In the absence of elevated renin or aldosterone levels, enhanced distal nephron secretion of K^+ may result from increased production of non-aldosterone mineralocorticoids in *congenital adrenal hyperplasia*. Glucocorticoid-stimulated kaliuresis does not normally occur due to the conversion of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase (11β-HSDH). Therefore, 11β-HSDH deficiency or suppression allows cortisol to bind to the aldosterone receptor and leads to the *syndrome of apparent mineralocorticoid excess*. Drugs that inhibit the activity of 11β-HSDH include glycyrrhetinic acid, present in licorice, chewing tobacco, and carbenoxolone. The presentation of Cushing's syndrome may include hypokalemia if the capacity of 11β-HSDH to inactivate cortisol is overwhelmed by persistently elevated glucocorticoid levels.

Liddle's syndrome is a rare familial (autosomal dominant) disease characterized by hypertension, hypokalemic metabolic alkalosis, renal K^+ wasting, and suppressed renin and aldosterone secretion. Increased distal delivery of Na^+ with a non-reabsorbable anion (not Cl^-) enhances K^+ secretion. Classically, this is seen with *proximal (type 2) renal tubular acidosis* (RTA) and vomiting, associated with bicarbonaturia. Diabetic ketoacidosis and toluene abuse (glue-sniffing) can lead to increased delivery of β-hydroxybutyrate and hippurate, respectively, to the CCD and to renal K^+ loss. High doses of penicillin derivatives administered to volume-depleted patients may likewise pro-

mote renal K^+ secretion as well as an osmotic diuresis. *Classic distal (type 1) RTA* is associated with hypokalemia due to increased renal K^+ loss, the mechanism of which is uncertain. Amphotericin B causes hypokalemia due to increased distal nephron permeability to Na^+ and K^+ and to renal K^+ wasting.

Bartter's syndrome is a disorder characterized by hypokalemia, metabolic alkalosis, hyperreninemic hyperaldosteronism secondary to ECF volume contraction, and juxtaglomerular apparatus hyperplasia. Finally, diuretic use and abuse are common causes of K^+ depletion. Carbonic anhydrase inhibitors, loop diuretics, and thiazides are all kaliuretic. The degree of hypokalemia tends to be greater with long-acting agents and is dose-dependent. Increased renal K^+ excretion is due primarily to increased distal solute delivery and secondary hyperaldosteronism (due to volume depletion).

CLINICAL FEATURES The clinical manifestations of K^+ depletion vary greatly between individual patients, and their severity depends on the degree of hypokalemia. Symptoms seldom occur unless the plasma K^+ concentration is less than 3 mmol/L. Fatigue, myalgia, and muscular weakness of the lower extremities are common complaints and are due to a lower (more negative) resting membrane potential. More severe hypokalemia may lead to progressive weakness, hypoventilation (due to respiratory muscle involvement), and eventually complete paralysis. Impaired muscle metabolism and the blunted hyperemic response to exercise associated with profound K^+ depletion increase the risk of rhabdomyolysis. Smooth-muscle function may also be affected and manifest as paralytic ileus.

The electrocardiographic changes of hypokalemia (Fig. 210-17) are due to delayed ventricular repolarization and do not correlate well with the plasma K^+ concentration. Early changes include flattening or inversion of the T wave, a prominent U wave, ST-segment depression, and a prolonged QU interval. Severe K^+ depletion may result in a prolonged PR interval, decreased voltage and widening of the QRS complex, and an increased risk of ventricular arrhythmias, especially in patients with myocardial ischemia or left ventricular hypertrophy. Hypokalemia may also predispose to digitalis toxicity. Hypokalemia is often associated with acid-base disturbances related to the underlying disorder. In addition, K^+ depletion results in intracellular acidification and an increase in net acid excretion or new HCO_3^- production. This is a consequence of enhanced proximal HCO_3^- reabsorption, increased renal ammoniagenesis, and increased distal H^+ secretion. This contributes to the generation of metabolic alkalosis frequently present in hypokalemic patients. NDI (see above) is not uncommonly seen in K^+ depletion and is manifest as polydipsia and polyuria. Glucose intolerance may also occur with hypokalemia and has been attributed to either impaired insulin secretion or peripheral insulin resistance.

DIAGNOSIS (Fig. 41-3) In most cases, the etiology of K^+ depletion can be determined by a careful history. Diuretic and laxative abuse as well as surreptitious vomiting may be difficult to identify but should be excluded. Rarely, patients with a marked leukocytosis (e.g., acute myeloid leukemia) and normokalemia may have a low measured plasma K^+ concentration due to white blood cell uptake of K^+ at room temperature. This *pseudohypokalemia* can be avoided by storing the blood sample on ice or rapidly separating the plasma (or serum) from the cells.

After eliminating decreased intake and intracellular shift as potential causes of hypokalemia, examination of the renal response can help to clarify the source of K^+ loss. The appropriate response to K^+ depletion is to excrete less than 15 mmol/d of K^+ in the urine, due to increased reabsorption and decreased distal secretion. Hypokalemia with minimal renal K^+ excretion suggests that K^+ was lost via the skin or gastrointestinal tract or that there is a remote history of vomiting or diuretic use. As described above, renal K^+ wasting may be due to factors that either increase the K^+ concentration in the CCD or increase the distal flow rate (or both). The ECF volume status, blood pressure,

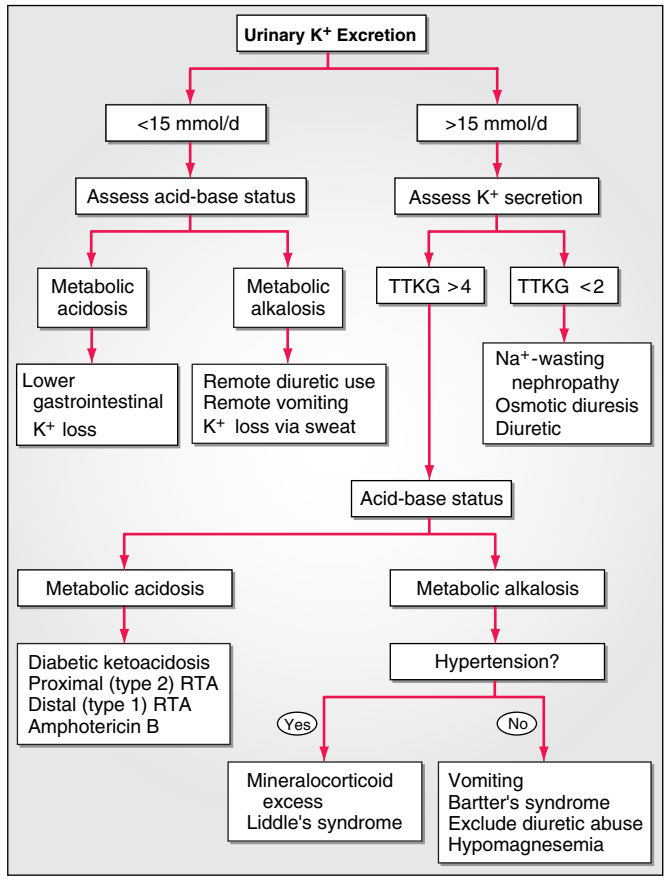

FIGURE 41-3 Algorithm depicting clinical approach to hypokalemia. TTKG, transtubular K^+ concentration gradient; RTA, renal tubular acidosis.

and associated acid-base disorder may help to differentiate the causes of excessive renal K^+ loss. A rapid and simple test designed to evaluate the driving force for net K^+ secretion is the *transtubular K^+ concentration gradient* (TTKG). The TTKG is the ratio of the K^+ concentration in the lumen of the CCD ($[K^+]_{CCD}$) to that in peritubular capillaries or plasma ($[K^+]_P$). The validity of this measurement depends on three assumptions: (1) few solutes are reabsorbed in the medullary collecting duct (MCD), (2) K^+ is neither secreted nor reabsorbed in the MCD, and (3) the osmolality of the fluid in the terminal CCD is known. Significant reabsorption or secretion of K^+ in the MCD seldom occurs, except in profound K^+ depletion or excess, respectively. When AVP is acting ($OSM_U \geqslant OSM_P$), the osmolality in the terminal CCD is the same as that of plasma, and the K^+ concentration in the lumen of the distal nephron can be estimated by dividing the urine K^+ concentration ($[K^+]_U$) by the ratio of the urine to plasma osmolality (OSM_U/OSM_P):

$$[K^+]_{CCD} = [K^+]_U \div (OSM_U/OSM_P)$$

$$TTKG = \frac{[K^+]_{CCD}}{[K^+]_P} = \frac{[K^+]_U \div (OSM_U/OSM_P)}{[K^+]_P}$$

Hypokalemia with a TTKG greater than 4 suggests renal K^+ loss due to increased distal K^+ secretion. Plasma renin and aldosterone levels are often helpful in differentiating the various causes of hyperaldosteronism. Bicarbonaturia and the presence of other non-reabsorbed anions also increase the TTKG and lead to renal K^+-wasting.

Rx TREATMENT

The therapeutic goals are to correct the K^+ deficit and to minimize ongoing losses. With the exception of periodic paralysis, hypokalemia resulting from transcellular shifts rarely requires intravenous K^+ supplementation, which can lead to rebound hyperkalemia. It is generally safer to correct hypokalemia via the oral route. The degree of K^+ depletion does not correlate well with the plasma K^+ concentration. A

decrement of 1 mmol/L in the plasma K^+ concentration (from 4.0 to 3.0 mmol/L) may represent a total body K^+ deficit of 200 to 400 mmol, and patients with plasma levels under 3.0 mmol/L often require in excess of 600 mmol of K^+ to correct the deficit. Furthermore, factors promoting K^+ shift out of cells (e.g., insulin deficiency in diabetic ketoacidosis) may result in underestimation of the K^+ deficit. Therefore, the plasma K^+ concentration should be monitored frequently when assessing the response to treatment. Potassium chloride is usually the preparation of choice and will promote more rapid correction of hypokalemia and metabolic alkalosis. Potassium bicarbonate and citrate (metabolized to HCO_3^-) tend to alkalinize the patient and would be more appropriate for hypokalemia associated with chronic diarrhea or RTA.

Patients with severe hypokalemia or those unable to take anything by mouth require intravenous replacement therapy with KCl. The maximum concentration of administered K^+ should be no more than 40 mmol/L via a peripheral vein or 60 mmol/L via a central vein. The rate of infusion should not exceed 20 mmol/h unless paralysis or malignant ventricular arrhythmias are present. Ideally, KCl should be mixed in normal saline since dextrose solutions may initially exacerbate hypokalemia due to insulin-mediated movement of K^+ into cells. Rapid intravenous administration of K^+ should be used judiciously and requires close observation of the clinical manifestations of hypokalemia (electrocardiogram and neuromuscular examination).

HYPERKALEMIA

ETIOLOGY Hyperkalemia, defined as a plasma K^+ concentration >5.0 mmol/L, occurs as a result of either K^+ release from cells or decreased renal loss. Increased K^+ intake is rarely the sole cause of hyperkalemia since the phenomenon of *potassium adaptation* ensures rapid K^+ excretion in response to increases in dietary consumption. Iatrogenic hyperkalemia may result from overzealous parenteral K^+ replacement or in patients with renal insufficiency. *Pseudohyperkalemia* represents an artificially elevated plasma K^+ concentration due to K^+ movement out of cells immediately prior to or following venipuncture. Contributing factors include prolonged use of a tourniquet with or without repeated fist clenching, hemolysis, and marked leukocytosis or thrombocytosis. The latter two result in an elevated serum K^+ concentration due to release of intracellular K^+ following clot formation. Pseudohyperkalemia should be suspected in an otherwise asymptomatic patient with no obvious underlying cause. If proper venipuncture technique is used and a plasma (not serum) K^+ concentration is measured, it should be normal. Intravascular hemolysis, tumor lysis syndrome, and rhabdomyolysis all lead to K^+ release from cells as a result of tissue breakdown.

Metabolic acidoses, with the exception of those due to the accumulation of organic anions, can be associated with mild hyperkalemia resulting from intracellular buffering of H^+ (see above). Insulin deficiency and hypertonicity (e.g., hyperglycemia) promote K^+ shift from the ICF to the ECF. The severity of exercise-induced hyperkalemia is related to the degree of exertion. It is due to release of K^+ from muscles and is usually rapidly reversible, often associated with rebound hypokalemia. Treatment with beta blockers rarely causes hyperkalemia but may contribute to the elevation in plasma K^+ concentration seen with other conditions. *Hyperkalemic periodic paralysis* (Chap. 367) is a rare autosomal dominant disorder characterized by episodic weakness or paralysis, precipitated by stimuli that normally lead to mild hyperkalemia (e.g., exercise). The genetic defect appears to be a single amino acid substitution due to a mutation in the gene for the skeletal muscle Na^+ channel. Hyperkalemia may occur with severe digitalis toxicity due to inhibition of the Na^+,K^+-ATPase pump. Depolarizing muscle relaxants such as succinylcholine can increase the plasma K^+ concentration, especially in patients with massive trauma, burns, or neuromuscular disease.

Chronic hyperkalemia is virtually always associated with decreased renal K^+ excretion due to either impaired secretion or diminished distal solute delivery (Table 41-4). The latter is seldom the only cause of impaired K^+ excretion but may significantly contribute to hyperkalemia in protein-malnourished (low urea excretion) and ECF volume–contracted (decreased distal NaCl delivery) patients. Decreased K^+ secretion by the principal cells results from either impaired Na^+ reabsorption or increased Cl^- reabsorption.

TABLE 41-4 Causes of Hyperkalemia

I. Renal failure
II. Decreased distal flow (i.e., decreased effective circulating arterial volume)
III. Decreased K^+ secretion
  A. Impaired Na^+ reabsorption
    1. Primary hypoaldosteronism: adrenal insufficiency, adrenal enzyme deficiency (21-hydroxylase, 3β-hydroxysteroid dehydrogenase, corticosterone methyl oxidase)
    2. Secondary hypoaldosteronism: hyporeninemia, drugs (ACE inhibitors, NSAIDs, heparin)
    3. Resistance to aldosterone: pseudohypoaldosteronism, tubulointerstitial disease, drugs (K^+-sparing diuretics, trimethoprim, pentamidine)
  B. Enhanced Cl^- reabsorption (chloride shunt)
    1. Gordon's syndrome
    2. Cyclosporine

Note: ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Hyporeninemic hypoaldosteronism is a syndrome characterized by euvolemia or ECF volume expansion and suppressed renin and aldosterone levels (Chaps. 321 and 323). This disorder is commonly seen in mild renal insufficiency, diabetic nephropathy, or chronic tubulointerstitial disease. Patients frequently have an impaired kaliuretic response to exogenous mineralocorticoid administration, suggesting that enhanced distal Cl^- reabsorption (electroneutral Na^+ reabsorption) may account for many of the findings of hyporeninemic hypoaldosteronism. NSAIDs inhibit renin secretion and the synthesis of vasodilatory renal prostaglandins. The resultant decrease in GFR and K^+ secretion is often manifest as hyperkalemia. As a rule, the degree of hyperkalemia due to hypoaldosteronism is mild in the absence of increased K^+ intake or renal dysfunction.

Angiotensin-converting enzyme (ACE) inhibitors block the conversion of angiotensin I to angiotensin II. Angiotensin receptor antagonists directly inhibit the actions of angiotensin II on AT1 angiotensin II receptors. The actions of both of these classes of drugs result in impaired aldosterone release. Patients at increased risk of ACE inhibitor or angiotensin receptor antagonist–induced hyperkalemia include those with diabetes mellitus, renal insufficiency, decreased effective circulating arterial volume, bilateral renal artery stenosis, or concurrent use of K^+-sparing diuretics or NSAIDs.

Decreased aldosterone synthesis may be due to *primary adrenal insufficiency* (Addison's disease) or congenital adrenal enzyme deficiency (Chap. 321). Heparin (including low-molecular-weight heparin) inhibits production of aldosterone by the cells of the zona glomerulosa and can lead to severe hyperkalemia in a subset of patients with underlying renal disease, diabetes mellitus, or those receiving K^+-sparing diuretics, ACE inhibitors, or NSAIDs. *Pseudohypoaldosteronism* is a rare familial disorder characterized by hyperkalemia, metabolic acidosis, renal Na^+ wasting, hypotension, high renin and aldosterone levels, and end-organ resistance to aldosterone. The gene encoding the mineralocorticoid receptor is normal in these patients, and the electrolyte abnormalities can be reversed with suprapharmacologic doses of an exogenous mineralocorticoid (e.g., 9α-fludrocortisone) or an inhibitor of 11β-HSDH (e.g., carbenoxolone). The kaliuretic response to aldosterone is impaired by K^+-sparing diuretics. Spironolactone is a competitive mineralocorticoid antagonist, whereas amiloride and triamterene block the apical Na^+ channel of the principal cell. Two other drugs that impair K^+ secretion by blocking distal nephron Na^+ reabsorption are trimethoprim and pentamidine. These antimicrobial agents may contribute to the hyperkalemia often seen in patients infected with HIV who are being treated for *Pneumocystis carinii* pneumonia.

