacking, most authorities put the number of positive responders at <50%. As yet, there is no way of determining prospectively who will benefit, so clinical trials are required. Typically, if there is no improvement after 1 month, treatment can be discontinued. The leukotriene blockers have been associated with uncovering of Churg-Strauss syndrome (Chap. 306).

Miscellaneous Agents It has been suggested that steroid-dependent patients might benefit from the use of immunosuppressant agents such as methotrexate, gold salts, or colchicine. The effects of these agents on steroid dosage and disease activity are minor, and side effects can be considerable. Opiates, sedatives, and tranquilizers should be absolutely avoided in the acutely ill patient with asthma because the risk of depressing alveolar ventilation is great, and respiratory arrest has been reported to occur shortly after their use. Admittedly, most individuals are anxious and frightened, but experience has shown that they can be calmed equally well by the physician's presence and reassurances. β-Adrenergic blockers and parasympathetic agonists are contraindicated because they can cause marked deterioration in lung function.

Expectorants and mucolytic agents have enjoyed great vogue in the past, but they do not add significantly to the treatment of the acute or chronic phases of this disease. The use of intravenous fluids in the treatment of acute asthma has also been advocated. There is little evidence that this adjunct hastens recovery. Nonstandard bronchodilators, such as intravenous magnesium sulfate, for the treatment of acute asthma attacks are not yet warranted in clinical practice because of the controversy surrounding their efficacy.

Special Instructions The treatment of patients with asthma who have coexisting conditions such as heart disease or pregnancy does not dif-

fer materially from that outlined above. Therapy with inhaled β_2-selective and anti-inflammatory agents is the mainstay. The lowest doses of adrenergics that produce the desired effects should be used.

Framework for Management ■ *EMERGENCY SITUATIONS* The most effective treatment for acute episodes of asthma requires a systematic approach based on the aggressive use of sympathomimetic agents and serial objective monitoring of key indices of improvement. Reliance on empiricism and subjective assessment is no longer acceptable. Multiple inhalations of a short-acting sympathomimetic, such as albuterol, are the cornerstone of most regimens. These drugs provide three to four times more relief than does intravenous aminophylline. Anticholinergic drugs are not first-line therapy because of their long lag time to onset (~30 to 40 min) and their relatively modest bronchodilator properties. In emergency situations, β_2-agonists can be given every 20 min by handheld nebulizer for 2 to 3 doses. The optimum cumulative dose of albuterol appears to lie between 5 and 10 mg. It does not matter how the adrenergic agonists are inhaled. Treatment with albuterol administered by jet nebulizer, metered dose inhaler, or dry powder inhaler all provide equal resolution in acute situations when the doses are matched. Continuous nebulization of β_2-agonists has also been employed, but it is unclear if it is materially better than the other forms of treatment. Ipratropium can be added to the regimen in an attempt to speed resolution. The benefits on lung function are small, but the need for admission has decreased in some studies. There are no hard and fast rules as to who should be admitted.

Acute episodes of bronchial asthma are one of the most common respiratory emergencies, and it is essential that the physician recognize which episodes of airway obstruction are life-threatening and which patients demand what level of care. These distinctions can be made readily by assessing selected clinical parameters in combination with measures of expiratory flow and gas exchange. The presence of a paradoxical pulse, use of accessory muscles, and marked hyperinflation of the thorax signify severe airways obstruction, and failure of these signs to remit promptly after aggressive therapy mandates objective monitoring of the patient with measurements of arterial blood gases and PEFR or FEV_1. Although pulse and respiratory rates are commonly recorded, there is no relationship between these variables and the severity of the obstruction or the outcome of treatment.

Patients with the most impairment typically require the most extensive therapy for resolution. If the PEFR or FEV_1 is ≤20% of predicted on presentation and does not double within an hour of receiving the preceding therapy, the patient is likely to require extensive treatment, including glucocorticoids, before the obstruction dissipates. This group represents ~20% of all the patients who present for acute care. They generally require inpatient treatment before becoming asymptomatic. In such patients, if the clinical signs of a paradoxical pulse and accessory muscle use are diminishing and/or the PEFR is increasing, there is no need to change medications or doses, but the patient needs to be followed closely. However, if the PEFR falls by >20% of its previous value or if the magnitude of the pulsus paradoxicus is increasing, serial measures of arterial blood gases are required, as well as a reconsideration of the therapeutic modalities being employed. If the patient has hypocarbia, one can afford to continue the current approaches a while longer. On the other hand, if the Pa_{CO_2} is within the normal range or is elevated, the patient should be monitored in an intensive care setting, and therapy should be intensified to reverse or arrest the patient's respiratory failure.

Treatment with 70 to 80% helium (balance oxygen) may be beneficial in patients with severe airway obstruction. This gas mixture reduces airway resistance and improves the effect of aerosolized bronchodilators. This form of treatment should be considered in patients whose airway obstruction and gas exchange are worsening despite aggressive therapy. However, there are no large-scale clinical trials comparing this approach with other forms of treatment. The criteria for intubation and ventilatory support have not been standardized. The decision to use this therapy should be made by physicians with the most experience in caring for severely ill asthmatic patients.

Chronic Treatment The goal of chronic therapy is to achieve a stable, asymptomatic state with the best pulmonary function possible using the least amount of medication. The specific recommmendations from consensus guidelines are to promote a state of health encompassing the following: (1) minimal or absent daytime or nocturnal chronic symptoms, (2) minimal or absent exacerbations, (3) no limitation on activities, (4) no absences from school or work, (5) maintenance of normal or near-normal pulmonary functions, (6) the minimal use of short-acting β_2-agonists (< once per day, <1 canister/month), (7) and minimal or absent adverse effects from medications. A primary step is to educate patients to function as partners in their management. The severity of the illness needs to be assessed and monitored with objective measures of lung function. Asthma triggers should be avoided or controlled, and plans should be made for both chronic management and treatment of exacerbations. Regular follow-up care is mandatory.

A stepwise pharmacologic approach recommended by the National Asthma Education and Prevention Program is presented in Table 236-3. The purpose of this schema is to assist and not replace the clinical decision-making required to meet individual patient needs. In general, the simplest approach works best. Infrequent symptoms (step 1) require only the use of an inhaled sympathomimetic on an "as-needed" basis. When the disease worsens to a persistent state (step 2), as manifested by nocturnal awakenings and daytime symptoms, inhaled steroids, mast cell–stabilizing agents, and/or leukotriene modifiers should be added. Methylxanthines can also be employed. If symptoms do not abate (step 3), the dose of inhaled steroids can be increased. An upper limit has not yet been established, but side effects of glucocorticoid excess begin to appear more frequently when the dose exceeds 2.0 mg/kg per d. Persistent asthma complaints can be treated with low- to medium-dose inhaled glucocorticoids and long-acting inhaled β_2-agonists. Alternative treatments include leukotriene modifiers or sustained-release theophylline. In patients with recurrent or perennial symptoms and unstable lung function (step 4), the preferred treatment is high-dose inhaled glucocorticoids and long-acting inhaled β_2-agonists. If needed, oral glucocorticoids in a single daily dose are added to the regimen. Acute symptoms are treated with short-acting rescue medications such as albuterol alone or in combination with a parasympatholytic.

Once control is reached and sustained for several weeks, a step-down reduction in therapy should be undertaken, beginning with the most toxic drug, to find the minimum amount of medication required to keep the patient well. During this process, the PEFR should be monitored and medication adjustments should be based on objective changes in lung function as well as on the patient's symptoms. The recommendations in the step-down mode are that treatment be reviewed every 1 to 6 months. In many instances, shorter periods can be employed. We have found that 2 to 4 weeks are a reasonable period. When a patient's asthma is destabilizing, frequent assessments are required. It is important to gain control as quickly as possible and then step down to the least medication necessary to maintain control. If there are difficulties in achieving this goal, then referral to an asthma specialist should be considered. Prior to increasing treatment, an important component is to review patients' inhaler technique, their adherence to therapeutic recommendations, and environment control.

PROGNOSIS AND CLINICAL COURSE The mortality rate from asthma is small. The most recent figures for the United States indicate fewer than 6000 deaths per year out of a population of ~10 million patients at risk. Death rates, however, appear to be rising in inner-city areas where there is limited availability of health care. Even so, only 0.09 to 0.25% of admissions to hospital are at risk of an untoward event.

Information on the clinical course of asthma suggests a good prognosis, particularly for those whose disease is mild and develops in childhood. The number of children who still have asthma 7 to 10 years after the initial diagnosis varies from 26 to 78%, averaging 46%; how-

TABLE 236-3 *Stepwise Approach for Managing Asthma in Adults*

Classify Severity: Clinical Features Before Treatment or Adequate Control

	Symptoms		PEFR or FEV_1 (PEFR Variability)	Daily Medications to Maintain Long-Term Control
	Day	Night		
Step 1: Mild intermittent	≤2 days/week	≤ 2 nights/month	≥80% (< 20%)	No daily medication needed. Severe exacerbations may occur, separated by long periods of normal lung function and no symptoms. A course of systemic glucocorticoids is recommended.
Step 2: Mild persistent	> 2 days/week but <1 per day	>2 nights/months	≥ 80% (20–30%)	Low-dose inhaled glucocorticoids Alternative treatment (listed alphabetically): cromolyn, leukotriene modifier, nedocromil, *or* sustained-release theophylline to serum concentration of 5–15 μg/mL.
Step 3: Moderate persistent	Daily	> 1 night/week	> 60%–< 80% (>30%)	Low- to medium-dose inhaled glucocorticoids and long-acting inhaled β_2-agonists. Alternative treatment: leukotriene modifier or theophylline instead of β_2 agents
Step 4: Severe persistent	Continual	Frequent	≤60% (> 30%)	High-dose inhaled glucocorticoids *and* Long-acting inhaled β_2-agonists *and*, if needed, Glucocorticoid tablets or syrup long term (2mg/kg per day, generally do not exceed 60 mg/d). (Make repeat attempts to reduce systemic glucocorticoids and maintain control with high-dose inhaled glucocorticoids.)
Quick relief for all patients	Short-acting bronchodilator: 2–4 puffs short-acting inhaled β_2-agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation; up to 3 treatments at 20-min intervals or a single nebulizer treatment as needed. Course of systemic glucocorticoids may be needed. Use of short-acting β_2-agonists >2 times a week in intermittent asthma (daily, or increasing use in persistent asthma) may indicate the need to initiate (increase) long-term control therapy.			

Note: PEFR, peak expiratory flow rate; FEV_1, forced expiratory volume in 1 s.

Source: Modified from National Asthma Education and Prevention Program.

ever, the percentage who continue to have severe disease is relatively low (6 to 19%).

Although there are reports of patients with asthma developing irreversible changes in lung function, these individuals frequently have comorbid stimuli such as cigarette smoking that could account for these findings. Even when untreated, individuals with asthma do not continuously move from mild to severe disease with time. Rather, their clinical course is characterized by exacerbations and remissions. Some studies suggest that spontaneous remissions occur in approximately 20% of those who develop the disease as adults, and that ~40% can be expected to experience improvement, with less frequent and severe attacks, as they grow older.

237 HYPERSENSITIVITY PNEUMONITIS AND PULMONARY INFILTRATES WITH EOSINOPHILIA

Joel N. Kline, Gary W. Hunninghake

HYPERSENSITIVITY PNEUMONITIS

First described in 1874, hypersensitivity pneumonitis (HP), or extrinsic allergic alveolitis, is an inflammatory disorder of the lung, involving alveolar walls and terminal airways, that is induced by repeated inhalation of a variety of organic agents by a susceptible host. Factors responsible for the expression of HP include both those related to the host (susceptibility) and the inciting agent. Causes of HP are typically designated with colorful names denoting the occupational or avocational risk associated with the disease; "farmer's lung" is the term most commonly used for HP due to inhalation of antigens present in moldy hay, such as thermophilic actinomyces, *Micropolyspora faeni*, and *Aspergillus* species. The frequency of HP is unknown but varies with the environmental exposure and the specific antigen involved. The prevalence of farmer's lung among Wisconsin dairy farmers has been reported as 4.2 per 1000 and a Finnish cohort study demonstrated an annual incidence of 5 per 10,000 farmers. The diagnosis of HP requires a constellation of clinical, radiographic, physiologic, pathologic, and immunologic criteria, each of which is rarely pathognomonic alone, and the preferred treatment is avoidance of the causative antigen.

ETIOLOGY Agents implicated as causes of HP are diverse and include those listed in Table 237-1. Many cases of HP occurring in various occupations involve exposure to similar agents, particularly the ther-

mophilic actinomycetes. In the United States, the most common types of HP are farmer's lung, bird fancier's lung, and chemical worker's lung. In *farmer's lung*, inhalation of proteins such as thermophilic bacteria and fungal spores that are present in moldy bedding and feed are most commonly responsible for the development of HP. These antigens are probably also responsible for the etiology of *mushroom worker's disease* (moldy composted growth medium is the source of the proteins) and *bagassosis* (moldy sugar cane is the source). *Bird fancier's lung* (and the related disorders of duck fever, turkey handler's lung, and dove pillow's lung) is a response to inhalation of proteins from feathers and droppings. *Chemical worker's lung* is an example of how simple chemicals, such as isocyanates, may also cause immune-mediated diseases. In this case, antihapten antibodies may be responsible for the development of HP. Although HP requires an immunologic response to the inciting agent, such a response alone does not ensure the development of disease. Environmental factors such as ambient humidity and temperature play an important role in the development of disease, as do the concentration, frequency, and duration of exposure as well as the nature and size of the antigen particles. In some cases, the responsible exposure environment (for example, metalworking fluid) may be identified without implicating a specific antigen. Finally, personal habits may alter the apperance and course of disease: smokers appear more likely to present with chronic rather than acute HP, suggesting that smoking may inhibit antibody production.

TABLE 237-1 *Selected Examples of Hypersensitivity Pneumonitis (HP)*

Disease	Antigen	Source of Antigen
Bagassosis	Thermophilic actinomycetes[a]	"Moldy" bagasse (sugar cane)
Bird fancier's, breeder's, or handler's lung[b]	Parakeet, pigeon, chicken, turkey proteins	Avian droppings or feathers
Cephalosporium HP	Contaminated basement (sewage)	*Cephalosporium*
Cheese washer's lung	*Penicillium casei*	Moldy cheese
Chemical worker's lung[a]	Isocyanates	Polyurethane foam, varnishes, lacquer
Coffee worker's lung	Coffee bean dust	Coffee beans
Compost lung	*Aspergillus*	Compost
Detergent worker's disease	*Bacillus subtilis* enzymes (subtilisins)	Detergent
Familial HP	*Bacillus subtilis*	Contaminated wood dust in walls
Farmer's lung[a]	Thermophilic actinomycetes[b]	"Moldy" hay, grain, silage
Fish food lung	Unknown	Fish food
Fish meal worker's lung	Fish meal dust	Fish meal
Furrier's lung	Animal fur dust	Animal pelts
Hot tub lung	*Cladosporium* sp.	Mold on ceiling
Humidifier or air-conditioner lung (ventilation pneumonitis)	*Aureobasidium pullulans*, *Candida albicans*, other microorganisms	Contaminated water in humidification or forced-air air-conditioning systems
Japanese summer-type HP	*Trichosporon cutaneum*, *asahii*, and *mucoides*	House dust? Bird droppings
Laboratory worker's HP	Male rat urine	Laboratory rat
Lycoperdonosis	*Lycoperdon* puffballs	Puffball spores
Malt worker's lung	*Aspergillus fumigatus* or *A. clavatus*	Moldy barley
Maple bark disease	*Cryptostroma corticale*	Maple bark
Miller's lung	*Sitophilus granarius* (wheat weevil)	Infested wheat flour
Miscellaneous medication	Amiodarone, bleomycin, efavrienz, hydralazine, hydroxyurea, iosoniazid, methotrexate, paclitaxel, penicillin, procarbazine, propanolol, sulfasalazine	Medication
Mushroom worker's lung	Thermophilic actinomycetes,[b] *Hypsizigus marmoreus*, others	Mushroom compost
Pituitary snuff taker's lung	Animal proteins	Heterologous pituitary snuff
Potato riddler's lung	Thermophilic actinomycetes,[a] *Aspergillus*	"Moldy" hay around potatoes
Sauna taker's lung	*Aureobasidium* sp., other	Contaminated sauna water
Sausage worker's lung	*Penicillium nalgiovense*	Dry sausage mold
Sequoiosis	*Aureobasidium*, *Graphium* sp.	Redwood sawdust
Streptomyces albus HP	*Streptomyces albus*	Contaminated fertilizer
Suberosis	Cork dust mold	Cork dust
Tap water lung	Unknown	Contaminated tap water
Thatched roof disease	*Sacchoromonospora viridis*	Dried grasses and leaves
Tobacco worker's disease	*Aspergillus* sp.	Mold on tobacco
Winegrower's lung	*Botrytis cinerea*	Mold on grapes
Wood trimmer's disease	*Rhizopus* sp., *Mucor* sp.	Contaminated wood trimmings
Woodman's disease	*Penicillium* sp.	Oak and maple trees
Woodworker's lung	Wood dust, *Alternaria*	Oak, cedar, pine, and mahogany dusts

[a] Thermophilic actinomycetes species include *Micropolyspora faeni*, *Thermoactinomyces vulgaris*, *T. saccharrii*, *T. viridis*, and *T. candidus*.
[b] Most common causes of hypersensitivity pneumonitis in the United States.

PATHOGENESIS The finding that precipitating antibodies against extracts of moldy hay were demonstrable in most patients with farmer's lung led to the early conclusion that HP was an immune complex–mediated reaction. Subsequent investigations of HP in human beings and animal models provided evidence for the importance of cell-mediated hypersensitivity. The very early (acute) reaction is characterized by an increase in polymorphonuclear leukocytes in the alveoli and small airways. This early lesion is followed by an influx of mononuclear cells into the lung and the formation of granulomas that appear to be the result of a classic delayed (T cell mediated) hypersensitivity reaction to repeated inhalation of antigen and adjuvant-active materials. Studies in animal models suggest that the disease is a T_H1-mediated immune response to antigen, with both interferon-α and interleukin (IL) 12 contributing to disease expression. Most likely, multiple cytokines [including also IL-1β, transforming growth factor (TGF) β, tumor necrosis factor (TNF) α and others] interact to promote HP; their source includes both alveolar macrophages and T lymphocytes in the lung. Observations support a genetic predisposition to the development of HP; certain polymorphisms of the TNF-α promoter region reportedly confer an enhanced susceptibility to pigeon breeder's disease.

The attraction and accumulation of inflammatory cells in the lung may be due to one or more of the following mechanisms: induction of the adhesion molecules L-selectin and E-selectin; elaboration by dendritic cells of CC chemokine 1 [dendritic cell–derived chemokine-1 (DC-CK-1)/cysteine-cysteine chemokine 18 (CCL18)]; and increased levels of Fas protein and FasL in the lung. Bronchoalveolar lavage (BAL) in patients with HP consistently demonstrates an increase in T lymphocytes in lavage fluid (a finding that is also observed in patients with other granulomatous lung disorders). Patients with recent or continual exposure to antigen may have an increase in polymorphonuclear leukocytes in lavage fluid; this has been associated with lung fibrosis. A role for oxidant injury has been proposed in HP, which is supported by the finding that BAL levels of the antioxidant glutathione are reduced following airway challenge in patients with HP, whereas they are increased in asymptomatic controls. In most patients examined during recovery from acute disease, the T lymphocytes in lavage fluid are predominantly the CD8+ T cell subset. In patients with very recent exposure to antigen, however, the numbers of CD4+ T cells may increase in lavage fluid. These observations and

others in animal models suggest that there is an active modulation of granuloma formation in the lung by immunoregulatory T cells and associated cytokines in this disorder.

CLINICAL PRESENTATION The clinical picture is that of an interstitial pneumonitis, which varies from patient to patient and seems related to the frequency and intensity of exposure to the causative antigen and perhaps other host factors. The presentation can be *acute*, *subacute*, or *chronic*. In the *acute form*, symptoms such as cough, fever, chills, malaise, and dyspnea may occur 6 to 8 h after exposure to the antigen and usually clear within a few days if there is no further exposure to antigen. The *subacute form* often appears insidiously over a period of weeks marked by cough and dyspnea and may progress to cyanosis and severe dyspnea requiring hospitalization. In some patients, a subacute form of the disease may persist after an acute presentation of the disorder, especially if there is continued exposure to antigen. In most patients with the acute or subacute form of HP, the symptoms, signs, and other manifestations of HP disappear within days, weeks, or months if the causative agent is no longer inhaled. Transformation to a chronic form of the disease may occur in patients with continued antigen exposure, but the frequency of such progression is uncertain. The *chronic form* of HP may be clinically indistinguishable from pulmonary fibrosis due to a wide variety of causes. Physical examination may reveal clubbing. This stage may progressively worsen, resulting in dependence on supplemental oxygen, pulmonary hypertension, and death from respiratory failure. An indolent, gradually progressive form of the disease can be associated with cough and exertional dyspnea without a prior history consistent with acute or subacute manifestations. Such a gradual onset frequently occurs with low-dose exposure to the antigen.

As strict definitions of acute, subacute, and chronic stages of hypersensitivity pneumonitis have not been generally agreed on, interpretation of epidemiologic and clinical studies can be difficult. Because of this, it has been proposed that hypersensitivity pneumonitis be described as recently diagnosed, recurrent or progressive, or residual disease. For these categories, required diagnostic criteria include the history of symptoms following an exposure to a putative HP agent and symptoms associated with re-exposure; compatible radiologic findings; if performed, lymphocytic alveolitis on BAL; and, if performed, compatible histopathology on biopsy. Supportive criteria include bibasilar crackles, diminished carbon monoxide diffusion capacity, and hypoxemia.

DIAGNOSIS Following acute exposure to antigen, neutrophilia and lymphopenia are frequently present. Eosinophilia is not a feature. All forms of the disease may be associated with elevations in erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, and serum immunoglobulins. Antinuclear antibodies are rarely present and appear to have no pathogenic role. Examination for *serum precipitins* against suspected antigens, such as those listed in Table 237-1, is an important part of the diagnostic workup and should be performed on any patient with interstitial lung disease, especially if a suggestive exposure history is elicited. If found, precipitins indicate sufficient exposure to the causative agent for generation of an immunologic response. The diagnosis of HP is not established solely by the presence of precipitins, however, as precipitins are found in sera of many individuals exposed to appropriate antigens who demonstrate no other evidence of HP. False-negative results may occur because of poor-quality antigens or an inappropriate choice of antigens. Extraction of antigens from the suspected source may at times be helpful.

Chest x-ray shows no specific or distinctive changes in HP. It can be normal even in symptomatic patients. The acute or subacute phase may be associated with poorly defined, patchy, or diffuse infiltrates or with discrete, nodular infiltrates. In the chronic phase, the chest x-ray usually shows a diffuse reticulonodular infiltrate. Honeycombing may eventually develop as the condition progresses. Apical sparing is common, suggesting that disease severity correlates with inhaled antigen load, but no particular distribution or pattern is classic for HP. Abnormalities rarely seen in HP include pleural effusion or thickening, and hilar adenopathy. High-resolution chest computed tomography (CT) has become the procedure of choice for imaging of HP, and a consensus is developing as to the typical appearance of the disease. Although pathognomonic features have not been identified, ground glass changes predominate in the lower lobes, especially in acute disease; this pattern is more common in workers whose exposure to antigen continues rather than those in whom removal from antigen exposure has occurred. Centrilobular nodules are also commonly seen. In chronic HP, patchy emphysema is seen more often than interstitial fibrosis, although neither predominates in the lower lobes; CT is far more sensitive than plain films at detecting these changes. Hilar or mediastinal adenopathy is not associated with HP, but its presence has no diagnostic significance (Fig. 237-1). Although not currently clinically used, *radionuclide studies* may have a role in the future diagnosis of HP: several case reports have inadvertently demonstrated rapid pulmonary uptake of radionuclides associated with a lymphocytic alveolitis in acute HP.

Pulmonary function studies in all forms of HP may show a restrictive or obstructive pattern with loss of lung volumes, impaired diffusion capacity, decreased compliance, and an exercise-induced hypoxemia. A resting hypoxemia may also be found. Bronchospasm and bronchial hyperreactivity are sometimes found in acute hypersensitivity pneumonitis. With antigen avoidance, the pulmonary function abnormalities are usually reversible, but they may gradually increase in severity or may occur rapidly following acute or subacute exposure to antigen.

Bronchoalveolar lavage is used in some centers to aid in diagnostic evaluation. A marked lymphocytic alveolitis on (BAL) is almost universal, although not pathognomonic. Lymphocytes typically have a decreased helper/suppressor ratio, and are activated. Alveolar neutrophilia is also prominent acutely, but tends to fade in the absence of recurrent exposure. Bronchoalveolar mastocytosis may correlate with disease activity. *Lung biopsy*, obtained through flexible bronchoscopy, open-lung procedures, or thoracoscopy, may be diagnostic. Although the histopathology is distinctive, it may not be pathognomonic of HP (Fig. 237-2). When the biopsy is taken during the active phase of disease, typical findings include an interstitial alveolar infiltrate consisting of plasma cells, lymphocytes, and occasional eosinophils and neutrophils, usually with accompanying loose, noncaseating peribronchial granulomas. Interstitial fibrosis may be present but most often is mild in earlier stages of the disease. Some degree of bronchiolitis is found in about half the cases, whereas vasculitis is not a feature of the

FIGURE 237-1 Chest CT scan of a case of acute hypersensitivity pneumonitis in which scattered regions of ground glass and nodular infiltrates are seen bilaterally. *(Courtesy of JS Wilson.)*

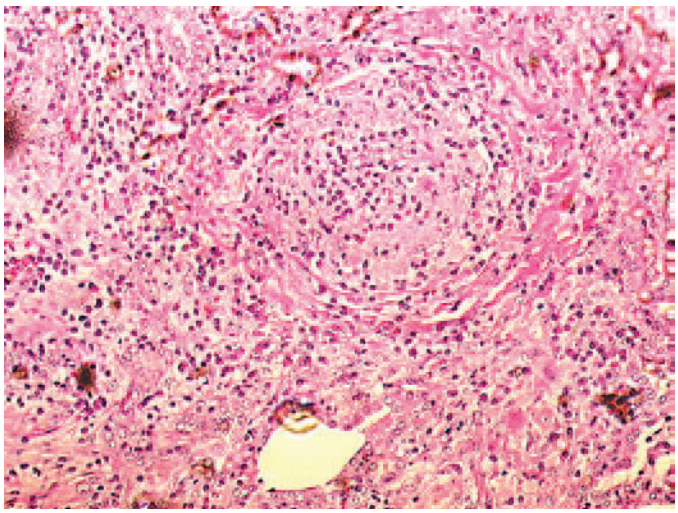

FIGURE 237-2 Open lung biopsy of a case of acute hypersensitivity pneumonitis demonstrating loose, nonnecrotizing granulomas and thickened interstitium with an associated interstitial inflammatory response. *(Courtesy of B DeYoung.)*

disorder. Rarely, bronchiolitis obliterans with organizing pneumonia (BOOP) can be seen. The triad of mononuclear bronchiolitis; interstitial infiltrates of lymphocytes and plasma cells; and single, nonnecrotizing, and randomly scattered parenchymal granulomas without mural vascular involvement is consistent with but not specific for HP.

Inhalation challenge studies have been described as useful to differentiate between HP and other interstitial lung diseases; a positive response to inhaled antigen may include fever, chills, dyspnea, diminished oxygen saturation, transient airflow obstruction, and peripheral and bronchoalveolar leukocytosis. These tests should be performed in a center that specializes in provocation testing for reasons of both safety and accuracy. Moreover, as the antigens used for provocation testing are not standardized, interpretation of these tests is difficult. In general, these tests may be used to support a diagnosis of HP, but they are not sufficiently accepted to either confirm or deny the diagnosis. The lack of standardized, nonirritating antigens and of proven controlled protocols makes *skin testing* useful only for research purposes. Similarly, in vitro tests of cell-mediated (delayed) hypersensitivity have not consistently been shown to correlate with clinical HP and have no place in the routine diagnostic workup.

In summary, the diagnosis in most cases is established by (1) consistent history, physical findings, pulmonary function tests, and chest x-ray; (2) exposure to a recognized antigen; and (3) finding an antibody to that antigen. In a few circumstances, (BAL) and/or lung biopsy may be needed. Provocation tests may be useful but are not essential. The most important tool in diagnosing HP may, in fact, be a high index of suspicion.

DIFFERENTIAL DIAGNOSIS Chronic HP may often be difficult to distinguish from a number of other interstitial lung disorders such as idiopathic pulmonary fibrosis, sarcoidosis, interstitial lung disease associated with a collagen vascular disorder, and drug-induced lung diseases. A negative history for use of relevant drugs and no evidence of a systemic disorder usually exclude the presence of drug-induced lung disease or a collagen vascular disorder. BAL often shows predominance of neutrophils in idiopathic pulmonary fibrosis and a predominance of CD4+ lymphocytes in sarcoidosis. Hilar/paratracheal lymphadenopathy or evidence of multisystern involvement also favors the diagnosis of sarcoidosis. In some patients, a lung biopsy may be required to differentiate chronic HP from other interstitial diseases. The lung disease associated with acute or subacute HP may clinically resemble other disorders that present with systemic symptoms and recurrent pulmonary infiltrates, including the allergic bronchopulmonary mycoses and other eosinophilic pneumonias.

Eosinophilic pneumonia is often associated with asthma and is typified by peripheral eosinophilia; neither of these is a feature of HP. Allergic bronchopulmonary aspergillosis (ABPA) is the most common example of the allergic bronchopulmonary mycoses and is sometimes confused with HP because of the presence of precipitating antibodies to *Aspergillus fumigatus*. ABPA is associated with allergic (atopic) asthma. Acute HP may be confused with *organic dust toxic syndrome* (ODTS), a condition that is more common than HP. ODTS follows heavy exposure to organic dusts and is characterized by transient fever and muscle aches, with or without dyspnea and cough. Serum precipitins are absent and the chest x-ray is usually normal. Studies have shown no immunologic basis for ODTS, and endotoxin is suspected to be involved in its pathogenesis. This distinction is important, as ODTS is a self-limited disorder without significant long-term sequelae, whereas continued antigen exposure in HP can result in permanent disability. Massive exposure to moldy silage may result in a syndrome termed *pulmonary mycotoxicosis*, with fever, chills, and cough and the presence of pulmonary infiltrates within a few hours of exposure. No previous sensitization is required, and precipitins are absent to *Aspergillus*, the suspected causative agent.

TREATMENT

Because effective treatment depends largely on avoiding the antigen, identification of the causative agent and its source is essential. This is usually possible if the physician takes a careful environmental and occupational history or, if necessary, visits the patient's environment. The simplest way to avoid the incriminated agent is to remove the patient from the environment or the source of the agent from the patient's environment. This recommendation cannot be taken lightly when it completely changes the lifestyle or livelihood of the patient. In many cases, however, the source of exposure (birds, humidifiers) can easily be removed. If occupational exposure is involved, an initial attempt can be made at antigen avoidance maneuvers least disruptive to the patient's livelihood, which usually means avoiding areas associated with heavy exposure and wearing an appropriate mask. This will not suffice for small-molecular-weight agents such as isocyanates, which require more elaborate respiratory systems. Pollen masks, personal dust respirators, airstream helmets, and ventilated helmets with a supply of fresh air are increasingly efficient means of purifying inhaled air. If symptoms recur or physiologic abnormalities progress in spite of these measures, then more effective measures to avoid antigen exposure must be pursued. Compromises with environmental control pertain primarily to the acute, recurrent, transient clinical form of HP and must be accompanied by careful follow-up. Subacute forms are ordinarily the result of a heavy, sustained exposure. The chronic form typically results from low-grade or recurrent exposure over many months to years, and the lung disease may already be partially or completely irreversible. These patients are usually advised to avoid all possible contact with the offending agent, although follow-up studies of farmer's lung and bird fancier's lung have found resolution of the disease despite continued exposure in some patients.

Patients with the *acute*, recurrent form of HP usually recover without need for glucocorticoids. *Subacute* HP may be associated with severe symptoms and marked physiologic impairment and may continue to progress for several days despite hospitalization. Urgent establishment of the diagnosis and prompt institution of glucocorticoid treatment are indicated in such patients. Such therapy may also hasten recovery in patients with lesser involvement. Prednisone at a dosage of 1 mg/kg per day or its equivalent is continued for 7 to 14 days and then tapered over the ensuing 2 to 6 weeks at a rate that depends on the patient's clinical status. Patients with *chronic* HP may gradually recover without therapy following environmental control. In many patients, however, a trial of prednisone may be useful to obtain maximal reversibility of the lung disease. Following initial prednisone therapy (1 mg/kg per day for 2 to 4 weeks), the drug is tapered to the lowest dosage that will maintain the functional status of the patient. Many patients will not require or benefit from long-term therapy if there is

no further exposure to antigen. Available studies report no effect of glucocorticoid therapy on long-term prognosis of farmer's lung.

PULMONARY INFILTRATES WITH EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (PIE, eosinophilic pneumonias) include distinct individual syndromes characterized by eosinophilic pulmonary infiltrates and, commonly, peripheral blood eosinophilia. Since Loeffler's initial description of a transient, benign syndrome of migratory pulmonary infiltrates and peripheral blood eosinophilia of unknown cause, this group of disorders has been enlarged to include several diseases of both known and unknown etiology (Table 237-2). These diseases may be considered as immunologically mediated lung diseases, but are not to be confused with HP, in which eosinophilia is not a feature. When an eosinophilic pneumonia is associated with bronchial asthma, it is important to determine if the patient has atopic asthma and has wheal-and-flare skin reactivity to *Aspergillus* or other relevant fungal antigens. If so, other criteria should be sought for diagnosis of ABPA (Table 237-3) or other, rarer examples of allergic bronchopulmonary mycosis such as those caused by *Penicillium*, *Candida*, *Curvularia*, or *Helminthosporium* spp. *A. fumigatus* is the most common cause of ABPA, although other *Aspergillus* species have also been implicated. ABPA has been reported to complicate cystic fibrosis. The chest roentgenogram in ABPA may show transient, recurrent infiltrates or may suggest the presence of proximal bronchiectasis. High-resolution chest CT is a sensitive, noninvasive technique for the recognition of proximal bronchiectasis. The bronchial asthma of ABPA likely involves an IgE-mediated hypersensitivity, whereas the bronchiectasis associated with this disorder is thought to result from a deposition of immune complexes in proximal airways. Adequate treatment usually requires the long-term use of systemic glucocorticoids.

Tropical eosinophilia is usually caused by filarial infection; however, eosinophilic pneumonias also occur with other parasites such as *Ascaris*, *Ancyclostoma* sp., *Toxocara* sp., and *Strongyloides stercoralis*. Tropical eosinophilia due to *Wuchereria bancrofti* or *W. malayi* occurs most commonly in southern Asia, Africa, and South America, and is treated successfully with diethylcarbamazine.

Drug-induced eosinophilic pneumonias are exemplified by acute reactions to nitrofurantoin, which may begin 2 h to 10 days after nitrofurantoin is started, with symptoms of dry cough, fever, chills, and dyspnea; an eosinophilic pleural effusion accompanying patchy or diffuse pulmonary infiltrates may also occur. Other drugs associated with eosinophilic pneumonias include sulfonamides, penicillin, chlorpropamide, thiazides, tricyclic antidepressants, hydralazine, mephenesin, mecamylamine, nickel carbonyl vapor, gold salts, isoniazid, para-amnosalicylic acid, indomethacin, and others. One recent report has identified anti-TNF-α monoclonal antibody therapy as a cause of eosinophilic pneumonitis. Treatment consists of withdrawal of the incriminated drugs and the use of glucocorticoids, if necessary. The eosinophilia-myalgia syndrome, caused by dietary supplements of impure L-tryptophan, is occasionally associated with pulmonary infiltrates.

TABLE 237-2 Pulmonary Infiltrates with Eosinophilia

ETIOLOGY KNOWN
Allergic bronchopulmonary mycoses
Parasitic infestations
Drug reactions
Eosinophilia-myalgia syndrome
IDIOPATHIC
Loeffler's syndrome
Acute eosinophilic pneumonia
Chronic eosinophilic pneumonia
Allergic granulomatosis of Churg and Strauss
Hypereosinophilic syndrome

TABLE 237-3 Diagnostic Features of Allergic Bronchopulmonary Aspergillosis (ABPA)

MAIN DIAGNOSTIC CRITERIA
Bronchial asthma
Pulmonary infiltrates
Peripheral eosinophilia (>1000/μL)
Immediate wheal-and-flare response to *A. fumigatus*
Serum precipitins to *A. fumigatus*
Elevated serum IgE
Central bronchiectasis
OTHER DIAGNOSTIC FEATURES
History of brownish plugs in sputum
Culture of *A. fumigatus* from sputum
Elevated IgE (and IgG) class antibodies specific for *A. fumigatus*

The group of idiopathic eosinophilic pneumonias consists of diseases of varying severity. *Loeffler's syndrome* was originally reported as a benign, acute eosinophilic pneumonia of unknown cause characterized by migrating pulmonary infiltrates and minimal clinical manifestations. In some patients, these clinical characteristics may prove to be secondary to parasites or drugs. *Acute eosinophilic pneumonia* has been described as an idiopathic acute febrile illness of less than 7 days' duration with severe hypoxemia, pulmonary infiltrates, and no history of asthma. *Chronic eosinophilic pneumonia* presents with significant systemic symptoms including fever, chills, night sweats, cough, anorexia, and weight loss of several weeks' to months' duration. The chest x-ray classically shows peripheral infiltrates resembling a photographic negative of pulmonary edema. Some patients also have bronchial asthma of the intrinsic or nonallergic type. Dramatic clearing of symptoms and chest x-rays is often noted within 48 h after initiation of glucocorticoid therapy.

Allergic angiitis and granulomatosis of Churg and Strauss is a multisystem vasculitic disorder that frequently involves the skin, kidney, and nervous system in addition to the lung. The disorder may occur at any age and is almost invariably found in patients with a history of bronchial asthma. The asthma often is progressive until the onset of fever and exaggerated eosinophilia, at which time the symptoms of asthma may ease. The illness may be fulminating and the prognosis grave unless treated aggressively with glucocorticoids and, at times, immunosuppressive therapy. The use of leukotriene-modifying agents (zafirlukast, zyleuton, and montelukast) has been associated with Churg-Strauss syndrome, but it remains uncertain whether the drugs cause the disease or rather unmask previously undiagnosed vasculitis, perhaps suppressed by the use of inhaled or systemic glucocorticoids.

The *hypereosinophilic syndrome* is characterized by the presence of over 1500 eosinophils per microliter of peripheral blood for 6 months or longer; lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and signs or symptoms of multisystem organ dysfunction. Consistent features are blood and bone marrow eosinophilia with tissue infiltration by relatively mature eosinophils. The heart may be involved with tricuspid valve abnormalities or endomyocardial fibrosis and a restrictive, biventricular cardiomyopathy. Other organs affected typically include the lungs, liver, spleen, skin, and nervous system. Therapy of the disorder consists of glucocorticoids and/or hydroxyurea, plus therapy as needed for cardiac dysfunction, which is frequently responsible for much of the morbidity and mortality in this syndrome. Pulmonary eosinophilia has also been associated with T cell lymphoma, and has been reported following lung and bone marrow transplantation.

238 ENVIRONMENTAL LUNG DISEASES

Frank E. Speizer

This chapter provides perspectives on ways to assess pulmonary diseases for which environmental or occupational causes are suspected. This assessment is important because removal of the patient from harmful exposure is often the only intervention that might prevent further significant deterioration or lead to improvement in a patient's condition. Furthermore, the identification of an environment-associated disease in a single patient may lead to primary preventive strategies affecting other similarly exposed people who have not yet developed disease.

The exact magnitude of the problem is unknown, but there is no question that large numbers of individuals are at risk for developing serious respiratory disease as a result of occupational or environmental exposures. For example, recent estimates suggest that approximately 2.4 million workers in the United States have been exposed to crystalline silica or asbestos dust in mining and nonmining industries. Even if only 5% of these workers (a conservative estimate) are to suffer from respiratory disease as a result of their exposure, this figure represents more than 100,000 individuals.

HISTORY AND PHYSICAL EXAMINATION

The patient's history is of paramount importance in assessing any potential occupational or environmental exposure. Inquiry into specific work practices should include questions about specific contaminants involved, the availability and use of personal respiratory protection devices, the size and ventilation of workspaces, and whether coworkers have similar complaints. The temporal association of exposure at work and symptoms may provide clues to occupation-related disease. In addition, the patient must be questioned about alternative sources for potentially toxic exposures, including hobbies or other environmental exposures at home. Short-term exposures to potential toxic agents in the distant past must also be considered (Chap. 376).

Many people are aware of the potential hazards in their workplaces, and many states require that employees be informed about potentially hazardous exposures. These requirements include the provision of specific educational materials (including Material Safety Data Sheets), personal protective equipment and instructions in its use, and information on environmental control procedures. Reminders posted in the workplace may warn workers about hazardous substances. Protective clothing, lockers, and shower facilities may be considered necessary parts of the job. However, even in these more progressive industries, the introduction of new processes, particularly when related to the use of new chemical compounds, may change exposure significantly, and often only the employee on the production line is aware of the change. For the physician who regularly sees patients from a particular industry, a visit to the work site can be very instructive. Alternatively, physicians can request inspections by appropriate federal and/or state authorities.

The physical examination of patients with environment-related lung diseases may help to determine the nature and severity of the pulmonary condition. Unfortunately, the pulmonary response to most injurious agents is the development of a limited number of nonspecific physical signs. These findings do not point to the specific causative agent, and other types of information must be used to arrive at an etiologic diagnosis.

PULMONARY FUNCTION TESTS AND CHEST RADIOGRAPHY

Many mineral dusts produce characteristic alterations in the mechanics of breathing and lung volumes that clearly indicate a restrictive pattern (Chaps. 234 and 243). Exposures to a number of organic dusts or chemical agents capable of producing occupational asthma result in pronounced obstructive patterns of pulmonary dysfunction that may be reversible (Chap. 236). Measurement of change in forced expiratory volume (FEV_1) before and after a working shift can be used to detect an acute inflammatory or bronchoconstrictive response. An acute decrement of FEV_1 over the first work shift of the week is a characteristic feature of cotton textile workers with byssinosis.

The chest radiograph is useful in detecting and monitoring the pulmonary response to mineral dusts. The International Labour Organisation (ILO) International Classification of Radiographs of Pneumoconioses classifies chest radiographs according to the nature and size of opacities seen and the extent of involvement of the parenchyma. In general, opacities may be round or irregular, small ($<$10 mm in diameter) or large. They may be few in number, with visible normal lung markings, partially obscure normal markings, or totally obscure normal markings. Although useful for screening large numbers of workers, the ILO system lacks specificity and may over- or underestimate the functional impact of pneumoconiosis. With dusts causing rounded, regular opacities like those evident in coal worker's pneumoconiosis, the degree of involvement on the chest radiograph may be extensive, while pulmonary function may be only minimally impaired. In contrast, in pneumoconiosis causing linear, irregular opacities like those seen in asbestosis, the radiograph may lead to underestimation of the severity of the impairment until relatively late in the disease. For the individual patient with a history of exposure, conventional computed tomography (CT) and high-resolution computed tomography (HRCT) have improved the sensitivity of identifying diffuse parenchymal abnormalities of the lung. The procedures have been shown to provide earlier detection of silicosis and asbestosis.

Other diagnostic procedures of use in identifying environment-induced lung disease include evaluation of heavy metal concentrations in urine (arsenic in smelter workers, cadmium in battery plant workers); bacteriologic studies (tuberculosis in medical care personnel, anthrax in wool sorters); fungal studies (coccidioidomycosis in southwestern farm workers, histoplasmosis in poultry or pigeon handlers); and serologic studies (psittacosis in pet shop workers or owners of sick birds, Q fever in tanners or slaughterhouse workers). Ultimately, a lung biopsy may be required both for morphologic diagnosis of the underlying pulmonary disease and for attempted identification of the specific etiologic agent.

MEASUREMENT OF EXPOSURE

If reliable environmental sampling data are available, this information should be used in assessing a patient's exposure. Since many of the chronic diseases result from exposure over many years, current environmental measurements should be combined with work histories to arrive at estimates of past exposure.

In situations where individual exposure to specific agents—either in a work setting or via ambient air pollutants—has been determined, transport of these agents through the airways may be an important factor affecting dose. Highly soluble gases such as sulfur dioxide are absorbed in the upper airway and presumably produce their effects by reflex response of sensitive neural fibrils in the trachea or larger airways. In contrast, nitrogen dioxide, which is less soluble, may reach the bronchioles and alveoli in sufficient quantities to result in an acute life-threatening disease in farmers exposed even briefly to the gas evolved from moldy hay in silos (silo-filler's disease).

Particle size and chemistry of air contaminants must also be considered. Particles above 10 to 15 μm in diameter, because of their settling velocities in air, do not penetrate beyond the upper airways. These larger particles are often referred to as "fugitive dusts" and include pollens, other windblown dusts, and dusts resulting from mechanical industrial processes. They have little or no role in chronic respiratory disease except perhaps as related to cancer (see below).

Particles below 10 μm in size are created by the burning of fossil fuels or high-temperature industrial processes resulting in condensation products from gases, fumes, or vapors. These particles are divided into three size fractions on the basis of their size characteristics and sources. Particles of approximately 2.5 to 10 μm (coarse-mode fraction) contain crustal elements, such as silica, aluminum, and iron. These particles mostly deposit relatively high in the tracheobronchial tree. Although the total mass of an ambient sample is dominated by these larger respirable particles, the number of particles, and therefore the surface area on which potential toxic agents can deposit and be carried to the lower airways, is dominated by particles smaller than 2.5 μm (fine-mode fraction or accumulation mode). The smallest particles, those less than 0.1 μm in size, represent the ultrafine fraction and make up the largest number of particles, which tend to remain in the airstream and deposit in the lung only on a random basis as they come into contact with the alveolar walls.

Besides the size characteristics of particles and the solubility of gases, the actual chemical composition, mechanical properties, and immunogenicity or infectivity of inhaled material determine in large part the nature of the diseases found among exposed persons.

OCCUPATIONAL EXPOSURES AND PULMONARY DISEASE

Table 238-1 provides broad categories of exposure in the workplace and diseases associated with chronic exposure in these industries.

ASBESTOSIS

Except in localized regions with single industrial exposures, such as coal-mining or granite-quarrying regions, the most frequent inorganic dust-related chronic pulmonary diseases are associated with industries using *asbestiform fibers*. *Asbestos* is a generic term for several different mineral silicates, including chrysolite, amosite, anthophyllite, and crocidolite. Besides workers involved in the mining, milling, and manufacturing of asbestos products, workers in the building trades, including pipe fitters and boilermakers, were exposed to asbestos, which was widely used in construction because of its exceptional thermal and electric insulation properties. In addition, asbestos was used in the manufacture of fire-smothering blankets and safety garments, as filler for plastic materials, in cement and floor tiles, and in friction materials, such as brake and clutch linings.

Exposure to asbestos is not limited to persons who directly handle the material. Cases of asbestos-related diseases have been encountered in individuals with only moderate exposure, such as the painter or electrician who works alongside the insulation worker in a shipyard or the housewife who does no more than shake out and wash her husband's work clothes. Community exposure has probably resulted from the use of asbestos-containing material sprayed on steel girders in many large buildings as a safety feature to prevent buckling in case of fire.

Asbestos was first used extensively in the 1940s. Starting in 1975 it was mostly replaced with synthetic mineral fibers, such as fiberglass or slag wool, but it continues to be used increasingly in the developing world. Despite current regulations mandating adequate training for any worker potentially exposed to asbestos, exposure probably continues among inexperienced demolition workers. The major health effects from exposure to asbestos are pulmonary fibrosis (asbestosis) and cancers of the respiratory tract, the pleura, and (in rare cases) the peritoneum.

Asbestosis is a diffuse interstitial fibrosing disease of the lung that is directly related to the intensity and duration of exposure. Except for its association with a history of exposure to asbestos (generally in a work setting), asbestosis resembles the other forms of diffuse interstitial fibrosis (Chap. 243). Usually, moderate to severe exposure has taken place for at least 10 years before the disease becomes manifest.

Physiologic studies reveal a restrictive pattern with a decrease in lung volumes. Flow rates are commonly reduced less than would be predicted on the basis of the volume reduction. An early sign of severe disease may be a reduction in diffusing capacity.

Pulmonary fibrosis may occur following sufficient exposure to any of the asbestiform fiber types. The fibrotic lesions result from proinflammatory effects of reactive oxygen species released from phagocytes reacting with transition metals on the surface of the fibers. The clinical manifestations are typical of those physical findings in any patient with pulmonary fibrosis (Chap. 243).

DIAGNOSIS The chest radiograph can be used to detect a number of manifestations of asbestos exposure as well as to identify specific lesions. Past exposure is specifically indicated by pleural plaques, which are characterized by either thickening or calcification along the parietal pleura, particularly along the lower lung fields, the diaphragm, and the cardiac border. Without additional manifestations, pleural plaques imply only exposure, not pulmonary impairment. Benign pleural effusions may occur, particularly in patients with asbestosis, but are not necessarily restricted to those with overt disease. The fluid is sterile but may be a serous or blood-stained exudate and may occur bilaterally. The effusion may be slowly progressive or may resolve spontaneously.

The radiographic diagnosis of asbestosis depends on the presence of irregular or linear opacities, usually first noted in the lower lung fields and spreading into the middle and upper lung fields as the disease progresses. An indistinct heart border or a "ground glass" appearance in the lung fields is seen in some cases. In cases in which the x-ray changes are less obvious, HRCT may show distinct changes of subpleural curvilinear lines 5 to 10 cm in length that appear to be parallel to the pleural surface.

In general, newly diagnosed cases will have resulted from exposure levels that were present many years before and, in spite of the patients' having left the industry, are attributable to that former exposure. Since the patient may be eligible for compensation within a specific time frame after the diagnosis of an asbestos-related disease is made, the physician making the diagnosis should be certain to inform the patient promptly. On occasion, the physician may have reason to suspect ongoing exposure from a patient's current job description or actual monitoring data. In such cases, federal or state health authorities may need to be notified.

Casual, nonoccupational exposure to undisturbed sources of asbestos-containing materials—e.g., in walls of schools or other buildings—represents little if any hazard to people who inhabit or work in such buildings. Because the association of smoking and asbestos exposure increases the risk of developing lung cancer (see below), it is extremely important to advise patients with a history of exposure to asbestos to stop smoking. No specific therapy is available in the management of patients with asbestosis. The supportive care is the same as that given to any patient with diffuse interstitial fibrosis from any cause.

Lung cancer (Chap. 75), either squamous cell carcinoma or adenocarcinoma, is the most frequent cancer associated with asbestos ex-

TABLE 238-1 *Categories of Occupational Exposures and Number of Workers at Risk for Respiratory Diseases*

Occupational Exposures	Estimated Number of Workers Exposed	Nature of Respiratory Responses
Inorganic dusts		
Asbestos: mining	~250,000	Fibrosis (asbestosis), COPD, cancer, mesothelioma
Processing, nonagricultural	4.20×10^6	
Silica: mining, stone cutting, construction, quarrying	2.3×10^6	Fibrosis (silicosis), PMF, silicotuberculosis
Coal dust: mining	200,000	Fibrosis, pneumoconiosis
Beryllium: processing alloys for high tech industries	800,000	Acute pneumonitis, chronic granulomatous disease
Other metals: aluminum, chromium, cobalt, nickel, titanium, tungsten	~500,000	Wide variety of conditions from acute pneumonitis to lung cancer and asthma
Organic dusts		
Cotton dust: milling, processing	>800,000	Chronic bronchitis, reduced pulmonary function, byssinosis
Grain dust: elevator agents, dock workers, milling, bakers	>500,000	Asthma, chronic phlegm production, obstructive airways disease
Other agricultural dusts: fungal spores, vegetable product, insect fragments, animal dander, bird and rodent feces, endotoxins, microorganisms, pollens	$\sim 5 \times 10^6$	Hypersensitivity pneumonitis (farmers' lung), asthma, chronic bronchitis
Toxic chemicals: wide variety of industries—see Table 238-3	$>9 \times 10^6$ (does not include firefighters)	See Table 238-2
Other respiratory environmental carcinogens: (proven or highly suspect): uranium and radon daughters, environmental tobacco smoke, nickel compounds, chromium salts, polycyclic hydrocarbons, mustard gas, diesel exhaust, welding fumes, woods or wood finishing products	Essentially unknowable, but a major fraction of U.S. population is exposed to low environmental levels of one or more of these agents	Estimates vary from ~3% to <10% of all lung cancers

Note: COPD, chronic obstructive pulmonary disease; PMF, progressive massive fibrosis.

posure. The excess frequency of lung cancer in asbestos workers is associated with a minimum lapse of 15 to 19 years between first exposure and development of the disease. Persons with more exposure are at greater risk of disease. In addition, there appears to be a significant multiplicative effect that leads to a far greater risk of lung cancer in persons who are cigarette smokers and have asbestos exposure than would be expected from the additive risk of each factor. To date, efforts to consider these high-risk individuals for special surveillance studies, including sputum cytologic examinations and repeated chest x-rays as frequently as every 4 to 6 months, have resulted in neither significant early detection nor prolonged survival once the lung cancer is found. The use of HRCT in such at-risk subjects is currently under investigation.

Mesotheliomas (Chap. 245), both pleural and peritoneal, are also associated with asbestos exposure. In contrast to lung cancers, these tumors do not appear to be associated with smoking. Relatively short-term asbestos exposures of 1 to 2 years or less occurring some 20 to 25 years in the past have been associated with the development of mesotheliomas (an observation that emphasizes the importance of obtaining a complete environmental exposure history). The risk for this type of tumor peaks 30 to 35 years after initial exposure. Since maximum exposure took place in the United States between 1930 and 1960, peak incidence of disease in men occurred in 1997, with a total of 2300 cases. Incidence is expected to decline over the next 30+ years to about 500 cases per year.

Although approximately 50% of mesotheliomas metastasize, the tumor generally is locally invasive, and death usually results from local extension. Most patients present with effusions that may obscure the underlying pleural tumor. In contrast to the findings in effusion due to other causes, because of the restriction placed on the chest wall, no shift of mediastinal structures toward the opposite side of the chest will be seen. The major diagnostic problem is differentiation from peripherally spreading pulmonary adenocarcinoma or from adenocarcinoma metastasized to pleura from an extrathoracic primary site. Although a needle biopsy may be diagnostic, an open biopsy is often necessary, and even the latter procedure may not provide a definitive diagnosis of the origin of the tumor.

Since epidemiologic studies have shown that more than 80% of mesotheliomas may be associated with asbestos exposure, documented mesothelioma in a worker with occupational exposure to asbestos may be compensable in many parts of the United States.

SILICOSIS

In spite of the technical adequacy of existing protective equipment, *free silica* (SiO_2), or crystalline quartz, is still a major occupational hazard. In the United States, estimates of potential numbers of exposed workers range between 1.2 and 3 million persons. The major occupational exposures include: mining; stonecutting; employment in abrasive industries, such as stone, clay, glass, and cement manufacturing; foundry work; packing of silica flour; and quarrying, particularly of granite. Most often, progressive pulmonary fibrosis (silicosis) occurs in a dose-response fashion after many years of exposure.

Workers exposed through sandblasting in confined spaces, tunneling through rock with high quartz content (15 to 25%), or the manufacture of abrasive soaps may develop acute silicosis with as little as 10 months' exposure. The disease may be rapidly fatal in less than 2 years, despite the discontinuation of exposure. A radiographic picture of profuse miliary infiltration or consolidation is characteristic of acute silicosis.

In long-term, less intense exposure, small rounded opacities in the upper lobes, with retraction and hilar adenopathy, classically appear on the radiograph after 15 to 20 years. Calcification of hilar nodes may occur in as many as 20% of cases and produces the characteristic "eggshell" pattern. These changes may be preceded by or associated with a reticular pattern of irregular densities that are uniformly present throughout the upper lung zones.

The nodular fibrosis may be progressive in the absence of further exposure, with coalescence and formation of nonsegmental conglomerates of irregular masses in excess of 1 cm in diameter. These masses become quite large and are characteristic of progressive massive fibrosis (PMF). Significant functional impairment with both restrictive and obstructive components may be associated with this form of silicosis. In the late stages of the disease, ventilatory failure may develop. In more subtle cases, CT may be helpful both in identifying nodules, which are preferentially located in the posterior aspect of the upper lobes, as well as in identifying larger opacities and more coalescence than might be noted on regular chest x-rays. Patients with silicosis are at greater risk of acquiring *Mycobacterium tuberculosis* infections (silicotuberculosis) and atypical mycobacterial infections. Because the frequency with which tuberculosis has been found at autopsy in patients with PMF exceeds considerably the frequency of premorbid diagnosis, treatment for tuberculosis is indicated in any patient with silicosis and a positive tuberculin test.

Other less hazardous silicates include Fuller's earth, kaolin, mica, diatomaceous earths, silica gel, soapstone, carbonate dusts, and cement dusts. The production of fibrosis in workers exposed to these agents is believed to be related either to the free silica content of these dusts or, for substances that contain no free silica, to the potentially large dust loads to which these workers may be exposed.

Other silicates, including *talc dusts*, may be contaminated with asbestos and/or free silica. Accidental exposure to significant quantities of talc may result in an acute syndrome with cough, cyanosis, and labored breathing (acute talcosis). Severe progressive fibrosis with respiratory failure may ensue within a few years. Fibrosis and/or pleural or lung cancer have been associated with chronic exposure to commercial talc. Pure talc does not produce fibrosis; thus, it is difficult to sort out whether the effects are due to the contamination of commercial talc by asbestos or by free silica.

COAL WORKER'S PNEUMOCONIOSIS (CWP)

Coal dust is associated with CWP, which has enormous social, economic, and medical significance in every nation in which coal mining is an important industry. Simple radiographically identified CWP is seen in 12% of all miners and in as many as 50% of anthracite miners with more than 20 years' work on the coal face. The prevalence of disease is lower in workers in bituminous coal mines. Since much western U.S. coal is bituminous, CWP is less prevalent in that region.

Much of the symptomatology associated with simple CWP appears to be similar and additive to the effects of cigarette smoking on the development of chronic bronchitis and obstructive lung disease (Chap. 242). In the early stages of simple CWP, radiographic abnormalities consist of small, irregular opacities (reticular pattern). With prolonged exposure, one sees small, rounded, regular opacities, 1 to 5 mm in diameter (nodular pattern). Calcification is generally not seen, although approximately 10% of older anthracite miners have calcified nodules.

Complicated CWP is manifested by the appearance on the chest radiograph of nodules ranging from 1 cm in diameter to the size of an entire lobe, generally confined to the upper half of the lungs. This condition, considered a form of PMF, is accompanied by a significant reduction in diffusing capacity and is associated with premature mortality.

Caplan's syndrome (Chap. 301), first described in coal miners but subsequently found in patients with a variety of pneumoconioses, includes seropositive rheumatoid arthritis with characteristic PMF. The syndrome suggests an immunopathologic mechanism. Over the past decade, the mechanisms by which the chronic inhalation of mineral dusts produce an increase in inflammatory cells (including macrophages and neutrophils), which in turn causes PMF, have been explored. All of these inorganic dusts can: (1) be directly cytotoxic; (2) stimulate reactive oxygen species; (3) activate macrophages to produce cytokines and enhance production of (anti)fibrogenic factors such as tumor necrosis factor-α; (4) increase protease activity; and (5) increase inactivation of α_1-antitrypsin and leukocyte elastase activity. The final pathologic pathway may be fibrosis resulting from the interactions of a variety of these mechanisms.

BERYLLIOSIS

Beryllium may produce an acute pneumonitis or, far more commonly, a chronic granulomatous disease. Unless one inquires specifically about occupational exposures to beryllium in the manufacture of alloys, ceramics, high-technology electronics, and (before the 1950s) the production of fluorescent lights, one may miss entirely the etiologic relationship to an occupational exposure. Nonspecific pulmonary function tests may be normal or may indicate evidence of restrictive disease. Between 2 and 15 years of exposure, depending on its intensity, are required for the disease to become manifest. On open lung biopsy, granulomatous formation similar to that seen in sarcoidosis (Chap. 309) may make differentiation impossible unless tissue levels of beryllium are measured. Recent studies have identified T cell clones in the lungs of affected patients that suggest a gene-by-environment interaction that is necessary for the disease to become manifest.

Other hard metals, including aluminum powders, chromium, cobalt, titanium dioxide, and tungsten, may produce an interstitial pneumonitis, but this is rare.

OTHER INORGANIC DUSTS

Other dusts are considered *nuisance dusts* because their major environmental and health effects seem to be reduction in visibility and irritation of eyes, ears, nasal passages, and other mucous membranes, respectively. If they penetrate to the lower airways, these dusts do not affect the architecture of the terminal bronchioles or acinar spaces nor do they destroy collagen. Generally, clinical effects are reversible. Pulmonary function tests are usually normal unless another disease process coexists. If the dusts are radiodense, macular collections may produce striking radiographic pictures that are so characteristic that patients with a history of significant exposure are easily diagnosed as having the condition that bears the name reflecting the nature of the dust. Examples of radiodense dusts include iron and iron oxides from welding or silver finishing (*siderosis*); tin oxide used in metallurgy, color stabilization, printing, and the manufacture of porcelain, glass, and fabric (*stannosis*); and barium sulfate used as a catalyst for organic reactions, drilling mud components, and electroplating (*baritosis*). Other metal dusts producing similar radiodense pictures include *cerium dioxide* and *antimony salts*.

Most of the inorganic dusts discussed thus far are associated with the production of either dust macules or interstitial fibrotic changes in the lung. Another set of dusts (Table 238-2), along with some of the dusts previously discussed, is associated with chronic mucous hypersecretion (chronic bronchitis), with or without reduction of expiratory flow rates. These conditions are caused by cigarette smoking, and any effort to attribute some component of the disease to occupational and environmental exposures must take cigarette smoking into account. Most studies suggest an additive effect of dust exposure and smoking. The pattern of the effect is similar to that of cigarette smoking, suggesting that small airway inflammation may be the initial site of pathologic response in those cases associated with the development of obstructive lung disease. Cigarette smoke is usually the more noxious agent, and dust effects may be discernible only in nonsmokers.

ORGANIC DUSTS

Some of the specific diseases associated with organic dusts are discussed in detail in the chapters on asthma (Chap. 236) and hypersensitivity pneumonitis (Chap. 237). Many of these diseases are named for the specific setting in which they are found, e.g., farmer's lung, malt worker's disease, or mushroom worker's disease. Often the temporal relation of symptoms to exposure furnishes the best evidence for the diagnosis. Three occupational groups are singled out for discussion because they represent the largest proportion of people affected by the diseases resulting from organic dusts.

COTTON DUST (BYSSINOSIS) Estimates of the number of exposed persons in the United States vary, but probably over 800,000 persons are exposed occupationally to cotton, flax, or hemp in the production of yarns for cotton, linen, and rope making. Although this discussion focuses on cotton, the same syndrome—albeit somewhat less severe—has been reported in association with exposure to flax, hemp, and jute.

Exposure occurs throughout the manufacturing process but is most pronounced in those portions of the factory involved with the treatment of the cotton prior to spinning—i.e., blowing, mixing, and carding (straightening of fibers). Attempts to control dust levels by use of exhaust hoods, general increases in ventilation, and wetting procedures in some settings have been highly successful. However, respiratory protective equipment appears to be required during certain operations to prevent workers from being exposed to levels of dust that exceed the current U.S. cotton dust standard.

TABLE 238-2 *Selected Occupational Dusts Believed to Be Associated with Mucous Hypersecretion and/or Obstructive Airway Disease and Other Respiratory Diseases*[a]

Agent (Exposure)	Mucous Hypersecretion	Obstruction	Other Conditions[b]
INORGANIC DUSTS			
Antimony (storage batteries, solder, ceramics, glass, plastics)	X		P
Arsenic (manufacture of pesticides, pigments, glass, alloys)	X		C
Barium and compounds including BaO, $BaSO_4$, $BaCO_3$ (catalysts, drilling mud, electroplating)	X		P
Cadmium dust (electroplating, battery manufacture, welding, smelting, aluminum soldering)	X	X	P
Cement dust (construction trades, manufacture of cement blocks)	X	X	
Chromium and CrO_3, CrF_2 (corrosion inhibitor pigment, metallurgy, electroplating)	X		C
Coal dust (mining)	X		P
Coke oven emissions (retort house, coke ovens)	X	X	P, C
Graphite (steelmaking, lubricants, pencils, paints, stove polish)	X	X	P
Iron dust (steel and nonferrous foundry workers, welding)	X		P
Mica (insulation, roofing shingles, oil refining, rubber manufacturing)	X		P
Phosphorus, elemental chlorides, sulfides (manufacture of fireworks, agricultural chemicals, insecticides, pesticides)	X	X	
Rock dusts (miners, tunnelers, quarry workers)	X		P
Vanadium pentoxide (welding electrodes, additive to steel, by-product in ash from oil burning)	X	X	
ORGANIC DUSTS (SEE CHAP. 237)			
Cotton dust, flax, hemp (manufacture of yarns for linen, rope, cotton; ginning, cottonseed crushing; waste fiber processing)	X	X	
Grain dusts (farmers, workers in grain elevators, barge and grain ship crew members)	X	X	
Moldy hay (farmers, other animal attendants)	X		HP

[a] The table excludes agents associated with asthma as the primary disease (see Chap. 236).
[b] Other conditions include hypersensitivity pneumonitis (HP), pneumoconiosis (P), and cancers (C).
Note: X indicates that mucous hypersecretion or obstruction is associated with exposure.

Byssinosis is characterized clinically as occasional (early stage) and then regular (late stage) chest tightness toward the end of the first day of the workweek ("Monday chest tightness"). In epidemiologic studies, depending on the level of exposure via the carding room air, up to 80% of employees may show a significant drop in their FEV_1 over the course of a Monday shift.

Initially the symptoms do not recur on subsequent days of the week. However, in 10 to 25% of workers, the disease may be progressive, with chest tightness recurring or persisting throughout the workweek. After more than 10 years of exposure, workers with recurrent symptoms are more likely to have an obstructive pattern on pulmonary function testing. There is an additive effect of cotton dust exposure plus cigarette smoking. The highest grades of impairment are generally seen in smokers.

Treatment in the early stages of the disease is directed toward reversing the bronchospasm with bronchodilators; however, the chest tightness appears to relate, at least in part, to histamine release, and antihistamines have been shown to lessen the anticipated fall in FEV_1 the first day of the week. Clearly, reduction of dust exposure is of primary importance. All workers with persistent symptoms or significantly reduced levels of pulmonary function should be moved to areas of lower risk of exposure. Regular surveillance of pulmonary function in the industry has made it easier to identify affected persons. Persons with reduced pulmonary function, a personal history of respiratory allergy, and a history of continued cigarette smoking should be considered at increased risk of developing byssinosis in association with work in the cotton industry.

GRAIN DUST Although the exact number of workers at risk in the United States is not known, at least 500,000 people work in grain elevators, and over 2 million farmers are potentially exposed to grain dust. The presentation of disease in grain elevator employees or in workers in flour or feed mills is virtually identical to the characteristic findings in cigarette smokers, i.e., persistent cough, mucous hypersecretion, wheeze and dyspnea on exertion, and reduced FEV_1 and FEV_1/FVC ratio (Chap. 234).

Dust concentrations in grain elevators vary greatly but appear to be in excess of 10,000 $\mu g/m^3$; approximately one-third of the particles, by weight, are in the respirable range. The effect of grain dust exposure is additive to that of cigarette smoking, with approximately 50% of workers who smoke having symptoms. Among nonsmoking grain elevator operators, approximately one-quarter have mucous hypersecretion, about five times the number that would be expected in unexposed nonsmokers. However, evidence of obstruction on pulmonary function studies is observed only in workers who smoke.

FARMER'S LUNG This condition results from exposure to moldy hay containing spores of thermophilic actinomycetes that produce a hypersensitivity pneumonitis (Chap. 237). There are few good population-based estimates of the frequency of occurrence of this condition in the United States. However, among farmers in Great Britain, the rate of disease ranges from approximately 10 to 50 per 1000. The prevalence of disease varies in association with rainfall, which determines the amount of fungal growth, and with differences in agricultural practices related to turning and stacking hay.

The patient with acute farmer's lung presents 4 to 8 h after exposure with fever, chills, malaise, cough, and dyspnea without wheezing. The history of exposure is obviously essential to distinguish this disease from influenza or pneumonia with similar symptoms. In the chronic form of the disease, the history of repeated attacks after similar exposure is important in differentiating this syndrome from other causes of patchy fibrosis (e.g., sarcoidosis).

A wide variety of other organic dusts are associated with the occurrence of hypersensitivity pneumonitis (Chap. 237). For those patients who present with hypersensitivity pneumonitis, specific and careful inquiry about occupations, hobbies, or other home environmental exposures will, in most cases, reveal the source of the etiologic agent.

TOXIC CHEMICALS

Exposure to toxic chemicals affecting the lung generally involves gases and vapors. A common accident is one in which the victim is trapped in a confined space where the chemicals have accumulated to toxic levels. In addition to the specific toxic effects of the chemical, the victim will often sustain considerable anoxia, which can play a dominant role in determining whether the individual survives.

Table 238-3 lists a variety of toxic agents that can produce acute and sometimes life-threatening reactions in the lung. All these agents in sufficient concentrations have been demonstrated, at least in animal studies, to affect the lower airways and disrupt alveolar architecture, either acutely or as a result of chronic exposure. Some of these agents may be generated acutely in the environment. For example, when plastics burn, a number of compounds, including hydrogen cyanide and hydrochloric acid, may be formed and released.

Firefighters and fire victims are at risk of *smoke inhalation*, a numerically important cause of acute cardiorespiratory failure. Smoke inhalation kills more fire victims than does thermal injury. Carbon monoxide poisoning with resulting significant hypoxemia can be life-threatening (Chap. 377). The use of synthetic materials (plastic, polyurethanes), which, when burned, may release a variety of other toxic agents (such as cyanide or hydrochloric acid), must be considered when evaluating smoke inhalation victims. Exposed victims may suffer some degree of lower respiratory tract inflammation and/or pulmonary edema.

Firefighters and victims may also be exposed to large quantities of particulate smoke. Significant long-term effects are not clearly associated with this particulate exposure except as related to the production of irritating effects on the upper airways; however, increased airway responsiveness in firefighters with repeated episodes of smoke inhalation has been demonstrated.

Some agents used in the manufacture of synthetic materials have resulted in some workers' being sensitized to extremely low levels of *isocyanates*, *aromatic amines*, or *aldehydes*. Repeated exposure to these agents causes some workers to develop chronic cough and sputum production, asthma, or episodes of low-grade fever and malaise.

Fluoropolymers, which at normal temperatures produce no reaction, upon heating become volatilized. The inhaled agents cause a characteristic syndrome of fever, chills, malaise, and occasionally mild wheezing leading to the diagnosis of *polymer fume fever* or, in the

TABLE 238-3 *Selected Common Toxic Chemical Agents Affecting the Lung*

Agent(s)	*Selected Exposures*	*Acute Effects from High or Accidental Exposure*	*Chronic Effects from Relatively Low Exposure*
Acid fumes: H_2SO_4, HNO_3	Manufacture of fertilizers, chlorinated organic compounds, dyes, explosives, rubber products, metal etching, plastics	Mucous membrane irritation, followed by chemical pneumonitis 2–3 days later	Bronchitis and suggestion of mildly reduced pulmonary function in children with lifelong residential exposure to high levels; clinical significance unknown
Ammonia	Refrigeration; petroleum refining; manufacture of fertilizers, explosives, plastics, and other chemicals	Same as for acid fumes	Chronic bronchitis
Cyanides	Electroplating; extraction of gold or silver; manufacture of mirrors, fumigants, photo supplies	Increase in respiratory rate followed by respiratory arrest, lactic acidosis, pulmonary edema, death	No data
Diazomethane	Methylating agent for acid compounds; laboratory workers	Violent coughing, dyspnea, wheezing, pulmonary edema	No data
Formaldehyde	Manufacture of resins, leathers, rubber, metals, and woods; laboratory workers, embalmers; emission from urethane foam insulation	Same as for acid fumes	Cancers in one species; no data on humans
Halides (Cl, Br, F)	Bleaching in pulp, paper, textile industry; manufacture of chemical compounds; synthetic rubber, plastics, disinfectant, rocket fuel, gasoline	Mucous membrane irritation, pulmonary edema; possible reduced FVC 1–2 yrs after exposure	Dryness of mucous membrane, epistaxis, dental fluorosis, tracheobronchitis
Hydrogen sulfide	By-product of many industrial processes, oil, other petroleum processes and storage	Respiratory paralysis similar to cyanides	Conjunctival irritation, chronic bronchitis, recurrent pneumonitis
Isocyanates (TDI, HDI, MDI)	Production of polyurethane foams, plastics, adhesives, surface coatings	Mucous membrane irritation, dyspnea, cough, wheeze, pulmonary edema	Upper respiratory tract irritation, cough, asthma, allergic alveolitis
Nitrogen dioxide	Silage, metal etching, explosives, rocket fuels, welding, by-product of burning fossil fuels	Cough, dyspnea, pulmonary edema may be delayed 4–12 h; possible result from acute exposure: bronchiolitis obliterans in 2–6 wks	Emphysema in animals, ?chronic bronchitis, associated with reduced lung function in children with lifelong residential exposure, clinical significance unknown
Ozone	Arc welding, flour bleaching, deodorizing, emissions from copying equipment, photochemical air pollutant	Mucous membrane irritant, pulmonary hemorrhage and edema, reduced pulmonary function transiently in children and adults exposed to summer haze	Chronic eye irritation
Phosgene	Organic compound, metallurgy, volatilization of chlorine-containing compounds	Delayed onset of bronchiolitis and pulmonary edema	Chronic bronchitis
Phthalic anhydride	Manufacture of resin esters, polyester resins, thermoactivated adhesives	Nasal irritation, cough	Asthma, chronic bronchitis
Sulfur dioxide	Manufacture of sulfuric acid, bleaches, coating of nonferrous metals, food processing, refrigerant, burning of fossil fuels, wood pulp industry	Mucous membrane irritant, epistaxis	?Chronic bronchitis

meat industry, *meat wrappers' asthma*. A similar self-limited, influenza-like syndrome—*metal fume fever*—results from acute exposure to fumes or smoke of zinc, copper, magnesium, and other volatilized metals. The syndrome may begin several hours after work and resolves within 24 h, only to return on repeated exposure. A proper occupational history should make the diagnosis evident.

ENVIRONMENTAL RESPIRATORY CARCINOGENS

Historically, it has been the astute clinician who has recognized a higher incidence of malignant tumors associated with certain environmental exposures. When these observations are linked to an occupational setting, they must be pursued by epidemiologic studies of relatively large groups of both current and former workers. Often the concentration and/or exact nature of the substances involved in the putative exposures cannot be determined. Rarely, the possibility that a substance can play an etiologic role in cancer is supported by observing that a few cases of a very rare tumor in a particular group represent "an epidemic." Examples are nasal sinus and lung cancer in nickel workers, angiosarcomas of the liver in vinyl chloride workers, and adenocarcinomas of the nose in woodworkers.

In addition to asbestos exposures, other occupational exposures associated with either proven or suspected respiratory carcinogens include those to acrylonitrile, arsenic compounds, beryllium (animal studies only), bis(chloromethyl) ether, chromium, polycyclic hydrocarbons (through coke oven emissions), iron oxide, isopropyl oil (nasal sinuses), mustard gas, the various ores used to produce pure nickel, talc (possible asbestos contamination in both mining and milling), vinyl chloride, welding materials, wood used in woodworking (nasal cancer only), and uranium. The occurrence of excess cancers in uranium miners raises the possibility that a large number of workers are at risk by virtue of exposure to similar radiation hazards. This number includes not only workers involved in processing uranium but also workers exposed in underground mining operations where radon daughters may be emitted from rock formations.

ASSESSMENT OF DISABILITY

Most commonly the need for disability assessment comes about because of the patient's complaint of shortness of breath. Pathophysiologically, dyspnea most often results from cardiac, respiratory, or neuromuscular diseases. With regard to respiratory diseases, the complaint most often relates to asthma. It is the physician's task to assess both the degree to which the symptoms are related to work or other environmental exposures and the severity of the symptoms, which result in the disability that may prevent the individual from performing his or her normal work tasks. Evaluating relation to work exposure requires a detailed work history, as previously discussed in this chapter. Objective assessment of severity of symptoms can generally be measured with pulmonary function tests including simple spirometry, lung volume measures, and diffusing capacity. In cases where these tests are normal, repeated measures of spirometry, airways hyperactivity, or degree of oxygen desaturation after modest exercise may be sufficient to demonstrate impairment. Occasionally, challenge to the putative work environment with repeated pulmonary function measures may be required.

With these data the physician should be able to make a judgment about the degree of impairment and its relation to exposure. How this information is formally used is often beyond the physician's control. Administrative panels, legal authorities, and sometimes confrontational employer/employee relations, as in a worker's compensation case, may have alternative reasons for collecting and using such data. Different authorities may have different guidelines and rules for setting levels of disability. What the physician may consider significant impairment may not be considered a disability for a worker with a sedentary job. Nevertheless, the treating physician is often asked for an opinion and must respond as objectively as possible. When this is being done for the physician's own patient, he or she needs to indicate to the patient what his or her specific role is and that most often the physician is not in the position of making the adjudicating decision. If the physician is operating as an independent medical examiner, he or she should make clear to the agency that hires him or her that, from a medical-ethical perspective, the patient will be informed of all findings.

GENERAL ENVIRONMENTAL EXPOSURES

AIR POLLUTION

Dramatic and disastrous episodes of air pollution inversion have been documented in many industrialized centers in the world. Each of these episodes has been associated with excess acute mortality in the very old, the very young, and those with chronic cardiopulmonary diseases. The most dramatic event was the London fog of 1952, in which approximately 4000 excess deaths occurred over a 2-week period following 5 days of severe cold and dense fog. Similar episodes in the United States, although less dramatic in terms of total deaths, occurred in Donora, Pennsylvania, in 1948 and in New York City in the 1960s. In these episodes, which were generally associated with cold temperature and air stagnation, patients with underlying cardiopulmonary disease were most severely affected.

In addition to significant excess mortality during these episodes, a large number of people required medical care for cardiorespiratory complaints. Subsequent follow-up studies failed to implicate these episodic disasters in the etiology of chronic respiratory disease in adults. On the other hand, many epidemiologic studies of both international and regional differences in the prevalences of chronic respiratory disease suggest that long-term exposures in polluted areas in the early to middle part of the twentieth century were associated with excess chronic respiratory disease.

In 1970, the U.S. government established air quality standards for several pollutants believed to be responsible for excess cardiorespiratory diseases. Primary standards regulated by the Environmental Protection Agency (EPA) designed to protect the public health with an adequate margin of safety exist for sulfur dioxide, particulates <10 μm in size, nitrogen dioxide, ozone, lead, and carbon monoxide. Standards for each of these pollutants are updated regularly through an extensive review process conducted by the EPA. In 1997, a new standard was added for particles less than 2.5 μm; however, up through 2002 that new standard has not been implemented.

Pollutants are generated from both stationary sources (power plants and industrial complexes) and mobile sources (automobiles), and none of the pollutants occurs in isolation. Thus, except for the change in carboxyhemoglobin from carbon monoxide exposure, it becomes extremely difficult to relate any specific health effect to any single pollutant. Furthermore, pollutants may be changed by chemical reactions after being emitted. For example, reducing agents, such as sulfur dioxide and particulate matter from a power plant stack, may react in air to produce acid sulfates and aerosols, which can be transported long distances in the atmosphere. Oxidizing substances, such as oxides of nitrogen and oxidants from automobile exhaust, may react with sunlight to produce ozone. Although originally a problem confined to the southwestern part of the United States, in recent years, at least during the summertime, elevated ozone and acid aerosol levels have been documented throughout the United States. Both acute and chronic effects of these exposures have also been documented.

The symptoms and diseases associated with air pollution are the same as the nononcogenic conditions commonly associated with cigarette smoking. In addition, respiratory illness in early childhood has been associated with chronic exposure to only modestly elevated levels of traffic-related gases and respirable particles. Recent population-based studies comparing cities that have relatively high levels of particulate exposures with less polluted communities suggest excess morbidity and mortality from cardiorespiratory conditions in long-term residents of the former communities. This finding, in part, has led to greater emphasis on publicizing pollution alert levels. One can only advise individuals with significant cardiopulmonary impairment

to stay indoors during periods when pollution exceeds current standards.

INDOOR EXPOSURE

Over the past 15 years, greater attention has been given to the effects of *passive cigarette smoking* (Chap. 375). Several studies have shown that the respirable particulate load in any household is directly proportional to the number of cigarette smokers living in the home. Increases in prevalence of respiratory illnesses and reduced levels of pulmonary function measured with simple spirometry have been found in children of smoking parents in a number of studies.

Evidence from numerous case-control and cohort studies shows modest excess disease associations for cardiopulmonary diseases and lung cancer. Because most of these excess relative risks appear to be below 50%, it is virtually impossible for any one of the studies to be considered definitive. Thus, the techniques of meta-analysis have been used effectively to combine data from the best of these studies. The most recent meta-analyses for lung cancer, cardiac disease, and respiratory disease in terms of excess mortality suggest an approximately 25% increase for each condition, even after adjustment for major potential confounders. According to measures of plasma cotinine, a metabolite of nicotine, a nonsmoker living with a smoker is exposed to approximately 1% of the level of tobacco smoke to which a smoker of 20 cigarettes a day is exposed. In spite of some prominent detractors, these combined relative risks appear to be consistent with the estimated exposure levels and suggest a consensus that the associations are causal.

Radon gas is believed to be a risk factor for lung cancer. The main radon product (radon 222) is a gas that results from the decay series of uranium 238, with the immediate precursor being radium 226. The amount of radium in earth materials determines how much radon gas will be emitted. Outdoors, the concentrations are trivial. Indoors, levels are dependent on the ventilation rate and the size of the space into which the gas is emitted. Levels associated with excess lung cancer risk may be present in as many as 10% of the houses in the United States. When smokers reside in the household, the problem is potentially greater, since the molecular size of radon particles allows them to readily attach to smoke particles that are inhaled. Fortunately, technology is available for assessing and reducing the level of exposure.

Other indoor exposures associated with an increased risk of atopy and asthma include those to such specific recognized putative biologic agents as cockroach antigen, dust mites, and pet danders. Other indoor chemical agents include formaldehyde, perfumes, and latex particles. Nonspecific responses associated with "tight-building syndrome," in which no particular agent has been implicated, have included a wide variety of complaints, among them respiratory symptoms, that are relieved only by avoiding exposure in the building in question. The degree to which "smells" or other sensory stimuli are involved in the triggering of potentially incapacitating psychological or physical responses has yet to be determined, and the long-term consequences of such environmental exposures are as yet unknown.

PORTAL OF ENTRY

The lung is a primary point of entry into the body for a number of toxic agents that affect other organ systems. For example, the lung is a route of entry for benzene (bone marrow), carbon disulfide (cardiovascular and nervous systems), cadmium (kidney), and metallic mercury (kidney, central nervous system). Thus, in any disease state of obscure origin, it is important to consider the possibility of inhaled environmental agents. Such consideration can sometimes furnish the clue needed to identify a specific external cause for a disorder that might otherwise be labeled "idiopathic."

239 PNEUMONIA

Thomas J. Marrie, G. Douglas Campbell, David H. Walker, Donald E. Low

To the pathologist, pneumonia is an infection of the alveoli, distal airways, and interstitium of the lung that is manifested by increased weight of the lungs, replacement of the normal lung's sponginess by consolidation, and alveoli filled with white blood cells, red blood cells, and fibrin. To the clinician, pneumonia is a constellation of symptoms and signs (fever, chills, cough, pleuritic chest pain, sputum production, hyper- or hypothermia, increased respiratory rate, dullness to percussion, bronchial breathing, egophony, crackles, wheezes, pleural friction rub) in combination with at least one opacity on chest radiography. There is often a degree of uncertainty about the clinical diagnosis of pneumonia, since a number of noninfectious disorders may mimic this entity.

Pneumonia can be broadly categorized as community-acquired or hospital-acquired (nosocomial). When pneumonia occurs in residents of long-term-care facilities (LTCFs), it is treated as community-acquired by some physicians and as nosocomial by others. It is also useful to subdivide cases of community-acquired pneumonia (CAP) into those that can be treated in an ambulatory setting and those that are severe enough to require admission to the hospital. Similarly, nosocomial pneumonia can be categorized as ventilator-associated or non-ventilator-associated. These categories provide a rough guide as to likely pathogens and disease severity.

HOST DEFENSES PROTECTING THE LUNGS With a surface area of ~70 m^2 that is exposed to the external environment, the lungs are protected by an elegant defense system aimed at preventing potential pathogens from reaching this site and at containing and eliminating the organisms that do gain entry. The pulmonary host defenses can be classified as innate (nonspecific) and acquired (specific).