Hyperkalemia frequently complicates acute oliguric renal failure due to increased K^+ release from cells (acidosis, catabolism) and decreased excretion. Increased distal flow rate and K^+ secretion per nephron compensate for decreased renal mass in chronic renal insufficiency. However, these adaptive mechanisms eventually fail to maintain K^+ balance when the GFR falls below 10 to 15 mL/min or oliguria ensues. Otherwise asymptomatic urinary tract obstruction is an often overlooked cause of hyperkalemia. Other nephropathies associated with impaired K^+ excretion include drug-induced interstitial nephritis, lupus nephritis, sickle cell disease, and diabetic nephropathy.

Gordon's syndrome is a rare condition characterized by hyperkalemia, metabolic acidosis, and a normal GFR. These patients are usually volume-expanded with suppressed renin and aldosterone levels as well as refractory to the kaliuretic effect of exogenous mineralocorticoids. It has been suggested that these findings could all be accounted for by increased distal Cl^- reabsorption (electroneutral Na^+ reabsorption), also referred to as a *Cl^- shunt*. A similar mechanism may be partially responsible for the hyperkalemia associated with cyclosporine nephrotoxicity. *Hyperkalemic distal (type 4) RTA* may be due to either hypoaldosteronism or a Cl^- shunt (aldosterone-resistant).

CLINICAL FEATURES Since the resting membrane potential is related to the ratio of the ICF to ECF K^+ concentration, hyperkalemia partially depolarizes the cell membrane. Prolonged depolarization impairs membrane excitability and is manifest as weakness, which may progress to flaccid paralysis and hypoventilation if the respiratory muscles are involved. Hyperkalemia also inhibits renal ammoniagenesis and reabsorption of NH_4^+ in the thick ascending limb of the loop of Henle. Thus, net acid excretion is impaired and results in metabolic acidosis, which may further exacerbate the hyperkalemia due to K^+ movement out of cells.

The most serious effect of hyperkalemia is cardiac toxicity, which does not correlate well with the plasma K^+ concentration. The earliest electrocardiographic changes include increased T-wave amplitude, or peaked T waves. More severe degrees of hyperkalemia result in a prolonged PR interval and QRS duration, atrioventricular conduction delay, and loss of P waves. Progressive widening of the QRS complex and merging with the T wave produces a sine wave pattern. The terminal event is usually ventricular fibrillation or asystole.

DIAGNOSIS (Fig. 41-4) With rare exceptions, chronic hyperkalemia is always due to impaired K^+ excretion. If the etiology is not readily apparent and the patient is asymptomatic, pseudohyperkalemia should be excluded, as described above. Oliguric acute renal failure and severe chronic renal insufficiency should also be ruled out. The history should focus on medications that impair K^+ handling and potential sources of K^+ intake. Evaluation of the ECF compartment, effective circulating volume, and urine output are essential components of the physical examination. The severity of hyperkalemia is determined by the symptoms, plasma K^+ concentration, and electrocardiographic abnormalities.

The appropriate renal response to hyperkalemia is to excrete at least 200 mmol of K^+ daily. In most cases, diminished renal K^+ loss is due to impaired K^+ secretion, which can be assessed by measuring the transtubular K^+ concentration gradient (TTKG). A TTKG <10 implies a decreased driving force for K^+ secretion due to either hypoaldosteronism or resistance to the renal effects of mineralocorticoid. This can be determined by evaluating the kaliuretic response to administration of mineralocorticoid (e.g., 9α-fludrocortisone). Primary adrenal insufficiency can be differentiated from hyporeninemic hypoaldosteronism by examining the renin-aldosterone axis. Renin and aldosterone levels should be measured in the supine and upright positions, following three days of Na^+ restriction (Na^+ intake <10 mmol/d) in combination with a loop diuretic to induce mild volume contraction. Aldosterone-resistant hyperkalemia can result from the various causes of impaired distal Na^+ reabsorption or from a Cl^- shunt. The former leads to salt wasting, ECF volume contraction, and high renin and aldosterone levels. In contrast, enhanced distal Cl^- reabsorption is associated with volume expansion and suppressed renin and aldosterone secretion. As mentioned above, hypoaldosteronism seldom causes severe hyperkalemia in the absence of increased dietary K^+ intake, renal insufficiency, transcellular K^+ shifts, or antikaliuretic drugs.

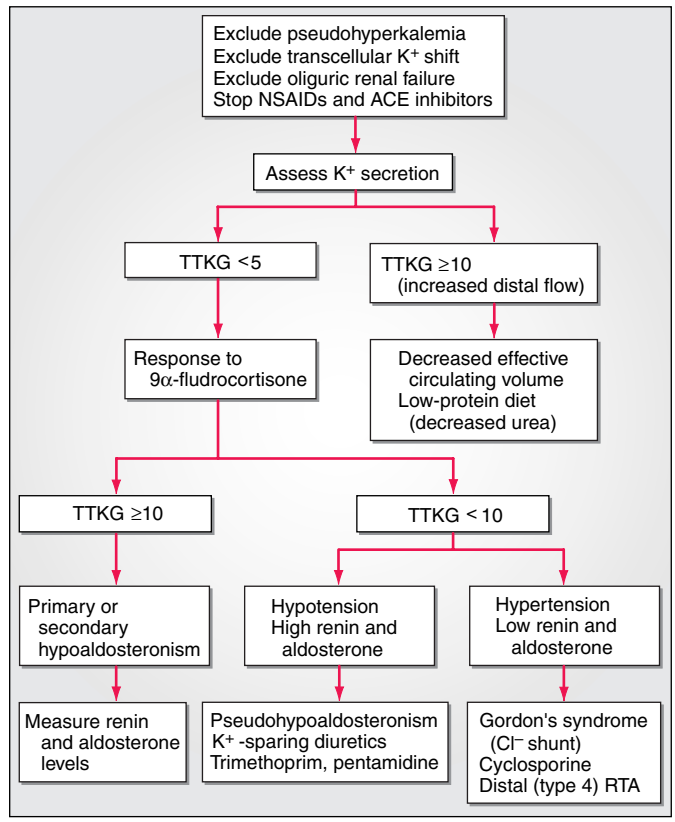

FIGURE 41-4 Algorithm depicting clinical approach to hyperkalemia. NSAID, nonsteroidal anti-inflammatory drug; ACE, angiotensin-converting enzyme; RTA, renal tubular acidosis; TTKG, transtubular K^+ concentration gradient.

TREATMENT

The approach to therapy depends on the degree of hyperkalemia as determined by the plasma K^+ concentration, associated muscular weakness, and changes on the electrocardiogram. Potentially fatal hyperkalemia rarely occurs unless the plasma K^+ concentration exceeds 7.5 mmol/L and is usually associated with profound weakness and absent P waves, QRS widening, or ventricular arrhythmias on the electrocardiogram.

Severe hyperkalemia requires emergent treatment directed at minimizing membrane depolarization, shifting K^+ into cells, and promoting K^+ loss. In addition, exogenous K^+ intake and antikaliuretic drugs should be discontinued. Administration of calcium gluconate decreases membrane excitability. The usual dose is 10 mL of a 10% solution infused over 2 to 3 min. The effect begins within minutes but is short-lived (30 to 60 min), and the dose can be repeated if no change in the electrocardiogram is seen after 5 to 10 min. Insulin causes K^+ to shift into cells by mechanisms described previously and will temporarily lower the plasma K^+ concentration. Although glucose alone will stimulate insulin release from normal pancreatic β cells, a more rapid response generally occurs when exogenous insulin is administered (with glucose to prevent hypoglycemia). A commonly recommended combination is 10 to 20 units of regular insulin and 25 to 50 g of glucose. Obviously, hyperglycemic patients should not be given glucose. If effective, the plasma K^+ concentration will fall by 0.5 to 1.5 mmol/L in 15 to 30 min and the effect will last for several hours. Alkali therapy with intravenous $NaHCO_3$ can also shift K^+ into cells. This is safest when administered as an isotonic solution of 3

ampules per liter (134 mmol/L $NaHCO_3$) and ideally should be reserved for severe hyperkalemia associated with metabolic acidosis. Patients with end-stage renal disease seldom respond to this intervention and may not tolerate the Na^+ load and resultant volume expansion. When administered parenterally or in nebulized form, β_2-adrenergic agonists promote cellular uptake of K^+ (see above). The onset of action is 30 min, lowering the plasma K^+ concentration by 0.5 to 1.5 mmol/L, and the effect lasts 2 to 4 h.

Removal of K^+ can be achieved using diuretics, cation-exchange resin, or dialysis. Loop and thiazide diuretics, often in combination, may enhance K^+ excretion if renal function is adequate. Sodium polystyrene sulfonate is a cation-exchange resin that promotes the exchange of Na^+ for K^+ in the gastrointestinal tract. Each gram binds 1 mmol of K^+ and releases 2 to 3 mmol of Na^+. When given by mouth, the usual dose is 25 to 50 g mixed with 100 mL of 20% sorbitol to prevent constipation. This will generally lower the plasma K^+ concentration by 0.5 to 1.0 mmol/L within 1 to 2 h and last for 4 to 6 h. Sodium polystyrene sulfonate can also be administered as a retention enema consisting of 50 g of resin and 50 mL of 70% sorbitol mixed in 150 mL of tap water. The sorbitol should be omitted from the enema in postoperative patients due to the increased incidence of sorbitol-induced colonic necrosis, especially following renal transplantation. The most rapid and effective way of lowering the plasma K^+ concentration is hemodialysis. This should be reserved for patients with renal failure and those with severe life-threatening hyperkalemia unresponsive to more conservative measures. Peritoneal dialysis also removes K^+ but is only 15 to 20% as effective as hemodialysis. Finally, the underlying cause of the hyperkalemia should be treated. This may involve dietary modification, correction of metabolic acidosis, cautious volume expansion, and administration of exogenous mineralocorticoid.

42 ACIDOSIS AND ALKALOSIS

Thomas D. DuBose, Jr.

NORMAL ACID-BASE HOMEOSTASIS

Systemic arterial pH is maintained between 7.35 and 7.45 by extracellular and intracellular chemical buffering together with respiratory and renal regulatory mechanisms. The control of arterial CO_2 tension (Pa_{CO_2}) by the central nervous system and respiratory systems and the control of the plasma bicarbonate by the kidneys stabilize the arterial pH by excretion or retention of acid or alkali. The metabolic and respiratory components that regulate systemic pH are described by the Henderson-Hasselbalch equation:

$$pH = 6.1 + \log \frac{HCO_3^-}{Pa_{CO_2} \times 0.0301}$$

Under most circumstances, CO_2 production and excretion are matched, and the usual steady-state Pa_{CO_2} is maintained at 40 mmHg. Underexcretion of CO_2 produces hypercapnia, and overexcretion causes hypocapnia. Nevertheless, production and excretion are again matched at a new steady-state Pa_{CO_2}. Therefore, the Pa_{CO_2} is regulated primarily by neural respiratory factors (Chap. 246) and is not subject to regulation by the rate of CO_2 production. Hypercapnia is usually the result of hypoventilation rather than of increased CO_2 production. Increases or decreases in Pa_{CO_2} represent derangements of neural respiratory control or are due to compensatory changes in response to a primary alteration in the plasma [HCO_3^-].

Primary changes in Pa_{CO_2} can cause acidosis or alkalosis, depending on whether Pa_{CO_2} is above or below the normal value of 40 mmHg (respiratory acidosis or alkalosis, respectively). Primary alteration of Pa_{CO_2} evokes cellular buffering and renal adaptation, a slow process that becomes more efficient with time. A primary change in the plasma [HCO_3^-] as a result of metabolic or renal factors results in compensatory changes in ventilation that blunt the changes in blood pH that would occur otherwise. Such respiratory alterations are referred to as *secondary*, or compensatory, changes, since they occur in response to primary metabolic changes.

The kidneys regulate plasma [HCO_3^-] through three main processes: (1) "reabsorption" of filtered HCO_3^-, (2) formation of titratable acid, and (3) excretion of NH_4^+ in the urine. The kidney filters approximately 4000 mmol of HCO_3^- per day. To reabsorb the filtered load of HCO_3^-, the renal tubules must therefore secrete 4000 mmol of hydrogen ions. Between 80 and 90% of HCO_3^- is reabsorbed in the proximal tubule. The distal nephron reabsorbs the remainder and secretes protons, as generated from metabolism, to defend systemic pH. While this quantity of protons, 40 to 60 mmol/d, is small, it must be secreted to prevent chronic positive H^+ balance and metabolic acidosis. This quantity of secreted protons is represented in the urine as titratable acid and NH_4^+. Metabolic acidosis in the face of normal renal function increases NH_4^+ production and excretion. NH_4^+ production and excretion are impaired in chronic renal failure, hyperkalemia, and renal tubular acidosis.

In sum, these regulatory responses, including chemical buffering, the regulation of Pa_{CO_2} by the respiratory system, and the regulation of [HCO_3^-] by the kidneys, act in concert to maintain a systemic arterial pH between 7.35 and 7.45.

DIAGNOSIS OF GENERAL TYPES OF DISTURBANCES

The most common clinical disturbances are simple acid-base disorders, i.e., metabolic acidosis or alkalosis or respiratory acidosis or alkalosis. Since compensation is not complete, the pH is abnormal in simple disturbances. More complicated clinical situations can give rise to mixed acid-base disturbances.

SIMPLE ACID-BASE DISORDERS Primary respiratory disturbances (primary changes in Pa_{CO_2}) invoke compensatory metabolic responses (secondary changes in [HCO_3^-]), and primary metabolic disturbances elicit predictable compensatory respiratory responses. Physiologic compensation can be predicted from the relationships displayed in Table 42-1. Primary changes in Pa_{CO_2} or [HCO_3^-] alter systemic pH and cause acidosis or alkalosis. To illustrate, metabolic acidosis due to an increase in endogenous acids (e.g., ketoacidosis) lowers extracellular fluid [HCO_3^-] and decreases extracellular pH. This stimulates the medullary chemoreceptors to increase ventilation and to return the ratio of [HCO_3^-] to Pa_{CO_2}, and thus pH, toward normal, although not to normal. The degree of respiratory compensation expected in a simple form of metabolic acidosis can be predicted from the relationship: $Pa_{CO_2} = (1.5 \times [HCO_3^-]) + 8$, i.e., the Pa_{CO_2} is expected to decrease 1.25 mmHg for each mmol per liter decrease in [HCO_3^-]. Thus, a patient

TABLE 42-1 *Prediction of Compensatory Responses on Simple Acid-Base Disturbances*

Disorder	Prediction of Compensation
Metabolic acidosis	$Pa_{CO_2} = (1.5 \times HCO_3^-) + 8$
	or
	Pa_{CO_2} will ↓ 1.25 mmHg per mmol/L ↓ in $[HCO_3^-]$
	or
	$Pa_{CO_2} = [HCO_3^-] + 15$
Metabolic alkalosis	Pa_{CO_2} will ↑ 0.75 mmHg per mmol/L ↑ in $[HCO_3^-]$
	or
	Pa_{CO_2} will ↑ 6 mmHg per 10 mmol/L ↑ in $[HCO_3^-]$
	or
	$Pa_{CO_2} = [HCO_3^-] + 15$
Respiratory alkalosis	
Acute	$[HCO_3^-]$ will ↓ 2 mmol/L per 10 mmHg ↓ in Pa_{CO_2}
Chronic	$[HCO_3^-]$ will ↓ 4 mmol/L per 10 mmHg ↓ in Pa_{CO_2}
Respiratory acidosis	
Acute	$[HCO_3^-]$ will ↑ 1 mmol/L per 10 mmHg ↑ in Pa_{CO_2}
Chronic	$[HCO_3^-]$ will ↑ 4 mmol/L per 10 mmHg ↑ in Pa_{CO_2}

with metabolic acidosis and $[HCO_3^-]$ of 12 mmol/L would be expected to have a Pa_{CO_2} between 24 and 28 mmHg. Values for Pa_{CO_2} below 24 or greater than 28 mmHg define a mixed disturbance (metabolic acidosis and respiratory alkalosis or metabolic alkalosis and respiratory acidosis, respectively). Another way to judge the appropriateness of the response in $[HCO_3^-]$ or Pa_{CO_2} is to use an acid-base nomogram (Fig. 42-1). While the shaded areas of the nomogram show the 95% confidence limits for normal compensation in simple disturbances, finding acid-base values within the shaded area does not necessarily rule out a mixed disturbance. Imposition of one disorder over another may result in values lying within the area of a third. Thus, the nomogram, while convenient, is not a substitute for the equations in Table 42-1.

MIXED ACID-BASE DISORDERS Mixed acid-base disorders—defined as independently coexisting disorders, not merely compensatory responses—are often seen in patients in critical care units and can lead to dangerous extremes of pH. A patient with diabetic ketoacidosis (metabolic acidosis) may develop an independent respiratory problem leading to respiratory acidosis or alkalosis. Patients with underlying pulmonary disease may not respond to metabolic acidosis with an appropriate ventilatory response because of insufficient respiratory reserve. Such imposition of respiratory acidosis on metabolic acidosis can lead to severe acidemia and a poor outcome. When metabolic acidosis and metabolic alkalosis coexist in the same patient, the pH may be normal or near normal. When the pH is normal, an elevated anion gap (see below) denotes the presence of a metabolic acidosis. A diabetic patient with ketoacidosis may have renal dysfunction resulting in simultaneous metabolic acidosis. Patients who have ingested an overdose of drug combinations such as sedatives and salicylates may have mixed disturbances as a result of the acid-base response to the individual drugs (metabolic acidosis mixed with respiratory acidosis or respiratory alkalosis, respectively). Even more complex are triple acid-base disturbances. For example, patients with metabolic acidosis due to alcoholic ketoacidosis may develop metabolic alkalosis due to vomiting and superimposed respiratory alkalosis due to the hyperventilation of hepatic dysfunction or alcohol withdrawal.

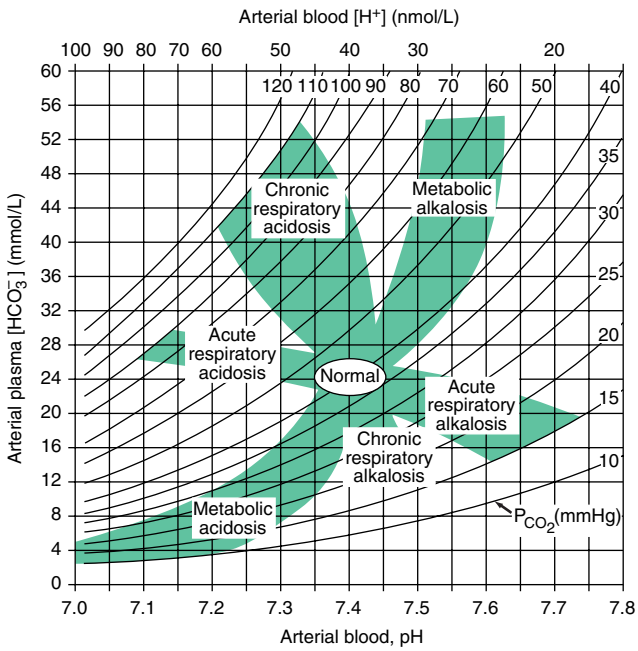

FIGURE 42-1 Acid-base nomogram. Shown are the 90% confidence limits of the normal respiratory and metabolic compensations for primary acid-base disturbances. *(From DuBose, used with permission.)*

DIAGNOSIS OF ACID-BASE DISORDERS A stepwise approach to the diagnosis of acid-base disorders follows and is summarized in Table 42-2. Care should be taken when measuring blood gases to obtain the arterial blood sample without using excessive heparin. In the determination of arterial blood gases by the clinical laboratory, both pH and Pa_{CO_2} are measured, and the $[HCO_3^-]$ is calculated from the Henderson-Hasselbalch equation. This calculated value should be compared with the measured $[HCO_3^-]$ (total CO_2) on the electrolyte panel. These two values should agree within 2 mmol/L. If they do not, the values may not have been drawn simultaneously, a laboratory error may be present, or an error could have been made in calculating the $[HCO_3^-]$. After verifying the blood acid-base values, one can then identify the precise acid-base disorder.

The most common causes of acid-base disorders should be kept in mind while probing the history for clues about the etiology. For example, established chronic renal failure is expected to cause a metabolic acidosis, and chronic vomiting frequently causes metabolic alkalosis. Patients with pneumonia, sepsis, or cardiac failure frequently have respiratory alkalosis, and patients with chronic obstructive pulmonary disease or a sedative drug overdose often display a respiratory acidosis. The drug history is important since loop or thiazide diuretics may cause metabolic alkalosis, and the carbonic anhydrase inhibitor acetazolamide can result in metabolic acidosis.

Blood for electrolytes and arterial blood gases should be drawn simultaneously prior to therapy, since an increase in $[HCO_3^-]$ occurs with metabolic alkalosis and respiratory acidosis. Conversely, a decrease in $[HCO_3^-]$ occurs in metabolic acidosis and respiratory alkalosis.

Metabolic acidosis leads to hyperkalemia as a result of cellular shifts in which H^+ is exchanged for K^+ or Na^+. For each decrease in blood pH of 0.10, the plasma $[K^+]$ should rise by 0.6 mmol/L. This relationship is not invariable. Diabetic ketoacidosis, lactic acidosis, diarrhea, and renal tubular acidosis (RTA) are often associated with potassium depletion because of urinary K^+ wasting.

Anion Gap All evaluations of acid-base disorders should include a simple calculation of the anion gap (AG); it represents those unmeasured anions in plasma (normally 10 to 12 mmol/L) and is calculated as

TABLE 42-2 *Steps in Acid-Base Diagnosis*

1. Obtain arterial blood gases (ABGs) and electrolytes (lytes) simultaneously.
2. Compare $[HCO_3]$ on ABG and lytes to verify accuracy.
3. Calculate anion gap (AG).
4. Know four causes of high AG acidosis (ketoacidosis, lactic acid acidosis, renal failure, and toxins).
5. Know two causes of high hyperchloremic or nongap acidosis (bicarbonate loss from GI tract, renal tubular acidosis).
6. Estimate compensatory response (Table 42-1).
7. Compare ΔAG and ΔHCO_3^-.
8. Compare change in $[Cl^-]$ with change in $[Na^+]$.

follows: AG = $Na^+ - (Cl^- + HCO_3^-)$. The unmeasured anions include anionic proteins, phosphate, sulfate, and organic anions. When acid anions, such as acetoacetate and lactate, accumulate in extracellular fluid, the AG increases, causing a high-AG acidosis. An increase in the AG is most often due to an increase in unmeasured anions and less commonly is due to a decrease in unmeasured cations (calcium, magnesium, potassium). In addition, the AG may increase with an increase in anionic albumin, either because of increased albumin concentration or alkalosis, which alters albumin charge. A decrease in the AG can be due to (1) an increase in unmeasured cations; (2) the addition to the blood of abnormal cations, such as lithium (lithium intoxication) or cationic immunoglobulins (plasma cell dyscrasias); (3) a reduction in the major plasma anion albumin concentration (nephrotic syndrome); (4) a decrease in the effective anionic charge on albumin by acidosis; or (5) hyperviscosity and severe hyperlipidemia, which can lead to an underestimation of sodium and chloride concentrations. A fall in serum albumin by 1 g/dL from the normal value (4.5 g/dL) decreases the anion gap by 2.5 meq/L.

In the face of a normal serum albumin, a high AG is usually due to non-chloride-containing acids that contain inorganic (phosphate, sulfate), organic (ketoacids, lactate, uremic organic anions), exogenous (salicylate or ingested toxins with organic acid production), or unidentified anions. By definition, therefore, a high-AG acidosis has two identifying features: a low $[HCO_3^-]$ and an elevated AG. The latter is present even if an additional acid-base disorder is superimposed to modify the $[HCO_3^-]$ independently. Simultaneous metabolic acidosis of the high-AG variety plus either chronic respiratory acidosis or metabolic alkalosis represents such a situation in which $[HCO_3^-]$ may be normal or even high. However, the AG is elevated, and $[Cl^-]$ is depressed.

Similarly, normal values for $[HCO_3^-]$, Pa_{CO_2}, and pH do not ensure the absence of an acid-base disturbance. For instance, an alcoholic who has been vomiting may develop a metabolic alkalosis with a pH of 7.55, Pa_{CO_2} of 48 mmHg, $[HCO_3^-]$ of 40 mmol/L, $[Na^+]$ of 135, $[Cl^-]$ of 80, and $[K^+]$ of 2.8. If such a patient were then to develop a superimposed alcoholic ketoacidosis with a β-hydroxybutyrate concentration of 15 m*M*, arterial pH would fall to 7.40, $[HCO_3^-]$ to 25 mmol/L, and the Pa_{CO_2} to 40 mmHg. Although these blood gases are normal, the AG is elevated at 30 mmol/L, indicating a mixed metabolic alkalosis and metabolic acidosis.

METABOLIC ACIDOSIS

Metabolic acidosis can occur because of an increase in endogenous acid production (such as lactate and ketoacids), loss of bicarbonate (as in diarrhea), or accumulation of endogenous acids (as in renal failure). Metabolic acidosis has profound effects on the respiratory, cardiac, and nervous systems. The fall in blood pH is accompanied by a characteristic increase in ventilation, especially the tidal volume (Kussmaul respiration). Intrinsic cardiac contractility may be depressed, but inotropic function can be normal because of catecholamine release. Both peripheral arterial vasodilation and central venoconstriction can be present; the decrease in central and pulmonary vascular compliance predisposes to pulmonary edema with even minimal volume overload. Central nervous system function is depressed, with headache, lethargy, stupor, and, in some cases, even coma. Glucose intolerance may also occur.

There are two major categories of clinical metabolic acidosis: high-anion-gap (AG) and normal-AG, or hyperchloremic acidosis (Table 42-3 and Table 42-4).

TABLE 42-3 Causes of High-Anion-Gap Metabolic Acidosis

Lactic acidosis	Toxins
Ketoacidosis	Ethylene glycol
Diabetic	Methanol
Alcoholic	Salicylates
Starvation	Renal failure (acute and chronic)

TABLE 42-4 Causes of Non-Anion-Gap Acidosis

I. Gastrointestinal bicarbonate loss
- A. Diarrhea
- B. External pancreatic or small-bowel drainage
- C. Ureterosigmoidostomy, jejunal loop, ileal loop
- D. Drugs
  1. Calcium chloride (acidifying agent)
  2. Magnesium sulfate (diarrhea)
  3. Cholestyramine (bile acid diarrhea)

II. Renal acidosis
- A. Hypokalemia
  1. Proximal RTA (type 2)
  2. Distal (classic) RTA (type 1)
- B. Hyperkalemia
  1. Generalized distal nephron dysfunction (type 4 RTA)
     - a. Mineralocorticoid deficiency
     - b. Mineralocorticoid resistance
     - c. $\downarrow Na^+$ delivery to distal nephron
     - d. Tubulointerstitial disease
     - e. Ammonium excretion defect

III. Drug-induced hyperkalemia (with renal insufficiency)
- A. Potassium-sparing diuretics (amiloride, triamterene, spironolactone)
- B. Trimethoprim
- C. Pentamidine
- D. Angiotensin-converting enzyme inhibitors and AT-II receptor blockers
- E. Nonsteroidal anti-inflammatory drugs
- F. Cyclosporine

IV. Other
- A. Acid loads (ammonium chloride, hyperalimentation)
- B. Loss of potential bicarbonate: ketosis with ketone excretion
- C. Expansion acidosis (rapid saline administration)
- D. Hippurate
- E. Cation exchange resins

Note: RTA, renal tubular acidosis; AT-II, angiotensin-II receptor blockers.

TREATMENT

Treatment of metabolic acidosis with alkali should be reserved for severe acidemia except when the patient has no "potential HCO_3^-" in plasma. Potential $[HCO_3^-]$ can be estimated from the increment (Δ) in the AG (ΔAG = patient's AG − 10). It must be determined if the acid anion in plasma is metabolizable (i.e., β-hydroxybutyrate, acetoacetate, and lactate) or nonmetabolizable (anions that accumulate in chronic renal failure and after toxin ingestion). The latter requires return of renal function to replenish the $[HCO_3^-]$ deficit, a slow and often unpredictable process. Consequently, patients with a normal AG acidosis (hyperchloremic acidosis), a slightly elevated AG (mixed hyperchloremic and AG acidosis), or an AG attributable to a nonmetabolizable anion in the face of renal failure should receive alkali therapy, either orally ($NaHCO_3$ or Shohl's solution) or intravenously ($NaHCO_3$), in an amount necessary to slowly increase the plasma $[HCO_3^-]$ into the 20 to 22 mmol/L range.

Controversy exists, however, in regard to the use of alkali in patients with a pure AG acidosis owing to accumulation of a metabolizable organic acid anion (ketoacidosis or lactic acidosis). In general, severe acidosis (pH <7.20) warrants the intravenous administration of 50 to 100 meq of $NaHCO_3$, over 30 to 45 min, during the initial 1 to 2 h of therapy. Provision of such modest quantities of alkali in this situation seems to provide an added measure of safety, but it is essential to monitor plasma electrolytes during the course of therapy, since the $[K^+]$ may decline as pH rises. The goal is to increase the $[HCO_3^-]$ to 10 meq/L and the pH to 7.15, not to increase these values to normal.

HIGH-ANION-GAP ACIDOSES There are four principal causes of a high-AG acidosis: (1) lactic acidosis, (2) ketoacidosis, (3) ingested toxins, and (4) acute and chronic renal failure (Table 42-3). Initial screening to differentiate the high-AG acidoses should include (1) a probe of the

history for evidence of drug and toxin ingestion and measurement of arterial blood gas to detect coexistent respiratory alkalosis (salicylates); (2) determination of whether diabetes mellitus is present (diabetic ketoacidosis); (3) a search for evidence of alcoholism or increased levels of β-hydroxybutyrate (alcoholic ketoacidosis); (4) observation for clinical signs of uremia and determination of the blood urea nitrogen (BUN) and creatinine (uremic acidosis); (5) inspection of the urine for oxalate crystals (ethylene glycol); and (6) recognition of the numerous clinical settings in which lactate levels may be increased (hypotension, shock, cardiac failure, leukemia, cancer, and drug or toxin ingestion).

Lactic Acidosis An increase in plasma L-lactate may be secondary to poor tissue perfusion (type A)—circulatory insufficiency (shock, circulatory failure), severe anemia, mitochondrial enzyme defects, and inhibitors (carbon monoxide, cyanide)—or to aerobic disorders (type B)—malignancies, diabetes mellitus, renal or hepatic failure, severe infections (cholera, malaria), seizures, AIDS, or drugs/toxins (biguanides, ethanol, methanol, isoniazid, AZT analogues, and fructose). Unrecognized bowel ischemia or infarction in a patient with severe atherosclerosis or cardiac decompensation receiving vasopressors is a common cause of lactic acidosis. D-Lactic acid acidosis, which may be associated with jejunoileal bypass or intestinal obstruction and is due to formation of D-lactate by gut bacteria, may cause both an increased AG and hyperchloremia.

℞ TREATMENT

The underlying condition that disrupts lactate metabolism must first be corrected; tissue perfusion must be restored when it is inadequate. Vasoconstrictors should be avoided, if possible, since they may worsen tissue perfusion. Alkali therapy is generally advocated for acute, severe acidemia (pH <7.15) to improve cardiac function and lactate utilization. However, $NaHCO_3$ therapy may paradoxically depress cardiac performance and exacerbate acidosis by enhancing lactate production (HCO_3^- stimulates phosphofructokinase). While the use of alkali in moderate lactic acidosis is controversial, it is generally agreed that attempts to return the pH or [HCO_3^-] to normal by administration of exogenous $NaHCO_3$ are deleterious. A reasonable approach is to infuse sufficient $NaHCO_3$ to raise the arterial pH to no more than 7.2 over 30 to 40 min.

$NaHCO_3$ therapy can cause fluid overload and hypertension because the amount required can be massive when accumulation of lactic acid is relentless. Fluid administration is poorly tolerated because of central venoconstriction, especially in the oliguric patient. If the underlying cause of the lactic acidosis can be remedied, blood lactate will be converted to HCO_3^- and may result in an overshoot alkalosis.