Anatomical features of the upper airway constitute the first line of innate defense. The nasal turbinates and the sharp angular turn from the naso- and anterior oropharynx into the posterior pharynx act as baffles where inhaled particulate matter can impact. The mucociliary transport system includes ciliated cells of the trachea, bronchi, and terminal bronchioles as well as the overlying mucus layer. The ciliated cells move a mucus layer (produced by goblet cells and submucosal glands), which "floats" on a solute layer to the back of the throat and is swallowed. Mucus consists of complex glycoproteins called *mucins* that trap microorganisms. To prevent pathogens from attaching to and colonizing upper respiratory tract surfaces, binding is inhibited by a decreased mucosal pH, the presence of naturally occurring bacterial and epithelial cell binding analogues, secretory IgA, and the constant

desquamation of epithelial cells. In addition, the naso-oropharynx is colonized with nonpathogenic bacteria that can interfere with attachment of pathogens to host cells by a variety of mechanisms.

The entry to the lower respiratory tract is protected by the glottis. If secretions do enter the lower respiratory tract, they can be cleared readily by coughing. In the lower respiratory tract, nonspecific defenses include macrophages, fibronectin, lysozymes, lactoferrin, IgG, defensins, cathelicidins, collectins (including surfactant proteins A and D), and complement. Surfactant is bactericidal to certain pathogens and, along with IgG and fibronectin, can opsonize bacteria. Alveolar macrophages (present at a density of one per alveolus) play a role in both innate and acquired immunity. Their long life span (20 to 80 days) and their ability to phagocytose multiple times are characteristics that particularly suit their role as primary lung phagocytes in innate immunity. As components of acquired immunity, alveolar macrophages present antigens to T cells and produce many regulatory cytokines and mediators. If, however, the concentration of organisms is great (e.g., with gross aspiration) or if especially virulent pathogens are present, the macrophages recruit polymorphonuclear leukocytes (PMNs), and a more intense inflammatory process ensues.

The epithelial cells act as a barrier to dissemination of microorganisms and serve an important immune function. Throughout the lower respiratory tract, these cells produce antimicrobial molecules and participate in the upregulation of inflammation by recruiting phagocytic cells and by producing certain chemokines, including interleukin (IL) 8, macrophage-inflammatory protein 2, granulocyte-macrophage colony-stimulating factor, and by-products of the arachidonic acid cascade. In addition, epithelial cells regulate the expression of endothelial adhesion molecules, thereby targeting the recruitment of PMNs to the lung.

The advantages of the specific host defenses, which require T cell activation, are that they specifically target the offending pathogen, further upregulate the inflammatory response, and result in lifelong immunity to the offending antigen. Lymphocytes and mononuclear phagocytes are present throughout the respiratory tract, from the submucosa of the nasopharynx to the interstitial and alveolar spaces of the pulmonary parenchyma; their presence ensures a fast response of immunoreactive cells to events in the respiratory tract. →***Specific host defenses are discussed in detail in Chap. 295.***

FACTORS IN PATHOGENESIS ■ Routes of Infection For pneumonia to occur, a potential pathogen must reach the lower respiratory tract in sufficient numbers or with sufficient virulence to overwhelm host defenses. Possible routes include gross aspiration, microaspiration, aerosolization, hematogenous spread from a distant infected site, and direct spread from a contiguous infected site. By far the most common route for bacterial pneumonia is microaspiration of oropharyngeal secretions colonized with pathogenic microorganisms. Oropharyngeal colonization by *Streptococcus pneumoniae* and by *Haemophilus influenzae* may occur among healthy individuals (with persistence for weeks) but is more likely with significant comorbidities, antibiotic therapy, or physiologic stress (e.g., due to surgery). Gross aspiration can occur postoperatively and in patients with central nervous system disorders that affect swallowing (seizures, strokes); common pathogens include anaerobic organisms and gram-negative bacilli. Hematogenous spread can take place in the setting of endocarditis, intravenous catheter infections, or infections at other sites, such as the urinary tract. *Staphylococcus aureus* (including methicillin-resistant *S. aureus*, or MRSA) frequently infects the lungs in association with intravascular catheter–related infections, in endocarditis, and with a decreased level of consciousness following head trauma. *Escherichia coli* commonly originates from urinary tract infections. Aerosolization is the route by which *Mycobacterium tuberculosis*, endemic fungi (*Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*), *Legionella* spp., *Coxiella burnetii*, and many respiratory viruses (especially influenza viruses A and B) reach the lungs.

Microbial Factors Pathogenic microorganisms have developed a variety of mechanisms to counteract host defenses. *Chlamydia pneumoniae* produces a ciliostatic factor; *Mycoplasma pneumoniae* can shear off cilia; influenza virus infection markedly reduces tracheal mucus velocity within hours of onset and for up to 12 weeks afterward. *S. pneumoniae* and *Neisseria meningitidis* produce proteases that can split secretory IgA. *Mycobacterium*, *Nocardia*, and *Legionella* spp. are resistant to the microbicidal activity of phagocytes. The pneumococcal capsule inhibits phagocytosis. Another virulence factor produced by all pneumococci is the 53-kDa polypeptide pneumolysin, a thiol-activated cytolysin that interacts with any cell whose membrane contains cholesterol. Pneumococci also produce neuraminidase, hyaluronidase, and IgA1 protease.

Host Factors Pneumonia is more common when host defense is impaired, as it is in severe underlying illness. Hypogammaglobulinemia, defects in phagocytosis or ciliary function, neutropenia, functional or anatomical asplenia, or a reduction in CD4+ T lymphocyte counts are all host defense deficits that can result in increased frequency or severity of pneumonia. Viral infection of alveolar macrophages may explain in part the very high rate of pneumococcal disease in the HIV-infected population. Anatomical defects such as obstructed bronchus, bronchiectasis, or sequestration of a pulmonary segment all lead to recurrent pneumonia or the failure of pneumonia to resolve.

A number of polymorphisms in or near the tumor necrosis factor α (TNF-α) gene are associated with variability in TNF-α production and with outcomes in pneumonia. In patients with CAP, the TNF-α 238 GA genotype is an independent risk factor for a fatal outcome, the lymphotoxin-α (LT-α) +250 AA genotype is a risk factor for septic shock, and the TNF-α 308:LT-α +250 GC haplotype is protective against septic shock. Patients with the DRB1*1501/DQB1*0602 haplotype have been found to mount significantly reduced responses to invasive group A streptococcal pulmonary infection and to be less likely to develop severe disease. In one study, 50% of patients with bacteremic pneumococcal pneumonia—but only 29% of uninfected controls—were homozygous for FcγRIIa-R31, which binds weakly to IgG2; this difference suggested that genetic factors may also be important risk factors for bacteremic pneumococcal pneumonia.

Functional or anatomical asplenia is an important risk factor for pneumonia presenting as overwhelming infection, with 80% of cases due to *S. pneumoniae*. Such overwhelming infection has a mortality rate of ~45%.

PATHOPHYSIOLOGY Vital capacity, lung compliance, functional residual capacity, and total lung capacity are below normal in patients with pneumonia. Ventilation-perfusion mismatch and intrapulmonary shunting are responsible for the hypoxemia that occurs in many patients with pneumonia.

PATHOLOGY The pathology of pneumonia manifests as four general patterns: lobar pneumonia, bronchopneumonia, interstitial pneumonia, and miliary pneumonia.

Lobar Pneumonia *Lobar pneumonia* classically involves an entire lung lobe relatively homogeneously, although in some patients a small portion of the lobe may be unaffected or at an earlier stage of involvement. Four stages of lobar pneumonia may exist simultaneously in the same lung, as the tendency of the progression to be synchronous is not absolute.

The first stage—*congestion*—occurs during the first 24 h and is characterized grossly by redness and a doughy consistency and microscopically by vascular congestion and alveolar edema. At this stage, many bacteria are present and are swept by the rapid expansion of edema fluid throughout the lobe via the pores of Kohn. Only a few neutrophils are seen at this stage. The second stage—termed *red hepatization* because of the color of the lung and the similarity of its airless, noncrepitant firmness to the consistency of liver—is characterized microscopically by the presence of many erythrocytes, neutrophils, desquamated epithelial cells, and fibrin in the alveolar spaces. In the third stage—*gray hepatization*—the lung is dry, friable, and

gray-brown to yellow as a consequence of a persistent fibrinopurulent exudate, a progressive disintegration of red blood cells, and the variable presence of hemosiderin. The exudate contains macrophages as well as neutrophils, but bacteria are seldom visible. The second and third stages last for 2 to 3 days each, with a 2- to 6-day duration of maximal consolidation. The final stage—*resolution*—is characterized by enzymatic digestion of the alveolar exudate; resorption, phagocytosis, or coughing up of the residual debris; and restoration of the pulmonary architecture. Fibrinous inflammation may extend to and across the pleural space, causing a rub heard by auscultation, and may lead to resolution or to organization and pleural adhesions.

Bronchopneumonia *Bronchopneumonia*, a patchy consolidation involving one or several lobes, usually involves the dependent lower and posterior portions of the lung—a pattern attributable to the distribution of aspirated oropharyngeal contents by gravity. The consolidated areas are usually poorly demarcated, although in some cases there is an abrupt delimitation of the pneumonia at interlobular septa. The neutrophilic exudate is centered in bronchi and bronchioles, with centrifugal spread to the adjacent alveoli and diminishing cellular exudate; often there is only edema in the periphery of the lesion.

Interstitial Pneumonia *Interstitial pneumonia* is defined by histopathologic identification of an inflammatory process predominantly involving the interstitium, including the alveolar walls and the connective tissue around the bronchovascular tree. The inflammation may be patchy or diffuse. The alveolar septa contain an infiltration of lymphocytes, macrophages, and plasma cells. The alveoli do not contain a significant exudate, but protein-rich hyaline membranes similar to those found in adult respiratory distress syndrome (ARDS) may line the alveolar spaces. Some viruses with tropism for epithelial cells of the airways and alveoli may cause necrosis of the epithelium. In some instances, there may be a significant inflammatory exudate, with extensive degradation of inflammatory cells. Bacterial superinfection of viral pneumonia can also produce a mixed pattern of interstitial and alveolar airspace inflammation.

Miliary Pneumonia The original description of miliary pneumonia was based on the resemblance of the diffusely distributed 2- to 3-mm lesions of hematogenous tuberculosis to millet seeds. The current concept of *miliary pneumonia* is based on its numerous discrete lesions resulting from the spread of the pathogen to the lungs via the bloodstream. The varying degrees of immunocompromise in miliary tuberculosis, histoplasmosis, and coccidioidomycosis manifest as variations in the tissue reaction (from granulomas with caseous necrosis to foci of necrosis); the fibrinous exudate; and the weak, poorly formed cellular reaction. Miliary herpesvirus, cytomegalovirus, or varicella-zoster virus infection in severely immunocompromised patients results in numerous acute necrotizing hemorrhagic lesions.

PULMONARY COMPLICATIONS OF PNEUMONIA Uncontrolled infection by particular agents may lead to necrotizing pneumonia, formation of abscesses, vascular invasion with infarction, cavitation, and extension to the pleura with empyema or bronchopleural fistula. Complications of mechanical ventilation and supplemental oxygen administration include interstitial emphysema, pneumothorax, and ARDS. In patients with severe damage, tissue repair may lead to fibrosis with various anatomical distributions, such as organizing pneumonia, bronchiolitis obliterans, and pleural adhesions.

COMMUNITY-ACQUIRED PNEUMONIA

EPIDEMIOLOGY With an annual cost of $9.7 billion, CAP affects 4 million adults per year in the United States, ~20% of whom are admitted to a hospital for treatment. The overall rate of pneumonia ranges from 8 to 15 per 1000 persons per year, with the highest rates at the extremes of age and during the winter months. Rates of pneumonia are higher for men than for women and for black than for white persons.

Independent risk factors for CAP include alcoholism [RR (relative risk) 9], asthma (RR 4.2), immunosuppression (RR 1.9), and an age of >70 years (RR 1.5 vs. an age of 60 to 69 years). Dementia, seizures, congestive heart failure, cerebrovascular disease, tobacco smoking, alcoholism, and chronic obstructive pulmonary disease (COPD) are risk factors for pneumococcal pneumonia. Independent risk factors for invasive pneumococcal disease include male gender, black race, chronic illness, current tobacco smoking, and passive exposure to tobacco smoke. Cigarette smoking is the strongest independent predictor of invasive pneumococcal disease among immunocompetent young adults. The rate of pneumococcal pneumonia is up to 40 times higher among HIV-infected patients than among age-matched patients not infected with HIV. Risk factors for Legionnaires' disease include male gender, current tobacco smoking, diabetes, hematologic malignancy, cancer, end-stage renal disease, and HIV infection. Probable aspiration, previous hospital admission, previous antimicrobial treatment, and bronchiectasis are predictive of pneumonia due to gram-negative bacteria, including *Pseudomonas aeruginosa*. Heavy drinkers (i.e., those consuming >100 g of ethanol per day for the preceding 2 years) have a higher incidence of gram-negative bacterial pneumonia, experience worse clinical symptoms, and require longer courses of intravenous antibiotic therapy than do nondrinkers. More prolonged fever, slower resolution, and a higher rate of empyema have been noted in pneumococcal pneumonia patients with chronic alcoholism than in their nondrinking counterparts. The clinical entity designated ALPS—alcoholism, leukopenia, and pneumococcal sepsis—is associated with a mortality rate of 80%. In addition, excessive alcohol use is an independent risk factor for the development of ARDS.

ETIOLOGY The organism causing pneumonia may be identified from cultures of blood, sputum, pleural fluid, pulmonary tissue, or endobronchial secretions obtained with a bronchial brush or via lavage. Other methods for determining the etiology of pneumonia include the detection of an IgM response or a fourfold rise in the titer of antibody to an antigen of a particular microorganism and the detection of an antigen in urine, serum, or pleural fluid. In some instances, amplification of DNA or RNA of a respiratory pathogen from one of the above specimens or from material collected with a nasopharyngeal swab can be used for this purpose.

Identification of an etiologic agent in a case of pneumonia should be categorized as definite, probable, or possible, depending on the source of the microorganism or the test used to detect it (Table 239-1). Such diagnostic categorization is useful not only in comparative studies of pneumonia etiology but also in the approach to the patient with pneumonia.

The past 30 years have seen the identification of new etiologic agents of CAP, often during the detailed investigation of dramatic outbreaks. Thus *Legionella pneumophila* was isolated during the investigation of an outbreak of pneumonia at a convention of the American Legion in Philadelphia in 1976. Other etiologic agents identified during this period include *C. pneumoniae*, hantavirus, Nipah virus, Hendra virus, and metapneumovirus. Investigations of an outbreak of severe acute respiratory syndrome (SARS) originating in China and Hong Kong during the winter of 2003 and subsequently found to be caused by a novel coronavirus are ongoing.

The >100 documented microbial causes of CAP include bacteria, fungi, viruses, and parasites. Fortunately, most cases of pneumonia are caused by a few common respiratory pathogens, including *S. pneumoniae*, *H. influenzae*, *S. aureus*, *M. pneumoniae*, *C. pneumoniae*, *Moraxella catarrhalis*, *Legionella* spp., aerobic gram-negative bacteria, influenza viruses, adenoviruses, and respiratory syncytial virus. The relative frequency of these pathogens differs with the age of the patient and the severity of the pneumonia (Table 239-2). Overall, *S. pneumoniae* accounts for ~50% of all cases of CAP requiring admission to the hospital, although in everyday practice the etiology of CAP is unknown in up to 70% of patients.

Determination of the etiology of pneumonia starts with the gathering of clues from the history and physical examination (Table 239-3)

TABLE 239-1 *Categories Reflecting the Certainty of an Etiologic Diagnosis of Pneumonia*

Category	Definition
Definite	Pathogen recovered from blood, pleural fluid, or lung tissue
	Isolation of *Legionella* spp. or *Mycobacterium tuberculosis* from sputum
	Positive urinary antigen test for *Legionella*
Probable	Isolation from a purulent sputum specimen of any of the following microorganisms, with a morphologically compatible organism seen in moderate or large numbers on Gram's staining: *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Pseudomonas aeruginosa*
	Fourfold or greater rise in titer of antibody to a respiratory pathogen between acute- and convalescent-phase serum samples
	Positive urinary antigen test for *S. pneumoniae* in adults[a]
Possible	1. Gram's stain of an acceptable sputum specimen[b] showing a predominance of gram-positive diplococci (*S. pneumoniae*), gram-positive cocci in clusters (*S. aureus*), or gram-negative coccobacilli (*H. influenzae*)
	2. Isolation of a pathogen from a purulent sputum specimen in the absence of a compatible Gram's stain
	3. High single or static titer of antibody to *Legionella pneumophila* (≥1:1024) or *Mycoplasma pneumoniae* (≥1:64)

[a] Nasopharyngeal carriage of *S. pneumoniae* may be associated with a positive test in children.
[b] An acceptable sputum specimen is one with >25 white blood cells and <10 squamous epithelial cells per low-power field.

and proceeds to a diagnostic workup tailored to the severity of the pneumonia or to other circumstances, such as the setting of an outbreak. All patients with pneumonia who are admitted to the hospital should have blood cultured, and sputum should be cultured when the patient has a productive cough. This basic workup should be supplemented with more aggressive diagnostic methods (such as bronchoscopy with bronchoalveolar lavage or bronchial brush specimens) for patients admitted to intensive care units (ICUs).

TABLE 239-2 *Frequency of Most Common Pathogens Causing Community-Acquired Pneumonia, According to Severity of Illness*

Severity of Pneumonia	Rank Order of Pathogens
Ambulatory	1. *Streptococcus pneumoniae*
	2. *Mycoplasma pneumoniae*
	3. *Chlamydia pneumoniae*
	4. *Haemophilus influenzae*
	5. Influenza viruses
	6. *Pneumocystis*
Treated on hospital ward	1. *S. pneumoniae*
	2. Mixed etiology
	3. Viruses
	4. *H. influenzae*
	5. *C. pneumoniae*
	6. *Legionella* spp.
	7. *M. pneumoniae*
	8. *Staphylococcus aureus*
	9. *Moraxella catarrhalis*
	10. Aerobic gram-negative bacilli
	11. *Mycobacterium tuberculosis*
	12. *Pneumocystis*
Treated in intensive care unit	1. *S. pneumoniae*
	2. *S. aureus*
	3. Viruses
	4. Mixed etiology
	5. Aerobic gram-negative bacilli
	6. *Legionella* spp.
	7. *M. pneumoniae*
	8. *Pneumocystis*
	9. *H. influenzae*

TABLE 239-3 *Clues to the Etiology of Pneumonia from History and Physical Examination*

Factor	Possible Agent(s)
OCCUPATIONAL HISTORY	
Health care worker	*Mycobacterium tuberculosis*
Veterinarian, farmer, abattoir worker	*Coxiella burnetii*
Cooling tower maintenance worker	*Legionella* spp.
HOST FACTOR	
Diabetic ketoacidosis	*Streptococcus pneumoniae*, *Staphylococcus aureus*
Alcoholism	*S. pneumoniae*, *Klebsiella pneumoniae*, *S. aureus*, oral anaerobes, *Acinetobacter* spp.
Chronic obstructive pulmonary disease	*S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*
Solid organ transplantation	*S. pneumoniae*, *H. influenzae*, *Legionella* spp., *Pneumocystis*, cytomegalovirus, *Strongyloides stercoralis*
Sickle cell disease	*S. pneumoniae*
HIV infection and CD4+ lymphocyte count of <200/μL	*S. pneumoniae*, *Pneumocystis*, *H. influenzae*, *Cryptococcus neoformans*, *M. tuberculosis*, *Rhodococcus equi*
Dementia, stroke, altered level of consciousness	Agents of aspiration pneumonitis (see text)
Structural lung disease (bronchiectasis)	*Pseudomonas aeruginosa*
TRAVEL AND OTHER ENVIRONMENTAL FACTORS	
Travel to Southeast Asia	*Burkholderia pseudomallei*,[a] *M. tuberculosis*
Travel to China, Taiwan, Toronto (Canada)[b]	Coronavirus causing severe acute respiratory syndrome (SARS)
Travel to many countries	*M. tuberculosis*
Travel to Arizona, parts of California	*Coccidioides immitis*
Travel to Ohio and St. Lawrence river valleys	*Histoplasma capsulatum*
Exposure to contaminated air-conditioning cooling towers, hot tub, grocery store mist machine; recent stay in a hotel; visit to or recent stay in a hospital with Legionellaceae-contaminated drinking water	*Legionella pneumophila*, other Legionellaceae
Exposure to mouse droppings in an endemic area	Hantavirus
Exposure to windstorm in an endemic area	*C. immitis*, *C. burnetii*
Pneumonia outbreak in shelter for homeless men or in jail	*S. pneumoniae*, *M. tuberculosis*
Pneumonia outbreak in military training camp	*S. pneumoniae*, *Chlamydia pneumoniae*, adenovirus
Pneumonia outbreak in nursing home	*C. pneumoniae*, *S. pneumoniae*, respiratory syncytial virus, influenza A virus, *M. tuberculosis*
Lawn mowing in an endemic area	*Francisella tularensis*
Exposure to bats, excavation or residence in an endemic area[c]	*H. capsulatum*
Exposure to parturient cats in an endemic area	*C. burnetii*
Sleeping in a rose garden	*Sporothrix schenckii*
Camping, cutting down trees in an endemic area	*Blastomyces dermatitidis*
Exposure to Vancouver Island (camping, residence)	*C. neoformans* var. *gattii*

TABLE 239-4 British Thoracic Society Rule for Definition of Severe Community-Acquired Pneumonia (Acronym: CURB)

Confusion
Urea[a]: >7 mmol/L
Respiratory rate: >30/min
Blood pressure: diastolic <60 mmHg or systolic <90 mmHg

[a] Blood urea nitrogen (BUN).

CLINICAL MANIFESTATIONS Pneumonia can range in severity from mild to fulminant and fatal, with serious disease developing even in previously healthy persons. The onset may be sudden and dramatic or insidious. Fever, cough (nonproductive or productive of purulent or rust-colored sputum), pleuritic chest pain, chills or rigors, and shortness of breath are typical—albeit nonspecific—manifestations of pneumonia. Symptoms reported with some frequency include headache, nausea, vomiting, diarrhea, myalgia, arthralgia, and/or fatigue. Falls and new-onset or worsening confusion may be important manifestations in an elderly person. The physical signs associated with pneumonia are tachypnea, dullness to percussion, increased tactile and vocal fremitus, egophony, whispering pectoriloquy, crackles, and pleural friction rub. In two studies, patients with a respiratory rate of >25/min had a pneumonia likelihood ratio of 1.5 to 3.4. In another study, patients with a heart rate of ≤100/min, a temperature of ≤37.8°C, and a respiratory rate of ≤20/min were five times less likely to have pneumonia than patients who had all of these abnormal parameters. A diagnosis of pneumonia based on physical examination has a sensitivity of 47 to 69% and a specificity of 58 to 75%; thus a clinical diagnosis of pneumonia should be confirmed by chest radiography. For patients who have pneumonia clinically diagnosed in an office setting, the physician must decide whether or not to obtain a chest radiograph. Even if the clinical assessment suggests mild disease, all patients with pneumonia who have an oral temperature of >38.5°C or who have pleuritic chest pain should have a chest radiograph. Pulmonary embolus is always a consideration with pleuritic chest pain, and further investigations are warranted if the chest radiograph is normal in this setting. If pneumonia is extensive in a patient with this degree of fever, further evaluation and perhaps hospitalization are necessary.

The single most useful clinical sign of the severity of pneumonia is a respiratory rate of >30/min in a person without underlying lung disease. Of the several measures of pneumonia severity, the simplest is the British Thoracic Society rule, which relies on three clinical findings and one laboratory finding (Table 239-4). If none of these features is present, the mortality rate is 2.4%; with one feature, the mortality rate is 8%; with two, 23%; with three, 33%; and with all four, 83%. The American Thoracic Society criteria for severe pneumonia are given in Table 239-5. To derive a scoring system for classifying pneumonia cases across the spectrum from mild to severe, the Pneumonia Patient Outcomes Research Team (PORT) assigned points to each of 20 items associated with mortality (Table 239-6). The resulting PORT score allowed categorization of patients with pneumonia into five risk groups (Table 239-7). Although this system was developed as a mortality prediction tool and is no substitute for clinical judgment, it is often used in making site-of-treatment decisions (see "Treatment," below).

Certain causes of pneumonia and organisms within a species are associated with a high mortality rate. The mortality rate is highest (>50%) for pneumonia due to *P. aeruginosa*, followed by the rates for *Klebsiella* spp., *E. coli*, *S. aureus*, and *Acinetobacter* spp. (all 30 to 35%). The capsular serotype 3 pneumococcus is associated with a much higher mortality rate than serotype 1, as are M serotypes 1 and 3 of group A *Streptococcus* (compared with other serotypes).

Young, otherwise healthy adults who develop pneumonia and who are treated as outpatients usually feel well enough to return to work in 4 or 5 days, and almost all will have recovered in 2 weeks. However, those with relatively severe symptoms may require longer to recover. About 2 to 4% of those who are treated as outpatients experience a progression of symptoms and require admission to the hospital. In general, those admitted during the first week after the initial visit are admitted because pneumonia has worsened, while those admitted later are often admitted because of worsening of comorbid illnesses (e.g., diabetes mellitus, congestive heart failure, asthma, or ischemic heart disease). Currently, up to 25% of persons treated for pneumonia as outpatients are >65 years old, and the natural history of ambulatory

TABLE 239-5 American Thoracic Society Definition of Severe Pneumonia

Category	Criteria
Major	Need for mechanical ventilation
	Requirement for vasopressors: >4 h
Minor	Systolic blood pressure: <90 mmHg
	Pa_{O_2}/FI_{O_2}: <250
	Multilobar involvement

TABLE 239-6 Severity-of-Illness Scoring System Based on Pneumonia Patient Outcomes Research Team (PORT) Cohort Study Data

Patient Characteristic	No. of Points
Age	
Men	Age, years
Women	Age, years −10
Nursing home residents	Age, years +10
Coexisting illnesses	
Neoplastic disease[a]	30
Liver disease[b]	20
Congestive heart failure[c]	10
Cerebrovascular disease[d]	10
Renal disease[e]	10
Physical examination findings	
Altered mental status[f]	20
Respiratory rate >30/min	20
Systolic blood pressure <90 mmHg	20
Temperature <35°C (<95°F) or >40°C (>104°F)	15
Pulse rate >125/min	10
Laboratory and radiographic findings	
Arterial pH < 7.35	30
Blood urea nitrogen >30 mg/dL (>11 mmol/L)	20
Sodium <130 mmol/L	20
Glucose >250 mg/dL (>14 mmol/L)	10
Hematocrit <30%	10
Partial pressure of arterial oxygen <60 mmHg	10
Pleural effusion	10

[a] Any cancer (except basal or squamous cell carcinoma of the skin) active at presentation or within 1 year of presentation with community-acquired pneumonia.
[b] Clinical or histologic cirrhosis or chronic active hepatitis.
[c] Diagnosis documented by history or by findings on physical examination, chest radiography, echocardiography, multiple gated acquisition scan, or left ventriculography.
[d] Clinical diagnosis of stroke or transient ischemic attack; stroke documented by magnetic resonance imaging or computed tomography.
[e] History of chronic renal disease or abnormal blood urea nitrogen and creatinine concentrations documented in medical record.
[f] Disorientation as to person, place, or time that is not known to be chronic; stupor or coma.

TABLE 239-7 Mortality Rate at 30 Days among Patients with Community-Acquired Pneumonia, According to PORT Risk Class[a]

		% Mortality	
Risk Class	Criteria	Outpatient	Inpatient
I	Age <50 years No existing illnesses or vital-sign abnormalities	0	0.5
II	70 points	0.4	0.9
III	71–90 points	0	1.25
IV	91–130 points	12.5	9.0
V	131 points	NA	27.1
Mean		0.6	8.0

[a] PORT, Pneumonia Patient Outcomes Research Team.

pneumonia in this group is probably different from that in younger patients.

Among patients admitted to the hospital for the treatment of pneumonia, clinical stability is usually attained in 3 to 7 days, depending on the definition used. In one study, a median of 2 days was required to achieve a heart rate of ≤100/min and 3 days to achieve a respiratory rate of ≤24/min, an oxygen saturation of ≥90%, and a temperature of ≤37.2°C. Once stability is attained, clinical deterioration is uncommon.

Since most patients admitted to the hospital with pneumonia are elderly and have multiple comorbid conditions, it is not uncommon for complications to occur during the hospital stay. The most common complications are respiratory failure, congestive heart failure, shock, atrial dysrhythmias, myocardial infarction, gastrointestinal bleeding, and renal insufficiency. Indeed, only ~30% of patients hospitalized for the treatment of pneumonia have no complications.

The in-hospital mortality rate from pneumonia is ~8%. The most common immediate causes of death among patients with pneumonia are respiratory failure, heart disease, and infections. About half of deaths are related to pneumonia, and the other half are due to comorbid illnesses. Pneumonia-related deaths are much more likely to occur during the first week of hospitalization. Factors independently associated with pneumonia-unrelated mortality include dementia, immunosuppression, active cancer, systolic hypotension, male gender, and multilobar pulmonary infiltrates. Increasing age and evidence of aspiration independently predict both pneumonia-related and comorbidity-related mortality.

DIAGNOSIS The usual standard for the diagnosis of pneumonia is chest radiography, which, however, is not 100% sensitive. High-resolution computed tomography (CT) occasionally detects pulmonary opacities in patients with symptoms and signs suggestive of pneumonia in whom chest radiographs are reported as not showing pneumonia. CT is also more likely than chest radiography to show bilateral involvement. If pneumonia is strongly suspected on clinical grounds and no opacity is seen on the initial chest radiograph, it is useful to repeat the radiograph in 24 to 48 h or to perform CT. It is important to remember that an opacity visible on chest radiograph may not be due to pneumonia; many other disease processes can result in opacities. Furthermore, there is variability among radiologists in the interpretation of chest radiographs; most commonly, subsegmental lower-lobe opacities in patients with suboptimal chest radiographs may be reported as atelectasis by one radiologist and as pneumonia by another. Occasionally, an etiologic diagnosis is suggested by the findings on chest radiography. For example, a cavitating upper-lobe lesion raises the likelihood of tuberculosis, and pneumatoceles suggest *S. aureus* pneumonia. An air-fluid level suggests a pulmonary abscess, which is often polymicrobial. In the immunocompromised host, a crescent (meniscus) sign suggests aspergillosis. In most instances, however, no etiologic inference can be made from radiographic findings.

Concomitant diseases (such as congestive heart failure or pulmonary fibrosis) may make both the clinical and the radiologic diagnosis of pneumonia difficult. However, serial clinical and radiographic observations usually allow the clinician to determine whether there are two diseases or just one and to identify which one is causing the clinical and radiographic findings.

Etiologic Diagnosis ■ *BLOOD CULTURE* Blood should be obtained for culture from patients to be treated on an ambulatory basis if they have been receiving antibiotic therapy and have presented because of any of the following: hyperthermia (temperature >38.5°C), hypothermia (temperature <36°C), homelessness, or alcohol abuse. All patients who are admitted to the hospital for CAP should have two sets of blood cultures done before initiation of antibiotic therapy (positivity rate: 6 to 20%). The most common isolates, in descending order, are *S. pneumoniae* (~60%), *S. aureus*, and *E. coli*.

SPUTUM STAINS AND CULTURE Gram's stain is used to screen a sputum sample for suitability for culture and to make a presumptive etiologic diagnosis. A sputum sample with >25 white blood cells and <10 squamous epithelial cells per low-power field is suitable for culture. There is a great deal of interobserver variability in the interpretation of gram-stained sputum smears. The presence of any gram-positive diplococci has a sensitivity of 100% but a specificity of 0 for a diagnosis of pneumococcal infection. The presence of >10 gram-positive diplococci per oil-immersion field has a sensitivity of 55% and a specificity of 85% for this diagnosis. Culture results should always be correlated with those of Gram's staining. If an organism is isolated from sputum and its morphologic correlate is not seen on Gram's staining, the isolate may be colonizing the upper airway. Certain microorganisms, if isolated from sputum, should always be considered pathogens. These include *M. tuberculosis*, *Legionella* spp., *B. dermatitidis*, *H. capsulatum*, and *C. immitis*. In practice, only about one-third of elderly patients admitted with CAP produce sputum suitable for culture, and one-third of these specimens fail to yield a pathogen.

Other types of sputum staining are also useful for determining the etiology of CAP. A variety of stains for acid-fast bacilli are used to diagnose tuberculosis; *Pneumocystis* pneumonia can be diagnosed with monoclonal antibody staining; and special stains for fungi are useful in selected patients, as are cytologic stains.

DETECTION OF ANTIGENS OF PULMONARY PATHOGENS IN URINE *L. pneumophila* serogroup 1 antigen can be detected in the urine of patients with Legionnaires' disease due to this organism by means of an enzyme-linked immunosorbent assay (ELISA). The sensitivity of this assay is 69 to 72% on average, 88 to 100% in severe disease, and 40 to 53% in mild disease. The assay's sensitivity is low in nosocomial Legionnaires' disease. The results may be negative early in the illness, and antigen excretion can be prolonged. The test should be used in patients in whom Legionnaires' disease is strongly suspected, including those with rapidly progressive pneumonia. The urine antigen test is now the most frequently used diagnostic method for Legionnaires' disease. A critical point, however, is that infection with *Legionella* spp. other than *L. pneumophila* serogroup 1 gives a negative test result.

S. pneumoniae urinary antigen detection by ELISA has a sensitivity of 80% and a specificity of 97 to 100% in patients with bacteremic pneumococcal pneumonia. The antigen may be detected for up to 1 month after the onset of pneumonia, and the results can be available in 15 min. In children, nasopharyngeal carriage of *S. pneumoniae* can result in a positive urinary antigen test.

SEROLOGY The detection of IgM antibody or the demonstration of a fourfold rise in the titer of antibody to a particular agent between acuta and convalescent-phase serum samples is generally considered good evidence that this agent is the cause of the pneumonia. The following etiologic agents are often diagnosed serologically: *M. pneumoniae*, *C. pneumoniae*, *Chlamydia psittaci*, *Legionella* spp., *C. burnetii*, adenovirus, parainfluenza viruses, and influenza virus A. The various serologic tests include complement fixation, indirect immunofluorescence, and ELISA. Separate IgM and IgG antibody detection tests can be performed with the latter two assays. One difficulty in relying on serology is that a polyclonal antibody response to one agent may result in a fourfold rise in antibody titer to others; thus the results may be nonspecific. Serologic testing is not recommended for routine use; however, if agents such as *C. burnetii* are suspected, such testing is necessary. Serology is also a useful part of the workup of outbreaks of pneumonia associated with negative blood and sputum cultures.

POLYMERASE CHAIN REACTION Amplification of the DNA or RNA of microorganisms that are not part of the pharyngeal flora (from microbial cells collected by throat swab) has been used to infer that the implicated microorganism is the cause of pneumonia. A multiplex polymerase chain reaction allows detection of DNA of *Legionella* spp., *M. pneumoniae*, and *C. pneumoniae*. This test is expensive and is not routinely available.

TREATMENT

Successful treatment of CAP involves all the elements listed in Tables 239-8, 239-9, and 239-10.

Site of Care As described above, the PORT score (based on a pneumonia-specific severity-of-illness scoring system; Tables 239-6 and 239-7) has been advocated as a tool to guide the decision regarding the site of care (home vs. hospital). Because of the low mortality rates in risk classes I and II, it is recommended that these patients be treated at home, while patients in risk classes IV and V require hospital admission. Patients in class III may benefit from a period of observation in the emergency room before a decision is made regarding the site of care. Reliance on this or any other such system as the sole criterion for this decision has several limitations: (1) These systems are mortality prediction tools only and do not take into account psychosocial reasons for admission. (2) Although illness is dynamic, scoring systems capture events at a single point in time. (3) A physician's judgment is often the most critical element in decision-making and should override any scoring system. For example, some patients in classes I to III may have a complicated hospital course and may even require admission to an ICU, although the scoring system would dictate that they should be sent home. In practice, a physician should use a number of approaches in deciding on the site of care—intuition, specific assessment of the severity of illness, and the parameters given in Table 239-10. When a patient with pneumonia is sent home from the emergency room or the physician's office, it is advisable to follow up with a telephone call within 48 h. In our experience, most patients have begun to feel better by this time, ~10% are unchanged, and ~5% are worse; this last group of patients should be reassessed by a physician. Patients who are treated on an ambulatory basis should be given written information about the warning signs of pneumonia exacerbation, such as shortness of breath while walking on level ground (for those who have no underlying lung disease), a temperature of >38.5°C after 72 h of antibiotic therapy, or a new onset of confusion or pleuritic chest pain. In addition, patients should be advised to report hemoptysis to their physicians.

TABLE 239-8 Approach to the Patient with Community-Acquired Pneumonia

1. Assess pneumonia severity. Pay attention to vital signs, including oxygen saturation. Always count the respiratory rate yourself for 1 min.
2. Ensure adequate oxygenation and support of circulation.
3. Perform etiologic workup (dictated by pneumonia severity).
4. Determine site of treatment: home, hospital (ward or intensive care unit), or long-term-care facility.
5. Institute empirical antibiotic therapy.
6. Rule out empyema in all patients with a pleural effusion of >1 cm on lateral decubitus chest radiography.
7. Never forget tuberculosis and *Pneumocystis* infection as possible etiologies. Check your hospital policy regarding the isolation of patients with CAP. In some centers where tuberculosis is common, all patients with CAP are isolated until sputum smears are found to be negative for acid-fast bacilli.
8. Consider pulmonary embolus in all patients with pleuritic chest pain.
9. Consider end-of-life decision-making.
10. Monitor and treat comorbid illnesses.
11. Monitor for achievement of stability of selected physiologic parameters.
12. Assess ability to perform activities of daily living.
13. Assess mental status.
14. Consider preventive measures:
    a. Smoking cessation counseling (if appropriate)
    b. Assessment of pneumococcal and influenza vaccination status, with vaccine administration as necessary
    c. Assessment of risk of aspiration and institution of preventive measures
15. Follow up to ensure radiographic clearance of pneumonia. All patients >40 years old and all tobacco smokers should have a follow-up chest radiograph to document pneumonia resolution.

Antibiotic Therapy ■ *EMPIRICAL TREATMENT AND DRUG RESISTANCE* Since the etiology of pneumonia is frequently unknown, initial antibiotic therapy is often empirical. There are currently three sets of North American guidelines for empirical antibiotic treatment of CAP: those developed under the auspices of the Infectious Diseases Society of America, the American Thoracic Society, and the Canadian Infectious Diseases and Canadian Thoracic Societies. Table 239-9 combines various elements of these guidelines with the opinions of the authors.

There are no data from randomized clinical trials to indicate that one antibiotic or combination of antibiotics is better than another for the empirical treatment of CAP. A retrospective review of 12,945 Medicare patients (all >65 years old) indicated that treatment with a macrolide plus a second-generation or nonpseudomonal third-generation cephalosporin was associated with a significantly lower mortality rate than treatment with a second- or third-generation cephalosporin alone. Use of a fluoroquinolone alone was likewise associated with a significantly lower mortality rate, while the combination of an aminoglycoside and any other antibiotic resulted in a significantly higher mortality rate. Data from the Medicare study also indicated that timely administration is important: Patients who received antibiotics within 8 h after arrival at the emergency room had a lower mortality rate than those who received the first dose >8 h afterward. Data from a retrospective review of bacteremic pneumococcal pneumonia indicated that therapy with a single antimicrobial agent was not as effective as therapy with two or more agents effective against *S. pneumoniae*; data from randomized clinical trials must confirm or refute this observation.

In the selection of empirical antibiotic therapy, risk factors for drug-resistant *S. pneumoniae* must be considered (Table 239-9). Before 1980, strains of *S. pneumoniae* were almost universally susceptible to penicillin and other antimicrobial drugs. [The current National Committee for Clinical Laboratory Standards interpretive breakpoints for the minimal inhibitory concentration (MIC) of penicillin are ≤0.06 μg/mL (susceptible), 0.12 to 1.0 μg/mL (intermediate), and ≥2.0 μg/mL (resistant). Isolates classified as either intermediately resistant or resistant are considered nonsusceptible. Isolates resistant to three or more classes of drugs are termed multidrug-resistant.] In the late 1980s, the prevalence of penicillin-nonsusceptible *S. pneumoniae* in the United States was 4.0%; less than a decade later, it was 35%. In the United States, a multicenter national surveillance study conducted from November 1999 through April 2000 found that 35% of pneumococci were nonsusceptible to penicillin, with 60% of these isolates resistant. Resistance to non-β-lactam antibiotics also emerged among North American *S. pneumoniae* strains during the 1990s. In 1999 to 2000, the rate of resistance among U.S. isolates of *S. pneumoniae* was 25.9% for macrolides, 8.8% for clindamycin, 16.4% for tetracyclines, 8.4% for chloramphenicol, and 30.3% for trimethoprim-sulfamethoxazole. Furthermore, 22.5% of clinical isolates of *S. pneumoniae* were multidrug-resistant. The dominant factor in the emergence of drug-resistant *S. pneumoniae* in North America has been human-to-human spread of relatively few clonal groups that harbor resistance determinants to multiple classes of antibiotics. Serotypes 6A, 6B, 9V, 14, 19F, and 23F accounted for 92.3% of penicillin-resistant pneumococcal isolates in one study.

Emergence of pneumococcal resistance to quinolones has been described in Canada, Spain, Hong Kong, Eastern and Central Europe, and (to a lesser extent) the United States. In Canada, the prevalence of ciprofloxacin-resistant pneumococci (MIC ≥ 4 μg/mL) increased from 0 in 1993 to 1.7% in 1997 to 1998 ($p = .01$); the figures for adults were 0 in 1993 and 3.7% in 1998. The Active Bacterial Core Surveillance program carried out by the U.S. Centers for Disease Control and Prevention during 1995 to 1999 reported levofloxacin nonsusceptibility rates of 0.2%. The emergence of quinolone resistance has been documented in two pandemic multidrug-resistant pneumococcal clones, Spain 23F-1 and Spain 9V-3. Strains of the Spain 23F-1 clone have been found to be resistant to quinolones in the United States, Europe, and Hong Kong.

The rapid increase in drug resistance has not been accompanied by clear evidence of therapy failure among patients with pneumococcal

CAP. There have been only a few controlled studies on the impact of pneumococcal resistance to penicillin on CAP outcomes. Overall, the results from these studies suggest that mortality is not higher among patients with penicillin-nonsusceptible pneumococcal isolates than among patients with susceptible isolates, particularly when an isolate's MIC is ≤2 μg/mL. Two case-control studies have reported adverse outcomes among patients with CAP due to penicillin-nonsusceptible pneumococci. In one study, after the exclusion of deaths occurring during the first 4 days of hospitalization, there was a significant risk of death among patients whose pneumococcal isolates had a penicillin MIC of at least 4 μg/mL or a cefotaxime MIC of at least 2 μg/mL. While the risk of death was not elevated among patients with penicillin-nonsusceptible pneumococcal pneumonia, the risk of suppurative complications was greater than that among patients with penicillin-susceptible infections.

Given their excellent activity against *S. pneumoniae* as well as against the so-called atypical pathogens *M. pneumoniae*, *C. pneumoniae*, and *Legionella* spp., macrolide antibiotics (either alone or combined with β-lactams) have been widely used to treat CAP. Despite the rapid escalation of macrolide resistance in *S. pneumoniae*, there is little evidence of therapy failures, especially among nonbacteremic patients treated in the community. However, there is now evidence of breakthrough bacteremia during macrolide or azalide treatment of patients infected with erythromycin-resistant *S. pneumoniae*. Doxycycline, which is active against penicillin-susceptible *S. pneumoniae* and against the atypical pathogens, is underused for the treatment of CAP in an ambulatory setting.

Although anecdotal, a number of reports have described failures of quinolone therapy for CAP due to *S. pneumoniae* resistant to the specific agent used. Among the risk factors that identify patients likely to be colonized or infected with quinolone-resistant pneumococci are an age of >64 years and a history of COPD and/or quinolone exposure. Indeed, patients with pneumonia who have been treated with a quinolone in the past 3 months should receive treatment with another class of antibiotics.

If there is clinical evidence of meningitis in a patient with CAP, vancomycin and ceftriaxone should be used (Table 239-9) to ensure that potentially drug-resistant *S. pneumoniae* is adequately treated.

TABLE 239-9 *Initial Empirical Antibiotic Therapy for Community-Acquired Pneumonia*

Treatment Setting; Patient's Condition	Regimen[a]
Outpatient; no cardiopulmonary disease, no risk factors for DRSP infection[b]	Macrolide (e.g., clarithromycin 500 mg bid PO × 10 days; or azithromycin 500 mg PO once, then 250 mg/d × 4 days) *or* Doxycycline 100 mg bid PO × 10 days
Outpatient; cardiopulmonary disease and/or (1) risk factors for DRSP infection or (2) high DRSP prevalence in community	Quinolone with enhanced activity against *Streptococcus pneumoniae*—e.g., levofloxacin 500 mg/d PO (or, with C_{cr} <50 mL/min, 250 mg/d), moxifloxacin 400 mg/d PO, or gatifloxacin 400 mg/d PO *or* β-Lactam (cefpodoxime 200 mg bid, cefuroxime axetil 750 mg tid, or amoxicillin 1000 mg tid, PO; amoxicillin/clavulanic acid 875/175 mg tid) plus macrolide or doxycycline *or* Telithromycin 800 mg q24h × 10 days
Hospital ward	Cefuroxime 750 mg q8h IV or ceftriaxone 1 g/d IV or cefotaxime 2 g q6h IV or ampicillin/sulbactam 1.5–3 g q6h IV *plus* Azithromycin 1 g/d IV followed by 500 mg/d IV *or* Quinolone with enhanced activity against *S. pneumoniae* (see above)[c]
Intensive care unit; no risk factors for *Pseudomonas aeruginosa* infection	Azithromycin 1 g IV, then start 500 mg IV 24 h later *plus* Ceftriaxone 1 g q12h IV *or* Cefotaxime 2 g q6h IV *or* Quinolone IV
Intensive care unit; risk factors for *P. aeruginosa*[b]	Imipenem (or meropenem) 500 mg q6h IV *or* Piperacillin/tazobactam 3.375 g q6h IV *plus* Ciprofloxacin 750 mg q8h IV
Nursing home[d]	Amoxicillin/clavulanic acid 875/125 mg tid PO *plus* Macrolide PO (see above) *or* Quinolone PO with enhanced activity against *S. pneumoniae* (see above) *or* Ceftriaxone 500–1000 mg/d IM or cefotaxime 500 mg IM q12h *plus* Macrolide (see above)
Aspiration pneumonitis (presumed to be due to effects of gastric acid or other irritants)	Wait 24 h; if symptoms persist, give antibiotic therapy delineated below for aspiration pneumonia.
Aspiration pneumonia; poor dental hygiene or putrid sputum, alcoholism (anaerobic infection suspected)	Metronidazole 500 mg q12h PO[e] *or* Piperacillin/tazobactam 3.375 g q6h IV *or* Imipenem 500 mg q6h IV *plus* One of the following: levofloxacin 500 mg/d IV or PO, moxifloxacin 400 mg/d PO, gatifloxacin 400 mg/d IV or PO, ceftriaxone, or cefotaxime
Aspiration pneumonia; community-acquired	Levofloxacin, moxifloxacin, gatifloxacin, ceftriaxone, or cefotaxime (see above)
Concomitant meningitis (suspected pneumococcal)	Vancomycin 1 g q12h IV *plus* Ceftriaxone 2 g q12h IV

[a] The optimal duration of therapy for CAP is unknown. With the exception of azithromycin (which has a long half-life), a 7- to 10-day course is usually recommended. Pneumonia due to *Legionella* spp., *P. aeruginosa*, or Enterobacteriaceae usually requires therapy of longer duration (often up to 21 days).

[b] Risk factors: (1) For penicillin-resistant *S. pneumoniae*: Previous use (within 3 months) of β-lactam antibiotics, alcoholism, age <5 years or >65 years, and (in some areas) residence in a nursing home. (2) For macrolide-resistant *S. pneumoniae*: Age <5 years or nosocomial acquisition of infection. (3) For quinolone-resistant *S. pneumoniae*: Older age, nursing home residence, chronic obstructive pulmonary disease, previous exposure to quinolones (especially ciprofloxacin in patients with chronic obstructive pulmonary disease) in the past 3 months, multiple hospitalizations, and β-lactam use. (4) For *P. aeruginosa*: Bronchiectasis, malnutrition, treatment with >10 mg of prednisone/d, previously undiagnosed HIV infection, and broad-spectrum antibiotic therapy for >7 days in the past month.

[c] Some authorities suggest that a β-lactam be added if a quinolone is chosen as empirical therapy until it is clear that quinolone-resistant pneumococci are not involved.

[d] For nursing home residents transferred to the hospital for treatment, see appropriate hospital/intensive care unit recommendations.

[e] Clindamycin could be used, but, because of the increased rate of *Clostridium difficile*–associated diarrhea associated with this drug, metronidazole is preferred.

Note: DRSP, drug-resistant *S. pneumoniae*.

SWITCH FROM INTRAVENOUS TO ORAL ANTIBIOTIC THERAPY Switching from intravenous to oral antibiotics can be done safely when (1) the white blood cell count is returning toward normal, (2) there are two normal temperature readings (<37.5°C) 16 h apart, and (3) there is improvement in cough and shortness of breath. Some antibiotics, such as amoxicillin and respiratory quinolones (moxifloxacin, gatifloxacin, and levofloxacin), are so well absorbed from the gastrointestinal tract that intravenous therapy is necessary only when the patient is hypotensive, is nauseated, and/or is vomiting.

DURATION OF ANTIBIOTIC THERAPY The standard duration of treatment for most patients with CAP is 10 to 14 days. However, no data from randomized clinical trials indicate the optimal duration. Patients treated on an ambulatory basis with an antibiotic with a long half-life

TABLE 239-10 Criteria for Hospital Admission of an Adult with Community-Acquired Pneumonia[a]

1. Respiratory rate >28/min
2. Systolic blood pressure <90 mmHg or 30 mmHg below baseline
3. New-onset confusion or impaired level of consciousness
4. Hypoxemia: P_{O_2} <60 mmHg while breathing room air or oxygen saturation <90%
5. Unstable comorbid illness (e.g., decompensated congestive heart failure, uncontrolled diabetes mellitus, alcoholism, immunosuppression)
6. Multilobar pneumonia, if hypoxemia is present
7. Pleural effusion that is >1 cm on lateral decubitus chest radiography and has the characteristics of a complicated parapneumonic effusion on pleural fluid analysis

[a] Patient should be admitted if any of the above criteria applies. Social factors such as homelessness must also be considered in the admission decision.

(e.g., azithromycin) require only 5 days of treatment. Patients with severe Legionnaires' disease require 21 days of therapy, as do those with pneumonia due to *P. aeruginosa* or other aerobic gram-negative bacilli.

Discharge from the Hospital The decision about when to discharge a patient with pneumonia is often a complicated matter. Once physiologic stability is achieved (defined as an oral temperature of <37.5°C for 24 h, a heart rate of <100/min, a respiratory rate of <24/min, a systolic blood pressure of >90 mmHg, an oxygen saturation of >90% while breathing room air, and the ability to eat and drink well enough to maintain hydration), clinical deterioration requiring admission to a critical-care unit or telemetry monitoring has occurred in <1% of patients. Since most patients hospitalized with CAP are elderly, it is necessary to assess functional and mental status before discharge. Comorbid illnesses should be stable, and any complications that have occurred during the hospital stay should have been addressed. Instability at the time of discharge is associated with higher rates of mortality and readmission than have been documented among patients stable at discharge.

In one study, patients with HIV infection and *Pneumocystis* pneumonia who were treated by an experienced medical team had a lower mortality rate than those who were treated by a team that managed such patients infrequently. Patients with pneumonia who were treated by subspecialists working outside their specialty had an 18% longer hospital stay and a slightly higher mortality rate than patients with pneumonia who were treated by general internists. High patient-to-nurse ratios are associated with increased mortality rates on surgical floors, and this association is likely to hold true and to be linked with suboptimal outcomes among patients hospitalized with pneumonia as well.

Failure to Improve When a patient with pneumonia fails to improve despite therapy, an organized approach that considers all the factors listed in Table 239-11 is useful. Many noninfectious conditions may mimic pneumonia, including lung cancer, pulmonary thromboembolic disease with infarction, collagen vascular diseases involving the lungs, and hypersensitivity pneumonitis due to drugs and a variety of antigens. A careful physical examination, with a search for metastatic foci of infection or physical signs suggestive of other diseases (e.g., subconjunctival petechiae, a new cardiac murmur suggestive of endocarditis), should be conducted and should be followed by blood, urine, and sputum cultures and repeat chest radiography. Depending on the results of chest radiography, high-resolution CT of the chest may be the next step. Indeed, CT of the chest in patients who fail to respond to therapy results in new findings not seen on chest radiographs 50% of the time, and these findings frequently lead to a change in therapy. If these investigations are unrewarding and pulmonary infection is still thought to be the most likely diagnosis, bronchoscopy with bronchoalveolar lavage is indicated. The respiratory secretions obtained should be cultured both aerobically and anaerobically as well as for *M. tuberculosis*, atypical mycobacteria, respiratory viruses, and fungi. Monoclonal antibody staining for *Pneumocystis* should be done. The secretions should also be examined cytologically; although this type of examination is usually undertaken to detect malignant cells, the investigator is occasionally surprised by the finding of *Strongyloides stercoralis* larvae in immunosuppressed patients with hyperinfection syndrome.

FOLLOW-UP Up to 2% of patients hospitalized with CAP are found to have cancer of the lung (with pneumonia distal to an obstructed bronchus). In 50% of these patients, the cancer is evident on the initial chest radiograph; however, in the remaining 50%, the cancer manifests as failure of the pneumonia to resolve radiographically and is evident only when bronchoscopy is performed to determine the reason for delayed pneumonia resolution. The rate of radiographic resolution of pneumonia is influenced by the age of the patient and the underlying lung disease. Thus patients with bacteremic pneumococcal pneumonia who are >60 years old and have COPD require up to 12 weeks for pneumonia resolution. The question, then, is the optimal timing of the follow-up chest radiograph among patients who are clinically well. In elderly patients with COPD, it is reasonable to wait 8 to 12 weeks. Nonsmoking patients <50 years of age who have no underlying lung disease should experience complete resolution of pneumonia within 6 weeks.

PREVENTION All patients with pneumonia who are tobacco smokers should be encouraged to join smoking cessation programs. Influenza and pneumococcal vaccination status should be ascertained and vaccines offered when appropriate. When a patient is prone to aspiration, preventive measures should be taken.

SELECTED COMPLICATIONS OF CAP ■ Complicated Pleural Effusion About 40% of patients hospitalized with CAP have a pleural effusion that can be documented by special techniques, such as CT of the chest. All patients with a pleural effusion should have a lateral decubitus chest radiograph with the affected side down. If the size of the effusion is >1 cm, the fluid should be aspirated. If the fluid has a pH of <7, a glucose level of <2.2 mmol/L, and a lactate dehydrogenase content of >1000 units and is positive on Gram's staining or culture, it should be drained. If frank pus is aspirated, insertion of a chest tube and treatment with intrapleural lytic agents are recommended. Thoracotomy and decortication may be necessary. All patients with a complicated pleural effusion, as defined above, should have a consultation with a thoracic surgeon.

Lung Abscess A lung abscess is a localized area of suppuration within lung tissue that leads to parenchymal destruction and is manifest radiographically as a cavity with an air-fluid level. Lung abscesses are currently uncommon, with an incidence of 4 to 5 cases per 10,000 hospital admissions. Risk factors for lung abscess include conditions associated with impaired cough reflex and/or aspiration, such as al-

TABLE 239-11 Possibilities to Consider When a Patient with Community-Acquired Pneumonia Fails to Improve Despite Treatment

1. Reconsider the diagnosis. Is this another illness presenting as pneumonia? Collagen vascular diseases involving the lung are frequently diagnosed at first as pneumonia.
2. Are you treating the wrong pathogen? For example, if you are treating conventional bacterial causes of pneumonia, is this case actually due to *Mycobacterium tuberculosis*, *Pneumocystis*, or another fungus?
3. Are you treating the right pathogen with the wrong drug? For example, if you are using nafcillin or cloxacillin to treat *Staphylococcus aureus* and your patient is infected with methicillin-resistant *S. aureus*, you should be using vancomycin or linezolid.
4. Is there a mechanical reason for the patient's failure to improve (e.g., obstructed bronchus due to carcinoma or sequestration of a segment of lung)?
5. Have you overlooked an undrained or metastatic pyogenic focus (e.g., empyema, brain abscess, endocarditis, splenic abscess, osteomyelitis)?
6. Does the patient have drug-associated fever?

coholism, anesthesia, drug abuse, epilepsy, and stroke. Dental caries, bronchiectasis, bronchial carcinoma, and pulmonary infarction are also risk factors. Most aspiration-associated lung abscesses are due to a combination of aerobic and anaerobic bacteria, with an average of six or seven bacterial species identified in an individual case. The implicated anaerobic bacteria include the *Bacteroides fragilis* group, *Bacteroides gracilis*, *Prevotella intermedia*, *Prevotella denticola*, *Prevotella melaninogenicus*, *Prevotella oralis*, *Fusobacterium nucleatum*, *Peptostreptococcus micros*, *Peptostreptococcus anaerobius*, and *Peptostreptococcus magnus*. *Streptococcus milleri* is one of the principal aerobic pathogens; *S. aureus*, *S. pneumoniae*, *H. influenzae*, *P. aeruginosa*, *E. coli*, and *Klebsiella pneumoniae* are also isolated frequently. Rarely, *S. pneumoniae* alone (usually capsular type 3) can cause a lung abscess. In HIV-infected patients, lung abscesses can be due to *Pneumocystis*, *Rhodococcus equi*, and *Cryptococcus neoformans* as well as the bacteria noted above.

The clinical presentation is usually indolent, with weight loss, malaise, night sweats, fever, and productive cough. Patients with anaerobic lung abscess have foul-smelling, often foul-tasting sputum. Clubbing of the fingers occurs in ~10% of patients, usually in those who have been symptomatic for >3 weeks.

Spontaneous drainage occurs via bronchial communication and is accompanied by the production of copious amounts of purulent sputum. Percutaneous catheter drainage can be both diagnostic and therapeutic. Antibiotic therapy should be directed at the organisms isolated and should be continued until the abscess has resolved radiographically. The treatment of a lung abscess requires a prolonged duration of therapy (usually 6 to 8 weeks, depending on clinical response). Medical management is unsuccessful in ~10% of cases. When medical management fails or the lung abscess is large, percutaneous drainage or lobectomy should be considered. When empyema is present, closed thoracostomy or open surgical drainage with or without decortication should be performed.

Not all pulmonary cavities are lung abscesses. Cavitating carcinoma, Wegener's granulomatosis, rheumatoid nodules, pulmonary infarcts, tuberculosis, and fungal infections are included in the differential diagnosis.

Recurrent Pneumonia Of patients admitted to the hospital for the treatment of CAP, 10 to 15% have another episode within 2 years. If the recurrence affects the same anatomical location as the previous episode, the most likely cause is an obstructed bronchus due to either a tumor or a foreign body. COPD and repeated macroaspiration are the most common causes of recurrent pneumonia. Persons without COPD, with pneumonia in a different location from the previous episode, and with no risk factors for aspiration should undergo evaluation for immunodeficiency, including HIV testing, immunoglobulin determination, protein electrophoresis, and enumeration of T and B cells. CT of the chest often detects pulmonary anatomical defects such as bronchiectasis that might be the cause of the recurrent pneumonia.

CAP IN LONG-TERM-CARE FACILITIES

EPIDEMIOLOGY About 4% of persons >65 years of age and 15% of those >85 years of age reside in LTCFs. LTCF residents range from healthy, self-sufficient individuals to frail persons who may be bedridden. Pneumonia is the leading cause of infection requiring transfer of nursing home residents to the hospital, accounting for 10 to 18% of all pneumonia admissions in North America. Profound disability (Karnofsky score of <10), bedridden state, urinary incontinence, male gender, difficulty swallowing, and inability to take oral medications are risk factors for pneumonia among LTCF residents, whereas receipt of influenza vaccine is protective. Malnutrition, tube feedings, hyperextended neck, contractures, and use of benzodiazepine and anticholinergic medications are risk factors for aspiration pneumonia in this population.

ETIOLOGY The most common etiologic agents associated with LTCF-acquired pneumonia are *S. aureus* (including MRSA), aerobic gram-negative bacilli, *S. pneumoniae*, *M. tuberculosis* (~2% of cases), and the agents of aspiration pneumonitis/pneumonia (about one-third of cases).

CLINICAL PRESENTATION In the frail or functionally impaired LTCF resident, pneumonia may present as an insidious or nonspecific deterioration in general health and/or activity level (e.g., confusion, falls, or sudden exacerbation of—or slow recovery from—an existing primary disease). An increase in respiratory rate to ≥28/min may be the first manifestation of pneumonia and often develops 24 to 48 h before clinical diagnosis. The in-hospital mortality rate can be as high as 30%, and the 1-year mortality rate is >50%.

Rx TREATMENT

Site of Care Nursing homes vary greatly in terms of the facilities and nursing staff available to provide care to very ill patients. Thus decisions about treatment site must be made with knowledge of the available resources as well as the wishes of patients and their families. Criteria helpful in deciding who should be transferred from an LTCF to the hospital for treatment of pneumonia are listed in Table 239-12.

Antibiotic Therapy Suggested regimens for the treatment of pneumonia in LTCF residents—either at the facility or in the hospital—are provided in Table 239-9.

PREVENTION Minimizing the risk of aspiration is a key factor in prevention of LTCF-associated pneumonia. Swallowing should be assessed in at-risk patients. Patients should be positioned upright for meals and during tube feeding. Use of sedatives/hypnotics should be minimized. Attention should be given to oral hygiene and dental care.

All residents should have a two-step Mantoux test at admission to the LTCF, and those with a positive result should be evaluated for evidence of active tuberculosis, with isoniazid treatment or prophylaxis given as needed. Humidifiers should be avoided or used only with sterile water. All LTCF workers should receive influenza vaccine annually.

SEVERE CAP

Severe CAP is generally defined as pneumonia requiring admission to the ICU. The criteria for severe CAP given in Table 239-4 are 100% sensitive and 72.8% specific and have a positive predictive value of 26.4%. Clinical judgment clearly remains paramount in this management decision.

EPIDEMIOLOGY The most common causes of severe CAP are listed in Table 239-2.

VENTILATORY SUPPORT While mechanical ventilation is commonly used to treat the hypoxemia associated with severe CAP, other therapies are also employed. Continuous positive airway pressure is widely used in hypoxemic patients with *Pneumocystis* pneumonia, and early studies suggest that it has the potential to hasten recovery. Hypoxemia is the result of intrapulmonary shunting and ventilation-perfusion mismatch, affecting up to 50% of cardiac output in patients with severe CAP. In patients with unilateral pneumonia, simply positioning the unaffected lung downward may result in improved ventilation-perfusion matching and an increase in Pa_{O_2} of 10 to 15 mmHg. More experimental ap-

TABLE 239-12 Criteria for Treatment of Pneumonia in a Nursing Home

1. Respiratory rate <30/min
2. Oxygen saturation ≥92% while breathing room air
3. Pulse rate <90/min
4. Temperature 36.5°C to 38.1°C
5. Systolic and diastolic blood pressure within 10 mmHg of usual readings
6. No feeding tube present
7. Patient conscious
8. Availability of medical and nursing care
9. Wishes of patient and family

proaches include the use of cyclooxygenase inhibitors (e.g., aspirin and indomethacin) to help partially reverse hypoxic pulmonary artery vasoconstriction and the aerosolization of prostacycline (PGI_2) or nitric oxide to reduce intrapulmonary shunting and pulmonary hypertension.

ASPIRATION PNEUMONITIS/PNEUMONIA

Aspiration syndromes refer to the clinical and pathophysiologic effects resulting from the introduction of foreign objects or substances into the lower respiratory tract. The most commonly involved areas—those that are most dependent in the supine position—are the posterior segments of the upper lobes and the superior segments of the lower lobes.

ETIOLOGY The usual causes of aspiration pneumonia in the elderly are Enterobacteriaceae, *S. aureus*, *S. pneumoniae*, and *H. influenzae*.

EPIDEMIOLOGY Aspiration syndromes include two distinct clinical entities. In aspiration pneumonitis, gastric contents (sterile as long as gastric acid is present) are aspirated into the lungs, with a consequent inflammatory response. Pneumonia results from the aspiration of oropharyngeal flora into the lungs, with consequent bacterial infection. The risk factors for aspiration include altered level of consciousness, incompetent gastroesophageal junction, elevated intragastric pressure or volume, and neuromuscular diseases that interfere with glottic closure.

The number of cases of aspiration pneumonia diagnosed in Medicare patients increased by 93.5% between 1991 and 1998. The mortality rate among patients with aspiration pneumonia was 23.1%, compared with 7.6% among those with pneumococcal pneumonia.

CLINICAL FEATURES The manifestations of aspiration pneumonia vary with the volume and nature of the material aspirated. Gastric acid aspiration results in a chemical pneumonitis that can be very severe, requiring assisted ventilation. A pH of <2.5 and a gastric aspirate volume of >0.3 mL/kg (20 to 25 mL in adults) are required for the development of aspiration pneumonitis. There is an acute onset of dyspnea, tachypnea, bronchospasm, and cyanosis, with a chest radiograph often showing diffuse opacities.

Many elderly patients are achlorhydric and so may not fit the typical presentation described above. Indeed, in many of these patients, aspiration pneumonitis is often indistinguishable from pneumonia. A history or a witnessed account of an aspiration event (one or more instances of vomiting, coughing while eating, displacement of a feeding tube, or vomitus or tube feeding on bedclothes or on the patient within 24 h of the diagnosis of pneumonia) is documented in only 40% of definite aspiration events among LTCF residents. Thus the diagnosis of aspiration pneumonitis/pneumonia requires a high index of suspicion. The location of the pneumonia depends on the position of the patient when aspiration occurred. An opacity involving the posterior segment of the upper lobes (especially the right upper lobe) is found in persons who have aspirated in the recumbent position, while aspiration in the upright or semirecumbent position results in involvement of the posterior basal segments of the lower lobes.

In the setting of aspiration of oropharyngeal contents and poor dental hygiene, anaerobic bacteria may be present, and lung abscess is not an uncommon complication. Particulate matter may be aspirated, with consequent mechanical obstruction of the airway.

Rx TREATMENT

Treatment for aspiration occurring in a community setting is outlined in Table 239-9.

PREVENTION Good oral hygiene reduces the risk of aspiration pneumonia among patients with cerebrovascular disease and swallowing impairment. Patients at high risk for aspiration (e.g., those who have had a stroke) should be assessed for aspiration. This evaluation is easily done by having an alert patient sit up and take increasing amounts of water, starting with one spoonful. Water leaking out of the corners of the mouth, coughing, and shortness of breath are all suggestive of aspiration and indicate the need for further evaluation.

CAP IN THE IMMUNOCOMPROMISED HOST

HIV-INFECTED PERSONS See Chap. 173.

TRANSPLANT RECIPIENTS (See also Chap. 117) Organ transplant recipients who develop pneumonia need a comprehensive diagnostic workup (diagnostic yield, 80%) and careful follow-up. Almost all of these patients require admission to the hospital. Newer immunosuppressive regimens and suppressive therapy for cytomegalovirus infection are changing the types and times of onset of opportunistic infections in this population.

An acute onset of symptoms, with presentation to the physician within 24 h, suggests bacterial pneumonia, pulmonary emboli with infarction, or pulmonary hemorrhage. A subacute onset over a few days to a week suggests viral, *Mycoplasma*, or *Pneumocystis* infection. A more chronic course over $\geq$1 week suggests fungal, nocardial, or tuberculous infection. Bacterial pneumonia is the most common infection in lung transplant recipients, accounting for almost half of the infections in this population. The incidence of pneumonia among these patients peaks in the first 4 to 8 weeks after transplantation and declines by the fourth month.

Nocardia spp., *R. equi*, and *Legionella* spp. are the major opportunistic bacterial pathogens in the lungs of organ transplant recipients; cytomegalovirus, varicella-zoster virus, influenza A and B viruses, respiratory syncytial virus, and adenovirus are the principal viral pathogens; and *Pneumocystis*, *C. neoformans*, *Aspergillus* spp., and Mucoraceae are the major fungal pathogens. *Aspergillus* spp., often in combination with aerobic gram-negative bacilli, is the most common cause of CAP among hematopoietic stem cell transplant recipients with graft-versus-host disease. CT of the chest is particularly useful if aspergillosis is suspected, in that it reveals pulmonary nodules, cavities, and halo or air-crescent signs.

HOSPITAL-ACQUIRED (NOSOCOMIAL) PNEUMONIA

EPIDEMIOLOGY Hospital-acquired pneumonia (HAP) is defined as pneumonia occurring at least 48 h after hospital admission and not incubating at the time of admission (Chap. 116). The incidence of HAP is estimated at 5 to 10 cases per 1000 hospital discharges, with ~300,000 cases annually. HAP is uncommon on obstetrical and psychiatric wards but reportedly develops in 5 to 10% of all hospital discharges on medical and surgical wards. HAP is the second most common nosocomial infection, accounting for up to 30% of all nosocomial infections; it carries the highest morbidity and mortality; it lengthens hospital stay by an average of 7 to 9 days per affected patient; and it increases costs by $2 billion annually. The incidence of HAP is highest among patients in the ICU who are undergoing mechanical ventilation. About 10% of general surgical postoperative patients, 20% of intubated patients, and up to 70% of patients with ARDS develop HAP during their stay in the ICU. A subset of HAP—ventilator-acquired pneumonia (VAP)—has been defined as pneumonia occurring after at least 48 h of mechanical ventilation and not incubating at the time of intubation. Because most patients undergo mechanical ventilation for only a short period, half of all cases of VAP occur within the first 4 days of intubation. The rate of VAP development is 3% for days 1 through 5, 2% for days 6 through 10, and 1% for days 11 through 15 after intubation. Among nonventilated patients, HAP is reported to occur at a median rate of 3.2 cases per 1000 ICU days; the corresponding figure for mechanically ventilated patients is 34.4 cases per 1000 ICU days. The incidence of pneumonia is reported to be 6 to 20 times higher among mechanically ventilated patients than among other hospitalized patients.

Crude mortality rates for HAP range from 30 to 70% and are highest among bacteremic patients, patients infected with high-risk pathogens (e.g., *P. aeruginosa*), and ICU patients. In the ICU setting, risk factors for death include shock, coma, ultimately or rapidly fatal un-

derlying disease, systemic inflammatory response syndrome, a high APACHE score, bilateral pulmonary infiltrates on chest radiography, ARDS, and respiratory failure. Despite high crude mortality rates, not all deaths are due to pneumonia; some patients with HAP die of their underlying illness. The attributable mortality due to HAP (i.e., the percentage of deaths among patients with HAP that would not have occurred in the absence of pneumonia) has been studied and remains controversial, but several studies suggest that one-third to one-half of all HAP deaths are due to infection.

About 1.5% of patients develop pneumonia postoperatively. The mortality rate at 1 month is tenfold higher (21% vs. 2%) among these patients than among those who do not develop postoperative pneumonia. An age of >80 years, poor functional status, recent weight loss, and alcohol use are predictors of postoperative pneumonia. Abdominal aortic aneurysm repair, thoracic surgery, and emergency surgery carry the highest risk for postoperative pneumonia, and general anesthesia carries a higher risk than other types of anesthesia.

PATHOGENESIS In addition to the factors that are important in the pathogenesis of CAP overall, other factors play an important role in the pathogenesis of HAP. Moreover, certain risk factors increase the likelihood of infection by specific pathogens (see below).

The patient's host defense system can be adversely affected by a number of risk factors. Factors that affect upper-respiratory host defenses (nasogastric or endotracheal intubation/reintubation, enteral feedings) increase the risk of both gross aspiration and microaspiration. Endotracheal intubation increases the risk of pneumonia in several ways. The tube serves as a direct conduit for bacterial introduction into the lower respiratory tract, prevents effective coughing to clear lower respiratory secretions, damages the tracheal epithelium, and allows the accumulation of oropharyngeal secretions (which are frequently colonized with bacteria) just above the cuff. Colonization of the endotracheal tube with pathogenic organisms can cause the formation of a biofilm that can be dislodged into the lower respiratory tract during suctioning. Poor infection-control measures and prolonged use of inappropriate antimicrobial agents increase the risk of spread of antimicrobial-resistant and/or especially virulent pathogens.

The presence of nasotracheal or nasogastric tubes increases the risk of nosocomial sinusitis, which occurs in more than half of all patients intubated for >7 days and which is also a risk factor for VAP. In one study, the same organism was isolated by transnasal culture and by protected specimen brushing in 20% of all patients with radiographic evidence of sinusitis. Moreover, the mortality rate was significantly lower when nosocomial sinusitis was identified and aggressively treated with antibiotics and nasal lavage every 8 h.

The role of the stomach as a reservoir for organisms that cause HAP remains controversial. It is accepted that elevation in gastric pH by antacids, H_2 antagonists, or enteral gastric feedings often leads to gastric bacterial overgrowth, which could be aspirated into the lower respiratory tract. Patients in the ICU are at high risk of aspiration because of reflux in the supine position, stomach placement of the enteral feeding tube, and large gastric volume.

In mechanically ventilated patients, tracheobronchitis frequently precedes the development of VAP by several days. Tracheobronchitis does not inevitably result in VAP, but bacterial concentrations in the bronchi may reach levels of at least 10^3 colony-forming units (CFU) per milliliter. In addition to fever and purulent sputum, tracheobronchitis may cause a false-positive culture result when lower respiratory tract secretions are sampled with a protected specimen brush (PSB).

ETIOLOGY In a national survey in the United States, 64% of all microorganisms isolated from the lungs of patients with nosocomial pneumonia were gram-negative bacilli, including *P. aeruginosa* (21%), *Acinetobacter* spp. (6%), and traditional enteric pathogens such as *Enterobacter* spp. (9%) and *K. pneumoniae* (8%).

S. aureus is the most common cause of nosocomial pneumonia in the United States. The increasing prevalence of MRSA among nosocomial isolates of *S. aureus* (from 2% in 1974 to as high as 64% in recent surveys) is of great concern in this context. In a comparative study of pneumonia due to MRSA and that due to methicillin-susceptible *S. aureus* (MSSA) in patients in an ICU, MRSA pneumonia resulted in a significantly greater frequency of bacteremia (36.4% vs. 10.5%; RR 3.4) and septic shock (27.3% vs. 7.9%; RR 3.4) and a significantly higher infection-associated mortality rate (54.5% vs. 2.6%; RR 20.7). Mortality rates among patients with MRSA and MSSA pneumonia who are treated with vancomycin are very high, possibly because of the low levels of vancomycin in the lungs 24 h after the initiation of treatment. In some in vitro studies, the bactericidal action of vancomycin against *S. aureus* has been weaker and slower than that of other antimicrobial agents, such as cloxacillin.

The Enterobacteriaceae account for ~30% of cases of ICU-acquired pneumonia. More than one-third of *Enterobacter* strains acquired in this setting are resistant to third-generation cephalosporins. The predominant mechanism of cephalosporin resistance in the Enterobacteriaceae is the production of β-lactamases, of which >300 have been described. The emergence of plasmid-mediated extended-spectrum β-lactamases (ESBLs) in members of the family Enterobacteriaceae has become a worldwide problem. ESBL molecular class A possesses an extended hydrolysis spectrum toward oxyimino-β-lactams and aztreonam but remains susceptible to cefoxitin and β-lactamase inhibitors.

The cephamycins (cefoxitin, cefotetan, and cefmetazole) are structurally different from the true cephalosporins and display enhanced stability in the presence of ESBLs. More than 90% of ESBL-producing organisms are susceptible to cephamycins.

Of major concern is the discovery of plasmid-mediated carbapenemases in Enterobacteriaceae. These enzymes inactivate all carbapenems, cephalosporins, and antipseudomonal penicillins.

Among patients on hospital wards who have no risk factors associated with specific pathogens, the pathogens most frequently causing nosocomial pneumonia include *S. pneumoniae*, *H. influenzae*, *S. aureus*, and enteric gram-negative bacilli (i.e., *E. coli*, *Klebsiella* spp., *Proteus* spp., and *Serratia marcescens*). These organisms have been designated "core pathogens" in the American Thoracic Society's guidelines for the treatment of nosocomial pneumonia.

The spectrum of potential pathogens is increased among patients with mild to moderate HAP if risk factors for specific pathogens are present. If the patient has had recent abdominal surgery or if an aspiration has been witnessed, the involvement of anaerobes should be considered. *S. aureus* (including MRSA) is more common among patients in a coma or with head trauma, diabetes mellitus, or renal failure. In the setting of potable-water contamination by *Legionella* spp., the use of high-dose glucocorticoids increases the risk of infection with this organism.

Among previously healthy patients with severe HAP requiring ICU care, length of stay before the onset of HAP affects the spectrum of pathogens. The most common pathogens among these patients with early-onset HAP or VAP (<5 days after admission) are the core pathogens (see above).

The most important risk factors for HAP due to resistant microorganisms are late onset of infection (>5 days after admission) and recent antibiotic therapy. The most common resistant organisms are MRSA, *Acinetobacter calcoaceticus-baumannii*, *Stenotrophomonas maltophilia*, and ESBL-producing Enterobacteriaceae. In addition, there are risk factors for specific resistant microorganisms. Glucocorticoid therapy, malnutrition, structural lung disease, mechanical ventilation, and underlying fatal medical conditions are risk factors for *P. aeruginosa*. Neurosurgery, head trauma, ARDS, and aspiration are risk factors for *Acinetobacter*. *S. maltophilia* is associated with increased ICU stay, tracheostomy, treatment with cefepime, and severe trauma with lung contusion. Isolation of MRSA has been associated with prior antibiotic therapy (especially with quinolones and macrolides), previous hospitalization, enteral feeding, surgery, and late-onset VAP. ESBL-producing Enterobacteriaceae have been associated with intu-

bation, previous antibiotic therapy, and central venous catheterization. The latter organisms may also be community-acquired and are now a problem in chronic-care facilities.

CLINICAL MANIFESTATIONS The definition of HAP includes the presence of a new or progressive infiltrate on chest radiography plus at least two of the following: fever [>37.8°C (>100°F)], leukocytosis (>10,000 white blood cells/μL), and the production of purulent sputum. Other findings, such as dyspnea, hypoxemia, and pleuritic chest pain, should prompt investigations for nosocomial pneumonia. It is important to exclude noninfectious causes of pulmonary infiltrates when evaluating a patient who presents with possible HAP.

DIAGNOSIS One of the most controversial areas in the management of HAP is how best to ascertain whether pneumonia is present and to determine the most appropriate therapy. Diagnostic accuracy is particularly important in mechanically ventilated patients, in whom VAP is frequently overdiagnosed. Invasive diagnostic testing is generally performed on intubated patients with VAP. The sampling methods used include endotracheal aspiration, PSB or bronchoalveolar lavage (BAL) sampling via a fiberoptic bronchoscope (FOB), or blinded invasive methods [blinded bronchial sampling (BBS), mini-BAL, and blinded PSB (BPSB)].

Endotracheal aspiration is most sensitive when patients have not received antimicrobial therapy. However, its specificity is low, and the sensitivity and specificity of cultures of endotracheal aspirates vary widely. If the patient has recently received any antibiotics, sensitivity and specificity are further decreased. The reported sensitivity and specificity of quantitative endotracheal aspiration range from 38 to 100% and from 14 to 100%, respectively. Visualization of elastin fibrils on Gram's staining and antibody coating of bacteria are unreliable indicators of infection.

Use of FOB-directed PSB and/or BAL has been advocated by many authorities; when performed at the same time, these studies are generally considered complementary. PSB is considered positive when at least 10^3 CFU of bacteria per brush are obtained, and BAL is considered positive when the recovered lavage fluid contains at least 10^4 CFU of bacteria per milliliter. The sensitivity of PSB ranges from 33 to 100% (median, 67%), and the specificity ranges from 50 to 100% (median, 95%). The sensitivity of BAL ranges from 42 to 93% (median, 73%), while the specificity ranges from 45 to 100% (median,

TABLE 239-13 *Empirical Antibiotic Therapy for Hospital-Acquired Pneumonia (HAP)*

Treatment Setting; Patient's Condition	*Risk Factor/Usual Pathogen(s)*	*Regimen*
Hospital ward; mild to moderate HAP, no risk factors for specific pathogens	—	Second-generation cephalosporin (cefuroxime 750 mg q8h IV) *or* Nonpseudomonal third-generation cephalosporin (ceftriaxone 1 g/d IV) *or* β-Lactam/β-lactamase inhibitor combination (piperacillin/tazobactam 3.375 g q6h IV) Penicillin allergy: Respiratory quinolone (levofloxacin 500 mg/d IV, moxifloxacin 400 mg/d IV, or gatifloxacin 400 mg/d IV) *or* Clindamycin plus aztreonam
Hospital ward; mild to moderate HAP with specific risk factors	—	Treat for usual pathogens (enteric gram-negative bacilli, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*) with cefuroxime, ceftriaxone, or piperacillin/tazobactam (see above) *plus* Treat for other pathogens related to risk factors (see below)
	Witnessed aspiration, recent abdominal surgery/anaerobes	Standard treatment (see above) *plus* Clindamycin 450–900 mg q8h IV *or* β-Lactam/β-lactamase inhibitor combination (piperacillin/tazobactam 3.375 g q6h IV)
	Coma, head trauma, diabetes mellitus, renal failure/*S. aureus*, risk for MRSA	Standard treatment (see above) *plus* Vancomycin 1 g q12h IV
	High-dose glucocorticoids/*Legionella*	Standard treatment (see above) *plus* Macrolide (azithromycin 500 mg/d IV) *or* Respiratory quinolone (see above)
Intensive care unit; severe HAP, early onset, no specific risk factors	—	Second-generation cephalosporin, nonpseudomonal third-generation cephalosporin, or β-lactam/β-lactamase inhibitor combination (see above) Penicillin allergy: Respiratory quinolone (see above)
Intensive care unit; severe HAP, late onset or specific risk factors	—	Treat for usual pathogens (enteric gram-negative bacilli, *S. aureus*, *S. pneumoniae*, *H. influenzae*) with cefuroxime, ceftriaxone, or piperacillin/tazobactam (see above) *plus* Treat for other pathogens related to risk factors (see below)
	Malnutrition, structural lung disease, glucocorticoid therapy/*Pseudomonas aeruginosa*; neurosurgery, head trauma, ARDS, aspiration/*Acinetobacter* spp.	Standard treatment (see above) *plus* Aminoglycoside or ciprofloxacin 500 mg q12h IV plus one of the following: antipseudomonal penicillin (piperacillin 4 g q6h IV or piperacillin/tazobactam 4.5 g q6h IV) or cefepime 1–2 g q12h IV or imipenem (or meropenem) 500 mg q8h IV
	Prior antibiotic therapy (especially with quinolones or macrolides), previous hospitalization, enteral feeding/MRSA	Standard treatment (see above) *plus* Vancomycin 1 g q12h IV

Note: ARDS, adult respiratory distress syndrome; MRSA, methicillin-resistant *S. aureus*.

82%). Both procedures require a well-trained, experienced operator and rapid transportation of samples to the laboratory. Because results are not available for at least 18 h, a portion of the BAL fluid should be centrifuged, the pellet stained with Giemsa or Gram's stain, and the stained preparation examined to determine the percentage of white blood cells with intracellular bacteria. Both 1% and 5% of cells containing intracellular bacteria have been used as significant breakpoints for diagnosing pneumonia. The effect of antibiotic therapy on the sensitivity and specificity of PSB and BAL is uncertain.

Blind mini-BAL and BBS have been introduced relatively recently. These tests are easier to perform and are less expensive than FOB-directed BAL. The sensitivity and specificity are 74 to 97% and 74 to 100%, respectively, for BPSB; 63 to 100% and 66 to 96% for mini-BAL; and 58 to 86% and 71 to 100% for blind mini-BAL and BBS. Risks from these procedures appear to be minimal.

TREATMENT

Most initial therapy for HAP is empirical (Table 239-13). The selection of drugs should be guided by an understanding of local patterns of antimicrobial resistance. If MRSA is highly prevalent in the institution and the patient is at risk for MRSA infection, empirical therapy should include vancomycin. Quinupristin-dalfopristin and linezolid can also be used to treat MRSA.

Evaluation of a patient whose condition is not improving or is actually deteriorating despite treatment involves the same considerations in HAP as in CAP (Table 239-11). Broadening the spectrum of antimicrobial therapy should be considered, with administration continued at least until the results of additional tests become available. Lower respiratory tract secretions should be sampled immediately by endotracheal aspiration, FOB-directed PSB or BAL, or a blinded sampling procedure.

PREVENTION A number of measures can reduce the risk of HAP. Health care providers must adhere strictly to hand-washing protocols. Surveillance of pneumonia rates should be routinely performed and reported. In patients undergoing mechanical ventilation, a concerted effort should be made to extubate rapidly, to minimize ventilator circuit changes, and to ensure careful periodic drainage of tubing condensate. Use of endotracheal tubes with a separate posterior lumen that allows continuous suctioning of subglottic secretions has been reported to decrease the incidence of early-onset VAP; heat-moisture exchanges reportedly reduce the risk of late-onset VAP. When the patient is receiving enteral feedings, a small-bore feeding tube should be placed distal to the pylorus, and large gastric residuals should be avoided. Elevation of the head of the bed by at least 30° lessens the risk of pneumonia, as does the use of kinetic beds. Earlier studies did not support the use of selective decontamination of the digestive tract as a method for preventing HAP. A recent study showed a significant reduction in mortality and colonization with resistant gram-negative aerobic bacteria among critically ill patients admitted to an ICU who underwent selective decontamination.