Ketoacidosis ■ *DIABETIC KETOACIDOSIS* This condition is caused by increased fatty acid metabolism and the accumulation of ketoacids (acetoacetate and β-hydroxybutyrate). Diabetic ketoacidosis usually occurs in insulin-dependent diabetes mellitus in association with cessation of insulin or an intercurrent illness, such as an infection, gastroenteritis, pancreatitis, or myocardial infarction, which increases insulin requirements temporarily and acutely. The accumulation of ketoacids accounts for the increment in the AG and is accompanied most often by hyperglycemia [glucose >17 mmol/L (300 mg/dL)]. It should be noted that since insulin prevents production of ketones, bicarbonate therapy is rarely needed except with extreme acidemia (pH <7.1), and then in only limited amounts (see "Treatment" for lactic acidosis). →***The management of this condition is described in Chap. 323.***

ALCOHOLIC KETOACIDOSIS Chronic alcoholics can develop ketoacidosis when alcohol consumption is abruptly curtailed; it is usually associated with binge drinking, vomiting, abdominal pain, starvation, and volume depletion. The glucose concentration is low or normal, and acidosis may be severe because of elevated ketones, predominantly β-hydroxybutyrate. Mild lactic acidosis may coexist because of alteration in the redox state. The nitroprusside ketone reaction (Acetest) can detect acetoacetic acid but not β-hydroxybutyrate, so that the degree of ketosis and ketonuria can be underestimated. Typically, insulin levels are low, and concentrations of triglyceride, cortisol, glucagon, and growth hormone are increased.

℞ TREATMENT

Extracellular fluid deficits should be repleted by intravenous administration of saline and glucose (5% dextrose in 0.9% NaCl). Hypophosphatemia, hypokalemia, and hypomagnesemia may coexist and should be corrected. Hypophosphatemia usually emerges 12 to 24 h after admission, may be exacerbated by glucose infusion, and, if severe, may induce rhabdomyolysis. Upper gastrointestinal hemorrhage, pancreatitis, and pneumonia may accompany this disorder.

Drug- and Toxin-Induced Acidosis ■ *SALICYLATES* (See also Chap. 377.) Salicylate intoxication in adults usually causes respiratory alkalosis, mixed metabolic acidosis–respiratory alkalosis, or a pure high-AG metabolic acidosis. In the latter example, which is less common, only a portion of the AG is due to the salicylates. Lactic acid production is also often increased.

℞ TREATMENT

This should begin with vigorous gastric lavage with isotonic saline (not $NaHCO_3$) followed by administration of activated charcoal. In the acidotic patient, to facilitate removal of salicylate, intravenous $NaHCO_3$ is administered in amounts adequate to alkalinize the urine and to maintain urine output (urine pH >7.5). While this form of therapy is straightforward in acidotic patients, a coexisting respiratory alkalosis may make this approach hazardous. Acetazolamide may be administered when an alkaline diuresis cannot be achieved, but this drug can cause systemic metabolic acidosis if HCO_3^- is not replaced. Hypokalemia may occur with an alkaline diuresis from $NaHCO_3$ and should be treated promptly and aggressively. Glucose-containing fluids should be administered because of the danger of hypoglycemia. Excessive insensible fluid losses may cause severe volume depletion and hypernatremia. If renal failure prevents rapid clearance of salicylate, hemodialysis can be performed against a bicarbonate dialysate.

ALCOHOLS Under most physiologic conditions, sodium, urea, and glucose generate the osmotic pressure of blood. Plasma osmolality is calculated according to the following expression: $P_{osm} = 2Na^+ + Glu + BUN$ (all in mmol/L), or, using conventional laboratory values in which glucose and BUN are expressed in milligrams per deciliter: $P_{osm} = 2Na^+ + Glu/18 + BUN/2.8$. The calculated and determined osmolality should agree within 10 to 15 mmol/kg H_2O. When the measured osmolality exceeds the calculated osmolality by more than 15 to 20 mmol/kg H_2O, one of two circumstances prevails. Either the serum sodium is spuriously low, as with hyperlipidemia or hyperproteinemia (pseudohyponatremia), or osmolytes other than sodium salts, glucose, or urea have accumulated in plasma. Examples include mannitol, radiocontrast media, isopropyl alcohol, ethylene glycol, ethanol, methanol, and acetone. In this situation, the difference between the calculated osmolality and the measured osmolality (*osmolar gap*) is proportional to the concentration of the unmeasured solute. With an appropriate clinical history and index of suspicion, identification of an osmolar gap is helpful in identifying the presence of poison-associated AG acidosis.

ETHYLENE GLYCOL (See also Chap. 377.) Ingestion of ethylene glycol (commonly used in antifreeze) leads to a metabolic acidosis and severe damage to the central nervous system, heart, lungs, and kidneys. The increased AG and osmolar gap are attributable to ethylene glycol and its metabolites, oxalic acid, glycolic acid, and other organic acids. Lactic acid production increases secondary to inhibition of the tricarboxylic acid cycle and altered intracellular redox state. Diagnosis is facilitated by recognizing oxalate crystals in the urine, the presence of

an osmolar gap in serum, and a high-AG acidosis. Treatment should not be delayed while awaiting measurement of ethylene glycol levels in this setting.

TREATMENT

This includes the prompt institution of a saline or osmotic diuresis, thiamine and pyridoxine supplements, fomepizole or ethanol, and hemodialysis. The intravenous administration of the alcohol dehydrogenase inhibitor fomepizole (4-methylpyrazole; 7 mg/kg as a loading dose) or ethanol intravenously to achieve a level of 22 mmol/L (100 mg/dL) serves to lessen toxicity because they compete with ethylene glycol for metabolism by alcohol dehydrogenase. Fomepizole, although expensive, offers the advantages of a predictable decline in ethylene glycol levels without the adverse effects, such as excessive obtundation, associated with ethyl alcohol infusion.

METHANOL (See also Chap. 377.) The ingestion of methanol (wood alcohol) causes metabolic acidosis, and its metabolites formaldehyde and formic acid cause severe optic nerve and cental nervous system damage. Lactic acid, ketoacids, and other unidentified organic acids may contribute to the acidosis. Due to its low molecular weight (32 Da), an osmolar gap is usually present.

TREATMENT

This is similar to that for ethylene glycol intoxication, including general supportive measures, fomepizole or ethanol administration, and hemodialysis.

RENAL FAILURE (See also Chaps. 260 and 261) The hyperchloremic acidosis of moderate renal insufficiency is eventually converted to the high-AG acidosis of advanced renal failure. Poor filtration and reabsorption of organic anions contribute to the pathogenesis. As renal disease progresses, the number of functioning nephrons eventually becomes insufficient to keep pace with net acid production. Uremic acidosis is characterized, therefore, by a reduced rate of NH_4^+ production and excretion, primarily due to decreased renal mass. [HCO_3^-] rarely falls below 15 mmol/L, and the AG rarely exceeds 20 mmol/L. The acid retained in chronic renal disease is buffered by alkaline salts from bone. Despite significant retention of acid (up to 20 mmol/d), the serum [HCO_3^-] does not decrease further, indicating participation of buffers outside the extracellular compartment. Chronic metabolic acidosis results in significant loss of bone mass due to reduction in bone calcium carbonate. Chronic acidosis also increases urinary calcium excretion, proportional to cumulative acid retention.

TREATMENT

Both uremic acidosis and the hyperchloremic acidosis of renal failure require oral alkali replacement to maintain the [HCO_3^-] between 20 and 24 mmol/L. This can be accomplished with relatively modest amounts of alkali (1.0 to 1.5 mmol/kg body weight per day). It is assumed that alkali replacement prevents the harmful effects of H^+ balance on bone and prevents or retards muscle catabolism. Sodium citrate (Shohl's solution) or $NaHCO_3$ tablets are equally effective alkalinizing salts. Citrate enhances the absorption of aluminum from the gastrointestinal tract and should never be given together with aluminum-containing antacids because of the risk of aluminum intoxication. When hyperkalemia is present, furosemide (60 to 80 mg/d) should be added.

HYPERCHLOREMIC (NONGAP) METABOLIC ACIDOSES Alkali can be lost from the gastrointestinal tract in diarrhea or from the kidneys (renal tubular acidosis, RTA). In these disorders (Table 42-4), reciprocal changes in [Cl^-] and [HCO_3^-] result in a normal AG. In pure hyperchloremic acidosis, therefore, the increase in [Cl^-] above the normal value approximates the decrease in [HCO_3^-]. The absence of such a relationship suggests a mixed disturbance.

In diarrhea, stools contain a higher [HCO_3^-] and decomposed HCO_3^- than plasma so that metabolic acidosis develops along with volume depletion. Instead of an acid urine pH (as anticipated with systemic acidosis), urine pH is usually around 6 because metabolic acidosis and hypokalemia increase renal synthesis and excretion of NH_4^+, thus providing a urinary buffer that increases urine pH. Metabolic acidosis due to gastrointestinal losses with a high urine pH can be differentiated from RTA (Chap. 265) because urinary NH_4^+ excretion is typically low in RTA and high with diarrhea. Urinary NH_4^+ levels can be estimated by calculating the urine anion gap (UAG): $UAG = [Na^+ + K^+]_u - [Cl^-]_u$. When $[Cl^-]_u > [Na^+ + K^+]$, and the urine gap is negative, the urine ammonium level is appropriately increased, suggesting an extrarenal cause of the acidosis. Conversely, when the urine anion gap is positive, the urine ammonium level is low, suggesting a renal cause of the acidosis.

Loss of functioning renal parenchyma by progressive renal disease leads to hyperchloremic acidosis when the glomerular filtration rate (GFR) is between 20 and 50 mL/min and to uremic acidosis with a high AG when the GFR falls to <20 mL/min. Such a progression occurs commonly with tubulointerstitial forms of renal disease, but hyperchloremic metabolic acidosis can persist with advanced glomerular disease. In advanced renal failure, ammoniagenesis is reduced in proportion to the loss of functional renal mass, and ammonium accumulation and trapping in the outer medullary collecting tubule may also be impaired. Because of adaptive increases in K^+ secretion by the collecting duct and colon, the acidosis of chronic renal insufficiency is typically normokalemic.

Proximal RTA (type 2 RTA) (Chap. 265) is most often due to generalized proximal tubular dysfunction manifested by glycosuria, generalized aminoaciduria, and phosphaturia (Fanconi syndrome). With a low plasma [HCO_3^-], the urine pH is acid (pH <5.5). The fractional excretion of [HCO_3^-] may exceed 10 to 15% when the serum $HCO_3^- > 20$ mmol/L. Since HCO_3^- is not reabsorbed normally in the proximal tubule, therapy with $NaHCO_3$ will enhance renal potassium wasting and hypokalemia.

The typical findings in classic distal RTA (type 1 RTA) include hypokalemia, hyperchloremic acidosis, low urinary NH_4^+ excretion (positive UAG, low urine [NH_4^+]), and inappropriately high urine pH (pH >5.5). Such patients are unable to acidify the urine below a pH of 5.5. Most patients have hypocitraturia and hypercalciuria, so nephrolithiasis, nephrocalcinosis, and bone disease are common. In type 4 RTA, hyperkalemia is disproportionate to the reduction in GFR because of coexisting dysfunction of potassium and acid secretion. Urinary ammonium excretion is invariably depressed, and renal function may be compromised, for example, due to diabetic nephropathy, amyloidosis, or tubulointerstital disease. →***See Chap. 265 for the pathophysiology, diagnosis, and treatment of RTA.***

Hyporeninemic Hypoaldosteronism (See also Chap. 321) This condition typically causes hyperchloremic metabolic acidosis, most commonly in older adults with diabetes mellitus or tubulointerstitial disease and renal insufficiency. Patients usually have mild to moderate renal insufficiency and acidosis, with elevation in serum [K^+] (5.2 to 6.0 mmol/L), concurrent hypertension, and congestive heart failure. Both the metabolic acidosis and the hyperkalemia are out of proportion to impairment in GFR. Nonsteroidal anti-inflammatory drugs trimethoprim, pentamidine, and angiotensin-converting enzyme (ACE) inhibitors can also cause hyperkalemia with hyperchloremic metabolic acidosis in patients with renal insufficiency (Table 42-4).

METABOLIC ALKALOSIS

Metabolic alkalosis is manifested by an elevated arterial pH, an increase in the serum [HCO_3^-], and an increase in Pa_{CO_2} as a result of compensatory alveolar hypoventilation. It is often accompanied by hypochloremia and hypokalemia. The patient with a high [HCO_3^-] and a low [Cl^-] has either metabolic alkalosis or chronic respiratory acidosis. As shown in Table 42-1, the Pa_{CO_2} increases 6 mmHg for each 10-mmol/L increase in the [HCO_3^-] above normal. Stated differently, in the range of [HCO_3^-] from 10 to 40 mmol/L, the predicted Pa_{CO_2}

is approximately equal to the $[HCO_3^-]$ + 15. The arterial pH establishes the diagnosis, since it is increased in metabolic alkalosis and decreased or normal in respiratory acidosis. Metabolic alkalosis frequently occurs in association with other disorders such as respiratory acidosis or alkalosis or metabolic acidosis.

PATHOGENESIS Metabolic alkalosis occurs as a result of net gain of $[HCO_3^-]$ or loss of nonvolatile acid (usually HCl by vomiting) from the extracellular fluid. Since it is unusual for alkali to be added to the body, the disorder involves a generative stage, in which the loss of acid usually causes alkalosis, and a maintenance stage, in which the kidneys fail to compensate by excreting HCO_3^- because of volume contraction, a low GFR, or depletion of Cl^- or K^+.

Under normal circumstances, the kidneys have an impressive capacity to excrete HCO_3^-. Continuation of metabolic alkalosis represents a failure of the kidneys to eliminate HCO_3^- in the usual manner. For HCO_3^- to be added to the extracellular fluid, it must be administered exogenously or synthesized endogenously, in part or entirely by the kidneys. The kidneys will retain, rather than excrete, the excess alkali and maintain the alkalosis if (1) volume deficiency, chloride deficiency, and K^+ deficiency exist in combination with a reduced GFR, which augments distal tubule H^+ secretion; or (2) hypokalemia exists because of autonomous hyperaldosteronism. In the first example, alkalosis is corrected by administration of NaCl and KCl, whereas in the latter it is necessary to repair the alkalosis by pharmacologic or surgical intervention, not with saline administration.

DIFFERENTIAL DIAGNOSIS To establish the cause of metabolic alkalosis (Table 42-5), it is necessary to assess the status of the extracellular fluid volume (ECFV), the recumbent and upright blood pressure, the serum $[K^+]$, and the renin-aldosterone system. For example, the presence of chronic hypertension and chronic hypokalemia in an alkalotic patient suggests either mineralocorticoid excess or that the hypertensive patient is receiving diuretics. Low plasma renin activity and normal urine $[Na^+]$ and $[Cl^-]$ in a patient who is not taking diuretics indicate a primary mineralocorticoid excess syndrome. The combination of hypokalemia and alkalosis in a normotensive, nonedematous patient can be due to Bartter's or Gitelman's syndrome, magnesium deficiency, vomiting, exogenous alkali, or diuretic ingestion. Determination of urine electrolytes (especially the urine $[Cl^-]$) and screening of the urine for diuretics may be helpful. If the urine is alkaline, with an elevated $[Na^+]$ and $[K^+]$ but low $[Cl^-]$, the diagnosis is usually either vomiting (overt or surreptitious) or alkali ingestion. If the urine is relatively acid and has low concentrations of Na^+, K^+, and Cl^-, the most likely possibilities are prior vomiting, the posthypercapnic state, or prior diuretic ingestion. If, on the other hand, neither the urine sodium, potassium, nor chloride concentrations are depressed, magnesium deficiency, Bartter's or Gitelman's syndrome, or current diuretic ingestion should be considered. Bartter's syndrome is distinguished from Gitelman's syndrome because of hypocalciuria and hypomagnesemia in the latter disorder. The genetic and molecular basis of these two disorders has been elucidated recently (Chap. 265).

Alkali Administration Chronic administration of alkali to individuals with normal renal function rarely, if ever causes alkalosis. However, in patients with coexistent hemodynamic disturbances, alkalosis can develop because the normal capacity to excrete HCO_3^- may be exceeded or there may be enhanced reabsorption of HCO_3^-. Such patients include those who receive oral or intravenous HCO_3^-, acetate loads (parenteral hyperalimentation solutions), citrate loads (transfusions), or antacids plus cation-exchange resins (aluminum hydroxide and sodium polystyrene sulfonate).

METABOLIC ALKALOSIS ASSOCIATED WITH ECFV CONTRACTION, K^+ DEPLETION, AND SECONDARY HYPERRENINEMIC HYPERALDOSTERONISM ■ Gastrointestinal Origin Gastrointestinal loss of H^+ from vomiting or gastric aspiration results in retention of HCO_3^-. The loss of fluid and NaCl in vomitus or nasogastric suction results in contraction of the ECFV and an increase in the secretion of renin and aldosterone. Volume contraction causes a reduction in GFR and an enhanced capacity of the renal tubule to reabsorb HCO_3^-. During active vomiting, there is continued addition of HCO_3^- to plasma in exchange for Cl^-, and the plasma $[HCO_3^-]$ exceeds the reabsorptive capacity of the proximal tubule. The excess $NaHCO_3$ reaches the distal tubule, where secretion is enhanced by an aldosterone and the delivery of the poorly reabsorbed anion, HCO_3^-. Because of contraction of the ECFV and hypochloremia, Cl^- is avidly conserved by the kidney. Correction of the contracted ECFV with NaCl and repair of K^+ deficits corrects the acid-base disorder.

TABLE 42-5 *Causes of Metabolic Alkalosis*

I. Exogenous HCO_3^- loads
  A. Acute alkali administration
  B. Milk-alkali syndrome

IV. Gain of function mutation of renal sodium channel with ECFV expansion, hypertension, K^+ deficiency, and hyporeninemic-hypoaldosteronism
  A. Liddle's syndrome

Note: ECFV, extracellular fluid volume; TALH, thick ascending limb of Henle's loop; DCT, distal convoluted tubule.

Renal Origin ■ *DIURETICS* (See also Chap. 216) Drugs that induce chloruresis, such as thiazides and loop diuretics (furosemide, bumetanide, torsemide, and ethracrynic acid), acutely diminish the ECFV without altering the total body bicarbonate content. The serum $[HCO_3^-]$ increases. The chronic administration of diuretics tends to generate an alkalosis by increasing distal salt delivery, so that K^+ and H^+ secretion are stimulated. The alkalosis is maintained by persistence of the contraction of the ECFV, secondary hyperaldosteronism, K^+ deficiency, and the direct effect of the diuretic (as long as diuretic administration

continues). Repair of the alkalosis is achieved by providing isotonic saline to correct the ECFV deficit.

BARTTER'S SYNDROME AND GITELMAN'S SYNDROME See Chap. 265.

NONREABSORBABLE ANIONS AND MAGNESIUM DEFICIENCY Administration of large quantities of nonreabsorbable anions, such as penicillin or carbenicillin, can enhance distal acidification and K^+ secretion by increasing the transepithelial potential difference (lumen negative). Mg^{2+} deficiency results in hypokalemic alkalosis by enhancing distal acidification through stimulation of renin and hence aldosterone secretion.

POTASSIUM DEPLETION Chronic K^+ depletion may cause metabolic alkalosis by increasing urinary acid excretion. Both NH_4^+ production and absorption are enhanced and HCO_3^- reabsorption is stimulated. Chronic K^+ deficiency upregulates the renal H^+, K^+-ATPase to increase K^+ absorption at the expense of enhanced H^+ secretion. Alkalosis associated with severe K^+ depletion is resistant to salt administration, but repair of the K^+ deficiency corrects the alkalosis.

AFTER TREATMENT OF LACTIC ACIDOSIS OR KETOACIDOSIS When an underlying stimulus for the generation of lactic acid or ketoacid is removed rapidly, as with repair of circulatory insufficiency or with insulin therapy, the lactate or ketones are metabolized to yield an equivalent amount of HCO_3^-. Other sources of new HCO_3^- are additive with the original amount generated by organic anion metabolism to create a surfeit of HCO_3^-. Such sources include (1) new HCO_3^- added to the blood by the kidneys as a result of enhanced acid excretion during the preexisting period of acidosis, and (2) alkali therapy during the treatment phase of the acidosis. Acidosis-induced contraction of the ECFV and K^+ deficiency act to sustain the alkalosis.

POSTHYPERCAPNIA Prolonged CO_2 retention with chronic respiratory acidosis enhances renal HCO_3^- absorption and the generation of new HCO_3^- (increased net acid excretion). If the Pa_{CO_2} is returned to normal, metabolic alkalosis results from the persistently elevated [HCO_3^-]. Alkalosis develops if the elevated Pa_{CO_2} is abruptly returned toward normal by a change in mechanically controlled ventilation. Associated ECFV contraction does not allow complete repair of the alkalosis by correction of the Pa_{CO_2} alone, and alkalosis persists until Cl^- supplementation is provided.

METABOLIC ALKALOSIS ASSOCIATED WITH ECFV EXPANSION, HYPERTENSION, AND HYPERALDOSTERONISM Mineralocorticoid administration or excess production [primary aldosteronism of Cushing's syndrome and adrenal cortical enzyme defects (Chap. 321)] increases net acid excretion and may result in metabolic alkalosis, which may be worsened by associated K^+ deficiency. ECFV expansion from salt retention causes hypertension and antagonizes the reduction in GFR and/or increases tubule acidification induced by aldosterone and by K^+ deficiency. The kaliuresis persists and causes continued K^+ depletion with polydipsia, inability to concentrate the urine, and polyuria. Increased aldosterone levels may be the result of autonomous primary adrenal overproduction or of secondary aldosterone release due to renal overproduction of renin. In both situations, the normal feedback of ECFV on net aldosterone production is disrupted, and hypertension from volume retention can result.

Liddle's syndrome (Chap. 265) results from increased activity of the collecting duct Na^+ channel (ENaC) and is a rare inherited disorder associated with hypertension due to volume expansion manifested as hypokalemic alkalosis and normal aldosterone levels.

Symptoms With metabolic alkalosis, changes in central and peripheral nervous system function are similar to those of hypocalcemia (Chap. 331); symptoms include mental confusion, obtundation, and a predisposition to seizures, paresthesia, muscular cramping, tetany, aggravation of arrhythmias, and hypoxemia in chronic obstructive pulmonary disease. Related electrolyte abnormalities include hypokalemia and hypophosphatemia.

TREATMENT

This is primarily directed at correcting the underlying stimulus for HCO_3^- generation. If primary aldosteronism is present, correction of the underlying cause will reverse the alkalosis. [H^+] loss by the stomach or kidneys can be mitigated by the use of H_2 receptor blockers, H^+, K^+-ATPase inhibitors, or the discontinuation of diuretics. The second aspect of treatment is to remove the factors that sustain HCO_3^- reabsorption, such as ECFV contraction or K^+ deficiency. Although K^+ deficits should be repaired, NaCl therapy is usually sufficient to reverse the alkalosis if ECFV contraction is present, as indicated by a low urine [Cl^-].

If associated conditions preclude infusion of saline, renal HCO_3^- loss can be accelerated by administration of acetazolamide, a carbonic anhydrase inhibitor, which is usually effective in patients with adequate renal function but can worsen K^+ losses. Dilute hydrochloric acid (0.1 *N* HCl) is also effective but can cause hemolysis. Alternatively, acidification can also be achieved with oral NH_4Cl, which should be avoided in the presence of liver disease. Hemodialysis against a dialysate low in [HCO_3^-] and high in [Cl^-] can be effective when renal function is impaired.

RESPIRATORY ACIDOSIS

Respiratory acidosis can be due to severe pulmonary disease, respiratory muscle fatigue, or abnormalities in ventilatory control and is recognized by an increase in Pa_{CO_2} and decrease in pH (Table 42-6). In acute respiratory acidosis, there is an immediate compensatory elevation (due to cellular buffering mechanisms) in HCO_3^-, which increases 1 mmol/L for every 10-mmHg increase in Pa_{CO_2}. In chronic respiratory acidosis (>24 h), renal adaptation increases the [HCO_3^-] by 4 mmol/L for every 10-mmHg increase in Pa_{CO_2}. The serum HCO_3^- usually does not increase above 38 mmol/L.

The clinical features vary according to the severity and duration of the respiratory acidosis, the underlying disease, and whether there is

TABLE 42-6 Respiratory Acid-Base Disorders

  2. Hypoventilation
  3. Permissive hypercapnia

accompanying hypoxemia. A rapid increase in Pa_{CO_2} may cause anxiety, dyspnea, confusion, psychosis, and hallucinations and may progress to coma. Lesser degrees of dysfunction in chronic hypercapnia include sleep disturbances, loss of memory, daytime somnolence, personality changes, impairment of coordination, and motor disturbances such as tremor, myoclonic jerks, and asterixis. Headaches and other signs that mimic raised intracranial pressure, such as papilledema, abnormal reflexes, and focal muscle weakness, are due to vasoconstriction secondary to loss of the vasodilator effects of CO_2.

Depression of the respiratory center by a variety of drugs, injury, or disease can produce respiratory acidosis. This may occur acutely with general anesthetics, sedatives, and head trauma or chronically with sedatives, alcohol, intracranial tumors, and the syndromes of sleep-disordered breathing, including the primary alveolar and obesity-hypoventilation syndromes (Chaps. 246 and 247). Abnormalities or disease in the motor neurons, neuromuscular junction, and skeletal muscle can cause hypoventilation via respiratory muscle fatigue. Mechanical ventilation, when not properly adjusted and supervised, may result in respiratory acidosis, particularly if CO_2 production suddenly rises (because of fever, agitation, sepsis, or overfeeding) or alveolar ventilation falls because of worsening pulmonary function. High levels of positive end-expiratory pressure in the presence of reduced cardiac output may cause hypercapnia as a result of large increases in alveolar dead space (Chap. 234). Permissive hypercapnia is being used with increasing frequency because of studies suggesting lower mortality rates than with conventional mechanical ventilation, especially with severe central nervous system or heart disease. Although the potential beneficial effects of permissive hypercapnia may be mitigated by correction of the acidemia, it seems prudent, nevertheless, to keep the pH in the range of 7.2 to 7.3 by administration of $NaHCO_3$.

Acute hypercapnia follows sudden occlusion of the upper airway or generalized bronchospasm as in severe asthma, anaphylaxis, inhalational burn, or toxin injury. Chronic hypercapnia and respiratory acidosis occur in end-stage obstructive lung disease. Restrictive disorders involving both the chest wall and the lungs can cause respiratory acidosis because the high metabolic cost of respiration causes ventilatory muscle fatigue. Advanced stages of intrapulmonary and extrapulmonary restrictive defects present as chronic respiratory acidosis.

The diagnosis of respiratory acidosis requires, by definition, the measurement of Pa_{CO_2} and arterial pH. A detailed history and physical examination often indicate the cause. Pulmonary function studies (Chap. 234), including spirometry, diffusion capacity for carbon monoxide, lung volumes, and arterial Pa_{CO_2} and O_2 saturation, usually make it possible to determine if respiratory acidosis is secondary to lung disease. The workup for nonpulmonary causes should include a detailed drug history, measurement of hematocrit, and assessment of upper airway, chest wall, pleura, and neuromuscular function.

Rx TREATMENT

The management of respiratory acidosis depends on its severity and rate of onset. Acute respiratory acidosis can be life-threatening, and measures to reverse the underlying cause should be undertaken simultaneously with restoration of adequate alveolar ventilation. This may necessitate tracheal intubation and assisted mechanical ventilation. Oxygen administration should be titrated carefully in patients with severe obstructive pulmonary disease and chronic CO_2 retention who are breathing spontaneously (Chap. 242). When oxygen is used injudiciously, these patients may experience progression of the respiratory acidosis. Aggressive and rapid correction of hypercapnia should be avoided, because the falling Pa_{CO_2} may provoke the same complications noted with acute respiratory alkalosis (i.e., cardiac arrhythmias, reduced cerebral perfusion, and seizures). The Pa_{CO_2} should be lowered gradually in chronic respiratory acidosis, aiming to restore the Pa_{CO_2} to baseline levels and to provide sufficient Cl^- and K^+ to enhance the renal excretion of HCO_3^-.

Chronic respiratory acidosis is frequently difficult to correct, but measures aimed at improving lung function (Chap. 242) can help some patients and forestall further deterioration in most.

RESPIRATORY ALKALOSIS

Alveolar hyperventilation decreases Pa_{CO_2} and increases the HCO_3^-/Pa_{CO_2} ratio, thus increasing pH (Table 42-6). Nonbicarbonate cellular buffers respond by consuming HCO_3^-. Hypocapnia develops when a sufficiently strong ventilatory stimulus causes CO_2 output in the lungs to exceed its metabolic production by tissues. Plasma pH and $[HCO_3^-]$ appear to vary proportionately with Pa_{CO_2} over a range from 40 to 15 mmHg. The relationship between arterial $[H^+]$ concentration and Pa_{CO_2} is about 0.7 mmol/L per mmHg (or 0.01 pH unit/mmHg), and that for plasma $[HCO_3^-]$ is 0.2 mmol/L per mmHg. Hypocapnia sustained longer than 2 to 6 h is further compensated by a decrease in renal ammonium and titratable acid excretion and a reduction in filtered HCO_3^- reabsorption. Full renal adaptation to respiratory alkalosis may take several days and requires normal volume status and renal function. The kidneys appear to respond directly to the lowered Pa_{CO_2} rather than to alkalosis per se. In chronic respiratory alkalosis a 1-mmHg fall in Pa_{CO_2} causes a 0.4- to 0.5-mmol/L drop in $[HCO_3^-]$ and a 0.3-mmol/L fall (or 0.003 rise in pH) in $[H^+]$.

The effects of respiratory alkalosis vary according to duration and severity but are primarily those of the underlying disease. Reduced cerebral blood flow as a consequence of a rapid decline in Pa_{CO_2} may cause dizziness, mental confusion, and seizures, even in the absence of hypoxemia. The cardiovascular effects of acute hypocapnia in the conscious human are generally minimal, but in the anesthetized or mechanically ventilated patient, cardiac output and blood pressure may fall because of the depressant effects of anesthesia and positive-pressure ventilation on heart rate, systemic resistance, and venous return. Cardiac arrhythmias may occur in patients with heart disease as a result of changes in oxygen unloading by blood from a left shift in the hemoglobin-oxygen dissociation curve (Bohr effect). Acute respiratory alkalosis causes intracellular shifts of Na^+, K^+, and PO_4^- and reduces free $[Ca^{2+}]$ by increasing the protein-bound fraction. Hypocapnia-induced hypokalemia is usually minor.

Chronic respiratory alkalosis is the most common acid-base disturbance in critically ill patients and, when severe, portends a poor prognosis. Many cardiopulmonary disorders manifest respiratory alkalosis in their early to intermediate stages, and the finding of normocapnia and hypoxemia in a patient with hyperventilation may herald the onset of rapid respiratory failure and should prompt an assessment to determine if the patient is becoming fatigued. Respiratory alkalosis is common during mechanical ventilation.

The hyperventilation syndrome may be disabling. Paresthesia, circumoral numbness, chest wall tightness or pain, dizziness, inability to take an adequate breath, and, rarely, tetany may themselves be sufficiently stressful to perpetuate the disorder. Arterial blood-gas analysis demonstrates an acute or chronic respiratory alkalosis, often with hypocapnia in the range of 15 to 30 mmHg and no hypoxemia. Central nervous system diseases or injury can produce several patterns of hyperventilation and sustained Pa_{CO_2} levels of 20 to 30 mmHg. Hyperthyroidism, high caloric loads, and exercise raise the basal metabolic rate, but ventilation usually rises in proportion so that arterial blood gases are unchanged and respiratory alkalosis does not develop. Salicylates are the most common cause of drug-induced respiratory alkalosis as a result of direct stimulation of the medullary chemoreceptor (Chap. 377). The methylxanthines, theophylline, and aminophylline stimulate ventilation and increase the ventilatory response to CO_2. Progesterone increases ventilation and lowers arterial Pa_{CO_2} by as much as 5 to 10 mmHg. Therefore, chronic respiratory alkalosis is a common feature of pregnancy. Respiratory alkalosis is also prominent in liver failure, and the severity correlates with the degree of hepatic insufficiency. Respiratory alkalosis is often an early finding in gram-negative septicemia, before fever, hypoxemia, or hypotension develop.

The diagnosis of respiratory alkalosis depends on measurement of

arterial pH and Pa_{CO_2}. The plasma $[K^+]$ is often reduced and the $[Cl^-]$ increased. In the acute phase, respiratory alkalosis is not associated with increased renal HCO_3^- excretion, but within hours net acid excretion is reduced. In general, the HCO_3^- concentration falls by 2.0 mmol/L for each 10-mmHg decrease in Pa_{CO_2}. Chronic hypocapnia reduces the serum $[HCO_3^-]$ by 5.0 mmol/L for each 10-mmHg decrease in Pa_{CO_2}. It is unusual to observe a plasma HCO_3^- <12 mmol/L as a result of a pure respiratory alkalosis.

When a diagnosis of respiratory alkalosis is made, its cause should be investigated. The diagnosis of hyperventilation syndrome is made by exclusion. In difficult cases, it may be important to rule out other conditions such as pulmonary embolism, coronary artery disease, and hyperthyroidism.

TREATMENT

The management of respiratory alkalosis is directed toward alleviation of the underlying disorder. If respiratory alkalosis complicates ventilator management, changes in dead space, tidal volume, and frequency can minimize the hypocapnia. Patients with the hyperventilation syndrome may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to underlying psychological stress. Antidepressants and sedatives are not recommended. β-Adrenergic blockers may ameliorate peripheral manifestations of the hyperadrenergic state.