240 BRONCHIECTASIS

Steven E. Weinberger

DEFINITION Bronchiectasis is an abnormal and permanent dilatation of bronchi. It may be either focal, involving airways supplying a limited region of pulmonary parenchyma, or diffuse, involving airways in a more widespread distribution. Although this definition is based on pathologic changes in the bronchi, diagnosis is often suggested by the clinical consequences of chronic or recurrent infection in the dilated airways and the associated secretions that pool within these airways.

PATHOLOGY The bronchial dilatation of bronchiectasis is associated with destructive and inflammatory changes in the walls of medium-sized airways, often at the level of segmental or subsegmental bronchi. The normal structural components of the wall, including cartilage, muscle, and elastic tissue, are destroyed and may be replaced by fibrous tissue. The dilated airways frequently contain pools of thick, purulent material, while more peripheral airways are often occluded by secretions or obliterated and replaced by fibrous tissue. Additional microscopic features include bronchial and peribronchial inflammation and fibrosis, ulceration of the bronchial wall, squamous metaplasia, and mucous gland hyperplasia. The parenchyma normally supplied by the affected airways is abnormal, containing varying combinations of fibrosis, emphysema, bronchopneumonia, and atelectasis. As a result of the inflammation, vascularity of the bronchial wall increases, with associated enlargement of the bronchial arteries and anastomoses between the bronchial and pulmonary arterial circulations.

Three different patterns of bronchiectasis were described by Reid in 1950. In *cylindrical bronchiectasis* the bronchi appear as uniformly dilated tubes that end abruptly at the point that smaller airways are obstructed by secretions. In *varicose bronchiectasis* the affected bronchi have an irregular or beaded pattern of dilatation resembling varicose veins. In *saccular (cystic) bronchiectasis* the bronchi have a ballooned appearance at the periphery, ending in blind sacs without recognizable bronchial structures distal to the sacs.

ETIOLOGY AND PATHOGENESIS Bronchiectasis is a consequence of inflammation and destruction of the structural components of the bronchial wall. Infection is the usual cause of the inflammation; microorganisms such as *Pseudomonas aeruginosa* and *Haemophilus influenzae* produce pigments, proteases, and other toxins that injure the respiratory epithelium and impair mucociliary clearance. The host inflammatory response induces epithelial injury, largely as a result of mediators released from neutrophils. As protection against infection is compromised, the dilated airways become more susceptible to colonization and growth of bacteria. Thus, a reinforcing cycle can result, with inflammation producing airway damage, impaired clearance of microorganisms, and further infection, which then completes the cycle by inciting more inflammation.

Infectious Causes Adenovirus and influenza virus are the main viruses that cause bronchiectasis in association with lower respiratory tract involvement. Virulent bacterial infections, especially with potentially necrotizing organisms such as *Staphylococcus aureus*, *Klebsiella*, and anaerobes, remain important causes of bronchiectasis when antibiotic treatment of a pneumonia is not given or is significantly delayed. Bronchiectasis has been reported in patients with HIV infection, perhaps at least partly due to recurrent bacterial infection. Tuberculosis can produce bronchiectasis by a necrotizing effect on pulmonary parenchyma and airways and indirectly as a consequence of airway obstruction from bronchostenosis or extrinsic compression by lymph nodes. Nontuberculous mycobacteria are frequently cultured from patients with bronchiectasis, often as secondary infections or colonizing organisms. However, it has now also been recognized that these organisms, especially those of the *Mycobacterium avium* complex, can serve as primary pathogens associated with the development and/or progression of bronchiectasis. Mycoplasmal and necrotizing fungal infections are rare causes of bronchiectasis.

Impaired host defense mechanisms are often involved in the predisposition to recurrent infections. The major cause of localized impairment of host defenses is endobronchial obstruction. Bacteria and secretions cannot be cleared adequately from the obstructed airway, which develops recurrent or chronic infection. Slowly growing endobronchial neoplasms such as carcinoid tumors may be associated with bronchiectasis. Foreign-body aspiration is another important cause of endobronchial obstruction, particularly in children. Airway obstruction can also result from bronchostenosis, from impacted secretions, or from extrinsic compression by enlarged lymph nodes.

Generalized impairment of pulmonary defense mechanisms occurs with immunoglobulin deficiency, primary ciliary disorders, or cystic fibrosis. Infections and bronchiectasis are therefore often more diffuse. With panhypogammaglobulinemia, the best described of the immunoglobulin disorders associated with recurrent infection and bronchiectasis, patients often also have a history of sinus or skin infections. Selective deficiency of an IgG subclass, especially IgG2, has also been described in a small number of patients with bronchiectasis.

The primary disorders associated with ciliary dysfunction, termed *primary ciliary dyskinesia*, are responsible for 5 to 10% of cases of bronchiectasis. Numerous defects are encompassed under this category, including structural abnormalities of the dynein arms, radial spokes, and microtubules. The cilia become dyskinetic; their coordinated, propulsive action is diminished, and bacterial clearance is impaired. The clinical effects include recurrent upper and lower respiratory tract infections, such as sinusitis, otitis media, and bronchiectasis. Because normal sperm motility also depends on proper ciliary function, males are generally infertile (Chap. 325). Approximately half of patients with primary ciliary dyskinesia fall into the subgroup of *Kartagener's syndrome*, in which situs inversus accompanies bronchiectasis and sinusitis.

In cystic fibrosis (Chap. 241), the tenacious secretions in the bronchi are associated with impaired bacterial clearance, resulting in colonization and recurrent infection with a variety of organisms, particularly mucoid strains of *P. aeruginosa* but also *S. aureus*, *H. influenzae*, *Escherichia coli*, and *Burkholderia cepacia*.

Noninfectious Causes Some cases of bronchiectasis are associated with exposure to a toxic substance that incites a severe inflammatory response. Examples include inhalation of a toxic gas such as ammonia or aspiration of acidic gastric contents, though the latter problem is often also complicated by aspiration of bacteria. An immune response in the airway may also trigger inflammation, destructive changes, and bronchial dilatation. This mechanism is presumably important for bronchiectasis with allergic bronchopulmonary aspergillosis (ABPA), which is due at least in part to an immune response to *Aspergillus* organisms that have colonized the airway (Chap. 237). Bronchiectasis accompanying ABPA often involves proximal airways and is associated with mucoid impaction. Bronchiectasis also occurs rarely in ulcerative colitis, rheumatoid arthritis, and Sjögren's syndrome, but it is not known whether an immune response triggers airway inflammation in these patients.

In α_1-antitrypsin deficiency, the usual respiratory complication is the early development of panacinar emphysema, but affected individuals may occasionally have bronchiectasis. In the *yellow nail syndrome*, which is due to hypoplastic lymphatics, the triad of lymphedema, pleural effusion, and yellow discoloration of the nails is accompanied by bronchiectasis in approximately 40% of patients.

CLINICAL MANIFESTATIONS Patients typically present with persistent or recurrent cough and purulent sputum production. Hemoptysis occurs in 50 to 70% of cases and can be due to bleeding from friable, inflamed airway mucosa. More significant, even massive bleeding is often a consequence of bleeding from hypertrophied bronchial arteries.

When a specific infectious episode initiates bronchiectasis, patients may describe a severe pneumonia followed by chronic cough and sputum production. Alternatively, patients without a dramatic initiating event often describe the insidious onset of symptoms. In some cases, patients are either asymptomatic or have a nonproductive cough, often associated with "dry" bronchiectasis in an upper lobe. Dyspnea or wheezing generally reflects either widespread bronchiectasis or underlying chronic obstructive pulmonary disease. With exacerbations of infection, the amount of sputum increases, it becomes more purulent and often more bloody, and patients may become febrile. Such episodes may be due solely to exacerbations of the airway infection, but associated parenchymal infiltrates sometimes reflect an adjacent pneumonia.

Physical examination of the chest overlying an area of bronchiectasis is quite variable. Any combination of crackles, rhonchi, and wheezes may be heard, all of which reflect the damaged airways containing significant secretions. As with other types of chronic intrathoracic infection, clubbing may be present. Patients with severe, diffuse disease, particularly those with chronic hypoxemia, may have associated cor pulmonale and right ventricular failure. Amyloidosis can result from chronic infection and inflammation but is now seldom seen.

RADIOGRAPHIC AND LABORATORY FINDINGS Though the chest radiograph is important in the evaluation of suspected bronchiectasis, the findings are often nonspecific. At one extreme, the radiograph may be normal with mild disease. Alternatively, patients with saccular bronchiectasis may have prominent cystic spaces, either with or without air-liquid levels, corresponding to the dilated airways. These may be difficult to distinguish from enlarged airspaces due to bullous emphysema or from regions of honeycombing in patients with severe interstitial lung disease. Other findings are due to dilated airways with thickened walls, which result from peribronchial inflammation. Because of decreased aeration and atelectasis of the associated pulmonary parenchyma, these dilated airways are often crowded together in parallel. When seen longitudinally, the airways appear as "tram tracks"; when seen in cross-section, they produce "ring shadows." Because the dilated airways may be filled with secretions, the lumen may appear dense rather than radiolucent, producing an opaque tubular or branched tubular structure.

Bronchography, which involves coating the airways with a radiopaque, iodinated lipid dye instilled through a catheter or bronchoscope, can provide excellent visualization of bronchiectatic airways. However, this technique has now been replaced by computed tomography (CT), which also provides an excellent view of dilated airways as seen in cross-sectional images (Fig. 240-1). With the advent of high-resolution CT scanning, in which the images are 1.0 to 1.5 mm thick, the sensitivity for detecting bronchiectasis has improved even further. Other features on high-resolution CT scanning can suggest a specific etiology of the bronchiectasis. For example, bronchiectasis of relatively proximal airways suggests ABPA, whereas the presence of multiple small pulmonary nodules (nodular bronchiectasis) suggests infection with *M. avium* complex.

Examination of sputum often reveals an abundance of neutrophils

FIGURE 240-1 High-resolution CT scan of bronchiectasis showing dilated airways in both lower lobes and in the lingula. When seen in cross-section, the dilated airways have a ringlike appearance. *(From SE Weinberger: Principles of Pulmonary Medicine, 3d ed. Philadelphia, Saunders, 1998; with permission).*

and colonization or infection with a variety of possible organisms. Appropriate staining and culturing of sputum often provide a guide to antibiotic therapy.

Additional evaluation is aimed at diagnosing the cause for the bronchiectasis. When bronchiectasis is focal, fiberoptic bronchoscopy may reveal an underlying endobronchial obstruction. In other cases, upper lobe involvement may be suggestive of either tuberculosis or ABPA. With more widespread disease, measurement of sweat chloride levels for cystic fibrosis, structural or functional assessment of nasal or bronchial cilia or sperm for primary ciliary dyskinesia, and quantitative assessment of immunoglobulins may explain recurrent airway infection. In an asthmatic person with proximal bronchiectasis or other historical features to suggest ABPA, skin testing, serology, and sputum culture for *Aspergillus* are helpful in confirming the diagnosis.

Pulmonary function tests may demonstrate airflow obstruction as a consequence of diffuse bronchiectasis or associated chronic obstructive lung disease. Bronchial hyperreactivity, e.g., to methacholine challenge, and some reversibility of the airflow obstruction with inhaled bronchodilators are relatively common.

TREATMENT

Therapy has four major goals: (1) elimination of an identifiable underlying problem; (2) improved clearance of tracheobronchial secretions; (3) control of infection, particularly during acute exacerbations; and (4) reversal of airflow obstruction. Appropriate treatment should be instituted when a treatable cause is found, for example, treatment of hypogammaglobulinemia with immunoglobulin replacement, tuberculosis with antituberculous agents, and ABPA with glucocorticoids.

Secretions are typically copious and thick and contribute to the symptoms. A variety of mechanical methods and devices accompanied by appropriate positioning can facilitate drainage in patients with copious secretions. Mucolytic agents to thin secretions and allow better clearance are controversial. Aerosolized recombinant DNase, which decreases viscosity of sputum by breaking down DNA released from neutrophils, has been shown to improve pulmonary function in cystic fibrosis, but similar benefits have not been found with bronchiectasis due to other etiologies.

Antibiotics have an important role in management. For patients with infrequent exacerbations characterized by an increase in quantity and purulence of the sputum, antibiotics are commonly used only during acute episodes. Although choice of an antibiotic may be guided by Gram's stain and culture of sputum, empiric coverage (e.g., with ampicillin, amoxicillin, trimethoprim-sulfamethoxazole, or cefaclor) is often given initially. When *P. aeruginosa* is present, oral therapy with a quinolone or parenteral therapy with an aminoglycoside or third-generation cephalosporin may be appropriate. In patients with chronic purulent sputum despite short courses of antibiotics, more prolonged courses, e.g., with an oral antibiotic or inhaled aminoglycosides, or intermittent but regular courses of single or rotating antibiotics have been used.

Bronchodilators to improve obstruction and aid clearance of secretions are particularly useful in patients with airway hyperreactivity and reversible airflow obstruction. Although surgical therapy was common in the past, more effective antibiotic and supportive therapy has largely replaced surgery. However, when bronchiectasis is localized and the morbidity is substantial despite adequate medical therapy, surgical resection of the involved region of lung should be considered.

When massive hemoptysis, often originating from the hypertrophied bronchial circulation, does not resolve with conservative therapy, including rest and antibiotics, therapeutic options are either surgical resection or bronchial arterial embolization (Chap. 30). Although resection may be successful if disease is localized, embolization is preferable with widespread disease. In patients with extensive disease, chronic hypoxemia and cor pulmonale may indicate the need for long-term supplemental oxygen. For selected patients who are disabled despite maximal therapy, lung transplantation is a therapeutic option.

241 CYSTIC FIBROSIS

Richard C. Boucher

Cystic fibrosis (CF) is a monogenic disorder that presents as a multisystem disease. The first signs and symptoms typically occur in childhood, but about 7% of patients in the United States are diagnosed as adults. Due to improvements in therapy, >38% of patients are now adults (18 years of age) and 13% are past the age of 30. The median survival is >32 years for males and 29 years for females with CF. Thus, CF is no longer only a pediatric disease, and internists must be prepared to recognize and treat its many complications. This disease is characterized by chronic airways infection that ultimately leads to bronchiectasis and bronchiolectasis, exocrine pancreatic insufficiency and intestinal dysfunction, abnormal sweat gland function, and urogenital dysfunction.

PATHOGENESIS

GENETIC CONSIDERATIONS

CF is an autosomal recessive disease resulting from mutations in a gene located on chromosome 7. The prevalence of CF varies with the ethnic origin of a population. CF is detected in approximately 1 in 3000 live births in the Caucasian population of North America and northern Europe, 1 in 17,000 live births of African Americans, and 1 in 90,000 live births of the Asian population of Hawaii. The most common mutation in the CF gene (~70% of CF chromosomes) is a 3-bp deletion that results in an absence of phenylalanine at amino acid position 508 (ΔF_{508}) of the CF gene protein product, known as the CF transmembrane conductance regulator (CFTR). The large number (>1000) of relatively uncommon (<2%) mutations identified in the CF gene makes it difficult to use DNA diagnostic technologies for identifying heterozygotes in popu-

lations at large, and no simple physiologic measurements allow heterozygote detection.

CFTR PROTEIN The CFTR protein is a single polypeptide chain, containing 1480 amino acids, that appears to function both as a cyclic AMP–regulated Cl^- channel and, as its name implies, a regulator of other ion channels. The fully processed form of CFTR is found in the plasma membrane in normal epithelia (Fig. 241-1). Biochemical studies indicate that the ΔF_{508} mutation leads to improper processing and intracellular degradation of the CFTR protein. Thus, absence of CFTR at appropriate cellular sites is often part of the pathophysiology of CF. However, other mutations in the CF gene produce CFTR proteins that are fully processed but are nonfunctional or only partially functional at the appropriate cellular sites.

EPITHELIAL DYSFUNCTION The epithelia affected by CF exhibit different functions in their native state, i.e., some are volume-absorbing (airways and distal intestinal epithelia), some are salt-absorbing but not volume-absorbing (sweat duct), whereas others are volume-secretory (proximal intestine and pancreas). Given this diverse array of native activities, it should not be surprising that CF produces very different effects on patterns of electrolyte and water transport. However, the unifying concept is that all affected tissues express abnormal ion transport function.

ORGAN-SPECIFIC PATHOPHYSIOLOGY ■ Lung The diagnostic biophysical hallmark of CF is the raised transepithelial electric potential difference detected in airway epithelia. The transepithelial potential difference reflects components of both the rate of active ion transport and the resistance to ion flow of the superficial epithelium. CF airway epithelia exhibit both raised Na^+ transport rates and decreased Cl^- secretion (Fig. 241-2). The Cl^- secretory defect reflects the absence of cyclic AMP–dependent kinase and protein kinase C–regulated Cl^- transport that is mediated by the Cl^- channel function of CFTR. An important observation is that there is an "alternative" Ca^{2+}-regulated Cl^- channel expressed in airway epithelia. This Cl^- channel is different from CFTR and is regulated by intracellular Ca^{2+} levels. This channel can substitute for CFTR with regard to net Cl^- transport and may be a potential therapeutic target.

Raised Na^+ absorption is a feature of CF airway epithelia. Na^+ transport abnormalities in CF are not a widespread feature of the CF epithelial phenotype and appear confined to volume-absorbing epithelia. Recent studies demonstrate that the increased Na^+ absorption reflects a second function of CFTR: it acts as a tonic inhibitor of the epithelial Na^+ channel. The molecular mechanism mediating this action of CFTR is still unknown.

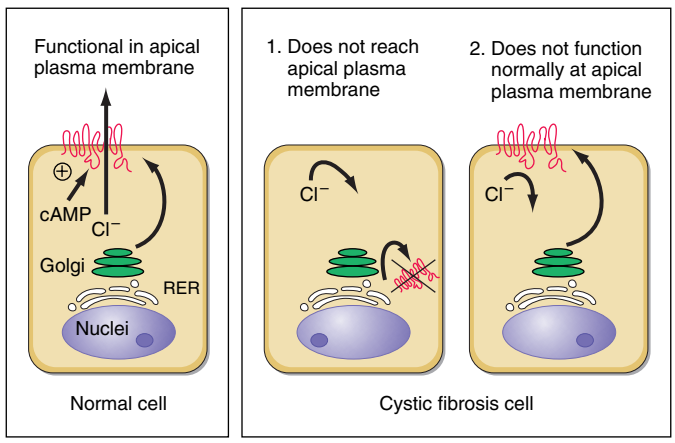

FIGURE 241-1 Cellular metabolism of the cystic fibrosis transmembrane regulator (CFTR) protein conductance (red). In a normal cell *(left)*, CFTR is synthesized in the rough endoplasmic reticulum (RER), is glycosylated in the Golgi apparatus, and functions as a Cl^- channel and regulator of other ion channels when located in the plasma membrane. Two possible outcomes of mutations in the CF gene are shown *(right)*. (1) If a mutation disturbs protein folding, e.g., the ΔF_{508} mutation, CFTR is degraded intracellularly so that no protein is transported to the plasma membrane. (2) With other mutations, the abnormal protein is processed and trafficks to the plasma membrane but functions abnormally at that site.

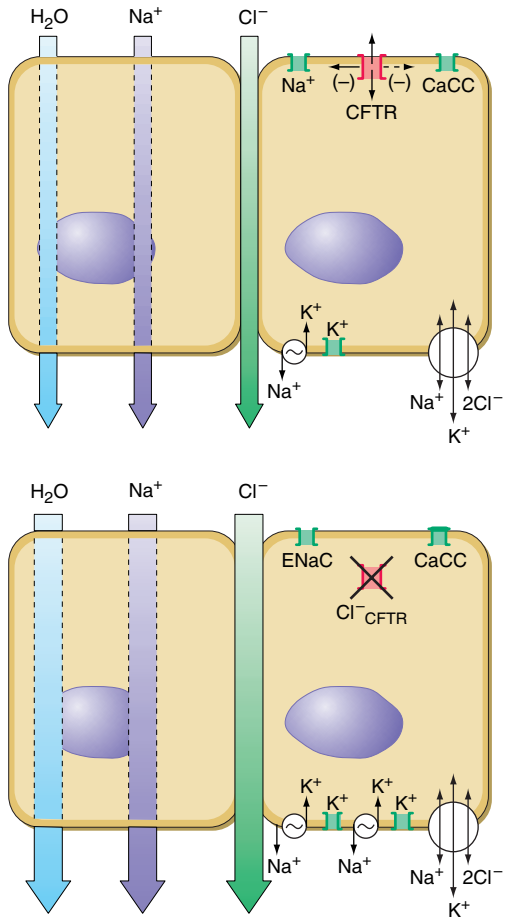

FIGURE 241-2 Comparison of ion transport properties of normal *(top)* and CF *(bottom)* airway epithelia. The vectors describe routes and magnitudes of Na^+ and Cl^- transport that is accompanied by osmotically driven water flow. The normal basal pattern for ion transport is absorption of Na^+ from the lumen via an amiloride-sensitive Na^+ channel. This process is accelerated in CF. The capacity to initiate cyclic AMP–mediated Cl^- secretion is diminished in CF airway epithelia due to absence/dysfunction of the CFTR Cl^- channel. The accelerated Na^+ absorption in CF reflects the absence of CFTR inhibitory effects on Na^+ channels.

Mucus clearance appears to be a primary innate defense mechanism for the airways against infection by inhaled bacteria. Normal airways can vary the rates of active Na^+ absorption and Cl^- secretion to adjust the volume of liquid (water) on airway surfaces for efficient mucus clearance. The central hypothesis of CF airways pathophysiology is that an abnormally high rate of Na^+ absorption and low rate of Cl^- secretion reduce the salt and water content of mucus and deplete the volume of the periciliary liquid. Both the thickening of mucus and the depletion of the periciliary liquid lead to adhesion of mucus to the airway surface. Mucus adhesion leads to a failure to clear mucus normally from the airways by either ciliary or airflow-dependent (cough) mechanisms. Recent data from both human cell culture models and CF mice in vivo support this hypothesis.

The infection that characterizes CF airways involves the mucus layer rather than epithelial or airway wall invasion. The unique predisposition of CF airways to chronic infection by *Staphylococcus aureus* and *Pseudomonas aeruginosa* is consistent with failure to clear mucus, but it has also suggested that as yet undefined abnormalities in airway surface liquid may also contribute to selection of these organisms. Recently, it has been demonstrated that reduced O_2 tension in CF mucus before, and particularly after, infection may in part select for these bacteria and be responsible for their phenotype. Thus, both mucus stasis and mucus hypoxia may contribute to the propensity for *Pseudomonas* to grow in biofilm colonies within mucus plaques adherent to CF airway surfaces.

Gastrointestinal Tract The gastrointestinal effects of CF are diverse. In the exocrine pancreas, the absence of the CFTR Cl^- channel in the apical membrane of pancreatic ductal epithelia limits the function of an apical membrane Cl^--HCO_3^- exchanger to secrete bicarbonate and Na^+ (by a passive process) into the duct. The failure to secrete Na^+ HCO_3^- and water leads to retention of enzymes in the pancreas and ultimately destruction of virtually all pancreatic tissue. The CF intestinal epithelium, because of the lack of Cl^- and water secretion, fails to flush secreted mucins and other macromolecules from intestinal crypts. The diminished CFTR-mediated secretion of liquid may be exacerbated by excessive absorption of liquid, reflecting abnormalities of CFTR-mediated regulation of Na^+ absorption (both mediated by Na^+ channels and possibly other Na^+ transporters, e.g., Na^+-H^+ exchangers). Both dysfunctions lead to dessicated intraluminal contents and obstruction of both the small and large intestine. In the hepatobiliary system, defective hepatic ductal salt (Cl^-) and water secretion causes retention of biliary secretion, focal biliary cirrhosis, and bile duct proliferation in approximately 25 to 30% of patients with CF. The inability of the CF gallbladder epithelium to secrete salt and water can lead to both chronic cholecystitis and cholelithiasis.

Sweat Gland CF patients secrete nearly normal volumes of sweat in the sweat acinus. However, CF patients are not able to absorb NaCl from sweat as it moves through the sweat duct due to the inability to absorb Cl^- across the ductal epithelial cells.

CLINICAL FEATURES

Most patients with CF present with signs and symptoms of the disease in childhood. Approximately 18% of patients present within the first 24 h of life with gastrointestinal obstruction, termed *meconium ileus*. Other common presentations within the first year or two of life include respiratory tract symptoms, most prominently cough and/or recurrent pulmonary infiltrates, and failure to thrive. A significant proportion of patients (~7%), however, are diagnosed after age 18.

RESPIRATORY TRACT Upper respiratory tract disease is almost universal in patients with CF. Chronic sinusitis is common in childhood and leads to nasal obstruction and rhinorrhea. The occurrence of nasal polyps approaches 25% and often requires surgery.

In the lower respiratory tract, the first symptom of CF is cough. With time, the cough becomes persistent and produces viscous, purulent, often greenish-colored sputum. Inevitably, periods of clinical stability are interrupted by "exacerbations," defined by increased cough, weight loss, increased sputum volume, and decrements in pulmonary function. These exacerbations require aggressive therapy, including frequent postural drainage and oral antibiotics, and often intravenous antibiotics (see below), with the goal being recovery of lung function. Over the course of years, the exacerbations become more frequent and the recovery of lost lung function incomplete, leading to respiratory failure.

CF patients exhibit a characteristic sputum microbiology. *Haemophilus influenzae* and *S. aureus* are often the first organisms recovered from samples of lung secretions in newly diagnosed patients with CF. *P. aeruginosa* is typically cultured from lower respiratory tract secretions thereafter. After repetitive antibiotic exposure, *P. aeruginosa*, often in a mucoid form, is usually the predominant organism recovered from sputum and may be present as several strains with different antibiotic sensitivities. *Burkholderia* (formerly *Pseudomonas*) *cepacia* has been recovered from CF sputum and is also pathogenic. Patient-to-patient spread of certain strains of this organism indicates that strict infection control in the hospital should be practiced. Other gram-negative rods recovered from CF sputum include *Xanthomonas xylosoxidans* and *B. gladioli*, and occasionally mucoid forms of *Proteus*, *Escherichia coli*, and *Klebsiella*. Up to 50% of CF patients have *Aspergillus fumigatus* in their sputum, and up to 10% of these patients exhibit the syndrome of allergic bronchopulmonary aspergillosis. *Mycobacterium tuberculosis* is rare in patients with CF. However, 10 to 20% of adult patients with CF have sputum cultures positive for nontuberculous mycobacteria, and in some patients these microorganisms are associated with disease.

The first lung function abnormalities observed in CF children, increased ratios of residual volume to total lung capacity, suggest that small airways disease is the first functional lung abnormality in CF. As the disease progresses, both reversible and irreversible changes in forced vital capacity and forced expiratory volume in 1 s are noted. The reversible component reflects the accumulation of intraluminal secretions and/or airway reactivity, which occurs in 40 to 60% of patients with CF. The irreversible component reflects chronic destruction of the airway wall and bronchiolitis.

The earliest chest x-ray change in CF lungs is hyperinflation, reflecting small airways obstruction. Later, signs of luminal mucus impaction, bronchial cuffing, and finally bronchiectasis, e.g., ring shadows, are noted. For reasons that are still unknown, the right upper lobe displays the earliest and most severe changes.

CF pulmonary disease is associated with many intermittent complications. Pneumothorax is common (>10% of patients). The production of small amounts of blood in sputum is common in CF patients with advanced pulmonary disease and appears to be associated with lung infection. Massive hemoptysis is life-threatening and difficult to localize bronchoscopically. With advanced lung disease, digital clubbing becomes evident in virtually all patients with CF. As late events, respiratory failure and cor pulmonale are prominent features of CF.

GASTROINTESTINAL TRACT The syndrome of meconium ileus in infants presents with abdominal distention, failure to pass stool, and emesis. The abdominal flat plate can be diagnostic, with small-intestinal air-fluid levels, a granular appearance representing meconium, and a small colon. In children and young adults, a syndrome termed *meconium ileus equivalent* or *distal intestinal obstruction syndrome* occurs. The syndrome presents with right lower quadrant pain, loss of appetite, occasionally emesis, and often a palpable mass. The syndrome can be confused with appendicitis, which occurs frequently in CF patients. The characteristic intestinal abnormalities are complicated by exocrine pancreatic insufficiency in >90% of patients with CF. Insufficient pancreatic enzyme release yields the typical pattern of protein and fat malabsorption, with frequent, bulky, foul-smelling stools. Signs and symptoms of malabsorption of fat-soluble vitamins, including vitamins E and K, are also noted. Pancreatic beta cells are typically spared, but function decreases with age, causing hyperglycemia and increasing requirements for insulin in older patients with CF.

GENITOURINARY SYSTEM Late onset of puberty is common in both males and females with CF. The delayed maturational pattern is likely secondary to the effects of chronic lung disease and inadequate nutrition on reproductive endocrine function. More than 95% of male patients with CF are azoospermic, reflecting obliteration of the vas deferens that is probably a result of defective liquid secretion. Some 20% of CF women are infertile due to effects of chronic lung disease on the menstrual cycle; thick, tenacious cervical mucus that blocks sperm migration; and possibly fallopian tube/uterine wall abnormalities in liquid transport. More than 90% of completed pregnancies produce viable infants, and women with CF are generally able to breast-feed infants normally.

DIAGNOSIS

Because of the large number of CF mutations, DNA analysis is not used for primary diagnosis. The diagnosis of CF rests on a combination of clinical criteria and analyses of sweat Cl^- values. The values for the Na^+ and Cl^- concentration in sweat vary with age, but typically in adults a Cl^- concentration of >70 meq/L discriminates between patients with CF and patients with other lung diseases.

DNA analyses are being performed increasingly in patients with CF. Comprehensive genotype-phenotype relationships have not yet been established sufficiently for prognosis. A relationship between ΔF_{508} homozygosity and pancreatic insufficiency has been established, but no predictive relationship holds for ΔF_{508} homozygosity and lung disease.

Between 1 and 2% of patients with the clinical syndrome of CF

have normal sweat Cl^- values. In most of these patients, the nasal transepithelial potential difference is raised into the diagnostic range for CF, and sweat acini do not secrete in response to injected β-adrenergic agonists. A single mutation of the CFTR gene, 3849 + 10 kb C→T, is associated with approximately 50% of CF patients with normal sweat Cl^- values.

TREATMENT

The major objectives of therapy for CF are to promote clearance of secretions and control infection in the lung, provide adequate nutrition, and prevent intestinal obstruction. Ultimately, gene therapy or therapies that restore the processing of misfolded CFTR may be the treatments of choice.

Lung Disease The principal techniques for clearing pulmonary secretions are breathing exercises, flutter valves, and chest percussion. Regular use of these maneuvers is effective in preserving lung function. There is increasing interest in the use of hypertonic saline (3 to 7%) aerosols to augment the clearance of secretions.

More than 95% of CF patients die of complications resulting from lung infection. Antibiotics are the principal agents available for treating lung infection, and their use should be guided by sputum culture results. Early intervention with antibiotics is useful, and long courses of treatment are the rule. Because of increased total-body clearance and volume of distribution of antibiotics in CF patients, the required doses are higher for patients with CF than for patients with similar chest infections who do not have CF.

Increased cough and mucus production are treated with antibiotics given orally. Typical oral agents used to treat *Staphylococcus* include a semisynthetic penicillin or a cephalosporin. Oral ciprofloxacin may reduce pseudomonal bacterial counts and control symptoms. However, its clinical usefulness may be limited by rapid emergence of resistant organisms, and, accordingly, courses should be intermittent (2 to 3 weeks) and not chronic. More severe exacerbations, or exacerbations associated with bacteria resistant to oral antibiotics, require intravenous antibiotics. Traditionally, intravenous therapy has been given in the hospital, but outpatient intravenous antibiotic administration has gained widespread acceptance. Usually, two drugs with different mechanisms of action (e.g., a cephalosporin and an aminoglycoside) are used to treat *P. aeruginosa* to hinder emergence of resistant organisms. Drug dosage should be monitored so that levels for gentamicin or tobramycin peak at ranges of ~10 μg/mL and exhibit troughs of <2 μg/mL. Cephalosporins (e.g., ceftazidime) and penicillin derivatives also require higher doses. Antibiotics directed at *Staphylococcus* and/or *H. influenzae* are added, depending on the results of the culture. Aerosolized antibiotics also have an important role in treating CF lung infection. Large doses of aminoglycosides, e.g., 300 mg tobramycin twice daily, via aerosol are effective at delaying exacerbations. Aerosol administration also permits other drugs, e.g., colistin, to be utilized that are relatively ineffective by the intravenous route.

A number of pharmacologic agents for increasing mucus clearance are in use. *N*-acetylcysteine, which solubilizes mucous glycoproteins, has not been shown to have clinically significant effects on mucus clearance and/or lung function. Recombinant human DNAse, however, degrades the concentrated DNA in CF sputum, decreases sputum viscosity, and increases airflow during short-term administration. Long-term (6 months) DNAse treatment increases the time between pulmonary exacerbations. Most patients receive a therapeutic trial of DNAse to test for efficacy, and a sizeable minority demonstrate persistent objective benefits. Clinical trials of experimental drugs aimed at restoring salt and water content of secretions are underway. However, these drugs are not yet available clinically.

Inhaled β-adrenergic agonists can be useful to control airways constriction. They achieve a short-term increase in airflow, but long-term benefit has not been shown. Inhaled anticholinergics provide an alternative. Oral glucocorticoids may reduce airways inflammation, but their long-term use has been limited by adverse side effects; however, they may be useful for treating allergic bronchopulmonary aspergillosis.

The chronic damage to airway walls reflects to some extent the destructive activities of inflammatory enzymes generated in part by inflammatory cells. To date, specific therapies with antiproteases have not been successfully developed. However, a subset of adolescents with CF appear to benefit from long-term, high dose nonsteroidal (ibuprofen) therapy.

A number of pulmonary complications require acute interventions. Atelectasis is best treated with chest physiotherapy and antibiotic therapy. Pneumothoraces involving ≤10% of the lung can be observed without intervention. The use of chest tubes to expand collapsed, diseased lung often requires long periods of time, and sclerosing agents should be used with caution because of possible limitations for subsequent lung transplantation. Small-volume hemoptysis requires no specific therapy other than treatment of lung infection and assessment of coagulation and vitamin K status. If massive hemoptysis occurs, bronchial artery embolization can be successful. The most ominous complications of CF are respiratory failure and cor pulmonale. The most effective conventional therapy for these conditions is vigorous medical management of the lung disease and O_2 supplementation. Ultimately, the only effective treatment for respiratory failure in CF is lung transplantation (Chap. 248). The 2-year survival for lung transplantation exceeds 60%, and deaths in transplant patients result principally from graft rejection, often involving obliterative bronchiolitis. The transplanted lungs do not develop a CF-specific phenotype.

Gastrointestinal Disease Maintenance of adequate nutrition is critical for the health of the patient with CF. Most (>90%) of CF patients benefit from pancreatic enzyme replacement. Capsules generally contain between 4000 and 20,000 units of lipase. The dose of enzymes (typically no more than 2500 units/kg per meal) should be adjusted on the basis of weight gain, abdominal symptomatology, and character of stools. Replacement of fat-soluble vitamins, particularly vitamins E and K, is usually required. Hyperglycemia most often becomes manifest in the adult and typically requires insulin treatment.

For treatment of acute obstruction due to distal intestinal obstruction syndrome, megalodiatrizoate or other hypertonic radiocontrast materials delivered by enema to the terminal ileum are utilized. For control of symptoms, adjustment of pancreatic enzymes and the supplementation of intake by salt solutions containing osmotically active agents, e.g., propyleneglycol, are utilized. Persistent symptoms may indicate a diagnosis of gastrointestinal malignancy, which is increased in incidence in patients with CF. Hepatic and gallbladder complications are treated as for patients without CF. End-stage liver disease can be treated by transplantation, which has a 2-year survival rate >50%.

Psychosocial Factors CF imposes a tremendous burden on patients. Health insurance, career options, family planning, and life expectancy become major issues. Thus, assisting patients with the psychosocial adjustments required by CF is critical.

242 CHRONIC OBSTRUCTIVE PULMONARY DISEASE

John J. Reilly, Jr., Edwin K. Silverman, Steven D. Shapiro

Chronic obstructive pulmonary disease (COPD) has been defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as a disease state characterized by airflow limitation that is not fully reversible (http://www.goldcopd.com/). COPD includes *emphysema*, an anatomically defined condition characterized by destruction and enlargement of the lung alveoli; *chronic bronchitis*, a clinically defined condition with chronic cough and phlegm; and *small airways disease*, a condition in which small bronchioles are narrowed. COPD is present only if chronic airflow obstruction occurs; chronic bronchitis *without* chronic airflow obstruction is *not* included within COPD.

COPD is the fourth leading cause of death and affects >16 million persons in the United States. COPD is also a disease of increasing public health importance around the world. GOLD estimates suggest that COPD will rise from the sixth to the third most common cause of death worldwide by 2020.

RISK FACTORS ■ Cigarette Smoking By 1964, the Advisory Committee to the Surgeon General of the United States concluded that cigarette smoking was a major risk factor for mortality from chronic bronchitis and emphysema. Subsequent longitudinal studies have shown accelerated decline in the volume of air exhaled within the first second of the forced expiratory maneuver (FEV_1) in a dose-response relationship to the intensity of cigarette smoking, which is typically expressed as pack-years (average number of packs of cigarettes smoked per day multiplied by the total number of years of smoking). This dose-response relationship between reduced pulmonary function and cigarette smoking intensity accounts for the higher prevalence rates for COPD with increasing age. The historically higher rate of smoking among males is the likely explanation for the higher prevalence of COPD among males; however, the prevalence of COPD among females is increasing as the gender gap in smoking rates has diminished in the past 50 years.

Although the causal relationship between cigarette smoking and the development of COPD has been absolutely proven, there is considerable variability in the response to smoking. Although pack-years of cigarette smoking is the most highly significant predictor of FEV_1 (Fig. 242-1), only 15% of the variability in FEV_1 is explained by pack-years. This finding suggests that additional environmental and/or genetic factors contribute to the impact of smoking on the development of airflow obstruction.

Although cigar and pipe smoking may also be associated with the development of COPD, the evidence supporting such associations is less compelling, likely related to the lower dose of inhaled tobacco byproducts during cigar and pipe smoking.

Airway Responsiveness and COPD A tendency for increased bronchoconstriction in response to a variety of exogenous stimuli, including methacholine and histamine, is one of the defining features of asthma (Chap. 236). However, many patients with COPD also share this feature of airway hyperresponsiveness. The considerable overlap between persons with asthma and those with COPD on airway responsiveness, airflow obstruction, and pulmonary symptoms led to the formulation of the Dutch hypothesis. This suggests that asthma, chronic bronchitis, and emphysema are variations of the same basic disease, which is modulated by environmental and genetic factors to produce these pathologically distinct entities. The alternative British hypothesis contends that asthma and COPD are fundamentally different diseases: Asthma is viewed as largely an allergic phenomenon, while COPD results from smoking-related inflammation and damage. Determination of the validity of the Dutch hypothesis vs. the British hypothesis awaits identification of the genetic predisposing factors for asthma and/or COPD, as well as the interactions between these postulated genetic factors and environmental risk factors.

Longitudinal studies that compared airway responsiveness at the beginning of the study to subsequent decline in pulmonary function have demonstrated that increased airway responsiveness is clearly a significant predictor of subsequent decline in pulmonary function. Thus, airways hyperresponsiveness is a risk factor for COPD.

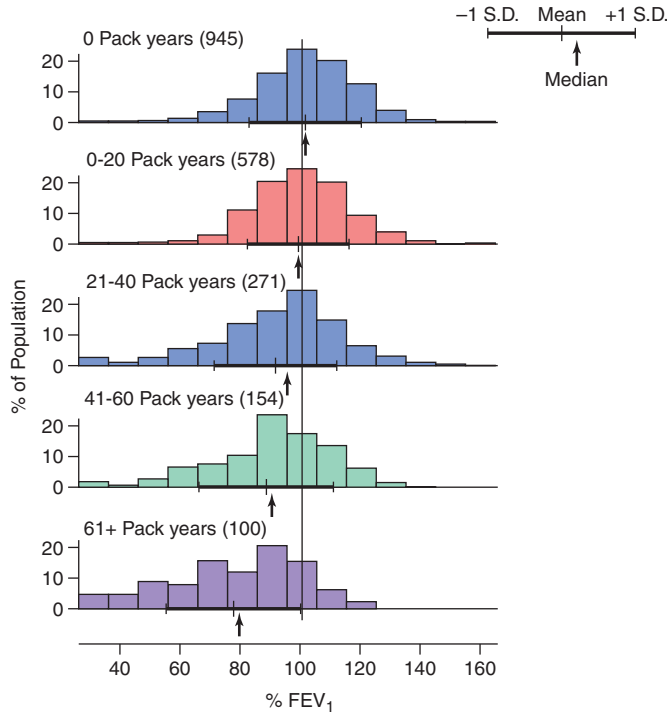

FIGURE 242-1 Distributions of forced expiratory volume in 1 s (FEV_1) values in a general population sample, stratified by pack-years of smoking. Means, medians, and ± 1 standard deviation of percent predicted FEV_1 are shown for each smoking group. Although a dose-response relationship between smoking intensity and FEV_1 was found, marked variability in pulmonary function was observed among subjects with similar smoking histories. (*From Burrows et al, with permission.*)

Respiratory Infections These have been studied as potential risk factors for the development and progression of COPD in adults; childhood respiratory infections have also been assessed as potential predisposing factors for the eventual development of COPD. The impact of adult respiratory infections on decline in pulmonary function is controversial, but significant long-term reductions in pulmonary function are not typically seen following an episode of bronchitis or pneumonia. The impact of the effects of childhood respiratory illnesses on the subsequent development of COPD has been difficult to assess due to a lack of adequate longitudinal data. Thus, although respiratory infections are important causes of exacerbations of COPD, the association of both adult and childhood respiratory infections to the development and progression of COPD remains to be proven.

Occupational Exposures Increased respiratory symptoms and airflow obstruction have been suggested as resulting from general exposure to dust at work. Several specific occupational exposures, including coal mining, gold mining, and cotton textile dust, have been suggested as risk factors for chronic airflow obstruction. However, although nonsmokers in these occupations developed some reductions in FEV_1, the importance of dust exposure as a risk factor for COPD, independent of cigarette smoking, is not certain. Among workers exposed to cadmium (a specific chemical fume), FEV_1, FEV_1/FVC, and DL_{CO} were significantly reduced (FVC, forced vital capacity; DL_{CO}, carbon monoxide diffusing capacity of the lung; Chap. 234), consistent with airflow obstruction and emphysema. Although several specific occupational dusts and fumes are likely risk factors for COPD, the

magnitude of these effects appears to be substantially less important than the effect of cigarette smoking.

Ambient Air Pollution Some investigators have reported increased respiratory symptoms in those living in urban compared to rural areas, which may relate to increased pollution in the urban settings. However, the relationship of air pollution to chronic airflow obstruction remains unproven. With high rates of COPD reported in nonsmoking women in many developing countries, indoor air pollution, usually associated with cooking, has been suggested as a potential contributor. In most populations, ambient air pollution is a much less important risk factor for COPD than cigarette smoking.

Passive, or Second-Hand, Smoking Exposure Exposure of children to maternal smoking results in significantly reduced lung growth. In utero tobacco smoke exposure also contributes to significant reductions in postnatal pulmonary function. Although passive smoke exposure has been associated with reductions in pulmonary function, the importance of this risk factor in the development of the severe pulmonary function reductions in COPD remains uncertain.

GENETIC CONSIDERATIONS

Although cigarette smoking is the major environmental risk factor for the development of COPD, the development of airflow obstruction in smokers is highly variable. Severe α_1 antitrypsin (α_1AT) deficiency is a proven genetic risk factor for COPD; there is increasing evidence that other genetic determinants also exist.

α_1 ANTITRYPSIN DEFICIENCY Many variants of the protease inhibitor (PI) locus that encodes α_1AT have been described. The common M allele is associated with normal α_1AT levels. The S allele, associated with slightly reduced α_1AT levels, and the Z allele, associated with markedly reduced α_1AT levels, also occur with frequencies >1% in most Caucasian populations. Rare individuals inherit null alleles, which lead to the absence of any α_1AT production through a heterogeneous collection of mutations. Individuals with two Z alleles or one Z and one null allele are referred to as Pi^Z , which is the most common form of severe α_1AT deficiency.

Although only 1 to 2% of COPD patients inherit severe α_1AT deficiency, these patients demonstrate that genetic factors can have a profound influence on the susceptibility for developing COPD. Pi^Z individuals often develop early-onset COPD, but the ascertainment bias in the published series of Pi^Z individuals—which have usually included many Pi^Z subjects who were tested for α_1AT deficiency because they had COPD—means that the fraction of Pi^Z individuals who will develop COPD and the age-of-onset distribution for the development of COPD in Pi^Z subjects remain unknown. Approximately 1 in 3000 individuals in the United States inherits severe α_1AT deficiency, but only a small minority of these individuals have been recognized.

A significant percentage of the variability in pulmonary function among Pi^Z individuals is explained by cigarette smoking; cigarette smokers with severe α_1AT deficiency are more likely to develop COPD at early ages. However, the development of COPD in Pi^Z subjects, even among current or ex-smokers, is not absolute. Among Pi^Z nonsmokers, impressive variability has been noted in the development of airflow obstruction. Other genetic and/or environmental factors likely contribute to this variability.

The clinical laboratory test used most frequently to screen for α_1AT deficiency is measurement of the immunologic level of α_1AT in serum (see "Laboratory Findings," below). Specific treatment in the form of α_1AT augmentation therapy is available for severe α_1AT deficiency as a weekly intravenous infusion (see "Treatment" below).

The risk of lung disease in heterozygous Pi^{MZ} individuals, who have intermediate serum levels of α_1AT (~60% of Pi^{MM} levels), is controversial. Although previous general population surveys have not typically shown increased rates of airflow obstruction in Pi^{MZ} compared to Pi^{MM} individuals, case-control studies that compared COPD patients to control subjects have usually found an excess of Pi^{MZ} genotypes in the COPD patient group. Several recent large population studies have suggested that Pi^{MZ} subjects are at slightly increased risk for the development of airflow obstruction, but it remains unclear if all Pi^{MZ} subjects are at slightly increased risk for COPD or if a subset of Pi^{MZ} subjects are at substantially increased risk for COPD due to other genetic or environmental factors.

OTHER GENETIC RISK FACTORS Studies of pulmonary function measurements performed in general population samples have suggested that genetic factors other than PI type influence variation in pulmonary function. Familial aggregation of airflow obstruction within families of COPD patients has also been demonstrated.

Association studies have compared the distribution of variants in genes hypothesized to be involved in the development of COPD in COPD patients and control subjects. However, the results have been quite inconsistent, and no genetic determinants of COPD other than severe α_1AT deficiency have been definitively proven. Recent genome scan linkage analyses of early-onset COPD families have found evidence for linkage of spirometric phenotypes to several chromosomal regions, but the specific genetic determinants in those regions have yet to be identified.

NATURAL HISTORY

The effects of cigarette smoking on pulmonary function appear to depend on the intensity of smoking exposure, the timing of smoking exposure during growth, and the baseline lung function of the individual; other environmental factors may have similar effects. Although rare individuals may demonstrate precipitous declines in pulmonary function, most individuals follow a steady trajectory of increasing pulmonary function with growth during childhood and adolescence, followed by a gradual decline with aging. Individuals appear to track in their quartile of pulmonary function based upon environmental and genetic factors that put them on different tracks. The risk of eventual mortality from COPD is closely associated with reduced levels of FEV_1. A graphic depiction of the natural history of COPD is shown as a function of the influences on tracking curves of FEV_1 in Fig. 242-2. Death or disability from COPD can result from a normal rate of decline after a reduced growth phase (curve B), an early initiation of pulmonary function decline after normal growth (curve C), or an accelerated decline after normal growth (curve D). The rate of decline in pulmonary function can be modified by changing environmental exposures (i.e., quitting smoking), with smoking cessation at an earlier age providing a more beneficial effect than smoking cessation after marked reductions in pulmonary function have already

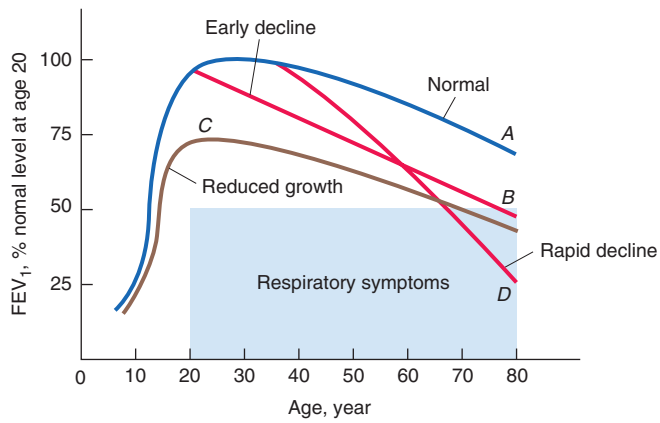

FIGURE 242-2 Hypothetical tracking curves of FEV_1 for individuals throughout their lifespans. The normal pattern of growth and decline with age is shown by curve *A*. Significantly reduced FEV_1 (<65% of predicted value at age 20) can develop from a normal rate of decline after a reduced pulmonary function growth phase (curve *B*), early initiation of pulmonary function decline after normal growth (curve *C*), or accelerated decline after normal growth (curve *D*). (*From B Rijcken: Doctoral dissertation, p 133, University of Groningen, 1991; with permission.*)

developed. Genetic factors likely contribute to the level of pulmonary function achieved during growth and to the rate of decline in response to smoking and potentially to other environmental factors as well.

PATHOPHYSIOLOGY Persistent reduction in forced expiratory flow rates is the most typical finding in COPD. Increases in the residual volume and the residual volume/total lung capacity ratio, nonuniform distribution of ventilation, and ventilation-perfusion mismatching also occur.

Airflow Obstruction Airflow limitation, also known as airflow obstruction, is typically determined by spirometry, which involves forced expiratory maneuvers after the subject has inhaled to total lung capacity (Fig. 234-4). Key phenotypes obtained from spirometry include FEV_1 and the total volume of air exhaled during the entire spirometric maneuver (FVC). Patients with airflow obstruction related to COPD have a chronically reduced ratio of FEV_1/FVC. In contrast to asthma, the reduced FEV_1 in COPD seldom shows large responses to inhaled bronchodilators, although improvements up to 15% are common. Asthma patients can also develop chronic (not fully reversible) airflow obstruction. Maximal inspiratory flow can be relatively well preserved in the presence of a markedly reduced FEV_1. Airflow during forced exhalation is the result of the balance between the elastic recoil of the lungs promoting flow and the resistance of the airways limiting flow. In normal lungs, as well as in lungs affected by COPD, maximal expiratory flow diminishes as the lungs empty because the lung parenchyma provides progressively less elastic recoil and because the cross-sectional area of the airways falls, raising the resistance to airflow. The decrease in flow coincident with decreased lung volume is readily apparent on the expiratory limb of a flow-volume curve. In the early stages of COPD, the abnormality in airflow is only evident at lung volumes at or below the functional residual capacity (closer to residual volume), appearing as a scooped-out lower part of the descending limb of the flow-volume curve. In more advanced disease the entire curve has decreased expiratory flow compared to normal.

Hyperinflation Lung volumes are also routinely assessed in pulmonary function testing. In COPD there is often "air trapping" (increased residual volume and increased ratio of residual volume to total lung capacity) and progressive hyperinflation (increased total lung capacity) late in the disease. Hyperinflation of the thorax during tidal breathing preserves maximum expiratory airflow, because as lung volume increases, elastic recoil pressure increases and airways enlarge so that airway resistance decreases. Consequently, hyperinflation helps to compensate for airway obstruction. However, hyperinflation can push the diaphragm into a flattened position with a number of adverse effects. First, by decreasing the zone of apposition between the diaphragm and the abdominal wall, positive abdominal pressure during inspiration is not applied as effectively to the chest wall, hindering rib cage movement and impairing inspiration. Second, because the muscle fibers of the flattened diaphragm are shorter than those of a more normally curved diaphragm they are less capable of generating inspiratory pressures than normal. Third, the flattened diaphragm (with increased radius of curvature, r) must generate greater tension (t) to develop the transpulmonary pressure (p) required to produce tidal breathing. This follows from Laplace's law, $p = 2t/r$. Also, because the thoracic cage is distended beyond its normal resting volume, during tidal breathing the inspiratory muscles must do work to overcome the resistance of the thoracic cage to further inflation instead of gaining the normal assistance from the chest wall recoiling outward towards its resting volume.

Gas Exchange Although there is considerable variability in the relationships between the FEV_1 and other physiologic abnormalities in COPD, certain generalizations may be made. The Pa_{O_2} usually remains near normal until the FEV_1 is decreased to ~50% of predicted, and even much lower FEV_1's can be associated with a normal Pa_{O_2}, at least at rest. An elevation of Pa_{CO_2} is not expected until the FEV_1 is ≲25% of predicted, and even then may not occur. Pulmonary hypertension severe enough to cause cor pulmonale and right ventricular failure due to COPD occurs only in those individuals who have marked decreases in FEV_1 (<25% of predicted) together with chronic hypoxemia ($Pa_{O_2} < 55$ mmHg), although earlier in the course some elevation of pulmonary artery pressure, particularly with exercise, may occur (Chap. 220).

Nonuniform ventilation and ventilation-perfusion mismatching are characteristic of COPD, reflecting the heterogeneous nature of the disease process within the airways and lung parenchyma. Nitrogen wash-out while breathing 100% oxygen is delayed due to regions that are poorly ventilated, and the profile of the nitrogen wash-out curve is consistent with multiple parenchymal compartments having different wash-out rates due to regional differences in compliance and airway resistance. Ventilation/perfusion mismatching accounts for essentially all of the reduction in Pa_{O_2} that occurs in COPD; shunting is minimal. This finding explains the effectiveness of modest elevations of inspired oxygen in treating hypoxemia due to COPD and therefore the need to consider problems other than COPD when hypoxemia is difficult to correct with modest levels of supplemental oxygen in the patient with COPD.

PATHOLOGY Cigarette smoke exposure may affect the large airways, small airways (<2 mm diameter), and alveolar space. Changes in large airways cause cough and sputum, while changes in small airways and alveoli are responsible for physiologic alterations. Emphysema and small airway pathology are both present in most persons with COPD, and their relative contributions to obstruction vary from one person to another. Small airway obstruction likely contributes more to initial obstruction, with emphysema predominating later in the course.

Large Airway Cigarette smoking often results in mucous gland enlargement and goblet cell hyperplasia. These changes are proportional to cough and mucus production that define chronic bronchitis, but these abnormalities are not related to airflow limitation. Goblet cells not only increase in number but in extent through the bronchial tree. Bronchi also undergo squamous metaplasia, which not only predisposes to carcinogenesis but also disrupts mucociliary clearance. Although not as prominent as in asthma, patients may have smooth-muscle hypertrophy and bronchial hyperreactivity leading to airflow limitation. Neutrophil influx has been associated with purulent sputum of upper respiratory tract infections that hamper patients with COPD. Independent of its proteolytic activity, neutrophil elastase is among the most potent secretagogues identified.

Small Airways The major site of increased resistance in most individuals with COPD is in airways ≤2 mm diameter. Characteristic cellular changes include goblet cell metaplasia and replacement of surfactant-secreting Clara cells with mucus-secreting and infiltrating mononuclear inflammatory cells. Smooth-muscle hypertrophy may also be present. These abnormalities may cause luminal narrowing by excess mucus, edema, and cellular infiltration. Reduced surfactant may increase surface tension at the air-tissue interface, predisposing to airway narrowing or collapse. Fibrosis in the wall may cause airway narrowing directly or, as in asthma, predispose to hyperreactivity. Respiratory bronchiolitis with mononuclear inflammatory cells collecting in distal airway tissues may cause proteolytic destruction of elastic fibers in the respiratory bronchioles and alveolar ducts where the fibers are concentrated as rings around alveolar entrances. The resulting distortion and narrowing of these structures could be involved in the early airflow obstruction in COPD related to cigarette smoking.

Because small airway patency is maintained by the surrounding lung parenchyma that provides radial traction on bronchioles at points of attachment to alveolar septa, loss of bronchiolar attachments as a result of extracellular matrix destruction may cause airway distortion and narrowing in COPD. Although the significance of alveolar attachments is not resolved, the concept of decreased alveolar attachments leading to small airway obstruction is appealing because it underscores the mechanistic relationship between loss of elastic recoil and increased resistance to airflow in small airways.

Lung Parenchyma Emphysema is characterized by destruction of gas-exchanging airspaces, i.e., the respiratory bronchioles, alveolar ducts, and alveoli. Their walls become perforated and later obliterated with coalescence of small distinct airspaces into abnormal and much larger airspaces. Macrophages accumulate in respiratory bronchioles of young smokers. Bronchoalveolar lavage fluid from such individuals contains roughly five times as many macrophages as lavage from nonsmokers. In smokers' lavage fluid, macrophages comprise >95% of the total cell count and neutrophils, nearly absent in nonsmokers' lavage, account for 1 to 2% of the cells. T lymphocytes, particularly CD8+ cells, are also increased in the alveolar space of smokers.

Emphysema is classified into distinct pathologic types, the most important types being centriacinar and panacinar. *Centriacinar emphysema*, the type most frequently associated with cigarette smoking, is characterized by enlarged airspaces found (initially) in association with respiratory bronchioles. Centriacinar emphysema is most prominent in the upper lobes and superior segments of lower lobes and is often quite focal. *Panacinar emphysema* refers to abnormally large airspaces evenly distributed within and across acinar units. Panacinar emphysema is usually observed in patients with α_1AT deficiency, which has a predilection for the lower lobes. Distinctions between centriacinar and panacinar emphysema are interesting and may ultimately be shown to have different mechanisms of pathogenesis. However, garden-variety, smoking-related emphysema is usually mixed, particularly in advanced cases, and these pathologic classifications are not helpful in the care of patients with COPD.

PATHOGENESIS Airflow limitation, the major physiologic change in COPD, can result from both small airway obstruction and emphysema, as discussed above. Pathologic findings that can contribute to small airway obstruction are described above, but their relative importance is unknown. Fibrosis surrounding the small airways appears to be a significant contributor. Mechanisms leading to collagen accumulation around the airways in the face of increased collagenase activity remain an enigma. Although seemingly counterintuitive, there are several potential mechanisms whereby a proteinase can predispose to fibrosis including proteolytic activation of transforming growth factor β, and insulin-like growth factor (IGF) binding protein degradation releasing profibrotic IGF. Largely due to availability of suitable animal models, we know much more about the mechanisms involved in emphysema than in small airway obstruction.

The pathogenesis of emphysema can be dissected into three interrelated events (Fig. 242-3): (1) Chronic exposure to cigarette smoke may lead to inflammatory cell recruitment within the terminal airspaces of the lung, (2) these inflammatory cells release elastolytic proteinases that damage the extracellular matrix of the lung, and (3) ineffective repair of elastin and perhaps other extracellular matrix components results in pulmonary emphysema.

Inflammation Synthesis of existing data regarding inflammatory cell responses in human lungs following cigarette smoke exposure suggests the following sequence of events: (1) Macrophages patrol the lower airspace under normal conditions, and (2) cigarette smoke comes into contact with and activates lung epithelial cells and alveolar macrophages, leading to cytokine/chemokine release followed by acute neutrophil recruitment and subacute accumulation of macrophages in the respiratory bronchioles and alveolar spaces. T cells (CD8+ > CD4+) and perhaps other inflammatory and immune cells are also recruited. Concomitant cigarette smoke–induced loss of cilia in the airway epithelium predisposes to bacterial infection with neutrophilia. Surprisingly, in end-stage lung disease, long after smoking cessation, there remains an exuberant inflammatory response, suggesting that mechanisms of cigarette smoke–induced inflammation that initiate the disease differ from mechanisms that sustain inflammation after smoking cessation. Thus, multiple interacting inflammatory cell types are present and contribute to disease pathogenesis.

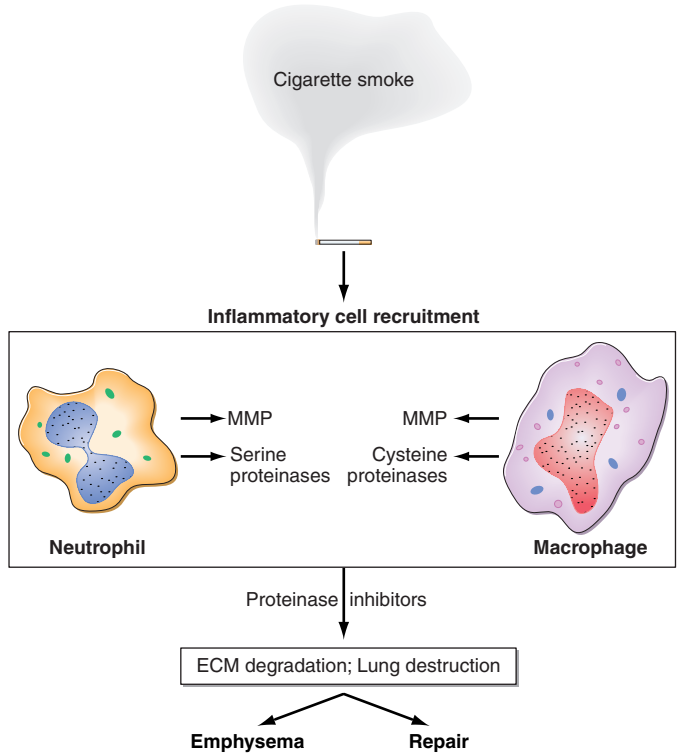

FIGURE 242-3 Pathogenesis of emphysema. Upon long-term exposure to cigarette smoke, inflammatory cells are recruited to the lung; they release proteinases in excess of inhibitors, and, if repair is abnormal, this leads to airspace destruction and enlargement or emphysema.

Extracellular Matrix Proteolysis Elastin, the principal component of elastic fibers, is a highly stable component of the extracellular matrix that is critical to the integrity of both the small airways and the lung parenchyma. The elastase:antielastase hypothesis proposed in the mid-1960s states that the balance of elastin-degrading enzymes and their inhibitors determines the susceptibility of the lung to destruction that results in airspace enlargement. Neutrophil elastase is a potent serine proteinase that clearly plays a major role in emphysema with associated α_1AT deficiency and also contributes to the usual forms of emphysema. The neutrophil also possesses serine proteinase 3 and cathepsin G as well as matrix metalloproteinases (MMPs), neutrophil collagenase (MMP-8), and gelatinase B (MMP-9). The macrophage is becoming recognized as a critical cell, producing several elastolytic MMPs including matrilysin (MMP-7), MMP-9, and macrophage elastase (MMP-12). Macrophages also produce potent cysteine proteinases (cathepsins S, L, and K). Animal models, including gene-targeted mice, suggest that macrophage elastases contribute to cigarette smoke–induced emphysema. Collagen degradation is more complex in that, while there is clearly collagen turnover in COPD, there is a net increase in collagen deposition, particularly around the small airways.

Cell Death Airspace enlargement with loss of alveolar units obviously requires disappearance of both extracellular matrix and cells. Traditional theories suggest that inflammatory cell proteinases degrade lung extracellular matrix as the primary event, with subsequent loss of cell anchoring leading to apoptosis. Recent studies suggest that endothelial and epithelial cell death could be primary events (presumably with secretion of proteinases to dissolve the matrix). Whether these mechanisms play a role in human COPD is unknown; however, it has been shown that there is increased septal cell death associated with reduced lung expression of vascular endothelial growth factor (VEGF) and its receptor VEGFR-2 (KDR/Flk-1) in human emphysematous lungs.

Ineffective Repair The ability of the adult lung to repair damaged alveoli appears limited. Whether the process of septation that is responsible for alveogenesis during lung development can be reinitiated is

not clear. In animal models, treatment with all-*trans* retinoic acid results in some repair. Also, lung resection results in compensatory lung growth in the remaining lung in animal models. In addition to restoring cellularity following injury, it appears difficult for an adult to restore completely an appropriate extracellular matrix, particularly functional elastic fibers.

TABLE 242-1 *GOLD Criteria for COPD Severity*

GOLD Stage	Severity	Symptoms	Spirometry
0	At Risk	Chronic cough, sputum production	Normal
I	Mild	With or without chronic cough or sputum production	$FEV_1/FVC < 0.7$ and $FEV_1 \geq 80\%$ predicted
IIA	Moderate	With or without chronic cough or sputum production	$FEV_1/FVC < 0.7$ and $50\% \leq FEV_1 < 80\%$ predicted
III	Severe	With or without chronic cough or sputum production	$FEV_1/FVC < 0.7$ and $30\% \leq FEV_1 < 50\%$ predicted
IV	Very Severe	With or without chronic cough or sputum production	$FEV_1/FVC < 0.7$ and $FEV_1 < 30\%$ predicted *or* $FEV_1 < 50\%$ predicted with respiratory failure or signs of right heart failure

Note: GOLD, Global Initiative for Chronic Obstructive Pulmonary Disease (COPD).

CLINICAL PRESENTATION ■ History

The three most common symptoms in COPD are cough, sputum production, and exertional dyspnea. Many patients have such symptoms for months or years before seeking medical attention. Although the development of airflow obstruction is a gradual process, many patients date the onset of their disease to an acute illness or exacerbation. A careful history, however, usually reveals the presence of symptoms prior to the acute exacerbation. The development of exertional dyspnea, often described as increased effort to breathe, heaviness, air hunger, or gasping, can be insidious. It is best elicited by a careful history focused on typical physical activities and how the patient's ability to perform them has changed. Activities involving significant arm work, particularly at or above shoulder level, are particularly difficult for patients with COPD. Conversely, activities that allow the patient to brace the arms and use accessory muscles of respiration are better tolerated. Examples of such activities include pushing a shopping cart, walking on a treadmill, or pushing a wheelchair. As COPD advances, the principal feature is worsening dyspnea on exertion with increasing intrusion on the ability to perform vocational or avocational activities. In the most advanced stages, patients are breathless doing simple activities of daily living.

Accompanying worsening airflow obstruction is an increased frequency of exacerbations (described below). Patients may also develop resting hypoxemia and require institution of supplemental oxygen.

Physical Findings In the early stages of COPD, patients may have an entirely normal physical examination. Current smokers may have signs of active smoking, including an odor of smoke or nicotine staining of fingernails. In patients with more severe disease, the physical examination is notable for a prolonged expiratory phase and expiratory wheezing. In addition, signs of hyperinflation include a barrel chest and enlarged lung volumes with poor diaphragmatic excursion as assessed by percussion. Patients with severe airflow obstruction may also exhibit use of accessory muscles of respiration, sitting in the characteristic "tripod" position to facilitate the actions of the sternocleidomastoid, scalene, and intercostal muscles. Patients may develop cyanosis, visible in the lips and nail beds. Patients with predominant emphysema are classically referred to as "pink puffers," a reference to the lack of cyanosis, the use of accessory muscles, and pursed-lip breathing. Such patients also have a dramatic decrease in breath sounds throughout the chest. Patients with a clinical syndrome of chronic bronchitis are classically labeled "blue bloaters," a reference to fluid retention and more marked cyanosis. Typically patients have elements of each and cannot be simply classified. Advanced disease may be accompanied by systemic wasting, with significant weight loss, bitemporal wasting, and diffuse loss of subcutaneous adipose tissue. This syndrome has been associated with both inadequate oral intake and elevated levels of inflammatory cytokines (TNF-α). Such wasting is an independent poor prognostic factor in COPD. Some patients with advanced disease have paradoxical inward movement of the rib cage with inspiration (Hoover's sign), the result of alteration of the vector of diaphragmatic contraction on the rib cage as a result of chronic hyperinflation.

Signs of overt right heart failure, termed *cor pulmonale*, are relatively infrequent since the advent of supplemental oxygen therapy. Prior to the availability of such therapy, patients with advanced disease would develop elevated jugular venous pressures, a right ventricular heave or third heart sound, hepatic congestion, ascites, and peripheral edema as the right ventricle decompensated as a result of chronic pulmonary hypertension.

Clubbing of the digits is not a sign of COPD, and its presence should alert the clinician to initiate an investigation for causes of clubbing. In this population, the development of lung cancer is the most likely explanation for newly developed clubbing.

Laboratory Findings The hallmark of COPD is airflow obstruction (discussed above). Pulmonary function testing shows airflow obstruction with a reduction in FEV_1 and FEV_1/FVC (Chap. 234). With worsening disease severity, lung volumes may increase, resulting in an increase in total lung capacity, functional residual capacity, and residual volume. In patients with emphysema, the diffusing capacity may be reduced, reflecting the parenchymal destruction characteristic of the disease. The degree of airflow obstruction is an important prognostic factor in COPD and is the basis for the GOLD disease classification (Table 242-1).

While arterial blood gases and oximetry are not sensitive (discussed above), they may demonstrate resting or exertional hypoxemia. Arterial blood gases provide additional information about alveolar ventilation and acid-base status by measuring arterial P_{CO_2} and pH. The change in pH with P_{CO_2} is 0.08 units/10 mmHg acutely and 0.03 units/10 mmHg in the chronic state. Knowledge of the arterial pH therefore allows the classification of ventilatory failure, defined as $P_{CO_2} > 45$ mmHg, into acute or chronic conditions (Chap. 250). The arterial blood gas is an important component of the evaluation of patients presenting with symptoms of an exacerbation. An elevated hematocrit suggests the presence of chronic hypoxemia, as does the presence of signs of right ventricular hypertrophy on electrocardiography.

Radiographic studies may assist in the classification of the type of COPD. Obvious bullae, paucity of parenchymal markings, or hyperlucency suggest the presence of emphysema. Increased lung volumes and flattening of the diaphragm suggest hyperinflation, but do not provide information about chronicity of the changes. Computed tomography (CT) scan is the current definitive test for establishing the presence or absence of emphysema. From a practical perspective, the CT scan does little to influence therapy of COPD except in those individuals considering surgical therapy for their disease (described below).

In patients presenting at ≤50 years, those with a strong family history, those with predominant basilar disease or those with a minimal smoking history, the serum level of (α_1AT) should be measured. The definitive diagnosis of α_1AT deficiency requires PI type determination. This is typically performed by isoelectric focusing of serum, which reflects the genotype at the PI locus for the common alleles and many of the rare PI alleles as well. Molecular genotyping can be performed for the common PI alleles (M, S, and Z).

TREATMENT

Stable Phase COPD Only two interventions, smoking cessation and oxygen therapy in chronically hypoxemic patients, have been demonstrated to influence the natural history of patients with COPD. All other current therapies are directed at improving symptoms and decreasing the frequency and severity of exacerbations. The institution of these therapies should involve an assessment of symptoms, potential risks, costs, and benefits of therapy. This should be followed by an assessment of response to therapy, and a decision should be made whether or not to continue treatment.

Pharmacotherapy ■ *SMOKING CESSATION* (See also Chap. 375) It has been shown that middle-aged smokers who were able to successfully stop smoking experienced a significant improvement in the rate of decline in pulmonary function, returning to annual changes similar to that of nonsmoking patients. Thus, all patients with COPD should be strongly urged to quit and educated about the benefits of quitting. An emerging body of evidence demonstrates that combining pharmacotherapy with traditional supportive approaches considerably enhances the chances of successful smoking cessation. There are two principal pharmacologic approaches to the problem: bupropion, originally developed as an antidepressant medication, and nicotine replacement therapy. The latter is available as gum, transdermal patches, inhaler, and nasal spray. Current recommendations from the U.S. Surgeon General are that all smokers considering quitting be offered pharmacotherapy, in the absence of any contraindication to treatment.

BRONCHODILATORS In general, bronchodilators are used for symptomatic benefit in patients with COPD. The inhaled route is preferred for medication delivery as the incidence of side effects is lower than that seen with the use of parenteral medication delivery.

ANTICHOLINERGIC AGENTS While regular use of ipratopium bromide does not appear to influence the rate of decline of lung function, it has been reported to improve symptoms and produce acute improvement in FEV_1. Side effects are minor, and a trial of inhaled anticholinergics is recommended in symptomatic patients with COPD.

BETA AGONISTS These provide symptomatic benefit. The main side effects are tremor and tachycardia. Long-acting inhaled β agonists, such as salmeterol, have benefits comparable to ipratopium bromide. Their use is more convenient than short-acting agents. The addition of a β agonist to inhaled anticholinergic therapy has been demonstrated to provide incremental benefit.

INHALED GLUCOCORTICOIDS Several recent trials have *failed* to find a beneficial effect for the regular use of inhaled glucocorticoids on the rate of decline of lung function, as assessed by FEV_1. Patients studied included those with mild to severe airflow obstruction and current and ex-smokers. Patients with significant acute response to inhaled β agonists were excluded from these trials. Inhaled glucocorticoids were demonstrated to reduce the frequency of exacerbations by 25 to 30%, but their use has been associated with increased rates of oropharyngeal candidiasis and an increased rate of loss of bone density. A trial of inhaled glucocorticoids should be considered in patients with frequent exacerbations, defined as two or more per year, and in patients who demonstrate a significant amount of acute reversibility in response to inhaled bronchodilators.

PARENTERAL CORTICOSTEROIDS The chronic use of oral glucocorticoids for treatment of COPD is not recommended because of an unfavorable benefit/risk ratio. The chronic use of oral glucocorticoids is associated with significant side effects, including osteoporosis, weight gain, cataracts, glucose intolerance, and increased risk of infection. A recent study demonstrated that patients tapered off chronic low-dose prednisone (~10 mg/d) did not experience any adverse effect on the frequency of exacerbations, health-related quality of life, or lung function. On average, patients lost ~4.5 kg (~10 lb) when steroids were withdrawn.

THEOPHYLLINE Theophylline produces modest improvements in expiratory flow rates and vital capacity and a slight improvement in arterial oxygen and carbon dioxide levels in patients with moderate to severe COPD. Nausea is a common side effect; tachycardia and tremor have also been reported.

OXYGEN Supplemental O_2 is the only therapy demonstrated to decrease mortality in patients with COPD. For patients with resting hypoxemia (resting O_2 saturation $<88\%$ or $<90\%$ with signs of pulmonary hypertension or right heart failure), the use of O_2 has been demonstrated to have a significant impact on mortality. The Medical Research Council Trial demonstrated that 12 h per day was superior to no O_2 supplementation. The Nocturnal Oxygen Therapy Trial demonstrated that O_2 use 19 h per day was superior to 12 h per day. Various delivery systems are available, including portable systems that patients may carry to allow mobility outside the home.

Supplemental O_2 is commonly prescribed for patients with exertional hypoxemia or nocturnal hypoxemia. Although the rationale for supplemental O_2 in these settings is physiologically sound, the benefits of such therapy are not well substantiated.

OTHER AGENTS *N*-acetyl cysteine has been used in patients with COPD for both its mucolytic and antioxidant properties. The latter aspect of its use is the subject of ongoing clinical trials. Specific treatment in the form of intravenous α_1AT augmentation therapy is available for individuals with severe α_1AT deficiency. Despite heat treatment of this product and the absence of reported cases of viral infection from therapy, hepatitis B vaccination is recommended prior to starting augmentation therapy. Although biochemical efficacy of α_1AT augmentation therapy has been shown, a randomized controlled trial of α_1AT augmentation therapy has never proven the efficacy of augmentation therapy in reducing decline of pulmonary function. Eligibility for α_1AT augmentation therapy requires a serum α_1AT level $<11\ \mu$ M. Typically, Pi^Z individuals will qualify, although other rare types associated with severe deficiency (e.g., null-null) are also eligible. Since only a fraction of individuals with severe α_1AT deficiency will develop COPD, α_1AT augmentation therapy is *not* recommended for severely α_1AT-deficient persons with normal pulmonary function and a normal chest CT scan.

Nonpharmacologic Therapies ■ *GENERAL MEDICAL CARE* Patients with COPD should receive the influenza vaccine annually. Polyvalent pneumococcal vaccine is also recommended, although proof of efficacy in this patient population is not definitive.

PULMONARY REHABILITATION This refers to a treatment program that incorporates education and cardiovascular conditioning. In COPD, pulmonary rehabilitation has been demonstrated to improve health-related quality of life, dyspnea, and exercise capacity. It has also been shown to reduce rates of hospitalization over a 6- to 12-month period.

LUNG VOLUME REDUCTION SURGERY (LVRS) Surgery to reduce the volume of lung in patients with emphysema was first introduced with minimal success in the 1950s and was reintroduced in the 1990s. It has been reported to produce symptomatic and functional benefit in selected patients, particularly those with emphysema, which is predominant in the upper lobes. The operation may be performed via either a median sternotomy or a thoracoscopic approach. Patients are excluded if they have significant pleural disease (a pulmonary artery systolic pressure $>$ 45 mmHg), extreme deconditioning, congestive heart failure, or other severe comorbid conditions. Recent data demonstrate that patients with an $FEV_1 < 20\%$ of predicted and either diffusely distributed emphysema on CT scan or $DL_{CO} < 20\%$ of predicted have an increased mortality after the procedure and thus are not candidates for LVRS.

The National Emphysema Treatment trial demonstrated that LVRS offers both a mortality benefit and a symptomatic benefit in certain patients with emphysema. The anatomic distribution of emphysema

and postrehabilitation exercise capacity are important prognostic characteristics. Patients with upper lobe–predominant emphysema and a low postrehabilitation exercise capacity are most likely to benefit from LVRS.

LUNG TRANSPLANTATION (See also Chap. 248) COPD is the single leading indication for lung transplantation. Current recommendations are that candidates for lung transplantation should be ≤65 years; have severe disability despite maximal medical therapy; and be free of comorbid conditions such as liver, renal, or cardiac disease. In contrast to LVRS, the anatomic distribution of emphysema and the presence of pulmonary hypertension are not contraindications to lung transplantation. Unresolved issues concerning lung transplantation and COPD include whether single- or double-lung transplant is the preferred procedure.

Exacerbations of COPD Exacerbations are a prominent feature of the natural history of COPD. Exacerbations are commonly considered to be episodes of increased dyspnea and cough and change in the amount and character of sputum. They may or may not be accompanied by other signs of illness, including fever, myalgias, and sore throat. Self-reported health-related quality of life correlates with frequency of exacerbations more closely than it does with the degree of airflow obstruction. Economic analyses have shown that >70% of COPD-related health care expenditures go to emergency department visits and hospital care; this translates to >$10 billion annually in the United States. The frequency of exacerbations increases as airflow obstruction increases; patients with moderate to severe airflow obstruction [GOLD stages III,IV (Table 242-1)] have one to three episodes per year.

The approach to the patient experiencing an exacerbation includes an assessment of the severity of the patient's illness, both acute and chronic components; an attempt to identify the precipitant of the exacerbation; and the institution of therapy.

PRECIPITATING CAUSES AND STRATEGIES TO REDUCE FREQUENCY OF EXACERBATIONS A variety of stimuli may result in the final common pathway of airway inflammation and increased symptoms that are characteristic of COPD exacerbations. Bacterial infections play a role in many, but by no means all, episodes. Viral respiratory infections are present in approximately one-third of COPD exacerbations. In a significant minority of instances (20 to 35%), no specific precipitant can be identified.

Despite the frequent implication of bacterial infection, chronic suppressive or "rotating" antibiotics are not beneficial in patients with COPD. This is in contrast to their apparent efficacy in patients with significant bronchiectasis. In patients with bronchiectasis due to cystic fibrosis, suppressive antibiotics have been shown to reduce frequency of hospital admissions.

The role of anti-inflammatory therapy in reducing exacerbation frequency is less well studied. Chronic oral glucocorticoids are not recommended for this purpose. Inhaled glucocorticoids did reduce the frequency of exacerbations by 25 to 30% in large clinical trials. It is important to realize that patients with significant pulmonary function reversibility to inhaled bronchodilators were excluded from these trials. Thus, the use of inhaled glucocorticoids should be considered in patients with frequent exacerbations or those who have an asthmatic component, i.e., significant reversibility on pulmonary function testing or marked symptomatic improvement after inhaled bronchodilators.

PATIENT ASSESSMENT The practitioner should attempt to establish the severity of the exacerbation as well as the severity of preexisting COPD. The more severe either of these two components, the more likely that the patient will require hospital admission. The history should include quantification of the degree of dyspnea by asking about breathlessness during activities of daily living and typical activities for the patient. The patient should be asked about fever; change in character of sputum; any ill contacts; and associated symptoms such as nausea, vomiting, diarrhea, myalgias, and chills. Inquiring about the frequency and severity of prior exacerbations can provide important information. The physical examination should incorporate an assessment of the degree of distress of the patient. Specific attention should be focused on tachycardia, tachypnea, use of accessory muscles, signs of perioral or peripheral cyanosis, the ability to speak in complete sentences, and the patient's mental status. The chest examination should establish the presence or absence of focal findings, degree of air movement, presence or absence of wheezing, asymmetry in the chest examination (suggesting large airway obstruction or pneumothorax mimicking an exacerbation), and the presence or absence of paradoxical motion of the abdominal wall.

Patients with severe underlying COPD who are in moderate or severe distress or those with focal findings should have a chest x-ray. Approximately 25% of x-rays in this clinical situation will be abnormal, with the most frequent findings being pneumonia and congestive heart failure. Patients with advanced COPD, those with a history of hypercarbia, those with mental status changes (confusion, sleepiness), or those in significant distress should have an arterial blood gas measurement. The presence of hypercarbia, defined as a $P_{CO_2} > 45$ mmHg, has important implications for treatment (discussed below). In contrast to its utility in the management of exacerbations of asthma, measurement of pulmonary function has not been demonstrated to be helpful in the diagnosis or management of exacerbations of COPD.

There are no definitive guidelines concerning the need for inpatient treatment of exacerbations. Patients with respiratory acidosis and hypercarbia, significant hypoxemia, or severe underlying disease or those whose living situation is not conducive to careful observation and the delivery of prescribed treatment should be admitted to the hospital.

Acute Exacerbations ■ *BRONCHODILATORS* Typically, patients are treated with an inhaled β agonist, often with the addition of an anticholinergic agent. These may be administered separately or together, and the frequency of administration depends on the severity of the exacerbation. Patients are often treated initially with nebulized therapy, as such treatment is often easier to administer in older patients or to those in respiratory distress. It has been shown, however, that conversion to metered-dose inhalers is effective when accompanied by education and training of patients and staff. This approach has significant economic benefits and also allows an easier transition to outpatient care. The addition of methylxanthines (such as theophylline) to this regimen can be considered, although convincing proof of its efficacy is lacking. If added, serum levels should be monitored in an attempt to minimize toxicity.

ANTIBIOTICS Patients with COPD are frequently colonized with potential respiratory pathogens and it is often difficult to identify conclusively a specific species of bacteria responsible for a particular clinical event. Bacteria frequently implicated in COPD exacerbations include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. In addition, *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* are found in 5 to 10% of exacerbations. The choice of antibiotic should be based on local patterns of antibiotic susceptibility of the above pathogens, as well as the patient's clinical condition. Most practitioners treat patients with moderate or severe exacerbations with antibiotics, even in the absence of data implicating a specific pathogen.

GLUCOCORTICOIDS Among patients admitted to hospital, the use of glucocorticoids has been demonstrated to reduce the length of stay, hasten recovery, and reduce the chance of subsequent exacerbation or relapse for a period of up to 6 months. A recent study demonstrated that 2 weeks of glucocorticoid therapy produced benefit indistinguishable from 8 weeks of therapy. The GOLD guidelines recommend 30 to 40 mg of oral prednisolone or its equivalent for a period of 10 to 14 days. Hyperglycemia, particularly in patients with preexisting diagnosis of diabetes, is the most frequently reported acute complication of glucocorticoid treatment.

OXYGEN Supplemental O_2 should be supplied to keep arterial saturations ≥90%. Hypoxic respiratory drive plays a small role in patients

with COPD. Studies have demonstrated that in patients with both acute and chronic hypercarbia, the administration of supplemental O_2 does not reduce minute ventilation. It does, in some patients, result in modest increases in arterial P_{CO_2}, chiefly by altering ventilation-perfusion relationships within the lung. This should not deter practitioners from providing the oxygen needed to correct hypoxemia.

MECHANICAL VENTILATORY SUPPORT Recent studies have demonstrated that the initiation of noninvasive positive pressure ventilation (NIPPV) in patients with respiratory failure, defined as $P_{CO_2} > 45$ mmHg, results in a significant reduction in mortality, need for intubation, complications of therapy, and hospital length of stay. Contraindications to NIPPV include cardiovascular instability, impaired mental status or inability to cooperate, copious secretions or the inability to clear secretions, craniofacial abnormalities or trauma precluding effective fitting of mask, extreme obesity, or significant burns.

Invasive (conventional) mechanical ventilation via an endotracheal tube is indicated for patients with severe respiratory distress despite initial therapy, life-threatening hypoxemia, severe hypercapnia and/or acidosis, markedly impaired mental status, respiratory arrest, hemodynamic instability, or other complications. The goal of mechanical ventilation is to correct the aforementioned conditions. Factors to consider during mechanical ventilatory support include the need to provide sufficient expiratory time in patients with severe airflow obstruction and the presence of auto-PEEP (positive end-expiratory pressure) which can result in patients having to generate significant respiratory effort to trigger a breath during a demand mode of ventilation. The mortality of patients requiring mechanical ventilatory support is 17 to 30% for that particular hospitalization. For patients aged ≥65 admitted to the intensive care unit for treatment, the mortality doubles over the next year to 60%, regardless of whether mechanical ventilation was required.

243 INTERSTITIAL LUNG DISEASES

Talmadge E. King, Jr.

The interstitial lung diseases (ILDs) represent a large number of conditions that involve the parenchyma of the lung—the alveoli, the alveolar epithelium, the capillary endothelium, and the spaces between these structures, as well as the perivascular and lymphatic tissues. This heterogeneous group of disorders is classified together because of similar clinical, roentgenographic, physiologic, or pathologic manifestations. These disorders are often associated with considerable morbidity and mortality, and there is little consensus regarding the best management of most of them.

ILDs have been difficult to classify because more than 200 known individual diseases are characterized by diffuse parenchymal lung involvement, either as the primary condition or as a significant part of a multiorgan process, as may occur in the connective tissue diseases (CTDs). One useful approach to classification is to separate the ILDs into two groups based on the major underlying histopathology: (1) those associated with predominant inflammation and fibrosis, and (2) those with a predominantly granulomatous reaction in interstitial or vascular areas (Table 243-1). Each of these groups can be further subdivided according to whether the cause is known or unknown. For each ILD there may be an acute phase, and there is usually a chronic one as well. Rarely, some are recurrent, with intervals of subclinical disease.

Sarcoidosis (Chap. 309), idiopathic pulmonary fibrosis (IPF), and pulmonary fibrosis associated with CTDs (Chaps. 300 to 306) are the most common ILDs of unknown etiology. Among the ILDs of known cause, the largest group comprises occupational and environmental exposures, especially the inhalation of inorganic dusts, organic dusts, and various fumes or gases (Chaps. 237 and 238). A clinical diagnosis is possible for many forms of ILD, especially if an occupational and environmental history is aggressively pursued. For other forms, tissue examination, usually obtained by thoracoscopic or open-lung biopsy, is critical to confirmation of the diagnosis. High-resolution computed tomography (HRCT) scanning promises to improve diagnostic accuracy further as histologic-image correlation is perfected.

PATHOGENESIS

The ILDs are nonmalignant disorders and are not caused by identified infectious agents. The precise pathway(s) leading from injury to fibrosis is not known. Although there are multiple initiating agent(s) of injury, the immunopathogenic responses of lung tissue are limited, and the mechanisms of repair have common features. As mentioned above, the two major histopathologic patterns are a granulomatous pattern and a pattern in which inflammation and fibrosis predominate.

GRANULOMATOUS LUNG DISEASE This process is characterized by an accumulation of T lymphocytes, macrophages, and epithelioid cells organized into discrete structures (granulomas) in the lung parenchyma. The granulomatous lesions can progress to fibrosis. Many patients with granulomatous lung disease remain free of severe impairment of lung function, or, when symptomatic, they improve after treatment. The main differential diagnosis is between sarcoidosis (Chap. 309) and hypersensitivity pneumonitis (Chap. 237).

INFLAMMATION AND FIBROSIS The initial insult is an injury to the epithelial surface causing inflammation in the air spaces and alveolar walls. If the disease becomes chronic, inflammation spreads to adjacent portions of the interstitium and vasculature and eventually causes interstitial fibrosis. Important histopathologic patterns found in the ILDs include: usual interstitial pneumonia (UIP), nonspecific interstitial pneumonia, respiratory bronchiolitis, organizing pneumonia [bronchiolitis obliterans with organizing pneumonia (BOOP) pattern], diffuse alveolar damage (acute or organizing), desquamative interstitial pneumonia, and lymphocytic interstitial pneumonia. The development of irreversible scarring (fibrosis) of alveolar walls, airways, or vasculature is the most feared outcome in all of these conditions because it is often progressive and leads to significant derangement of ventilatory function and gas exchange.

INITIAL EVALUATION

Patients with ILDs come to medical attention mainly because of the onset of progressive exertional dyspnea or a persistent, nonproductive cough. Hemoptysis, wheezing, and chest pain may be present. Often, the identification of interstitial opacities on chest x-ray focuses the diagnostic approach toward one of the ILDs.

TABLE 243-1 *Major Categories of Alveolar and Interstitial Inflammatory Lung Disease*

Lung Response: Alveolitis, Interstitial Inflammation, and Fibrosis	
KNOWN CAUSE	
Asbestos	Radiation
Fumes, gases	Aspiration pneumonia
Drugs (antibiotics, amiodarone, gold) and chemotherapy drugs	Residual of adult respiratory distress syndrome
UNKNOWN CAUSE	
Idiopathic interstitial pneumonias	Pulmonary alveolar proteinosis
Idiopathic pulmonary fibrosis (usual interstitial pneumonia)	Lymphocytic infiltrative disorders (lymphocytic interstitial pneumonitis associated with connective tissue disease)
Desquamative interstitial pneumonia	Eosinophilic pneumonias
Respiratory bronchiolitis-associated interstitial lung disease	Lymphangioleiomyomatosis
Acute interstitial pneumonia (diffuse alveolar damage)	Amyloidosis
Cryptogenic organizing pneumonia (bronchiolitis obliterans with organizing pneumonia)	Inherited diseases
Nonspecific interstitial pneumonia	Tuberous sclerosis, neurofibromatosis, Niemann-Pick disease, Gaucher's disease, Hermansky-Pudlak syndrome
Connective tissue diseases	Gastrointestinal or liver diseases (Crohn's disease, primary biliary cirrhosis, chronic active hepatitis, ulcerative colitis)
Systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, systemic sclerosis, Sjögren's syndrome, polymyositis-dermatomyositis	Graft-vs.-host disease (bone marrow transplantation; solid organ transplantation)
Pulmonary hemorrhage syndromes	
Goodpasture's syndrome, idiopathic pulmonary hemosiderosis, isolated pulmonary capillaritis	
Lung Response: Granulomatous	
KNOWN CAUSE	
Hypersensitivity pneumonitis (organic dusts)	Inorganic dusts: beryllium silica
UNKNOWN CAUSE	
Sarcoidosis	Bronchocentric granulomatosis
Langerhans cell granulomatosis (eosinophilic granuloma of the lung)	Lymphomatoid granulomatosis
Granulomatous vasculitides	
Wegener's granulomatosis, allergic granulomatosis of Churg-Strauss	

HISTORY ■ Duration of Illness *Acute presentation* (days to weeks), while unusual, occurs with allergy (drugs, fungi, helminths), acute idiopathic interstitial pneumonia, eosinophilic pneumonia, and hypersensitivity pneumonitis. These conditions may be confused with atypical pneumonias because of diffuse alveolar opacities on chest x-ray. *Subacute presentation* (weeks to months) may occur in all ILDs but is seen especially in sarcoidosis, drug-induced ILDs, the alveolar hemorrhage syndromes, cryptogenic organizing pneumonia (COP), and the acute immunologic pneumonia that complicates systemic lupus erythematosus (SLE) or polymyositis. In most ILDs the symptoms and signs form a *chronic presentation* (months to years). Examples include IPF, sarcoidosis, pulmonary Langerhans cell histiocytosis (PLCH) (also known as Langerhans cell granulomatosis, eosinophilic granuloma, or histiocytosis X), pneumoconioses, and CTDs. *Episodic presentations* are unusual and include eosinophilic pneumonia, hypersensitivity pneumonitis, COP, vasculitides, pulmonary hemorrhage, and Churg-Strauss syndrome.

Age Most patients with sarcoidosis, ILD associated with CTD, lymphangioleiomyomatosis (LAM), PLCH, and inherited forms of ILD (familial IPF, Gaucher's disease, Hermansky-Pudlak syndrome) present between the ages of 20 and 40 years. Most patients with IPF are older than 50 years.

Gender LAM and pulmonary involvement in tuberous sclerosis occur exclusively in premenopausal women. Also, ILD in Hermansky-Pudlak syndrome and in the CTDs is more common in women; an exception is ILD in rheumatoid arthritis (RA), which is more common in men. Because of occupational exposures, pneumoconioses also occur more frequently in men.

Family History Family associations (with an autosomal dominant pattern) have been identified in tuberous sclerosis and neurofibromatosis. An autosomal recessive pattern of inheritance occurs in Niemann-Pick disease, Gaucher's disease, and the Hermansky-Pudlak syndrome. Familial clustering has been increasingly identified in sarcoidosis. Familial lung fibrosis has been associated with mutations in the surfactant protein C gene and is characterized by several patterns of interstitial pneumonia, including nonspecific interstitial pneumonia, desquamative interstitial pneumonia, and UIP.

Smoking History Patients with PLCH, desquamative interstitial pneumonia (DIP), Goodpasture's syndrome, respiratory bronchiolitis, and pulmonary alveolar proteinosis are almost always current or former smokers. Two-thirds to 75% of patients with IPF have a history of smoking.

Occupation and Environmental History A strict chronologic listing of the patient's lifelong employment must be sought, including specific duties and known exposures. In hypersensitivity pneumonitis (see Fig. 237-1), respiratory symptoms, fever, chills, and an abnormal chest roentgenogram are often temporally related to a hobby (pigeon breeder's disease) or to the workplace (farmer's lung) (Chap. 237). Symptoms may diminish or disappear after the patient leaves the site of exposure for several days; similarly, symptoms may reappear on returning to the exposure site.

Other Important Past History Parasitic infections may cause pulmonary eosinophilia, and therefore a travel history should be taken in patients with known or suspected ILD. History of risk factors for HIV infection should be elicited from all patients with ILD because several processes may occur at the time of initial presentation or during the clinical course, e.g., HIV infection, BOOP, acute interstitial pneumonia (AIP), lymphocytic interstitial pneumonitis, or diffuse alveolar hemorrhage.

RESPIRATORY SYMPTOMS AND SIGNS Dyspnea is a common and prominent complaint in patients with ILD, especially the idiopathic interstitial pneumonias, hypersensitivity pneumonitis, COP, sarcoidosis, eosinophilic pneumonias, and PLCH. Some patients, especially patients with sarcoidosis, silicosis, PLCH, hypersensitivity pneumonitis, lipoid pneumonia, or lymphangitis carcinomatosis, may have extensive parenchymal lung disease on chest x-ray without significant dyspnea, especially early in the course of the illness. Wheezing is an uncommon manifestation of ILD but has been described in patients with chronic eosinophilic pneumonia, Churg-Strauss syndrome, respiratory bronchiolitis, and sarcoidosis. Clinically significant chest pain is uncommon in most ILDs. However, substernal discomfort is common in sarcoidosis. Sudden worsening of dyspnea, especially if associated with acute chest pain, may indicate a spontaneous pneumothorax, which occurs in PLCH, tuberous sclerosis, LAM, and neurofibromatosis. Frank hemoptysis and blood-streaked sputum are rarely presenting manifestations of ILD but can be seen in the diffuse alveolar hemorrhage (DAH) syndromes, LAM, tuberous sclerosis, and the granulomatous vasculitides. Fatigue and weight loss are common in all ILDs.

PHYSICAL EXAMINATION The findings are usually not specific. Most commonly, physical examination reveals tachypnea and bibasilar end-inspiratory dry crackles, which are common in most forms of ILD associated with inflammation but are less likely to be heard in the

granulomatous lung diseases. Crackles may be present in the absence of radiographic abnormalities on the chest radiograph. Scattered late inspiratory high-pitched rhonchi—so-called inspiratory squeaks—are heard in patients with bronchiolitis. The cardiac examination is usually normal except in the mid or late stages of the disease, when findings of pulmonary hypertension and cor pulmonale may become evident (Chap. 220). Cyanosis and clubbing of the digits occur in some patients with advanced disease.

LABORATORY Antinuclear antibodies, anti-immunoglobulin antibodies (rheumatoid factors), and circulating immune complexes are identified in some patients, even in the absence of a defined CTD. A raised LDH is a nonspecific finding common to ILDs. Elevation of the serum angiotensin-converting enzyme level is common in sarcoidosis. Serum precipitins confirm exposure when hypersensitivity pneumonitis is suspected, although they are not diagnostic of the process. Antineutrophil cytoplasmic or anti-basement membrane antibodies are useful if vasculitis is suspected. The electrocardiogram is usually normal unless pulmonary hypertension is present; then it demonstrates right-axis deviation, right ventricular hypertrophy, or right atrial enlargement or hypertrophy. Echocardiography also reveals right ventricular dilatation and/or hypertrophy in the presence of pulmonary hypertension.

CHEST IMAGING STUDIES ■ Chest X-ray ILD may be first suspected on the basis of an abnormal chest radiograph, which most commonly reveals a bibasilar reticular pattern. A nodular or mixed pattern of alveolar filling and increased reticular markings may also be present (see Fig. 233-1). A subgroup of ILDs exhibit nodular opacities with a predilection for the upper lung zones [sarcoidosis, PLCH, chronic hypersensitivity pneumonitis, silicosis, berylliosis, RA (necrobiotic nodular form), ankylosing spondylitis]. The chest x-ray correlates poorly with the clinical or histopathologic stage of the disease. The radiographic finding of honeycombing correlates with pathologic findings of small cystic spaces and progressive fibrosis; when present, it portends a poor prognosis. In most cases, the chest radiograph is nonspecific and usually does not allow a specific diagnosis.

Computed Tomography HRCT is superior to the plain chest x-ray for early detection and confirmation of suspected ILD (Fig. 243-1). Also, HRCT allows better assessment of the extent and distribution of disease, and it is especially useful in the investigation of patients with a normal chest radiograph. Coexisting disease is often best recognized on HRCT scanning, e.g., mediastinal adenopathy, carcinoma, or emphysema. In the appropriate clinical setting HRCT may be sufficiently characteristic to preclude the need for lung biopsy in IPF, sarcoidosis, hypersensitivity pneumonitis, asbestosis, lymphangitic carcinoma, and PLCH. When a lung biopsy is required, HRCT scanning is useful for determining the most appropriate area from which biopsy samples should be taken.

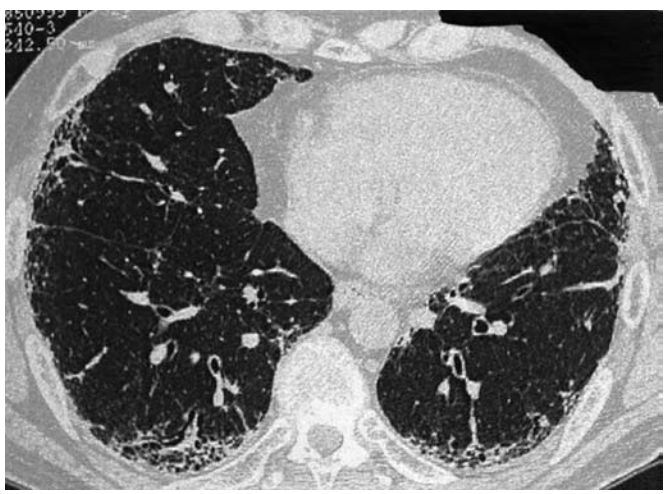

FIGURE 243-1 Idiopathic pulmonary fibrosis. High-resolution computed tomographic image shows bibasal, peripheral predominant reticular abnormality with traction bronchiectasis and honeycombing. The lung biopsy showed the typical features of usual interstitial pneumonia.

Radionuclide Scanning Gallium-67 or ^{99m}Tc-diethylenetriamene pentaacetate (DTPA) scanning have limited roles in evaluating the inflammatory component of ILD.

PULMONARY FUNCTION TESTING ■ Spirometry and Lung Volumes Measurement of lung function is important in assessing the extent of pulmonary involvement in patients with ILD. Most forms of ILD produce a restrictive defect with reduced total lung capacity (TLC), functional residual capacity, and residual volume (Chap. 234). Forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) are reduced, but these changes are related to the decreased TLC. The FEV_1/FVC ratio is usually normal or increased. Lung volumes decrease as lung stiffness worsens with disease progression. A few disorders produce interstitial opacities on chest x-ray and obstructive airflow limitation on lung function testing (uncommon in sarcoidosis and hypersensitivity pneumonitis, while common in tuberous sclerosis and LAM).

Diffusing Capacity A reduction in the diffusing capacity of the lung for carbon monoxide (DL_{CO}) is a common but nonspecific finding in most ILDs. This decrease is due, in part, to effacement of the alveolar capillary units but, more importantly, to mismatching of ventilation and perfusion ($\dot{V}/\dot{Q}$). Lung regions with reduced compliance due to either fibrosis or cellular infiltration may be poorly ventilated but may still maintain adequate blood flow and the ventilation-perfusion mismatch in these regions acts like true venous admixture. The severity of the reduction in DL_{CO} does not correlate with disease stage.

Arterial Blood Gas The resting arterial blood gas may be normal or reveal hypoxemia (secondary to a mismatching of ventilation to perfusion) and respiratory alkalosis. A normal arterial O_2 tension (or saturation by oximetry) at rest does not rule out significant hypoxemia during exercise or sleep. CO_2 retention is rare and is usually a manifestation of end-stage disease.

CARDIOPULMONARY EXERCISE TESTING Because hypoxemia at rest is not always present and because severe exercise-induced hypoxemia may go undetected, it is useful to perform exercise testing with measurement of arterial blood gases to detect abnormalities of gas exchange. Arterial oxygen desaturation, a failure to decrease dead space appropriately with exercise [i.e., a high V_D/V_T ratio (Chap. 234)], and an excessive increase in respiratory rate with a lower-than-expected recruitment of tidal volume provide useful information about physiologic abnormalities and extent of disease. Serial assessment of resting and exercise gas exchange is an excellent method for following disease activity and responsiveness to treatment, especially in patients with IPF.

FIBEROPTIC BRONCHOSCOPY AND BRONCHOALVEOLAR LAVAGE (BAL) In selected diseases (e.g., sarcoidosis, hypersensitivity pneumonitis, DAH syndrome, cancer, pulmonary alveolar proteinosis), cellular analysis of BAL fluid may be useful in narrowing the differential diagnostic possibilities among various types of ILD. The role for BAL in defining the stage of disease and assessment of disease progression or response to therapy remains poorly understood, and the usefulness of BAL in the clinical assessment and management remains to be established.

TISSUE AND CELLULAR EXAMINATION Lung biopsy is the most effective method for confirming the diagnosis and assessing disease activity. The findings may identify a more treatable process than originally suspected, particularly chronic hypersensitivity pneumonitis, COP, respiratory bronchiolitis–associated ILD, or sarcoidosis. Biopsy should be obtained before initiation of treatment. A definitive diagnosis avoids confusion and anxiety later in the clinical course if the patient does not respond to therapy or suffers serious side effects from it.

Fiberoptic bronchoscopy with multiple transbronchial lung biop-

sies (four to eight biopsy samples) is often the initial procedure of choice, especially when sarcoidosis, lymphangitic carcinomatosis, eosinophilic pneumonia, Goodpasture's syndrome, or infection are suspected. If a specific diagnosis is not made by transbronchial biopsy, then surgical lung biopsy by video-assisted thoracic surgery or open thoracotomy is indicated. Adequate-sized biopsies from multiple sites, usually from two lobes, should be obtained. Relative contraindications to lung biopsy include serious cardiovascular disease, honeycombing and other roentgenographic evidence of diffuse end-stage disease, severe pulmonary dysfunction, or other major operative risks, especially in the elderly.

TREATMENT

Although the course of ILD is variable, progression is common and often insidious. All treatable possibilities should be carefully considered. Since therapy does not reverse fibrosis, the major goals of treatment are permanent removal of the offending agent, when known, and early identification and aggressive suppression of the acute and chronic inflammatory process, thereby reducing further lung damage.

Hypoxemia ($Pa_{O_2} < 55$ mmHg) at rest and/or with exercise should be managed by supplemental oxygen. If cor pulmonale develops, diuretic therapy and phlebotomy may occasionally be required (Chap. 220).

DRUG THERAPY Glucocorticoids are the mainstay of therapy for suppression of the alveolitis present in ILD, but the success rate is low. There have been no placebo-controlled trials of glucocorticoids in ILD, so there is no direct evidence that steroids improve survival in many of the diseases for which they are commonly used. Glucocorticoid therapy is recommended for symptomatic ILD patients with idiopathic interstitial pneumonias, eosinophilic pneumonias, COP, CTD, sarcoidosis, acute inorganic dust exposures, acute radiation pneumonitis, DAH, and drug-induced ILD. In organic dust disease, glucocorticoids are recommended for both the acute and chronic stages.

The optimal dose and proper length of therapy with glucocorticoids in the treatment of most ILDs are not known. A common starting dose is prednisone, 0.5 to 1 mg/kg in a once-daily oral dose (based on the patient's lean body weight). This dose is continued for 4 to 12 weeks, at which time the patient is reevaluated. If the patient is stable or improved, the dose is tapered to 0.25 to 0.5 mg/kg and is maintained at this level for an additional 4 to 12 weeks depending on the course. Rapid tapering or a shortened course of glucocorticoid treatment can result in recurrence. If the patient's condition continues to decline while on glucocorticoids, a second agent (see below) is often added and the prednisone dose is lowered to or maintained at 0.25 mg/kg per day.

Cyclophosphamide and azathioprine (1 to 2 mg/kg lean body weight per day), with or without glucocorticoids, have been tried with variable success in IPF, vasculitis, and other ILDs. An objective response usually requires at least 8 to 12 weeks to occur. In situations in which these drugs have failed or could not be tolerated, other agents, including methotrexate, colchicine, penicillamine, and cyclosporine, have been tried. However, their role in the treatment of ILDs remains to be determined.

Many cases of ILD are chronic and irreversible despite the therapy discussed above, and lung transplantation may then be considered (Chap. 248).

INDIVIDUAL FORMS OF ILD

IDIOPATHIC PULMONARY FIBROSIS IPF is the most common form of idiopathic interstitial pneumonia. Separating IPF from other forms of lung fibrosis is an important step in the evaluation of all patients presenting with ILD. IPF has a distinctly poor response to therapy and prognosis.

Clinical Manifestations Exertional dyspnea, a nonproductive cough, and inspiratory crackles with or without digital clubbing may be present on physical examination. The HRCT lung scans typically show patchy, predominantly basilar, subpleural reticular opacities, often associated with traction bronchiectasis and honeycombing (Fig. 243-1). Atypical findings that should suggest an alternative diagnosis include: extensive ground-glass abnormality, nodular opacities, upper or mid-zone predominance, and prominent hilar or mediastinal lymphadenopathy. Pulmonary function tests often reveal a restrictive pattern, a reduced DL_{CO}, and arterial hypoxemia that is exaggerated or elicited by exercise.

Histologic Findings Confirmation of the presence of the UIP pattern on histologic examination is essential to confirm this diagnosis. Transbronchial biopsies are not helpful in making the diagnosis of UIP, and surgical biopsy is usually required. The histologic hallmark and chief diagnostic criterion of UIP is a heterogeneous appearance at low magnification with alternating areas of normal lung, interstitial inflammation, foci of proliferating fibroblasts, dense collagen fibrosis, and honeycomb changes. These histologic changes affect the peripheral, subpleural parenchyma most severely. The interstitial inflammation is usually patchy and consists of a lymphoplasmacytic infiltrate in the alveolar septa, associated with hyperplasia of type 2 pneumocytes. The fibrotic zones are composed mainly of dense collagen, although scattered foci of proliferating fibroblasts are a consistent finding. The extent of fibroblastic proliferation is predictive of disease progression. Areas of honeycomb change are composed of cystic fibrotic air spaces that are frequently lined by bronchiolar epithelium and filled with mucin. Smooth-muscle hyperplasia is commonly seen in areas of fibrosis and honeycomb change. Histopathologic examinations during this accelerated phase show a combination of UIP and diffuse alveolar damage. A UIP-like pattern can also be seen with CTDs, pneumoconioses (e.g., asbestosis), radiation injury, certain drug-induced lung diseases (e.g., nitrofurantoin), and chronic aspiration. Also, a fibrotic pattern may be found in the chronic stage of several specific disorders such as sarcoidosis, chronic hypersensitivity pneumonitis, organized chronic eosinophilic pneumonia, and PLCH. Since other histopathologic features are frequently present in these syndromes, the term UIP is used for those patients in whom the lesion is idiopathic and not associated with another condition.

TREATMENT

The clinical course is variable, with a 5-year survival rate of 20 to 40% after diagnosis. Treatment options include glucocorticoids, cytotoxic agents (e.g., azathioprine, cyclophosphamide), and antifibrotic agents (e.g., colchicine, pirfenidone, or interferon gamma-1b), alone or in combination with glucocorticoids. However, there is no firm evidence that any of these treatment approaches improves survival or the quality of life. Because of the poor prognosis in untreated patients, a therapeutic trial may be tried. If therapy is recommended, it should be started at the first identification of clinical or physiologic evidence of impairment of lung function. Lung transplantation should be considered for those patients who experience progressive deterioration despite optimal medical management and who meet the established criteria (Chap. 248).

DESQUAMATIVE INTERSTITIAL PNEUMONIA DIP is a rare but distinct clinical and pathologic entity found exclusively in cigarette smokers. The histologic hallmark is the extensive accumulation of macrophages in intraalveolar spaces with minimal interstitial fibrosis. The peak incidence is in the fourth and fifth decades. Most patients present with dyspnea. Lung function testing shows a restrictive pattern with reduced DL_{CO} and arterial hypoxemia. The chest x-ray and HRCT scans usually shows diffuse hazy opacities. Clinical recognition of DIP is important because the process is associated with a better prognosis (10-year survival rate is ~70%) and a better response to smoking cessation and systemic glucocorticoids than the more common IPF. Respiratory bronchiolitis–associated ILD is considered to be a subset of DIP and is characterized by the accumulation of macrophages in peribronchical alveoli.

ACUTE INTERSTITIAL PNEUMONIA (HAMMAN-RICH SYNDROME) AIP is a rare, fulminant form of lung injury characterized histologically by diffuse alveolar damage on lung biopsy. Most patients are older than 40 years. AIP is similar in presentation to the acute respiratory distress syndrome (ARDS) (Chap. 251) and probably corresponds to the subset of cases of idiopathic ARDS. The onset is usually abrupt in a previously healthy individual. A prodromal illness, usually lasting 7 to 14 days before presentation, is common. Fever, cough, and dyspnea are frequent manifestations at presentation. Diffuse, bilateral, air-space opacification is present on chest radiograph. HRCT scans show bilateral, patchy, symmetric areas of ground-glass attenuation. Bilateral areas of air-space consolidation may also be present. A predominantly subpleural distribution may be seen. The diagnosis of AIP requires the presence of a clinical syndrome of idiopathic ARDS and pathologic confirmation of organizing diffuse alveolar damage. Therefore, lung biopsy is required to confirm the diagnosis. Most patients have moderate to severe hypoxemia and develop respiratory failure. Mechanical ventilation is often required. The mortality rate is high (>60%), with most patients dying within 6 months of presentation. Recurrences have been reported. However, those who recover often have substantial improvement in lung function. The main treatment is supportive. It is not clear that glucocorticoid therapy is effective.

NONSPECIFIC INTERSTITIAL PNEUMONIA (NSIP) This condition defines a subgroup of the idiopathic interstitial pneumonias that can be distinguished clinically and pathologically from UIP, DIP, AIP, and idiopathic BOOP. NSIP is a subacute restrictive process with a presentation similar to IPF but usually at a younger age. It is often associated with a febrile illness and there is a relative lack of clubbing. HRCT shows bilateral, subpleural ground-glass opacities, often associated with lower lobe volume loss (Fig. 243-2). Patchy areas of air-space consolidation and reticular abnormalities may be present, but honeycombing is unusual. Unlike patients with IPF (UIP), the majority of patients with NSIP have a good prognosis with most showing improvement after treatment with glucocorticoids.

ILD ASSOCIATED WITH CONNECTIVE TISSUE DISORDERS Clinical findings suggestive of a CTD (musculoskeletal pain, weakness, fatigue, fever, joint pains or swelling, photosensitivity, Raynaud's phenomenon, pleuritis, dry eyes, dry mouth) should be sought in any patient with ILD. The CTDs may be difficult to rule out since the pulmonary manifestations occasionally precede the more typical systemic manifestations by months or years. The most common form of pulmonary involvement is a chronic interstitial pattern similar to that in patients with IPF. However, determining the precise nature of lung involvement in most of the CTDs is difficult due to the high incidence of lung involvement caused by disease-associated complications of esophageal dysfunction (predisposing to aspiration and secondary infections), respiratory muscle weakness (atelectasis and secondary infections), complications of therapy (opportunistic infections), and associated malignancies.

FIGURE 243-2 Nonspecific interstitial pneumonia. High-resolution computed tomography through the lower lung shows volume loss with extensive ground-glass abnormality, reticular abnormality and traction bronchiectasis. There is sparing on the lung immediately adjacent to the pleura. Histology showed a combination of inflammation and mild fibrosis.

Progressive Systemic Sclerosis (PSS) (See also Chap. 303) Clinical evidence of ILD is present in about one-half of patients with PSS, and pathologic evidence in three-quarters. Pulmonary function tests show a restrictive pattern and impaired diffusing capacity, often before any clinical or radiographic evidence of lung disease appears. Pulmonary vascular disease alone or in association with pulmonary fibrosis, pleuritis, or recurrent aspiration pneumonitis is strikingly resistant to current modes of therapy.

Rheumatoid Arthritis (See also Chap. 301) ILD associated with RA is more common in men. Pulmonary manifestations of RA include pleurisy with or without effusion, ILD in up to 20% of cases, necrobiotic nodules (nonpneumoconiotic intrapulmonary rheumatoid nodules) with or without cavities, Caplan's syndrome (rheumatoid pneumoconiosis), pulmonary hypertension secondary to rheumatoid pulmonary vasculitis, BOOP, and upper airway obstruction due to arytenoid arthritis.

Systemic Lupus Erythematosus (See also Chap. 300) Lung disease is a common complication in SLE. Pleuritis with or without effusion is the most common pulmonary manifestation. Other lung manifestations include the following: atelectasis, diaphragmatic dysfunction with loss of lung volumes, pulmonary vascular disease, pulmonary hemorrhage, uremic pulmonary edema, infectious pneumonia, and BOOP. Acute lupus pneumonitis characterized by pulmonary capillaritis leading to alveolar hemorrhage is uncommon. Chronic, progressive ILD is uncommon. It is important to exclude pulmonary infection. Although pleuropulmonary involvement may not be evident clinically, pulmonary function testing, particularly DL_{CO}, reveals abnormalities in many patients with SLE.

Polymyositis and Dermatomyositis (PM/DM) (See also Chap. 369) ILD occurs in ~10% of patients with PM/DM, and the clinical features are similar to those of IPF. Diffuse reticular or nodular opacities with or without an alveolar component occur radiographically, with a predilection for the lung bases. ILD occurs more commonly in the subgroup of patients with an anti-Jo-1 antibody that is directed to histidyl tRNA synthetase. Weakness of respiratory muscles contributing to aspiration pneumonia may be present. A rapidly progressive illness characterized by diffuse alveolar damage may cause respiratory failure.

Sjögren's Syndrome (See also Chap. 304) General dryness and lack of airways secretion cause the major problems of hoarseness, cough, and bronchitis. Lymphocytic interstitial pneumonitis, lymphoma, pseudolymphoma, bronchiolitis, and bronchiolitis obliterans are associated with this condition. Lung biopsy is frequently required to establish a precise pulmonary diagnosis. Glucocorticoids have been used in the management of ILD associated with Sjögren's syndrome with some degree of clinical success.

DRUG-INDUCED ILD Many classes of drugs have the potential to induce diffuse ILD, which is manifest most commonly as exertional dyspnea and nonproductive cough. A detailed history of the medications taken by the patient is needed to identify drug-induced disease, including over-the-counter medications, oily nose drops, or petroleum products (mineral oil). In most cases, the pathogenesis is unknown, although a combination of direct toxic effects of the drug (or its metabolite) and indirect inflammatory and immunologic events is likely. The onset of the illness may be abrupt and fulminant, or it may be insidious, extending over weeks to months. The drug may have been taken for several years before a reaction develops (e.g., amiodarone), or the lung

disease may occur weeks to years after the drug has been discontinued (e.g., carmustine). The extent and severity of disease are usually dose related. Treatment consists of discontinuation of any possible offending drug and supportive care.

CRYPTOGENIC ORGANIZING PNEUMONIA Also known as idiopathic BOOP, COP is a clinicopathologic syndrome of unknown etiology. The onset is usually in the fifth and sixth decades. The presentation may be of a flulike illness with cough, fever, malaise, fatigue, and weight loss. Inspiratory crackles are frequently present on examination. Pulmonary function is usually impaired, with a restrictive defect and arterial hypoxemia being most common. The roentgenographic manifestations are distinctive, revealing bilateral, patchy, or diffuse alveolar opacities in the presence of normal lung volume. Recurrent and migratory pulmonary opacities are common. HRCT shows areas of air-space consolidation, ground-glass opacities, small nodular opacities, and bronchial wall thickening and dilation. These changes occur more frequently in the periphery of the lung and in the lower lung zone. Lung biopsy shows granulation tissue within small airways, alveolar ducts, and airspaces, with chronic inflammation in the surrounding alveoli. Glucocorticoid therapy induces clinical recovery in two-thirds of patients. A few patients have rapidly progressive courses with fatal outcomes despite glucocorticoids.

Foci of organizing pneumonia (i.e., a "BOOP pattern") is a nonspecific reaction to lung injury found adjacent to other pathologic processes or as a component of other primary pulmonary disorders (e.g., cryptococcosis, Wegener's granulomatosis, lymphoma, hypersensitivity pneumonitis, and eosinophilic pneumonia). Consequently, the clinician must carefully reevaluate any patient found to have this histopathologic lesion to rule out these possibilities.

EOSINOPHILIC PNEUMONIA See Chap. 237

PULMONARY ALVEOLAR PROTEINOSIS Although not strictly an ILD, pulmonary alveolar proteinosis (PAP) resembles and is therefore considered with these conditions. It has been proposed that a defect in macrophage function, more specifically an impaired ability to process surfactant, may play a role in the pathogenesis of PAP. This diffuse disease is characterized by the accumulation of an amorphous, periodic acid–Schiff–positive lipoproteinaceous material in the distal air spaces. There is little or no lung inflammation, and the underlying lung architecture is preserved. Mutant mice lacking the gene for granulocyte-macrophage colony-stimulating factor (GM-CSF) have a similar accumulation of surfactant and surfactant apoprotein in the alveolar spaces. Moreover, reconstitution of the respiratory epithelium of GM-CSF knockout mice with the GM-CSF gene completely corrects the alveolar proteinosis. Data from BAL studies in patients suggest that PAP is an autoimmune disease with neutralizing antibody of immunoglobulin G isotype against GM-CSF. These findings suggest that neutralization of GM-CSF bioactivity by the antibody causes dysfunction of alveolar macrophages, which results in reduced surfactant clearance. There are three distinct classes of PAP: acquired (>90% of all cases), congenital, and secondary. Congenital PAP is transmitted in an autosomal recessive manner and is caused by homozygosity for a frame shift mutation (121ins2) in the SP-B gene, which leads to an unstable SP-B mRNA, reduced protein levels, and secondary disturbances of SP-C processing. Secondary PAP is rare among adults and is caused by lysinuric protein intolerance, acute silicosis and other inhalational syndromes, immunodeficiency disorders, and malignancies (almost exclusively of hematopoietic origin) and hematopoietic disorders.

The typical age of presentation is 30 to 50 years, and males predominate. The clinical presentation is usually insidious and manifested by progressive exertional dyspnea, fatigue, weight loss, and low-grade fever. A nonproductive cough is common, but occasionally expectoration of "chunky" gelatinous material may occur. Polycythemia, hypergammaglobulinemia, and increased LDH levels are frequent. Markedly elevated serum levels of lung surfactant proteins A and D have been found in PAP. Radiographically, bilateral symmetric alveolar opacities located centrally in mid and lower lung zones result in a "bat-wing" distribution. HRCT shows a ground-glass opacification and thickened intralobular structures and interlobular septa. Whole lung lavage(s) through a double-lumen endotracheal tube provides relief to many patients with dyspnea or progressive hypoxemia and also may provide long-term benefit.

PULMONARY LYMPHANGIOLEIOMYOMATOSIS Pulmonary LAM is a rare condition that afflicts premenopausal women and should be suspected in young women with emphysema, recurrent pneumothorax, or chylous pleural effusion. It is often misdiagnosed as asthma or chronic obstructive pulmonary disease. Pathologically, LAM is characterized by the proliferation of atypical pulmonary interstitial smooth muscle and cyst formation. The immature-appearing smooth-muscle cells react with monoclonal antibody HMB45, which recognizes a 100-kDa glycoprotein (gp100) originally found in human melanoma cells. Caucasians are affected much more commonly than members of other racial groups. The disease accelerates during pregnancy and abates after oopherectomy. Common complaints at presentation are dyspnea, cough, and chest pain. Hemoptysis may be life threatening. Spontaneous pneumothorax occurs in 50% of patients; it may be bilateral and necessitate pleurodesis. Meningioma and renal angiomyolipomas (hamartomas), characteristic findings in the genetic disorder tuberous sclerosis, are also common in patients with LAM. Chylothorax, chyloperitonium (chylous ascites), chyluria, and chylopericardium are other complications. Pulmonary function testing usually reveals an obstructive or mixed obstructive-restrictive pattern, and gas exchange is often abnormal. HRCT shows thin-walled cysts surrounded by normal lung without zonal predominance. Progression is common, with a median survival of 8 to 10 years from diagnosis. Oophorectomy, progesterone (10 mg/d), and, more recently, tamoxifen and luteinizing hormone–releasing hormone analogues have been used. Lung transplantation offers the only hope for cure despite reports of recurrent disease in the transplanted lung.

SYNDROMES OF ILD WITH DIFFUSE ALVEOLAR HEMORRHAGE Injury to arterioles, venules, and the alveolar septal (alveolar wall or interstitial) capillaries can result in hemoptysis secondary to disruption of the alveolar-capillary basement membrane. This results in bleeding into the alveolar spaces, which characterizes DAH. Pulmonary capillaritis, characterized by a neutrophilic infiltration of the alveolar septae, may lead to necrosis of these structures, loss of capillary structural integrity, and the pouring of red blood cells into the alveolar space. Fibrinoid necrosis of the interstitium and red blood cells within the interstitial space are sometimes seen. Bland pulmonary hemorrhage (i.e., DAH without inflammation of the alveolar structures) may also occur.

The clinical onset is often abrupt, with cough, fever, and dyspnea. Severe respiratory distress requiring ventilatory support may be evident at initial presentation. Although hemoptysis is expected, it can be absent at the time of presentation in one-third of the cases. For patients without hemoptysis, new alveolar opacities, a falling hemoglobin level, and hemorrhagic BAL fluid point to the diagnosis. The chest radiograph is nonspecific and most commonly shows new patchy or diffuse alveolar opacities. Recurrent episodes of DAH may lead to pulmonary fibrosis, resulting in interstitial opacities on the chest radiograph. An elevated white blood cell count and falling hematocrit are frequent. Evidence for impaired renal function caused by focal segmental necrotizing glomerulonephritis, usually with crescent formation, may also be present.

Varying degrees of hypoxemia may occur and are often severe enough to require ventilatory support. The DL_{CO} may be increased, resulting from the increased hemoglobin within the alveoli compartment. Evaluation of either lung or renal tissue by immunofluorescent techniques indicates an absence of immune complexes (pauci-immune) in Wegener's granulomatosis, microscopic polyangiitis pauci-immune glomerulonephritis, and isolated pulmonary capillaritis. A granular pattern is found in the CTDs, particularly SLE, and a char-

acteristic linear deposition is found in Goodpasture's syndrome. Granular deposition of IgA-containing immune complexes is present in Henoch-Schönlein purpura.

The mainstay of therapy for the DAH associated with systemic vasculitis, CTD, Goodpasture's syndrome, and isolated pulmonary capillaritis is intravenous methylprednisolone, 0.5 to 2.0 g daily in divided doses for up to 5 days, followed by a gradual tapering, and then maintenance on an oral preparation. Prompt initiation of therapy is important, particularly in the face of renal insufficiency, since early initiation of therapy has the best chance of preserving renal function. The decision to start other immunosuppressive therapy (cyclophosphamide or azathioprine) acutely depends on the severity of illness.

Goodpasture's Syndrome Pulmonary hemorrhage and glomerulonephritis are features in most patients with this disease. Autoantibodies to renal glomerular and lung alveolar basement membranes are present. This syndrome can present and recur as DAH without an associated glomerulonephritis. In such case, circulating anti-basement membrane antibody is often absent, and the only way to establish the diagnosis is by demonstrating linear immunofluorescence in lung tissue. The underlying histology may be bland hemorrhage or DAH associated with capillaritis. Plasmapheresis has been recommended as adjunctive treatment.

INHERITED DISORDERS ASSOCIATED WITH ILD Pulmonary opacities and respiratory symptoms typical of ILD can develop in related family members and in several inherited diseases. These include the phakomatoses, tuberous sclerosis and neurofibromatosis (Chap. 358), and the lysosomal storage diseases, Niemann-Pick disease and Gaucher's disease (Chap. 340). The Hermansky-Pudlak syndrome (Chap. 101) is an autosomal recessive disorder in which granulomatous colitis and ILD may occur. It is characterized by oculocutaneous albinism, bleeding diathesis secondary to platelet dysfunction, and the accumulation of a chromolipid, lipofuscin material in cells of the reticuloendothelial system. A UIP-like pattern is found on lung biopsy, but the alveolar macrophages may contain cytoplasmic ceroid-like inclusions.

ILD WITH A GRANULOMATOUS RESPONSE IN LUNG TISSUE OR VASCULAR STRUCTURES Inhalation of organic dusts, which cause hypersensitivity pneumonitis, or of inorganic dust, such as silica, which elicits a granulomatous inflammatory reaction leading to ILD, produces diseases of known etiology (Table 243-1) that are discussed in Chaps. 237 and 238. Sarcoidosis (Chap. 309) is prominent among granulomatous diseases of unknown cause in which ILD is an important feature.

Pulmonary Langerhans Cell Histiocytosis PLCH is a rare, smoking-related, diffuse lung disease that primarily affects men between the ages of 20 and 40 years. The clinical presentation varies from an asymptomatic state to a rapidly progressive condition. The most common clinical manifestations at presentation are cough, dyspnea, chest pain, weight loss, and fever. Pneumothorax occurs in about 25% of patients. Hemoptysis and diabetes insipidus are rare manifestations. The radiographic features vary with the stage of the disease. The combination of ill-defined or stellate nodules (2 to 10 mm in diameter), reticular or nodular opacities, bizarre-shaped upper zone cysts, preservation of lung volume, and sparing of the costophrenic angles are characteristics of PLCH. HRCT that reveals a combination of nodules and thin-walled cysts is virtually diagnostic of PLCH. The most frequent pulmonary function abnormality is a markedly reduced DL_{CO}, although varying degrees of restrictive disease, airflow limitation, and diminished exercise capacity may occur. Discontinuance of smoking is the key treatment, resulting in clinical improvement in one-third of patients. Most patients with PLCH suffer persistent or progressive disease. Death due to respiratory failure occurs in ~10% of patients.

Granulomatous Vasculitides (See also Chap. 306) The granulomatous vasculitides are characterized by pulmonary angiitis (i.e., inflammation and necrosis of blood vessels) with associated granuloma formation (i.e., infiltrates of lymphocytes, plasma cells, epithelioid cells, or histiocytes, with or without the presence of multinucleated giant cells, sometimes with tissue necrosis). The lungs are almost always involved, although any organ system may be affected. Wegener's granulomatosis and allergic angiitis and granulomatosis (Churg-Strauss syndrome) primarily affect the lung but are associated with a systemic vasculitis as well. The granulomatous vasculitides generally limited to the lung include necrotizing sarcoid granulomatosis and benign lymphocytic angiitis and granulomatosis. Granulomatous infection and pulmonary angiitis due to irritating embolic material (e.g., talc) are important known causes of pulmonary vasculitis.

LYMPHOCYTIC INFILTRATIVE DISORDERS This group of disorders features lymphocyte and plasma cell infiltration of the lung parenchyma. The disorders either are benign or can behave as low-grade lymphomas. Included are angioimmunoblastic lymphadenopathy with dysproteinemia, a rare lymphoproliferative disorder characterized by diffuse lymphadenopathy, fever, hepatosplenomegaly, and hemolytic anemia, with ILD in some cases.

Lymphocytic Interstitial Pneumonitis This rare form of ILD occurs in adults, some of whom have an autoimmune disease or dysproteinemia. It has been reported in patients with Sjögren's syndrome and HIV infection.

Lymphomatoid Granulomatosis This multisystem disorder of unknown etiology is an angiocentric malignant (T cell) lymphoma characterized by a polymorphic lymphoid infiltrate, an angiitis, and granulomatosis. Although it may affect virtually any organ, it is most frequently characterized by pulmonary, skin, and central nervous system involvement.

BRONCHOCENTRIC GRANULOMATOSIS Rather than a specific clinical entity, bronchocentric granulomatosis (BG) is a descriptive histologic term that describes an uncommon and nonspecific pathologic response to a variety of airway injuries. There is evidence that BG is caused by a hypersensitivity reaction to *Aspergillus* or other fungi in patients with asthma. About half of the patients described have chronic asthma with severe wheezing and peripheral blood eosinophilia. In patients with asthma, BG probably represents one pathologic manifestation of allergic bronchopulmonary aspergillosis or another allergic mycosis. In patients without asthma, BG has been associated with RA and a variety of infections, including tuberculosis, echinococcosis, histoplasmosis, coccidioidomycosis, and nocardiosis. The chest roentgenogram reveals irregularly shaped nodular or mass lesions with ill-defined margins, which are usually unilateral and solitary, with an upper-lobe predominance. Glucocorticoids are the treatment of choice, often with excellent outcome, although recurrences may occur as therapy is tapered or stopped.

244 PULMONARY THROMBOEMBOLISM

Samuel Z. Goldhaber

PREDISPOSITION TO PULMONARY THROMBOEMBOLISM

Acquired and genetic factors contribute to the likelihood of venous thromboembolism. Acquired predispositions include long-haul air travel, obesity, cigarette smoking, oral contraceptives, pregnancy, postmenopausal hormone replacement, surgery, trauma, and medical conditions such as antiphospholipid antibody syndrome, cancer, systemic arterial hypertension, and chronic obstructive pulmonary disease. Thrombophilia contributes greatly to the risk of venous thrombosis, often due to an inherited risk factor in combination with an acquired predisposition. The two most common autosomal dominant genetic mutations are the factor V Leiden and the prothrombin gene mutations (Chap. 56). Only a minority of patients with venous thromboembolism has identifiable predisposing genetic factors. Some patients with predisposing genetic factors will never develop clinical evidence of clotting.

PATHOPHYSIOLOGY

EMBOLIZATION When venous thrombi dislodge from their site of formation, they embolize to the pulmonary arterial circulation or, paradoxically, to the arterial circulation through a patent foramen ovale or atrial septal defect. About half of patients with pelvic vein thrombosis or proximal leg deep venous thrombosis (DVT) have pulmonary thromboembolism (PE), which is usually asymptomatic. Isolated calf vein thrombi pose a lower risk of PE, but they are the most common source of paradoxical embolism. With increased use of chronic indwelling central venous catheters for hyperalimentation and chemotherapy, as well as more frequent insertion of permanent pacemakers and internal cardiac defibrillators, upper extremity venous thrombosis is becoming a more common problem. These thrombi may also embolize and cause PE.

PHYSIOLOGY Pulmonary embolism can have the following effects:

1. *Increased pulmonary vascular resistance* due to vascular obstruction or platelet secretion of neurohumoral agents including serotonin
2. *Impaired gas exchange* due to increased alveolar dead space from vascular obstruction, hypoxemia from alveolar hypoventilation relative to perfusion in the nonobstructed lung, right-to-left shunting, and impaired carbon monoxide transfer due to loss of gas exchange surface
3. *Alveolar hyperventilation* due to reflex stimulation of irritant receptors
4. *Increased airway resistance* due to constriction of airways distal to the bronchi
5. *Decreased pulmonary compliance* due to lung edema, lung hemorrhage, or loss of surfactant

Right Ventricular Dysfunction Progressive right heart failure is the usual cause of death from PE. In the International Cooperative Pulmonary Embolism Registry (ICOPER), the presence of right ventricular dysfunction on baseline echocardiography of PE patients was associated with a doubling of the 3-month mortality rate. As pulmonary vascular resistance increases, right ventricular wall tension rises and perpetuates further right ventricular dilatation and dysfunction. Consequently, the interventricular septum bulges into and compresses an intrinsically normal left ventricle. Increased right ventricular wall tension also compresses the right coronary artery and may precipitate myocardial ischemia and right ventricular infarction. Underfilling of the left ventricle may lead to a fall in left ventricular output and systemic arterial pressure, thereby provoking myocardial ischemia due to compromised coronary artery perfusion. Eventually, circulatory collapse and death may ensue.

DIAGNOSIS

The clinical setting, including risk factors such as family history or personal prior history of venous thromboembolism, can help suggest the diagnosis of PE. Semi-quantitative clinical scoring systems such as the Wells Diagnostic Scoring System are beginning to replace "gestalt" estimates of clinical likelihood (Table 244-1).

CLINICAL SYNDROMES Patients with *massive PE* present with systemic arterial hypotension and usually have anatomically widespread thromboembolism. Primary therapy with thrombolysis or embolectomy offers the greatest chance of survival. Those with *moderate to large PE* have right ventricular hypokinesis on echocardiography but normal systemic arterial pressure. Optimal management is controversial; such patients may benefit from thrombolysis or embolectomy rather than anticoagulation alone. Patients with *small to moderate PE* have both normal right heart function and normal systemic arterial pressure. They have a good prognosis with either adequate anticoagulation. The presence of *pulmonary infarction* usually indicates a small PE, but one that is exquisitely painful, because it lodges peripherally, near the innervation of pleural nerves. However, larger, more central PEs can occur concomitantly with peripheral pulmonary infarction.

Nonthrombotic pulmonary embolism may be easily overlooked. Possible etiologies include fat embolism after blunt trauma and long bone fractures, tumor embolism, or air embolism. Intravenous drug users may inject themselves with a wide array of substances, such as hair, talc, or cotton. *Amniotic fluid embolism* occurs when fetal membranes leak or tear at the placental margin. The pulmonary edema seen in this syndrome is probably due primarily to alveolar capillary leakage.

SYMPTOMS AND SIGNS Dyspnea is the most frequent symptom of PE, and tachypnea is its most frequent sign. Whereas dyspnea, syncope, hypotension, or cyanosis indicates a massive PE, pleuritic pain, cough, or hemoptysis often suggests a small embolism located distally near the pleura. On physical examination, young and previously healthy individuals may simply appear anxious but otherwise seem deceptively well, even with an anatomically large PE. They may only have dyspnea with moderate exertion. They often lack "classic" signs such as tachycardia, low-grade fever, neck vein distention, or an accentuated pulmonic component of the second heart sound. Sometimes, a paradoxical bradycardia occurs.

In older patients who complain of vague chest discomfort, the diagnosis of PE may not be apparent unless signs of right heart failure are present. Unfortunately, because acute coronary ischemic syndromes are so common, one may overlook the possibility of life-threatening PE and may inadvertently discharge these patients from the hospital after the exclusion of myocardial infarction with serial blood tests to detect cardiac injury and serial electrocardiograms.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of PE is broad (Table 244-2). Although PE is known as "the great masquerader," quite often other illnesses simulate PE. For example, when the proposed diagnosis of PE is supposedly confirmed with a combination of dysp-

TABLE 244-1 *Wells Diagnostic Scoring System[a] for Suspected PE*

	Points
• Clinical signs and symptoms of DVT (minimum of leg swelling and pain with palpation of the deep veins)	3.0
• An alternative diagnosis is less likely than PE	3.0
• Heart rate >100 beats/min	1.5
• Immobilization or surgery in the previous 4 weeks	1.5
• Previous DVT/PE	1.5
• Hemoptysis	1.0
• Malignancy (on treatment, treated in the past 6 months, or palliative)	1.0

[a] The Wells Scoring System has a maximum of 12.5 points. If the score is ≤ 4 points, the likelihood of PE is only 8%.

Note: DVT, deep vein thrombosis; PE, pulmonary thromboembolism.

TABLE 244-2 Differential Diagnosis of Pulmonary Thromboembolism

Acute coronary syndrome, including unstable angina and acute myocardial infarction
Pneumonia, bronchitis, exacerbation of asthma or chronic obstructive pulmonary disease
Congestive heart failure
Pericarditis
Pleurisy, including "viral syndrome," costochondritis, other musculoskeletal discomfort
Rib fracture, pneumothorax
Primary pulmonary hypertension
Anxiety

nea, chest pain, and an abnormal lung scan, the correct diagnosis of pneumonia might become apparent 12 h later when an infiltrate blossoms on chest x-ray, purulent sputum is first produced, and high fever and shaking chills develop.

Some patients have PE and a coexisting illness such as pneumonia or heart failure. In such circumstances, clinical improvement will often fail to occur despite standard medical treatment of the concomitant illness. This situation can serve as a clinical clue to the possible coexistence of PE.

NONIMAGING DIAGNOSTIC MODALITIES These are generally less expensive but also less specific than diagnostic modalities that employ imaging.

Blood Tests The quantitative *plasma* ***D****-dimer enzyme-linked immunosorbent assay (ELISA)* level is elevated (>500 ng/mL) in more than 90% of patients with PE, reflecting plasmin's breakdown of fibrin and indicating endogenous (though clinically ineffective) thrombolysis. However, the D-dimer assay is not specific and therefore has no useful role among patients who are already hospitalized. Levels increase in patients with myocardial infarction, sepsis, or almost any systemic illness. The plasma D-dimer ELISA has a high negative predictive value and can be used to help exclude PE. In a prospective 1-year evaluation, the Emergency Department at Brigham and Women's Hospital mandated obtaining a D-dimer ELISA in all 1106 patients suspected of PE. It served as an excellent screening test, with a sensitivity of 96.4% and negative predictive value of 99.6%.

Data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) indicate that, contrary to classic teaching, *arterial blood gases* lack diagnostic utility for PE, even though the P_{O_2} and P_{CO_2} will often both decrease. Among patients suspected of PE, neither the room air arterial P_{O_2} nor calculation of the alveolar-arterial oxygen gradient can reliably differentiate or triage patients who actually have PE at angiography.

Electrocardiogram Classic abnormalities include sinus tachycardia; new-onset atrial fibrillation or flutter; and an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III (Chap. 210). Often, the QRS axis is greater than 90°. T-wave inversion in leads V_1 to V_4, perhaps the most frequent but least publicized change, reflects right ventricular strain.

NONINVASIVE IMAGING MODALITIES ■ Chest Roentgenography A normal or near-normal chest x-ray in a dyspneic patient suggests PE. Well-established abnormalities include focal oligemia (Westermark's sign), a peripheral wedged-shaped density above the diaphragm (Hampton's hump), or an enlarged right descending pulmonary artery (Palla's sign).

Venous Ultrasonography Confirmed DVT is usually an adequate surrogate for PE. Ultrasonography of the deep venous system relies upon loss of vein compressibility as the primary criterion for DVT. About one-half of patients with PE have no imaging evidence of DVT, probably because the clot has already embolized to the lung or is in the pelvic veins, where ultrasonography is usually inadequate. Therefore, the workup for PE should continue if there is high clinical suspicion, despite a normal ultrasound examination.

Chest CT Computed tomography (CT) of the chest with intravenous contrast (ordinarily, 100 mL administered at 3 to 4 mL/s via an antecubital vein) is superseding lung scanning (see below) as the principal imaging test for the diagnosis of PE. Chest CT effectively diagnoses large, central PE (Fig. 244-1). New generation multislice scanners image the entire thorax with 1-mm thin sections during a single 12- to 15-s breath-hold and can detect peripherally located thrombi in fifth order branches. In patients without PE, the lung parenchymal images may establish alternative diagnoses not apparent on chest x-ray that explain the presenting symptoms and signs, such as pneumonia, emphysema, pulmonary fibrosis, pulmonary mass, or aortic pathology.

Lung Scanning (See also Chap. 235) Small particulate aggregates of albumin labeled with a gamma-emitting radionuclide are injected intravenously and are trapped in the pulmonary capillary bed. The perfusion scan defect indicates absent or decreased blood flow, possibly due to PE. Ventilation scans, obtained with radiolabeled inhaled gases such as xenon or krypton, improve the specificity of the perfusion scan. Abnormal ventilation scans indicate abnormal nonventilated lung, thereby providing possible explanations for perfusion defects other than acute PE. A high probability scan for PE is defined as having two or more segmental perfusion defects in the presence of normal ventilation (Fig. 244-2).

The diagnosis of PE is very unlikely in patients with normal and near-normal scans but is about 90% certain in patients with high-probability scans. Unfortunately, most patients have nondiagnostic scans, and fewer than half of patients with angiographically confirmed PE have a high-probability scan. Importantly, as many as 40% of patients with high clinical suspicion for PE and "low-probability" scans do, in fact, have PE at angiography.

Magnetic Resonance (MR) (Contrast-Enhanced) MR pulmonary angiography utilizes gadolinium contrast agent, which unlike iodinated contrast agents used in CT angiography, is not nephrotoxic. The risk of a contrast reaction with gadolinium is very low, and no ionizing radiation is used. When compared with first-generation chest CT scanning, results are similar. MR also assesses right ventricular function, thus making it a promising single test for both diagnosis of PE and assessment of hemodynamic effect.

Echocardiography More than half of patients with PE will have normal echocardiograms Nevertheless, this imaging test helps with the rapid triage of extremely ill patients who may have PE. Bedside echocardiography can usually reliably differentiate among illnesses that have radically different treatment, including acute myocardial infarction, pericardial tamponade, dissection of the aorta, and PE complicated by right heart failure. McConnell's sign, i.e., right ventricular free wall hypokinesis with normal right ventricular apical motion, appears to be specific for PE. Detection of right ventricular dysfunction due to PE

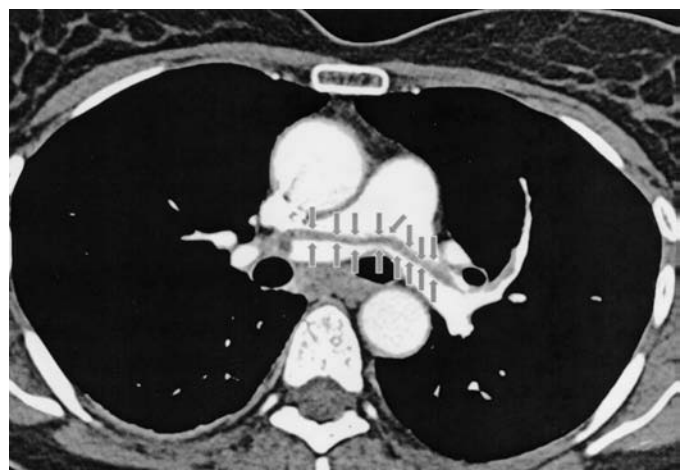

FIGURE 244-1 Bilateral "saddle" pulmonary thromboembolism computed tomography scan of the chest. The arrows outline the "saddle" *(Courtesy of Philip Costello, MD.)*

helps to stratify the risk, delineate the prognosis, and plan optimal management.

INVASIVE DIAGNOSTIC MODALITIES ■ Pulmonary Angiography Selective pulmonary angiography is the most specific examination available for establishing the definitive diagnosis of PE and can detect emboli as small as 1 to 2 mm. A definitive diagnosis of PE depends upon visualization of an intraluminal filling defect in more than one projection. Secondary signs of PE include abrupt occlusion ("cut-off") of vessels; segmental oligemia or avascularity; a prolonged arterial phase with slow filling; or tortuous, tapering peripheral vessels. Chest CT scanning is replacing diagnostic pulmonary angiography, because it is less invasive. In the current era of chest CT with contrast, pulmonary angiography is reserved for (1) patients with technically inadequate CT scans, (2) scans performed on older machines that cannot image fourth- and fifth-order pulmonary arteries, and (3) patients who will undergo interventions such as catheter embolectomy or catheter-directed thrombolysis.

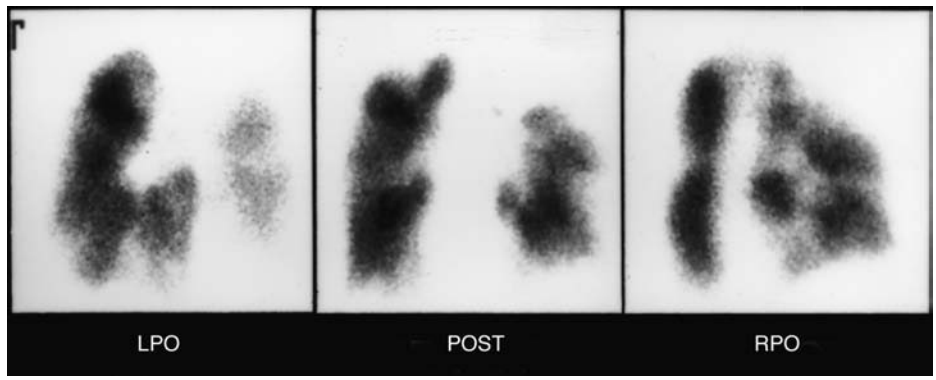

FIGURE 244-2 Three views of the pulmonary perfusion scan illustrating multiple segmental perfusion defects in both lung fields. The ventilation scan, which is normal, is not shown. The marked mismatch between normal ventilation and abnormal perfusion makes this lung scan *high probability* for pulmonary thromboembolism. LPO, left posterior oblique; POST, posterior; RPO, right posterior oblique.

Contrast Phlebography Venous ultrasonography has virtually replaced contrast phlebography, which is costly, uncomfortable, and occasionally results in contrast allergy or contrast-induced phlebitis.

INTEGRATED DIAGNOSTIC APPROACH We advocate an integrated diagnostic approach to streamline the workup of PE (Fig. 244-3). This strategy combines the clinical likelihood of PE with the results of noninvasive testing, especially D-dimer ELISA, venous ultrasonography, and chest CT or lung scanning to determine whether pulmonary angiography is warranted.

TREATMENT

Primary Therapy versus Secondary Prevention *Primary therapy* consists of clot dissolution with thrombolysis or removal of PE by embolectomy. Anticoagulation with heparin and warfarin or placement of an inferior vena caval filter constitutes *secondary prevention* of recurrent PE rather than primary therapy.

Risk Stratification Risk stratification is crucial in determining treatment strategy. The presence of hemodynamic instability, right ventricular dysfunction, or elevation of the troponin level due to right ventricular microinfarction can identify high-risk patients.

Primary therapy should be reserved for patients at high risk of an adverse clinical outcome. When right ventricular function remains normal in a hemodynamically stable patient, a good clinical outcome is highly likely with anticoagulation alone (Fig. 244-4).

Adjunctive Therapy Important adjunctive measures include pain relief (especially with nonsteroidal anti-inflammatory agents), supplemental oxygenation, and psychological support. Dobutamine—a β-adrenergic agonist with positive inotropic and pulmonary vasodilating actions—may be effective in the treatment of right heart failure and cardiogenic shock. Volume loading should be undertaken cautiously because increased right ventricular dilatation can lead to even further reductions in left ventricular forward output.

Heparin Heparin binds to and accelerates the activity of antithrombin III, an enzyme that inhibits the coagulation factors thrombin (factor IIa), Xa, IXa, XIa, and XIIa. Heparin thus prevents additional thrombus formation and permits endogenous fibrinolytic mechanisms to lyse clot that has already formed. After 5 to 7 days of heparin, residual thrombus begins to stabilize in the endothelium of the vein or pulmonary artery. However, heparin does *not* directly dissolve thrombus that already exists.

MODIFIED CONSENSUS GUIDELINES FOR THE TREATMENT OF PULMONARY EMBOLISM FROM THE AMERICAN COLLEGE OF CHEST PHYSICIANS

1. Treat DVT or PE with therapeutic levels of unfractionated intravenous heparin, adjusted subcutaneous heparin, or low-molecular-weight heparin for at least 5 days, and overlap with oral anticoagulation for at least 4 to 5 days. Consider a longer course of heparin, approximately 10 days, for massive PE or severe iliofemoral DVT.
2. For most patients, heparin and oral anticoagulation can be started

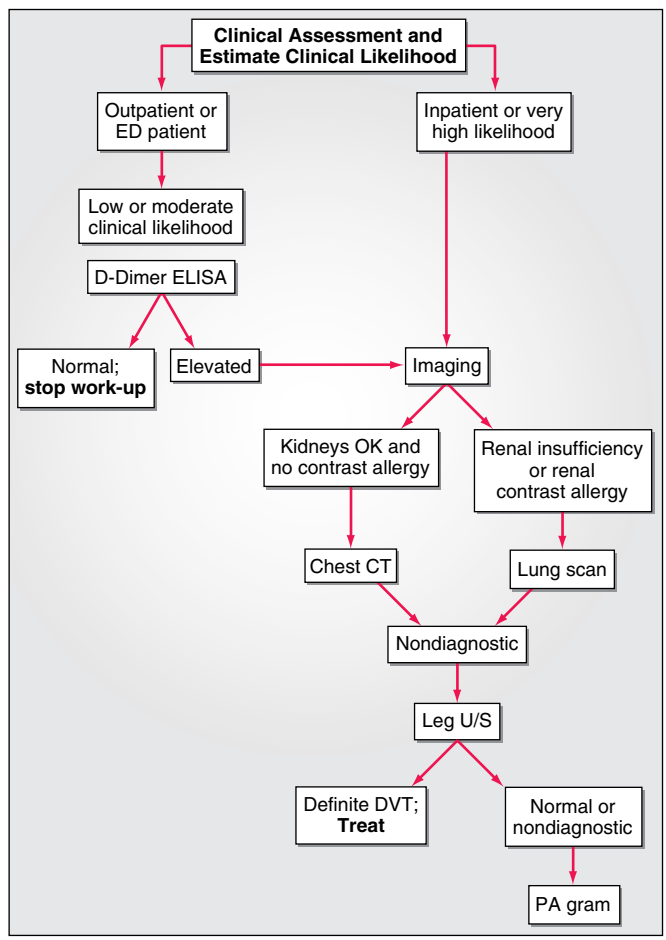

FIGURE 244-3 Diagnosis strategy for pulmonary thromboembolism: An integrated diagnostic approach. ED, emergency department; ELISA, enzyme-linked immunosorbent assay; CT, computed tomography; U/S, ultrasound; DVT, deep vein thrombosis; PA gram, pulmonary arteriogram.

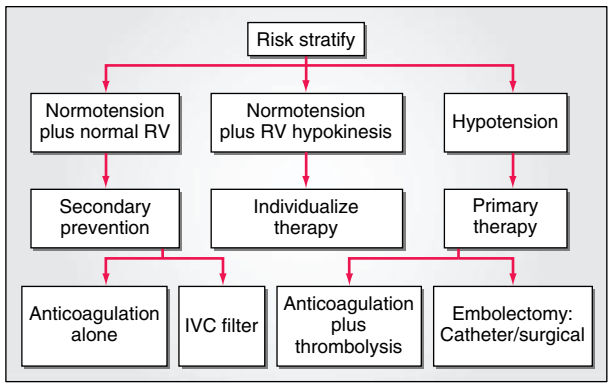

FIGURE 244-4 Acute management of pulmonary thromboembolism: RV, right ventricular; IVC, inferior vena cava.

together and heparin discontinued on day 5 or 6 if the INR has been therapeutic for two consecutive days.

3. Treat patients with reversible or time-limited risk factors for at least 3 months. Patients with a first episode of idiopathic DVT should be treated indefinitely. A proven regimen is warfarin, target INR of 2.0 to 3.0 for 6 months, followed by low-intensity warfarin, target INR of 1.5 to 2.0.
4. The use of thrombolytic agents continues to be highly individualized, and clinicians should have some latitude in using these agents. Patients with hemodynamically unstable PE or massive iliofemoral thrombosis are the best candidates.
5. Inferior vena caval filter placement is recommended when there is a contraindication to or failure of anticoagulation, for chronic recurrent embolism with pulmonary hypertension, and with concurrent performance of surgical pulmonary embolectomy or pulmonary endarterectomy.

Modified from TM Hyers et al: Antithrombotic therapy for venous thromboembolic disease Chest 119:176S, 2001.

LOW-MOLECULAR-WEIGHT HEPARINS These fragments of unfractionated heparin exhibit less binding to plasma proteins and endothelial cells and consequently have greater bioavailability, a more predictable dose response, and a longer half-life than unfractionated heparin. No laboratory monitoring or dose adjustment is needed unless the patient is markedly obese or has renal insufficiency. Therefore, low-molecular-weight heparins, although more expensive, are far more convenient to use than unfractionated heparin. A meta-analysis of more than 3500 acute DVT patients showed that those treated with low-molecular-weight heparin had an overall 29% reduction in mortality and major bleeding compared with the unfractionated heparin group.

DOSING For unfractionated heparin, a typical intravenous bolus is 5000 to 10,000 units followed by a continuous infusion of 1000 to 1500 units/h. An activated partial thromboplastin time that is at least twice the control value should provide a therapeutic level of heparin. Nomograms based upon a patient's weight may assist in adjusting the dose of heparin. The most popular nomogram utilizes an initial bolus of 80 units/kg, followed by an initial infusion rate of 18 units/kg per hour.

Enoxaparin has received U.S. Food and Drug Administration (FDA) approval for both prophylaxis and treatment of patients who present primarily with symptomatic DVT, with or without concomitant (but usually asymptomatic) PE. The preferred dose is 1 mg/kg twice daily. An alternative back-up regimen for patients who can only receive one injection daily is 1.5 mg/kg daily. The FDA has approved dalteparin for prophylaxis but not for treatment of venous thromboembolism.

COMPLICATIONS The most important adverse effect of heparin is hemorrhage. For life-threatening or intracranial hemorrhage, protamine sulfate can be administered. Heparin-induced thrombocytopenia and osteopenia are far less common with low-molecular-weight heparins than with unfractionated heparin. Thrombosis due to heparin-induced thrombocytopenia should be managed with a direct thrombin inhibitor: *argatroban* for patients with renal insufficiency or *hirudin* for patients with hepatic failure. Heparin-associated elevations in transaminase levels occur commonly but are rarely associated with clinical toxicity.

Warfarin This vitamin K antagonist prevents γ carboxylation activation of coagulation factors II, VII, IX, and X. The full effect of warfarin often requires 5 days, even if the prothrombin time, used for monitoring, becomes elevated more rapidly. When warfarin is initiated during an active thrombotic state, the levels of protein C and S decline, thus creating a paradoxical thrombogenic potential. By overlapping either unfractionated or low-molecular-weight heparin and warfarin for 5 days, the early procoagulant effect of unopposed warfarin can be counteracted. Thus, heparin acts as a "bridge" until the full anticoagulant effect of warfarin is obtained.

DOSING In an average-sized adult, warfarin is usually initiated in a dose of 5 mg. Doses of 7.5 or 10 mg can be used in obese or large-framed young patients who are otherwise healthy. Patients who are malnourished or who have received prolonged courses of antibiotics are probably deficient in vitamin K and should receive smaller initial doses of warfarin, such as 2.5 mg. An uncommon genetic mutation delays the metabolism of warfarin, resulting in a very low dose requirement, 1 to 2 mg daily, to achieve a therapeutic affect. The prothrombin time is standardized with the INR, which assesses the anticoagulant effect of warfarin (Chap. 103). The target INR is usually 2.5, with a range of 2.0 to 3.0.

COMPLICATIONS As with heparin, bleeding is the most important and common complication associated with warfarin administration. Life-threatening bleeding can be treated with cryoprecipitate or fresh-frozen plasma (usually 2 units) to achieve immediate hemostasis. Recombinant factor VIIa is an effective, novel therapy for life-threatening bleeding in the setting of excessive warfarin. For less serious bleeding, or an excessively high INR in the absence of bleeding, vitamin K may be administered. Reversing excessive INRs by withholding warfarin and prescribing a low dose of oral vitamin K, such as 2.5 mg, will facilitate reestablishing a stable dose of warfarin.

Warfarin-induced skin necrosis is a rare complication that may be related to warfarin-induced reduction of protein C. It is usually associated with administration of a high initial dose of warfarin during an acute thrombotic state in which heparin is withheld.

During pregnancy, warfarin should be avoided if possible because of warfarin embryopathy, which is most common with exposure during the sixth through twelfth weeks of gestation. However, women can take warfarin postpartum and breast feed safely. Warfarin can also be administered safely during the second trimester.

DURATION OF ANTICOAGULATION Patients with PE following surgery or trauma ordinarily have a low rate of recurrence after 6 months of anticoagulation. In contrast, among patients with "idiopathic" PE, the recurrence rate is surprisingly high after cessation of anticoagulation. The PREVENT Trial establishes intensive anticoagulation with warfarin for 6 months, target INR of 2.0 to 3.0 followed by an indefinite duration of anticoagulation with low-intensity warfarin, target INR of 1.5 to 2.0.

Inferior Vena Caval Filters The two principal indications for insertion of an inferior vena caval filter are: (1) active bleeding that precludes anticoagulation, and (2) recurrent venous thrombosis despite intensive anticoagulation. Prevention of recurrent PE in patients with right heart failure who are not candidates for thrombolysis or prophylaxis of extremely high-risk patients are "softer" indications that are being utilized less frequently. The filter itself may fail by permitting the passage of small to medium-sized clots or because large thrombi embolize to the pulmonary arteries via collateral veins that develop. A more common complication is caval thrombosis with marked bilateral leg swelling. Paradoxically, by providing a nidus for clot formation, filters double the DVT rate over the ensuing 2 years following placement.

Thrombolysis Successful thrombolytic therapy rapidly reverses right heart failure and leads to a lower rate of death and recurrent PE. Thrombolysis usually: (1) dissolves much of the anatomically obstructing pulmonary arterial thrombus; (2) prevents the continued release of serotonin and other neurohumoral factors that exacerbate pulmonary hypertension; and (3) dissolves much of the source of the thrombus in the pelvic or deep leg veins, thereby decreasing the likelihood of recurrent PE.

The preferred thrombolytic regimen is 100 mg of recombinant tissue plasminogen activator (tPA) administered as a continuous peripheral intravenous infusion over 2 h. Patients appear to respond to thrombolysis for up to 14 days after the PE has occurred. MAPPET-3 (Management Strategy and Prognosis of Pulmonary Embolism Trial) is the largest randomized trial of thrombolysis (using 100 mg of tPA plus anticoagulation versus anticoagulation alone); 247 patients were enrolled with hemodynamically stable PE. Escalation of therapy (including use of pressors or intubation) was necessary in 24% of those receiving anticoagulation alone compared with 12% of those receiving tPA.

Contraindications to thrombolysis include intracranial disease, recent surgery, or trauma. There is a 1 to 2% risk of intracranial hemorrhage. Careful screening of patients for contraindications to thrombolysis is the best way to minimize bleeding risk.

Embolectomy The risk of intracranial hemorrhage with thrombolysis has prompted reevaluation of surgical embolectomy for acute PE. At Brigham and Women's Hospital, 29 patients with massive PE were operated on in 25 months, with an 89% survival rate. This high survival rate may be attributed to improved surgical technique, rapid diagnosis and triage, and careful patient selection. A possible alternative to open surgical embolectomy is catheter embolectomy.

Pulmonary Thromboendarterectomy Patients who develop chronic pulmonary hypertension due to prior PE may become severely dyspneic at rest or with minimal exertion. They should be considered for pulmonary thromboendarterectomy which, if successful, can markedly reduce and at times even cure pulmonary hypertension (Chap. 220).

PREVENTION

Prophylaxis against PE is of paramount importance because venous thromboembolism is difficult to detect and poses an excessive medical and economic burden. Mechanical and pharmacologic measures often succeed in preventing this complication (Table 244-3). Patients at high risk can receive a combination of mechanical and pharmacologic modalities. Graduated compression stockings and pneumatic compression devices may complement mini-dose unfractionated heparin (5000 units subcutaneously twice or preferably three times daily), low-molecular-weight heparin, a pentasaccharide or warfarin administration. Computerized reminder systems can increase the use of preventive care among these patients. Patients who have undergone total hip replacement, total knee replacement, or cancer surgery will benefit from extended pharmacologic prophylaxis for a total of 4 to 6 weeks, especially with low-molecular-weight heparin.

TABLE 244-3 Prevention of Pulmonary Thromboembolism

Condition	Prophylaxis Strategy
High-risk general surgery	Mini-UFH + GCS *or* LMWH + GCS
Thoracic surgery	Mini-UFH + IPC
Cancer surgery, including gynecologic cancer surgery	LMWH, consider 1 month of prophylaxis
Total hip replacement, total knee replacement, hip fracture surgery	LMWH, fondaparinux (a pentasaccharide) 2.5 mg sc, once daily *or* (except for total knee replacement) warfarin (target INR 2.5)
Neurosurgery	GCS + IPC
Neurosurgery for brain tumor	Mini-UFH *or* LMWH, + IPC, + predischarge venous ultrasonography
Benign gynecologic surgery	Mini-UFH + GCS
Medically ill patients	Mini-UFH *or* LMWH
Anticoagulation contraindicated	GCS + IPC
Long-haul air travel	Consider LMWH for very high risk patients

Note: Mini-UFH, minidose unfractionated heparin, 5000 units subcutaneously twice (less effective) or three times daily (more effective); GCS, graduated compression stockings, usually 10–18 mm Hg; LMWH, low-molecular-weight heparin, typically in the United States, enoxaparin, 40 mg once daily, or dalteparin, 2500 or 5000 units once daily; IPC, intermittent pneumatic compression devices.

245 DISORDERS OF THE PLEURA, MEDIASTINUM, DIAPHRAGM, AND CHEST WALL

Richard W. Light

DISORDERS OF THE PLEURA

PLEURAL EFFUSION The pleural space lies between the lung and chest wall and normally contains a very thin layer of fluid, which serves as a coupling system. A pleural effusion is present when there is an excess quantity of fluid in the pleural space.

Etiology Pleural fluid accumulates when pleural fluid formation exceeds pleural fluid absorption. Normally, fluid enters the pleural space from the capillaries in the parietal pleura and is removed via the lymphatics situated in the parietal pleura. Fluid can also enter the pleural space from the interstitial spaces of the lung via the visceral pleura or from the peritoneal cavity via small holes in the diaphragm. The lymphatics have the capacity to absorb 20 times more fluid than is normally formed. Accordingly, a pleural effusion may develop when there is excess pleural fluid formation (from the interstitial spaces of the lung, the parietal pleura, or the peritoneal cavity) or when there is decreased fluid removal by the lymphatics.

Diagnostic Approach When a patient is found to have a pleural effusion, an effort should be made to determine the cause (Fig. 245-1). The first step is to determine whether the effusion is a transudate or an exudate. A *transudative pleural effusion* occurs when *systemic factors* that in-

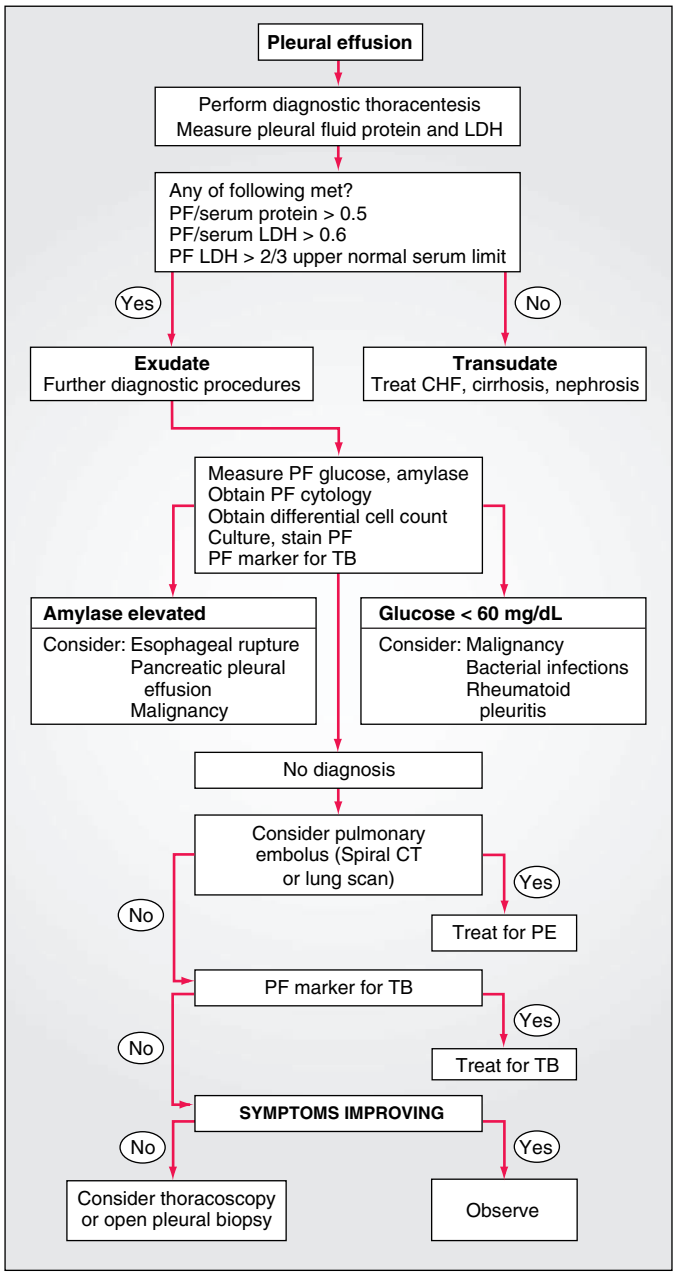

FIGURE 245-1 Approach to the diagnosis of pleural effusions. CHF, congestive heart failure; CT, computed tomography; LDH, lactate dehydrogenase; PE, pulmonary embolism; TB, tuberculosis; PF, pleural fluid.

fluence the formation and absorption of pleural fluid are altered. The leading causes of transudative pleural effusions in the United States are left ventricular failure, pulmonary embolism, and cirrhosis. An *exudative pleural effusion* occurs when *local factors* that influence the formation and absorption of pleural fluid are altered. The leading causes of exudative pleural effusions are bacterial pneumonia, malignancy, viral infection, and pulmonary embolism. The primary reason to make this differentiation is that additional diagnostic procedures are indicated with exudative effusions to define the cause of the local disease.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none:

1. pleural fluid protein/serum protein >0.5
2. pleural fluid LDH/serum LDH >0.6
3. pleural fluid LDH more than two-thirds normal upper limit for serum

The above criteria misidentify approximately 25% of transudates as exudates. If one or more of the exudative criteria are met and the patient is clinically thought to have a condition producing a transudative effusion, the difference between the albumin levels in the serum and the pleural fluid should be measured. If this gradient is greater than 12 g/L (1.2 g/dL), the exudative categorization by the above criteria can be ignored because almost all such patients have a transudative pleural effusion.

If a patient has an exudative pleural effusion, the following tests on the pleural fluid should be obtained: description of the fluid, glucose level, differential cell count, microbiologic studies, and cytology.

Effusion due to Heart Failure The most common cause of pleural effusion is left ventricular failure. The effusion occurs because the increased amounts of fluid in the lung interstitial spaces exit in part across the visceral pleura. This overwhelms the capacity of the lymphatics in the parietal pleura to remove fluid. A diagnostic thoracentesis should be performed if the effusions are not bilateral and comparable in size, if the patient is febrile, or if the patient has pleuritic chest pain to verify that the patient has a transudative effusion. Otherwise the patient is best treated with diuretics. If the effusion persists despite diuretic therapy, a diagnostic thoracentesis should be performed.

Hepatic Hydrothorax Pleural effusions occur in approximately 5% of patients with cirrhosis and ascites. The predominant mechanism is the direct movement of peritoneal fluid through small holes in the diaphragm into the pleural space. The effusion is usually right-sided and frequently is large enough to produce severe dyspnea. If medical management does not control the ascites and the effusion, the best treatment is a liver transplant. If the patient is not a candidate for this, the best alternative is insertion of a transjugular intrahepatic portal systemic shunt.

Parapneumonic Effusion Parapneumonic effusions are associated with bacterial pneumonia, lung abscess, or bronchiectasis and are probably the most common exudative pleural effusion in the United States. *Empyema* refers to a grossly purulent effusion.

Patients with aerobic bacterial pneumonia and pleural effusion present with an acute febrile illness consisting of chest pain, sputum production, and leukocytosis. Patients with anaerobic infections present with a subacute illness with weight loss, a brisk leukocytosis, mild anemia, and a history of some factor that predisposes them to aspiration.

The possibility of a parapneumonic effusion should be considered whenever a patient with a bacterial pneumonia is initially evaluated. The presence of free pleural fluid can be demonstrated with a lateral decubitus radiograph, computed tomography (CT) of the chest, or ultrasound. If the free fluid separates the lung from the chest wall by more than 10 mm on one of these examinations, a therapeutic thoracentesis should be performed. Factors indicating the likely need for a procedure more invasive than a thoracentesis (in increasing order of importance) include:

1. loculated pleural fluid
2. pleural fluid pH < 7.20
3. pleural fluid glucose <3.3 mmol/L (<60 mg/dL)
4. positive Gram stain or culture of the pleural fluid
5. the presence of gross pus in the pleural space

If the fluid recurs after the initial therapeutic thoracentesis, a repeat thoracentesis should be performed if any of the above characteristics are present. If the fluid recurs a second time, tube thoracostomy should be performed if any of the poor prognostic factors are present. If the fluid cannot be completely removed with the therapeutic thoracentesis, consideration should be given to inserting a chest tube and instilling a thrombolytic (streptokinase, 250,000 units) or performing thoracoscopy with the breakdown of adhesions. Decortication should be considered when the above are ineffective.

Effusion Secondary to Malignancy Malignant pleural effusions secondary to metastatic disease are the second most common type of exudative

pleural effusion. The three tumors that cause approximately 75% of all malignant pleural effusions are lung carcinoma, breast carcinoma, and lymphoma. Most patients complain of dyspnea, which is frequently out of proportion to the size of the effusion. The pleural fluid is an exudate, and its glucose level may be reduced if the tumor burden in the pleural space is high.