Section 8 Alterations in Sexual Function and Reproduction

43 SEXUAL DYSFUNCTION

Kevin T. McVary

Male sexual dysfunction affects 10 to 25% of middle-aged and elderly men. Female sexual dysfunction occurs with a similar frequency. Demographic changes, the popularity of newer treatments, and greater awareness of sexual dysfunction by patients and society have led to increased diagnosis and associated health care expenditures for the management of this common disorder. Because many patients are reluctant to initiate discussion of their sex lives, the physician should address this topic directly to elicit a history of sexual dysfunction.

PHYSIOLOGY OF MALE SEXUAL RESPONSE

Normal male sexual function requires (1) an intact libido; (2) the ability to achieve and maintain penile erection; (3) ejaculation; and (4) detumescence. *Libido* refers to sexual desire and is influenced by a variety of visual, olfactory, tactile, auditory, imaginative, and hormonal stimuli. Sex steroids, particularly testosterone, act to increase libido. Libido can be diminished by hormonal or psychiatric disorders or by medications.

Penile tumescence leading to erection depends on the increased flow of blood into the lacunar network after complete relaxation of the arteries and corporal smooth muscle. The microarchitecture of the corpora is composed of a mass of smooth muscle (trabecula) which contains a network of endothelial-lined vessels (lacunar spaces). Subsequent compression of the trabecular smooth muscle against the fibroelastic tunica albuginea causes a passive closure of the emissary veins and accumulation of blood in the corpora. In the presence of a full erection and a competent valve mechanism, the corpora become noncompressible cylinders from which blood does not escape.

The central nervous system exerts an important influence by either stimulating or antagonizing spinal pathways that mediate erectile function and ejaculation. The erectile response is mediated by a combination of central (psychogenic) and peripheral (reflexogenic) innervation. Sensory nerves that originate from receptors in the penile skin and glans converge to form the dorsal nerve of the penis, which travels to the S2-S4 dorsal root ganglia via the pudendal nerve. Parasympathetic nerve fibers to the penis arise from neurons in the intermediolateral columns of S2-S4 sacral spinal segments. Sympathetic innervation originates from the T-11 to the L-2 spinal segments and descends through the hypogastric plexus.

Neural input to smooth muscle tone is crucial to the initiation and maintenance of an erection. There is also an intricate interaction between the corporal smooth muscle cell and its overlying endothelial cell lining (Fig. 43-1*A*). Nitric oxide, which induces vascular relaxation, promotes erection and is opposed by endothelin-1 (ET-1), which mediates vascular contraction. Nitric oxide is synthesized from L-arginine by nitric oxide synthase, and is released from the nonadrenergic, noncholinergic (NANC) autonomic nerve supply to act postjunctionally on smooth muscle cells. Nitric oxide increases the production of cyclic 3′,5′-guanosine monophosphate (cyclic GMP), which induces relaxation of the smooth muscle (Fig. 43-1*B*). Cyclic GMP is gradually broken down by phosphodiesterase type 5 (PDE-5). Inhibitors of PDE-5, such as the oral medication sildenafil, maintain erections by reducing the breakdown of cyclic GMP. However, if nitric oxide is not produced at some level, the addition of PDE-5 inhibitor is not effective, as the drug facilitates but does not initiate the initial enzyme cascade. In addition to nitric oxide, vasoactive prostaglandins (PGE_1, $PGF_{2\alpha}$) are synthesized within the cavernosal tissue and increase cyclic AMP levels, also leading to relaxation of cavernosal smooth muscle cells.

Ejaculation is stimulated by the sympathetic nervous system, which results in contraction of the epididymis, vas deferens, seminal vesicles, and prostate, causing seminal fluid to enter the urethra. Seminal fluid emission is followed by rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles, leading to ejaculation. *Premature ejaculation* is usually related to anxiety or a learned behavior and is amenable to behavioral therapy or treatment with medications such as selective serotonin reuptake inhibitors (SSRIs). *Retrograde ejaculation* results when the internal urethral sphincter does not close, and it may occur in men with diabetes or after surgery involving the bladder neck.

Detumescence is mediated by released norepinephrine from the sympathetic nerves, release of endothelin from the vascular surface, and contraction of smooth muscle induced by activation of postsynaptic α-adrenergic receptors. These events increase venous outflow and restore the flaccid state. Venous leak can cause premature detumescence and is thought to be caused by insufficient relaxation of the corporal smooth muscle rather than a specific anatomic defect. *Pria-*

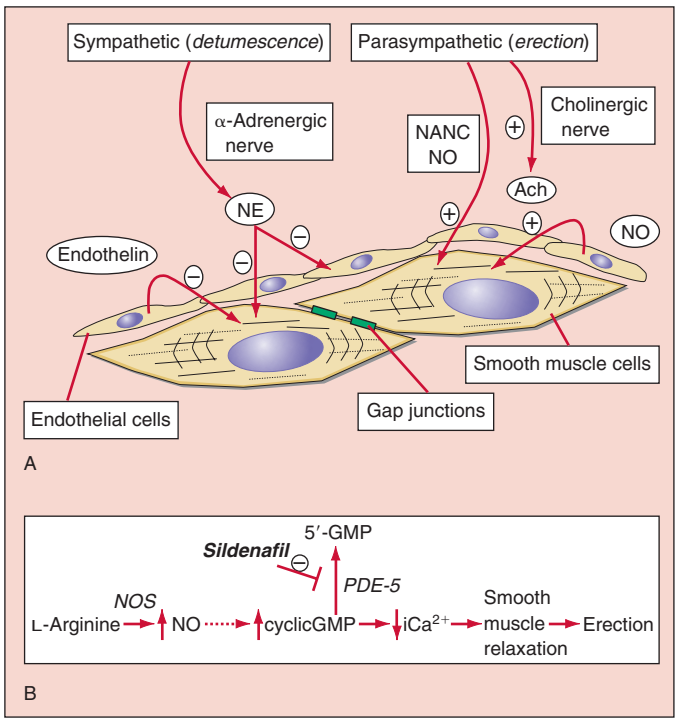

FIGURE 43-1 Pathways that control erection and detumescence. *A*. Erection is mediated by cholinergic parasympathetic pathways, and nonadrenergic, noncholinergic (NANC) pathways, which release nitric oxide (NO). Endothelial cells also release NO, which induces vascular smooth muscle cell relaxation, allowing enhanced blood flow, and leading to erection. Detumescence is mediated by sympathetic pathways that release norepinephrine and stimulate α-adrenergic pathways, leading to contraction of vascular smooth muscle cells. Endothelin, released from endothelial cells, also induces contraction. *B*. Biochemical pathways of NO synthesis and action. Sildenafil enhances erectile function by inhibiting phosphodiesterase type 5 (PDE-5), thereby maintaining high levels of cyclic 3′,5′-guanosine monophosphate (cyclic GMP). NOS, nitric oxide synthase; iCa^{2+}, intracellular calcium.

pism refers to a persistent and painful erection and may be associated with sickle cell anemia, hypercoagulable states, spinal cord injury, or injection of vasodilator agents into the penis.

ERECTILE DYSFUNCTION

EPIDEMIOLOGY Erectile dysfunction (ED) is not considered a normal part of the aging process. Nonetheless, it is associated with certain physiologic and psychological changes related to age. In the Massachusetts Male Aging Study (MMAS), a community-based survey of men between the ages of 40 and 70, 52% of responders reported some degree of ED. Complete ED occurred in 10% of respondents, moderate ED occurred in 25%, and minimal ED in 17%. The incidence of moderate or severe ED more than doubled between the ages of 40 and 70. In the National Health and Social Life Survey (NHSLS), which was a nationally representative sample of men and women age 18 to 59 years, 10% of men reported being unable to maintain an erection (corresponding to the proportion of men in the MMAS reporting severe ED). Incidence was highest among men in the 50 to 59 age group (21%) and among men who were poor (14%), divorced (14%), and less educated (13%).

The incidence of ED is also higher among men with certain medical disorders such as diabetes mellitus, heart disease, hypertension, and decreased HDL levels. Smoking is a significant risk factor in the development of ED. Medications used to treat diabetes or cardiovascular disease are additional risk factors (see below). There is a higher incidence of ED among men who have undergone radiation or surgery for prostate cancer and in those with a lower spinal cord injury. Psychological causes of ED include depression, anger, or stress from unemployment or other causes.

PATHOPHYSIOLOGY ED may result from three basic mechanisms: (1) failure to initiate (psychogenic, endocrinologic, or neurogenic); (2) failure to fill (arteriogenic); or (3) failure to store (venoocclusive dysfunction) adequate blood volume within the lacunar network. These categories are not mutually exclusive, and multiple factors contribute to ED in many patients. For example, diminished filling pressure can lead secondarily to venous leak. Psychogenic factor frequently coexist with other etiologic factors and should be considered in all cases. Diabetic, atherosclerotic, and drug-related causes account for >80% of cases of ED in older men.

Vasculogenic The most frequent organic cause of ED is a disturbance of blood flow to and from the penis. Atherosclerotic or traumatic arterial disease can decrease flow to the lacunar spaces, resulting in decreased rigidity and an increased time to full erection. Excessive outflow through the veins, despite adequate inflow, may also contribute to ED. This situation may be due to insufficient relaxation of trabecular smooth muscle and may occur in anxious individuals with excessive adrenergic tone or in those with damaged parasympathetic outflow. Structural alterations to the fibroelastic components of the corpora may cause a loss of compliance and an inability to compress the tunical veins. This condition may result from aging, increased cross-linking of collagen fibers induced by nonenzymatic glycosylation, hypoxia, or altered synthesis of collagen associated with hypercholesterolemia.

Neurogenic Disorders that affect the sacral spinal cord or the autonomic fibers to the penis preclude nervous system relaxation of penile smooth muscle, thus leading to ED. In patients with spinal cord injury, the degree of ED depends on the completeness and level of the lesion. Patients with incomplete lesions or injuries to the upper part of the spinal cord are more likely to retain erectile capabilities than those with complete lesions or injuries to the lower part. Although 75% of patients with spinal cord injuries have some erectile capability, only 25% have erections sufficient for penetration. Other neurologic disorders commonly associated with ED include multiple sclerosis and peripheral neuropathy. The latter is often due to either diabetes or alcoholism. Pelvic surgery may cause ED through disruption of the autonomic nerve supply.

Endocrinologic Androgens increase libido, but their exact role in erectile function remains unclear. Individuals with castrate levels of testosterone can achieve erections from visual or sexual stimuli. Nonetheless, normal levels of testosterone appear to be important for erectile function, particularly in older males. Androgen replacement therapy can improve depressed erectile function when it is secondary to hypogonadism; it is not useful for ED when endogenous testosterone levels are normal. Increased prolactin may decrease libido by suppressing gonadotropin-releasing hormone (GnRH), and it also leads to decreased testosterone levels. Treatment of hyperprolactinemia with dopamine agonists can restore libido and testosterone.

Diabetic ED occurs in 35 to 75% of men with diabetes mellitus. Pathologic mechanisms are primarily related to diabetes-associated vascular and neurologic complications. Diabetic macrovascular complications are mainly related to age, whereas microvascular complications correlate with the duration of diabetes and the degree of glycemic control (Chap. 323). Individuals with diabetes also have reduced amounts of nitric oxide synthase in both endothelial and neural tissues.

Psychogenic Two mechanisms contribute to the inhibition of erections in psychogenic ED. First, psychogenic stimuli to the sacral cord may inhibit reflexogenic responses, thereby blocking activation of vasodilator outflow to the penis. Second, excess sympathetic stimulation in an anxious man may increase penile smooth muscle tone. The most common causes of psychogenic ED are performance anxiety, depression, relationship conflict, loss of attraction, sexual inhibition, conflicts over sexual preference, sexual abuse in childhood, and fear of pregnancy or sexually transmitted disease. Almost all patients with ED, even when it has a clear-cut organic basis, develop a psychogenic component as a reaction to ED.

Medication-Related Medication-induced ED (Table 43-1) is estimated to occur in 25% of men seen in general medical outpatient clinics. Among the antihypertensive agents, the thiazide diuretics and beta blockers have been implicated most frequently. Calcium channel blockers and angiotensin-converting enzyme inhibitors are less frequently cited. These drugs may act directly at the corporal level (e.g., calcium channel blockers) or indirectly by reducing pelvic blood pressure, which is important in the development of penile rigidity. α Adrenergic blockers are less likely to cause ED. Estrogens, GnRH agonists, H_2 antagonists, and spironolactone cause ED by suppressing gonadotropin production or by blocking androgen action. Antidepressant and antipsychotic agents—particularly neuroleptics, tricyclics, and SSRIs—are associated with erectile, ejaculatory, orgasmic, and sexual desire difficulties.

Although many medications can cause ED, patients frequently have concomitant risk factors that confound the clinical picture. If there is a strong association between the institution of a drug and the onset of ED, alternative medications should be considered. Otherwise, it is often practical to treat the ED without attempting multiple changes in medications, as it may be difficult to establish a causal role for the drug.

CLINICAL EVALUATION A good physician-patient relationship helps to unravel the possible causes of ED, many of which require discussion of personal and sometimes embarrassing topics. For this reason, a primary care provider is often ideally suited to initiate the evaluation. A complete medical and sexual history should be taken in an effort to assess whether the cause of ED is organic, psychogenic, or multifactorial (Fig. 43-2). Initial questions should focus on the onset of symptoms, the presence and duration of partial erections, and the progression of ED. A history of nocturnal or early morning erections is useful for distinguishing physiologic from psychogenic ED. Nocturnal erections occur during rapid eye movement (REM) sleep and require intact neurologic and circulatory systems. Organic causes of ED are generally characterized by a gradual and persistent change in rigidity or the inability to sustain nocturnal, coital, or self-stimulated erections. The patient should also be questioned about the presence of penile curvature or pain with coitus. It is also important to address libido, as decreased sexual drive and ED are sometimes the earliest signs of endocrine abnormalities (e.g., increased prolactin, decreased testosterone levels). It is useful to ask whether the problem is confined to coitus with one or other partners; ED arises not uncommonly in association with new or extramarital sexual relationships. Situational ED, as opposed to consistent ED, suggests psychogenic causes. Ejaculation is much less commonly affected than erection, but questions should be asked about whether ejaculation is normal, premature, delayed, or absent. Relevant risk factors should be identified, such as diabetes mellitus, coronary artery disease, lipid disorders, hypertension, peripheral vascular disease, smoking, alcoholism, and endocrine or neurologic disorders. The patient's surgical history should be explored with an emphasis on bowel, bladder, prostate, or vascular procedures. A complete drug history is also important. Social changes that may precipitate ED are also crucial to the evaluation, including health worries, spousal death, divorce, relationship difficulties, and financial concerns.

TABLE 43-1 *Drugs Associated with Erectile Dysfunction*

Classification	Drugs
Diuretics	Thiazides
	Spironolactone
Antihypertensives	Calcium channel blockers
	Methyldopa
	Clonidine
	Reserpine
	β-Blockers
	Guanethidine
Cardiac/anti-hyperlipidemics	Digoxin
	Gemfibrozil
	Clofibrate
Antidepressants	Selective serotonin reuptake inhibitors
	Tricyclic antidepressants
	Lithium
	Monoamine oxidase inhibitors
Tranquilizers	Butyrophenones
	Phenothiazines
H_2 antagonists	Ranitidine
	Cimetidine
Hormones	Progesterone
	Estrogens
	Corticosteroids
	GnRH agonists
	5α-Reductase inhibitors
	Cyproterone acetate
Cytotoxic agents	Cyclophosphamide
	Methotrexate

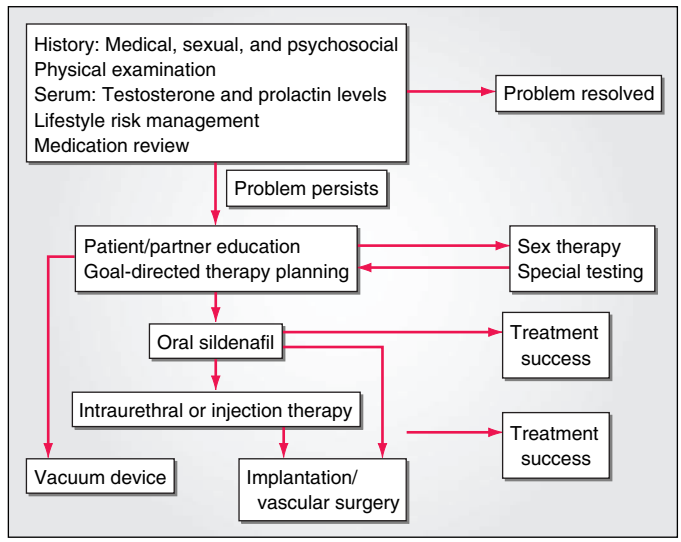

FIGURE 43-2 Algorithm for the evaluation and management of patients with ED.