The diagnosis is usually made via cytology of the pleural fluid. If the initial cytologic examination is negative, then thoracoscopy is the best next procedure if malignancy is strongly suspected. At the time of thoracoscopy, a procedure such as pleural abrasion should be performed to effect a pleurodesis. If thoracoscopy is unavailable, then needle biopsy of the pleura should be performed.

Patients with a malignant pleural effusion are treated symptomatically for the most part, since the presence of the effusion indicates disseminated disease and most malignancies associated with pleural effusion are not curable with chemotherapy. The only symptom that can be attributed to the effusion itself is dyspnea. If the patient's lifestyle is compromised by dyspnea, and if the dyspnea is relieved with a therapeutic thoracentesis, then one of the following procedures should be considered: (1) tube thoracostomy with the instillation of a sclerosing agent such as doxycycline, 500 mg; or (2) outpatient insertion of a small indwelling catheter.

Mesothelioma Malignant mesotheliomas are primary tumors that arise from the mesothelial cells that line the pleural cavities. Most are related to asbestos exposure. Patients with mesothelioma present with chest pain and shortness of breath. The chest radiograph reveals a pleural effusion, generalized pleural thickening, and a shrunken hemithorax. Thoracoscopy or open pleural biopsy is usually necessary to establish the diagnosis. Various treatment modalities, including radical surgery, chemotherapy, and radiation therapy, have been tried, but none has been proven to be more effective than symptomatic therapy. It is recommended that chest pain be treated with opiates and that shortness of breath be treated with oxygen and/or opiates.

Effusion Secondary to Pulmonary Embolization The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is pulmonary embolism. Dyspnea is the most common symptom. The pleural fluid is usually exudative but can be transudative. The diagnosis is established by spiral CT scan or pulmonary arteriography (Chap. 244). Treatment of the patient with a pleural effusion secondary to pulmonary embolism is the same as for any patient with pulmonary emboli. If the pleural effusion increases in size after anticoagulation, the patient probably has recurrent emboli or another complication such as a hemothorax or a pleural infection.

Tuberculous Pleuritis (See also Chap. 150) In many parts of the world, the most common cause of an exudative pleural effusion is tuberculosis (TB), but this is relatively uncommon in the United States. Tuberculous pleural effusions are thought to be due primarily to a hypersensitivity reaction to tuberculous protein in the pleural space. Patients with tuberculous pleuritis present with fever, weight loss, dyspnea, and/or pleuritic chest pain. The pleural fluid is an exudate with predominantly small lymphocytes. The diagnosis is established by demonstrating high levels of TB markers in the pleural fluid (adenosine deaminase $>$ 45 IU/L, interferon $\gamma >$ 140 pg/mL, or positive polymerase chain reaction (PCR) for tuberculous DNA). Alternatively, the diagnosis can be established by culture of the pleural fluid, needle biopsy of the pleura, or thoracoscopy. The recommended treatment of pleural and pulmonary tuberculosis is identical (Chap. 150).

Effusion Secondary to Viral Infection Viral infections are probably responsible for a sizable percentage of undiagnosed exudative pleural effusions. In many series, no diagnosis is established for approximately 20% of exudative effusions, and these effusions resolve spontaneously with no long-term residua. The importance of these effusions is that one should not be too aggressive in trying to establish a diagnosis for the undiagnosed effusion, particularly if the patient is improving clinically.

AIDS Pleural effusions are uncommon in such patients. The most common cause is Kaposi's sarcoma, followed by parapneumonic effusion. Other common causes are TB, cryptococcosis, and primary effusion lymphoma. Pleural effusions are very uncommon with *Pneumocystis carinii* infection.

Chylothorax A chylothorax occurs when the thoracic duct is disrupted and chyle accumulates in the pleural space. The most common cause of chylothorax is trauma, but it also may result from tumors in the mediastinum. Patients with chylothorax present with dyspnea, and a large pleural effusion is present on the chest radiograph. Thoracentesis reveals milky fluid, and biochemical analysis reveals a triglyceride level that exceeds 1.2 mmol/L (110 mg/dL). Patients with chylothorax and no obvious trauma should have a lymphangiogram and a mediastinal CT scan to assess the mediastinum for lymph nodes. The treatment of choice for most chylothoraces is implantation of a pleuroperitoneal shunt. Patients with chylothoraces should not undergo prolonged tube thoracostomy with chest tube drainage because this will lead to malnutrition and immunologic incompetence.

Hemothorax When a diagnostic thoracentesis reveals bloody pleural fluid, a hematocrit should be obtained on the pleural fluid. If the hematocrit is $>$50% that of the peripheral blood, the patient has a hemothorax. Most hemothoraces are the result of trauma; other causes include rupture of a blood vessel or tumor. Most patients with hemothorax should be treated with tube thoracostomy, which allows continuous quantification of bleeding. If the bleeding emanates from a laceration of the pleura, apposition of the two pleural surfaces is likely to stop the bleeding. If the pleural hemorrhage exceeds 200 mL/h, consideration should be given to thoracotomy.

Miscellaneous Causes of Pleural Effusion There are many other causes of pleural effusion (Table 245-1). Key features of some of these conditions are as follows: If the pleural fluid amylase level is elevated, the diagnosis of esophageal rupture or pancreatic disease is likely. If the

19. Pericardial disease
20. Chylothorax

patient is febrile, has predominantly polymorphonuclear cells in the pleural fluid, and has no pulmonary parenchymal abnormalities, an intraabdominal abscess should be considered. The diagnosis of an asbestos pleural effusion is one of exclusion. Benign ovarian tumors can produce ascites and a pleural effusion (Meigs' syndrome), as can the ovarian hyperstimulation syndrome. Several drugs can cause pleural effusion; the associated fluid is usually eosinophilic. Pleural effusions commonly occur following coronary artery bypass surgery. Effusions occurring within the first weeks are typically left-sided and bloody, with large numbers of eosinophils, and respond to one or two therapeutic thoracenteses. Effusions occurring after the first few weeks are typically left-sided and clear yellow, with predominantly small lymphocytes, and tend to recur. Other medical manipulations that induce pleural effusions include abdominal surgery, endoscopic variceal sclerotherapy, radiation therapy, liver or lung transplantation, or the intravascular insertion of central lines.

PNEUMOTHORAX Pneumothorax is the presence of gas in the pleural space. A *spontaneous pneumothorax* is one that occurs without antecedent trauma to the thorax. A *primary spontaneous pneumothorax* occurs in the absence of underlying lung disease, while a *secondary spontaneous pneumothorax* occurs in its presence. A *traumatic pneumothorax* results from penetrating or nonpenetrating chest injuries. A *tension pneumothorax* is a pneumothorax in which the pressure in the pleural space is positive throughout the respiratory cycle.

Primary Spontaneous Pneumothorax Primary spontaneous pneumothoraces are usually due to rupture of apical pleural blebs, small cystic spaces that lie within or immediately under the visceral pleura. Primary spontaneous pneumothoraces occur almost exclusively in smokers, which suggests that these patients have subclinical lung disease. Approximately one-half of patients with an initial primary spontaneous pneumothorax will have a recurrence. The initial recommended treatment for primary spontaneous pneumothorax is simple aspiration. If the lung does not expand with aspiration, or if the patient has a recurrent pneumothorax, thoracoscopy with stapling of blebs and pleural abrasion is indicated. Thoracoscopy or thoracotomy with pleural abrasion is almost 100% successful in preventing recurrences.

Secondary Spontaneous Pneumothorax Most secondary spontaneous pneumothoraces are due to chronic obstructive pulmonary disease, but pneumothoraces have been reported with virtually every lung disease. Pneumothorax in patients with lung disease is more life-threatening than it is in normal individuals because of the lack of pulmonary reserve in these patients. Nearly all patients with secondary spontaneous pneumothorax should be treated with tube thoracostomy and the instillation of a sclerosing agent such as doxycycline. Patients with secondary spontaneous pneumothoraces who have a persistent air leak, an unexpanded lung after 3 days of tube thoracostomy, or a recurrent pneumothorax should be subjected to thoracoscopy with bleb resection and pleural abrasion.

Traumatic Pneumothorax Traumatic pneumothoraces can result from both penetrating and nonpenetrating chest trauma. Traumatic pneumothoraces should be treated with tube thoracostomy unless they are very small. If a hemopneumothorax is present, one chest tube should be placed in the superior part of the hemithorax to evacuate the air, and another should be placed in the inferior part of the hemithorax to remove the blood. Iatrogenic pneumothorax is a type of traumatic pneumothorax that is becoming more common. The leading causes are transthoracic needle aspiration, thoracentesis, and the insertion of central intravenous catheters. The treatment differs according to the degree of distress and can be observation, supplemental oxygen, aspiration, or tube thoracostomy.

Tension Pneumothorax This condition usually occurs during mechanical ventilation or resuscitative efforts. The positive pleural pressure is life-threatening both because ventilation is severely compromised and because the positive pressure is transmitted to the mediastinum, which results in decreased venous return to the heart and reduced cardiac output.

Difficulty in ventilation during resuscitation or high peak inspiratory pressures during mechanical ventilation strongly suggests the diagnosis. The diagnosis is made by the finding of an enlarged hemithorax with no breath sounds and shift of the mediastinum to the contralateral side. Tension pneumothorax must be treated as a medical emergency. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or marked hypoxemia. A large-bore needle should be inserted into the pleural space through the second anterior intercostal space. If large amounts of gas escape from the needle after insertion, the diagnosis is confirmed. The needle should be left in place until a thoracostomy tube can be inserted.

DISORDERS OF THE MEDIASTINUM

The mediastinum is the region between the pleural sacs. It is separated into three compartments. The *anterior mediastinum* extends from the sternum anteriorly to the pericardium and brachiocephalic vessels posteriorly. It contains the thymus gland, the anterior mediastinal lymph nodes, and the internal mammary arteries and veins. The *middle mediastinum* lies between the anterior and posterior mediastina and contains the heart; the ascending and transverse arches of the aorta; the venae cavae; the brachiocephalic arteries and veins; the phrenic nerves; the trachea, main bronchi, and their contiguous lymph nodes; and the pulmonary arteries and veins. The *posterior mediastinum* is bounded by the pericardium and trachea anteriorly and the vertebral column posteriorly. It contains the descending thoracic aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and the posterior group of mediastinal lymph nodes.

MEDIASTINAL MASSES The first step in evaluating a mediastinal mass is to place it in one of the three mediastinal compartments, since each has different characteristic lesions. The most common lesions in the anterior mediastinum are thymomas, lymphomas, teratomatous neoplasms, and thyroid masses. The most common masses in the middle mediastinum are vascular masses, lymph node enlargement from metastases or granulomatous disease, and pleuropericardial and bronchogenic cysts. In the posterior mediastinum, neurogenic tumors, meningoceles, meningomyeloceles, gastroenteric cysts, and esophageal diverticula are commonly found.

CT scanning is the most valuable imaging technique for evaluating mediastinal masses and is the only imaging technique that should be done in most instances. Barium studies of the gastrointestinal tract are indicated in many patients with posterior mediastinal lesions, since hernias, diverticula, and achalasia are readily diagnosed in this manner. An ^{131}I nuclear medicine scan can efficiently establish the diagnosis of intrathoracic goiter.

A definite diagnosis can be obtained with mediastinoscopy or anterior mediastinotomy in many patients with masses in the anterior or middle mediastinal compartments. A diagnosis can be established without thoracotomy via percutaneous fine-needle aspiration biopsy or endoscopic ultrasound-guided biopsy of mediastinal masses. In many cases the diagnosis can be established and the mediastinal mass removed with video-assisted thoracoscopy.

ACUTE MEDIASTINITIS Most cases of acute mediastinitis either are due to esophageal perforation or occur after median sternotomy for cardiac surgery. Patients with esophageal rupture are acutely ill with chest pain and dyspnea due to the mediastinal infection. The esophageal rupture can occur spontaneously or as a complication of esophagoscopy or the insertion of a Blakemore tube. Appropriate treatment is exploration of the mediastinum with primary repair of the esophageal tear and drainage of the pleural space and the mediastinum.

The incidence of mediastinitis following median sternotomy is 0.4 to 5.0%. Patients most commonly present with wound drainage. Other presentations include sepsis or a widened mediastinum. The diagnosis is usually established with mediastinal needle aspiration. Treatment includes immediate drainage, debridement, and parenteral antibiotic therapy, but the mortality still exceeds 20%.

CHRONIC MEDIASTINITIS The spectrum of chronic mediastinitis ranges from granulomatous inflammation of the lymph nodes in the mediastinum to fibrosing mediastinitis. Most cases are due to TB or histoplasmosis, but sarcoidosis, silicosis, and other fungal diseases are at times causative. Patients with granulomatous mediastinitis are usually asymptomatic. Those with fibrosing mediastinitis usually have signs of compression of some mediastinal structure such as the superior vena cava or large airways, phrenic or recurrent laryngeal nerve paralysis, or obstruction of the pulmonary artery or proximal pulmonary veins. Other than antituberculous therapy for tuberculous mediastinitis, no medical or surgical therapy has been demonstrated to be effective for mediastinal fibrosis.

PNEUMOMEDIASTINUM In this condition, there is gas in the interstices of the mediastinum. The three main causes are: (1) alveolar rupture with dissection of air into the mediastinum; (2) perforation or rupture of the esophagus, trachea, or main bronchi; and (3) dissection of air from the neck or the abdomen into the mediastinum. Typically, there is severe substernal chest pain with or without radiation into the neck and arms. The physical examination usually reveals subcutaneous emphysema in the suprasternal notch and *Hamman's sign*, which is a crunching or clicking noise synchronous with the heartbeat and best heard in the left lateral decubitus position. The diagnosis is confirmed with the chest radiograph. Usually no treatment is required, but the mediastinal air will be absorbed faster if the patient inspires high concentrations of oxygen. If mediastinal structures are compressed, the compression can be relieved with needle aspiration.

DISORDERS OF THE DIAPHRAGM

DIAPHRAGMATIC PARALYSIS The presence of bilateral diaphragmatic paralysis almost always causes severe morbidity in adults. The most common causes include high spinal cord injury, thoracic trauma (including cardiac surgery), multiple sclerosis, anterior horn disease, and muscular dystrophy. Most patients with severe diaphragmatic weakness present with hypercapnic respiratory failure, frequently complicated by cor pulmonale and right ventricular failure, atelectasis, and pneumonia.

The degree of diaphragmatic weakness is best quantitated by measuring transdiaphragmatic pressures. The treatment of choice is assisted ventilation for all or part of each day. This is best accomplished without tracheostomy using nasal intermittent positive airway pressure. If the nerve to the diaphragm is intact, diaphragmatic pacing may be a viable alternative. If the paralysis occurs during open heart surgery, recovery frequently occurs, but it may take 6 months or more.

Unilateral paralysis of the diaphragm is much more common than is bilateral paralysis. The most common cause is nerve invasion from malignancy, usually a bronchogenic carcinoma. If the patient does not have malignancy, then usually no cause for the paralysis is found. The diagnosis is suggested by finding an elevated hemidiaphragm on the chest roentgenogram. Confirmation is best established with the "sniff test." When a patient is observed with fluoroscopy while sniffing, the paralyzed diaphragm will move paradoxically upward due to the negative intrathoracic pressure. Patients with a unilateral paralyzed diaphragm are usually asymptomatic. Their vital capacity and total lung capacity are each reduced about 25%. If a patient has a mediastinal mass in conjunction with the diaphragmatic paralysis, further workup should be done. However, if the patient is asymptomatic with a normal chest radiograph, no invasive procedures are warranted.

DISORDERS OF THE CHEST WALL

KYPHOSCOLIOSIS Kyphoscoliosis is a combination of excessive anteroposterior and lateral curvature of the thoracic spine. Abnormalities of the spinal curvature are common, occurring in about 3% of the population. However, deformity of a sufficient degree to lead to symptoms and signs referable to the heart or lungs is rare, occurring in fewer than 3% of those with abnormal curvature. The major pathophysiologic effects of severe kyphoscoliosis are restrictive lung disease and ventilation-perfusion imbalances that result in chronic alveolar hypoventilation, hypoxic vasoconstriction, and eventually pulmonary arterial hypertension and cor pulmonale.

The severity of the cardiopulmonary disease correlates roughly with the degree of scoliosis. If the angle of curvature is $<60°$, ventilatory impairment is rare, while if it is $>90°$, marked ventilatory abnormalities develop commonly.

Although much effort has been devoted to restoring the normal curvature by either internal fixation or an external device, these efforts result in more improvement in the cosmetic appearance than in pulmonary function. However, the earlier that corrective actions are undertaken, the better the results. Once cardiorespiratory failure has developed, there is a high mortality from operative intervention. Patients with kyphoscoliosis and recurrent episodes of respiratory failure benefit from chronic nocturnal mechanical ventilation or nasal continuous positive airway pressure.

PECTUS EXCAVATUM (FUNNEL CHEST) In this congenital condition, the lower portion of the sternum is displaced posteriorly and the anterior ribs are markedly bowed, which results in a depressed panel in the anterior chest. Respiratory symptoms are uncommon, and pulmonary function tests are nearly normal. Surgical correction is seldom indicated and then only to treat psychological upset resulting from the cosmetic deformity.

PECTUS CARINATUM (PIGEON BREAST) This condition is the reverse of pectus excavatum with the sternum protruding anteriorly. This deformity is associated with congenital atrial or ventricular septal defects and severe prolonged childhood asthma. The deformity itself does not cause symptoms, and surgery is for cosmetic purposes only.

HYPOVENTILATION

DEFINITION AND ETIOLOGY Alveolar hypoventilation exists by definition when arterial P_{CO_2} (Pa_{CO_2}) increases above the normal range of 37 to 43 mmHg, but in clinically important hypoventilation syndromes Pa_{CO_2} is generally in the range of 50 to 80 mmHg. Hypoventilation disorders can be acute or chronic. The acute disorders, which represent life-threatening emergencies, are discussed in Chap. 251; this chapter deals with chronic hypoventilation syndromes.

Chronic hypoventilation can result from numerous disease entities (Table 246-1), but in all cases the underlying mechanism involves a defect in either the metabolic respiratory control system, the respiratory neuromuscular system, or the ventilatory apparatus. Disorders associated with impaired respiratory drive, defects in the respiratory neuromuscular system, some chest wall disorders such as obesity, and

TABLE 246-1 *Chronic Hypoventilation Syndromes*

Mechanism	Site of Defect	Disorder
Impaired respiratory drive	Peripheral and central chemoreceptors	Carotid body dysfunction, trauma Prolonged hypoxia Metabolic alkalosis
	Brainstem respiratory neurons	Bulbar poliomyelitis, encephalitis Brainstem infarction, hemorrhage, trauma Brainstem demyelination, degeneration Chronic drug administration Primary alveolar hypoventilation syndrome
Defective respiratory neuromuscular system	Spinal cord and peripheral nerves	High cervical trauma Poliomyelitis Motor neuron disease Peripheral neuropathy
	Respiratory muscles	Myasthenia gravis Muscular dystrophy Chronic myopathy
Impaired ventilatory apparatus	Chest wall	Kyphoscoliosis Fibrothorax Thoracoplasty Ankylosing spondylitis Obesity hypoventilation
	Airways and lungs	Laryngeal and tracheal stenosis Obstructive sleep apnea Cystic fibrosis Chronic obstructive pulmonary disease

upper airway obstruction produce an increase in Pa_{CO_2}, despite normal lungs, because of a reduction in overall minute volume of ventilation and hence in alveolar ventilation. In contrast, most disorders of the chest wall and disorders of the lower airways and lungs may produce an increase in Pa_{CO_2}, despite a normal or even increased minute volume of ventilation, because of severe ventilation-perfusion mismatching that results in net alveolar hypoventilation.

Several hypoventilation syndromes involve combined disturbances in two elements of the respiratory system. For example, patients with chronic obstructive pulmonary disease may hypoventilate not simply because of impaired ventilatory mechanics but also because of a reduced central respiratory drive, which can be inherent or secondary to a coexisting metabolic alkalosis (related to diuretic and steroid therapy).

PHYSIOLOGIC AND CLINICAL FEATURES Regardless of cause, the hallmark of all alveolar hypoventilation syndromes is an increase in alveolar P_{CO_2} (PA_{CO_2}) and therefore in Pa_{CO_2} (Fig. 246-1). The resulting respiratory acidosis eventually leads to a compensatory increase in plasma HCO_3^- concentration and a decrease in Cl^- concentration. The increase in PA_{CO_2} produces an obligatory decrease in PA_{O_2}, resulting in hypoxemia. If severe, the hypoxemia manifests clinically as cyanosis and can stimulate erythropoiesis and induce secondary polycythemia. The combination of chronic hypoxemia and hypercapnia may also induce pulmonary vasoconstriction, leading eventually to pulmonary hypertension, right ventricular hypertrophy, and congestive heart failure. The disturbances in arterial blood gases are typically magnified during sleep because of a further reduction in central respiratory drive. The resulting increased nocturnal hypercapnia may cause cerebral vasodilation leading to morning headache; sleep quality may also be severely impaired, resulting in morning fatigue, daytime somnolence, mental confusion, and intellectual impairment. Other clinical features associated with hypoventilation syndromes are related to the specific underlying disease (Table 246-1).

DIAGNOSIS Investigation of the patient with chronic hypoventilation involves several laboratory tests that will usually localize the disorder

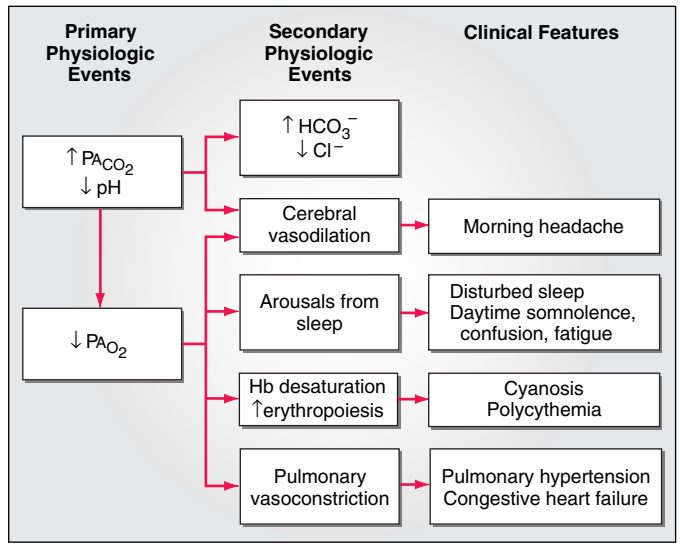

FIGURE 246-1 Physiologic and clinical features of alveolar hypoventilation. Hb, hemoglobin; PA_{CO_2}, alveolar P_{CO_2}; PA_{O_2}, alveolar P_{O_2}. *(After Phillipson and Slutsky.)*

to either the metabolic respiratory control system, the neuromuscular system, or the ventilatory apparatus (Fig. 246-2). Defects in the control system impair responses to chemical stimuli, including ventilatory, occlusion pressure, and diaphragmatic electromyographic (EMG) responses. During sleep, hypoventilation is usually more marked, and central apneas and hypopneas are common. However, because the behavioral respiratory control system (which is anatomically distinct from the metabolic control system), the neuromuscular system, and the ventilatory apparatus are intact, such patients can usually hyperventilate voluntarily, generate normal inspiratory and expiratory muscle pressures (PI_{max}, PE_{max}, respectively) against an occluded airway, generate normal lung volumes and flow rates on routine spirometry, and have normal respiratory system resistance and compliance and a normal alveolar-arterial $P_{O_2}[(A - a)P_{O_2}]$ difference. Patients with defects in the respiratory neuromuscular system also have impaired responses to chemical stimuli but in addition are unable to hyperventilate voluntarily or to generate normal static respiratory muscle pressures, lung volumes, and flow rates. However, at least in the early stages of the disease, the resistance and compliance of the respiratory system and the alveolar-arterial oxygen difference are normal.

In contrast to patients with disorders of the respiratory control or neuromuscular systems, patients with disorders of the chest wall, lungs, and airways typically demonstrate abnormalities of respiratory system resistance and compliance and have a widened $(A - a)P_{O_2}$. Because of the impaired mechanics of breathing, routine spirometric tests are abnormal, as is the ventilatory response to chemical stimuli. However, because the neuromuscular system is intact, tests that are independent of resistance and compliance are usually normal, including tests of respiratory muscle strength and of respiratory control that do not involve airflow.

TREATMENT

The management of chronic hypoventilation must be individualized to the patient's particular disorder, circumstances, and needs and should include measures directed toward the underlying disease. Coexistent metabolic alkalosis should be corrected, including elevations of HCO_3^- that are inappropriately high for the degree of chronic hypercapnia. Administration of supplemental oxygen is effective in attenuating hypoxemia, polycythemia, and pulmonary hypertension but can aggravate CO_2 retention and the associated neurologic symptoms. For this reason, supplemental oxygen must be prescribed judiciously and the results monitored carefully. Pharmacologic agents that stimulate respiration (particularly progesterone) are of benefit in some patients, but generally, results are disappointing.

Site of defect	Responses to CO_2, hypoxia: Ventil.	P.1	EMGdi	Sleep studies	Voluntary hyperventil.	PI_{max} PE_{max}	Volume flow rates	Resistance, compliance	(A − a) Po_2
Metabolic control system (chemoreceptors, brainstem integrating neurons)	↓	↓	↓	↑ Hypoventil, central apneas	N	N	N	N	N
Respiratory neuromuscular system (brainstem motoneurons, spinal cord, respiratory nerves, and muscles)	↓	↓	↓	↑ Hypoventil, central apneas	↓	↓	↓	N	N
Ventilatory apparatus (chest wall, lungs, airways)	↓	N	N	Variable	↓	N	Abnormal	Abnormal	↑

FIGURE 246-2 Pattern of laboratory test results in alveolar hypoventilation syndromes, based on the site of defect. Ventil, ventilation; P.1, mouth pressure generated after 0.1 s of inspiration against an occluded airway; EMGdi, diaphragmatic EMG; PI_{max}, PE_{max}, maximum inspiratory or expiratory pressure that can be generated against an occluded airway; $(A - a)P_{O_2}$, alveolar-arterial P_{O_2} difference; N, normal. Defects in the metabolic control system impair central respiratory drive in response to chemical stimuli (CO_2 or hypoxia); therefore responses of EMGdi, P.1, and minute volume of ventilation are reduced and hypoventilation during sleep is aggravated. In contrast, tests of voluntary respiratory control, muscle strength, lung mechanics, and gas exchange $[(A - a)P_{O_2}]$ are normal. Defects in the respiratory neuromuscular system impair muscle strength; therefore all tests dependent on muscular activity (voluntary or in response to metabolic stimuli) are abnormal, but lung resistance, lung compliance, and gas exchange are normal. Defects in the ventilatory apparatus usually impair gas exchange. Because resistance and compliance are also impaired, all tests dependent on ventilation (whether voluntary or in response to chemical stimuli) are abnormal; in contrast, tests of muscle activity or strength that do not involve airflow (i.e., P.1, EMGdi, PI_{max}, PE_{max}) are normal. *(After Phillipson and Slutsky.)*

Most patients with chronic hypoventilation related to impairment of respiratory drive or neuromuscular disease eventually require mechanical ventilatory assistance for effective management. When hypoventilation is severe, treatment may be required on a 24-h basis, but in most patients ventilatory assistance only during sleep produces dramatic improvement in clinical features and daytime arterial blood gases. In patients with reduced respiratory drive but intact respiratory lower motor neurons, phrenic nerves, and respiratory muscles, diaphragmatic pacing through an implanted phrenic electrode can be very effective. However, for patients with defects in the respiratory nerves and muscles, electrophrenic pacing is contraindicated. Such patients can usually be managed effectively with either intermittent negative-pressure ventilation in a cuirass or intermittent positive-pressure ventilation delivered through a tracheostomy or nose mask. For patients who require ventilatory assistance only during sleep, positive-pressure ventilation through a nose mask is the preferred method because it obviates a tracheostomy and avoids the problem of upper airway occlusion that can arise in a negative-pressure ventilator. Hypoventilation related to restrictive disorders of the chest wall (Table 246-1) can also be managed effectively with nocturnal intermittent positive-pressure ventilation through a nose mask or tracheostomy.

HYPOVENTILATION SYNDROMES

PRIMARY ALVEOLAR HYPOVENTILATION Primary alveolar hypoventilation (PAH) is a disorder of unknown cause characterized by chronic hypercapnia and hypoxemia in the absence of identifiable neuromuscular disease or mechanical ventilatory impairment. The disorder is thought to arise from a defect in the metabolic respiratory control system, but few neuropathologic studies have been reported in such patients. Studies in animals suggest an important role for genetic factors in the pathogenesis of hypoventilation, and familial cases in humans have been described. Isolated PAH is relatively rare, and although it occurs in all age groups, the majority of reported cases in adults have been in males aged 20 to 50 years. The disorder typically develops insidiously and often first comes to attention when severe respiratory depression follows administration of standard doses of sedatives or anesthetics. As the degree of hypoventilation increases, patients typically develop lethargy, fatigue, daytime somnolence, disturbed sleep, and morning headaches; eventually cyanosis, polycythemia, pulmonary hypertension, and congestive heart failure occur (Fig. 246-1). Despite severe arterial blood gas derangements, dyspnea is uncommon, presumably because of impaired chemoreception and ventilatory drive. If left untreated, PAH is usually progressive over a period of months to years and ultimately fatal.

The key diagnostic finding in PAH is a chronic respiratory acidosis in the absence of respiratory muscle weakness or impaired ventilatory mechanics (Fig. 246-2). Because patients can hyperventilate voluntarily and reduce Pa_{CO_2} to normal or even hypocapnic levels, hypercapnia may not be demonstrable in a single arterial blood sample, but the presence of an elevated plasma HCO_3^- level should draw attention to the underlying chronic disturbance. Despite normal ventilatory mechanics and respiratory muscle strength, ventilatory responses to chemical stimuli are reduced or absent (Fig. 246-2), and breath-holding time may be markedly prolonged without any sensation of dyspnea.

Patients with PAH maintain rhythmic respiration when awake, although the level of ventilation is below normal. However, during sleep, when breathing is critically dependent on the metabolic control system, there is typically a further deterioration in ventilation with frequent episodes of central hypopnea or apnea.

PAH must be distinguished from other central hypoventilation syndromes that are secondary to underlying neurologic disease of the brainstem or chemoreceptors (Table 246-1). This distinction requires a careful neurologic investigation for evidence of brainstem or autonomic disturbances. Unrecognized respiratory neuromuscular disorders, particularly those that produce diaphragmatic weakness, are often misdiagnosed as PAH. However, such disorders can usually be suspected on clinical grounds (see below) and can be confirmed by the finding of reduced voluntary hyperventilation, as well as PI_{max} and PE_{max}.

Some patients with PAH respond favorably to respiratory stimulant medications and to supplemental oxygen. However, the majority eventually require mechanical ventilatory assistance. Excellent long-term benefits can be achieved with diaphragmatic pacing by electrophrenic stimulation or with negative- or positive-pressure mechanical ventilation. The administration of such treatment only during sleep is sufficient in most patients.

RESPIRATORY NEUROMUSCULAR DISORDERS Several primary disorders of the spinal cord, peripheral respiratory nerves, and respiratory muscles produce a chronic hypoventilation syndrome (Table 246-1). Hypoventilation usually develops gradually over a period of months to years and often first comes to attention when a relatively trivial increase in mechanical ventilatory load (such as mild airways obstruction) produces severe respiratory failure. In some of the disorders (such as motor neuron disease, myasthenia gravis, and muscular dystrophy), involvement of the respiratory nerves or muscles is usually a later

feature of a more widespread disease. In other disorders, respiratory involvement can be an early or even isolated feature, and hence the underlying problem is often not suspected. Included in this category are the postpolio syndrome (a form of chronic respiratory insufficiency that develops 20 to 30 years following recovery from poliomyelitis), the myopathy associated with adult acid maltase deficiency, and idiopathic diaphragmatic paralysis.

Generally, respiratory neuromuscular disorders do not result in chronic hypoventilation unless there is significant weakness of the diaphragm. Distinguishing features of bilateral diaphragmatic weakness include orthopnea, paradoxical movement of the abdomen in the supine posture, and paradoxical diaphragmatic movement under fluoroscopy. However, the absence of these features does not exclude diaphragmatic weakness. Important laboratory features are a rapid deterioration of ventilation during a maximum voluntary ventilation maneuver and reduced PI_{max} and PE_{max} (Fig. 246-2). More sophisticated investigations reveal reduced or absent transdiaphragmatic pressures, calculated from simultaneous measurement of esophageal and gastric pressures; reduced diaphragmatic EMG responses (recorded from an esophageal electrode) to transcutaneous phrenic nerve stimulation; and marked hypopnea and arterial oxygen desaturation during rapid eye movement sleep, when there is normally a physiologic inhibition of all nondiaphragmatic respiratory muscles and breathing becomes critically dependent on diaphragmatic activity.

The management of chronic alveolar hypoventilation due to respiratory neuromuscular disease involves treatment of the underlying disorder, where feasible, and mechanical ventilatory assistance as described for the PAH syndrome. However, electrophrenic diaphragmatic pacing is contraindicated in these disorders, except for high cervical spinal cord lesions in which the phrenic lower motor neurons and nerves are intact.

OBESITY-HYPOVENTILATION SYNDROME Massive obesity represents a mechanical load to the respiratory system because the added weight on the rib cage and abdomen serves to reduce the compliance of the chest wall. As a result, the functional residual capacity (i.e., end-expiratory lung volume) is reduced, particularly in the recumbent posture. An important consequence of breathing at a low lung volume is that some airways, particularly those in the lung bases, may be closed throughout part or even all of each tidal breath, resulting in underventilation of the lung bases and widening of the $(A - a)P_{O_2}$. Nevertheless, in the majority of obese individuals, central respiratory drive is increased sufficiently to maintain a normal Pa_{CO_2}. However, a small proportion of obese patients develop chronic hypercapnia, hypoxemia, and eventually polycythemia, pulmonary hypertension, and right-sided heart failure. Studies in mice demonstrate that genetically obese mice lacking circulating leptin also develop chronic hypoventilation that can be reversed by leptin infusions. In humans with obesity-hypoventilation syndrome, serum leptin levels are elevated, suggesting that leptin resistance may play a role in the pathogenesis of the disorder. In many patients, obstructive sleep apnea is a prominent feature, and even in those patients without sleep apnea, sleep-induced hypoventilation is an important element of the disorder and contributes to its progression. Most patients demonstrate a decrease in central respiratory drive, which may be inherent or acquired, and many have mild to moderate degrees of airflow obstruction, usually related to smoking. Based on these considerations, several therapeutic measures can be of considerable benefit, including weight loss, cessation of smoking, elimination of obstructive sleep apnea, and enhancement of respiratory drive by medications such as progesterone.

HYPERVENTILATION AND ITS SYNDROMES

DEFINITION AND ETIOLOGY Alveolar hyperventilation exists when Pa_{CO_2} decreases below the normal range of 37 to 43 mmHg. *Hyperventilation* is not synonymous with *hyperpnea*, which refers to an increased minute volume of ventilation without reference to Pa_{CO_2}. Although hyperventilation is frequently associated with dyspnea, patients who are hyperventilating do not necessarily complain of shortness of breath; and conversely, patients with dyspnea need not be hyperventilating.

   b. Pain
   c. Pregnancy

Numerous disease entities can be associated with alveolar hyperventilation (Table 246-2), but in all cases the underlying mechanism involves an increase in respiratory drive that is mediated through either the behavioral or the metabolic respiratory control systems (Fig. 246-3). Thus hypoxemia drives ventilation by stimulating the peripheral chemoreceptors, and several pulmonary disorders and congestive heart failure drive ventilation by stimulating afferent vagal receptors in the lungs and airways. Low cardiac output and hypotension stimulate the peripheral chemoreceptors and inhibit the baroreceptors, both of which increase ventilation. Metabolic acidosis, a potent respiratory stimulant, excites both the peripheral and central chemoreceptors and increases the sensitivity of the peripheral chemoreceptors to coexistent hypoxemia. Hepatic failure can also produce hyperventilation, presumably as a result of metabolic stimuli acting on the peripheral and central chemoreceptors.

Several neurologic and psychological disorders are thought to drive ventilation through the behavioral respiratory control system. Included in this category are psychogenic or anxiety hyperventilation and severe cerebrovascular insufficiency, which may interfere with the inhibitory influence normally exerted by cortical structures on the brainstem respiratory neurons. Rarely, disorders of the midbrain and hypothalamus induce hyperventilation, and it is conceivable that fever and sepsis also cause hyperventilation through effects on these structures. Several drugs cause hyperventilation by stimulating the central or peripheral chemoreceptors or by direct action on the brainstem respiratory neurons. Chronic hyperventilation is a normal feature of pregnancy and

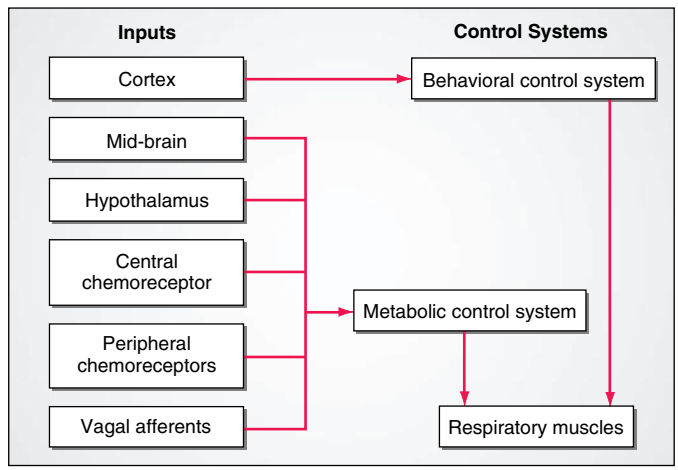

FIGURE 246-3 Schematic diagram of the mechanisms involved in alveolar hyperventilation. *(From Slutsky and Phillipson.)*

results from the effects of progesterone and other hormones acting on the respiratory neurons.

PHYSIOLOGIC AND CLINICAL FEATURES Because hyperventilation is associated with increased respiratory drive, muscle effort, and minute volume of ventilation, the most frequent symptom associated with hyperventilation is dyspnea. However, there is considerable discrepancy between the degree of hyperventilation, as measured by Pa_{CO_2}, and the degree of associated dyspnea. From a physiologic standpoint, hyperventilation is beneficial in patients who are hypoxemic, because the alveolar hypocapnia is associated with an increase in alveolar and arterial P_{O_2}. Conversely, hyperventilation can also be detrimental. In particular, the alkalemia associated with hypocapnia may produce neurologic symptoms, including dizziness, visual impairment, syncope, and seizure activity (secondary to cerebral vasoconstriction); parasthesia, carpopedal spasm, and tetany (secondary to decreased free serum calcium); and muscle weakness (secondary to hypophosphatemia); and may be associated with panic attacks. Severe alkalemia can also induce cardiac arrhythmias and evidence of myocardial ischemia. Patients with a primary respiratory alkalosis are also prone to periodic breathing and central sleep apnea (Chap. 247).

DIAGNOSIS In most patients with a hyperventilation syndrome, the cause is readily apparent on the basis of history, physical examination, and knowledge of coexisting medical disorders (Table 246-2). In patients in whom the cause is not clinically apparent, investigation begins with arterial blood gas analysis, which establishes the presence of alveolar hyperventilation (decreased Pa_{CO_2}) and its severity. Equally important is the arterial pH, which generally allows the disorder to be classified as either a primary respiratory alkalosis (elevated pH) or a primary metabolic acidosis (decreased pH). Also of importance is the Pa_{O_2} and calculation of the $(A - a)P_{O_2}$, since a widened alveolar-arterial oxygen difference suggests a pulmonary disorder as the underlying cause. The finding of a reduced plasma HCO_3^- level establishes the chronic nature of the disorder and points toward an organic cause. Measurements of ventilation and arterial or transcutaneous P_{CO_2} during sleep are very useful in suspected psychogenic hyperventilation, since such patients do not maintain the hyperventilation during sleep.

The disorders that most frequently give rise to unexplained hyperventilation are pulmonary vascular disease (particularly chronic or recurrent thromboembolism) and psychogenic or anxiety hyperventilation. Hyperventilation due to pulmonary vascular disease is associated with exertional dyspnea, a widened $(A - a)P_{O_2}$ and maintenance of hyperventilation during exercise. In contrast, patients with psychogenic hyperventilation typically complain of dyspnea at rest and not during mild exercise and of the need to sigh frequently. They are also more likely to complain of dizziness, sweating, palpitations, and paresthesia. During mild to moderate exercise, their hyperventilation tends to disappear and $(A - a)P_{O_2}$ is normal, but heart rate and cardiac output may be increased relative to metabolic rate.

Rx TREATMENT

Mild alveolar hyperventilation is usually of relatively minor clinical consequence and therefore is generally managed by appropriate treatment of the underlying cause. In the few patients in whom alkalemia is thought to be inducing significant cerebral vasoconstriction, paresthesia, tetany, or cardiac disturbances, acute inhalation of a low concentration of CO_2 can be very beneficial. For patients with disabling psychogenic hyperventilation, careful explanation of the basis of their symptoms can be reassuring and is often sufficient. Others have benefited from β-adrenergic antagonists or an exercise program. Specific treatment for anxiety may also be indicated.

247 SLEEP APNEA

Eliot A. Phillipson

Sleep apnea is defined as an intermittent cessation of airflow at the nose and mouth during sleep. By convention, apneas of at least 10 s duration have been considered important, but in most patients the apneas are 20 to 30 s in duration and may be as long as 2 to 3 min. *Sleep apnea syndrome* refers to a clinical disorder that arises from recurrent apneas during sleep. The clinical importance of sleep apnea arises from the fact that it is one of the leading causes of excessive daytime sleepiness and contributes to important cardiovascular disorders. Indeed, epidemiologic studies have established a prevalence of clinically important sleep apnea of at least 2% in middle-aged women and 4% in middle-aged men.

Sleep apneas can be central or obstructive in type. In central sleep apnea (CSA) the neural drive to all the respiratory muscles is transiently abolished. In contrast, in obstructive sleep apnea (OSA) airflow ceases despite continuing respiratory drive because of occlusion of the oropharyngeal airway.

OBSTRUCTIVE SLEEP APNEA

PATHOGENESIS The definitive event in OSA is occlusion of the upper airway usually at the level of the oropharynx. The resulting apnea leads to progressive asphyxia until there is a brief arousal from sleep, whereupon airway patency is restored and airflow resumes. The patient then returns to sleep, and the sequence of events is repeated, often up to 400 to 500 times per night, resulting in marked fragmentation of sleep.

The immediate factor leading to collapse of the upper airway in OSA is the generation of a critical subatmospheric pressure during inspiration that exceeds the ability of the airway dilator and abductor muscles to maintain airway stability. During wakefulness, upper airway muscle activity is greater than normal in patients with OSA, presumably to compensate for airway narrowing (see below) and a high upper airway resistance. Sleep plays a permissive but crucial role by reducing the activity of the muscles and their protective reflex response to subatmospheric airway pressures. Alcohol is frequently an important cofactor because of its depressant influence on the upper airway muscles and on the arousal response that terminates each apnea. In most patients the patency of the airway is also compromised structurally and is therefore predisposed to occlusion. In a minority of patients the structural compromise is due to obvious anatomic disturbances, such as adenotonsillar hypertrophy, retrognathia, and macroglossia. However, in the majority of patients the structural defect is simply a subtle reduction in airway size that can often be appreciated clinically as "pharyngeal crowding" and that can usually be demonstrated by imaging techniques. Obesity frequently contributes to the reduction in size of the upper airways, either by increasing fat deposition in the soft tissues of the pharynx or by compressing the pharynx by superficial fat masses in the neck. More sophisticated studies also demonstrate a high airway compliance—i.e., the airway is "floppy" and therefore prone to collapse.

PATHOPHYSIOLOGIC AND CLINICAL FEATURES The narrowing of the upper airways during sleep, which predisposes to OSA, inevitably results in snoring. In most patients, snoring usually antedates the development of obstructive events by several years. However, the majority of snor-

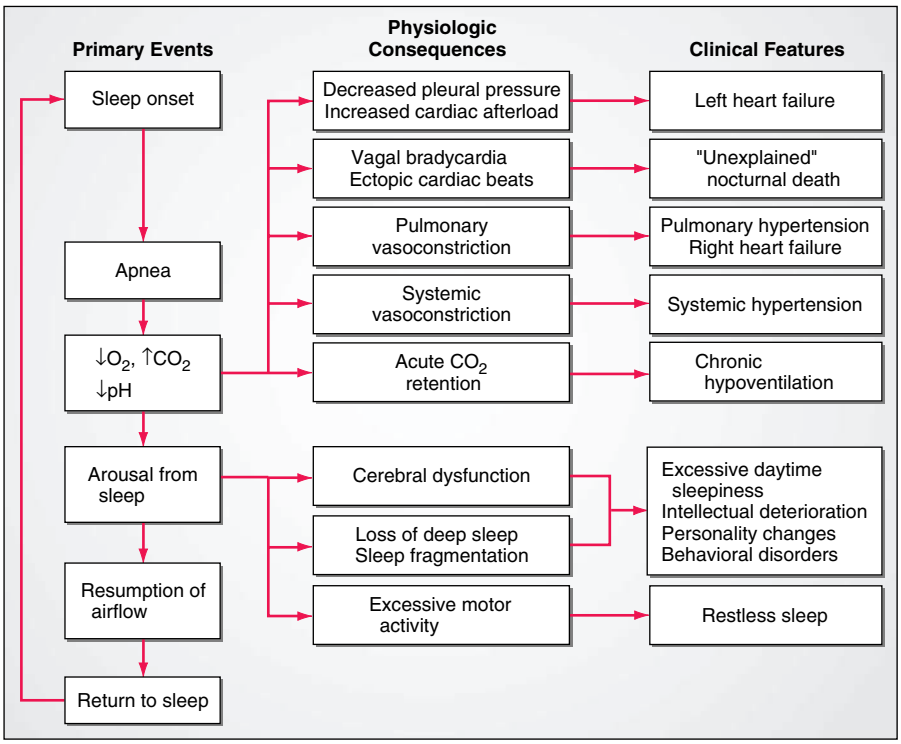

FIGURE 247-1 The primary sequence of events, physiologic responses, and clinical features of obstructive sleep apnea.

ing individuals do not have an OSA disorder, nor is there definitive evidence that snoring per se is associated with long-term health risks. Hence, in the absence of other symptoms, snoring alone does not warrant an investigation for OSA but does call for preventive counselling, particularly with regard to weight gain and alcohol consumption, and, when habitual, warrants conservative treatment similar to that for mild OSA (see below).

The recurrent episodes of nocturnal asphyxia and of arousal from sleep that characterize OSA lead to a series of secondary physiologic events, which in turn give rise in some patients to the clinical complications of the syndrome (Fig. 247-1). The most common manifestations are cognitive and behavioral disturbances that are thought to arise from the fragmentation of sleep and loss of slow-wave sleep induced by the recurrent arousal responses, and from nocturnal cerebral hypoxia. The most pervasive manifestation is excessive daytime sleepiness. Initially, daytime sleepiness manifests under passive conditions, such as reading or watching television; but as the disorder progresses, sleepiness encroaches into all daily activities and can become disabling and dangerous. Several studies have demonstrated two to seven times more motor vehicle accidents in patients with OSA compared with other drivers. Other related symptoms include intellectual impairment, memory loss, and personality disturbances.

The other major manifestations of OSA are cardiorespiratory in nature and are thought to arise from the recurrent episodes of nocturnal asphyxia and of negative intrathoracic pressure, which increases left ventricular afterload (Fig. 247-1). Many patients demonstrate a cyclical slowing of the heart during the apneas to 30 to 50 beats per minute, followed by a tachycardia of 90 to 120 beats per minute during the ventilatory phase. A small number of patients develop severe bradycardia or dangerous tachyarrhythmias, leading to the notion that OSA may result in sudden death during sleep, but corroborative data are lacking. Unlike in healthy subjects, in patients with OSA systemic blood pressure fails to decrease during sleep. In fact, blood pressure typically rises abruptly at the termination of each obstructive event as a result of sympathetic nervous activation and reflex vasoconstriction. Furthermore, over 50% of patients with OSA have systemic hypertension. Several epidemiologic studies have implicated OSA as a risk factor for the development of systemic hypertension, and studies in an animal model demonstrate directly that OSA can cause sustained increases in daytime blood pressure. Emerging data also suggest that OSA can precipitate myocardial ischemia in patients with coronary artery disease and can adversely affect left ventricular function, both acutely and chronically, in patients with congestive heart failure. This complication is probably due to the combined effects of increased left ventricular afterload during each obstructive event, secondary to increased negative intrathoracic pressure (Fig. 247-1), recurrent nocturnal hypoxemia, and chronically elevated sympathoadrenal activity. Treatment of OSA in such patients often results in dramatic improvement in left ventricular function and in clinical cardiac status.

DIAGNOSIS Although OSA occurs at any age, and is considerably more prevalent in women than was previously thought, the typical patient is a male aged 30 to 60 years who presents with a history of snoring, excessive daytime sleepiness, nocturnal choking or gasping, witnessed apneas during sleep, moderate obesity and large neck circumference, and often mild to moderate hypertension. In women with OSA, who are typically postmenopausal, the complaint of snoring is less frequent than in men, and daytime fatigue may be more common than outright sleepiness.

The definitive investigation for suspected OSA is polysomnography, a detailed overnight sleep study that includes recording of (1) electrographic variables (electroencephalogram, electrooculogram, and submental electromyogram) that permit the identification of sleep and its various stages, (2) ventilatory variables that permit the identification of apneas and their classification as central or obstructive, (3) arterial O_2 saturation by ear or finger oximetry, and (4) heart rate. Continuous measurement of transcutaneous P_{CO_2} (which reflects arterial P_{CO_2}) can also be very useful, particularly in patients with CSA. The key diagnostic finding in OSA is episodes of airflow cessation or reduction at the nose and mouth despite evidence of continuing respiratory effort. By the time most patients come to clinical attention they have at least 10 to 15 obstructive events per hour of sleep. Although controversial, recent data suggest that a high upper airway resistance during sleep (manifested by snoring) that is accompanied by recurrent arousals from sleep, even in the absence of apneas and hypopneas, can result in a clinically important sleep-related syndrome. Therefore, the absence of outright apneas and hypopneas in a symptomatic patient may not definitely exclude a sleep-related respiratory disorder.

Because polysomnography is a time-consuming and expensive test, there is considerable interest in the role of screening tests and of unattended home sleep-monitoring for the investigation of OSA. However, the predictive value of most screening tests is too low to be clinically definitive, and the role of unattended, simplified sleep studies in routine practice has yet to be established. Nevertheless, in patients with a high probability of OSA (based on a history of habitual snoring, nocturnal choking or gasping, witnessed apneas during sleep, and daytime sleepiness or fatigue), overnight recording of arterial O_2 saturation by oximetry can be used to *confirm* the diagnosis and obviate the need for full polysomnography by demonstrating recurrent episodes of desaturation (at a rate of at least 10 to 15 events per hour). Negative results in such a patient do not exclude the diagnosis and mandate that the patient proceeds to polysomnography. In contrast, when the probability of OSA is low (only occasional snoring, no witnessed apneas, and no daytime sleepiness, fatigue, or other symptoms), the absence of nocturnal desaturation can be used to *exclude* OSA and obviate the need for full polysomnography. Based on these scenarios, it has been

TABLE 247-1 *Management of Obstructive Sleep Apnea (OSA)*

Mechanism	Mild to Moderate OSA	Moderate to Severe OSA

estimated that overnight oximetry can obviate the need for polysomnography in about one-third of clinic patients referred for consideration of OSA.

TREATMENT

Several approaches to treatment of OSA have been advocated, based on an understanding of the mechanisms involved ((Table 247-1). In establishing a treatment strategy, defining the severity of the disorder is essential, as indicated by the degree of clinical symptoms (particularly daytime sleepiness and fatigue) and the objective level of nocturnal respiratory and sleep disturbance. In severe OSA (significant daytime sleepiness or >30 obstructive events and arousals per hour of sleep), nasal continuous positive airway pressure (CPAP) is the treatment of choice. Nasal CPAP prevents upper airway occlusion by splinting the pharyngeal airway with a positive pressure delivered through a nasal mask. It is well tolerated and effective in >80% of patients, provided that they have received proper training. The established beneficial effects of CPAP include improvements in sleep quality, reduced daytime sleepiness and driving accidents, and decreased nocturnal hypertension. In patients with ischemic heart disease or congestive heart failure who also have OSA, nasal CPAP is the preferred treatment and the only one demonstrated to have a beneficial effect on cardiac status.

In patients with severe OSA who cannot tolerate nasal CPAP, upper airway surgery can be considered, with uvulopalatopharyngoplasty being the most commonly performed procedure. This operation is designed to increase the pharyngeal lumen by resecting redundant soft tissue. When applied to unselected patients with OSA, the response rate is <50%, but more discriminating selection of patients yields a higher rate of success. Other surgical approaches, including maxillofacial surgery, have variable results, but can be particularly effective in patients with craniofacial skeletal abnormalities.

In patients with mild to moderate OSA, nasal CPAP is superior to more conservative therapy but is often less well tolerated. Such patients can sometimes be managed effectively by modest weight reduction, avoidance of alcohol, improvement of nasal patency, cessation of smoking, and avoidance of sleeping in the supine posture. In addition, intraoral appliances, designed to modify the position of the mandible and tongue, can be effective and often better tolerated than nasal CPAP. Medications are generally ineffective in the management of OSA, except in patients with predominantly rapid eye movement (REM) sleep–related events in whom protriptyline or fluoxetine may be beneficial.

CENTRAL SLEEP APNEA

PATHOGENESIS The definitive event in CSA is transient abolition of central drive to the ventilatory muscles. Several underlying mechanisms can result in CSA (Table 247-2). First are defects in the metabolic respiratory control system and respiratory neuromuscular apparatus. Such defects usually produce a chronic alveolar hypoventilation syndrome (in addition to CSA) that becomes more severe during sleep when the stimulatory effect of wakefulness on breathing is abolished.

TABLE 247-2 *Mechanisms Underlying Central Sleep Apnea*

Underlying Mechanism	Clinical Example
Defects in metabolic control system or respiratory muscles	Primary and secondary central alveolar hypoventilation syndromes Respiratory muscle weakness
Transient instabilities in central respiratory drive	Sleep onset Hyperventilation-induced hypocapnia Idiopathic Hypoxia (high altitude, pulmonary disease) Cardiovascular disease, pulmonary congestion Central nervous system disease Prolonged circulation time

Source: From Phillipson, with permission.

In contrast are CSA disorders that arise from transient instabilities in an otherwise intact respiratory control system. Common to all these disorders is a P_{CO_2} level during sleep that falls transiently below the critical P_{CO_2} required for respiratory rhythm generation. This type of instability is frequent at sleep onset, because the P_{CO_2} level of wakefulness is generally lower than that required for rhythm generation in sleep; hence with loss of the stimulatory effect of wakefulness on breathing (referred to as the *waking neural drive*), an apnea develops at sleep onset until P_{CO_2} rises to the critical level (Fig. 247-2). However, if the central nervous system state fluctuates at sleep onset between "asleep" and "awake," a pattern of periodic breathing with central apneas or hypopneas develops as respiration follows the changes in state.

In most patients with CSA, the tendency to develop periodic breathing and central apneas during sleep is enhanced by some degree of chronic hyperventilation during wakefulness that drives the P_{CO_2} level below the threshold required for rhythm generation during sleep.

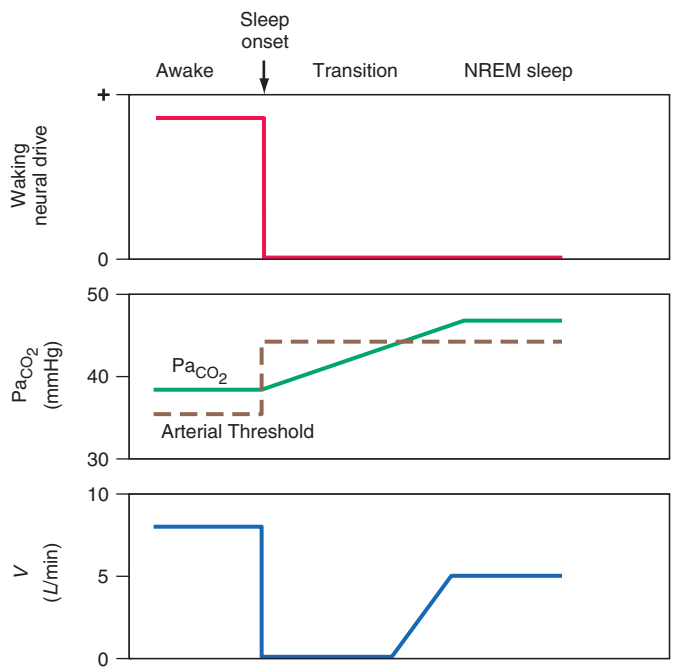

FIGURE 247-2 Schematic diagram of the mechanisms underlying central sleep apnea at sleep onset. With loss of the waking neural drive to breathing, the arterial threshold P_{CO_2} for rhythm generation increases above the Pa_{CO_2} present during wakefulness; ventilation (V) falls to zero and apnea ensues until Pa_{CO_2} rises above the threshold for rhythm generation during sleep. NREM, nonrapid eye movement. (*From TD Bradley, EA Phillipson, Clin Chest Med 13:439, 1992.*)

Such hyperventilation is frequently idiopathic in nature. Hypoxia, whether due to high altitude or to underlying cardiorespiratory disease, enhances the tendency to periodic breathing and CSA by a similar mechanism. Periodic breathing and CSA are also common in patients with congestive heart failure, in whom the periodic breathing is characterized by a classic crescendo-decrescendo pattern (Cheyne-Stokes respiration). Patients with heart failure and CSA have a higher left ventricular end-diastolic volume and filling pressure than do heart failure patients without CSA, suggesting that their hyperventilation results, at least in part, from pulmonary congestion and stimulation of pulmonary vagal receptors.

PATHOPHYSIOLOGIC AND CLINICAL FEATURES In those patients whose CSA is a component of a chronic alveolar hypoventilation syndrome, daytime hypercapnia and hypoxemia are usually evident, and the clinical picture is dominated by a history of recurrent respiratory failure, polycythemia, pulmonary hypertension, and right-sided heart failure. Complaints of sleeping poorly, morning headache, and daytime fatigue and sleepiness are also prominent. In contrast, in patients whose CSA results from an instability in respiratory drive, the clinical picture is dominated by features related to sleep disturbance, including recurrent nocturnal awakenings, morning fatigue, and daytime sleepiness. In patients with congestive heart failure, CSA can be an important (and frequently overlooked) cause of daytime sleepiness and fatigue. In addition, studies indicate a higher mortality rate and higher rate of cardiac transplantation in congestive heart failure patients with CSA than in those without CSA, even when matched for functional class and left ventricular ejection fraction. This outcome probably relates to the fact that CSA can trigger sympathetic nervous activation in patients with heart failure and thereby exert a secondary deleterious effect on the underlying cardiac disorder.

DIAGNOSIS Initially, many patients with CSA, particularly of the idiopathic type, are suspected clinically of having OSA because of a history of snoring, sleep disturbance, and daytime sleepiness. However, obesity and hypertension are less prominent in CSA than in OSA. Definitive diagnosis of CSA requires a polysomnographic study, with the *key observation being recurrent apneas that are not accompanied by respiratory effort*. Measurements of transcutaneous P_{CO_2} are particularly useful in CSA. Those patients with a defect in respiratory control or neuromuscular function typically demonstrate an elevated P_{CO_2} that tends to increase progressively during the night, particularly during REM sleep. In contrast, patients with instabilities in the respiratory control system typically demonstrate a mild degree of hypocapnia, which is an integral pathogenetic feature of their disorder (see above).

TREATMENT

The management of patients whose CSA is a component of an alveolar hypoventilation syndrome is essentially the same as management of the underlying hypoventilation disorder (Chap. 246). Management of patients whose CSA arises from an instability of respiratory drive is more problematic. Patients with hypoxemia usually respond favorably to nocturnal supplemental oxygen. For those with idiopathic CSA, respiratory stimulation with acetazolamide or central nervous system sedation with triazolam have been advocated, but results are variable and efficacy has not been established. Nasal CPAP (as for OSA) can be effective in idiopathic CSA, although definitive long-term trials are lacking and the treatment is less well tolerated than in patients with OSA. The mechanism by which CPAP abolishes central apneas may involve a small increase in Pa_{CO_2} as a result of the added expiratory mechanical load. In patients whose CSA is secondary to congestive heart failure, CPAP is particularly effective in improving sleep quality and daytime cardiac function. In fact, short-term randomized trials have demonstrated that CPAP has a beneficial effect on several surrogate markers of mortality in patients with congestive heart failure, including left ventricular ejection fraction, functional mitral regurgitation, and norepinephrine concentrations. Small, 5-year follow-up studies in such patients demonstrate that CPAP results in a decreased mortality rate. Larger randomized trials are currently in progress.

248 LUNG TRANSPLANTATION

Elbert P. Trulock, G. Alexander Patterson, Joel D. Cooper

Lung transplantation is a therapeutic consideration for patients with most nonmalignant end-stage lung diseases. Activity grew rapidly through the mid-1990s and then reached a plateau of 1400 to 1500 transplants per year worldwide. Unfortunately, the demand exceeds the supply of donor organs, and deaths while awaiting transplantation are not unusual. Nonetheless, in appropriately selected recipients, transplantation prolongs survival and improves quality of life, but it is also associated with significant morbidity and mortality.

INDICATIONS

The indications for lung transplantation have spanned the gamut of lung diseases. The distribution reflects the prevalence and natural history of the various diseases, and the most common indications are shown in Table 248-1. "Other indications" in this table comprise many less prevalent lung diseases. During the past decade the proportion of recipients with primary pulmonary hypertension (PPH) steadily declined from 13% in 1990 to 4% in 2001 as medical therapy improved, and the fraction of recipients with chronic obstructive lung disease (COPD) or α_1-antitrypsin deficiency emphysema increased from 21 to 42%. During the same era, there was a trend toward more bilateral lung transplants, and since 1995 the annual numbers of single and bilateral procedures have been nearly equal.

RECIPIENT SELECTION

Transplantation should be considered when other therapeutic options have been expended and when the patient's prognosis will be improved by the procedure. Survival rates after transplantation can be compared with predictive indices for the underlying disease, but each patient's clinical course must be integrated into the assessment, too. Quality of life is the primary motive for transplantation for many patients, and the prospect of an improved quality-adjusted survival is often attractive to them, even if the survival advantage itself seems marginal.

Disease-specific guidelines for referring patients for transplantation are summarized in Table 248-2. These criteria are derived from prognostic information about the diseases and from clinical experience, and they are intended to identify patients who may benefit from transplantation. Although no randomized trial of transplantation has been carried out, relative risk analyses have demonstrated that transplantation

TABLE 248-1 *Indications for Adult Lung Transplantation (1995–2001)*

Diagnosis	Single Lung Transplantation (n = 4663)		Bilateral Lung Transplantation (n = 4118)		Total (n = 8781)	
Chronic obstructive pulmonary disease	2536	54.4%	926	22.5%	3462	39.4%
Idiopathic pulmonary fibrosis	1110	23.8%	376	9.1%	1486	16.9%
Cystic fibrosis	52	1.1%	1360	33.0%	1412	16.1%

confers a survival advantage in patients with COPD, idiopathic pulmonary fibrosis (IPF), cystic fibrosis (CF), and PPH.

Candidates for lung transplantation are thoroughly screened for any comorbidity that might adversely affect the outcome, and consensus guidelines for selecting potential recipients have been published. In general, suitable candidates should have clinically and physiologically severe lung disease (Table 248-2), but otherwise they must be in reasonably good health. The typical upper age limit is approximately 65 years at most centers. Absolute exclusions include HIV infection, chronic hepatitis B antigenemia or chronic active hepatitis C infection, uncured malignancy, active cigarette smoking, drug or alcohol dependency or abuse, uncontrolled or untreatable pulmonary or extrapulmonary infection, irreversible physical deconditioning, chronic noncompliance with medical care, and significant dysfunction of any vital organ other than the lungs.

Other problems that either increase the risk of complications or will be aggravated by the posttransplantation medical regimen constitute relative contraindications. Some typical issues are ventilator-dependent respiratory failure, previous thoracic surgical procedures, osteoporosis, systemic hypertension, diabetes mellitus, severe obesity or cachexia, and psychosocial problems. Chronic infection poses a unique concern in patients with bronchiectasis. Infection with antibiotic-resistant *Pseudomonas* species is not unusual after years of treatment, and infection with *Burkholderia* species complicates the course of some patients with CF. In addition, infection with *Aspergillus* species or nontuberculous mycobacteria occurs in some cases. Pretransplantation *Burkholderia* infection has been associated with persistent posttransplantation infection and poor outcomes; however, pretransplantation infection with *Pseudomonas* species that are not panresistant to antibiotics, with *Aspergillus* that is not invasive, and with mycobacteria has not compromised the results of transplantation. The potential impact of these and many other factors have to be judged in their clinical context to determine an individual candidate's suitability for transplantation.

TABLE 248-2 *Disease-Specific Guidelines for Selecting Candidates for Lung Transplantation*

- COPD and α_1-antitrypsin deficiency emphysema
  - $FEV_1 < 25\%$ of predicted normal value (post-bronchodilator)
  - $Pa_{CO_2} > 55$ mmHg
  - Pulmonary arterial hypertension (mean pulmonary artery pressure > 25 mmHg)
- Cystic fibrosis/bronchiectasis
  - $FEV_1 < 30\%$ of predicted normal value
  - $Pa_{CO_2} > 50$ mmHg
  - $Pa_{O_2} > 50$ mmHg (on room air)
  - Pulmonary arterial hypertension
  - Adverse clinical course in spite of optimal medical management
    - Increasing hospitalizations
    - Recurrent, massive hemoptysis
    - Rapidly declining FEV_1
    - Cachexia
- Idiopathic pulmonary fibrosis
  - VC or TLC < 60–70% of predicted normal value
  - $DL_{CO} < 50$–60% of predicted normal value
  - Pulmonary arterial hypertension
  - Hypoxemia ($Pa_{O_2} < 60$ mmHg or $SpO_2 < 90\%$) at rest or with activity (on room air)
  - Progressive disease in spite of drug therapy
- Primary pulmonary hypertension
  - New York Heart Association functional class III or IV in spite of optimal drug therapy
  - Unfavorable hemodynamic profile
    - Right atrial pressure > 15 mmHg
    - Mean pulmonary artery pressure > 55 mmHg
    - Cardiac index < 2 (L/min)/m^2

Abbreviations: VC, vital capacity; TLC, total lung capacity; FEV_1, forced expiratory volume in 1 s; DL_{CO}, diffusing capacity for carbon monoxide; Pa_{O_2} and Pa_{CO_2}, partial pressure of oxygen and carbon dioxide, respectively, in arterial blood; SpO_2, oxygen saturation by pulse oximetry.

WAITING LIST AND ORGAN ALLOCATION

Suitable candidates for transplantation are placed on a waiting list, but there is a critical shortage of cadaveric donor organs. Organ allocation policies are influenced by ethical, medical, geographic, and political factors, and systems vary from country to country. Under the present lung allocation algorithm in the United States, after matching for body size and blood group compatibility between the donor and patients on the waiting list, donor lungs are assigned to recipients by their seniority on the waiting list. At this time, there is no priority for medical urgency, but the allocation scheme is being reviewed, and modifications may be proposed.

In the United States the median time to transplantation was 1064 days for patients who initially registered on the national waiting list in 1998. Because of the long waiting time, approximately 10% of patients who were at risk have died each year before an organ became available. However, the death rate while waiting has been much higher for patients with IPF, PPH, and CF than for those with COPD or α_1-antitrypsin deficiency emphysema.

TRANSPLANT PROCEDURE

Bilateral transplantation is mandatory for bronchiectasis because the risk of spillover infection from a remaining native lung precludes single lung transplantation. Heart-lung transplantation is obligatory for Eisenmenger's syndrome with complex anomalies that are not readily amenable to surgical repair and for concomitant end-stage lung disease and cardiac disease. However, cardiac replacement is *not* necessary for cor pulmonale because right ventricular function will recover when pulmonary vascular afterload is normalized by lung transplantation.

Either bilateral or single lung transplantation is an acceptable alternative for other diseases unless there are special considerations. However, bilateral transplantation provides more reserve lung function as a buffer against complications, and in recipients with COPD and α_1-antitrypsin deficiency emphysema, survival has been significantly

TABLE 248-3 *Recipient Survival, by Pretransplantation Diagnosis (1990–2000)*

Diagnosis	n	Survival Rate, %			
		3 Months	1 Year	3 Years	5 Years
Chronic obstructive pulmonary disease	4643	89	79	61	45
α_1-Antitrypsin deficiency emphysema	1288	85	74	59	50
Cystic fibrosis	1809	87	79	62	52
Idiopathic pulmonary fibrosis	1981	79	66	50	38
Primary pulmonary hypertension	714	81	68	53	48

Source: Data from Hertz et al.

better after bilateral transplantation. Nevertheless, single lung transplantation has been the preponderant procedure for COPD and IPF (Table 248-1). Bilateral transplantation has become the preferable operation for pulmonary vascular disease.

Living donor lobar transplantation has played a limited role in adult lung transplantation. It has been performed predominantly in teenagers or young adults with CF. A right lower lobe is obtained from one living donor and a left lower lobe from another, and these lobes are implanted to replace the right and left lungs, respectively, in the recipient. Since a lobe must replace a whole lung, donor-recipient size considerations are crucial, and the procedure is feasible only in recipients of relatively small stature. The results have been comparable to those with transplantation from cadaveric donors. The usual morbidities associated with a lobectomy have been encountered among the donors, but no deaths have yet been reported. Because of ethical concerns, this approach has been restricted to patients who were unlikely to survive the wait for a cadaveric donor.

POSTTRANSPLANTATION MANAGEMENT

Most recipients are managed with a three-drug maintenance immunosuppressive regimen that includes a calcineurin inhibitor (cyclosporine or tacrolimus), a purine synthesis antagonist (azathioprine or mycophenolate mofetil) and prednisone. Prophylaxis for *Pneumocystis carinii* pneumonia is standard, and prophylaxis against cytomegalovirus (CMV) infection is prescribed in many protocols. The dose of cyclosporine or tacrolimus is adjusted by blood-level monitoring. Both are metabolized by the hepatic cytochrome P450 system, and interactions with other medications that affect the pertinent cytochrome P450 pathways can profoundly alter the clearance and blood levels of these key immunosuppressants.

Routine management is designed to prevent complications or to detect them as soon as possible. The techniques include periodic contact with a transplant nurse coordinator, appointments with a physician, chest radiographs, blood tests, spirometry, and bronchoscopy. Lung function rapidly improves and then stabilizes by 3 to 6 months after transplantation. Subsequently, the coefficient of variation in spirometric measurements is small, and a sustained decline of 10 to 15% or more signals a potentially significant problem.

OUTCOMES

RESULTS Survival results are published regularly from large registries (Table 248-3) and can be accessed via the Internet (www.ishlt.org; www.ustransplant.org).

The main sources of perioperative mortality include technical complications of the operation, primary graft failure that is usually caused by ischemia-reperfusion lung injury, and infections. Although acute rejection and CMV infection are common problems in the first year, they have rarely been fatal. Beyond the first year, chronic rejection and non-CMV infections have caused the majority of deaths.

OUTCOMES Regardless of the pretransplantation diagnosis, successful transplantation has impressively restored cardiopulmonary function. Both overall and health-related quality of life have been enhanced after lung transplantation. With multidimensional profiles, improvements have extended across most domains and have been sustained longitudinally unless a complication such as chronic rejection has developed. However, fewer than one-half of recipients have reported either full- or part-time employment in 1-, 3-, and 5-year posttransplantation surveys.

COST The cost-effectiveness of lung transplantation has not been thoroughly analyzed. In the 1990s transplant hospitalization costs in the range of $160,000 were reported from two centers, but the charge would certainly be higher now. At these centers, the cost per quality-adjusted life-year gained through transplantation was estimated at approximately $155,000 to $175,000. Obviously, as recipients survive longer, the cost per quality-adjusted life-year will decrease, and the cost per quality-adjusted life-year for a 5-year survivor was appraised at $31,494 at one of the centers.

COMPLICATIONS

GRAFT DYSFUNCTION Graft dysfunction is not unusual in the first week after transplantation, and it has been referred to as *reperfusion edema*, *reimplantation response*, and *ischemia-reperfusion injury*. It is a form of acute lung injury with increased vascular permeability, but the severity is variable. Pulmonary venous obstruction and hyperacute rejection can produce a similar clinical picture in the first few days. The treatment is the conventional, supportive paradigm for acute lung injury, but inhaled nitric oxide and extracorporeal membrane oxygenation have been used successfully in severe cases. Most recipients recover, but graft failure is a leading cause of early death.

AIRWAY COMPLICATIONS The bronchial blood supply to the donor lung is disrupted. Consequently, when the lung is implanted in the recipient, the bronchus is dependent on retrograde bronchial blood flow through the pulmonary circulation and is vulnerable to ischemia.

The prevalence of major airway complications—dehiscence, stenosis, and bronchomalacia—has ranged from 4 to 20%, but the associated mortality has been very low. Management depends on the specific features. Laser therapy is effective for removing granulation tissue or fibrous webs. Sometimes, a stricture or stenosis can be managed by dilatation, but stent placement is often necessary for strictures and for bronchomalacia.

ACUTE REJECTION This is an immunologic response to direct or indirect alloantigen recognition, and it is characterized by arteriolar and bronchiolar lymphocytic inflammation. With current immunosuppressive regimens, 50% or more of recipients have at least one episode of acute rejection in the first year. Symptoms and signs can include cough, low-grade fever, dyspnea, hypoxemia, inspiratory crackles, interstitial infiltrates, and declining lung function. The signs and symptoms are nonspecific and overlap with infections like CMV pneumonia, hence the diagnosis should be confirmed by transbronchial biopsy. Treatment usually includes a short course of high-dose steroid therapy and adjustment of the maintenance immunosuppressive regimen.

CHRONIC REJECTION This complication is the main impediment to better medium-term survival rates, and it is the source of substantial morbidity because of its impact on lung function and quality of life. Both alloimmune inflammatory and non-alloimmune fibroproliferative mechanisms are probably important in the pathogenesis.

Clinically, chronic rejection is a form of graft dysfunction that is synonymous with bronchiolitis obliterans syndrome (BOS) (Chap. 243). BOS is characterized primarily by airflow limitation, and a formal diagnosis of BOS requires either a sustained decrement of 20% or more in the FEV_1 or biopsy proof of bronchiolitis obliterans. Clinically, the most useful is the $FEF_{25-75\%}$, which will usually decline before the FEV_1 and may presage BOS.

The prevalence of BOS approaches 50% by 3 years after transplantation. Both antecedent acute rejection and lymphocytic bronchiolitis are risk factors for subsequent BOS, and CMV pneumonitis has been implicated inconsistently. BOS is usually treated with augmented immunosuppression. While immunosuppressive therapy may stabilize

lung function, the overall results of treatment have been disappointing, probably because the fibroproliferative process is already well established.

INFECTION The lung allograft is especially susceptible to infection, and infection has been one of the leading causes of death. In addition to a blunted immune response from the immunosuppressive drugs, other normal defenses are breached; the cough reflex is diminished, and mucociliary clearance is impaired in the transplanted lung. The spectrum of infections includes both opportunistic and nonopportunistic pathogens.

Bacterial bronchitis and pneumonia can occur at any time but are almost universal in the early postoperative period. Later, episodes of bronchitis are quite common, especially in recipients with BOS, and *P. aeruginosa* is often the culprit.

CMV is the most frequent viral infection after lung transplantation. Although gastroenteritis, colitis, and hepatitis can occur, CMV viremia and CMV pneumonia are the main illnesses. Most episodes occur in the first 6 months, and treatment with ganciclovir is effective unless resistance develops with repeated exposure. *Aspergillus* species have been the most problematic fungal infection.

OTHER COMPLICATIONS Other potential complications of the transplant operation are phrenic nerve injury with diaphragmatic dysfunction and vagal nerve injury with gastroparesis. Side effects and toxicities of the immunosuppressive drugs can cause new medical problems or aggravate preexisting conditions.

249 PRINCIPLES OF CRITICAL CARE MEDICINE

John P. Kress, Jesse B. Hall

The care of critically ill patients requires a thorough understanding of pathophysiology and is centered initially around resuscitation of patients at extremes of physiologic deterioration. This resuscitation is often fast-paced and may have to be begun without a detailed awareness of the patient's chronic medical problems. While physiologic stabilization is taking place, intensivists attempt to gather important background medical information to supplement the real-time assessment of the patient's current physiologic conditions. Numerous tools are available to assist intensivists in the accurate assessment of pathophysiology and to support incipient organ failures, thus offering a window of opportunity for diagnosing and treating underlying disease(s) in a stabilized patient. Indeed, the use of invasive interventions such as mechanical ventilation and renal replacement therapy as well as diagnostic tools such as central venous and pulmonary artery catheters are commonplace in the intensive care unit (ICU).

ASSESSMENT OF SEVERITY OF ILLNESS Categorization of a patient's illness into grades of severity occurs frequently in the ICU. There are numerous severity-of-illness scoring systems that have been developed and validated over the past two decades. While these scoring systems have been validated as tools to assess populations of critically ill patients accurately, their utility in predicting individual patient outcomes is not clear.

Severity-of-illness scoring systems are important for defining populations of critically ill patients. This allows effective comparison of groups of patients enrolled in clinical trials. To be assured that a purported benefit of a therapy is real, investigators must be assured that different groups involved in a clinical trial have similar illness severities. These scores are also useful in guiding hospital administrative policies. Allocation of resources, such as nursing and ancillary care, can be directed by such scoring systems. Severity-of-illness scoring systems can also assist in the assessment of quality of ICU care over time.

Currently, the most commonly utilized scoring systems are the APACHE (acute physiology and chronic health evaluation) system, the MPM (mortality probability model), and the SAPS (simplified acute physiology score) system. These were all designed to predict outcomes in critical illness. All of these severity-of-illness scoring systems have common variables. These common threads include age; vital signs; assessments of respiratory, renal, and neurologic function; and an evaluation of chronic medical illnesses.

APACHE II Scoring System (Table 249-1) APACHE II is the most commonly used severity-of-illness scoring system in North America. Age, type of ICU admission (after elective surgery vs. nonsurgical or after emergency surgery), a chronic health problem score, and 12 physiologic variables (the most severely abnormal of each in the first 24 h of ICU admission) are used to derive a score. The predicted hospital mortality is derived from a formula that takes into account the APACHE II score; the need for emergency surgery; and a weighted, disease-specific diagnostic category (Fig. 249-1). The validation of this score is based upon 5815 ICU admissions from 13 different hospitals. Importantly, several studies have reported limitations of scoring systems such as APACHE II in predicting outcomes in specific subgroups of patients, such as postoperative coronary artery bypass graft patients. This is presumably related to the "controlled" temporary physiologic derangements that can occur in such patients (e.g., hypothermia, hypotension). More recently, the APACHE III scoring system has been released. This scoring system is similar to APACHE II, in that it is based upon age, physiologic abnormalities, and chronic medical comorbidities. Although the APACHE III score can be calculated, conversion of the score to a mortality probability is only available as a proprietary commercial product.

The SAPS II score, used more frequently in Europe, is not disease-specific but rather incorporates three underlying disease variables (AIDS, metastatic cancer, and hematologic malignancy). The MPM can be used to calculate a direct probability of death in patients admitted to the ICU. It has been validated in 19,124 ICU admissions in 12 countries.

Severity-of-illness scoring systems suffer from the problem of inability to predict survival in individual patients. Accordingly, the use of these scoring systems to direct therapy and clinical decision-making cannot be recommended at present. Rather, these tools should be used as important data to complement clinical bedside decision-making. While they can provide valuable statistical probabilities for outcomes in similar groups of patients, they cannot reliably forecast outcomes in individual cases.

SHOCK (See also Chap. 253)

INITIAL EVALUATION Shock is a common condition necessitating admission to the ICU or occurring in the course of critical care. Shock is defined by the presence of multisystem end-organ hypoperfusion. Clinical indicators include reduced mean arterial pressure, tachycardia, tachypnea, cool skin and extremities, acute altered mental status, and oliguria. Hypotension is usually, though not always, present. The end result of multiorgan hypoperfusion is tissue hypoxia, often clinically manifested by lactic acidosis. Since the mean arterial pressure is the product of the cardiac output (CO) and the systemic vascular resistance (SVR), reductions in blood pressure can be categorized by decreased CO and/or decreased SVR. Accordingly, the initial evaluation of a hypotensive patient should evaluate the adequacy of the CO. This should be part of the earliest assessment of the patient by the clinician at the bedside once shock is considered (Fig. 249-2). Clinical evidence of diminished CO includes a narrow pulse pressure (the difference between systolic and diastolic blood pressure—a marker that correlates well with stroke volume) and cool extremities with delayed capillary refill. Signs of increased CO include a widened pulse pressure (particularly with a reduced diastolic pressure), warm extremities with bounding pulses, and rapid capillary refill. If a hypotensive patient has clinical signs of increased CO, it can be inferred that the reduced blood pressure is a result of decreased SVR.

In hypotensive patients with clinical evidence of reduced CO, an assessment of intravascular and cardiac volume status is appropriate. A hypotensive patient with decreased intravascular and cardiac volume status may have a history suggesting hemorrhage or other volume losses (e.g., vomiting, diarrhea, polyuria). The jugular venous pressure is often reduced in such a patient, while the change in pulse pressure as a function of respiration is increased. A hypotensive patient with an increased intravascular and cardiac volume status may have S_3 and/or S_4 gallop sounds on cardiac examination, increased jugular venous pressure, extremity edema, and rales on lung auscultation. The chest x-ray may show cardiomegaly, widening of the vascular pedicle, Kerley B lines, and pulmonary edema. Chest pain and electrocardiographic changes consistent with ischemia may also be noted.

In hypotensive patients with clinical evidence of *increased* CO, a

POINTS ASSIGNED TO AGE AND CHRONIC DISEASE AS PART OF THE APACHE II SCORE	
Age, Years	**Score**
<45	0
45–54	2
55–64	3
65–74	5
≥75	6
Chronic Health (History of Chronic Conditions)[d]	**Score**
None	0
If patient is admitted after elective surgery	2
If patient is admitted after emergency surgery or for reason other than after elective surgery	5

[a] APACHE II score is the sum of the acute physiology score (vital signs, oxygenation, laboratory values) Glasgow coma score, age, and chronic health points. Worst values during first 24 h in the ICU should be used.
[b] Glasgow coma score (GCS) = eye-opening score + verbal (intubated or nonintubated) score + motor score.
[c] For GCS component of acute physiology score, subtract GCS from 15 to obtain points assigned.
[d] Chronic health conditions: liver, cirrhosis with portal hypertension or encephalopathy; cardiovascular, class IV angina (at rest or with minimal self-care activities); pulmonary, chronic hypoxemia or hypercapnia, polycythemia, ventilator dependent; kidney, chronic peritoneal or hemodialysis; immune, immunocompromised host.
Note: $(A - a)\,D_{O_2}$, alveolar-arterial oxygen difference; WBC, white blood (cell) count.

search for causes of decreased SVR is appropriate. The most common cause of high CO hypotension is sepsis (Chap. 254). Other causes include liver failure, severe pancreatitis, burns and other trauma that elicit the systemic inflammatory response syndrome (SIRS), anaphylaxis, thyrotoxicosis, and peripheral arteriovenous shunts. In summary, the three most common categories of shock (Table 253-1, p. 1600) are cardiogenic, hypovolemic, and high CO with decreased SVR (high-output hypotension). These categories may overlap and occur simultaneously (e.g., hypovolemic and septic shock, septic and cardiogenic shock).

The initial assessment of a patient in shock as outlined above should take only a few minutes. It is important that aggressive, early resuscitation be instituted based on the initial assessment, particularly since there are recent data suggesting that early resuscitation of septic and cardiogenic shock may improve survival. If the initial bedside assessment yields equivocal or confounding data, more objective assessments such as echocardiography and/or central venous or pulmonary artery catheterization may be useful. The goal of early resuscitation is to reestablish adequate tissue perfusion to prevent or minimize end-organ injury.

MECHANICAL VENTILATORY SUPPORT (See also Chap. 252) During the initial resuscitation of patients in shock, principles of advanced cardiac life support should be followed. Since patients in shock may be obtunded and unable to protect the airway, an early assessment of the patient's airway is mandatory during resuscitation from shock. Early intubation and mechanical ventilation are often required. Reasons for institution of endotracheal intubation and mechanical ventilation include acute hypoxemic respiratory failure and ventilatory failure, which frequently accompany shock. Acute hypoxemic respiratory failure (Chap. 250) may occur in cardiogenic shock (high-pressure pulmonary edema, Chap. 255) and in septic shock (Chap. 254). Ventilatory failure often occurs as a result of an increased load on the respiratory system, which may present in the form of acute metabolic acidosis (often lactic acidosis) or decreased compliance of the lungs ("stiff" lungs) as a result of pulmonary edema. Inadequate perfusion of respiratory muscles in the setting of shock may be another reason for early intubation and mechanical ventilation. Normally, the respiratory muscles receive a very small percentage of the CO. However, in patients who are in shock with respiratory distress for the reasons listed above, the percentage of CO dedicated to respiratory muscles may increase tenfold or more. Lactic acid production from inefficient respiratory muscle activity presents an additional ventilatory load.

Mechanical ventilation may relieve the patient of the work of breathing and allow redistribution of a limited CO to other vital organs,

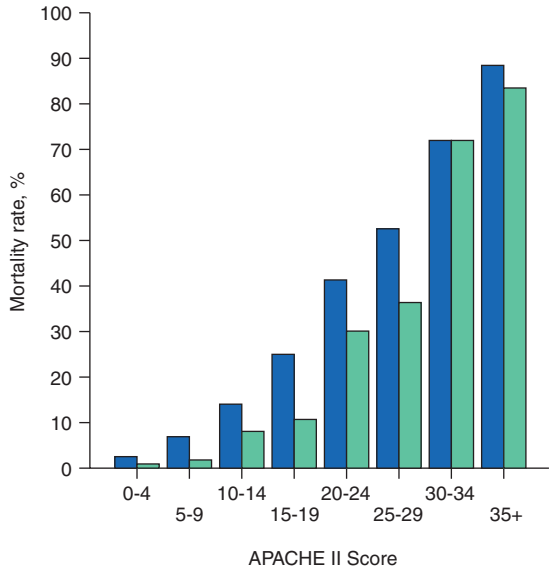

FIGURE 249-1 APACHE II mortality curve. Blue ■, nonoperative; green, postoperative.

often with an improvement in lactic acidosis. Patients demonstrate signs of respiratory muscle fatigue with a number of clinical signs including inability to speak full sentences, use of accessory respiratory muscles, paradoxical abdominal muscle activity, extreme tachypnea (>40 breaths/min), and decreasing respiratory rate despite an increasing drive to breathe. When patients with shock are treated with mechanical ventilation, a major goal of ventilator settings is to assume all or the majority of the work of breathing, facilitating a state of minimal respiratory muscle work. With the institution of mechanical ventilation for shock, further worsening of blood pressure is frequently seen. The reasons for this include impedance of venous return with positive-pressure ventilation, reduced endogenous catecholamine secretion once the stress associated with respiratory failure is abated, and drugs used to facilitate endotracheal intubation (e.g., barbiturates, benzodiazepines, opiates), all of which may result in hypotension. Accordingly, hypotension after endotracheal intubation and positive-pressure ventilation should be anticipated. Many of these patients have a component of hypovolemia, which may respond to intravenous volume administration. →***For further discussion of individual forms of shock, see Chap. 253, Chap. 254, and Chap. 255.***

RESPIRATORY FAILURE (See also Chap. 250)

Respiratory failure is one of the most common reasons patients are admitted to the ICU. In some ICU settings, ≥75% of patients require mechanical ventilation during their ICU stay. Respiratory failure can be categorized mechanically, based on pathophysiologic derangements in respiratory function. Accordingly, four different types of respiratory failure can be described, based upon these pathophysiologic derangements.

TYPE I OR ACUTE HYPOXEMIC RESPIRATORY FAILURE This form of respiratory failure occurs when alveolar flooding and subsequent intrapulmonary shunt physiology occur. Alveolar flooding may be a consequence of pulmonary edema, pneumonia, or alveolar hemorrhage. Pulmonary edema can be further categorized as occurring due to elevated intravascular pressures seen in heart failure and intravascular volume overload or to acute lung injury ("low-pressure pulmonary edema") (Chaps. 29 and 255). The acute respiratory distress syndrome (ARDS) describes an extreme degree of lung injury. This syndrome is defined by diffuse bilateral airspace edema seen by chest radiography (Figs. 233-2 and 251-2), the absence of evidence of left atrial hypertension (pulmonary capillary occlusion pressure <18 mmHg), profound shunt physiology with a ratio of Pa_{O_2} to fraction of inspired oxygen (Pa_{O_2}/FI_{O_2}) of <200 (a Pa_{O_2}/FI_{O_2} < 300 is described as *acute lung injury*), and a clinical setting where this syndrome is known to occur. Common clinical settings associated with acute lung injury and ARDS include sepsis, gastric aspiration, pneumonia, near-drowning, multiple blood transfusions, and pancreatitis.

The mortality rate of patients with ARDS was traditionally very high (50 to 70%), but recent changes in ventilator management strategy have led to reports of mortality in the low 30% range (see below). For many years, physicians have suspected that mechanical ventilation of patients with acute lung injury and ARDS may propagate lung injury. Cyclical collapse and reopening of alveoli may be partly responsible for this. As shown in Fig. 249-3, the pressure-volume relationship of the lung in ARDS is not linear. Alveoli may collapse at very low lung volumes. Animal studies have suggested that stretching and overdistention of injured alveoli during mechanical ventilation can further injure the lung.

Concern over this alveolar overdistention, termed *ventilator-induced "volutrauma,"* led to a multicenter, randomized, prospective trial to compare traditional ventilator strategies for acute lung injury and ARDS (large tidal volume—12 mL/kg ideal body weight) to a low tidal volume (6 mL/kg ideal body weight). This study showed a dramatic reduction in mortality in the low tidal volume group (large tidal volume—39.8% mortality—versus low tidal volume—31% mortality) and confirmed that ventilator management could impact outcomes in these patients.

TYPE II RESPIRATORY FAILURE This ventilatory failure occurs as a result of alveolar hypoventilation and results in the inability to effectively eliminate carbon dioxide. Mechanisms by which this occurs are categorized as: (1) impaired central nervous system (CNS) drive to breathe, (2) impaired strength with failure of neuromuscular function in the respiratory system, (3) and increased load(s) on the respiratory system. Reasons for diminished CNS drive to breathe include drug overdose,

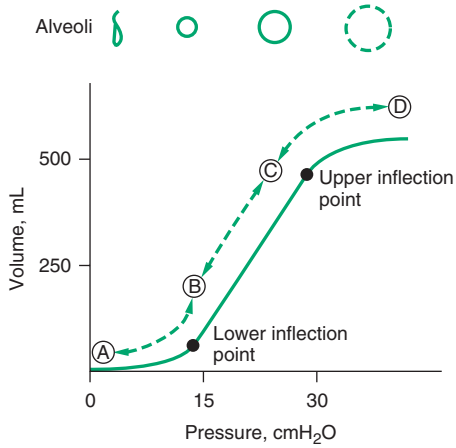

FIGURE 249-3 Pressure-volume relationship of the lungs of a patient with acute respiratory distress syndrome. At the lower inflection point, collapsed alveoli begin to open and the lung compliance changes. At the upper inflection point, alveoli become overdistended. The shape and size of alveoli are illustrated at the top.

brainstem injury, sleep-disordered breathing, and hypothyroidism. Reduced strength can be due to impaired neuromuscular transmission (e.g., myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, phrenic nerve injury) or respiratory muscle weakness (e.g., myopathy, electrolyte derangements, fatigue).

The overall load on the respiratory system can be classified into: resistive loads (e.g., bronchospasm), loads due to reduced lung compliance [e.g., alveolar edema, atelectasis, intrinsic positive end-expiratory pressure (autoPEEP)—see below], loads due to reduced chest wall compliance (e.g., pneumothorax, pleural effusion, abdominal distention), and loads due to increased minute ventilation requirements (e.g., pulmonary embolus with increased dead space fraction, sepsis).

The mainstays of therapy for type II respiratory failure are treatments directed at reversing the underlying cause(s) of ventilatory failure. Noninvasive positive-pressure ventilation using a mechanical ventilator with a tight-fitting face or nasal mask that avoids endotracheal intubation can often be used to stabilize these patients. This approach has clearly been shown to be beneficial in treating patients with exacerbations of chronic obstructive pulmonary disease. Noninvasive ventilation has been tested less extensively in other types of ventilatory failure but may be attempted nonetheless, in the absence of contraindications (hemodynamic instability, inability to protect airway, respiratory arrest).

TYPE III RESPIRATORY FAILURE This form occurs as a result of lung atelectasis. Because atelectasis occurs so commonly in the perioperative period, this is also called *perioperative respiratory failure*. After general anesthesia, decreases in functional residual capacity lead to collapse of dependent lung units. Such atelectasis can be treated by frequent changes in position, chest physiotherapy, upright positioning, and aggressive control of incisional and/or abdominal pain. Noninvasive positive-pressure ventilation may also be used to reverse regional atelectasis.

TYPE IV RESPIRATORY FAILURE This form occurs because of hypoperfusion of respiratory muscles in patients in shock. Normally, respiratory muscles consume <5% of the total CO and oxygen delivery. Patients in shock often suffer respiratory distress due to pulmonary edema, lactic acidosis, and anemia. In this setting, up to 40% of the CO may be distributed to the respiratory muscles. Intubation and mechanical ventilation can allow redistribution of the CO away from the respiratory muscles and back to vital organs while the shock is treated.

CARE OF THE MECHANICALLY VENTILATED PATIENT Mechanically ventilated patients frequently require sedatives and analgesics. Most patients undergoing mechanical ventilation experience pain, which can be elicited by the presence of the endotracheal tube and endotracheal suctioning. Accordingly, early and aggressive attention to pain control is extremely important. Opiates are the mainstay of therapy for pain control in mechanically ventilated patients. After assuring adequate pain control, additional indications for sedation for mechanically ventilated patients include: anxiolysis; treatment of subjective dyspnea; psychosis; facilitation of nursing care; reduction of autonomic hyperactivity, which may precipitate myocardial ischemia; and reducing global oxygen consumption (V_{O_2}).

Neuromuscular blocking agents are occasionally needed to facilitate mechanical ventilation in patients with profound dyssynchrony with the ventilator despite optimal sedation. The use of neuromuscular blocking agents may result in prolonged weakness—a myopathy known as the *postparalytic syndrome*. As a result, these agents are typically used as a last resort when aggressive sedation fails to achieve patient-ventilator synchrony. Because neuromuscular blocking agents result in pharmacologic paralysis without altering mental status, sedative-induced amnesia is mandatory when such agents are administered. Amnesia can be reliably achieved with benzodiazepines, such as lorazepam or midazolam, or with the intravenous anesthetic agent propofol. Outside of the setting of pharmacologic paralysis, there are few data supporting the idea that amnesia is mandatory in all patients who require intubation and mechanical ventilation. Sedatives and opiates may accumulate in critically ill patients when they are given for prolonged periods of time, since many of these patients have impaired hepatic and renal function. A protocol-driven approach to sedation of mechanically ventilated patients with daily interruption of sedative infusions has been shown to prevent excessive drug accumulation and shorten the duration of mechanical ventilation and length of stay in the ICU.

Weaning from Ventilation While a thorough understanding of the pathophysiology of respiratory failure is essential in order to optimize patient care, recognition of a patient's readiness to be liberated from mechanical ventilation is similarly important. Several studies have shown that subjecting patients to daily spontaneous breathing trials can identify those ready for extubation. Accordingly, all intubated, mechanically ventilated patients should undergo a daily screening of respiratory function. If oxygenation is stable (i.e., $Pa_{O_2}/FI_{O_2} > 200$ and PEEP $\leq$ 5 cmH_2O), cough and airway reflexes are intact, and no vasopressor agents or sedatives are being administered, the patient has passed the screening test and should undergo a spontaneous breathing trial. This trial consists of a period of breathing through the endotracheal tube without ventilator support [both continuous positive airway pressure (CPAP) of 5 cmH_2O and an open T-piece breathing system can be used] for 30 to 120 min. The spontaneous breathing trial is declared a failure and stopped if any of the following occur: (1) respiratory rate > 35 breaths/min for >5 min (2) oxygen saturation < 90%, (3) heart rate > 140 beats/min or a 20% increase or decrease from baseline, (4) systolic blood pressure < 90 mmHg or >180 mmHg, or (5) increased anxiety or diaphoresis. If, at the end of the spontaneous breathing trial, the ratio of the respiratory rate to tidal volume in liters (f/VT) is <105, the patient can be extubated. Such protocol-driven approaches to patient care can have an important impact on the duration of mechanical ventilation and ICU length of stay.

MULTIORGAN SYSTEM FAILURE

The syndrome of multiorgan system failure is a common problem associated with critical illness. This syndrome is defined by the simultaneous presence of physiologic dysfunction and/or failure of two or more organs. Typically, this occurs in the setting of severe sepsis, shock of any kind, severe inflammatory conditions such as pancreatitis, and trauma. That multiorgan system failure occurs commonly in the ICU is a testament to our current ability to stabilize and support single organ failure. The ability to manage single organ failure aggressively (e.g., mechanical ventilation for respiratory failure, renal replacement therapy for acute renal failure) has greatly reduced early mortality in critical illness. As such, it is uncommon for critically ill patients to die

in the initial stages of resuscitation. Instead, many patients succumb to critical illness later in the ICU stay, after the initial presenting problem has been stabilized.

While there is debate regarding specific definitions of organ failure, several general principles governing the syndrome of multiorgan system failure apply. First, organ failure, no matter how defined, must persist beyond 24 h. Second, mortality risk increases as patients accrue additional organ failures. Third, prognosis is worsened by increased duration of organ failure. These observations remain true across various critical care settings (e.g., both medical and surgical). SIRS is a common basis for multiorgan system failure. Although infection is a common cause of SIRS, "sterile" triggers such as pancreatitis, trauma, and burns often are responsible for multiorgan system failure.

Gastrointestinal Tract Considerable attention has been directed to the liver and gastrointestinal tract as contributors to the syndrome of multiorgan system failure. Kupffer cells and macrophages in the liver play an important role in the uptake and clearance of endotoxin, cytokines, leukotrienes, and bacteria migrating from the lumen of the bowel to regional lymph nodes and then to the circulation (a process called *translocation*). Since the liver is positioned downstream from the venous drainage of the gastrointestinal tract, it plays a vital role in first-pass clearance of translocated bacteria, endotoxin, and cytokines. Mesenteric hypoperfusion plays a pivotal role in endotoxemia and bacterial translocation from the lumen of the gastrointestinal tract. It appears that mesenteric hypoperfusion leads to loss of integrity of the intestinal mucosa, with subsequent leakage of intact bacteria and endotoxin into mesenteric lymph nodes, mesenteric venous drainage, and the portal venous system. An imbalance favoring a pro-inflammatory state ensues, with overexpression of tumor necrosis factor-α and interleukins (IL), such as IL-1, IL-6, and IL-10. Leukocyte (particularly neutrophil) adherence to endothelial cells and subsequent diapedesis follows, propagating SIRS, which may progress in an unregulated manner.

Lungs While the gastrointestinal tract has received much attention with regard to its role as a nidus for the propagation of multiorgan system failure, other organs may also release inflammatory mediators in an unregulated manner and contribute to the propagation of SIRS and subsequent multiorgan system failure. Recent data suggest that the lungs may be a source of inflammatory cytokines, particularly when patients suffer from acute lung injury or ARDS (Chap. 251). It has been proposed that mechanical ventilation may propagate lung injury and the release of inflammatory cytokines from the lung itself.

MONITORING IN THE ICU

Because respiratory and circulatory failure occur commonly in critically ill patients, monitoring of the respiratory and cardiovascular systems is undertaken frequently in the ICU. Evaluation of respiratory gas exchange is routine in critical illness. The "gold standard" remains arterial blood-gas analysis, where pH, partial pressures of oxygen and carbon dioxide, and oxygen saturation are measured directly. With arterial blood-gas analysis, the two main functions of the lung—oxygenation of arterial blood and elimination of CO_2—can be assessed directly. Importantly, the blood pH, which has a profound effect on the drive to breathe, can only be assessed by sampling of arterial blood. Though sampling of arterial blood is generally safe, it may be painful and cannot provide continuous information for clinicians routinely. Given these limitations, noninvasive monitoring of respiratory function is often employed in the critical care setting.

PULSE OXIMETRY This is the most commonly utilized noninvasive monitor of respiratory function. The technique takes advantage of differences in the absorptive properties of oxygenated and deoxygenated hemoglobin. At wavelengths of 660 nm, oxyhemoglobin reflects light more effectively than does deoxyhemoglobin, whereas the reverse is true in the infrared spectrum (940 nm). A pulse oximeter passes both wavelengths of light through a perfused digit such as a finger, and the relative intensity of light transmission at these two wavelengths is recorded. This allows the derivation of the relative percent of oxyhemoglobin. Since arterial pulsations produce phasic changes in the intensity of transmitted light, the pulse oximeter is designed to detect only light of alternating intensity. This allows distinction of arterial and venous blood saturation.

RESPIRATORY SYSTEM MECHANICS These can be measured during mechanical ventilation (Chap. 252). When volume-controlled modes of mechanical ventilation are used, accompanying airway pressures can be easily measured. The peak airway pressure is determined by two variables—the airways resistance and respiratory system compliance. At the end of inspiration, inspiratory flow can be stopped transiently. This end-inspiratory pause (*plateau pressure*) is a static measurement, impacted only by respiratory system compliance, not airways resistance. The difference between the peak (airways resistance + respiratory system compliance) and plateau (respiratory system compliance only) airway pressure provides a quantitative assessment of airways resistance. Accordingly, during volume-controlled ventilation, patients with increases in airways resistance (e.g., in asthma) typically have increased peak airway pressures as well as an abnormally high gradient between peak and plateau airway pressures (typically >15 cmH_2O). In such patients, the use of bronchodilators and/or glucocorticoids may be beneficial.

The plateau airway pressure is a static measurement, determined by the compliance of the respiratory system. Pathophysiologic processes such as pleural effusions, pneumothorax, increased abdominal girth from ascites or obesity all reduce chest wall compliance. Lung compliance may be reduced by pneumonia, pulmonary edema from any cause, or autoPEEP, which occurs when there is insufficient time for emptying of alveoli prior to the next inspiratory cycle. Since the alveoli have not decompressed completely, alveolar pressure remains positive at end-exhalation (functional residual capacity). This phenomenon is caused most commonly by critical narrowing of distal airways in disease processes such as asthma and chronic obstructive pulmonary disease. Modern mechanical ventilators allow breath-to-breath display of pressure and flow, which may allow detection of problems such as patient-ventilator dyssynchrony, airflow obstruction, and autoPEEP.

CIRCULATORY STATUS Monitors to characterize the circulatory status of critically ill patients are used commonly in the ICU. One of the most frequently used is the pulmonary artery catheter, also known as the right heart catheter or Swan-Ganz catheter. This catheter was originally designed as a tool to guide therapy in acute myocardial infarction but is currently used in the ICU for evaluation and treatment of a variety of other conditions such as ARDS, septic shock, congestive heart failure, and acute renal failure. This device has never been validated as a tool associated with reduction in morbidity and mortality.

Pulmonary Artery Catheter (See also Chap. 212) This is inserted via a central vein (jugular, subclavian, femoral) and is sequentially directed to the right atrium, right ventricle, and pulmonary artery after a balloon is inflated to facilitate its flow-directed placement. Waveform pressures in the right atrium, right ventricle, and pulmonary artery can be measured. When the balloon at the end of the pulmonary artery catheter is inflated, the catheter advances into a distal pulmonary artery until it "wedges" into place. Once the catheter is wedged, the measured pressure is transmitted from the "downstream" pulmonary veins and left atrium. Accordingly, the pulmonary capillary occlusion, or wedge, pressure is equal to the left atrial pressure under most circumstances. With a pulmonary artery catheter, the cardiac output can be measured directly using the thermodilution technique. When cool saline is injected into the proximal port of the catheter, the temperature change at the distal port can be measured. The measured temperature change is related to the volume of saline injected (which is known) and the CO. Blood from the pulmonary artery can be obtained from this catheter to measure oxygen saturation. This "mixed" venous saturation allows assessment of the adequacy of whole-body oxygen delivery.

Oxygen delivery is a function of CO and the content of O_2 in the

arterial blood. The vast majority of O_2 delivered to tissues is bound to hemoglobin, and the dissolved O_2 contributes very little to O_2 content in arterial blood or O_2 delivery. The normal tissue extraction ratio for O_2 is ~25%. A pulmonary artery catheter allows measurements of O_2 delivery and oxygen extraction ratio.

The mixed venous O_2 saturation allows assessment of global tissue perfusion. A reduced mixed venous O_2 saturation may be caused by inadequate cardiac output, reduced hemoglobin concentration, and/or reduced arterial O_2 saturation. An abnormally high O_2 consumption, which may be caused by a multitude of problems such as fever, agitation, shivering, or thyrotoxicosis, may also lead to a reduced mixed venous O_2 saturation if O_2 delivery is not concomitantly increased.

Pulmonary artery catheters are invasive monitors and may be associated with a number of complications. Since the catheter is inserted via a central vein, all of the complications associated with central venous catheterization are present. These include central venous catheter–related infections, pneumothorax, arterial puncture with or without cannulation, bleeding, air embolism, venous thrombosis, and catheter embolism. The insertion of the pulmonary artery catheter also carries a number of risks, including dysrrhythmias, heart block, cardiac perforation, and balloon fragmentation. After the catheter is placed, pulmonary infarction, pulmonary artery rupture, and pulmonic valve insufficiency may occur. Fortunately, most of these complications are quite rare.

Misinterpretation of data derived from the pulmonary artery catheter may be the most common "complication" seen with these monitors. Pressure measurements in various cardiac chambers require careful zeroing of the pressure transducer relative to atmospheric pressure and placement at the proper adjustment, generally 5 cm inferior to the sternal angle in a supine patient. Another potential source of error is the variation in arterial pressure measurements as a function of the respiratory cycle. The atrial chambers are subjected to pleural pressure; therefore, atrial pressure typically falls during inspiration in a spontaneously breathing patient. Conversely, atrial pressure often rises during inspiration in a patient undergoing positive-pressure ventilation. As such, atrial pressure measurements should be made at end-expiration when there is no movement of air in or out of the thorax, often difficult to recognize in patients on mechanical ventilation.

PREVENTION OF COMPLICATIONS OF CRITICAL ILLNESS

SEPSIS IN THE CRITICAL CARE UNIT (See also Chap. 254) Sepsis is a significant problem in the care of critically ill patients. It is the leading cause of death in noncoronary ICUs in the United States. Current estimates suggest that >750,000 patients are affected each year, and these numbers are expected to increase as the population continues to age and a greater percentage of persons vulnerable to infection will likely seek medical care.

Many therapeutic interventions in the ICU are invasive and predispose patients to infectious complications. These interventions include endotracheal intubation, indwelling vascular catheters, nasally placed enteral feeding tubes, transurethral bladder catheters, and other catheters placed into sterile body cavities (e.g., tube thoracostomy, percutaneous intraabdominal drainage catheters). The longer such devices remain in place, the more prone to these infections patients become. For example, ventilator-associated pneumonia correlates strongly with the duration of intubation and mechanical ventilation. Therefore, an important aspect of preventive care is the timely removal of invasive devices as soon as they are no longer needed. Multidrug resistant organisms are commonplace in the ICU.

An important aspect of critical care is infection control in the ICU. Simple measures such as frequent handwashing are effective but underutilized strategies. Protective isolation of patients with colonization or infection by drug-resistant organisms is another frequently used strategy in the critical care setting. Antibiotic-coated vascular catheters or endotracheal tubes with specialized suction ports above the cuff to decrease pooling and aspiration of oral secretions are other strategies that may be used, with varying degrees of effectiveness reported. Surveillance programs monitoring adherence to infection control practices such as those described here may reduce the incidence of nosocomial infections.

DEEP VENOUS THROMBOSES All ICU patients are at high risk for this complication, given their predilection toward immobility. Therefore, all ICU patients should receive some form of prophylaxis against deep venous thrombosis (DVT). Traditional forms of prophylaxis are subcutaneous low-dose heparin or low-molecular-weight heparin injections and sequential compression devices for the lower extremities. Recently, an observational study reported an alarming incidence of the occurrence of DVTs despite the use of these standard prophylactic regimens. Heparin prophylaxis may result in heparin-induced thrombocytopenia—another relatively common nosocomial complication in critically ill patients. Low-molecular-weight heparins such as enoxaparin are more effective than unfractionated heparin for DVT prophylaxis in high-risk patients, such as those undergoing orthopedic surgery, and they have a lower incidence of heparin-induced thrombocytopenia. Fondaparinux, a selective factor Xa inhibitor, is even more effective than enoxaparin in high-risk orthopedic patients.

STRESS ULCERS Prophylaxis against stress ulcers is frequently administered in most ICUs. Typically, histamine-2 antagonists are administered. Currently available data suggest that high-risk patients, such as those with shock or respiratory failure requiring mechanical ventilation, benefit from such prophylactic treatment. Proton pump inhibitors are also used as agents for prophylaxis against stress ulcers, though outcomes data supporting the benefits of these drugs are largely lacking.

ANEMIA (See also Chap. 52) This is a common problem in critically ill patients. Most suffer from anemia of chronic inflammation. Recent studies have demonstrated that erythropoietin levels are inappropriately reduced in most ICU patients and that exogenous erythropoietin administration may reduce transfusion requirements in the ICU. Phlebotomy contributes significantly to anemia in ICU patients. The hemoglobin level that merits transfusion in critically ill patients has been a long standing area of controversy. A large, multicenter study involving patients in many different ICU settings challenged a conventional notion that a hemoglobin level of 100 g/L (10 g/dL) is needed in critically ill patients. Patients prospectively randomized to red blood cell transfusions only when the hemoglobin level was ≤70 g/L (7 g/dL) had no difference in mortality than those liberally transfused to a target hemoglobin of 100 g/L (10 g/dL). It is noteworthy that even those with risk factors for coronary artery disease did not show increased morbidity or mortality with a restrictive transfusion strategy. Red blood cell transfusion is associated with impairment of immune function, increased risk of infections, acute lung injury, and volume overload—all of which may explain the findings in this study. Accordingly, a conservative transfusion strategy should be the rule in managing critically ill patients who are not actively hemorrhaging.

ACUTE RENAL FAILURE (See also Chap. 260) This complication occurs in a significant percentage of critically ill patients. The most common underlying etiology is acute tubular necrosis, usually precipitated by hypoperfusion and/or nephrotoxic agents. Currently, there are no pharmacologic agents available for prevention of renal injury in critical illness. A recent study showed convincingly that low-dose dopamine is *not* effective in protecting the kidneys from acute injury. Other drugs, such as fenoldapam and vasopressin, have the potential to prove useful as agents for renal protection; however, more data are needed before firm conclusions can be drawn.

MALNUTRITION This is a common problem in the critically ill patient; it may exacerbate respiratory failure, impair wound healing, and debilitate effective immune response. Nutritional support in the management of these patients is of the greatest importance. Early enteral feeding is reasonable, though no data are available to suggest that this improves patient outcome per se. Certainly, enteral feeding, if possible, is preferred over parenteral nutrition, which is associated with

numerous complications including hyperglycemia, fatty liver, cholestasis, and sepsis. In addition, enteral feeding may prevent bacterial translocation across the gut mucosa (see "Multiorgan system failure", above). The catabolic state induced by critical illness mandates aggressive nutritional support; these patients often have higher caloric needs than normal patients, and nutrition support teams can play an important role in their management. Another recent study showed a significant mortality benefit when glucose levels were aggressively normalized in a large group of ICU patients, most of whom had recently undergone operations.

NEUROLOGIC DYSFUNCTION IN CRITICALLY ILL PATIENTS

Neurologic dysfunction is common in critically ill patients and a frequent cause of admission to the ICU.

DELIRIUM (See also Chap. 257) This state is defined by (1) an acute onset of changes or fluctuations in the course of mental status, (2) inattention, (3) disorganized thinking, and (4) an altered level of consciousness (i.e., other than alert). A recent study reported delirium in >80% of patients admitted to the ICU. A rapid test—the Confusion Assessment Method—to assess critically ill patients for delirium is available and has recently been validated. This assessment asks patients to answer simple questions and perform simple tasks and can be completed by the bedside nurse in about 2 min. The differential diagnosis of delirium in the ICU patient is broad and includes infectious etiologies (including sepsis), medications (particularly sedatives and analgesics), drug withdrawal, metabolic/electrolyte derangements, intracranial pathology (e.g., stroke, intracranial hemorrhage), seizures, hypoxia, hypertensive crisis, shock, and vitamin deficiencies (particularly thiamine).

ANOXIC CEREBRAL INJURY (See also Chap. 258) This condition is common following cardiac arrest and often results in severe and permanent brain injury in patients whose cardiac arrest is resuscitated. Active cooling of patients after cardiac arrest has been shown to improve neurologic outcomes. As such, all patients who present to the ICU after circulatory arrest from ventricular fibrillation or pulseless ventricular tachycardia should be actively cooled with cooling blankets and ice packs if necessary to achieve a core body temperature of 32 to 34°C.

STROKE (See also Chap. 349) This is a common cause of critical neurologic illness. Hypertension must be managed carefully, since abrupt reductions in blood pressure may be associated with further brain ischemia and injury. Acute ischemic stroke treated with tissue plasminogen activator (tPA) shows improved neurologic outcome when treatment is given within 3 h of onset of symptoms. However, mortality is not improved when tPA is compared to placebo, despite improved neurologic outcome, and cerebral hemorrhage is significantly higher in patients given tPA. A treatment benefit is *not* seen when tPA is given beyond 3 h. Heparin has not been shown to demonstrate improved outcomes convincingly in patients with acute ischemic stroke.

SUBARACHNOID HEMORRHAGE (See also Chap. 349) This may occur secondary to aneurysm rupture and is often complicated by cerebral vasospasm, rebleeding, and hydrocephalus. Vasospasm can be detected by either transcranial Doppler assessment or cerebral angiography; it is typically treated with the calcium channel blocker nimodipine; aggressive intravenous fluid administration; and therapy aimed at increasing the blood pressure, typically with vasoactive drugs such as phenylephrine. The intravenous fluids and vasoactive drugs (hypertensive hypervolemic therapy) are used to overcome the cerebral vasospasm. Early surgical clipping of aneurysms is advocated to prevent complications related to rebleeding. Hydrocephalus, typically heralded by a decreased level of consciousness, may require ventriculostomy drainage.

STATUS EPILEPTICUS (See also Chap. 348) Recurrent or relentless seizure activity is a medical emergency. Cessation of seizure activity is required to prevent irreversible neurologic injury. Lorazepam is the most effective benzodiazepine for treating status epilepticus and is the treatment of choice for controlling seizures acutely. Phenytoin or fosphenytoin should be given concomitantly since lorazepam has a short half-life. Other drugs such as gabapentin, carbamazapine, and phenobarbital should be reserved for patients with contraindications to phenytoin (e.g., allergy or pregnancy) or ongoing seizures despite phenytoin.

BRAIN DEATH (See also Chap. 258) Although critically ill patients usually die from irreversible cessation of circulatory and respiratory function, a diagnosis of death may also be established by irreversible cessation of all functions of the entire brain, including the brainstem, even if circulatory and respiratory functions remain intact as a result of artificial life support. Patients must demonstrate absence of cerebral function (unresponsive to all external stimuli) and brainstem functions [e.g., unreactive pupils, absent ocular movement to head turning or ice water irrigation of ear canals, positive apnea test (no drive to breathe)]. Absence of brain function must have an established cause and be permanent without possibility of recovery (e.g., must confirm the absence of sedative effect, hypothermia, hypoxemia, neuromuscular paralysis, or severe hypotension). If there is uncertainty about the cause of coma, studies of cerebral blood flow and electroencephalography should be performed.

WITHHOLDING AND WITHDRAWING CARE (See also Chap. 9)

The withholding and withdrawing of care occurs commonly in the ICU setting. Concerns about the provision of care deemed futile are occasionally raised during the care of critically ill patients. The Task Force on Ethics of the Society of Critical Care Medicine reported in a consensus statement that it is ethically sound to withhold or withdraw care if a patient or surrogate makes such a request or if the goals of therapy are not achievable according to the physician. Since all medical treatments are justified by their expected benefits, the loss of such an expectation justifies the act of withdrawing or withholding such a treatment. As such, the act of withdrawing care is fundamentally similar to the act of withholding care. An underlying stipulation derived from this task force report is that the informed patient should have his or her wishes respected with regard to life-sustaining therapy. Implicit in this stipulation is the need to ensure that patients are thoroughly and accurately informed regarding the plausibility and expected results of various therapies. The act of informing patients and/or surrogate decision makers is the responsibility of the physician and other health care providers. In the event a patient or surrogate desires therapy deemed futile by the treating physician, the physician is not ethically obligated to provide such treatment. Rather, arrangements may be made to transfer the patient's care to another care provider.

Decisions to withhold or withdraw care should occur only after extensive discussions with the patient (if this is possible), surrogate(s), and other health-care providers, usually in the form of one or more multiple formal meetings. In addition, most institutions have ethics committees to assist in the withholding and withdrawal of care. Though not required routinely, such committees are available to safeguard against patients or surrogates making capricious requests to withhold or withdraw care. In addition, such consultation may be considered in the event that a patient or surrogate does not agree with the physician's impression that care should be withheld or withdrawn.

It is noteworthy that decisions to withhold and withdraw life support from the critically ill are increasing, with recent reports of up to 90% of patients dying in the ICU after care was withheld or withdrawn. Critical care providers should meet regularly with patients and/or surrogates to discuss prognosis when the withholding or withdrawal of care is being considered. After a consensus amongst caregivers has been reached regarding withholding or withdrawal of care, this should be relayed to the patient and/or surrogate decision maker. If a decision to withhold or withdraw life-sustaining care for a patient has been reached, aggressive attention to analgesia and anxiolysis is needed. Opiates and benzodiazepines are typically used to achieve these goals.

Patients may have their death hastened by the aggressive administration of analgesic and anxiolytic drugs; however, if the intent of this therapy is to alleviate suffering and not to hasten death, this "double effect" is ethically acceptable.

250 RESPIRATORY FAILURE

Craig Lilly, Edward P. Ingenito, Steven D. Shapiro

DEFINITION AND CLASSIFICATION Respiratory failure is defined as a failure of gas exchange due to inadequate function of one or more essential components of the respiratory system. Clinically, respiratory failure can be manifest either as hypoxemia ($P_{O_2} < 60$ mmHg at sea level), i.e., inadequate blood oxygenation; hypercarbia ($P_{CO_2} > 45$ mmHg), i.e., excess of circulating carbon dioxide; or frequently, a combination of both types of gas exchange abnormalities. Respiratory failure is classified as hypoxemic, hypercarbic, or combined.

Respiratory failure is also commonly described in terms of its acuity, since it may develop either acutely or chronically. In *acute respiratory failure*, a sudden, catastrophic event leads to life-threatening respiratory insufficiency. In *chronic respiratory failure*, gradual worsening of respiratory function leads to progressive impairment of gas exchange, the metabolic effects of which are partially compensated by adaptations in other systems. In patients with long-standing respiratory disease, compensated *chronic respiratory insufficiency* may exist for many years, resulting in a state in which patients do not have true respiratory failure but have little or no functional respiratory reserve. In such cases, even a mild insult to the respiratory system can precipitate *acute on chronic respiratory failure*.

Independent of cause, as respiratory demand exceeds the functional capacity of the respiratory system, respiratory failure evolves and immediate medical intervention is required.

EPIDEMIOLOGY Respiratory failure is a common diagnosis among patients in medical intensive care units (ICUs) and is associated with a poor prognosis.The incidence of respiratory failure is 137 cases per 100,000 population, or 360,000 cases per year in the United States, with 36% of these individuals failing to survive the hospitalization. Both the incidence of and mortality from respiratory failure increase exponentially with age and in the presence of other comorbid conditions. Therapeutic advances in both mechanical ventilation and airway management have improved the prognosis for patients with respiratory failure over the past several decades. Even patients with irreversible chronic respiratory failure can now be provided with ventilator support systems that allow an acceptable quality of life and can be managed at home. Lung transplantation is also an option for selected patients with chronic respiratory failure (Chap. 248), although the widespread use of transplantation is limited by both the availability of organ donors and the number of qualified transplant centers.

PHYSIOLOGY Describing respiratory failure as either hypoxemic or hypercarbic provides some information about the physiologic deficit. However, a better understanding of the underlying pathophysiology and potential treatment strategies can be gained by considering the individual components of the respiratory system that are required for effective function under physiologic conditions. Normal respiration requires the integrated function of five separate components.

1. *Nervous system*. This is the control system, and it comprises the dorsal and ventral nuclei of the medullary respiratory control group and their associated afferent and efferent neural pathways. These act in concert with the cerebral cortex to determine respiratory rate and breathing effort. Respiratory failure due to diseases that cause dysfunction of the central control system can be thought of as *controller dysfunction*, or central apnea.
2. *Musculature* (the pump). The inspiratory muscles of breathing consist primarily of the diaphragm, but accessory muscles also contribute, including the internal intercostals, suprasternal, and sternocleidomastoid, as do supporting structures of the chest wall, which lower the pressure in the pleural space between the chest wall and lung during inspiration, establishing a pressure gradient between the airway opening and alveolar compartment that causes gas to flow into the lung. Respiratory failure due to diseases that cause ineffective function of the respiratory pump can be thought of as *pump dysfunction*. Under normal conditions, only elastic recoil is required for expiration, but during respiratory failure accessory muscles of expiration are required.
3. *Airways* (a complex conduit system for bulk delivery of gases). These consist of the upper airways, cartilaginous bronchi, and small airways distal to the terminal bronchioles capable of conducting gas quickly and evenly into and out of the alveolar compartment where gas exchange can occur. Respiratory failure involving diseases that cause marked obstruction or dysfunction of the air passages can be thought of as *airway system dysfunction*.
4. *Alveolar units* (an efficient, distensible, compact membrane system). This system consists of the respiratory bronchioles, alveolar ducts, and alveoli; these provide sufficient surface area to allow for rapid exchange of gases and sufficient elasticity so that following expansion, the membrane can generate adequate recoil pressure to empty the lung passively during exhalation. Respiratory failure as a result of diseases that cause collapse, flooding, or injury to the alveolar network can be thought of as *alveolar compartment dysfunction*.
5. *Vasculature* (a network of conduits capable of transporting dissolved gases to and from the functioning organs throughout the body). This consists of the pulmonary capillary network, intimately associated with the membrane system, but distinct both in structure and with respect to the types of diseases that can alter its normal function. Respiratory failure as a result of disease involving the pulmonary vasculature can be thought of as *pulmonary vascular dysfunction*.

Failure of any *one* of these essential components or significant dysfunction of more than one essential component can lead to *failure of the integrated system* and produce clinical respiratory failure.

Many diseases cause dysfunction of several of the essential components of the respiratory system, and ultimately this leads to abnormalities in gas exchange. Understanding which components of the respiratory system have failed in a given case provides valuable insight into the underlying disease process that cannot be gained from a simple

analysis of the gas exchange abnormalities. For example, a patient with severe asthma, a patient with a large pulmonary embolus, and a patient with pulmonary edema may all present with hypoxemic respiratory failure. In each case, however, the cause and treatment of the respiratory failure are distinct. Developing a clinical approach for evaluating the five different functional components of the respiratory system is essential for identifying the cause of respiratory failure and quickly developing an effective management plan.

CLINICAL EVALUATION ■ Initial Assessment and Stabilization of Respiratory Failure Initial evaluation of the respiratory system includes an immediate determination of upper airway patency and an examination for central and peripheral cyanosis, followed by measurement of the respiratory rate and observation of the depth and pattern of respiration. One should simultaneously note the presence or absence of signs of respiratory distress including flaring of nostrils, pursed-lip breathing, and use of accessory muscles of respiration. Next, one should assess the configuration of the chest wall and its movement during the respiratory cycle. This is followed by palpation and auscultation over each hemithorax. These observations allow an initial assessment of respiratory drive, pump function, and delivery of gas to the lungs. This examination is supplemented by an estimation of the oxygen and carbon dioxide content of arterial blood determined by arterial blood-gas measurement. Oximetry provides a rapid way to determine blood oxygen content but does not provide information regarding alveolar ventilation and P_{CO_2} levels; an arterial blood-gas measurement is required to assess these parameters.

In contrast to many clinical conditions, the emergent nature of acute respiratory failure and the potential for rapid progression to a life-threatening situation require that initial therapy be implemented before the specific etiology of the respiratory failure is diagnosed and treated. Adequate airway protection, oxygenation, and ventilation should be assured prior to further diagnostic testing. Thus, in concert with the initial assessment one must stabilize the patient with respiratory failure quickly since hypoxemia and hypercarbia can rapidly lead to circulatory failure and death (see "Initial Management," below). Cardiovascular stability must also be rapidly assessed and achieved (see Chap. 253). From the standpoint of respiratory failure, the first priority is to establish adequate oxygenation and ventilation. Administration of supplemental oxygen might be all that is initially required, but if the patient is in distress, artificial ventilation is needed. Initially, ventilation is often administered manually using a bag-valve-mask device followed by use of a mechanical ventilator (Chap. 252). Once an endotracheal tube has been placed and secured, and its position verified, ventilator support can be initiated to help normalize oxygenation and CO_2 elimination. Following stabilization of the patient, a systematic and thorough evaluation of the cause of respiratory failure can safely be carried out.

Clinical Evaluation of Respiratory Failure Based on Physiologic Principles Simple bedside techniques can be used to assess which of the five components of the respiratory system are no longer functioning normally in a patient with respiratory failure (Table 250-1). This assessment can provide great insight into the clinical cause of respiratory failure and assist with management planning.

CONTROLLER DYSFUNCTION This is perhaps the least common primary cause of respiratory failure, and it can be difficult to assess in the intubated ICU patient because many medications used to ensure comfort also affect the level of consciousness and limit respiratory drive. Nevertheless, useful information can frequently be obtained about respiratory drive by simple observation and history. The most frequent cause of controller dysfunction is the presence of medications that impair respiratory drive, many of which also impair the level of consciousness. A history of the use of respiratory depressants or an impaired level of consciousness prior to the administration of medications to facilitate intubation suggests the possibility of controller dysfunction. The awake, minimally sedated patient with either significant hypercarbia or hypoxemia who demonstrates no elevation in respiratory rate (i.e., <12 breaths/min) and no use of accessory muscles is likely to have a defect in regulating respiratory drive. In respiratory failure due solely to controller dysfunction, such as an opiate overdose, the degree of hypoxemia is in direct proportion to the degree of hypercarbia, i.e., the patient will have a normal alveolar-arterial gradient (Chap. 234). This can be calculated with the information obtained from an arterial blood-gas measurement. More formal tests of respiratory drive, including determining if the respiratory rate increases to at least 25 breaths/min when the patient inhales a mixture of 5% CO_2 and 15% O_2 (the CO_2 challenge test) and measuring the pressure generated 0.1 s after the start of inhalation (the $P_{0.1}$ test), have been described for outpatient investigation of respiratory controller problems, but they are not used in the ICU setting.

PUMP DYSFUNCTION This is a common cause of respiratory failure in ICU patients with respiratory failure and is usually multifactorial. Various medications, prolonged periods of mechanical ventilator support, and polyradiculopathy associated with critical illness can all adversely affect the respiratory muscles. In the patient who is not intubated, one must assess degree of respiratory distress as described above. In addition, abdominal paradoxus indicates diaphragmatic fatigue, a hallmark of pump failure. For patients who are mechanically ventilated, a

TABLE 250-1 *Methods for Assessing Controller, Pump, Airway, Alveolar Compartment, and Pulmonary Vascular Dysfunction at the Bedside*

Type of Dysfunction	Test	Method of Determination	Findings Consistent with Dysfunction
Controller	Respiratory rate	Clinical observation in spontaneously breathing patient	$<$ 12/min in presence of hypoxia or hypercarbia and acidemia
Pump	Vital capacity, inspiratory force	Bedside measurement in awake patient	Presence of paradoxical respiratory motions. VC $<$ 10 mL/kg IF $<$ -20 cmH_2O RSBI $>$ 105
Airway	Wheezing or ronchi on auscultation	Physical examination	Presence of wheezing
	Airway resistance measurement	Bedside measurement in cooperative or sedated patient	Raw $>$ 10 cmH_2O/L per second
	Clinical evidence of auto-PEEP	Auscultation or bedside measurement in sedated patient	Presence of autoPEEP
Alveolar	Arterial blood gas	Arterial blood sample	Exam suggestive of consolidation
	Respiratory system compliance	Bedside measurement in sedated patient	Abnormal Pa_{O_2}/FI_{O_2} ratio or elevated Pa_{CO_2}; Crs $>$ 30 mL/cmH_2O
	Chest radiograph	Bedside x-ray	Alveolar infiltrates
Pulmonary vascular	Assessment of right heart function	JVP–central venous pressure	Elevation
		ECG	Right heart strain or RBBB

Note: VC, vital capacity; IF, inspiratory force; RSBI, rapid-shallow-breathing index; raw, raw airway resistance; auto-PEEP, intrinsic positive end-expiratory pressure; Crs, respiratory system compliance; JVP, jugular venous pressure; ECG, electrocardiogram; RBBB, right bundle branch block.

variety of simple bedside tests have been used to assess respiratory muscle function. Measurement of vital capacity and inspiratory force are the most frequently used; they provide an assessment of both the volume the respiratory muscles can generate against the impedance of the respiratory system and the isovolumetric pressure the respiratory muscles can generate during a maximal effort. Vital capacity < 10 mL/kg and inspiratory force measurements that fail to achieve a negative pressure of at least -20 cmH_20 indicate a component of respiratory muscle insufficiency. The rapid-shallow-breathing index (respiratory rate/tidal volume) is an integrative index of respiratory performance that predicts success of liberation from mechanical ventilation when it is <105. More sophisticated measurements of respiratory muscle function, including transdiaphragmatic pressure measurements using esophageal balloons and bedside electromyography and nerve conduction studies, can be used in special circumstances to obtain detailed information about respiratory muscle dysfunction when warranted.

AIRWAY DYSFUNCTION This can also be readily assessed at the bedside in the patient with respiratory failure using simple bedside measurements and clinical assessment. Stridor suggests the presence of large airway or laryngeal obstruction. Bronchospasm can be diagnosed by auscultation and detection of wheezing and/or rhonchi. Coarse breath sounds or rhonchi present during the inspiratory phase of respiration usually indicate obstruction of the large airways, frequently from retained secretions. High-pitched wheezing during expiration indicates obstruction of the small airways and is commonly associated with bronchospasm. In cases of severe airflow obstruction, wheezing may be reduced because airflow is minimal. In these cases, the obstruction may be manifest as dynamic hyperinflation or intrinsic positive end-expiratory pressure (autoPEEP), and detected by persistent, faint wheezing that continues throughout expiration to the point of initiation of the subsequent inspiration.

Simple bedside measurements can also be used to detect airflow obstruction, although they require that the patient be synchronous with the ventilator and not tachypneic. Therefore these tests are best performed in the sedated patient. By programming the ventilator to impose a brief pause (0.5 to 1 s in duration) at the end of inspiration, the driving pressure to overcome airway resistance during inspiration, equal to the peak inspiratory pressure minus the airway pressure measured at the end of the pause (i.e., plateau pressure), can be determined. Dividing this pressure difference by the end-inspiratory flow rate gives an estimate of airway resistance. Normal values in the intubated patient range from 3 to 8 cmH_2O/L per second, depending upon the size of the endotracheal tube. Values significantly greater than this indicate airflow obstruction. More detailed information about lung impedance, including airway resistance and dynamic compliance, can be obtained by measuring transpulmonary pressures, volumes, and flows using an esophageal balloon and bedside pneumotachograph system. However, such detailed measurements are usually made only for research purposes.

ALVEOLAR COMPARTMENT DYSFUNCTION This can be assessed using several distinct and complementary bedside techniques, in addition to simple gas exchange measurements. Findings on physical examination that are suggestive of consolidation, such as tubular breath sounds, dullness to percussion, and egophony, establish alveolar compartment dysfunction. Lung stiffness, as reflected in static respiratory system compliance, can be assessed by measuring the distending pressure required to inflate the lung once inspiratory flow has ceased. This is calculated by measuring the end-inspiratory plateau pressure and dividing the inspiratory volume by end-inspiratory plateau pressure minus whatever level of PEEP is being applied. A normal value of static respiratory system compliance measured using this approach is 35 to 50 mL/cmH_2O. Values <30 during conventional tidal volume inflation (7 to 12 mL/kg tidal volumes) indicate increased stiffness of the lung, chest wall, or both.

The chest radiograph is also a useful tool for assessing the pathology of the alveolar compartment. Radiographic densities consistent with air-space disease point to alveolar infection, injury, or flooding and, together with a reduced lung compliance and reduced arterial oxygen level, favor a diagnosis of alveolar compartment dysfunction.

PULMONARY VASCULAR DYSFUNCTION This cannot be directly assessed at the bedside but may be reflected by signs of right heart dysfunction, such as elevated jugular venous pressures, a pronounced or delayed pulmonic component of the second heart sound, a right-sided heave, a right-sided third heart sound, or a murmur of tricuspid regurgitation. In the absence of these signs it can be suggested by exclusion in cases where abnormal gas exchange exists in the apparent absence of controller, pump, airway, or alveolar compartment dysfunction. Pulmonary vascular disease can cause abnormalities in routine clinical tests including the electrocardiogram (ECG) and chest radiograph. It can cause right heart strain or right bundle branch block which will show on the electrocardiogram, and pulmonary artery enlargement can be seen on radiographic studies. More definitive testing including echocardiography, right heart catheterization, or contrast-enhanced computed tomography of the chest is often required to identify the presence of pulmonary vascular disease.

Making a Definitive Diagnosis Approaching respiratory failure from a physiologic perspective can provide important clues about its specific etiology, which in turn can lead to the formulation of a more effective diagnostic approach and a definitive therapeutic plan. Once a patient has been stabilized by establishing a stable airway and providing mechanical ventilatory support (if indicated), a thorough evaluation of the cause of respiratory failure can be safely undertaken. Table 250-2 summarizes common disease states representative of each type of respiratory system dysfunction listed above. The associated blood-gas findings and additional confirmatory tests that may be useful in further evaluating each of these conditions are also presented.

INITIAL MANAGEMENT Treatment for many of the specific disorders identified in Table 250-2 is addressed in subsequent chapters; in this chapter the focus is on the initial management that is common to all patients with respiratory failure. As discussed above, one must first focus on physiologic stabilization. The first priority is to establish adequate oxygenation through the administration of supplemental oxygen in patients with hypoxemia. For patients with hypercarbic respiratory failure leading to significant acidemia or hypoxemia inadequately corrected by supplemental oxygen, the mainstay of supportive care for respiratory failure is mechanical ventilation (Chap. 252). Although mechanical ventilation can sometimes be provided without placement of an artificial airway (i.e., mask ventilation), in the majority of cases the first step in stabilizing the patient with respiratory failure involves placement of an endotracheal tube. This can be achieved via either the orotracheal or nasotracheal route, usually using a combination of parenteral and local anesthesia to ensure patient comfort. Following placement, the tube must be secured and its position verified so as to provide 100% O_2 and adequate ventilation immediately.

Obstruction of the upper airway is a medical emergency. In an unconscious patient this is often due to occlusion by the tongue or soft tissues of the pharynx. The airway is immediately opened with the head tilt–chin lift maneuver and the patient assessed for spontaneous respirations. When a spontaneously breathing patient is unable to dislodge a foreign object, a forceful subdiaphragmatic thrust can facilitate removal of the object. Removal may require laryngoscopy and removal with forceps. Liquids such as vomitus or blood are removed by suctioning under direct vision. In some cases of respiratory failure the airway is secure without instrumentation, but in most a stable airway is achieved by passing an endotracheal tube. When the airway cannot be secured using these techniques a tracheostomy or cricothyrotomy should be performed.

One of the most effective ways to improve the O_2 content of blood is to increase its concentration in alveolar gas by administering O_2, initally with an FI_{O_2} of 100%. Oxygen delivery to the alveoli can also

TABLE 250-2 *Clinical Syndromes Associated with Dysfunction of the Components of the Respiratory System*

Type of Dysfunction	Specific Representative Conditions	Predominant Gas Exchange Abnormality	Additional Testing/Evaluation
Controller	Sedative medications	Hypercarbia	Review of medications
	Chronic obstructive or interstitial lung disease	Hypoxemia + hypercarbia	History of daytime somnulence, lung function
	Toxic overdoses	Hypoxemia + hypercarbia	Toxicology screen
	Hypothermia post operatively	Hypercarbia	Measurement of core body temperature
	Brainstem stroke	Hypercarbia	Head CT/MRI scans
Pump	Medications/toxins Paralytics Aminoglycosides Steroids Botulism	Hypercarbia	Review of medical history
	Myopathy	Hypercarbia	Strength testing, EMG/NCV studies
	Myositis	Hypercarbia	Clinical exam, serum CK and aldolase
	Metabolic abnormalities Hypothyroidism Hypophosphatemia	Hypercarbia	TSH, serum phosphate
	Myasthenia gravis	Hypercarbia	EMG/NVC studies, Tensilon test

Airway	Asthma	Mild: hypoxemia + hypocarbia Severe: hypoxemia + hypercarbia	Pulmonary function testing Functional response to bronchodilators
	Emphysema/chronic bronchitis	Hypoxemia + hypercarbia	Pulmonary function testing, chest x-ray
	Bronchiolitis	Hypoxemia + hypercarbia	Pulmonary function testing, chest CT, lung biopsy
	Endobronchial tumor, mass, or stricture	Variable	Pulmonary function testing, CT imaging, bronchoscopy
Alveolar	Pneumonia	Hypoxemia + hypercarbia	Smear and culture of secretions
	Pulmonary edema	Hypoxemia + hypercarbia	Examination of the heart Chest x-ray
	Pulmonary hemorrhage	Hypoxemia + hypercarbia	Chest x-ray, bronchoscopy
	ARDS	Hypoxemia + hypercarbia	Chest x-ray, arterial blood gas
	Drug reaction	Hypoxemia + hypercarbia	Drug exposure, toxicology screen, lung biopsy
	Pulmonary contusion	Hypoxemia + hypercarbia	Chest wall pain, chest x-ray
Pulmonary vascular	Acute pulmonary embolus	New-onset hypoxemia with or without hypercarbia	Ventilation-perfusion scanning, CT pulmonary embolism study
	Pulmonary hypertension	Exertional hypoxemia	Echocardiogram, right heart catheterization
	AVM or intracardiac shunt	Hypoxemia that is refractory to oxygen therapy	Echocardiogram with bubble study, high-resolution CT scan

Note: CT, computed tomography; MRI, magnetic resonance imaging; CK, creatine kinase; TSH, thyroid stimulating hormone; EMG, electromyography; NCV, nerve conduction velocity study; ARDS, adult respiratory distress syndrome; AVM, arteriovenous malformation.

be improved by applying PEEP in patients receiving mechanical ventilatory support. Increasing alveolar ventilation with a mechanical ventilator eliminates CO_2 and corrects acidemia. In the setting of acute respiratory failure, it is important to document that adequate oxygenation and elimination of CO_2 have been achieved before adjustment of the O_2 content and other ventilator settings.

The effective management of respiratory failure depends on identifying and optimally managing all of the treatable factors that impair the respiratory system. This includes removing excess secretion by suctioning, treating infections with effective antimicrobials, suppressing inflammation with anti-inflammatory or immunosuppressive drugs, treating obstruction with bronchodilators, avoiding the harmful effects of excess oxygen or mechanical forces from the mechanical ventilator, dissolving blood clots with anticoagulants or thrombolytics, providing pulmonary vasodilatation, and removing transudated fluid with diuretics. Some forms of chronic respiratory system failure, such as sleep apnea syndrome and post-polio syndrome, are ultimately responsive to nocturnal mechanical ventilation or continuous positive airway pressure (Chap. 252). Finally, selected patients with isolated severe chronic respiratory failure may have the quality of their lives improved by lung transplantation.

251 ACUTE RESPIRATORY DISTRESS SYNDROME

Bruce D. Levy, Steven D. Shapiro

Acute respiratory distress syndrome (ARDS) is a clinical syndrome of severe dyspnea of rapid onset, hypoxemia, and diffuse pulmonary infiltrates leading to respiratory failure. ARDS is caused by diffuse lung injury from many underlying medical and surgical disorders. The lung injury may be direct, as occurs in toxic inhalation, or indirect, as occurs in sepsis (Table 251-1). The clinical features of ARDS are listed in Table 251-2. Acute lung injury (ALI) is a less severe disorder but has the potential to evolve into ARDS (Table 251-2). The arterial (a) P_{O_2} (in mmHg)/ FI_{O_2} (inspiratory O_2 fraction) <200 mmHg is characteristic of ARDS, while a Pa_{O_2}/FI_{O_2} between 200 and 300 identifies patients with ALI who are likely to benefit from aggressive therapy.

The annual incidences of ALI and ARDS are estimated to be 30/100,000 and 10/100,000, respectively. Approximately 10% of all intensive care unit (ICU) admissions suffer from acute respiratory failure (Chap. 250), with ~20% of these patients meeting criteria for ALI or ARDS.

ETIOLOGY While many medical and surgical illnesses have been associated with the development of ALI and ARDS, most cases (>80%) are caused by a relatively small number of clinical disorders, namely, severe sepsis syndrome and/or bacterial pneumonia (~40 to 50%), trauma, multiple transfusions, aspiration of gastric contents, and drug overdose. Among patients with trauma, pulmonary contusion, multiple bone fractures, and chest wall trauma/flail chest are the most frequently reported surgical conditions in ARDS, whereas head trauma, near-drowning, toxic inhalation, and burns are rare causes. The risks of developing ARDS are increased in patients suffering from more than one predisposing medical or surgical condition; e.g., the risk for ARDS increases from 25% in patients with severe trauma to 56% in patients with trauma and sepsis.

Several other clinical variables have been associated with the development of ARDS. These include older age, chronic alcohol abuse, metabolic acidosis, and severity of critical illness. Trauma patients with an acute physiology and chronic health evaluation (APACHE) II score ≥ 16 (Chap. 249) have a 2.5-fold increase in the risk of developing ARDS, and those with a score > 20 have an incidence of ARDS that is more threefold greater than those with APACHE II scores ≤ 9.

CLINICAL COURSE AND PATHOPHYSIOLOGY The natural history of ARDS is marked by three phases—exudative, proliferative, and fibrotic—each with characteristic clinical and pathologic features (Fig. 251-1).

Exudative Phase In this phase, alveolar capillary endothelial cells and type I pneumocytes (alveolar epithelial cells) are injured, leading to the loss of the normally tight alveolar barrier to fluid and macromolecules. Edema fluid that is rich in protein accumulates in the interstitial and alveolar spaces. Significant concentrations of cytokines (e.g., interleukin 1, interleukin 8, and tumor necrosis factor α) and lipid mediators (e.g., leukotriene B_4) are present in the lung in this early phase. In response to proinflammatory mediators, leukocytes (especially neutrophils) traffick into the pulmonary interstitium and alveoli. In addition, condensed plasma proteins aggregate in the air spaces with cellular debris and dysfunctional pulmonary surfactant to form hyaline membrane whorls. Pulmonary vascular injury also occurs early in ARDS, with vascular obliteration by microthrombi and fibrocellular proliferation.

Alveolar edema predominantly involves *dependent* portions of the lung, leading to diminished aeration and atelectasis. Collapse of large sections of dependent lung markedly decreases lung compliance. Consequently, intrapulmonary shunting and hypoxemia develop and the work of breathing rises, leading to dyspnea. The pathophysiologic alterations in alveolar spaces are exacerbated by microvascular occlusion, which leads to reductions in pulmonary arterial blood flow to ventilated portions of the lung, increasing the dead space, and pulmonary hypertension. Thus, in addition to severe hypoxemia, hypercapnia secondary to an increase in pulmonary dead space is also prominent in early ARDS.

The exudative phase encompasses the first 7 days of illness after exposure to a precipitating ARDS risk factor, with the patient experiencing the onset of respiratory symptoms. Although usually present within 12 to 36 h after the initial insult, symptoms can be delayed by 5 to 7 days. Dyspnea develops with a sensation of rapid shallow breathing and an inability to get enough air. Tachypnea and increased work of breathing frequently result in respiratory fatigue and ultimately in respiratory failure. Laboratory values are generally nonspecific and primarily indicative of underlying clinical disorders. The chest radiograph usually reveals alveolar and interstitial opacities involving at least three-quarters of the lung fields (Fig. 251-2). While characteristic for ARDS or ALI, these radiographic findings are not specific and can be indistinguishable from cardiogenic pulmonary edema (Chaps. 29 and 255). Unlike the latter, however, the chest x-ray in ARDS rarely shows cardiomegaly, pleural effusions or pulmonary vascular redistribution. Chest computed tomography (CT) scanning in ARDS reveals extensive heterogeneity of lung involvement (Fig. 251-3).

Because the early features of ARDS and ALI are nonspecific, alternative diagnoses must be considered. In the differential diagnosis of ARDS, the most common disorders are cardiogenic pulmonary edema, diffuse pneumonia, and alveolar hemorrhage. Less frequent diagnoses to consider include acute interstitial lung diseases [e.g., acute interstitial pneumonitis (Chap. 243)], acute immunologic injury [e.g, hypersensitivity pneumonitis (Chap. 237)], toxin injury (e.g., radiation pneumonitis), and neurogenic pulmonary edema (Chap. 29).

Proliferative Phase This phase of ARDS usually lasts from day 7 to day 21. Most patients recover rapidly and are liberated from mechanical ventilation during this phase. Despite this improvement, many still experience dyspnea, tachypnea, and hypoxemia. Some patients develop progressive lung injury and early changes of pulmonary fibrosis during the proliferative phase. Histologically, the first signs of resolution are often evident in this phase with the initiation of lung repair,

TABLE 251-1 *Clinical Disorders Commonly Associated with ARDS*

Direct Lung Injury	*Indirect Lung Injury*
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma
Pulmonary contusion	Multiple bone fractures
Near-drowning	Flail chest
Toxic inhalation injury	Head trauma
	Burns
	Multiple transfusions
	Drug overdose
	Pancreatitis
	Post-cardiopulmonary bypass

TABLE 251-2 *Diagnostic Criteria for ALI and ARDS*

Oxygenation	*Onset*	*Chest Radiograph*	*Absence of Left Atrial Hypertension*
ALI: $Pa_{O_2}/FI_{O_2} \leq$ 300 mmHg	Acute	Bilateral alveolar or interstitial infiltrates	PCWP ≤ 18 mmHg *or* no clinical evidence of increased left atrial pressure
ARDS: $Pa_{O_2}/FI_{O_2} \leq$ 200 mmHg			

Note: ALI, acute lung injury; ARDS, acute respiratory distress syndrome; Pa_{O_2} = arterial partial pressure of O_2; FI_{O_2}, inspired O_2 percentage; PCWP, pulmonary capillary wedge pressure.

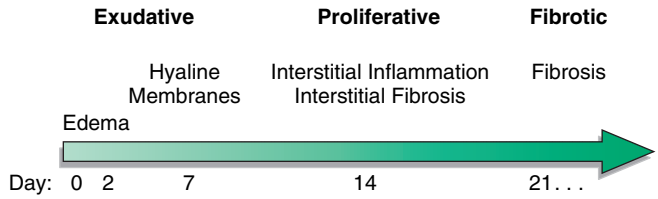

FIGURE 251-1 Diagram illustrating the time course for the development and resolution of ARDS. The exudative phase is notable for early alveolar edema and neutrophil-rich leukocytic infiltration of the lungs with subsequent formation of hyaline membranes from diffuse alveolar damage. Within 7 days, a proliferative phase ensues with prominent interstitial inflammation and early fibrotic changes. Approximately 3 weeks after the initial pulmonary injury, some patients enter the fibrotic phase, with substantial fibrosis and bullae formation.

organization of alveolar exudates, and a shift from a neutrophil to a lymphocyte-predominant pulmonary infiltrate. As part of the reparative process, there is a proliferation of type II pneumocytes along alveolar basement membranes. These specialized epithelial cells synthesize new pulmonary surfactant and differentiate into type I pneumocytes. The presence of alveolar type III procollagen peptide, a marker of pulmonary fibrosis, is associated with a protracted clinical course and increased mortality from ARDS.

Fibrotic Phase While many patients with ARDS recover lung function 3 to 4 weeks after the initial pulmonary injury, some will enter a fibrotic phase that may require long-term support on mechanical ventilators and/or supplemental oxygen. Histologically, the alveolar edema and inflammatory exudates of earlier phases are now converted to extensive ductal and interstitial fibrosis. Acinar architecture is markedly disrupted, leading to emphysema-like changes with large bullae. Intimal fibroproliferation in the pulmonary microcirculation leads to progressive vascular occlusion and pulmonary hypertension. The physiologic consequences include an increased risk of pneumothorax, reductions in lung compliance, and increased pulmonary dead space. Patients in this late phase experience a substantial burden of excess morbidity. Lung biopsy evidence for pulmonary fibrosis in any phase of ARDS is associated with increased mortality.

TREATMENT

General Principles Recent reductions in ARDS/ALI mortality are largely the result of general advances in the care of critically ill patients (Chap. 249). Thus, caring for these patients requires close attention to: (1) the recognition and treatment of the underlying medical and surgical disorders (e.g., sepsis, aspiration, trauma); (2) minimizing procedures and their complications; (3) prophylaxis against venous thromboembolism, gastrointestinal bleeding, and central venous catheter infections; (4) the prompt recognition of nosocomial infections; and (5) provision of adequate nutrition.

Management of Mechanical Ventilation (See also Chap. 252) ■ *VENTILATOR-INDUCED LUNG INJURY* Despite its life-saving potential, mechanical ventilation can aggravate lung injury. Experimental models have demonstrated that ventilator-induced lung injury appears to require two processes: repeated alveolar overdistention and recurrent alveolar collapse. Clearly evident by chest CT (Fig. 251-3), ARDS is a heterogeneous disorder, principally involving dependent portions of the lung with relative sparing of other regions. Because of their differing compliance, attempts to fully inflate the consolidated lung may lead to overdistention and injury to the more "normal" areas of lung. Ventilator-induced injury can be demonstrated in experimental models of ALI, with high tidal volume ventilation resulting in additional, synergistic alveolar damage. These findings led to the hypothesis that ventilating patients suffering from ALI or ARDS with lower tidal volumes would protect against ventilator-induced lung injury and improve clinical outcomes.

A large-scale, randomized controlled trial sponsored by the National Institutes of Health and conducted by the ARDS Network compared low tidal volume (6 mL/kg predicted body weight) ventilation to conventional tidal volume (12 mL/kg predicted body weight) ventilation. Mortality was significantly lower in the low tidal volume patients (31%) compared to the conventional tidal volume patients (40%). This improvement in survival represents the most substantial benefit in ARDS mortality demonstrated for *any* therapeutic intervention in ARDS to date.

PREVENTION OF ALVEOLAR COLLAPSE In ARDS, the presence of alveolar and interstitial fluid and the loss of surfactant can lead to a marked reduction of lung compliance. Without an increase in end-expiratory pressure, significant alveolar collapse can occur at end-expiration, impairing oxygenation. In most clinical settings, positive end-expiratory pressure (PEEP) is empirically set to minimize FI_{O_2} and maximize Pa_{O_2}. On most modern mechanical ventilators, it is possible to construct a static pressure–volume curve for the respiratory system. The lower inflection point on the curve represents alveolar opening (or "recruitment"). The pressure at this point, usually 12 to 15 mmHg in ARDS, is a theoretical "optimal PEEP" for alveolar recruitment. Titration of the PEEP to the lower inflection point on the static pressure–volume curve has been hypothesized to keep the lung open, improving oxygenation and protecting against lung injury. The ARDS Network investigators are currently studying the effect of PEEP on clinical out-

FIGURE 251-2 A representative anteroposterior (AP) chest x-ray in the exudative phase of ARDS that shows diffuse interstitial and alveolar infiltrates, which can be difficult to distinguish from left ventricular failure.

FIGURE 251-3 A representative computed tomographic scan of the chest during the exudative phase of ARDS in which *dependent* alveolar edema and atelectasis predominate.

TABLE 251-3 *A Stepwise Approach to Mechanical Ventilation in ARDS*

1. Calculate predicted body weight (PBW) in kilogram	Men = 50 + 5.42[height (cm) − 60] Women = 45.5 + 5.42[height (cm) − 60]
2. Ventilator mode	Volume cycle, assist control
3. Tidal volume (VT)	Initial VT 8 mL/kg PBW Reduce to 6 mL/kg over 2–4 h if ventilation adequate Goal inspiratory plateau pressures < 30 cmH_2O; reduce VT to as low as 4 mL/kg as needed (and permitted by ventilation) to achieve this goal
4. Oxygenation	Pa_{O_2} goal = 55 – 80 mmHg or pulse oximetry oxygen saturation 88–95% Use the minimal amount of PEEP to keep $FI_{O_2} \leq 0.6$ and meet Pa_{O_2} goal
5. Respiratory rate and acidosis management	Goal arterial pH = 7.30–7.40 If pH < 7.30, increase respiratory rate up to 35 breaths/min If pH < 7.30 and respiratory rate = 35, consider starting intravenous bicarbonate (or equivalent buffer)

If the above strategy fails and the patient is suffering from persistent hypoxemic respiratory failure, *consider* the following:

1. Neuromuscular blocking agents (if not already in use)
2. Prone position ventilation
3. Recruitment maneuvers
4. Inverse ratio ventilation, nitric oxide, high-frequency ventilation, extracorporeal membrane oxygenation, or partial liquid ventilation as part of a clinical research trial.

Note: PEEP, positive end-expiratory pressure.

comes in ARDS; until the results of these studies are available, it is advisable to set PEEP to minimize FI_{O_2} and optimize Pa_{O_2} using parameters similar to those used by the ARDS Network (Table 251-3).

Oxygenation can also be improved by increasing mean airway pressure with "inverse ratio ventilation." In this technique, the inspiratory (*I*) time is lengthened so that it is longer than the expiratory (*E*) time (*I*:*E* >1:1). With diminished time to exhale, dynamic hyperinflation leads to increased end-expiratory pressure, similar to ventilator-prescribed PEEP. This mode of ventilation has the advantage of improving oxygenation with lower peak pressures than conventional ventilation. Although inverse ratio ventilation can improve oxygenation and help reduce FI_{O_2} to ≤ 0.60 to avoid possible oxygen toxicity, no mortality benefit in ARDS has been demonstrated.

Mechanical ventilation in the prone position improves arterial oxygenation, but its effect on important clinical outcomes remains uncertain. Moreover, unless the critical care team is experienced in "proning," repositioning critically ill patients can be hazardous, leading to accidental endotracheal extubation, loss of central venous catheters, and orthopedic injury. Until further studies validate its efficacy, prone position ventilation should be reserved for only the most critically ill ARDS patients.

OTHER STRATEGIES IN MECHANICAL VENTILATION Several additional mechanical ventilation strategies that utilize specialized equipment have been tested in ARDS patients, most with mixed or disappointing results in adults. These include high-frequency ventilation (HFV), i.e., ventilating at extremely high respiratory rates (5 to 20 cycles per second) and low tidal volumes (1 to 2 mL/kg). Also, lung replacement therapy with extracorporeal membrane oxygenation (ECMO), which provides a clear survival benefit in neonatal respiratory distress syndrome, has yet to have proven survival benefit in adults with ARDS. Ongoing research on partial liquid ventilation (PLV) with perfluorocarbon, an inert, high-density liquid that easily solubilizes oxygen and carbon dioxide, has revealed promising preliminary data on pulmonary function in patients with ARDS, but also without survival benefit.

RECOMMENDATIONS Based on current evidence, the approach to mechanical ventilation in Table 251-3 is recommended. Data in support of the efficacy of "adjunctive" ventilator therapies (e.g., high PEEP, inverse ratio ventilation, prone positioning, HFV, ECMO, and PLV) remain incomplete, so these modalities are not routinely used.

Fluid Management Increased pulmonary vascular permeability leading to interstitial and alveolar edema rich in protein is a central feature of ARDS. In addition, impaired vascular integrity augments the normal increase in extravascular lung water that occurs with increasing left atrial pressure. Maintaining a normal or low left atrial filling pressure minimizes pulmonary edema and prevents further decrements in arterial oxygenation and lung compliance, improves pulmonary mechanics, shortens ICU stay and the duration of mechanical ventilation, and is associated with a lower mortality. Thus, aggressive attempts to reduce left atrial filling pressures with fluid restriction and diuretics should be an important aspect of ARDS management, limited only by hypotension and hypoperfusion of critical organs, such as the kidneys.

Glucocorticoids Inflammatory mediators and leukocytes are abundant in the lungs of patients with ARDS. Many attempts have been made to treat both early and late ARDS with glucocorticoids to reduce this potentially deleterious pulmonary inflammation. Few studies have shown any benefit. The ARDS Network is currently conducting a large-scale study of glucocorticoids in ALI and ARDS. Current evidence does *not* support their use in the care of early ARDS patients. On the other hand, if patients fail to improve after 1 week of supportive therapy and have no contraindications to glucocorticoid therapy, providers may wish to consider an *empirical* trial of them in an attempt to speed ARDS resolution.

Other Therapies Clinical trials of surfactant replacement therapy have proven disappointing. Similarly, although several randomized clinical trials of inhaled nitric oxide (NO) in ARDS have demonstrated improved oxygenation, no significant improvement in survival or decrements in time on mechanical ventilation has been observed. Therefore, the use of NO is *not* currently recommended in ARDS.

Recommendations Many clinical trials have been undertaken to improve the outcome of patients with ARDS; most have been unsuccessful in modifying the natural history. The large number and uncertain clinical efficacy of ARDS therapies can make it difficult for clinicians to select a rational treatment plan, and these patients' critical illness can tempt physicians to try unproven and potentially harmful therapies. While results of large clinical trials must be judiciously administered to *individual* patients, an evidenced-based recommendation for ARDS management is summarized in Table 251-4.

PROGNOSIS ■ Mortality Recent mortality estimates for ARDS range from 41 to 65%. There is substantial variability, but a trend towards improved ARDS outcomes appears evident. Of interest, mortality in ARDS

is largely attributable to nonpulmonary causes, with sepsis and nonpulmonary organ failure accounting for >80% of deaths. Thus, improvement in survival is likely secondary to advances in the care of septic/infected patients and those with multiple organ failure (Chap. 249).

Several risk factors for mortality to help estimate prognosis have been identified. Similar to the risk factors for developing ARDS, the major risk factors for ARDS mortality are also nonpulmonary. Advanced age is an important risk factor. Patients >75 years have a substantially increased mortality (~60%) compared to those <45 (~20%). Also, patients >60 years with ARDS and sepsis have a threefold higher mortality compared to those <60. Preexisting organ dysfunction from chronic medical illness is an important additional risk factor for increased mortality. In particular, chronic liver disease, cirrhosis, chronic alcohol abuse, chronic immunosuppression, sepsis, chronic renal disease, any nonpulmonary organ failure, and increased APACHE II scores (Chap. 249) have also been linked to increased ARDS mortality. Several factors related to the presenting clinical disorders also increase risk for ARDS mortality. Patients with ARDS from direct lung injury (including pneumonia, pulmonary contusion, and aspiration; Table 251-1) have nearly twice the mortality of those with indirect causes of lung injury, while surgical and trauma patients with ARDS, especially those without direct lung injury, have a better survival rate than other ARDS patients.

Surprisingly, there is little value in predicting ARDS mortality from the extent of hypoxemia and any of the following measures of the severity of lung injury: the level of PEEP used in mechanical ventilation, the respiratory compliance, the extent of alveolar infiltrates on chest radiography, and the lung injury score (a composite of all these variables). However, recent data indicate that an early (within 24 h of presentation) elevation in dead space may predict increased mortality from ARDS.

Functional Recovery in ARDS Survivors While it is common for patients with ARDS to experience prolonged respiratory failure and remain dependent on mechanical ventilation for survival, it is a testament to the resolving powers of the lung that the majority of patients recover nearly normal lung function. Patients usually recover their maximum lung function within 6 months. One year after endotracheal extubation, over a third of ARDS survivors have normal spirometry values and diffusion capacity. Most of the remaining patients have only mild abnormalities in their pulmonary function. Unlike the risk for mortality, recovery of lung function is strongly associated with the extent of lung injury in early ARDS. Low static respiratory compliance, high levels of required PEEP, longer durations of mechanical ventilation, and high lung injury scores are all associated with worse recovery of pulmonary function. When caring for ARDS survivors it is important to be aware of the potential for a substantial burden of emotional and respiratory symptoms. There are significant rates of depression and posttraumatic stress disorder in ARDS survivors.

252 MECHANICAL VENTILATORY SUPPORT

Edward P. Ingenito, Jeffrey M. Drazen

Ventilators are specially designed pumps that can support the ventilatory function of the respiratory system and improve oxygenation through application of high oxygen content gas and positive pressure. They are a mainstay of physiologic supportive care (see also Chap. 249).

INDICATIONS FOR MECHANICAL VENTILATION

There are two basic types of respiratory failure, the primary indication for initiation of mechanical ventilation (see also Chap. 250).

1. *Hypoxemic respiratory failure* most commonly results from pulmonary conditions such as severe pneumonia, pulmonary edema, pulmonary hemorrhage, and respiratory distress syndrome causing ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and shunt. Hypoxemic respiratory failure is present when arterial O_2 saturation (Sa_{O_2}) < 90% is observed despite an inspired O_2 fraction (FI_{O_2}) > 0.6. The goal of ventilator treatment in this setting is to provide adequate Sa_{O_2} through a combination of supplemental O_2 and specific patterns of ventilation that enhance oxygenation by improving $\dot{V}/\dot{Q}$ matching and reducing intrapulmonary shunt.

2. *Hypercarbic respiratory failure* results from disease states causing either a decrease in minute ventilation or an increase in physiologic dead space such that, despite adequate total minute ventilation, alveolar ventilation is inadequate to meet metabolic demands. Common clinical conditions associated with hypercarbic respiratory failure include neuromuscular diseases, such as myasthenia gravis, ascending polyradiculopathy, and myopathies, and diseases that cause respiratory muscle fatigue due to increased workload, such as asthma, chronic obstructive pulmonary disease, and restrictive lung disease. *Acute* hypercarbic respiratory failure is characterized by arterial P_{CO_2} values >50 mmHg and an arterial pH <7.30.

Mechanical ventilation generally should be instituted in acute hypercarbic respiratory failure. In contrast, the decision to institute ventilator support when components of both acute and chronic hypercarbic respiratory failure are present depends on blood gas parameters and clinical evaluation. In particular, if a patient is not in respiratory distress and is not mentally impaired by CO_2 accumulation, it is not mandatory to initiate mechanical ventilation while other forms of treatment are being administered. The goal of ventilator treatment in hypercarbic respiratory failure is to normalize arterial pH through changes in CO_2 tensions. In patients with severe obstructive or restrictive lung disease, potentially injurious elevation in airway pressures may limit tidal volumes to the extent that normalization of pH is not possible, a situation known as *permissive hypercapnia*.

Accepted therapeutic applications of mechanical ventilation include controlled hyperventilation to reduce cerebral blood flow in patients with increased intracranial pressure (ICP) or to improve pulmonary hemodynamics in patients with postoperative pulmonary hypertension. Mechanical ventilation has also been used to reduce the work of breathing in patients with congestive heart failure, especially in the presence of myocardial ischemia. Ventilator support is also frequently used in conjunction with endotracheal intubation to prevent aspiration of gastric contents in otherwise unstable patients during gastric lavage for suspected drug overdose or during upper gastrointestinal endoscopy. In the critically ill patient, intubation and mechanical ventilation are indicated before essential diagnostic or therapeutic studies if it appears that respiratory failure may occur during these maneuvers.

PHYSIOLOGIC ASPECTS OF MECHANICAL VENTILATION

Mechanical ventilators provide warmed and humidified gas to the airway opening in conformance with various specific volume, pressure, and time patterns. The ventilator serves as the energy source for inspiration, replacing the muscles of the diaphragm and chest wall. Expiration is passive, driven by the recoil of the lungs and chest wall; at the completion of inspiration, internal ventilator circuitry vents the airway to atmospheric pressure or a specified level of positive end-expiratory pressure (PEEP).

PEEP helps maintain patency of alveoli and small airways in the presence of destabilizing factors and therefore reverses hypoxemia and atelectasis by improving matching of ventilation and perfusion. PEEP levels between 0 and 10 cmH_2O are generally safe and effective; higher levels are recommended only in the management of significant refractory hypoxemia unresponsive to increments in FI_{O_2} up to 0.6.

ESTABLISHING AND MAINTAINING AN AIRWAY A cuffed endotracheal tube is often inserted to allow positive-pressure ventilators to deliver conditioned gas, at pressures above atmospheric pressure, to the lungs in a controlled fashion. If neuromuscular paralysis is to be induced during intubation, the use of agents whose mechanism of action includes depolarization at the neuromuscular junction, such as succinylcholine chloride, should be avoided in patients with renal failure, tumor lysis syndrome, crush injuries, medical conditions associated with elevated serum potassium levels, and muscular dystrophy syndromes. Opiates and benzodiazepines can have a deleterious effect on hemodynamics in patients with depressed cardiac function or low systemic vascular resistance and should be used cautiously in this setting. Morphine can promote histamine release from tissue mast cells and may worsen bronchospasm in patients with asthma; fentanyl, sufentanil, and alfentanil are acceptable alternatives to morphine. Ketamine may increase systemic arterial pressure as well as ICP and has been associated with dramatic hallucinatory responses; it should be used with caution in patients with hypertensive crisis, increased ICP, or a history of psychiatric disorders. Newer agents such as etomidate and propofol have also been used for both induction and maintenance of anesthesia in patients receiving mechanical ventilator support. They are shorter acting and have fewer adverse hemodynamic effects, but are significantly more expensive than older agents.

Patients who require ventilator support for extended periods of time may be candidates for tracheostomy. Although definitive guidelines for performing a tracheostomy in the ventilated patient have not been established, in current clinical practice patients who are anticipated to require ventilator therapy for more than 3 weeks should be considered for this procedure. While it does not clearly reduce the incidence of laryngeal injury or tracheal stenosis, tracheostomy has been associated with improved patient comfort and enhanced ability to partake in rehabilitation-oriented activities.

VENTILATOR MODES *Mode* refers to the manner in which ventilator breaths are triggered, cycled, and limited; commonly used modes of mechanical ventilation are given in Table 252-1. The *trigger*, either an inspiratory effort or a time-based signal, defines what the ventilator senses to initiate an assisted breath. *Cycle* refers to the factors that determine the end of inspiration. For example, in volume-cycled ventilation, inspiration ends when a specific tidal volume is delivered to the patient. Other types of cycling include pressure cycling, time cycling, and flow cycling. *Limiting factors* are operator-specified values, such as airway pressure, that are monitored by transducers internal to the ventilator circuit throughout the respiratory cycle; if the specified

TABLE 252-1 *Clinical Characteristics of Commonly Used Modes of Mechanical Ventilation*

Ventilator Mode	Independent Variables (Set by User)	Dependent Variables (Monitored by User)	Trigger/Cycle Limit	Advantages	Disadvantages	Initial Settings
ACMV[a]	FI_{O_2} Tidal volume Ventilator rate Level of PEEP Inspiratory flow pattern Peak inspiratory flow Pressure limit	Peak airway pressure, Pa_{O_2}, Pa_{CO_2} Mean airway pressure I/E ratio	Patient/timer Pressure limit	Timer backup Patient-vent synchrony Patient controls minute ventilation	Not useful for weaning Potential for dangerous respiratory alkalosis	FI_{O_2} = 1.0[b] V_t = 10–15 mL/kg[a] f = 12–15/min PEEP = 0–5 cmH_2O Inspiratory flow = 60 L/min
SIMV[a]	Same as for ACMV	Same as for ACMV	Same as for ACMV	Timer backup useful for weaning	Potential dysynchrony	Same as for ACMV[a]
CPAP	FI_{O_2} Level of CPAP	Tidal volume Rate, flow pattern Airway pressure Pa_{O_2}, Pa_{CO_2}, I/E ratio	No trigger Pressure limit	Allows assessment of spontaneous function Helps prevent atelectasis	No backup	FI_{O_2} = 0.5–1.0[b] CPAP = 5–15 cmH_2O
PCV[a]	FI_{O_2} Inspiratory pressure level Ventilator rate Level of PEEP Pressure limit I/E ratio	Tidal volume Flow rate, pattern Minute ventilation Pa_{O_2}, Pa_{CO_2}	Timer/patient Timer/pressure limit	System pressures regulated Useful for barotrauma treatment Timer backup	Requires heavy sedation Not useful for weaning	FI_{O_2} = 1.0[b] PC = 20–40 cmH_2O[a] PEEP = 5–10 cmH_2O f = 12–15/min I/E = 0.7/1–4/1
PSV	FI_{O_2} Inspiratory pressure level PEEP Pressure limit	Same as for PCV + I/E ratio	Inspiratory flow Pressure limit	Assures synchrony Good for weaning	No timer backup	FI_{O_2} = 0.5–1.0[b] PS = 10–30 cmH_2O 5 cmH_2O usually the level used PEEP = 0–5 cmH_2O

[a] Open lung ventilation (OLV) involves the use of any of these specific modes with tidal volumes (or applied pressures) to achieve 5–6 mL/kg, and positive end expiratory pressures achieve maximal alveolar recruitment.

[b] FI_{O_2} is usually set to 1.0 initially, unless there is a specific clinical indication to minimize FI_{O_2}, such as history of chemotherapy with bleomycin. Once adequate oxygenation is documented by blood gas analysis, FI_{O_2} should be decreased in decrements of 0.1–0.2 as tolerated, until the lowest FI_{O_2} required for an Sa_{O_2} >90% is achieved.

Abbreviations: f, frequency; I/E, inspiration/expiration; FI_{O_2}, inspired O_2; PEEP, positive end-expiratory pressure; for ventilator modes, see text; V_t, tidal ventilation.

values are exceeded, inspiratory flow is immediately stopped, and the ventilator circuit is vented to atmospheric pressure or the specified PEEP.