The physical examination is an essential element in the assessment of ED. Signs of hypertension as well as evidence of thyroid, hepatic, hematologic, cardiovascular, or renal diseases should be sought. An assessment should be made of the endocrine and vascular systems, the external genitalia, and the prostate gland. The penis should be carefully palpated along the corpora to detect fibrotic plaques. Reduced testicular size and loss of secondary sexual characteristics are suggestive of hypogonadism. Neurologic examination should include assessment of anal sphincter tone, the bulbocavernosus reflex, and testing for peripheral neuropathy.

Although hyperprolactinemia is uncommon, a serum prolactin level should be measured, as decreased libido and/or erectile dysfunction may be the presenting symptoms of a prolactinoma or other mass lesions of the sella (Chap. 318). The serum testosterone level should be measured and, if low, gonadotropins should be measured to determine whether hypogonadism is primary (testicular) or secondary (hypothalamic-pituitary) in origin (Chap. 325). Serum chemistries, CBC, and lipid profiles may be of value, if not performed recently, as they can yield evidence of anemia, diabetes, hyperlipidemia, or other systemic diseases associated with ED. Determination of serum PSA should be conducted according to recommended clinical guidelines (Chap. 81).

Additional diagnostic testing is rarely necessary in the evaluation of ED. However, in selected patients, specialized testing may provide insight into pathologic mechanisms of ED and aid in the selection of

treatment options. Optional specialized testing includes: (1) studies of nocturnal penile tumescence and rigidity; (2) vascular testing (in-office injection of vasoactive substances, penile Doppler ultrasound, penile angiography, dynamic infusion cavernosography/cavernosometry); (3) neurologic testing (biothesiometry-graded vibratory perception; somatosensory evoked potentials); and (4) psychological diagnostic tests. The information potentially gained from these procedures must be balanced against their invasiveness and cost.

TREATMENT

Patient Education Patient and partner education is essential in the treatment of ED. In goal-directed therapy, education facilitates understanding of the disease, results of the tests, and selection of treatment. Discussion of treatment options helps to clarify how treatment is best offered, and to stratify first- and second-line therapies. Patients with high-risk lifestyle issues, such as smoking, alcohol abuse, or recreational drug use, should be counseled on the role these factors play in the development of ED.

Oral Agents Sildenafil is the only approved and effective oral agent for the treatment of ED. Sildenafil has markedly improved the management of ED because it is effective for the treatment of a broad range of causes of ED, including psychogenic, diabetic, vasculogenic, post-radical prostatectomy (nerve-sparing procedures), and spinal cord injury. Sildenafil is a selective and potent inhibitor of PDE-5, the predominant phosphodiesterase isoform found in the penis. It is administered in doses of 25, 50, or 100 mg, and enhances erections after sexual stimulation. The onset of action is approximately 60 to 90 min. Reduced initial doses should be considered for patients who are elderly, have renal insufficiency, or are taking medications that inhibit the CYP3A4 metabolic pathway in the liver (e.g., erythromycin, cimetidine, ketoconazole, and, possibly, itraconazole and mibefradil), as they may increase the serum concentration of sildenafil. The drug does not affect ejaculation, orgasm, or sexual drive. Side effects associated with sildenafil include headaches (19%), facial flushing (9%), dyspepsia (6%) and nasal congestion (4%). Approximately 7% of men may experience transient altered color vision (blue halo effect). Sildenafil is contraindicated in men receiving nitrate therapy for cardiovascular disease, including agents delivered by oral, sublingual, transnasal, or topical routes. These agents can potentiate its hypotensive effect and may result in profound shock. Likewise, amyl/butyl nitrates "poppers" may have a fatal synergistic effect on blood pressure. Sildenafil should also be avoided in patients with congestive heart failure and cardiomyopathy because of the risk of vascular collapse. Because sexual activity leads to an increase in physiologic expenditure [5 to 6 metabolic equivalents (METS)], physicians have been advised to exercise caution in prescribing any drug for sexual activity to those with active coronary disease, heart failure, borderline hypotension, hypovolemia, and to those on complex antihypertensive regimens.

Androgen Therapy Testosterone replacement is used to treat both primary and secondary causes of hypogonadism (Chap. 325). Androgen supplementation in the setting of normal testosterone is rarely efficacious and is discouraged. Methods of androgen replacement include parenteral administration of long-acting testosterone esters (enanthate and cypionate), oral preparations (17 α-alkylated derivatives), and transdermal patches, and gels (Chap. 325). The long-acting 17 β-hydroxy esters of testosterone are the safest, most cost-effective, and practical preparations available. The administration of 200 to 300 mg intramuscularly every 2 to 3 weeks provides a practical option but is far from an ideal physiologic replacement. Oral androgen preparations have the potential for hepatotoxicity and should be avoided. Transdermal delivery of testosterone using patches or gels more closely mimics physiologic testosterone levels, but it is unclear whether this translates into improved sexual function. Testosterone therapy is contraindicated in men with androgen-sensitive cancers and may be inappropriate for men with bladder neck obstruction. It is generally advisable to measure PSA before giving androgen. Hepatic function should be tested before and during testosterone therapy.

Vacuum Constriction Devices Vacuum constriction devices (VCD) are a well-established, noninvasive therapy. They are a reasonable treatment alternative for select patients who cannot take sildenafil or do not desire other interventions. VCD draw venous blood into the penis and use a constriction ring to restrict venous return and maintain tumescence. Adverse events with VCD include pain, numbness, bruising, and altered ejaculation. Additionally, many patients complain that the devices are cumbersome and that the induced erections have a nonphysiologic appearance.

Intraurethral Alprostadil If a patient fails to respond to oral agents, a reasonable next choice is intraurethral or self-injection of vasoactive substances. Intraurethral prostaglandin E_1 (alprostadil), in the form of a semisolid pellet (doses of 125 to 1000 μg), is delivered with an applicator. Approximately 65% of men receiving intraurethral alprostadil respond with an erection when tested in the office, but only 50% of those achieve successful coitus at home. Intraurethral insertion is associated with a markedly reduced incidence of priapism in comparison to intracavernosal injection.

Intracavernosal Self-Injection Injection of synthetic formulations of alprostadil is effective in 70 to 80% of patients with ED, but discontinuation rates are high because of the invasive nature of administration. Doses range between 1 and 40 μg. Injection therapy is contraindicated in men with a history of hypersensitivity to the drug and in men at risk for priapism (hypercoagulable states, sickle cell disease). Side effects include local adverse events, prolonged erections, pain, and fibrosis with chronic use. Various combinations of alprostadil, phentolamine, and/or papaverine are sometimes used.

Surgery A less frequently used form of therapy for ED involves the surgical implantation of a semi-rigid or inflatable penile prosthesis. These surgical treatments are invasive, associated with potential complications, and generally reserved for treatment of refractory ED. Despite their high cost and invasiveness, penile prostheses are associated with high rates of patient satisfaction.

SEX THERAPY A course of sex therapy may be useful for addressing specific interpersonal factors that may affect sexual functioning. Sex therapy generally consists of in-session discussion and at-home exercises specific to the person and the relationship. It is preferable if therapy includes both partners, provided the patient is involved in an ongoing relationship.

FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) has traditionally included disorders of desire, arousal, pain, and muted orgasm. The associated risk factors for FSD are similar to those in males: cardiovascular disease, endocrine disorders, hypertension, neurologic disorders, and smoking (Table 43-2).

TABLE 43-2 Risk Factors for Female Sexual Dysfunction

Neurologic disease: stroke, spinal cord injury, Parkinsonism
Trauma, genital surgery, radiation
Endocrinopathies: diabetes, hyperprolactinemia
Liver and/or renal failure
Cardiovascular disease
Psychological factors and interpersonal relationship disorders: sexual abuse, life stressors
Medications
Antiandrogens: Cimetidine, spironolactone
Antidepressants, Alcohol, hypnotics, sedatives
Antiestrogens or GnRH antagonists
Antihistamines, sympathomimetic amines
Antihypertensives: Diuretics, calcium channel blockers
Alkylating agents
Anticholinergics

EPIDEMIOLOGY Epidemiologic data are limited but the available estimates suggest that as many as 43% of women complain of at least one sexual problem. Despite the recent interest in organic causes of FSD, desire and arousal phase disorders (including lubrication complaints) remain the most common presenting problems when surveyed in a community-based population.

PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE Although there are the obvious anatomic differences as well as variation in the density of vascular and neural beds in males and females, the primary effectors of sexual response are strikingly similar. Intact sensation is important for arousal. Thus, reduced levels of sexual functioning are more common in women with peripheral neuropathies (e.g., diabetes). Vaginal lubrication is a transudate of serum that results from the increased pelvic blood flow associated with arousal. Vascular insufficiency from a variety of causes may compromise adequate lubrication and result in dyspareunia. Similar to the male response, cavernosal and arteriole smooth muscle relaxation occurs via increased NOS activity and produces engorgement in the clitoris and surrounding vestibule. Orgasm requires an intact sympathetic outflow tract; hence, orgasmic disorders are common in female patients with spinal cord injuries.

CLINICAL EVALUATION The evaluation of FSD previously occurred mainly in a psychosocial context. However, inconsistencies between diagnostic categories based on only psychosocial considerations, and the emerging recognition of organic etiologies, has led to a new classification of FSD. This diagnostic scheme is based on four components that are not mutually exclusive: (1) *Hypoactive sexual desire*—the persistent or recurrent lack of sexual thoughts and/or receptivity to sexual activity, which causes personal distress. Hypoactive sexual desire may result from endocrine failure or may be associated with psychological or emotional disorders; (2) *Sexual arousal disorder*—the persistent or recurrent inability to attain or maintain sexual excitement, which causes personal distress; (3) *Orgasmic disorder*—the persistent or recurrent loss of orgasmic potential after sufficient sexual stimulation and arousal, which causes personal distress; (4) *Sexual pain disorder*—persistent or recurrent genital pain associated with noncoital sexual stimulation, which causes personal distress. This newer classification emphasizes "personal distress" as a requirement for dysfunction and provides clinicians an organized framework for evaluation prior to or in conjunction with more traditional counseling methods.

TREATMENT

Patient Education Patient and partner education is essential in the treatment of FSD. Educating the couple about normal anatomy and physiologic responses is often necessary. Physiologic changes associated with aging and/or disease should be explained. Maximizing physical health and avoiding lifestyles (e.g., smoking, alcohol abuse) and medications likely to produce FSD are prudent (Table 43-2).

Hormonal Therapy In postmenopausal women, estrogen replacement therapy may be helpful in treating vaginal atrophy, decreasing coital pain, and improving clitoral sensitivity (Chap. 327). Estrogen replacement in the form of local cream is the preferred method, as it avoids systemic side effects. Androgen levels in women decline substantially before menopause. However, low levels of testosterone or dehydroepiandrosterone (DHEA) are not effective predictors of a positive therapeutic outcome with androgen therapy. The widespread use of exogenous androgens is not supported by the literature except in select circumstances (premature ovarian failure or menopausal states) and in secondary arousal disorders.

Oral Agents The efficacy of PDE-5 inhibitors in FDS has been a marked disappointment given the proposed role of nitric oxide-dependent physiology in the normal female sexual response. The use of sildenafil for FSD should be discouraged pending proof that it is effective.

Clitoral Vacuum Device In patients with arousal and orgasmic difficulties, the option of using a clitoral vacuum device may be explored. This handheld battery-operated device has a small soft plastic cup that applies a vacuum over the stimulated clitoris. This causes increased cavernosal blood flow, engorgement, and vaginal lubrication.

44 HIRSUTISM AND VIRILIZATION

David A. Ehrmann

Hirsutism, defined as excessive male-pattern hair growth, affects approximately 10% of women. If often represents a variation of normal hair growth, but rarely it is a harbinger of a serious underlying condition. Hirsutism is often idiopathic but may be caused by conditions associated with androgen excess, such as polycystic ovarian syndrome (PCOS) or congenital adrenal hyperplasia (CAH) (Table 44-1). Cutaneous manifestations commonly associated with hirsutism include acne and male-pattern balding (androgenic alopecia). *Virilization* refers to the state in which androgen levels are sufficiently high to cause additional signs and symptoms such as deepening of the voice, breast atrophy, increased muscle bulk, clitoromegaly, and increased libido; virilization is an ominous sign that suggests the possibility of an ovarian or adrenal neoplasm.

HAIR FOLLICLE GROWTH AND DIFFERENTIATION

Hair can be categorized as either *vellus* (fine, soft, and not pigmented) or *terminal* (long, coarse, and pigmented). The number of hair follicles does not change over an individual's lifetime, but the follicle size and type of hair can change in response to numerous factors, particularly androgens. Androgens are necessary for terminal hair and sebaceous gland-development and mediate differentiation of pilosebaceous units (PSUs) into either a terminal hair follicle or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter, the sebaceous component proliferates and the hair remains vellus.

There are three phases in the cycle of hair growth: (1) *anagen* (growth phase), (2) *catagen* (involution phase), and (3) *telogen* (rest phase). Depending on the body site, hormonal regulation may play an important role in the hair growth cycle. For example, the eyebrows, eyelashes, and vellus hairs are androgen-insensitive, whereas the axillary and pubic areas are sensitive to low levels of androgens. Hair growth on the face, chest, upper abdomen, and back requires greater levels of androgens and is therefore more characteristic of the pattern typically seen in males. Androgen excess in women leads to increased hair growth in most androgen-sensitive sites except in the scalp region, where hair loss occurs because androgens cause scalp hairs to spend less time in the anagen phase.

Although androgen excess underlies most cases of hirsutism, there is only a modest correlation between androgen levels and the quantity of hair growth. This is due to the fact that hair growth from the follicle also depends on local growth factors, and there is variability in end-

organ sensitivity. Genetic factors and ethnic background also influence hair growth. In general, dark-haired individuals tend to be more hirsute than blonde or fair individuals. Asians and Native Americans have relatively sparse hair in regions sensitive to high androgen levels, whereas people of Mediterranean descent are more hirsute.

CLINICAL ASSESSMENT

Historic elements relevant to the assessment of hirsutism include the age of onset and rate of progression of hair growth and associated symptoms or signs (e.g., acne). Depending on the cause, excess hair growth is typically first noted during the second and third decades. The growth is usually slow but progressive. Sudden development and rapid progression of hirsutism suggests the possibility of an androgen-secreting neoplasm, in which case virilization may also be present.

The age of onset of menstrual cycles (menarche) and the pattern of the menstrual cycle should be ascertained; irregular cycles from the time of menarche onward are more likely to result from ovarian rather than adrenal androgen excess. Associated symptoms such as galactorrhea should prompt evaluation for hyperprolactinemia (Chap. 318) and possibly hypothyroidism (Chap. 320). Hypertension, striae, easy bruising, centripetal weight gain, and weakness suggest hypercortisolism (Cushing's syndrome; Chap. 321). Rarely, patients with growth hormone excess (i.e., acromegaly) will present with hirsutism. Use of medications such as phenytoin, minoxidil, or cyclosporine may be associated with androgen-independent causes of excess hair growth (i.e., hypertrichosis). A family history of infertility and/or hirsutism may indicate disorders such as nonclassic CAH (Chap. 321).

Physical examination should include measurement of height, weight, and calculation of body mass index (BMI). A BMI >25 kg/m^2 is indicative of excess weight for height, and values >30 kg/m^2 are often seen in association with hirsutism. Notation should be made of blood pressure, as adrenal causes may be associated with hypertension. Cutaneous signs sometimes associated with androgen excess and insulin resistance include acanthosis nigricans and skin tags.