Assist Control Mode Ventilation (ACMV) An inspiratory cycle is initiated either by the patient's inspiratory effort or, if no patient effort is detected within a specified time window, by a timer signal within the ventilator. Every breath delivered, whether patient or timer triggered, consists of the operator-specified tidal volume. Ventilatory rate is determined either by the patient or by the operator-specified backup rate, whichever is of higher frequency (Fig. 252-1*A*). ACMV is commonly used for initiation of mechanical ventilation because it ensures a backup minute ventilation in the absence of an intact respiratory drive and allows for synchronization of the ventilator cycle with the patient's inspiratory effort.

Problems can arise when ACMV is used in patients with tachypnea due to nonrespiratory or nonmetabolic factors such as anxiety, pain, or airway irritation. Respiratory alkalemia may develop and trigger myoclonus or seizures. Dynamic hyperinflation (so-called auto-PEEP) may occur if the patient's respiratory mechanics are such that inadequate time is available for complete exhalation between inspiratory cycles. Auto-PEEP can limit venous return, decrease cardiac output, and increase airway pressures, predisposing to barotrauma. ACMV is not effective for weaning patients from mechanical ventilation because it provides full ventilator assistance on each patient-initiated breath.

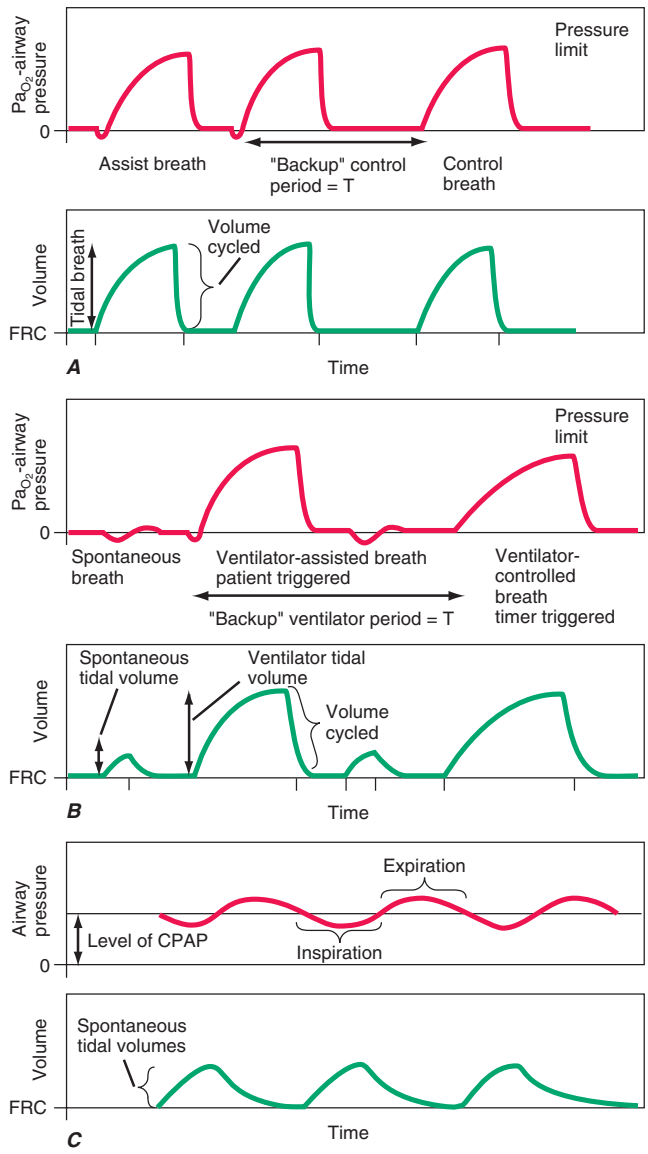

FIGURE 252-1 *A.* Airway pressure and lung volume versus time profile during assist control mode ventilation (ACMV). Assisted breaths are triggered by the patient's effort. Controlled breaths are triggered by the ventilator timer. Every breath, whether triggered by the patient or by the timer, is a complete volume-cycled breath, with airway pressure as a dependent variable. The pressure limit is set above the peak inspiratory pressure. *B.* Airway pressure and lung volume versus time profiles during synchronized intermittent mandatory ventilation (SIMV). Spontaneous breaths occur between patient-triggered assisted breaths and timer-triggered breaths. The tidal volume of the spontaneous breaths is determined by the patient's effort and lung impedance. Assisted and controlled breaths are volume cycled. *C.* Airway pressure and lung volume versus time profiles during continuous positive airway pressure (CPAP). Breathing is spontaneous, and no ventilator assist is provided. The spontaneous profile is superimposed on an elevated mean airway pressure that the user specifies. FRC, functional residual capacity.

Synchronized Intermittent Mandatory Ventilation (SIMV) The major difference between SIMV and ACMV is that in the former the patient is allowed to breathe spontaneously, i.e., without ventilator assist, between delivered ventilator breaths. However, mandatory breaths are delivered in synchrony with the patient's inspiratory efforts at a frequency determined by the operator. If the patient fails to initiate a breath, the ventilator delivers a fixed-tidal-volume breath and resets the internal timer for the next inspiratory cycle (Fig. 252-1*B*). SIMV differs from ACMV in that only the preset number of breaths is ventilator-assisted.

SIMV allows patients with an intact respiratory drive to exercise inspiratory muscles between assisted breaths, making it useful for both supporting and weaning intubated patients. SIMV may be difficult to use in patients with tachypnea because they may attempt to exhale during the ventilator-programmed inspiratory cycle. When this occurs, the airway pressure may exceed the inspiratory pressure limit, the ventilator-assisted breath will be aborted, and minute volume may drop below that programmed by the operator. In this setting, if the tachypnea is in response to respiratory or metabolic acidosis, a change to ACMV will increase minute ventilation and help normalize the pH while the underlying process is further evaluated.

Continuous Positive Airway Pressure (CPAP) This is not a true support-mode of ventilation, inasmuch as all ventilation occurs through the patient's spontaneous efforts. The ventilator provides fresh gas to the breathing circuit with each inspiration and charges the circuit to a constant, operator-specified pressure that can range from 0 to 20 cmH_2O (Fig. 252-1*C*). CPAP is used to assess extubation potential in patients who have been effectively weaned and are requiring little ventilator support and in patients with intact respiratory system function who require an endotracheal tube for airway protection.

Pressure-Control Ventilation (PCV) This form of ventilation is time triggered, time cycled, and pressure limited. During the inspiratory phase, a given pressure is imposed at the airway opening, and the pressure remains at this user-specified level throughout inspiration (Fig. 252-2*A*). Since inspiratory airway pressure is specified by the operator, tidal volume and inspiratory flow rate are *dependent* rather than *independent* variables and are not user specified. PCV is the preferred mode of ventilation for patients with documented barotrauma, because airway pressures can be limited, and for postoperative thoracic surgical patients, in whom the shear forces across a fresh suture line should be limited. When PCV is used, minute ventilation and tidal volume must be monitored; minute ventilation is altered through changes in rate or in the pressure-control value.

PCV with the use of a prolonged inspiratory time is frequently applied to patients with severe hypoxemic respiratory failure. This approach, called inverse inspiratory-to-expiratory ratio ventilation (IRV), increases mean distending pressures without increasing peak airway pressures. It is thought to work in conjunction with PEEP to open collapsed alveoli and improve oxygenation. IRV may be associated with fewer deleterious effects than conventional volume-cycled ventilation, which requires higher peak airway pressures to achieve an equivalent reduction in shunt fraction, but there are no convincing data to show that IRV improves outcomes.

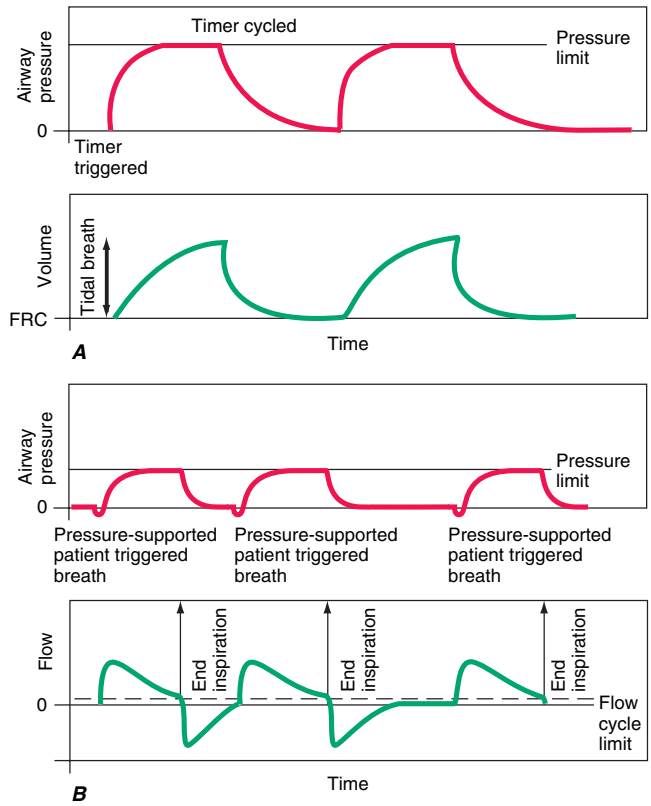

FIGURE 252-2 *A.* Airway pressure and lung volume versus time profiles during pressure-control ventilation (PCV). All breaths are timer triggered, timer cycled, and pressure limited. Peak airway pressure is set by the operator, and tidal volume is a dependent variable. The profiles shown here display the pressure limit as slightly higher than pressure-control level. This need not be the case, but it is appropriate to set the pressure limit only slightly above the pressure-control level when using this mode of ventilation for management of the patient with barotrauma. *B.* Airway pressure and airway flow versus time profiles during pressure-support ventilation (PSV). All breaths are patient triggered and flow cycled. Inspiration is cycled off when the inspiratory flow drops below a predetermined threshold internally set in the ventilator circuit. In the example shown, the pressure limit is slightly greater than the pressure-support level. Since each can be set independently, this need not be the case. FRC, functional residual capacity.

Pressure-Support Ventilation (PSV) This form of ventilation is patient triggered, flow cycled, and pressure limited; it is specifically designed for use in the weaning process. During PSV, the inspiratory phase is terminated when inspiratory airflow falls below a certain level; in most ventilators this flow rate cannot be adjusted by the operator. When PSV is used, patients receive ventilator assist only when the ventilator detects an inspiratory effort (Fig. 252-2*B*). PSV can also be used in combination with SIMV to ensure volume-cycled backup for patients whose respiratory drive is depressed.

PSV is well tolerated by most patients who are being weaned; PSV parameters can be set to provide fully or nearly fully ventilatory support and can be withdrawn slowly over a period of days in a systematic fashion to gradually load the respiratory muscles.

Open Lung Ventilation (OLV) OLV is not a distinct mode of ventilation, but rather a strategy for applying either volume-cycled or pressure-control ventilation to patients with severe respiratory failure. In OLV, the primary objectives of ventilator support are maintenance of adequate oxygenation and avoidance of cyclic opening and closing of alveolar units by selecting a level of PEEP that allows the majority of units to remain inflated during tidal ventilation. Achievement of eucapnia and normal blood pH through adjustments in ventilator tidal volume and breathing frequency are of lower priority. Clinical and experimental observations indicate that high airway pressures and repeated opening and closing of alveoli can cause microstructural lung damage, propagation of lung injury through generation of inflammatory cytokines, and direct barotrauma. Current data suggest that a small tidal volume (i.e., 6 mL/kg) provides adequate ventilatory support with a lower incidence of adverse effects than more conventional tidal volumes of 10 to 15 mL/kg. Hypercapnia and consequent respiratory acidosis tend to be well tolerated physiologically, except in patients with significant hemodynamic compromise, ventricular dysfunction, cardiac dysrrhythmias, or increased ICP. Furthermore, there are recent data to suggest that hypercapnia may have direct beneficial anti-inflammatory effects. OLV has been used most extensively in the management of patients with hypoxemic respiratory failure due to acute lung injury. Although few randomized clinical trials of OLV have been performed, available data suggest that this strategy reduces the mortality rate and improves gas exhange in patients with acute lung injury.

Prone Positioning during Mechanical Ventilation Patients with acute respiratory distress syndrome (ARDS) experience hypoxemia as a result of intrapulmonary shunt due to regional atelectasis (see Chap. 251). Recent studies in patients with ARDS have demonstrated that collapse occurs most extensively in the dependent regions of the lung. Prone positioning increases transdiaphragmatic pressures in these atelectatic, dorsal lung zones by altering their position relative to the hydrostatic pressures generated by abdominal contents. Thus, distending pressures in these areas are increased through positioning without the need to apply additional airway pressures that can overdistend less damaged areas of lung and potentially cause additional damage. While conceptually appealing and simple to implement, a recently completed randomized trial in patients with acute lung injury failed to demonstrate a survival advantage with prone positioning despite demonstration of transient physiologic benefit.

Noninvasive Ventilation (NIV) Noninvasive ventilator support through a tight-fitting facemask or nasal mask, traditionally used for treatment of sleep apnea, has recently been used as primary ventilator support in patients with impending respiratory failure. Facemask and nasal devices for administering NIV therapy are most frequently combined with PSV or bi-level positive airway pressure ventilation, inasmuch as both of these modes are well tolerated by the conscious patient and optimize patient-ventilator synchrony. NIV has met with varying degrees of success when applied to patients with acute or chronic respiratory failure. The major limitation to its widespread application has been patient intolerance, because the tight-fitting mask required for NIV can cause both physical and emotional discomfort in patients with dyspnea. Aggressive medical therapy directed at the cause of impending respiratory failure, together with an experienced respiratory therapy and physician team, appear to be the keys to successful use of NIV in intensive care units.

GUIDELINES FOR MANAGING THE VENTILATED PATIENT

Most patients who are started on ventilator support receive ACMV or SIMV, because these modes ensure user-specified backup minute ventilation in the event that the patient fails to initiate respiratory efforts. Once the intubated patient has been stabilized with respect to oxygenation, definitive therapy for the underlying process responsible for respiratory failure is formulated and initiated. Subsequent modifications in ventilator therapy must be provided in parallel with changes in the patient's clinical status. As improvement in respiratory function is noted, the first priorities are to reduce PEEP and supplemental O_2. Once a patient can achieve adequate arterial saturation with an $FI_{O_2} \leq 0.5$ and 5 cmH_2O PEEP, attempts should be made to reduce the level of mechanical ventilatory support. Patients previously on full ventilator support should be switched to a ventilator mode that allows for weaning, such as SIMV, PSV, or SIMV combined with PSV. Ventilator therapy can then be gradually removed, as outlined in the section on weaning. Patients whose condition continues to deteriorate after ventilator support is initiated may require increased O_2, PEEP, and alternative modes of ventilation such as IRV or OLV.

GENERAL SUPPORT IN THE VENTILATED PATIENT

Patients who are started on mechanical ventilation usually require some form of sedation and analgesia to maintain an acceptable level of comfort. Often, this regimen consists of a combination of a benzodiazepine and opiate administered intravenously. Medications commonly used for this purpose include lorazepam, midazolam, diazepam, morphine, and fentanyl.

Immobilized patients in the intensive care unit on mechanical ventilator support are at increased risk for deep venous thrombosis; accepted practice consists of administering prophylaxis in the form of subcutaneous heparin and/or pneumatic compression boots. Fractionated low-molecular-weight heparin has also been used for this purpose; it appears to be equally effective and is associated with a decreased incidence of heparin-associated thrombocytopenia.

Prophylaxis against diffuse gastrointestinal mucosal injury is indicated for patients who have suffered a neurologic insult or those with severe respiratory failure in association with ARDS. Histamine receptor antagonists (H_2-receptor antagonists), antacids, and cytoprotective agents such as carafate have all been used for this purpose and appear to be effective. Recent data suggest that carafate use is associated with a reduction in the incidence of nosocomial pneumonias, since it does not cause changes in stomach pH and is less likely to permit colonization of the gastrointestinal tract by nosocomial organisms at neutral pH.

Nutrition support by enteral feeding through either a nasogastric or an orogastric tube should be maintained in all intubated patients whenever possible. In those patients with a normal baseline nutritional state, support should be initiated within 7 days. In malnourished patients, nutrition support should be initiated within 72 h. Delayed gastric emptying is common in critically ill patients on sedative medications but often responds to promotility agents such as metoclopramide. Parenteral nutrition is an alternative to enteral nutrition in patients with severe gastrointestinal pathology.

COMPLICATIONS OF MECHANICAL VENTILATION

Endotracheal intubation and positive-pressure mechanical ventilation have direct and indirect effects on several organ systems, including the lung and upper airways, the cardiovascular system, and the gastrointestinal system. Pulmonary complications include barotrauma, nosocomial pneumonia, oxygen toxicity, tracheal stenosis, and deconditioning of respiratory muscles. *Barotrauma*, which occurs when high pressures (i.e., > 50 cmH_2O) overdistend and disrupt lung tissue, is clinically manifest by interstitial emphysema, pneumomediastinum, subcutaneous emphysema, or pneumothorax. Although the first three conditions may resolve simply through the reduction of airway pressures, clinically significant pneumothorax, as indicated by hypoxemia, decreased lung compliance, and hemodynamic compromise, requires tube thoracostomy.

Patients intubated for longer than 72 h are at high risk for ventilator associated pneumonia as a result of aspiration from the upper airways through small leaks around the endotracheal tube cuff; the most common organisms responsible for this condition are enteric gram-negative rods, *Staphylococcus aureus*, and anaerobic bacteria. Because the endotracheal tube and upper airways of patients on mechanical ventilation are commonly colonized with bacteria, the diagnosis of nosocomial pneumonia requires "protected brush" bronchoscopic sampling of airway secretions coupled with quantitative microbiologic techniques to differentiate colonization from infection.

Hypotension resulting from elevated intrathoracic pressures with decreased venous return is almost always responsive to intravascular volume repletion. In patients judged to have hypotension or respiratory failure on the basis of alveolar edema, hemodynamic monitoring with a pulmonary arterial catheter may be of value in optimizing O_2 delivery via manipulation of intravascular volume and FI_{O_2} and PEEP levels.

Gastrointestinal effects of positive-pressure ventilation include *stress ulceration* and *mild to moderate cholestasis*. It is common practice to provide prophylaxis with H_2-receptor antagonists or sucralfate for stress-related ulcers. Mild cholestasis [i.e., total bilirubin values ≤ 68 μmol/L (≤ 4.0 mg/dL)] attributable to the effects of increased intrathoracic pressures on portal vein pressures is common and generally self-limited. Cholestasis of a more severe degree should not be attributed to a positive-pressure ventilation response and is more likely due to a primary hepatic process.

WEANING FROM MECHANICAL VENTILATION

Removal of mechanical ventilator support requires that a number of criteria be met. Upper airway function must be intact for a patient to remain extubated but is difficult to assess in the intubated patient. Therefore, if a patient can breathe on his or her own through an endotracheal tube but develops stridor or recurrent aspiration once the tube is removed, upper airway dysfunction or an abnormal swallowing mechanism should be suspected and plans for achieving a stable airway developed. An intact cough during suctioning is a good indicator of a patient's ability to mobilize secretions. Respiratory drive and chest wall function are assessed by observation of respiratory rate, tidal volume, inspiratory pressure, and vital capacity. The weaning index, defined as the ratio of breathing frequency to tidal volume (breaths per minute per liter), is both sensitive and specific for predicting the likelihood of successful extubation. When this ratio is less than 105 with the patient breathing without mechanical assistance through an endotracheal tube, successful extubation is likely. An inspiratory pressure of more than -30 cmH_2O and a vital capacity of greater than 10 mL/kg are considered indicators of acceptable chest wall and diaphragm function. Alveolar ventilation is generally adequate when elimination of CO_2 is sufficient to maintain arterial pH in the range of 7.35 to 7.40, and an $Sa_{O_2} > 90\%$ can be achieved with an $FI_{O_2} < 0.5$ and a PEEP ≤ 5 cmH_2O. Although many patients may not meet all criteria for weaning, the likelihood that a patient will tolerate extubation without difficulty increases as more criteria are met.

Many approaches to weaning patients from ventilator support have been advocated. T-piece and CPAP weaning are best tolerated by patients who have undergone mechanical ventilation for brief periods and require little respiratory muscle reconditioning, whereas SIMV and PSV are best for patients who have been intubated for extended periods and require gradual respiratory-muscle reconditioning.

T-piece weaning involves brief spontaneous breathing trials with supplemental O_2. These trials are usually initiated for 5 min/h followed by a 1-h interval of rest. T-piece trials are increased in 5- to 10-min increments until the patient can remain ventilator independent for periods of several hours. Extubation can then be attempted. CPAP weaning is similar to T-piece weaning except that trials of spontaneous breathing are conducted on the ventilator in CPAP mode.

Weaning by means of SIMV involves gradually tapering the mandatory backup rate in increments of 2 to 4 breaths per minute while monitoring blood gas parameters and respiratory rates. Rates of greater than 25 breaths per minute on withdrawal of mandatory ventilator breaths generally indicate respiratory muscle fatigue and the need to combine periods of exercise with periods of rest. Exercise periods are gradually increased until a patient remains stable on SIMV at 4 breaths per minute or less without needing rest at higher SIMV rates. A CPAP or T-piece trial can then be attempted before planned extubation.

PSV, as described in detail above, is used primarily for weaning from mechanical ventilation. PSV is usually initiated at a level adequate for full ventilator support (PSV_{max}); i.e., PSV is set slightly below the peak inspiratory pressures required by the patient during volume-cycled ventilation. The level of pressure support is then gradually withdrawn in increments of 5 cmH_2O until a level is reached at which the respiratory rate increases to 25 breaths per minute. At this point, intermittent periods of higher-pressure support are alternated with periods of lower-pressure support to provide muscle reconditioning without causing diaphragmatic fatigue. Gradual withdrawal of PSV continues until the level of support is just adequate to overcome the resistance of the endotracheal tube (approximately 5 to 10 cmH_2O). Support can be discontinued and the patient extubated.

Section 2 Shock and Cardiac Arrest

253 APPROACH TO THE PATIENT WITH SHOCK

Ronald V. Maier

Shock is the clinical syndrome that results from inadequate tissue perfusion. Irrespective of cause, the hypoperfusion-induced imbalance between the delivery of and requirements for oxygen and substrate leads to cellular dysfunction. The cellular injury created by the inadequate delivery of oxygen and substrates also induces the production and release of inflammatory mediators that further compromise perfusion through functional and structural changes within the microvasculature. This leads to a vicious cycle in which impaired perfusion is responsible for cellular injury which causes maldistribution of blood flow, further compromising cellular perfusion; the latter causes multiple organ failure and, if the process is not interrupted, leads to the death of the patient. The clinical manifestations of shock are the result, in part, of sympathetic neuroendocrine responses to hypoperfusion as well as the breakdown in organ function induced by severe cellular dysfunction.

When very severe and/or persistent, inadequate oxygen delivery leads to irreversible cell injury; thus, only rapid restoration of oxygen delivery can reverse the progression of the shock state. The fundamental approach to management, therefore, is to recognize overt and impending shock in a timely fashion and to intervene emergently to restore perfusion. This requires the expansion or reexpansion of blood volume. Control of any inciting pathologic process, e.g., continued hemorrhage, impairment of cardiac function, or infection, must occur simultaneously.

Clinical shock is usually accompanied by hypotension, i.e., a mean arterial pressure $<$60 mmHg in previously normotensive persons. Multiple classification schemes have been developed in an attempt to synthesize the seemingly dissimilar processes leading to shock. Strict adherence to a classification scheme may be difficult from a clinical standpoint because of the frequent combination of two or more causes of shock in any individual patient, but the classification shown in Table 253-1 provides a useful reference point from which to discuss and further delineate the underlying processes.

PATHOGENESIS AND ORGAN RESPONSE

MICROCIRCULATION Normally when cardiac output falls, systemic vascular resistance rises to maintain a level of systemic pressure that is adequate for perfusion of the heart and brain at the expense of other tissues such as muscle, skin, and especially the gastrointestinal tract. Systemic vascular resistance is determined primarily by the luminal diameter of arterioles. The metabolic rates of the heart and brain are high, and their stores of energy substrate are low. These organs are critically dependent on a continuous supply of oxygen and nutrients, and neither tolerates severe ischemia for more than brief periods. Autoregulation, i.e., the maintenance of blood flow over a wide range of perfusion pressures, is critical in sustaining cerebral and coronary perfusion despite significant hypotension. However, when mean arterial pressure drops to $\lesssim$60 mmHg, flow to these organs falls and their function deteriorates.

TABLE 253-1 Classification of Shock

Hypovolemic	Septic
Traumatic	Hyperdynamic
Cardiogenic	Hypodynamic
Intrinsic	Neurogenic
Compressive	Hypoadrenal

Arteriolar vascular smooth muscle has both α- and β-adrenergic receptors. The α_1 receptors mediate vasoconstriction, while the β_2 receptors mediate vasodilation. Efferent sympathetic fibers release norepinephrine, which acts primarily on α_1 receptors in one of the most fundamental compensatory responses to reduced perfusion pressure. Other constrictor substances that are increased in most forms of shock include angiotensin II, vasopressin, endothelin-1, and thromboxane A_2. Both norepinephrine and epinephrine are released by the adrenal medulla, and the concentrations of these catecholamines in the bloodstream rise. Circulating vasodilators in shock include prostacyclin [prostaglandin (PG)I_2], nitric oxide (NO), and, importantly, products of local metabolism such as adenosine that match flow to the metabolic needs of the tissue. The balance between these various vasoconstrictor and vasodilator influences acting upon the microcirculation determines local perfusion.

Transport to cells depends on microcirculatory flow; capillary permeability; the diffusion of oxygen, carbon dioxide, nutrients, and products of metabolism through the interstitium; and the exchange of these products across cell membranes. Impairment of the microcirculation, which is central to the pathophysiologic responses in the late stages of all forms of shock, results in the derangement of cellular metabolism, which is ultimately responsible for organ failure.

The endogenous response to mild or moderate hypovolemia is an attempt at restitution of intravascular volume through alterations in hydrostatic pressure and osmolarity. Constriction of arterioles leads to reductions in both the capillary hydrostatic pressure and the number of capillary beds perfused, thereby limiting the capillary surface area across which filtration occurs. When filtration is reduced while intravascular oncotic pressure remains constant or rises, there is net reabsorption of fluid into the vascular bed, in accord with Starling's law of capillary-interstitial liquid exchange (Chap. 29). Metabolic changes (including hyperglycemia and elevations in the products of glycolysis, lipolysis, and proteolysis) raise extracellular osmolarity, leading to an osmotic gradient between cells and interstitium that increases interstitial and intravascular volume at the expense of intracellular volume.

CELLULAR RESPONSES Interstitial transport of nutrients is impaired, leading to a decline of intracellular high-energy phosphate stores. Mitochondrial dysfunction and uncoupling of oxidative phosphorylation are the most likely causes for decreased amounts of ATP. As a consequence, there is an accumulation of hydrogen ions, lactate, and other products of anaerobic metabolism. As shock progresses, these vasodilator metabolites override vasomotor tone, causing further hypotension and hypoperfusion. Dysfunction of cell membranes is thought to represent a common end-stage pathophysiologic pathway in the various forms of shock. Normal cellular transmembrane potential falls,

and there is an associated increase in intracellular sodium and water, leading to cell swelling, which interferes further with microvascular perfusion.

NEUROENDOCRINE RESPONSE Hypovolemia, hypotension, and hypoxia are sensed by baroreceptors and chemoreceptors, which contribute to an autonomic response that attempts to restore blood volume, maintain central perfusion, and mobilize metabolic substrates. Hypotension disinhibits the vasomotor center, resulting in increased adrenergic output and reduced vagal activity. Release of norepinephrine induces peripheral and splanchnic vasoconstriction, a major contributor to the maintenance of central organ perfusion, while reduced vagal activity increases the heart rate and cardiac output. The effects of circulating epinephrine released by the adrenal medulla in shock are largely metabolic, causing increased glycogenolysis and gluconeogenesis and reduced pancreatic insulin release. Epinephrine also inhibits production and release of inflammatory mediators through stimulation of β-adrenergic receptors on innate immune cells.

Severe pain and other severe stress cause the hypothalamic release of adrenocorticotropic hormone (ACTH). This stimulates cortisol secretion, which contributes to decreased peripheral uptake of glucose and amino acids, enhances lipolysis, and increases gluconeogenesis. Increased pancreatic secretion of glucagon during stress accelerates hepatic gluconeogenesis and further elevates blood glucose concentration. These hormonal actions act synergistically in the maintenance of blood volume. Many critically ill patients exhibit low plasma cortisol levels and an impaired response to ACTH stimulation. The importance of the cortisol response to stress is illustrated by the profound circulatory collapse that occurs in hypoadrenal patients (see below).

Renin release is increased in response to adrenergic discharge and reduced perfusion of the juxtaglomerular apparatus in the kidney. Renin induces the formation of angiotensin I, which is then converted to angiotensin II, an extremely potent vasoconstrictor and stimulator of aldosterone release by the adrenal cortex and of vasopressin by the posterior pituitary. Aldosterone contributes to the maintainance of intravascular volume by enhancing renal tubular reabsorption of sodium, resulting in the excretion of a low-volume, concentrated, sodium-free urine. Vasopressin has a direct action on vascular smooth muscle, contributing to vasoconstriction, and acts on the distal renal tubules to enhance water reabsorption.

CARDIOVASCULAR RESPONSE Three variables—ventricular filling (preload), the resistance to ventricular ejection (afterload), and myocardial contractility—are paramount in controlling stroke volume (Chap. 215). Cardiac output, the major determinant of tissue perfusion, is the product of stroke volume and heart rate. Hypovolemia leads to decreased ventricular preload, which in turn reduces the stroke volume. An increase in heart rate is a useful but limited compensatory mechanism to maintain cardiac output. A shock-induced reduction in myocardial compliance is frequent, reducing ventricular end-diastolic volume and hence stroke volume at any given ventricular filling pressure. Restoration of intravascular volume returns stroke volume to normal but only at elevated filling pressures. In addition, sepsis, ischemia, myocardial infarction, severe tissue trauma, hypothermia, general anesthesia, prolonged hypotension, and acidemia may all impair myocardial contractility and also reduce the stroke volume at any given ventricular end-diastolic volume. The resistance to ventricular ejection is significantly influenced by the systemic vascular resistance, which is elevated in most forms of shock. However, resistance is depressed in the early hyperdynamic stage of septic shock (see below), thereby allowing the cardiac output to be maintained or elevated.

The venous system contains nearly two-thirds of the total circulating blood volume, most in the small veins, and serves as a dynamic reservoir for autoinfusion of blood. Active venoconstriction as a consequence of α-adrenergic activity is an important compensatory mechanism for the maintenance of venous return and therefore of ventricular filling during shock. On the other hand, venous dilatation, as occurs in neurogenic shock, reduces ventricular filling and hence stroke volume and cardiac output (see below).

PULMONARY RESPONSE The response of the pulmonary vascular bed to shock parallels that of the systemic vascular bed, and the relative increase in pulmonary vascular resistance, particularly in septic shock, may exceed that of the systemic vascular resistance. Shock-induced tachypnea reduces tidal volume and increases both dead space and minute ventilation. Relative hypoxia and the subsequent tachypnea induce a respiratory alkalosis. Recumbency and involuntary restriction of ventilation secondary to pain reduce functional residual capacity and may lead to atelectasis. Shock is recognized as a major cause of acute lung injury and subsequent acute respiratory distress syndrome (ARDS; Chap. 251). These disorders are characterized by noncardiogenic pulmonary edema secondary to diffuse pulmonary capillary endothelial and alveolar epithelial injury, hypoxemia, and bilateral diffuse pulmonary infiltrates. Hypoxemia results from perfusion of underventilated and nonventilated alveoli. Loss of surfactant and lung volume in combination with increased interstitial and alveolar edema reduce lung compliance. The work of breathing and the oxygen requirements of respiratory muscles increase.

RENAL RESPONSE Acute renal failure (Chap. 260), a serious complication of shock and hypoperfusion, occurs less frequently than heretofore because of early aggressive volume repletion. Acute tubular necrosis is now more frequently seen as a result of the interactions of shock, sepsis, the administration of nephrotoxic agents (such as aminoglycosides and angiographic contrast media), and rhabdomyolysis; the latter may be particularly severe in skeletal muscle trauma. The physiologic response of the kidney to hypoperfusion is to conserve salt and water. In addition to decreased renal blood flow, increased afferent arteriolar resistance accounts for diminished glomerular filtration rate, which together with increased aldosterone and vasopressin is responsible for reduced urine formation. Toxic injury causes necrosis of tubular epithelium and tubular obstruction by cellular debris with back-leak of filtrate. The depletion of renal ATP stores that occurs with prolonged renal hypoperfusion contributes to subsequent impairment of renal function. There is no convincing evidence that low-dose dopamine protects against acute renal failure.

METABOLIC DERANGEMENTS During shock, there is disruption of the normal cycles of carbohydrate, lipid, and protein metabolism. Through the citric acid cycle, alanine in conjunction with lactate (which is converted from pyruvate in the periphery in the presence of oxygen deprivation) enhances the hepatic production of glucose. With reduced availability of oxygen, the breakdown of glucose to pyruvate and ultimately lactate represents an inefficient cycling of substrate with minimal net energy production. An elevated plasma lactate/pyruvate ratio is consistent with anaerobic metabolism and reflects inadequate tissue perfusion. Decreased clearance of exogenous triglycerides coupled with increased hepatic lipogenesis causes a significant rise in serum triglyceride concentrations. There is increased protein catabolism, a negative nitrogen balance, and, if the process is prolonged, severe muscle wasting.

INFLAMMATORY RESPONSES Activation of an extensive network of proinflammatory mediator systems plays a significant role in the progression of shock and contributes importantly to the development of organ injury and failure.

Multiple humoral mediators are activated during shock and tissue injury. The complement cascade, activated through both the classic and alternate pathways, generates the anaphylatoxins C3a and C5a. Direct complement fixation to injured tissues can progress to the C5-C9 attack complex, causing further cell damage. Activation of the coagulation cascade causes microvascular thrombosis, with subsequent lysis leading to repeated episodes of ischemia and reperfusion. Components of the coagulation system, such as thrombin, are potent proinflammatory mediators that cause expression of adhesion molecules on endothelial cells and activation of neutrophils, leading to microvascular injury. Coagulation also activates the kallekrein-kininogen cascade, contributing to hypotension.

TABLE 253-2 *Normal Hemodynamic Parameters*

Parameter	Calculation	Normal Values
Cardiac output (CO)	SV × HR	4–8 L/min
Cardiac index (CI)	CO/BSA	2.6–4.2 (L/min)/m^2
Stroke volume (SV)	CO/HR	50–100 mL/beat
Systemic vascular resistance (SVR)	[(MAP − RAP)/CO] × 80	700–1600 dynes · s/cm^5
Pulmonary vascular resistance (PVR)	[(PAP_m − PCWP)/CO] × 80	20–130 dynes · s/cm^5
Left ventricular stroke work (LVSW)	SV(MAP − PCWP) × 0.0136	60–80 g-m/beat
Right ventricular stroke work (RVSW)	SV(PAP_m − RAP)	10–15 g-m/beat

Note: HR, heart rate; BSA, body surface area; MAP, mean arterial pressure; RAP, right atrial pressure; PAP_m, pulmonary artery pressure—mean; PCWP, pulmonary capillary wedge pressure.

Eicosanoids are vasoactive and immunomodulatory products of arachidonic acid metabolism that include cyclooxygenase-derived prostaglandins and thromboxane A_2 as well as lipoxygenase-derived leukotrienes and lipoxins. Thromboxane A_2 is a potent vasoconstrictor that contributes to the pulmonary hypertension and acute tubular necrosis of shock. PGI_2 and PGE_2 are potent vasodilators that enhance capillary permeability and edema formation. The cysteinyl leukotrienes LTC_4 and LTD_4 are pivotal mediators of the vascular sequelae of anaphylaxis, as well as of shock states resulting from sepsis or tissue injury. LTB_4 is a potent neutrophil chemoattractant and secretagogue that stimulates the formation of reactive oxygen species. Platelet-activating factor, an ether-linked, arachidonyl-containing phospholipid mediator, causes pulmonary vasoconstriction, bronchoconstriction, systemic vasodilation, increased capillary permeability, and the priming of macrophages and neutrophils to produce enhanced levels of inflammatory mediators.

Tumor necrosis factor (TNF) α, produced by activated macrophages, reproduces many components of the shock state including hypotension, lactic acidosis, and respiratory failure. Interleukin (IL) 1, produced by tissue-fixed macrophages, is critical to the inflammatory response. Chemokines such as IL-8 are potent neutrophil chemoattractants and activators that upregulate adhesion molecules on the neutrophil to enhance aggregation, adherence, and damage to the vascular endothelium. While the endothelium normally produces nitric oxide (NO), the inflammatory response stimulates the inducible isoform of NO synthase (iNOS), which is overexpressed and produces toxic NO and oxygen-derived free radicals which contribute to the hyperdynamic cardiovascular response in sepsis.

Multiple inflammatory cells, including neutrophils, macrophages, and platelets, are a major contributor to inflammation-induced injury. Margination of activated neutrophils in the microcirculation is a common pathologic finding in shock, causing secondary injury due to the release of toxic oxygen radicals and proteases. Tissue-fixed macrophages produce virtually all major components of the inflammatory response and orchestrate the progression and duration of the inflammatory response.

TABLE 253-3 *Oxygen Transport Calculations*

Parameter	Calculation	Normal Values
Oxygen-carrying capacity of hemoglobin		1.39 mL/g
Plasma O_2 concentration		P_{O_2} × 0.0031
Arterial O_2 concentration (Ca_{O_2})	1.39 Sa_{O_2} + 0.0031 Pa_{O_2}	20 vol%
Venous O_2 concentration (Cv_{O_2})	1.39 Sv_{O_2} + 0.0031 Pv_{O_2}	15.5 vol%
Arteriovenous O_2 difference (Ca_{O_2} − Cv_{O_2})	1.39 (Sa_{O_2} − Sv_{O_2}) + 0.0031 (Pa_{O_2} − Pv_{O_2})	3.5 vol%
Oxygen delivery (D_{O_2})	Ca_{O_2} × CO (L/min) × 10 (dL/L) 1.39 Sa_{O_2} × CO × 10	800–1600 mL/min
Oxygen uptake (V_{O_2})	(Ca_{O_2} − Cv_{O_2}) × CO × 10 1.39 (Sa_{O_2} − Sv_{O_2}) × CO × 10	150–400 mL/min
Oxygen delivery index ($D_{O_2}I$)	D_{O_2}/BSA	520–720 (mL/min)/m^2
Oxygen uptake index ($V_{O_2}I$)	V_{O_2}/BSA	115–165 (mL/min)/m^2
Oxygen extraction ratio (O_2ER)	[1 − ($\dot{V}_{O_2}/\dot{D}_{O_2}$)] × 100	22–32%

Note: P_{O_2}, partial pressure of oxygen; Sa_{O_2}, saturation of hemoglobin with O_2 in arterial blood; Pa_{O_2}, partial pressure of O_2 in arterial blood; Sv_{O_2}, saturation of hemoglobin with O_2 in venous blood; Pv_{O_2}, partial pressure of O_2 in venous blood; CO, cardiac output; BSA, body surface area.

APPROACH TO THE PATIENT

Monitoring Patients in shock require care in an intensive care unit. Careful and continuous assessment of the physiologic status is necessary. Arterial pressure through an indwelling line, pulse, and respiratory rate should be monitored continuously; a Foley catheter should be inserted to follow urine flow; and mental status assessed frequently.

Although there is ongoing debate as to the indications for using the flow-directed pulmonary artery catheter (PAC, Swan-Ganz catheter), most intensivists believe that the ability to predict the hemodynamic profiles of patients in shock accurately without a PAC is poor. The PAC is placed percutaneously via the subclavian or jugular vein through the central venous circulation and right heart into the pulmonary artery. There are ports both proximal in the right atrium and distal in the pulmonary artery to provide access for infusions and for cardiac output measurements. Right atrial and pulmonary artery pressures are measured, and the pulmonary capillary wedge pressure (PCWP) serves as an approximation of the left atrial pressure. Normal hemodynamic parameters are shown in Table 212-3 and Table 253-2.

Cardiac output is determined by the thermodilution technique, and high-resolution thermistors can also be used to determine right ventricular end-diastolic volume to monitor further the response of the right heart to fluid resuscitation. A PAC with an oximeter port offers the additional advantage of on-line monitoring of the mixed venous oxygen saturation, an important index of tissue perfusion. Systemic and pulmonary vascular resistances are calculated as the ratio of the pressure drop across these vascular beds to the cardiac output (Chap. 212). Determinations of oxygen content in arterial and venous blood, together with cardiac output and hemoglobin concentration, allow calculation of oxygen delivery, oxygen consumption, and oxygen-extraction ratio (Table 253-3). The hemodynamic patterns associated with the various forms of shock are shown in Table 253-4.

In resuscitation from shock, it is critical to restore tissue perfusion and optimize oxygen delivery, hemodynamics, and cardiac function rapidly. A reasonable goal of therapy is to achieve normal mixed venous oxygen saturation and arteriovenous oxygen-extraction ratio. To enhance oxygen delivery, red cell mass, arterial oxygen saturation, and cardiac output may be augmented singly or simultaneously. An increase in oxygen delivery not accompanied by an increase in oxygen consumption implies that oxygen availability is adequate and that oxygen consumption is not flow-dependent. Conversely, an elevation of oxygen consumption with increased cardiac output implies that the oxygen supply was inadequate. A reduction in systemic vascular resistance accompanying an increase in cardiac output indicates that compensatory vasoconstriction is reversing due to improved tissue perfusion. The determination of stepwise expansion of blood volume on cardiac performance allows identification of the optimum preload (Starling's law). An algorithm for the resuscitation of the patient in shock is shown in Fig. 253-1.

SPECIFIC FORMS OF SHOCK

HYPOVOLEMIC SHOCK This most common form of shock results either from the loss of red blood cell mass and plasma from hemorrhage or from the loss of plasma volume alone arising

TABLE 253-4 *Physiologic Characteristics of the Various Forms of Shock*

Type of Shock	CVP and PCWP	Cardiac Output	Systemic Vascular Resistance	Venous O_2 Saturation

Note: CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure.

from extravascular fluid sequestration or gastrointestinal, urinary, and insensible losses. The signs and symptoms of nonhemorrhagic hypovolemic shock are the same as those of hemorrhagic shock, although they may have a more insidious onset. The normal physiologic response to hypovolemia is to maintain perfusion of the brain and heart while restoring an effective circulating blood volume. There is an increase in sympathetic activity, hyperventilation, collapse of venous capacitance vessels, release of stress hormones, and expansion of intravascular volume through the recruitment of interstitial and intracellular fluid and reduction of urine output.

Mild hypovolemia (≤20% of the blood volume) generates mild tachycardia but relatively few external signs, especially in a supine resting young patient (Table 253-5). With moderate hypovolemia (~20 to 40% of the blood volume) the patient becomes increasingly anxious and tachycardic; although normal blood pressure may be maintained in the supine position, there may be significant postural hypotension and tachycardia. If hypovolemia is severe (≥~40% of the blood volume), the classic signs of shock appear; the blood pressure declines and becomes unstable even in the supine position, and the patient develops marked tachycardia, oliguria, and agitation or confusion. Perfusion of the central nervous system is well maintained until shock becomes severe. Hence, mental obtundation is an ominous clinical sign. The transition from mild to severe hypovolemic shock can be insidious or extremely rapid. If severe shock is not reversed rapidly, especially in elderly patients and those with comorbid illnesses, death is imminent. A very narrow time frame separates the derangements found in severe shock that can be reversed with aggressive resuscitation from those of progressive decompensation and irreversible cell injury.

Diagnosis Hypovolemic shock is readily diagnosed when there are signs of hemodynamic instability and the source of volume loss is obvious. The diagnosis is more difficult when the source of blood loss is occult, as into the gastrointestinal tract, or when plasma volume alone is depleted. After acute hemorrhage, hemoglobin and hematocrit values do not change until compensatory fluid shifts have occurred or exogenous fluid is administered. Thus, an initial normal hematocrit does not disprove the presence of significant blood loss. Plasma losses cause hemoconcentration, and free water loss leads to hypernatremia. These findings should suggest the presence of hypovolemia.

It is essential to distinguish between hypovolemic and cardiogenic shock (see below) because definitive therapy differs significantly. Both forms are associated with a reduced cardiac output and a compensatory sympathetic mediated response characterized by tachycardia and elevated systemic vascular resistance. However, the findings in cardiogenic shock of jugular venous distention, rales, and an S_3 gallop distinguish it from hypovolemic shock and signify that ongoing volume expansion is undesirable.

TREATMENT

Initial resuscitation requires rapid reexpansion of the circulating blood volume along with interventions to control ongoing losses. In accordance with Starling's law (Chap. 215), stroke volume and cardiac output rise with the increase in preload. After resuscitation, the compliance of the ventricles may remain reduced due to increased interstitial fluid in the myocardium. Therefore, elevated filling pressures are required to maintain adequate ventricular performance.

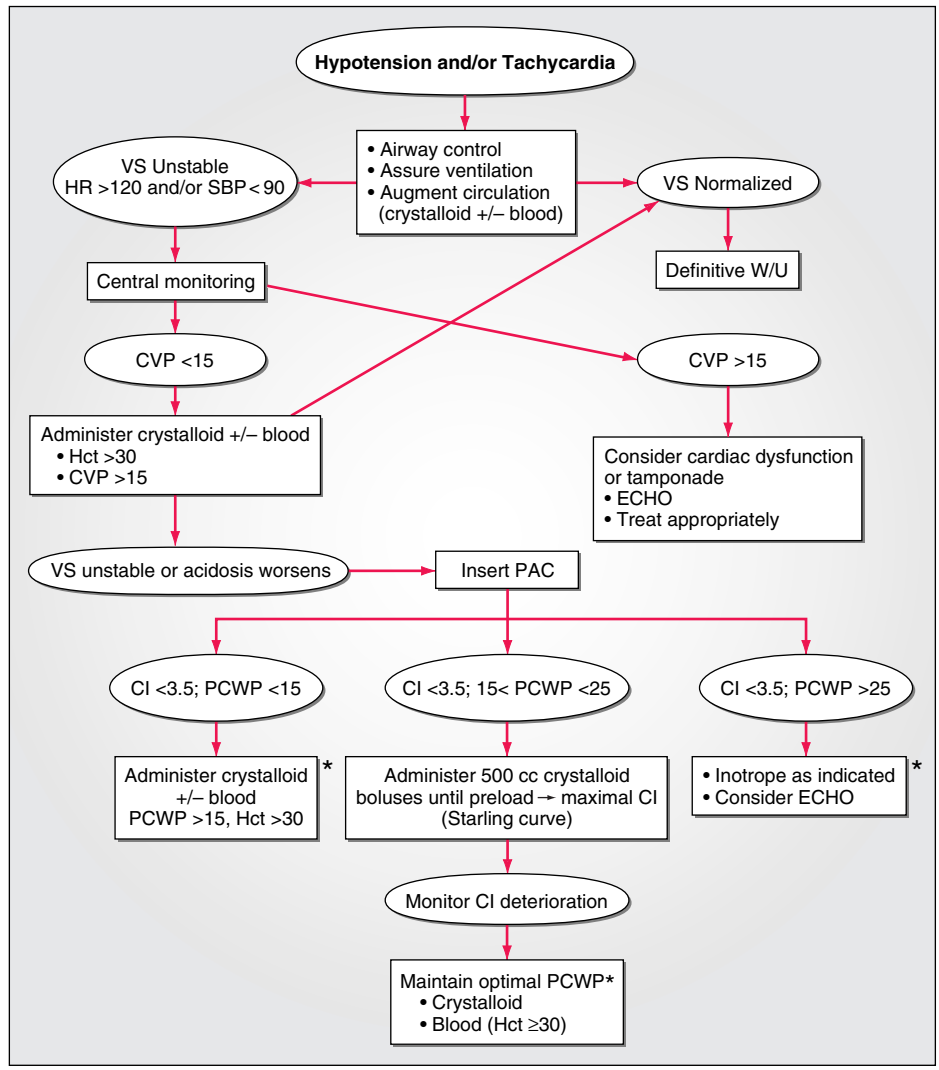

FIGURE 253-1 An algorithm for the resuscitation of the patient in shock. VS, vital signs; HR, heart rate; SBP, systolic blood pressure; W/U, work up; CVP, central venous pressure; Hct, hematocrit; ECHO, echocardiogram; PAC, pulmonary artery catheter; CI, cardiac index in (L/min)/m^2; PCWP, pulmonary capillary wedge pressure in mmHg.

*Monitor SV_{O_2}, SVRI, and RVEDVI as additional markers of correction for perfusion and hypovolemia. Consider age-adjusted CI. SV_{O_2}, saturation of hemoglobin with O_2 in venous blood; SVRI, systemic vascular resistance index; RVEDVI, right-ventricular end-diastolic volume index.

TABLE 253-5 *Hypovolemic Shock*

Mild (<20% Blood Volume)	*Moderate (20–40% Blood Volume)*	*Severe (>40% Blood Volume)*
Cool extremities	Same, plus:	Same, plus:
Increased capillary refill time	Tachycardia	Hemodynamic instability
Diaphoresis	Tachypnea	Marked tachycardia
Collapsed veins	Oliguria	Hypotension
Anxiety	Postural changes	Mental status deterioration (coma)

Volume resuscitation is initiated with the rapid infusion of isotonic saline (although care must be taken to avoid hyperchloremic acidosis) or a balanced salt solution such as Ringer's lactate through large-bore intravenous lines. No distinct benefit from the use of colloid has been demonstrated and, in trauma patients, it is associated with a higher mortality. The infusion of 2 to 3 L over 20 to 30 min should restore normal hemodynamic parameters. Continued hemodynamic instability implies that shock has not been reversed and/or that there are significant ongoing blood or volume losses. Continuing blood loss, with hemoglobin concentrations declining to ≤100 g/L (10 g/dL), should initiate blood transfusion, preferably as fully cross-matched blood. In extreme emergencies, type-specific or O-negative packed red cells may be transfused. In the presence of severe and/or prolonged hypovolemia, inotropic support with dopamine, vasopressin, or dobutamine may be required to maintain adequate ventricular performance, after blood volume has been restored. Infusion of norepinephrine to increase arterial pressure by raising peripheral resistance is inappropriate, other than as a temporizing measure in severe shock while blood volume is reexpanded.

Successful resuscitation also requires support of respiratory function. Supplemental oxygen should be provided, and endotracheal intubation may be necessary to maintain arterial oxygenation. Following resuscitation from isolated hemorrhagic shock, end-organ damage is frequently less than following septic or traumatic shock. This may be due to the absence of the massive activation of inflammatory mediator response systems and the consequent nonspecific organ injury seen in the latter conditions.

TRAUMATIC SHOCK Shock following trauma is, in large measure, due to hypovolemia. However, even when hemorrhage has been controlled, patients can continue to suffer loss of plasma volume into the interstitium of injured tissues. These fluid losses are compounded by injury-induced inflammatory responses, which contribute to the secondary microcirculatory injury. This causes secondary tissue injury and maldistribution of blood flow, intensifying tissue ischemia and leading to multiple organ system failure. Trauma to the heart, chest, or head can also contribute to the shock. For example, pericardial tamponade or tension pneumothorax impairs ventricular filling, while myocardial contusion depresses myocardial contractility.

Rx TREATMENT

Inability of the patient to maintain a systolic blood pressure ≥90 mmHg after trauma-induced hypovolemia is associated with a mortality rate of ~50%. To prevent decompensation of homeostatic mechanisms, therapy must be promptly administered.

The initial management of the seriously injured patient requires attention to the "ABCs" of resuscitation: assurance of an airway (A), adequate ventilation (breathing, B), and establishment of an adequate blood volume to support the circulation (C). Control of hemorrhage requires immediate attention. Early stabilization of fractures, debridement of devitalized or contaminated tissues, and evacuation of hematomata all reduce the subsequent inflammatory response to the initial insult and minimize subsequent organ injury. Supplementation of depleted endogenous antioxidants also reduces subsequent organ failure and mortality.

INTRINSIC CARDIOGENIC SHOCK This form of shock is caused by failure, often sudden, of the heart as an effective pump. It occurs most commonly as a complication of acute myocardial infarction (AMI; Chaps. 228 and 255), but it may also be seen in patients with severe brady- or tachyarrhythmias, valvular heart disease, significant cardiac contusion, or in the terminal stage of chronic heart failure of any cause, including ischemic heart disease and dilated cardiomyopathy. Cardiogenic shock is characterized by a low cardiac output, diminished peripheral perfusion, pulmonary congestion, and elevation of systemic vascular resistance and pulmonary vascular pressures. Acute right heart failure can arise as the result of right ventricular infarction or may complicate ARDS and severe pulmonary hypertension of any etiology. As a consequence of right ventricular failure, left ventricular preload falls, and this, in turn, reduces systemic perfusion. In contrast to other forms of shock, absolute or relative hypovolemia is usually not present in cardiogenic shock.

The ineffective contractile activity of either the right or left side of the heart leads to the accumulation of blood in the venous circulation upstream to the failing ventricle. Cardiogenic shock with left-sided heart failure increases fluid in the lungs that can overwhelm the capacity of the pulmonary lymphatics and causes interstitial and eventually alveolar edema. Interstitial lung edema usually occurs at pulmonary capillary pressures >18 mmHg, and overt pulmonary alveolar edema develops at pressures >24 mmHg (Chap. 29). Pulmonary edema impacts cardiac function further by impairing diffusion of oxygen, setting up a vicious cycle. The increase in interstitial and intraalveolar fluid causes a progressive reduction in lung compliance, thereby increasing the work of ventilation while increasing perfusion of poorly ventilated alveoli.

In establishing the diagnosis of cardiogenic shock, a history of cardiac disease or of AMI is of value. Associated physical findings include those of hemodynamic instability, peripheral vasoconstriction, and pulmonary and/or systemic venous congestion, as well as findings specific to the underlying cardiac abnormalities. An electrocardiogram may provide evidence of AMI or preexisting cardiac disease. The chest x-ray may show pulmonary edema and cardiomegaly. Transthoracic or transesophageal echocardiograms assist in the diagnosis of structural abnormalities and/or functional impairment of contractility. Serum cardiac markers will support the diagnosis of acute cardiac injury. Hemodynamic monitoring is usually necessary in the presence of shock. Placement of a PAC is helpful and will show a reduced cardiac output and an elevated PCWP, and direct measurement of right atrial pressure allows calculation of systemic vascular resistance which is elevated.

Rx TREATMENT

For all forms of cardiogenic shock, preload, afterload, and contractility should be modified using the information provided by the PAC. A PCWP of 15 to 20 mmHg should be the initial goal. If the PCWP is excessively elevated, inotropic agents may provide significant reduction. The goal is to increase contractility without significant increases in heart rate. Dopamine, norepinephrine, or vasopressin exert both inotropic and vasoconstrictor actions that are useful in the presence of persistent hypotension. Dobutamine, a positive inotropic agent with vasodilator properties, or vasodilators may be substituted when arterial pressure has been restored. Pulmonary congestion may be responsive to intravenous furosemide. Patients with an inadequate response to these measures can be supported by using intraaortic balloon counterpulsation to permit recovery of myocardial function. Additional measures to consider in cases of refractory cardiogenic shock include urgent myocardial revascularization in patients with AMI, correction of anatomic cardiac defects such as rupture of the papillary muscles of the interventricular septum, the placement of ventricular assist devices, and even urgent cardiac transplantation.

COMPRESSIVE CARDIOGENIC SHOCK With compression, the heart and surrounding structures are less compliant and, thus, normal filling pressures generate inadequate diastolic filling. Blood or fluid within the

poorly distensible pericardial sac may cause tamponade (Chap. 222). Any cause of increased intrathoracic pressure, such as tension pneumothorax, herniation of abdominal viscera through a diaphragmatic hernia, or excessive positive pressure ventilation to support pulmonary function, can also cause compressive cardiogenic shock while simultaneously impeding venous return. Acute right heart failure with a sudden decline in cardiac output can be caused by pulmonary embolism obstructing right ventricular outflow and impairing left ventricular filling. Although initially responsive to increased filling pressures produced by volume expansion, as compression increases, cardiogenic shock recurs.

The diagnosis of compressive cardiogenic shock is most frequently based on clinical findings, the chest radiograph, and an echocardiogram. The diagnosis of compressive cardiac shock may be more difficult to establish in the setting of trauma when hypovolemia and cardiac compression are present simultaneously. The classic findings of pericardial tamponade include the triad of hypotension, neck vein distention, and muffled heart sounds (Chap. 222). Pulsus paradoxus, i.e., an inspiratory reduction in systolic pressure >10 mmHg, may also be noted. The diagnosis is confirmed by echocardiography, and treatment consists of immediate pericardiocentesis. A tension pneumothorax produces ipsilateral decreased breath sounds, tracheal deviation away from the affected thorax, and jugular venous distention. Radiographic findings include increased intrathoracic volume, depression of the diaphragm of the affected hemithorax, and shifting of the mediastinum to the contralateral side. Chest decompression must be carried out immediately. Release of air and restoration of normal cardiovascular dynamics are both diagnostic and therapeutic.

SEPTIC SHOCK (See also Chap. 254) This form of shock is caused by the systemic response to a severe infection. It occurs most frequently in elderly or immunocompromised patients and in those who have undergone an invasive procedure in which bacterial contamination has occurred. Infections of the lung, abdomen, or urinary tract are most common, and approximately half of the patients have bacteremia. Gram-positive and -negative bacteria, viruses, fungi, rickettsiae, and protozoa have all been reported to produce the clinical picture of septic shock, and the overall response is generally independent of the specific type of invading organism. The clinical findings in septic shock are a consequence of the combination of metabolic and circulatory derangements driven by the systemic infection and the release of toxic components of the infectious organisms, e.g., the endotoxin of gram-negative bacteria or the exotoxins and enterotoxins of gram-positive bacteria. Organism toxins lead to the release of cytokines, including IL-1 and TNF-α, from tissue macrophages. Tissue factor expression and fibrin deposition are increased, and disseminated intravascular coagulation may develop. The inducible form of NO synthase is stimulated, and NO, a powerful vasodilator, is released. Hemodynamic changes in septic shock occur in two characteristic patterns: early, or hyperdynamic, and late, or hypodynamic, septic shock.

Hyperdynamic Response In hyperdynamic septic shock, tachycardia is present, the cardiac output is normal or elevated, and the systemic vascular resistance is reduced while the pulmonary vascular resistance is elevated. The extremities are usually warm. However, splanchnic vasoconstriction with decreased visceral flow is present. The venous capacitance is increased, which decreases venous return. With volume expansion cardiac output becomes supranormal. Myocardial contractility is depressed in septic shock by mediators including NO, IL-1, and/or TNF-α. Inflammatory mediator–induced processes include increased capillary permeability and continued loss of intravascular volume.

In septic shock, in contrast to other types of shock, total oxygen delivery may be increased while oxygen extraction is reduced due to maldistribution of microcirculatory perfusion and impaired mitochondrial utilization. In this setting the presence of a normal mixed venous oxygen saturation is not indicative of adequate peripheral perfusion, and even though the cardiac output may be elevated, it is still inadequate to meet the total metabolic needs. The toxicity of the infectious agents and their byproducts and the subsequent metabolic dysfunction drive the progressive deterioration of cellular and organ function. ARDS, thrombocytopenia, and neutropenia are common complications.

Hypodynamic Response As sepsis progresses, vasoconstriction occurs and the cardiac output declines. The patient usually becomes markedly tachypneic, febrile, diaphoretic, and obtunded, with cool, mottled, and often cyanotic extremities. Oliguria, renal failure, and hypothermia develop; there may be striking increases in serum lactate.

℞ TREATMENT

Aggressive volume expansion with a crystalloid solution to a PCWP of ~15 mmHg and the restoration of arterial oxygenation with inspired oxygen and frequently with mechanical ventilation are the highest priorities. In the presence of sepsis, augmentation of cardiac output may require inotropic support with dopamine, norepinephrine, or vasopressin in the presence of hypotension or with dobutamine if arterial pressure is normal. High-dose, *a*ctivated *p*rotein *C* (APC) provides a survival benefit in patients with severe sepsis and septic shock. Antibiotics should be administered, either appropriate for the results of cultures or empirical therapy based on the likely source of infection. Surgical debridement or drainage may also be necessary to control the infection.

NEUROGENIC SHOCK Interruption of sympathetic vasomotor input after a high cervical spinal cord injury, inadvertent cephalad migration of spinal anesthesia, or severe head injury may result in neurogenic shock. In addition to arteriolar dilatation, venodilation causes pooling in the venous system, which decreases venous return and cardiac output. The extremities are often warm, in contrast to the usual vasoconstriction-induced coolness in hypovolemic or cardiogenic shock. Treatment involves a simultaneous approach to the relative hypovolemia and to the loss of vasomotor tone. Excessive volumes of fluid may be required to restore normal hemodynamics. Once hemorrhage has been ruled out, norepinephrine may be necessary to augment vascular resistance.

HYPOADRENAL SHOCK (See also Chap. 321) The normal host response to the stress of illness, operation, or trauma requires that the adrenal glands hypersecrete cortisol in excess of that normally required. Hypoadrenal shock occurs in settings in which unrecognized adrenal insufficiency complicates the host response to the stress induced by acute illness or major surgery. Adrenocortical insufficiency may occur as a consequence of the chronic administration of high doses of exogenous glucocorticoids. Recent studies have shown that critical illness, including trauma and sepsis, may also induce a relative hypoadrenal state. Other, less common causes include adrenal insufficiency secondary to idiopathic atrophy, tuberculosis, metastatic disease, bilateral hemorrhage, and amyloidosis. The shock produced by adrenal insufficiency is characterized by reductions in systemic vascular resistance, hypovolemia, and reduced cardiac output. The diagnosis of adrenal insufficiency may be established by means of an ACTH stimulation test.

℞ TREATMENT

In the hemodynamically unstable patient, dexamethasone sodium phosphate, 4 mg, should be given intravenously. This agent is preferred because unlike hydrocortisone it does not interfere with the ACTH stimulation test. If the diagnosis of absolute or relative adrenal insufficiency has been established as shown by non-response to corticotropin stimulation, the patient has a reduced risk of death if treated with hydrocortisone, 100 mg every 6 to 8 h, and tapered as the patient achieves hemodynamic stability. Simultaneous volume resuscitation and pressor support are required.

ADJUNCTIVE THERAPIES

As described above, the sympathomimetic amines dobutamine, dopamine, and norepinephrine are widely used in the treatment of all forms of shock. Arginine-vasopressin (antidiuretic hormone) is also being used increasingly and may better protect vital organ blood flow and prevent pathologic vasodilation.

POSITIONING Positioning of the patient may be a valuable adjunct in the initial treatment of hypovolemic shock. Elevating the foot of the bed (i.e., placing it on "shock blocks") and assumption of the Trendelenburg position without flexion at the knees are effective but may increase work of breathing and risk for aspiration. Simply elevating both legs may be the optimal approach.

PNEUMATIC ANTISHOCK GARMENT (PASG) The PASG and the military antishock trousers (MAST) are inflatable external compression devices that can be wrapped around the legs and abdomen and have been widely used in the prehospital setting as a means of providing temporary support of central hemodynamics in shock. They cause an increase in systemic vascular resistance and blood pressure by arterial compression, without causing a significant change in cardiac output. The most appropriate use appears to be as a means to tamponade bleeding and augment hemostasis. Inflation of the suit provides splinting of fractures of the pelvis and lower extremities and arrests hemorrhage.

REWARMING Hypothermia is a potential adverse consequence of massive volume resuscitation. The infusion of large volumes of refrigerated blood products and room-temperature crystalloid solutions can rapidly drop core temperatures if fluid is not run through warming devices. Hypothermia may depress cardiac contractility and thereby further impair cardiac output and oxygen delivery. Hypothermia, particularly temperatures <35° C, directly impairs the coagulation pathway, sometimes causing a significant coagulopathy. Rapid rewarming to >35° C significantly decreases the requirement for blood products and produces an improvement in cardiac function. The most effective method for rewarming is extracorporeal countercurrent warmers through femoral artery and vein cannulation. This process does not require a pump and can rewarm from 30° to 35°C in <30 min.

254 SEVERE SEPSIS AND SEPTIC SHOCK

Robert S. Munford

DEFINITIONS (See Table 254-1) Animals mount both local and systemic responses to microbes that traverse epithelial barriers and invade underlying tissues. Fever or hypothermia, leukocytosis or leukopenia, tachypnea, and tachycardia are the cardinal signs of the systemic response often called the *systemic inflammatory response syndrome* (SIRS). SIRS may have an infectious or a noninfectious etiology. If infection is suspected or proven, a patient with SIRS is said to have *sepsis*. When sepsis is associated with dysfunction of organs distant from the site of infection, the patient has *severe sepsis*. Severe sepsis may be accompanied by hypotension or evidence of hypoperfusion. When hypotension cannot be corrected by infusing fluids, the diagnosis is *septic shock*. These definitions were proposed by a consensus conference committee in 1992 and are now widely used; there is evidence that the different stages form a continuum. As sepsis progresses to septic shock, the risk of dying increases substantially. Sepsis is usually reversible, whereas patients with septic shock often succumb despite aggressive therapy.

ETIOLOGY Severe sepsis can be a response to any class of microorganism. Microbial invasion of the bloodstream is not essential for the development of severe sepsis, since local inflammation can also elicit distant organ dysfunction and hypotension. In fact, blood cultures yield bacteria or fungi in only ~20 to 40% of cases of severe sepsis and 40 to 70% of cases of septic shock. Individual gram-negative or gram-positive bacteria account for ~70% of these isolates; the remainder are fungi or a mixture of microorganisms (Table 254-2). In patients whose blood cultures are negative, the etiologic agent is often established by culture or microscopic examination of infected material from a local site. In some case series, a majority of patients with a clinical picture of severe sepsis or septic shock have had negative microbiologic data. Factors that predispose to infections with positive blood cultures are listed in (Table 254-3). Among patients who have positive blood cultures, the risk of developing severe sepsis is greater in persons >50 years old and in those with a primary pulmonary, abdominal, or neuromeningeal site of infection.

EPIDEMIOLOGY The septic response is a contributing factor in >200,000 deaths per year in the United States. The incidence of severe sepsis and septic shock has increased over the past 20 years, and the annual number of cases is now >300,000. Approximately two-thirds of cases occur in patients hospitalized for other illnesses. The increasing incidence of severe sepsis in the United States is attributable to the aging of the population, the increasing longevity of patients with chronic diseases, and the relatively high frequency with which sepsis develops in patients with AIDS. The widespread use of antimicrobial agents, glucocorticoids, indwelling catheters and mechanical devices, and mechanical ventilation also plays a role.

PATHOPHYSIOLOGY Most cases of severe sepsis are triggered by bacteria or fungi that do not ordinarily cause systemic disease in immunocompetent hosts (Table 254-2). These microbes probably exploit deficiencies in innate host defenses (e.g., phagocytes, complement, and natural antibodies) to survive within the body. Microbial pathogens, in contrast, are able to circumvent innate defenses by elaborating toxins or other virulence factors. In both cases, the body can fail to kill the invaders despite mounting a vigorous inflammatory reaction that can progress to severe sepsis. The septic response may also be induced by microbial exotoxins that act as superantigens (e.g., toxic shock syndrome toxin 1; Chap. 120).

Host Mechanisms for Sensing Microbes Animals have exquisitely sensitive mechanisms for recognizing and responding to conserved microbial molecules. The lipid A moiety of lipopolysaccharide (LPS, also called *endotoxin*; Chap. 105) is the best-studied example. Lipid A is the bioactive center of the LPS of all gram-negative bacteria found in nature. A host protein (LPS-binding protein, or LBP) binds lipid A and transfers LPS to CD14 on the surfaces of monocytes, macrophages, and neutrophils. LPS and CD14 then interact with toll-like receptor (TLR) 4 and MD-2 to form a molecular complex that transduces the LPS signal to the interior of the cell. This signal rapidly triggers the production and release of mediators, such as tumor necrosis factor (TNF) α (see below), that amplify the LPS signal and transmit it to other cells and tissues. Bacterial peptidoglycan, lipoteichoic acids, DNA, certain polysaccharides, and fimbriae elicit responses in animals that are similar to those induced by LPS; whereas some of

TABLE 254-1 Definitions Used to Describe the Condition of Septic Patients

Bacteremia	Presence of bacteria in blood, as evidenced by positive blood cultures
Septicemia	Presence of microbes or their toxins in blood
Systemic inflammatory response syndrome (SIRS)	Two or more of the following conditions: (1) fever (oral temperature >38°C) or hypothermia (<36°C); (2) tachypnea (>24 breaths/min); (3) tachycardia (heart rate > 90 beats/min); (4) leukocytosis (>12,000/μL), leukopenia (<4,000/μL), or >10% bands; may have a noninfectious etiology
Sepsis	SIRS that has a proven or suspected microbial etiology
Severe sepsis (similar to "sepsis syndrome")	Sepsis with one or more signs of organ dysfunction—for example: 1. *Cardiovascular:* Arterial systolic blood pressure ≤90 mmHg or mean arterial pressure ≤ 70 mmHg that responds to administration of intravenous fluid 2. *Renal:* Urine output < 0.5 mL/kg per hour for 1 h despite adequate fluid resuscitation 3. *Respiratory:* Pa_{O_2}/FI_{O_2} ≤ 250 or, if the lung is the only dysfunctional organ, ≤200 4. *Hematologic:* Platelet count < 80,000/μL or 50% decrease in platelet count from highest value recorded over previous 3 days 5. *Unexplained metabolic acidosis:* A pH ≤ 7.30 or a base deficit ≥ 5.0 mEq/L and a plasma lactate level > 1.5 times upper limit of normal for reporting lab 6. *Adequate fluid resuscitation:* Pulmonary artery wedge pressure ≥ 12 mmHg or central venous pressure ≥ 8 mmHg
Septic shock	Sepsis with hypotension (arterial blood pressure <90 mmHg systolic, or 40 mmHg less than patient's normal blood pressure) for at least 1 h despite adequate fluid resuscitation; *or* Need for vasopressors to maintain systolic blood pressure ≥ 90 mmHg *or* mean arterial pressure ≥ 70 mmHg
Refractory septic shock	Septic shock that lasts for >1 h and does not respond to fluid or pressor administration
Multiple-organ dysfunction syndrome (MODS)	Dysfunction of more than one organ, requiring intervention to maintain homeostasis

Source: Adapted from the American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee and Bernard et al.

these molecules also bind CD14, they interact with several different TLRs. CD14 thus attracts numerous non-self molecules to the surfaces of cells, greatly increasing the sensitivity with which these molecules can be recognized by the host. Having numerous TLR-based receptor complexes (10 different TLRs have been identified so far) allows cells to recognize many conserved microbial molecules. The ability of some of the TLRs to serve as receptors for host ligands (e.g., hyaluronans) raises the possibility that they play a role in producing noninfectious sepsis-like states. Other molecular pattern-recognition proteins that are important for sensing microbial invasion include complement (principally the alternative pathway), mannose-binding lectin, bactericidal permeability-increasing protein, and C-reactive protein.

TABLE 254-2 Microorganisms Involved in Episodes of Severe Sepsis at Eight Academic Medical Centers

Microorganisms	Episodes with Bloodstream Infection, % (n = 436)	Episodes with Documented Infection but No Bloodstream Infection, % (n = 430)	Total Episodes, % (n = 866)
Gram-negative bacteria[a]	35	44	40
Gram-positive bacteria[b]	40	24	31
Fungi	7	5	6
Polymicrobial	11	21	16
Classic pathogens[c]	<5	<5	<5

[a] Enterobacteriaceae, pseudomonads, *Haemophilus* spp., other gram-negative bacteria.
[b] *Staphylococcus aureus*, coagulase-negative staphylococci, enterococci, *Streptococcus pneumoniae*, other streptococci, other gram-positive bacteria.
[c] Such as *Neisseria meningitidis*, *S. pneumoniae*, *H. influenzae*, and *Streptococcus pyogenes*.

TABLE 254-3 Conditions That May Predispose to Infections with Positive Blood Cultures

Microbial Isolate	Condition
Gram-negative bacilli	Diabetes mellitus Lymphoproliferative diseases Cirrhosis of the liver Burns Invasive procedures or devices Neutropenia Indwelling urinary catheter Diverticulitis, perforated viscus
Gram-positive bacteria	Intravascular catheters Indwelling mechanical devices Burns Neutropenia Intravenous drug use Infection with superantigen-producing *Streptococcus pyogenes*
Fungi	Neutropenia Broad-spectrum antimicrobial therapy

Local and Systemic Host Responses to Invading Microbes Recognition of microbial molecules by tissue phagocytes triggers the production and/or release of numerous host molecules (cytokines, chemokines, prostanoids, leukotrienes, and others) that increase blood flow to the infected tissue, enhance the permeability of local blood vessels, recruit neutrophils to the site of infection, and elicit pain. These phenomena are familiar elements of local inflammation, the body's major innate immune mechanism for eliminating microbial invaders. Systemic responses may be activated by neural and/or humoral communication with the hypothalamus and brainstem; these responses may enhance local defenses by increasing blood flow to the infected area, augmenting the number of circulating neutrophils, and elevating blood levels of numerous molecules (such as the microbial recognition proteins discussed above) that have anti-infective functions.

CYTOKINES AND OTHER MEDIATORS Cytokines can exert endocrine, paracrine, and autocrine effects (Chap. 295). TNF-α stimulates leukocytes and vascular endothelial cells to release other cytokines (as well as additional TNF-α), to express cell-surface molecules that enhance neutrophil-endothelial adhesion at sites of infection, and to increase prostaglandin and leukotriene production. Animals that are unable to produce or respond to TNF-α are abnormally susceptible to infection. Whereas blood levels of TNF-α are not elevated in individuals with localized infections, they increase in most patients with severe sepsis or septic shock. Moreover, intravenous infusion of TNF-α can elicit many of the characteristic abnormalities of sepsis, including fever, tachycardia, tachypnea, leukocytosis, myalgias, and somnolence. In animals, larger doses of TNF-α induce shock, disseminated intravascular coagulation (DIC), and death.

Although TNF-α is a central mediator, it is only one of many proinflammatory molecules that contribute to innate host defense. Chemokines, most prominently interleukin (IL) 8, attract circulating neutrophils to the infection site. IL-1β exhibits many of the same activities as TNF-α. TNF-α, IL-1β, interferon γ, IL-12, and other cytokines probably interact synergistically with one another and with additional mediators. Recent evidence suggests that proinflammatory cytokines that circulate in blood often originate in an inflamed local site.

COAGULATION FACTORS Intravascular thrombosis, a hallmark of the local inflammatory response, may help wall off invading microbes and pre-

vent infection and inflammation from spreading to other tissues. Intravascular fibrin deposition, thrombosis, and DIC can also be important features of the systemic response. IL-6 and other mediators promote intravascular coagulation initially by inducing blood monocytes and vascular endothelial cells to express tissue factor (Chap. 53). When tissue factor is expressed on cell surfaces, it binds to factor VIIa to form an active complex that can convert factors X and IX to enzymatically active forms. The result is activation of both extrinsic and intrinsic clotting pathways, culminating in the generation of fibrin. Clotting is also favored by impaired function of the protein C–protein S inhibitory pathway and depletion of antithrombin and protein C, while fibrinolysis is prevented by increased plasma levels of plasminogen activator inhibitor 1. Thus, there may be a striking propensity to intravascular fibrin deposition, thrombosis, and bleeding (Chap. 127). Contact-system activation occurs during sepsis but contributes more to the development of hypotension than to DIC.

CONTROL MECHANISMS Elaborate control mechanisms operate within both local sites of inflammation and the systemic circulation. The available evidence suggests that the body's systemic responses to injury and infection normally prevent inflammation within organs distant from a site of infection.

The signaling apparatus that links microbial recognition to cellular responses is greatly diminished in the blood. Whereas LBP plays a role in recognizing the presence of LPS, for example, in plasma it also prevents LPS signaling by transferring LPS molecules into plasma lipoprotein particles, which sequester the lipid A moiety so that it cannot interact with cells. At concentrations found in blood, LBP also inhibits monocyte responses to LPS, and the soluble (circulating) form of CD14 strips off LPS that has bound to monocyte cell surfaces. The blood concentrations of both LBP and soluble CD14 increase during the response to infection, enhancing the body's ability to prevent activation of blood cells by LPS.

Systemic responses to infection also diminish cellular responses to microbial molecules. Circulating levels of anti-inflammatory cytokines (e.g., IL-6 and IL-10) increase even in patients with mild infections. Glucocorticoids inhibit cytokine synthesis by monocytes in vitro; the increase in blood cortisol levels early in the systemic response presumably plays a similar inhibitory role. Epinephrine inhibits the TNF-α response to endotoxin infusion in humans while augmenting and accelerating the release of IL-10; prostaglandin E_2 has a similar "reprogramming" effect on the responses of circulating monocytes to LPS and other bacterial agonists. Cortisol, epinephrine, IL-10, and C-reactive protein reduce the ability of neutrophils to attach to vascular endothelium, favoring their demargination and thus contributing to leukocytosis while preventing neutrophil-endothelial adhesion in uninflamed organs.

The acute-phase response increases the blood concentrations of numerous molecules that have anti-inflammatory actions. Blood levels of IL-1 receptor antagonist (IL-1Ra) often greatly exceed those of circulating IL-1β, for example, and this excess may result in inhibition of the binding of IL-1β to its receptors. High levels of soluble TNF receptors neutralize TNF-α that enters the circulation. Other acute-phase proteins are protease inhibitors; these may neutralize proteases released from neutrophils and other inflammatory cells.

Organ Dysfunction and Shock As the body's responses to infection intensify, the mixture of circulating cytokines and other molecules becomes very complex: elevated blood levels of more than 50 molecules have been found in patients with septic shock. Although high concentrations of both pro- and anti-inflammatory molecules are found, the net mediator balance in the plasma of these extremely sick patients may actually be anti-inflammatory. In addition, blood leukocytes from patients with severe sepsis are often hyporesponsive to agonists such as LPS. In patients with severe sepsis, persistence of leukocyte hyporesponsiveness has been associated with an increased risk of dying. How the body's pro- and anti-inflammatory forces contribute to hypotension and the dysfunction of organs distant from a site of infection is not known.

ENDOTHELIAL INJURY Most investigators have favored widespread vascular endothelial injury as the major mechanism for multiorgan dysfunction. In keeping with this idea, one study found high numbers of vascular endothelial cells in the peripheral blood of septic patients. Leukocyte-derived mediators and platelet-leukocyte-fibrin thrombi may contribute to vascular injury, but the vascular endothelium also seems to play an active role. Stimuli such as TNF-α induce vascular endothelial cells to produce and release cytokines, procoagulant molecules, platelet-activating factor (PAF), nitric oxide, and other mediators. In addition, regulated cell-adhesion molecules promote the adherence of neutrophils to endothelial cells. While these responses can attract phagocytes to infected sites and activate their antimicrobial arsenals, endothelial cell activation can also promote increased vascular permeability, microvascular thrombosis, DIC, and hypotension.

Tissue oxygenation may be diminished as the number of functional capillaries is reduced by luminal obstruction due to swollen endothelial cells, decreased deformability of circulating erythrocytes, leukocyte-platelet-fibrin thrombi, or compression by edema fluid. One study using orthogonal polarization spectral imaging of the microcirculation in the tongue found that sepsis-associated derangements in capillary flow could be reversed by applying acetylcholine to the surface of the tongue; this observation suggested a neuroendocrine basis for the loss of capillary filling. Cellular ATP and antioxidant stores may become depleted as the production of lactate increases. Programmed cell death may ensue.

SEPTIC SHOCK The hallmark of septic shock is a decrease in peripheral vascular resistance that occurs despite increased levels of vasopressor catecholamines. Cardiac output increases, as does blood flow to peripheral tissues. Oxygen utilization by these tissues may be greatly impaired by maldistribution of blood flow as well as by microcirculatory dysfunction (see above).

Prominent hypotensive molecules include nitric oxide, β-endorphin, bradykinin, PAF, and prostacyclin. Agents that inhibit the synthesis or action of each of these mediators can prevent or reverse endotoxic shock in animals. However, in clinical trials, neither a PAF receptor antagonist nor a bradykinin antagonist improved the survival rate of patients with septic shock, and a nitric oxide synthetase inhibitor, L-N^G-methylarginine HCl, actually increased the mortality rate.

Patients with septic shock often show diminished vasoconstrictor responses to catecholamines. This loss of sensitivity has been attributed to downregulation of adrenergic receptors and to elevated levels of nitric oxide. In patients with septic shock, plasma vasopressin levels do not increase to augment vasoconstriction; in several small series of patients with septic shock, infusion of vasopressin has increased blood pressure and reduced the requirement for catecholamine infusion. Administering hydrocortisone may also improve vascular sensitivity to catecholamines in many patients with septic shock.

Severe Sepsis: A Single Pathogenesis? In some cases, circulating bacteria and their products almost certainly elicit multiorgan dysfunction and hypotension by directly stimulating inflammatory responses within the vasculature. In patients with fulminant meningococcemia, for example, mortality has correlated well with blood endotoxin levels and with the occurrence of DIC (Chap. 127). In most patients with nosocomial infections, in contrast, circulating bacteria or bacterial molecules may reflect uncontrolled infection at a local tissue site and have little or no direct impact on distant organs; in these patients, inflammatory mediators arising from the local site seem to be the key triggers for severe sepsis and septic shock. Support for this concept comes from a study in which *Pseudomonas aeruginosa* bacteremia was induced in rabbits either by constant intravenous infusion of bacteria or by intratracheal inoculation to produce pneumonia. Only the animals with pneumonia developed septic shock. Hypotension occurred only when TNF could move from the lungs into the blood. Shock could be prevented by use of a *P. aeruginosa* strain that did not disrupt alveolar epithelial permeability or by administration of an anti-TNF antibody prior to the

onset of pneumonia. Clinical observations also suggest that uncontrolled local inflammation may drive the septic reaction. In a large series of patients with positive blood cultures, the risk of developing severe sepsis was strongly related to the site of primary infection: bacteremia arising from a pulmonary or abdominal source was eightfold more likely to be associated with severe sepsis than was bacteremic urinary tract infection, even after controlling for age, the kind of bacteria isolated from the blood, and other factors. A third pathogenesis may be represented by severe sepsis due to superantigen-producing *Staphylococcus aureus* or *Streptococcus pyogenes*, since the T cell activation induced by these toxins produces a cytokine profile that differs substantially from that elicited by gram-negative bacterial infection.

In summary, the pathogenesis of severe sepsis may differ according to the infecting microbe, the site of the primary infection, the presence or absence of immune defects, and the prior physiologic status of the host. Genetic factors may also be important. In patients who have sustained major trauma, for example, studies in different ethnic groups have identified associations between allelic polymorphisms in TNF-α and interferon-γ genes and risk of developing severe sepsis. Further studies in this area are needed.

CLINICAL MANIFESTATIONS The manifestations of the septic response are usually superimposed on the symptoms and signs of the patient's underlying illness and primary infection. The rate at which signs and symptoms develop may differ from patient to patient, and there are striking individual variations in presentation. For example, some patients with sepsis are normo- or hypothermic; the absence of fever is most common in neonates, in elderly patients, and in persons with uremia or alcoholism.

Hyperventilation is often an early sign. Disorientation, confusion, and other manifestations of encephalopathy may also develop early in the septic response, particularly in the elderly and in individuals with preexisting neurologic impairment. Focal neurologic signs are uncommon, although preexisting focal deficits may become more prominent.

Hypotension and DIC predispose to acrocyanosis and ischemic necrosis of peripheral tissues, most commonly the digits. Cellulitis, pustules, bullae, or hemorrhagic lesions may develop when hematogenous bacteria or fungi seed the skin or underlying soft tissue. Bacterial toxins may also be distributed hematogenously and elicit diffuse cutaneous reactions. On occasion, skin lesions may suggest specific pathogens. When sepsis is accompanied by cutaneous petechiae or purpura, infection with *Neisseria meningitidis* (or, less commonly, *Haemophilus influenzae*) should be suspected (Fig. 127-1); in a patient who has been bitten by a tick while in an endemic area, petechial lesions also suggest Rocky Mountain spotted fever (Fig. 158-1). A cutaneous lesion seen almost exclusively in neutropenic patients is ecthyma gangrenosum, usually caused by *P. aeruginosa*. It is a bullous lesion, surrounded by edema, that undergoes central hemorrhage and necrosis (see Fig. 136-1). Histopathologic examination shows bacteria in and around the wall of a small vessel, with little or no neutrophilic response. Hemorrhagic or bullous lesions in a septic patient who has recently eaten raw oysters suggest *Vibrio vulnificus* bacteremia, while such lesions in a patient who has recently suffered a dog bite may indicate bloodstream infection due to *Capnocytophaga canimorsus* or *C. cynodegmi*. Generalized erythroderma in a septic patient suggests the toxic shock syndrome due to *S. aureus* or *S. pyogenes*.

Gastrointestinal manifestations such as nausea, vomiting, diarrhea, and ileus may suggest acute gastroenteritis. Stress ulceration can lead to upper gastrointestinal bleeding. Cholestatic jaundice, with elevated levels of serum bilirubin (mostly conjugated) and alkaline phosphatase, may precede other signs of sepsis. Hepatocellular or canalicular dysfunction appears to underlie most cases, and the results of hepatic function tests return to normal with resolution of the infection. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

Many tissues may be unable to extract oxygen normally from the blood, so that anaerobic metabolism occurs despite near-normal mixed venous oxygen saturation. Blood lactate levels rise early, in part because of increased glycolysis with impaired clearance of the resulting lactate and pyruvate by the liver and kidneys. As hypoperfusion develops, tissue hypoxia generates more lactic acid, contributing to metabolic acidosis. The blood glucose concentration often increases, particularly in patients with diabetes, although impaired gluconeogenesis and excessive insulin release on occasion produce hypoglycemia. The cytokine-driven acute-phase response inhibits the synthesis of transthyretin while enhancing the production of C-reactive protein, fibrinogen, and complement components. Protein catabolism is often markedly accelerated.

MAJOR COMPLICATIONS ■ Cardiopulmonary Complications Ventilation-perfusion mismatching produces a fall in arterial P_{O_2} early in the course. Increasing alveolar capillary permeability results in an increased pulmonary water content, which decreases pulmonary compliance and interferes with oxygen exchange. Progressive diffuse pulmonary infiltrates and arterial hypoxemia (Pa_{O_2}/FI_{O_2}, < 200) indicate the development of the acute respiratory distress syndrome (ARDS). ARDS develops in ~50% of patients with severe sepsis or septic shock. The failure of the respiratory muscles can exacerbate hypoxemia and hypercapnia. An elevated pulmonary capillary wedge pressure (>18 mmHg) suggests fluid volume overload or cardiac failure rather than ARDS. Pneumonia caused by viruses or by *Pneumocystis* may be clinically indistinguishable from ARDS.

Sepsis-induced hypotension (see "Septic Shock," above) usually results from a generalized maldistribution of blood flow and blood volume and from hypovolemia that is due, at least in part, to diffuse capillary leakage of intravascular fluid. Other factors that may decrease effective intravascular volume include dehydration from antecedent disease or insensible fluid losses, vomiting or diarrhea, and polyuria. During early septic shock, systemic vascular resistance is usually elevated and cardiac output may be low. After fluid repletion, in contrast, cardiac output typically increases and systemic vascular resistance falls. Indeed, normal or increased cardiac output and decreased systemic vascular resistance distinguish septic shock from cardiogenic, extracardiac obstructive, and hypovolemic shock; other processes that can produce this combination include anaphylaxis, beriberi, cirrhosis, and overdoses of nitroprusside or narcotics.

Depression of myocardial function, manifested as increased end-diastolic and systolic ventricular volumes with a decreased ejection fraction, develops within 24 h in most patients with severe sepsis. Cardiac output is maintained despite the low ejection fraction because ventricular dilatation permits a normal stroke volume. In survivors, myocardial function returns to normal over several days. Although myocardial dysfunction may contribute to hypotension, refractory hypotension is usually due to a low systemic vascular resistance, and death results from refractory shock or the failure of multiple organs rather than from cardiac dysfunction per se.

Renal Complications Oliguria, azotemia, proteinuria, and nonspecific urinary casts are frequently found. Many patients are inappropriately polyuric; hyperglycemia may exacerbate this tendency. Most renal failure is due to acute tubular necrosis induced by hypotension or capillary injury, although some patients also have glomerulonephritis, renal cortical necrosis, or interstitial nephritis. Drug-induced renal damage may complicate therapy, particularly when hypotensive patients are given aminoglycoside antibiotics.

Coagulation Although thrombocytopenia occurs in 10 to 30% of patients, the underlying mechanisms are not understood. Platelet counts are usually very low (<50,000/μL) in patients with DIC; these low counts may reflect diffuse endothelial injury or microvascular thrombosis.

Neurologic Complications When the septic illness lasts for weeks to months, "critical-illness" polyneuropathy may prevent weaning from ventilatory support and produce distal motor weakness. Electrophys-

iologic studies are diagnostic. Guillain-Barré syndrome, metabolic disturbances, and toxin activity must be ruled out.

LABORATORY FINDINGS Abnormalities that occur early in the septic response may include leukocytosis with a left shift, thrombocytopenia, hyperbilirubinemia, and proteinuria. Leukopenia may develop. The neutrophils may contain toxic granulations, Döhle bodies, or cytoplasmic vacuoles. As the septic response becomes more severe, thrombocytopenia worsens (often with prolongation of the thrombin time, decreased fibrinogen, and the presence of D-dimers, suggesting DIC), azotemia and hyperbilirubinemia become more prominent, and levels of aminotransferases rise. Active hemolysis suggests clostridial bacteremia, malaria, a drug reaction, or DIC; in the case of DIC, microangiopathic changes may be seen on a blood smear.

During early sepsis, hyperventilation induces respiratory alkalosis. With respiratory muscle fatigue and the accumulation of lactate, metabolic acidosis (with increased anion gap) typically supervenes. Evaluation of arterial blood gases reveals hypoxemia, which is initially correctable with supplemental oxygen but whose later refractoriness to 100% oxygen inhalation indicates right-to-left shunting. The chest radiograph may be normal or may show evidence of underlying pneumonia, volume overload, or the diffuse infiltrates of ARDS. The electrocardiogram may show only sinus tachycardia or nonspecific ST–T-wave abnormalities.

Most diabetic patients with sepsis develop hyperglycemia. Severe infection may precipitate diabetic ketoacidosis, which may exacerbate hypotension (Chap. 323). Hypoglycemia occurs rarely. The serum albumin level, initially within the normal range, declines as sepsis continues. Serum lipid concentrations are often elevated. Hypocalcemia is rare.

DIAGNOSIS There is no specific diagnostic test for the septic response. Diagnostically sensitive findings in a patient with suspected or proven infection include fever or hypothermia, tachypnea, tachycardia, and leukocytosis or leukopenia (Table 254-1); acutely altered mental status, thrombocytopenia, or hypotension also suggests the diagnosis. The septic response can be quite variable, however. In one study, 36% of patients with severe sepsis had a normal temperature, 40% had a normal respiratory rate, 10% had a normal pulse rate, and 33% had normal white blood cell counts. Moreover, the systemic responses of uninfected patients with other conditions may be similar to those characteristic of sepsis. Noninfectious etiologies of SIRS (Table 254-1) include pancreatitis, burns, trauma, adrenal insufficiency, pulmonary embolism, dissecting or ruptured aortic aneurysm, myocardial infarction, occult hemorrhage, cardiac tamponade, post-cardiopulmonary bypass syndrome, anaphylaxis, and drug overdose.

Definitive etiologic diagnosis requires isolation of the microorganism from blood or a local site of infection. At least two blood samples (10 mL each) should be obtained (from different venipuncture sites) for culture. Because gram-negative bacteremia is typically low-grade (<10 organisms per milliliter of blood), multiple blood cultures or prolonged incubation of cultures may be necessary; *S. aureus* grows more readily and is detectable in blood cultures within 48 h in most instances. In many cases, blood cultures are negative; this result can reflect prior antibiotic administration, the presence of slow-growing or fastidious organisms, or the absence of microbial invasion of the bloodstream. In these cases, Gram's staining and culture of material from the primary site of infection or of infected cutaneous lesions may help establish the microbial etiology. The skin and mucosae should be examined carefully and repeatedly for lesions that might yield diagnostic information. With overwhelming bacteremia (e.g., pneumococcal sepsis in splenectomized individuals or fulminant meningococcemia), microorganisms are sometimes visible on buffy coat smears of peripheral blood.

Detection of endotoxin in blood by the limulus lysate test may portend a poor outcome, but this assay is not useful for diagnosing gram-negative bacterial infections, including gram-negative bacteremia. Although blood levels of IL-6 may also correlate with prognosis, cytokine assays are poorly standardized and currently have limited clinical value.

TREATMENT

Patients in whom sepsis is suspected must be managed expeditiously. This task is best accomplished by personnel who are experienced in the care of the critically ill. Successful management requires urgent measures to treat the local site of infection, to provide hemodynamic and respiratory support, and to eliminate the offending microorganism. The outcome is also influenced by the patient's underlying disease, which should be managed aggressively.

ANTIMICROBIAL AGENTS Antimicrobial chemotherapy should be initiated as soon as samples of blood and other relevant sites have been cultured. The choice of initial therapy is based on knowledge of the likely pathogens at specific sites of local infection. Available information about patterns of antimicrobial susceptibility among bacterial isolates from the community, the hospital, and the patient also should be taken into account. It is important, pending culture results, to initiate empirical antimicrobial therapy that is effective against both gram-positive and gram-negative bacteria (Table 254-4). Maximal recommended doses of antimicrobial drugs should be given intravenously, with adjustment for impaired renal function when necessary. When culture results become available, the regimen can often be simplified, as a single antimicrobial agent is frequently adequate for the treatment of a known pathogen. Most patients require antimicrobial therapy for at least 1 week; the duration of treatment is typically influenced by factors such as the site of tissue infection, the adequacy of surgical drainage, the patient's underlying disease, and the antimicrobial susceptibility of the bacterial isolate(s).

REMOVAL OF THE SOURCE OF INFECTION Removal or drainage of a focal source of infection is essential. Sites of occult infection should be sought carefully. Indwelling intravenous catheters should be removed, the tip rolled over a blood agar plate for quantitative culture, and a new catheter inserted at a different site. Foley and drainage catheters should be replaced. The possibility of paranasal sinusitis (often caused by gram-negative bacteria) should be considered if the patient has undergone nasal intubation. In patients with extensive abnormalities on chest radiographs, computed tomography (CT) of the chest may identify unsuspected parenchymal, mediastinal, or pleural disease. In the neutropenic patient, cutaneous sites of tenderness and erythema, particularly in the perianal region, must be carefully sought. In patients with sacral or ischial decubitus ulcers, it is important to exclude pelvic or other soft tissue pus collections (by CT or magnetic resonance imaging, if necessary). In patients with severe sepsis arising from the urinary tract, sonography or CT should be used to rule out ureteral obstruction, perinephric abscess, and renal abscess. These studies are not so urgent in patients with less severe urosepsis, provided that a clinical response is evident within 48 to 72 h.

HEMODYNAMIC, RESPIRATORY, AND METABOLIC SUPPORT The primary goal is to restore adequate oxygen and substrate delivery to the tissues. Adequate organ perfusion is essential. Effective intravascular volume depletion is common in patients with sepsis, and initial management of hypotension should include the administration of intravenous fluids, typically 1 to 2 L of normal saline over 1 to 2 h. To avoid pulmonary edema, the pulmonary capillary wedge pressure should be maintained between 12 and 16 mmHg or the central venous pressure between 8 and 12 cmH_2O. The urine output rate should be kept at >0.5 mL/kg per hour by continuing fluid administration; a diuretic such as furosemide may be used if needed. In about one-third of patients, hypotension and organ hypoperfusion respond to fluid resuscitation; a reasonable goal is to maintain a mean arterial blood pressure of >65 mmHg (systolic pressure, >90 mmHg) and a cardiac index of ≥4 L/min per m^2. If these guidelines cannot be met by volume infusion, inotropic and vasopressor therapy is indicated. Circulatory adequacy is also assessed by clinical parameters (mentation, urine output, skin

perfusion) and, when possible, by measurements of oxygen delivery and consumption. A recent study found that prompt resuscitative measures, including maintenance of central venous oxygen saturation at >70% (by administration of dobutamine, if needed), were associated with significantly improved survival in patients who were admitted to the emergency department with severe sepsis.

Adrenal insufficiency should be considered in septic patients with refractory hypotension, fulminant *N. meningitidis* bacteremia, prior glucocorticoid use, disseminated tuberculosis, or AIDS. The cosyntropin ($\alpha^{1\text{-}24}$-ACTH) stimulation test (Chap. 321) may suggest absolute or partial adrenal insufficiency. Supplemental hydrocortisone (50 mg intravenously every 6 h) may be given while the results of the cosyntropin test are awaited (see "Antimediator Agents," below).

Plasma vasopressin levels do not increase in patients with septic shock. Recent studies have found that vasopressin infusion can reverse septic shock in some patients, reducing or eliminating the need for catecholamine pressors. An adequately powered and randomized trial of vasopressin infusion has not been performed, however, and its impact on end-organ function and survival is not known.

TABLE 254-4 *Initial Antimicrobial Therapy for Severe Sepsis with No Obvious Source in Adults with Normal Renal Function*

Clinical Condition	Antimicrobial Regimens (Intravenous Therapy)
Immunocompetent adult	The many acceptable regimens include (1) ceftriaxone (2 g q24h) *or* ticarcillin-clavulanate (3.1 g q4–6h) *or* piperacillin-tazobactam (3.375 g q4–6h); (2) imipenem-cilastatin (0.5 g q6h) *or* meropenem (1 g q8h) *or* cefepime (2 g q12h). Gentamicin *or* tobramycin (5–7 mg/kg q24h) may be *added* to either regimen. If the patient is allergic to β-lactam agents, use ciprofloxacin (400 mg q12h) *or* levofloxacin (500–750 mg q12h) *plus* clindamycin (600 mg q8h). If the institution has a high incidence of MRSA infections, add vancomycin (15 mg/kg q12h) to each of the above regimens.
Neutropenia[a] (<500 neutrophils/μL)	Regimens include (1) imipenem-cilastatin (0.5 g q6h) *or* meropenem (1 g q8h) *or* cefepime (2 g q8h); (2) ticarcillin-clavulanate (3.1 g q4h) *or* piperacillin-tazobactam (3.375 g q4h) *plus* tobramycin (5–7 mg/kg q24h). Vancomycin (15 mg/kg q12h) and cefepime should be used if the patient has an infected vascular catheter, if staphylococci are suspected, if the patient has received quinolone prophylaxis, if the patient has received intensive chemotherapy that produces mucosal damage, or if the institution has a high incidence of MRSA infections.
Splenectomy	Cefotaxime (2 g q6–8h) *or* ceftriaxone (2 g q12h) should be used. If the local prevalence of cephalosporin-resistant pneumococci is high, *add* vancomycin. If the patient is allergic to β-lactam drugs, vancomycin (15 mg/kg q12h) *plus* ciprofloxacin (400 mg q12h) *or* levofloxacin (750 mg q12h) *or* aztreonam (2 g q8h) should be used.
IV drug user	Nafcillin or oxacillin (2 g q8h) plus gentamicin (5–7 mg/kg q24h). If the local prevalence of MRSA is high or if the patient is allergic to β-lactam drugs, vancomycin (15 mg/kg q12h) with gentamicin should be used.
AIDS	Cefepime (2 g q8h), ticarcillin-clavulanate (3.1 g q4h), *or* piperacillin-tazobactam (3.375 g q4h) *plus* tobramycin (5–7 mg/kg q24h) should be used. If the patient is allergic to β-lactam drugs, ciprofloxacin (400 mg q12h) *or* levofloxacin (750 mg q12h) *plus* vancomycin (15 mg/kg q12h) *plus* tobramycin should be used.

[a] Adapted in part from WT Hughes et al: Clin Infect Dis 25:551, 1997.
Note: MRSA, methicillin-resistant *Staphylococcus aureus*.

Ventilator therapy is indicated for progressive hypoxemia, hypercapnia, neurologic deterioration, or respiratory muscle failure. Sustained tachypnea (respiratory rate, >30 breaths/min) is frequently a harbinger of impending respiratory collapse; mechanical ventilation is often initiated to ensure adequate oxygenation, divert blood from the muscles of respiration, prevent aspiration of oropharyngeal contents, and reduce the cardiac afterload. Erythrocyte transfusion is indicated if oxygen delivery is compromised by a low hemoglobin concentration (<7 g/dL).

Bicarbonate is sometimes administered for severe metabolic acidosis (arterial pH <7.2). DIC, if complicated by major bleeding, should be treated with transfusion of fresh-frozen plasma and platelets. Successful treatment of the underlying infection is essential to reverse both acidosis and DIC.

GENERAL SUPPORT In patients with prolonged severe sepsis (i.e., that lasting more than 2 or 3 days), nutritional supplementation may reduce the impact of protein hypercatabolism; available evidence favors the enteral delivery route. Recovery is also assisted by preventing skin breakdown, deep venous thrombosis, nosocomial infections, and stress ulcers.

OTHER MEASURES Despite aggressive management, many patients with severe sepsis or septic shock die. Three kinds of agents that may help prevent these deaths are being investigated: (1) drugs that neutralize bacterial endotoxin, thereby potentially benefiting the fraction (approximately half) of septic patients who have gram-negative bacterial infection; (2) anti-inflammatory drugs that interfere with one or more mediators of the inflammatory response; and (3) anticoagulant drugs intended to prevent or reverse microthrombosis.

Antiendotoxin Agents Despite much effort to develop drugs that neutralize endotoxin in vivo, the potential of endotoxin as a target for therapeutic intervention remains controversial. In placebo-controlled clinical trials, two monoclonal antibodies to endotoxin did not prevent the death of patients with severe gram-negative bacterial sepsis. These antibodies did not bind to LPS with high affinity, and one was later reported to be a polyreactive autoantibody. A theoretically more promising agent is bactericidal permeability-increasing (BPI) protein, a human neutrophil protein that neutralizes lipid A and may be lethal for many gram-negative bacteria. In one clinical trial, infusion of BPI protein decreased the incidence of severe thrombotic events among children with fulminant meningococcemia. Other investigational drugs include nontoxic lipid A analogues that reduce host responses to endotoxins by competing with lipid A for interaction with the TLR4 signaling complex.

Antimediator Agents Other adjunctive therapies are intended to control the inflammatory response, regardless of the microbial stimulus. However, numerous agents that directly or indirectly interfere with the actions of inflammatory mediators have not prevented the death of patients with severe sepsis or septic shock. Many factors have probably contributed to the unsuccessful outcomes of these trials, including problems with study design (inappropriate end points, inadequate sample size, population heterogeneity, multiple covariates) and drug administration (wrong dose, time, or duration of administration). Anti-inflammatory drugs tested in clinical trials include methylprednisolone, dexamethasone, ibuprofen, PAF antagonists, recombinant IL-1Ra, genetically engineered soluble receptors for TNF-α, and monoclonal antibodies to TNF-α.

Whereas large doses of glucocorticoids have not improved survival, recent evidence suggests that many septic patients have inadequate adrenal reserve and that these individuals may benefit from low doses of glucocorticoid and mineralocorticoid. A recent study measured each patient's plasma cortisol response to a bolus infusion of 250 μg of synthetic ACTH. In the study population of severely septic patients, an increment of $\leq$9 μg/dL correlated with partial adrenal insufficiency and identified a group of patients who benefited from the

administration of hydrocortisone (50 mg intravenously every 6 h) and 9-α-fludrocortisone (50 μg/d via nasogastric tube) for 7 days. The 28-day mortality was 53% among adrenal-deficient (nonresponder) patients who received combined steroid therapy and 63% in the placebo group ($p < .02$). Patients who had normal adrenal reserve did not benefit from steroid administration. Although these results have not been confirmed in a second clinical trial, the strategy has a strong physiologic rationale.

Anticoagulant Agents Recombinant activated protein C (aPC) recently became the first drug to be approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with severe sepsis or septic shock. In a randomized controlled trial in which drug or placebo was given within 24 h of the patient's first sepsis-related organ dysfunction, 28-day mortality was significantly lower among recipients of aPC than among patients who received placebo (24.7% vs. 30.8%; $p < .005$). In addition, aPC recipients were more likely than placebo recipients to have severe bleeding (3% vs. 2%). Survival improved only for patients who had an APACHE II score of ≥25 during the 24 h before initiation of aPC infusion. Specifically, the FDA has approved aPC for use in adults (>18 years of age) who meet the APACHE II criterion and have a low risk of hemorrhage-related side effects. The drug is administered as a constant intravenous infusion of 24 μg/kg per hour for 96 h. Each patient's clotting parameters must be monitored carefully. Intracranial hemorrhage, the most serious complication noted to date, has occurred infrequently but seems to be more common among patients with platelet counts of <30,000/μL or meningitis at the time of infusion.

The long-term impact of aPC treatment is uncertain. In the pivotal clinical trial, the treatment and placebo groups did not differ significantly in the percentage of patients who had been discharged from the hospital by treatment day 28. Long-term survival data have not been released by the sponsor. Although the theoretical rationale for treating septic patients with anticoagulants is strong, two other human anticoagulant proteins (antithrombin III and tissue factor pathway inhibitor) did not improve patient survival in recent clinical trials, and the apparent efficacy of aPC did not correlate with preinfusion blood levels of protein C or other clotting parameters. In vitro studies suggest that aPC has anti-inflammatory activities that could contribute to its therapeutic effect.

Studies are needed to determine the relative benefits of hydrocortisone and mineralocorticoid treatment (in patients with adrenal insufficiency), vasopressin, and aPC and to learn how these agents should best be used—singly, together, or in combination with other agents.

PROGNOSIS Approximately 20 to 35% of patients with severe sepsis and 40 to 60% of patients with septic shock die within 30 days. Others die within the ensuing 6 months. Late deaths often result from poorly controlled infection, complications of intensive care, failure of multiple organs, or the patient's underlying disease.

Prognostic stratification systems such as APACHE II indicate that factoring in the patient's age, underlying condition, and various physiologic variables can yield estimates of the risk of dying of severe sepsis. Of the individual covariates, the severity of underlying disease most strongly influences the risk of dying. Septic shock is also a strong predictor of short- and long-term mortality. Case-fatality rates are similar for culture-positive and culture-negative severe sepsis.

PREVENTION Prevention offers the best opportunity to reduce morbidity and mortality. In developed countries, most episodes of severe sepsis and septic shock are complications of nosocomial infections. These cases might be prevented by reducing the number of invasive procedures undertaken, by limiting the use (and duration of use) of indwelling vascular and bladder catheters, by reducing the incidence and duration of profound neutropenia (<500 neutrophils/μL), and by more aggressively treating localized nosocomial infections. Indiscriminate use of antimicrobial agents and glucocorticoids should be avoided, and optimal infection-control measures (Chap. 116) should be used. Several studies point to associations between allelic polymorphisms in cytokine genes and risk of developing severe sepsis; if these associations prove to be broadly applicable, such polymorphisms can be used prospectively to identify high-risk patients and to target preventive and/or therapeutic measures to them. Studies indicate that 50 to 70% of patients who develop nosocomial severe sepsis or septic shock have experienced a less severe stage of the septic response (e.g., SIRS, sepsis) on at least one previous day in the hospital. Research is needed to develop adjunctive agents that can damp the septic response before organ dysfunction or hypotension occurs.

255 CARDIOGENIC SHOCK AND PULMONARY EDEMA

Judith S. Hochman, David Ingbar

Cardiogenic shock and pulmonary edema are life-threatening conditions that should be treated as medical emergencies. The most common etiology for both is severe left ventricular (LV) dysfunction, leading to pulmonary congestion and/or systemic hypoperfusion (Fig. 255-1). ***→The pathophysiology of pulmonary edema and shock are discussed in Chaps. 29 and 253, respectively.***

CARDIOGENIC SHOCK

Cardiogenic shock (CS) is characterized by systemic hypoperfusion due to severe depression of the cardiac index [<2.2 (L/min)/m^2] and sustained systolic arterial hypotension (<90 mmHg), despite an elevated filling pressure [pulmonary capillary wedge pressure (PCWP) > 18 mmHg]. It is associated with in-hospital mortality rates >50%. The major causes of CS are listed in Table 255-1. Circulatory failure based on cardiac dysfunction may be caused by primary myocardial failure, most commonly secondary to acute myocardial infarction (MI) (Chap. 228), and less frequently by cardiomyopathy or myocarditis (Chap. 221) or cardiac tamponade (Chap. 222).

INCIDENCE CS is the leading cause of death of patients hospitalized with MI. Early reperfusion therapy for acute MI decreases the incidence of CS. The rate of CS complicating acute MI fell from 20% in the 1960s but has plateaued at ~8% for over 20 years. Shock is typically associated with ST elevation MI and is less common with non-ST elevation MI (Chap. 228).

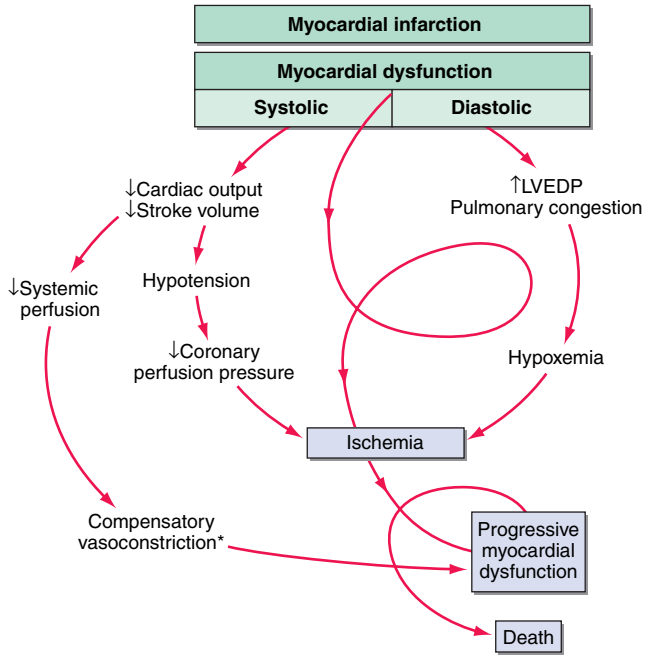

FIGURE 255-1 Pathophysiology of cardiogenic shock. Systolic and diastolic myocardial dysfunction result in a reduction in cardiac output and often pulmonary congestion. Systemic and coronary hypoperfusion occur, resulting in progressive ischemia. Although a number of compensatory mechanisms are activated in an attempt to support the circulation, these compensatory mechanisms may become maladaptive and produce a worsening of hemodynamics. *Release of inflammatory cytokines after myocardial infarction may lead to inducible nitrous oxide expression, excess NO, and inappropriate vasodilation. This causes further reduction in systemic and coronary perfusion. A vicious spiral of progressive myocardial dysfunction occurs that ultimately results in death if it is not interrupted. LVEDP, left ventricular end-diastolic pressure. (*From SM Hollenberg et al: Ann Intern Med 131:47, 1999.*)

LV failure accounts for ~80% of the cases of CS complicating acute MI. Acute severe mitral regurgitation (MR), ventricular septal rupture (VSR), predominant right ventricular (RV) failure, and free wall rupture or tamponade account for the remainder.

PATHOPHYSIOLOGY CS is characterized by a vicious circle in which depression of myocardial contractility, usually due to ischemia, results in reduced cardiac output and arterial pressure, which result in hypoperfusion of the myocardium and further ischemia and depression of the cardiac output (Fig. 255-1). Systolic myocardial dysfunction reduces stroke volume and, together with diastolic dysfunction, leads to elevated LV end-diastolic pressure and PCWP as well as to pulmonary congestion. Reduced coronary perfusion leads to worsening ischemia and progressive myocardial dysfunction and a rapid downward spiral, which, if uninterrupted, is often fatal. A systemic inflammatory response syndrome may accompany large infarctions and shock. Inflammatory cytokines, inducible nitric oxide synthase, and excess nitric oxide and peroxynitrite may contribute to the genesis of CS as they do to other forms of shock (Chap. 253). Hypoxemia and lactic acidosis develop as a result of pump failure and then contribute to the vicious circle by worsening myocardial ischemia and hypotension. Severe acidosis (pH <7.25) reduces the efficacy of endogenous and exogenously administered catecholamines. Refractory sustained ventricular or atrial tachyarrhythmias can cause or exacerbate CS.

Autopsy specimens often reflect the stuttering course and piecemeal necrosis of the left ventricle, often showing varying stages of infarction. Reinfarction is apparent as new areas of necrosis contiguous with or remote from a slightly older infarct. Typically, at least 40% of the LV myocardium is damaged by a combination of old scar and new infarcts. Infarctions that extend through the full myocardial thickness and result in rupture of the interventricular septum, papillary muscle, or ventricular free wall may result in shock (Chap. 228 and p. 1616).

PATIENT PROFILE In patients with acute MI, older age, female sex, prior MI, diabetes, and anterior MI location are all associated with increased risk of CS. Shock associated with a first inferior MI should prompt a search for a mechanical cause. In patients with non-ST elevation acute coronary syndrome (ACS), prior heart failure (HF), coronary artery bypass graft (CABG) surgery, and peripheral vascular disease are additional important risk factors. Reinfarction soon after MI increases the risk of CS. Severe and extensive coronary artery atherosclerotic lesions are typically present in MI patients who develop shock. Two-thirds of patients with CS have flow-limiting stenoses in all three major coronary arteries, and 20% have left main coronary artery stenosis.

TIMING Shock is present on admission in only 10 to 15% of patients who develop CS complicating MI; one-half develop it rapidly thereafter, within 6 h of MI onset. Another quarter develop shock later on the first day. Subsequent onset of CS may be due to reinfarction, marked infarct expansion, or a mechanical complication.

DIAGNOSIS Due to the unstable condition of these patients, supportive therapy must be initiated simultaneously with diagnostic evaluation (Fig. 255-2). A focused history and physical examination should be performed, blood specimens sent to the laboratory, and an electrocardiogram and chest x-ray obtained. A two-dimensional echocardiogram with color flow Doppler is an invaluable diagnostic tool in patients suspected of CS.

Clinical Findings Most patients have continuing chest pain and dyspnea and appear pale, apprehensive, cyanotic, and diaphoretic. Mentation may be altered, with varying degrees of somnolence, confusion, and

TABLE 255-1 Etiologies of Cardiogenic Shock (CS)[a] and Cardiogenic Pulmonary Edema[b]

ETIOLOGIES OF CARDIOGENIC SHOCK OR PULMONARY EDEMA
Acute myocardial infarction/ischemia
LV failure
VSR
Papillary muscle/chordal rupture—severe MR
Ventricular free wall rupture with subacute tamponade
Other conditions complicating large MIs
Hemorrhage
Infection
Excess negative inotropic or vasodilator medications
Prior valvular heart disease
Hyperglycemia/ketoacidosis
Post-cardiac arrest
Post-cardiotomy
Refractory sustained tachyarrhythmias
Acute fulminant myocarditis
End-stage cardiomyopathy
Hypertrophic cardiomyopathy with severe outflow obstruction
Aortic dissection with aortic insufficiency or tamponade
Pulmonary embolus
Severe valvular heart disease
Critical aortic or mitral stenosis
Acute severe aortic or MR
Toxic-metabolic
Beta-blocker or calcium channel antagonist overdose
OTHER ETIOLOGIES OF CARDIOGENIC SHOCK[c]
RV failure due to:
Acute myocardial infarction
Acute coronary pulmonale
Refractory sustained bradyarrhythmias
Pericardial tamponade
Toxic/metabolic
Severe acidosis, severe hypoxemia

[a] The etiologies of CS are listed. Most of these can cause pulmonary edema instead of shock or pulmonary edema with CS.
[b] Etiologies of noncardiogenic pulmonary edema are in Chap. 29.
[c] These cause CS but not pulmonary edema.
Note: LV, left ventricular; VSR, ventricular septal rupture; MR, mitral regurgitation; RV, right ventricular.

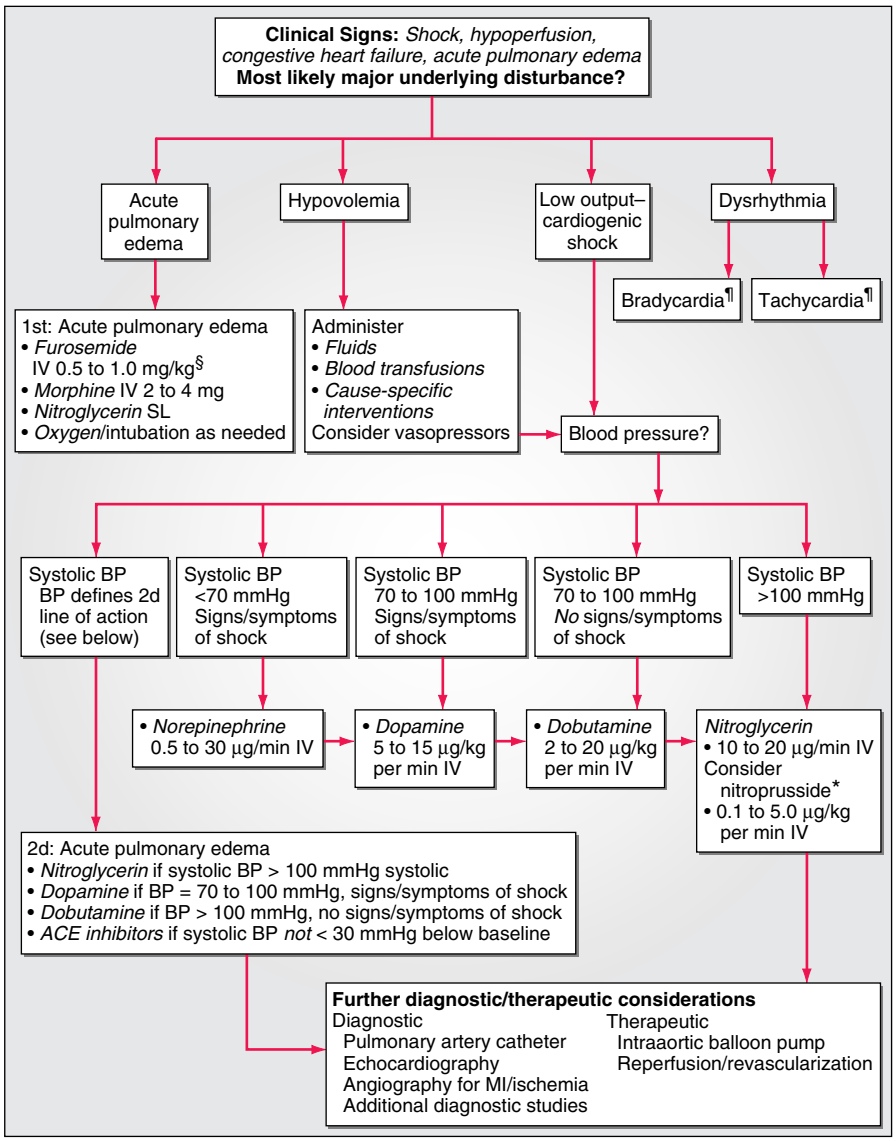

FIGURE 255-2 The emergency management of patients with cardiogenic shock, acute pulmonary edema, or both is outlined. *Nitroprusside is contraindicated in states of reduced coronary artery perfusion. §Furosemide: <0.5 mg/kg for new-onset acute pulmonary edema without hypervolemia; 1 mg/kg for acute on chronic volume overload, renal insufficiency. ¶For management of bradycardia and tachycardia, see Chaps. 213 and 214. ACE, angiotensin-converting enzyme; BP, blood pressure; MI, myocardial infarction. *[Modified from Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Part 7: The Era of Reperfusion. Section 1: Acute Coronary Syndromes (Acute Myocardial Infarction). Circulation 102 (suppl I): I-172, 2000. Reprinted with permission from Circulation].*

agitation. The pulse is typically weak and rapid, often in the range of 90 to 110 beats/min, or severe bradycardia due to high-grade heart block may be present. Systolic arterial pressure is reduced (<90 mmHg) with a narrow pulse pressure (<30 mmHg), but occasionally arterial pressure may be maintained by very high systemic vascular resistance. Tachypnea, Cheyne-Stokes respirations, and jugular venous distention may be present. The precordium is typically quiet, with a weak apical pulse. S1 is usually soft, and an S3 gallop may be audible. Acute, severe MR and VSR are usually associated with characteristic systolic murmurs (Chap. 228). Rales are audible in most patients with LV failure causing CS. Oliguria (urine output < 30 mL/h) is common.

Laboratory Findings The white blood cell count is typically elevated with a left shift. In the absence of prior renal insufficiency, renal function is initially normal, but blood urea nitrogen and creatinine rise progressively. Hepatic transaminases may be markedly elevated due to liver hypoperfusion. Lactic acid levels are elevated in severe shock, and electrolytes may reflect anion-gap acidosis. Prior to ventilatory support with supplemental O_2, arterial blood gases usually demonstrate hypoxemia and metabolic acidosis, which may be compensated by respiratory alkalosis. Cardiac markers, creatine phosphokinase and its MB fraction, are markedly elevated, as are troponins I and T.

Electrocardiogram In CS due to acute MI with LV failure, Q waves and/or >2-mm ST elevation in multiple leads or left bundle branch block are usually present. More than one-half of all infarcts associated with shock are anterior. Global ischemia due to severe left main stenosis is usually accompanied by severe (e.g., >3 mm) ST depressions in multiple leads.

The chest x-ray typically shows pulmonary vascular congestion and often pulmonary edema, but these findings may be absent in up to a third of patients. The heart size is usually normal when CS results from a first MI but is enlarged when it occurs in a patient with a previous MI.

Echocardiogram A two-dimensional echocardiogram with color flow Doppler (Chap. 211) should be obtained promptly in patients with suspected CS to help define its etiology. Doppler mapping demonstrates a left-to-right shunt in patients with VSR and the severity of MR when the latter is present. Proximal aortic dissection with aortic regurgitation or tamponade may be visualized or evidence for pulmonary embolism obtained (Chap. 244).

Pulmonary Artery Catheterization There is controversy regarding the use of pulmonary artery balloon flotation (Swan-Ganz) catheters in patients with established or suspected CS (Chaps. 212 and 249). However, given the ominous prognosis, their use is generally recommended for measurement of filling pressures and cardiac output to confirm the diagnosis and help optimize use of intravenous fluids, inotropic agents, and vasopressors (Table 255-2). Blood samples for O_2 saturation measurement should be obtained from the right atrium, right ventricle, and pulmonary artery to rule out a left-to-right shunt. Mixed venous O_2 saturations are low and arterial-venous O_2 differences are elevated, reflecting increased O_2 extraction and low cardiac index, and the PCWP is elevated. However, these measurements, as well as systemic arterial pressure, may have returned toward normal in the presence of sympathomimetic amines. Systemic vascular resistance may be normal or elevated in CS. Equalization of right- and left-sided filling pressures (right atrial and PCWP) suggests cardiac tamponade as the cause of CS (Chap. 222).

Left Heart Catheterization and Coronary Angiography Measurement of LV pressure, definition of the coronary anatomy, and left ventriculography provide useful information and are indicated in most patients with CS complicating MI. Because of the procedural risk in this critically ill population, cardiac catheterization should be performed when there is a plan and capability for immediate coronary intervention (see below) or when a definitive diagnosis has not been made by other tests.

TREATMENT (Fig. 255-2)

General Measures In addition to the usual treatment of acute MI (Chap. 228), initial therapy is aimed at maintaining systemic and coronary perfusion by raising systolic blood pressure to ~90 mmHg with vaso-

pressors and adjusting volume status to a level that ensures optimum LV filling pressure (PCWP ~ 20 mmHg). Hypoxemia and acidosis must be corrected; most patients require endotracheal intubation to correct these abnormalities and reduce the work of breathing (see "Pulmonary Edema," below). Negative inotropic agents should be discontinued and the doses of renally cleared medications adjusted. Hyperglycemia should be corrected with continuous infusion of insulin. Bradyarrhythmias may require transvenous pacing. Recurrent ventricular tachycardia or rapid atrial fibrillation may require immediate treatment (Chap. 214).

Vasopressors Various intravenous drugs may be used to augment blood pressure and cardiac output in patients with CS. All have important disadvantages, and none has been shown to change the outcome in patients with established shock. *Norepinephrine* is a potent vasoconstrictor and inotropic stimulant that increases myocardial O_2 consumption; it should be reserved for patients with CS and refractory hypotension without elevated systemic vascular resistance. It should be started at a dosage of 2 to 4 μg/min and titrated upward as necessary. If systolic pressure cannot be maintained at 90 mmHg with a dosage of 15 μg/min, it is unlikely that a further increase will be beneficial.

Dopamine is useful in many patients; at low doses (≤2 μg/kg per min), it dilates the renal vascular bed; at moderate doses (2 to 10 μg/kg per min), it has positive chronotropic and inotropic effects as a consequence of β-receptor stimulation. At higher doses, a vasoconstrictor effect results from α-receptor stimulation. It is started at an infusion rate of 2 to 5 μg/kg per min, and the dosage is increased every 2 to 5 min to a maximum of 20 to 50 μg/kg per min. Systolic blood pressure should be maintained at ~90 mmHg. *Dobutamine* is a synthetic sympathomimetic amine with positive inotropic action and minimal positive chronotropic activity at low doses (2.5 μg/kg per min) but moderate chronotropic activity at higher doses. Although the usual dosage is up to 10 μg/kg per min, its vasodilating activity precludes its use when a vasoconstrictor effect is required.

Aortic Counterpulsation In CS, mechanical assistance with an intraaortic balloon pumping (IABP) system capable of augmenting both arterial diastolic pressure and cardiac output is helpful in rapidly stabilizing patients. A sausage-shaped balloon at the end of a catheter is introduced into the aorta percutaneously via the femoral artery, and the balloon is automatically inflated during early diastole, augmenting coronary blood flow. The balloon collapses in early systole, reducing the afterload against which the left ventricle ejects. IABP improves hemodynamic status at least temporarily in the majority of patients. In contrast to vasopressors and inotropic agents, myocardial O_2 consumption is reduced, leading to amelioration of ischemia. In the absence of early revascularization, however, long-term survival after this mode of therapy in patients with CS is disappointing. IABP is useful as a stabilizing measure in patients with CS prior to and during cardiac catheterization and percutaneous coronary intervention (PCI) or prior to urgent surgery. IABP is contraindicated if aortic regurgitation is present or aortic dissection is suspected. Ventricular assist devices may be considered for eligible young patients with refractory shock as a bridge to cardiac transplantation.

Reperfusion-Revascularization The rapid establishment of blood flow in the infarct-related artery is essential in the management of CS and forms the centerpiece of management. The randomized SHOCK Trial demonstrated 132 lives saved per 1000 patients treated with early revascularization with PCI or CABG compared to initial medical therapy including IABP with fibrinolytics followed by delayed revascularization (Fig. 255-3). The greatest benefit was in patients <75 years. Early revascularization with PCI or CABG is a class I recommendation for such patients with ST elevation or left bundle branch block MI who develop CS within 36 h of MI and who can be revascularized within 18 h of development of shock. When mechanical revascularization is not possible, IABP and fibrinolytic therapy are recommended. Older patients should be managed on an individual basis.

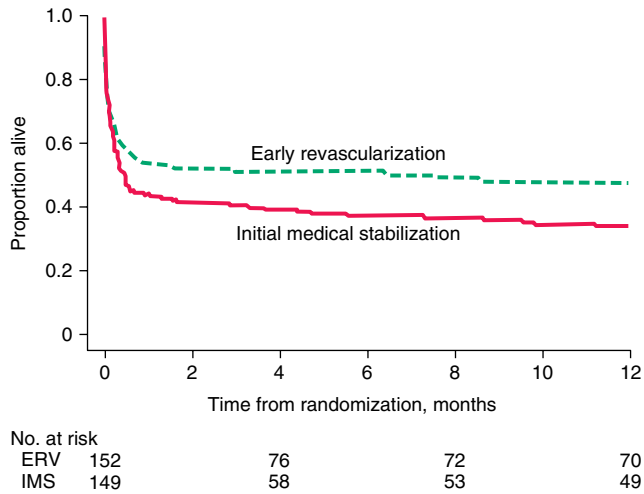

FIGURE 255-3 Early revascularization (ERV) (percutaneous coronary intervention or coronary artery bypass graft) for cardiogenic shock complicating acute myocardial infarction resulted in substantially improved 1-year survival compared to initial mechanical stabilization (IMS), including intraaortic balloon pumping and fibrinolytic agents, followed by selective delayed revascularization in the SHOCK Trial (SHould we emergently revascularize Occluded coronaries for Cardiogenic shocK?) *(Reprinted with permission from JAMA.)*

PROGNOSIS Within this high-risk condition, there is a wide range of expected death rates based on age, severity of hemodynamic abnormalities, severity of the clinical manifestations of hypoperfusion, and the performance of early revascularization. Independent risk factors are advanced age; depressed cardiac index, ejection fraction, and arterial pressure; elevated PCWP; more extensive coronary artery disease; and renal insufficiency.

SHOCK SECONDARY TO RIGHT VENTRICULAR INFARCTION Although transient hypotension is common in patients with RV infarction and inferior MI (Chap. 228), persistent CS due to RV failure accounts for only 3% of CS complicating MI. The salient features of RV shock are absence of pulmonary congestion, high right atrial pressure (which may be seen only after volume loading), RV dilatation and dysfunction, only mildly or moderately depressed LV function, and predominance of single-vessel proximal right coronary artery occlusion. Management includes intravenous fluid administration to optimize right atrial pressure (10 to 15 mmHg); avoidance of excess fluids, which cause a shift of the interventricular septum into the LV; sympathomimetic amines; IABP; and the early reestablishment of infarct-artery flow.

MITRAL REGURGITATION (See also Chap 228) Acute severe MR may complicate MI and result in CS and/or pulmonary edema. This complication most often occurs on the first day, with a second peak several days later. The diagnosis is confirmed by echo-Doppler. Rapid stabilization with IABP is recommended, with administration of dobutamine as needed to raise cardiac output. Reducing the load against which the left ventricle pumps (afterload) reduces the volume of regurgitant flow of blood into the left atrium. Mitral valve surgery is the definitive therapy and should be performed early in the course in suitable candidates.

VENTRICULAR SEPTAL RUPTURE (See also Chap 228) Echo-Doppler demonstrates shunting of blood from the left to the right ventricle and may visualize the opening in the interventricular septum. Timing and management are similar to that for MR with IABP support and surgical correction for suitable candidates.

FREE WALL RUPTURE Myocardial rupture is a dramatic complication of STEMI that is most likely to occur during the first week after the onset of symptoms; its frequency increases with the age of the patient. First infarction, a history of hypertension, no history of angina pectoris, and a relatively large Q-wave infarct are associated with a higher incidence of cardiac rupture. The clinical presentation typically is a sudden loss of pulse, blood pressure, and consciousness while the ECG continues to show sinus rhythm (apparent electromechanical dissociation or pulseless electrical activity). The myocardium continues to contract, but forward flow is not maintained as blood escapes into the pericardium. Cardiac tamponade (Chap. 222) ensues, and closed-chest massage is ineffective. This condition is almost universally fatal, although dramatic cases of urgent pericardiotensis followed by successful surgical repair have been reported.

ACUTE FULMINANT MYOCARDITIS (See also Chap 221) Myocarditis can mimic acute MI with ST deviation or bundle branch block on the electrocardiogram and marked elevation of cardiac markers. Acute myocarditis causes CS in ~15% of cases. These patients are typically younger than those with CS due to acute MI and often do not have typical ischemic chest pain. Echocardiography typically shows global LV dysfunction. Initial management is the same as for CS complicating acute MI (Fig. 255-2) but of course does not involve coronary revascularization.

PULMONARY EDEMA

→***The etiologies and pathophysiology of pulmonary edema are discussed in Chap. 29.***

DIAGNOSIS

Acute pulmonary edema usually presents with the rapid onset or aggravation of dyspnea at rest, tachypnea, tachycardia, and severe hypoxemia. In addition to rales, wheezing due to airway compression from peribronchial cuffing may be audible. Hypertension is usually present due to endogenous release of catecholamines.

It is often difficult to distinguish cardiogenic and noncardiogenic causes of acute pulmonary edema. *Echocardiography* with color flow Doppler may identify systolic and diastolic ventricular dysfunction and valvular lesions and aid in the differentiation of these two causes. Pulmonary edema associated with electrocardiographic ST elevation and evolving Q waves is usually diagnostic of acute MI and should prompt immediate institution of MI protocols and coronary artery reperfusion therapy (Chap. 228). Brain natriuretic peptide levels, when elevated, support heart failure as the etiology of acute dyspnea with pulmonary edema (Chap. 216).

The use of a *balloon flotation catheter* permits measurement of PCWP and helps to differentiate high pressure (cardiogenic) and normal pressure (noncardiogenic) causes of pulmonary edema. Pulmonary artery catheterization (see p. 1614) is indicated when the etiology of the pulmonary edema is uncertain, when it is refractory to therapy, or when it is accompanied by hypotension.

℞ TREATMENT

The treatment of pulmonary edema depends upon the specific etiology. Given the acute, life-threatening nature of the condition, a number of measures must be applied immediately to support the circulation, gas exchange, and lung mechanics as outlined in Fig. 255-2. In addition, conditions that frequently complicate pulmonary edema, such as infection, acidemia, anemia, and renal failure, must be corrected.

Support of Oxygenation and Ventilation Patients with acute cardiogenic pulmonary edema often have an identifiable cause of acute LV failure such as arrhythmia, ischemia, or myocardial decompensation (Chap. 216) that can be rapidly treated, with improvement in gas exchange. In contrast, noncardiogenic edema usually resolves much less quickly, and most patients require mechanical ventilation.

OXYGEN THERAPY Support of oxygenation is essential to ensure adequate O_2 delivery to peripheral tissues, including the heart.

POSITIVE PRESSURE VENTILATION The work of breathing and the O_2 requirements of this work are increased and may pose a significant physiologic stress on the heart. For patients with inadequate oxygenation or ventilation in spite of supplemental O_2, assisted ventilation should be initiated. This can be accomplished either by noninvasive ventilation using a face or nasal mask or by endotracheal intubation and ventilation. Continuous or bilevel positive airway pressure (Chap. 252) can rest the respiratory muscles, improve oxygenation and cardiac function, and reduce the need for intubation. In refractory cases, mechanical ventilation can relieve the work of breathing more completely than noninvasive ventilation. Mechanical ventilation with positive end-expiratory pressure can have multiple beneficial effects on pulmonary edema: (1) it can decrease both preload and afterload, thereby improving cardiac function; (2) it can redistribute lung water from the intraalveolar to the extraalveolar space where it does not interfere as much with gas exchange; and (3) it can increase lung volume to avoid atelectasis.

Reduction of Preload In most forms of pulmonary edema, the quantity of extravascular lung water is related to both the PCWP and the intravascular volume status.

DIURETICS The "loop diuretics" furosemide, bumetanide, and torsemide are effective in most forms of pulmonary edema, even in the presence of hypoalbuminemia, hyponatremia, or hypochloremia. Furosemide is also a venodilator that can reduce preload rapidly, prior to any diuresis, and is the diuretic of choice.The initial dose of furosemide should be ≤0.5 mg/kg, but a higher dose (1 mg/kg) is required in patients with

renal insufficiency, chronic diuretic use, or hypervolemia or after failure of a lower dose.

NITRATES Nitroglycerin and isosorbide dinitrate act predominantly as venodilators, with coronary vasodilating properties as well. They are rapid in onset and effective when administered by a variety of routes. Sublingual nitroglycerin (0.4 mg × 3 every 5 min) is first-line therapy for acute cardiogenic pulmonary edema. If pulmonary edema persists and in the absence of hypotension, sublingual may be followed by intravenous nitroglycerin, commencing at 5 to 10 μg/min. Intravenous nitroprusside (0.1 to 5 μg/kg per min) is a potent and predominantly arterial vasodilator that is useful for patients with pulmonary edema and hypertension and for cautious afterload and preload reduction if systolic pressure >100 mmHg. It requires close monitoring and titration, including the use of an arterial catheter for continuous blood pressure measurement in the intensive care unit.

MORPHINE Given in 2- to 4-mg intravenous boluses, morphine is a transient venodilator that reduces preload while relieving dyspnea and anxiety. These effects can diminish stress, catecholamine levels, tachycardia, and ventricular afterload in patients with pulmonary edema and systemic hypertension.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS ACE inhibitors reduce both afterload and preload and are recommended in hypertensive patients. A low dose of a short-acting agent may be initiated and followed by increasing oral doses. In acute MI with heart failure, ACE inhibitors reduce short- and long-term mortality.

OTHER PRELOAD-REDUCING AGENTS Intravenous recombinant brain natriuretic peptide (nesiritide) is a potent vasodilator with diuretic properties and is effective in the treatment of pulmonary edema. The starting dose is a 2-μg/kg intravenous bolus, followed by a 0.01-μg/kg per min infusion.

PHYSICAL METHODS Reduction of venous return reduces preload. Patients without hypotension should be maintained in the sitting position with the legs dangling along the side of the bed.

INOTROPIC AND INODILATOR DRUGS The sympathomimetic amines dopamine and dobutamine (see above) are potent inotropic agents. The bipyridine phosphodiesterase-3 inhibitors (inodilators), such as amrinone (0.75-mg/kg loading dose followed by 5 to 20 μg/kg per min) or milrinone (50 μg/kg followed by 0.25 to 0.75 μg/kg per min) stimulate myocardial contractility while promoting peripheral and pulmonary vasodilation. Such agents are indicated in patients with cardiogenic pulmonary edema and severe LV dysfunction.

DIGITALIS GLYCOSIDES Once a mainstay of treatment because of their positive inotropic action (Chap. 216), digitalis glycosides are rarely used at present. However, they may be useful for control of ventricular rate in patients with rapid atrial fibrillation or flutter and LV dysfunction, since they do not have the negative inotropic effects of other drugs that inhibit atrioventricular nodal conduction.

INTRAAORTIC COUNTERPULSATION IABP may help to relieve cardiogenic pulmonary edema. It is indicated as a stabilizing measure when acute severe mitral regurgitation or ventricular septal rupture cause refractory pulmonary edema, especially in preparation for surgical repair. IABP or LV-assist devices (Chap. 217) are useful as bridging therapy to cardiac transplantation in patients with refractory pulmonary edema secondary to myocarditis or cardiomyopathy.

TREATMENT OF TACHYARRHYTHMIAS AND ATRIAL-VENTRICULAR RESYNCHRONIZATION (See also Chap. 214) Sinus tachycardia or atrial fibrillation results from elevated left atrial pressure and sympathetic stimulation. Tachycardia itself can also limit LV filling time and raise left atrial pressure further. While relief of pulmonary congestion will slow the sinus rate or ventricular response in atrial fibrillation, a primary tachyarrhythmia may require cardioversion. In patients with reduced LV function and without atrial contraction or with lack of synchronized atrioventricular contraction, placement of an atrioventricular sequential pacemaker should be considered (Chap. 213).

Special Considerations ■ *THE RISK OF IATROGENIC CARDIOGENIC SHOCK* In the treatment of pulmonary edema vasodilators lower blood pressure, and, particularly when used in combination, their use may lead to hypotension, coronary artery hypoperfusion, and shock (Fig. 255-1). In general, patients with a *hypertensive* response to pulmonary edema tolerate and are benefited by these medications. In normotensive patients, low doses of single agents should be instituted sequentially, as needed.

ACUTE CORONARY SYNDROMES Acute ST-segment elevation MI complicated by pulmonary edema is associated with in-hospital mortality rates of 20 to 40%. After immediate stabilization, coronary artery blood flow must be rapidly reestablished. When available, primary PCI is preferable; alternatively, a fibrinolytic agent should be administered. Early coronary angiography and revascularization by PCI or CABG are also indicated for patients with non-ST elevation acute coronary syndrome. IABP use may be required to stabilize patients for coronary angiography if hypotension develops or for refractory pulmonary edema in patients with LV failure who are candidates for revascularization (Chap. 228).

UNUSUAL TYPES OF EDEMA Specific etiologies of pulmonary edema may require particular therapy. One type is reexpansion pulmonary edema that develops after removal of air or fluid that has been in the pleural space for some time. These patients may develop hypotension or oliguria resulting from rapid fluid shifts into the lung. Diuretics and preload reduction are contraindicated, and intravascular volume repletion is often needed while supporting oxygenation and gas exchange.

The risk of development of high-altitude pulmonary edema can be prevented by use of dexamethasone, calcium channel-blocking drugs, or long-acting inhaled β_2-adrenergic agonists. Treatment includes descent from altitude, bed rest, oxygen, and, if feasible, inhaled nitric oxide; nifedipine may also be effective.

For pulmonary edema resulting from upper airway obstruction, recognition of the obstructing cause is key, since treatment then is to relieve or bypass the obstruction.

256 CARDIOVASCULAR COLLAPSE, CARDIAC ARREST, AND SUDDEN CARDIAC DEATH

Robert J. Myerburg, Agustin Castellanos

OVERVIEW AND DEFINITIONS

The vast majority of naturally occurring sudden deaths are caused by cardiac disorders. The magnitude of sudden *cardiac* death (SCD) as a public health problem is highlighted by estimates that more than 400,000 deaths occur each year in the United States by this mechanism, accounting for 50% of all cardiac deaths. SCD is a direct consequence of cardiac arrest, which is potentially reversible if responded to promptly. Since resuscitation techniques and emergency rescue systems are available to respond to and save victims of out-of-hospital cardiac arrest, which was uniformly fatal in the past, understanding the SCD problem has practical importance.

SCD must be defined carefully. In the context of time, "sudden" is defined, for most clinical and epidemiologic purposes, as 1 h or less between a change in clinical status heralding the onset of the terminal clinical event, and the cardiac arrest itself. An exception is unwitnessed deaths in which pathologists may expand the definition of time to 24 h after the victim was last seen to be alive and stable.

Because of community-based interventions, victims may remain biologically alive for days or even weeks after a cardiac arrest that has resulted in irreversible central nervous system damage. Confusion in terms can be avoided by adhering strictly to definitions of cardiovascular collapse, cardiac arrest, and death (Table 256-1). Death is biologically, legally, and literally an absolute and irreversible event. Death may be delayed in a survivor of cardiac arrest, but "survival after sudden death" is an irrational term. A generally accepted definition of SCD is *natural death due to cardiac causes*, heralded by abrupt loss of consciousness within *1 h* of the onset of acute symptoms, in an individual who may have known *preexisting* heart disease but in whom the *time* and *mode* of death are *unexpected*. When biologic death of the cardiac arrest victim is delayed because of interventions, the relevant pathophysiologic event remains the sudden and unexpected cardiac arrest that leads ultimately to death, even though delayed by artificial methods. The language used should reflect the fact that the index event was a cardiac arrest and that death was due to its delayed consequences.

TABLE 256-1 *Distinction Between Cardiovascular Collapse, Cardiac Arrest, and Death*

Term	Definition	Qualifiers or Exceptions
Cardiovascular collapse	A sudden loss of effective blood flow due to cardiac and/or peripheral vascular factors which may reverse spontaneously (e.g., neurocardiogenic syncope; vasovagal syncope) or only with interventions (e.g., cardiac arrest)	Nonspecific term that includes cardiac arrest and its consequences and also events that characteristically revert spontaneously
Cardiac arrest	Abrupt cessation of cardiac pump function which may be reversible by a prompt intervention but will lead to death in its absence	Rare spontaneous reversions; likelihood of successful interventions relates to mechanism of arrest, clinical setting, and prompt return of circulation
Death	Irreversible cessation of all biologic functions	None

CLINICAL DEFINITION OF FORMS OF CARDIOVASCULAR COLLAPSE

Cardiovascular collapse is a general term connoting loss of effective blood flow due to acute dysfunction of the heart and/or peripheral vasculature. Cardiovascular collapse may be caused by vasodepressor syncope (vasovagal syncope, postural hypotension with syncope, neurocardiogenic syncope; Chap. 20), a transient severe bradycardia, or cardiac arrest. The latter is distinguished from the transient forms of cardiovascular collapse in that it usually requires an intervention to achieve resuscitation. In contrast, vasodepressor syncope and many primary bradyarrhythmic syncopal events are transient and non-life-threatening, with spontaneous return of consciousness.

The most common electrical mechanism for true cardiac arrest is ventricular fibrillation (VF), which is responsible for 65 to 80% of cardiac arrests. Severe persistent bradyarrhythmias, asystole, and pulseless electrical activity (PEA; an organized electrical activity without mechanical response, formerly called electromechanical dissociation) cause another 20 to 30%. Sustained ventricular tachycardia (VT) with hypotension is a less common cause. Acute low cardiac output states, having precipitous onset, may also present clinically as a cardiac arrest. These hemodynamic causes include massive acute pulmonary emboli, internal blood loss from ruptured aortic aneurysm, intense anaphylaxis, and cardiac rupture after myocardial infarction (MI).

ETIOLOGY, INITIATING EVENTS, AND CLINICAL EPIDEMIOLOGY

Clinical and epidemiologic studies have identified population subgroups at high risk for SCD. In addition, a large body of pathologic data provides information on the underlying *structural abnormalities* in victims of SCD, and studies of clinical physiology have begun to identify a group of *transient functional factors* that may convert a long-standing underlying structural abnormality from a stable to an unstable state (Table 256-2). This information has developed into an understanding of the causes and mechanisms of SCD.

Cardiac disorders constitute the most common causes of sudden *natural* death. After an initial peak incidence of sudden death between birth and 6 months of age (the sudden infant death syndrome), the incidence of sudden death declines sharply and remains low through childhood and adolescence. Among adolescents and young adults, the incidence of SCD is approximately 1 per 100,000 population per year. The incidence begins to increase in adults over the age of 30 years, reaching a second peak in the age range of 45 to 75 years, when the incidence approximates 1 to 2 per 1000 per year among the unselected adult population. Increasing age within this range is associated with increasing risk for sudden *cardiac* death, and the proportion of cardiac causes among all sudden natural deaths increases dramatically with advancing years. From 1 to 13 years of age, only one of five sudden *natural* deaths is due to cardiac causes. Between 14 and 21 years of age, the proportion increases to 30%, and then to 88% in the middle-aged and elderly.

Young and middle-aged men and women have very different susceptibilities to SCD, but the gender differences decrease with advancing age. In the 45- to 64-year-old age group, the male SCD excess is nearly 7:1. It falls to less than 2:1 in the 65- to 74-year-old age group. The difference in risk for SCD parallels the differences in age-related risks for other manifestations of coronary heart disease (CHD) between men and women. As the gender gap for manifestations of CHD closes in the seventh and eighth decades of life, the excess risk of SCD in males also narrows. Despite the lower incidence among younger women, coronary risk factors such as cigarette smoking, diabetes, hyperlipidemia, and hypertension are highly influential, and SCD remains an important clinical and epidemiologic problem. The inci-

TABLE 256-2 Cardiac Arrest and Sudden Cardiac Death

STRUCTURAL CAUSES

I. Coronary heart disease
  A. Coronary artery abnormalities
    1. Chronic atherosclerotic lesions
    2. Acute (active) lesions (plaque fissuring, platelet aggregation, acute thrombosis)
    3. Anomalous coronary artery anatomy
  B. Myocardial infarction
    1. Healed
    2. Acute
II. Myocardial hypertrophy
  A. Secondary
  B. Hypertrophic cardiomyopathy
    1. Obstructive
    2. Nonobstructive
III. Dilated cardiomyopathy—primary muscle disease
IV. Inflammatory and infiltrative disorders
  A. Myocarditis
  B. Noninfectious inflammatory diseases
  C. Infiltrative diseases
  D. Right ventricular dysplasia
V. Valvular heart disease
VI. Electrophysiologic abnormalities, structural
  A. Anomalous pathways in Wolff-Parkinson-White syndrome
  B. Conducting system disease
VII. Inherited disorders of molecular structure associated with electrophysiologic abnormalities (e.g., congenital long QT syndromes, Brugada syndrome)

FUNCTIONAL CONTRIBUTING FACTORS

I. Alterations of coronary blood flow
  A. Transient ischemia
  B. Reperfusion after ischemia
II. Low cardiac output states
  A. Heart failure
    1. Chronic
    2. Acute decompensation
  B. Shock
III. Systemic metabolic abnormalities
  A. Electrolyte imbalance (e.g., hypokalemia)
  B. Hypoxemia, acidosis
IV. Neurophysiologic disturbances
  A. Autonomic fluctuations: central, neural, humoral
  B. Receptor function
V. Toxic responses
  A. Proarrhythmic drug effects
  B. Cardiac toxins (e.g., cocaine, digitalis intoxication)
  C. Drug interactions

dence of SCD among the African-American population appears to be higher than among the white population, but the reasons remain uncertain.

Hereditary factors contribute to the risk of SCD. In a nonspecific sense, they represent expressions of the hereditary predisposition to CHD. In addition, however, there are recent data suggesting a familial predisposition to SCD as a specific form of expression of CHD. In a few syndromes, such as hypertrophic cardiomyopathy, congenital long QT interval syndromes, right ventricular dysplasia, and the syndrome of right bundle branch block and non-ischemic ST-segment elevations (Brugada syndrome), there is a specific inherited risk of SCD (Chap. 214).

The structural causes of and functional factors contributing to the SCD syndrome are listed in Table 256-2. Worldwide, and especially in western cultures, coronary atherosclerotic heart disease is the most common structural abnormality associated with SCD in middle-aged and older adults. Up to 80% of all SCDs in the United States are due to the consequences of coronary atherosclerosis. The cardiomyopathies (dilated and hypertrophic, collectively; Chap. 221) account for another 10 to 15% of SCDs, and all the remaining diverse etiologies cause only 5 to 10% of all SCDs. The inherited arrhythmia syndromes (see above and Table 256-2) are more common causes in adolescents and young adults.

Transient ischemia in the previously scarred or hypertrophied heart, hemodynamic and fluid and electrolyte disturbances, fluctuations in autonomic nervous system activity, and transient electrophysiologic changes caused by drugs or other chemicals (e.g., proarrhythmia) have all been implicated as mechanisms responsible for transition from electrophysiologic stability to instability. In addition, reperfusion of ischemic myocardium may cause transient electrophysiologic instability and arrhythmias.

PATHOLOGY

Data from postmortem examinations of SCD victims parallel the clinical observations on the prevalence of CHD as the major structural etiologic factor. More than 80% of SCD victims have pathologic findings of CHD. The pathologic description often includes a combination of long-standing, extensive atherosclerosis of the epicardial coronary arteries and unstable coronary artery lesions, which include a combination of fissured or ruptured plaques, platelet aggregates, hemorrhage, and thombosis. In one study, chronic coronary atherosclerosis involving two or more major vessels with ≥75% stenosis was observed in 75% of the victims. In another study, atherosclerotic plaque fissuring, platelet aggregates, and/or acute thrombosis were observed in 95 of 100 individuals who had pathologic studies after SCD.

As many as 70 to 75% of males who die suddenly have preexisting healed MIs, while only 20 to 30% have recent acute MIs, despite the prevalence of unstable plaques and thrombi. Regional or global left ventricular (LV) hypertrophy coexists with prior MIs.

PREDICTION AND PREVENTION OF CARDIAC ARREST AND SUDDEN CARDIAC DEATH

SCD accounts for approximately one-half the total cardiovascular mortality rate. As shown in Fig. 256-1*A*, the very high risk subgroups provide more focused populations ("percent per year") for predicting cardiac arrest or SCD; but the impact of such subgroups on the overall problem of SCD, indicated by the absolute number of preventable events ("events per year"), is relatively small. The requirements for achieving a major population impact are effective prevention of underlying diseases and/or new epidemiologic probes that will allow better resolution of subgroups at specific risk within the large general populations.

Strategies for predicting and preventing SCD are categorized as primary and secondary, in addition to responses intended to abort cardiac arrests. *Primary prevention* refers to the attempt to identify individual patients at specific risk for SCD and institute preventive strategies. *Secondary prevention* refers to measures taken to prevent recurrent cardiac arrest or death in individuals who have survived a previous cardiac arrest. The primary prevention strategies currently used depend upon magnitude of risk among the various population subgroups. Because the annual incidence of SCD among the unselected adult population is limited to 1 to 2 per 1000 population per year (Fig. 256-1*A*), and more than 30% of all SCDs due to coronary artery disease occur as the first clinical manifestation of the disease (Fig. 256-2*A*), the only practical strategies are profiling for risk of developing CHD and risk factor control (Fig. 256-2*B*). The most powerful long-term risk factors include age, cigarette smoking, elevated serum cholesterol, diabetes mellitus, elevated blood pressure, LV hypertrophy, and nonspecific electrocardiographic abnormalities. Markers of inflammation (e.g., C-reactive protein levels) that may predict plaque destabilization, have recently been added to risk classifications. The presence of multiple risk factors progressively increases incidence, but not sufficiently or specifically enough to warrant therapies targeted to potentially fatal arrhythmias (Fig. 256-1*A*). However, recent studies offer the hope that genetic markers for specific risk may

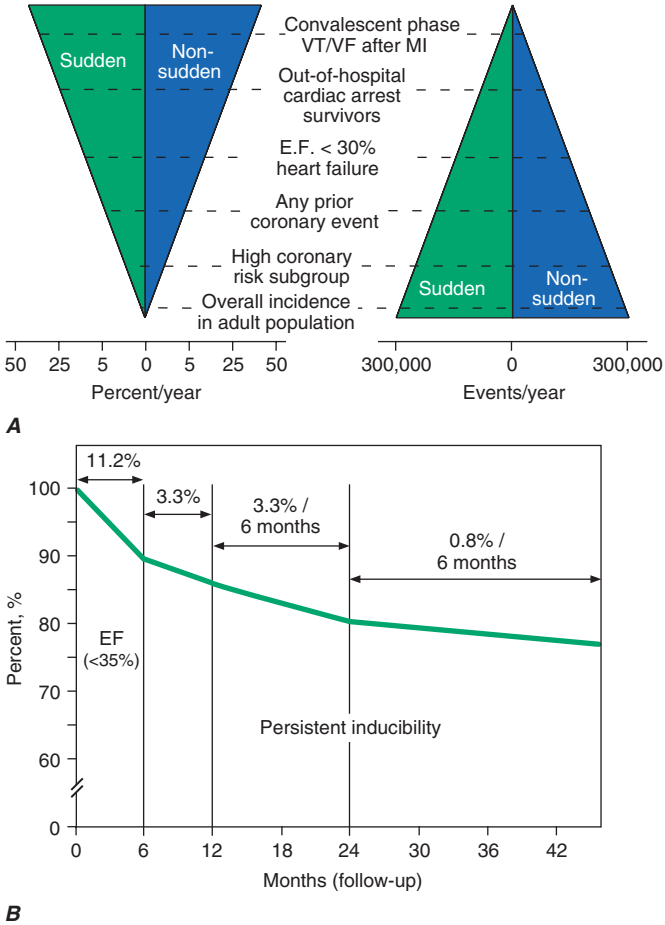

FIGURE 256-1 *A.* Incidence of sudden and nonsudden cardiac deaths in population subgroups, and the relation of total number of events per year to incidence figures. Approximations of subgroup incidence figures, and the related population pool from which they are derived, are presented. Approximately 50% of all cardiac deaths are sudden and unexpected. The incidence triangle on the left ("Percent/Year") indicates the approximate percentage of sudden and nonsudden deaths in each of the population subgroups indicated, ranging from the lowest percentage in unselected adult populations (0.1 to 2% per year) to the highest percentage in patients with VT or VF during convalescence after an MI (approximately 50% per year). The triangle on the right indicates the total number of events per year in each of these groups, to reflect incidence in context with the size of the population subgroups. The highest risk categories identify the smallest number of total annual events, and the lowest incidence category accounts for the largest number of events per year. (EF, ejection fraction; VT, ventricular tachycardia; VF, ventricular fibrillation; MI, myocardial infarction.) *B.* Time dependence of risk among survivors of out-of-hospital cardiac arrest. Recurrence risk is highest in the first 6 months of the index event. Survival is expressed as a percentage. High risk is best predicted initially by an ejection fraction $\leq$ 35% during the first 6 months, and subsequently persistent inducibility of VT during electrophysiologic testing becomes an added major risk. $n = 101$ at $t = 0$. [*After T Furukawa et al, in RJ Myerburg et al, Circulation 85(Suppl 1):2, 1992. Reproduced with permission of the American Heart Association.*]

be available in the future. These studies suggest that a family history of SCD associated with acute coronary syndromes predicts a higher likelihood of cardiac arrest as the initial manifestation of coronary artery disease in first-degree family members.

After coronary artery disease has been identified in a patient, additional strategies for risk profiling become available (Fig. 256-2*B*), but the majority of SCDs occur among the large unselected groups rather than in the specific high-risk subgroups that become evident among populations with established disease (compare events per year with percent per year in Fig. 256-1*A*). Under most conditions of higher level of risk, particularly those indexed to a major recent cardiovascular event (e.g., MI, recent onset of heart failure, survival after out-of-hospital cardiac arrest), the highest risk of SCD occurs during the initial 6 to 18 months and then plateaus towards the baseline risk of the underlying disease (Fig. 256-1*B*). Accordingly, preventive interventions are more likely to be effective when initiated early.

Among patients in the acute, convalescent, and chronic phases of myocardial infarction (Chap. 228), subgroups at high absolute risk of SCD can be identified. During the acute phase, the potential risk of cardiac arrest from onset through the first 48 hours may be as high as 15 to 20%, emphasizing the importance for patients to respond promptly to the onset of symptoms. Those who survive acute-phase VF, however, are not at continuing risk for recurrent cardiac arrest indexed to that event. During the convalescent phase after MI (3 days to ~6 weeks), an episode of sustained VT or VF predicts a mortality risk of up to 50% at 12 months. At least 50% of the deaths are sudden. Aggressive intervention techniques may reduce this incidence.

After passage into the chronic phase of MI, the longer-term risk for total and SCD mortality is predicted by a number of factors (Fig. 256-2*B*). The most important for both SCD and non-sudden death is the extent of myocardial damage sustained as a result of the acute MI. This is measured by the magnitude of reduction of the ejection fraction (EF), functional capacity, and/or the occurrence of heart failure. Various studies have demonstrated that an EF $<$ 40% contributes significantly to this risk. In addition, inducibility of VT or VF during electrophysiologic testing of patients who have ambient ventricular arrhythmias [premature ventricular contractions (PVCs) and nonsustained VT] and an EF $<$ 35 or 40% is a strong predictor of SCD risk. Patients in this subgroup are now considered candidates for implantable cardioverter defibrillators (ICDs) (see below). Risk falls off sharply with EFs $>$ 40% after MI and the absence of ambient arrhythmias, and conversely continues to rise with EFs $<$ 30% even without the ambient arrhythmia markers.

The cardiomyopathies (dilated and hypertrophic) are the second most common category of diseases associated with risk of SCD, following CHD (Table 256-2). Some risk factors have been identified, largely related to extent of disease, documented ventricular arrhythmias, and symptoms of arrhythmias (e.g., unexplained syncope). The rare diseases associated with SCD in younger populations (adolescents, young adults, competitive athletes), such as the long QT interval syndromes, right ventricular dysplasia, hypertrophic cardiomyopathy, and Brugada syndrome, may be recognized or suspected based on symptoms, family history of premature sudden death or known presence of the specific entity, or incidental clinical data. Despite the low absolute incidence of SCD among the younger population ($<$1/100,000 per year), routine electrocardiographic (ECG) screening has been suggested for identifying individuals at risk.

Secondary prevention strategies are applied to surviving victims of a cardiac arrest that was not associated with an acute MI or a transient risk of SCD (e.g., drug exposures, correctable electrolyte imbalances). The extent of underlying disease (CHD, dilated cardiomyopathy), or merely its presences in association with life-threatening arrhythmias (e.g., long QT syndromes, right ventricular dysplasia) predicts a 1- to 2-year SCD or cardiac arrest recurrence risk of up to 30% in the absence of specific interventions (see below).

CLINICAL CHARACTERISTICS OF CARDIAC ARREST

PRODROME, ONSET, ARREST, DEATH

SCD may be presaged by days, weeks, or months of increasing angina, dyspnea, palpitations, easy fatigability, and other nonspecific complaints. However, these *prodromal complaints* are generally predictive of any major cardiac event; they are not specific for predicting SCD.

The *onset of the terminal event*, leading to cardiac arrest, is defined as an acute change in cardiovascular status preceding cardiac arrest by up to 1 h. When the onset is instantaneous or abrupt, the probability that the arrest is cardiac in origin is $>$95%. Continuous ECG recordings, fortuitously obtained at the onset of a cardiac arrest, commonly demonstrate changes in cardiac electrical activity during the minutes or hours before the event. There is a tendency for the heart rate to increase and for advanced grades of PVCs to evolve. Most cardiac

arrests that are caused by VF begin with a run of sustained or nonsustained VT, which then degenerates into VF.

Sudden unexpected loss of effective circulation may be separated into "arrhythmic events" and "circulatory failure." Arrhythmic events are characterized by a high likelihood of patients being awake and active immediately prior to the event, are dominated by VF as the electrical mechanism, and have a short duration of terminal illness (<1 h). In contrast, circulatory failure deaths occur in patients who are inactive or comatose, have a higher incidence of asystole than VF, have a tendency to a longer duration of terminal illness, and are dominated by noncardiac events preceding the terminal illness.

The onset of cardiac arrest may be characterized by typical symptoms of an acute cardiac event, such as prolonged angina or the pain of onset of MI; acute dyspnea or orthopnea; or the sudden onset of palpitations, sustained tachycardia, or light-headedness. However, in many patients, the onset is precipitous, with minimal forewarning.

Cardiac arrest is, by definition, abrupt. Mentation may be impaired in patients with sustained VT during the onset of the terminal event. However, complete loss of consciousness is *a sine qua non* in cardiac arrest. Although rare spontaneous reversions occur, it is usual that cardiac arrest progresses to death within minutes (i.e., SCD has occurred) if active interventions are not undertaken promptly.

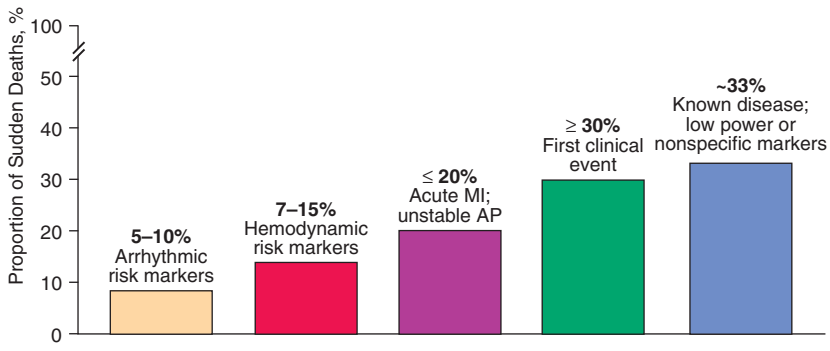
The probability of achieving successful resuscitation from cardiac arrest is related to the interval from onset to institution of resuscitative efforts, the setting in which the event occurs, the mechanism (VF, VT, pulseless electrical activity, asystole), and the clinical status of the patient prior to the cardiac arrest. Return of circulation and survival rates as a result of defibrillation decrease linearly from the first minute to 10 minutes. By 5 minutes, survival rates are no better than 25 to 30% in out-of-hospital settings. Those settings in which it is possible to institute prompt cardiopulmonary resuscitation (CPR) with rapid defibrillation of VF provide a better chance of a successful outcome. However, the outcome in intensive care units and other in-hospital environments is heavily influenced by the patient's preceding clinical status. The immediate outcome is good for cardiac arrest occurring in the intensive care unit in the presence of an acute cardiac event or transient metabolic disturbance, but survival among patients with far-advanced chronic cardiac disease or advanced noncardiac diseases (e.g., renal failure, pneumonia, sepsis, diabetes, cancer) is low, and not much more successful in the in-hospital than in the out-of-hospital setting.

The success rate for initial resuscitation and survival to hospital discharge after an out-of-hospital cardiac arrest depends heavily on the mechanism of the event. When the mechanism is VT, the outcome is best; VF is the next most successful; and asystole and PEA generate dismal outcome statistics. Advanced age also influences adversely the chances of successful resuscitation.

Progression to biologic death is a function of the mechanism of cardiac arrest and the length of the delay before interventions. VF or asystole without CPR within the first 4 to 6 min has a poor outcome even if defibrillation is successful, because of superimposed brain damage; and there are few survivors among patients who had no life support activities for the first 8 min after onset. Outcome statistics are improved by lay bystander intervention (basic life support—see below) prior to definitive interventions (advanced life support), and even more by early defibrillation. In regard to the latter, evaluations of deployment of automatic external defibrillators (AEDs) in communities (e.g., police vehicles, large buildings, stadiums) are beginning to generate encouraging data.

Death during the hospitalization after a successfully resuscitated cardiac arrest relates closely to the severity of central nervous system injury. Anoxic encephalopathy and infections subsequent to prolonged respirator dependence account for 60% of the deaths. Another 30% occur as a consequence of low cardiac output states that fail to respond to interventions. Recurrent arrhythmias are the least common cause of death, accounting for only 10% of in-hospital deaths.

In the setting of acute MI, it is important to distinguish between primary and secondary cardiac arrests. *Primary cardiac arrests* refer to those that occur in the absence of hemodynamic instability, and *secondary cardiac arrests* are those that occur in patients in whom abnormal hemodynamics dominate the clinical picture before cardiac arrest. The success rate for immediate resuscitation in primary cardiac arrest during acute MI in a monitored setting should approach 100%.



A

Target	*Examples*	*Goal*	*Sensitivity*
• ASHD risk factors	• Framingham risk index	• Predict evolution of disease	• Very low
• Anatomic screening	• Electron beam tomography	• Identify CAD	• Very low
• Clinical markers	• EF; angiography	• Define extent of disease	• Variable; extent of disease; low specificity
	• EPS	• Identify arrhythmia markers	• Low-to-intermediate for screening
	• EPS combined with EF	• Define high risk groups	• High for specific groups
• Transient risk predictors	• T-wave alternans; QT dispersions	• EKG markers of risk	• Primary predictive value unknown
	• Pathophysiologic controls (e.g., HRV)	• Quantify autonomic regulation	• Uncertain; some measures useful(?)
	• Inflammatory markers	• Predict unstable plaques	• Unknown; potentially high
• Individual risk predictors	• Familial/genetic profiles	• Predict specific SCD risk before disease expression	• High potential for future profiling

B

FIGURE 256-2 Population subsets, risk predictors, and distribution of sudden cardiac deaths (SCDs) according to clinical circumstances. *A*. The population subset with high-risk arrhythmia markers in conjunction with low ejection fraction is a group at high risk of SCD, but accounts for <10% of the total SCD burden attributable to coronary artery disease. In contrast, nearly two-thirds of all SCD victims present with SCD as the first and only manifestation of underlying disease or have known disease but are considered relatively low-risk, because of the absence of high-risk markers. *B*. Risk profile for prediction and prevention of SCD is difficult. The highest absolute numbers of events occur among the general population who may have risk factors for coronary heart disease or expressions of disease that do not predict high risk. This results in a low sensitivity for predicting and preventing SCD. New approaches that include epidemiologic modeling of transient risk factors and methods of predicting individual patient risk offer hope for greater sensitivity in the future. AP, angina pectoris; ASHD, arteriosclerotic heart disease; CAD, coronary artery disease; EPS, electrophysiologic study; HRV, heart rate variability. *(From Myerburg, reproduced with permission of the publisher).*

In contrast, as many as 70% of patients with secondary cardiac arrest succumb immediately or during the same hospitalization.

TREATMENT

The individual who collapses suddenly is managed in four stages: (1) the initial response and basic life support, (2) advanced life support, (3) postresuscitation care, and (4) long-term management. The initial response and basic life support can be carried out by physicians, nurses, paramedical personnel, and trained lay persons. There is a requirement for increasingly specialized skills as the patient moves through the stages of advanced life support, postresuscitation care, and long-term management.

Initial Response and Basic Life Support The initial evaluation will confirm whether a sudden collapse is indeed due to a cardiac arrest. Observations of the state of consciousness, respiratory movements, skin color, and the presence or absence of pulses in the carotid or femoral arteries will promptly determine whether a life-threatening cardiac arrest has occurred. For lay responders, the pulse check is no longer recommended. As soon as a cardiac arrest is suspected, confirmed, or even considered to be impending, calling an emergency rescue system (e.g., 911) is the immediate priority. With the development of AEDs that are easily used by nonconventional emergency responders, an additional layer for response has evolved. Immediate defibrillation by emergency medical rescue personnel on fire rescue vehicles, police, public conveyance personnel, security officers in various locations with large numbers of people, and trained lay persons is becoming available to save more cardiac arrest victims.

Agonal respiratory movements may persist for a short time after the onset of cardiac arrest, but it is important to observe for severe stridor with a persistent pulse as a clue to aspiration of a foreign body or food. If this is suspected, a Heimlich maneuver (see below) may dislodge the obstructing body. A precordial blow, or "thump," delivered firmly by the clenched fist to the junction of the middle and lower third of the sternum may occasionally revert VT or VF, but there is concern about converting VT to VF. Therefore, it has been recommended to use precordial thumps as an advanced life support technique when monitoring and defibrillation are available. This conservative application of the technique remains controversial.

The third action during the initial response is to clear the airway. The head is tilted back and chin lifted so that the oropharynx can be explored to clear the airway. Dentures or foreign bodies are removed, and the Heimlich maneuver is performed if there is reason to suspect that a foreign body is lodged in the oropharynx. If respiratory arrest precipitating cardiac arrest is suspected, a second precordial thump is delivered after the airway is cleared.

Basic life support, more popularly known as CPR, is intended to maintain organ perfusion until definitive interventions can be instituted. The elements of CPR are the maintenance of ventilation of the lungs and compression of the chest. Mouth-to-mouth respiration may be used if no specific rescue equipment is immediately available (e.g., plastic oropharyngeal airways, esophageal obturators, masked Ambu bag). Conventional ventilation techniques during CPR require the lungs to be inflated twice in succession every 15 chest compressions.

Chest compression is based on the assumption that cardiac compression allows the heart to maintain a pump function by sequential filling and emptying of its chambers, with competent valves maintaining forward direction of flow. The palm of one hand is placed over the lower sternum, with the heel of the other resting on the dorsum of the lower hand. The sternum is depressed, with the arms remaining straight, at a rate of approximately 100 per minute. Sufficient force is applied to depress the sternum 4 to 5 cm, and relaxation is abrupt.