An objective clinical assessment of hair distribution and quantity is central to the evaluation in any woman presenting with hirsutism. This assessment permits the distinction between hirsutism and hypertrichosis and provides a baseline reference point to gauge the response to treatment. A simple and commonly used method to grade hair growth is the modified scale of Ferriman and Gallwey (Fig. 44-1), where each of nine androgen-sensitive sites is graded from 0 to 4. Approximately 95% of Caucasian women have a score below 8 on this scale; thus, it is normal for most women to have some hair growth in androgen-sensitive sites. Scores above 8 suggest excess androgen-mediated hair growth, a finding that should be assessed further by hormonal evaluation (see below). In racial/ethnic groups that are less likely to manifest hirsutism (e.g., Asian women), additional cutaneous

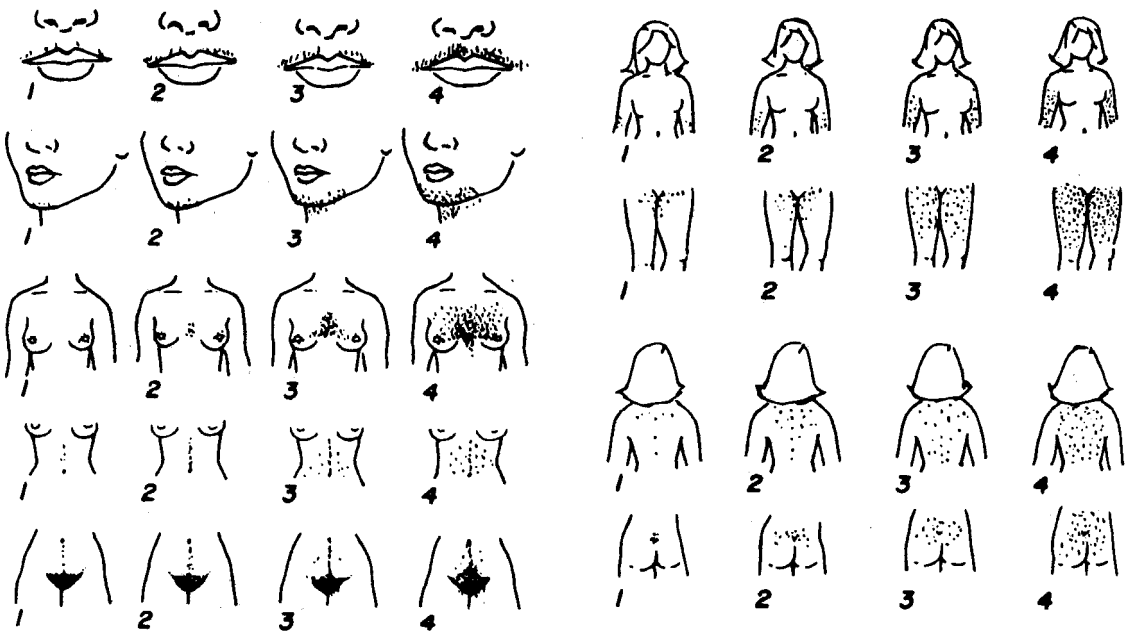

FIGURE 44-1 Hirsutism scoring scale of Ferriman and Gallwey. The nine body areas possessing androgen-sensitive areas are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal hirsutism score is less than 8. *[Reproduced from DA Ehrmann et al: Hyperandrogenism, hirsutism, and polycystic ovarian syndrome, in LJ DeGroot et al (eds), Endocrinology, 4th ed. Philadelphia, Saunders, 2000; with permission.]*

evidence of androgen excess should be sought, including pustular acne or thinning hair.

HORMONAL EVALUATION

Androgens are secreted by the ovaries and adrenal glands in response to their respective tropic hormones, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH). The principal circulating steroids involved in the etiology of hirsutism are testosterone, androstenedione, dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS). The ovaries and adrenal glands normally contribute about equally to testosterone production. Approximately half of the total testosterone originates from direct glandular secretion, and the remainder is derived from the peripheral conversion of androstenedione and DHEA (Chap. 325).

Although it is the most important circulating androgen, testosterone is, in effect, the penultimate androgen in mediating hirsutism; it is converted to the more potent dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is located in the PSU. DHT has a higher affinity for, and slower dissociation from, the androgen receptor. The local production of DHT allows it to serve as the primary mediator of androgen action at the level of the pilosebaceous unit. There are two isoenzymes of 5α-reductase: type 2 is found in the prostate gland and in hair follicles, whereas type 1 is found primarily in sebaceous glands.

One approach to testing for hyperandrogenemia is depicted in Fig. 44-2. In addition to measuring blood levels of testosterone and DHEAS, it is also important to measure the level of free (or unbound) testosterone. The fraction of testosterone that is not bound to its carrier protein, sex-hormone binding globulin (SHBG), is biologically available for conversion to DHT and for binding to androgen receptors. Hyperinsulinemia and/or androgen excess decrease hepatic production of SHBG, resulting in levels of total testosterone within the high-normal range, whereas the unbound hormone is more substantially elevated. Although there is a decline in ovarian testosterone production after menopause, ovarian estrogen production decreases to an even greater extent, and the concentration of SHBG is reduced. Consequently, there is an increase in the relative proportion of unbound testosterone, and it may exacerbate hirsutism after menopause.

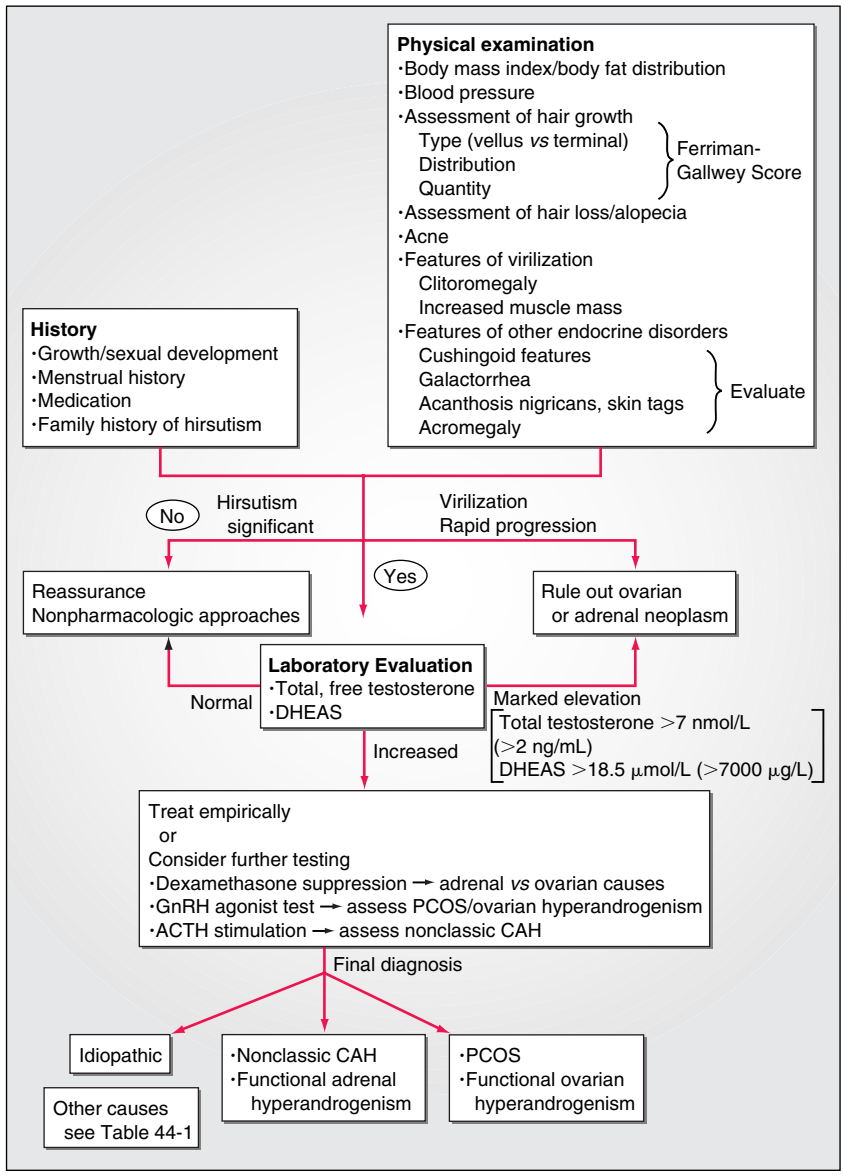

FIGURE 44-2 Algorithm for the evaluation and differential diagnosis of hirsutism. ACTH, adrenocorticotropic hormone; CAH, congenital adrenal hyperplasia; DHEAS, sulfated form of dehydroepiandrosterone; GnRH, gonadotropin-releasing hormone; PCOS, polycystic ovarian syndrome.

Because adrenal androgens are readily suppressed by low doses of glucocorticoids, the dexamethasone androgen-suppression test may broadly distinguish ovarian from adrenal androgen overproduction. A blood sample is obtained before and after administering dexamethasone (0.5 mg orally every 6 h for 4 days). An adrenal source is suggested by suppression of unbound testosterone into the normal range; incomplete suppression suggests ovarian androgen excess.

A baseline plasma total testosterone level >12 nmol/L (>3.5 ng/mL) usually indicates a virilizing tumor, whereas a level >7 nmol/L (>2 ng/mL) is suggestive. A basal DHEAS level >18.5 μmol/L (>7000 μg/L) suggests an adrenal tumor. Although DHEAS has been proposed as a "marker" of predominant adrenal androgen excess, it is not unusual to find modest elevations in DHEAS among women with PCOS. Computed tomography (CT) or magnetic resonance imaging (MRI) should be used to localize an adrenal mass, and ultrasound will usually suffice to identify an ovarian mass, if clinical evaluation and hormonal levels suggest these possibilities.

PCOS is the most common cause of ovarian androgen excess (Chap. 326). However, the increased ratio of LH to follicle-stimulating hormone that is characteristic of carefully studied patients with PCOS is not seen in up to half of these women due to the pulsatility of gonadotropins. If performed, ultrasound shows enlarged ovaries and increased stroma in many women with PCOS. However, polycystic ovaries may also be found in women without clinical or laboratory features of PCOS. Therefore, polycystic ovaries are a relatively insensitive and nonspecific finding for the diagnosis of ovarian hyperandrogenism. Gonadotropin-releasing hormone agonist testing can be used to make a specific diagnosis of ovarian hyperandrogenism. A peak 17-hydroxyprogesterone level ≥7.8 nmol/L (≥2.6 μg/L), after the administration of 100 μg nafarelin (or 10 μg/kg leuprolide) subcutaneously, is virtually diagnostic of ovarian hyperandrogenism.

Nonclassic CAH is most commonly due to 21-hydroxylase deficiency but can also be caused by autosomal recessive defects in other steroidogenic enzymes necessary for adrenal corticosteroid synthesis (Chap. 321). Because of the enzyme defect, the adrenal gland cannot secrete glucocorticoids efficiently (especially cortisol). This results in diminished negative feedback inhibition of ACTH, leading to compensatory adrenal hyperplasia and the accumulation of steroid precursors that are subsequently converted to androgen.

Deficiency of 21-hydroxylase can be reliably excluded by determining a morning 17-hydroxyprogesterone level <6 nmol/L (<2 μg/L) (drawn in the follicular phase). Alternatively, 21-hydroxylase deficiency can be diagnosed by measurement of 17-hydroxyprogesterone 1 h after administration of 250 μg of synthetic ACTH (cosyntropin) intravenously.

TREATMENT

Treatment of hirsutism may be accomplished pharmacologically or by mechanical means of hair removal. Nonpharmacologic treatments should be considered in all patients, either as the only treatment or as an adjunct to drug therapy.

Nonpharmacologic treatments include (1) bleaching; (2) depilatory (removal from the skin surface) such as shaving and chemical treatments; or (3) epilatory (removal of the hair including the root) such as plucking, waxing, electrolysis, and laser therapy. Despite perceptions to the contrary, shaving does not increase the rate or density of hair growth. Chemical depilatory treatments may be useful for mild hirsutism that affects only limited skin areas, though they can cause skin irritation. Wax treatment removes hair temporarily but is uncomfortable. Electrolysis is effective for more permanent hair removal, particularly in the hands of a skilled electrologist. Laser phototherapy appears to be efficacious for hair removal. It delays hair regrowth and causes permanent hair removal in most patients. The long-term effects and complications associated with laser treatment are being evaluated.

Pharmacologic therapy is directed at interrupting one or more of the steps in the pathway of androgen synthesis and action: (1) suppression of adrenal and/or ovarian androgen production; (2) enhancement of androgen-binding to plasma-binding proteins, particularly SHBG; (3) impairment of the peripheral conversion of androgen precursors to active androgen; and (4) inhibition of androgen action at the target tissue level. Attenuation of hair growth is typically not evident until 4 to 6 months after initiation of medical treatment and, in most cases, leads to only a modest reduction in hair growth.

Combination estrogen-progestin therapy, in the form of an oral contraceptive, is usually the first-line endocrine treatment for hirsutism and acne, after cosmetic and dermatologic management. The estrogenic component of most oral contraceptives currently in use is either ethinyl estradiol or mestranol. The suppression of LH leads to reduced production of ovarian androgens. The reduced androgen levels also result in a dose-related increase in SHBG, thereby lowering the fraction of unbound plasma testosterone. Combination therapy has also been demonstrated to decrease DHEAS, perhaps by reducing ACTH levels. Estrogens also have a direct, dose-dependent suppressive effect on sebaceous cell function.

The choice of a specific oral contraceptive should be predicated on the progestational component, as progestins vary in their suppressive effect on SHBG levels and in their androgenic potential. Ethynodiol diacetate has relatively low androgenic potential, whereas progestins such as norgestrel and levonorgestrel are pargenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate exemplifies the newer generation of progestins that are virtually nonandrogenic. Drospirenone, an analogue of spironolactone that has both antimineralocorticoid and antiandrogenic activities, has been approved for use as a progestational agent in combination with ethinyl estradiol. Its properties suggest that it should be the preferred choice for the treatment of hirsutism.

Oral contraceptives are contraindicated in women with a history of thromboembolic disease or in women with increased risk of breast or other estrogen-dependent cancers (Chap. 327). There is a relative contraindication to the use of oral contraceptives in smokers or in those with hypertension or a history of migraine headaches. In most trials, estrogen-progestin therapy alone improves the extent of acne by a maximum of 50 to 70%. The effect on hair growth may not be evident for 6 months, and the maximum effect may require 9 to 12 months owing to the length of the hair growth cycle. Improvements in hirsutism are typically in the range of 20%, but there may be an arrest of further progression of hair growth.

Adrenal androgens are more sensitive than cortisol to the suppressive effects of glucocorticoids. Therefore, glucocorticoids are the mainstay of treatment in patients with CAH. Although glucocorticoids have been reported to restore ovulatory function in some women with PCOS, this effect is highly variable. Because of side effects from excessive glucocorticoids, low doses should be used. Dexamethasone (0.2 to 0.5 mg) or prednisone (5 to 10 mg) should be taken at bedtime to achieve maximal suppression by inhibiting the nocturnal surge of ACTH.

Cyproterone acetate is the prototypic antiandrogen. It acts mainly by competitive inhibition of the binding of testosterone and DHT to the androgen receptor. In addition, it may act to enhance the metabolic clearance of testosterone by inducing hepatic enzymes. Although not available for use in the United States, cyproterone acetate is widely used in Canada, Mexico, and Europe. Cyproterone (50 to 100 mg) is given on days 1 to 15 and ethinyl estradiol (50 μg) is given on days 5 to 26 of the menstrual cycle. Side effects include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido.

Spironolactone, usually used as a mineralocorticoid antagonist, is also a weak antiandrogen. It is almost as effective as cyproterone acetate when used at high enough doses (100 to 200 mg daily). Patients should be monitored intermittently for hyperkalemia or hypotension, though these side effects are uncommon. Pregnancy should be avoided because of the risk of feminization of a male fetus. Spironolactone can also cause menstrual irregularity. It is often used in combination with an oral contraceptive, which suppresses ovarian androgen production and helps prevent pregnancy.

Flutamide is a potent nonsteroidal antiandrogen that is effective in treating hirsutism, but concerns about the induction of hepatocellular dysfunction have limited its use. Finasteride is a competitive inhibitor of 5α-reductase type 2. Beneficial effects on hirsutism have been reported, but the predominance of 5α-reductase type 1 in the PSU appears to account for its limited efficacy. Finasteride would also be expected to impair sexual differentiation in a male fetus, and it should not be used in women who may become pregnant.

Eflornithine cream (Vaniqa) has been approved as a novel treatment for unwanted facial hair in women, but long-term efficacy remains to be established. It can cause skin irritation under exaggerated conditions of use. Ultimately, the choice of any specific agent(s) must be tailored to the unique needs of the patient being treated. As noted previously, pharmacologic treatments for hirsutism should be used in conjunction with nonpharmacologic approaches. It is also helpful to review the pattern of female hair distribution in the normal population to dispel unrealistic expectations.

45 INFERTILITY AND FERTILITY CONTROL

Janet E. Hall

The concept of reproductive choice is now firmly entrenched in developed countries and has dramatically altered reproductive behavior. The availability of effective contraceptive methods prevents unintended pregnancies and has important economic and social implications. Infertility, on the other hand, can be accompanied by substantial stress and disappointment. Fortunately, the ability to diagnose and to treat various causes of infertility now provides an array of effective new approaches to this condition.

INFERTILITY

DEFINITION AND PREVALENCE *Infertility* is defined as the inability to conceive after 12 months of unprotected sexual intercourse. In a study of 5574 English and American women who ultimately conceived, pregnancy occurred in 50% within 3 months, 72% within 6 months, and 85% within 12 months. These findings are consistent with predictions based on *fecundability*, the probability of achieving pregnancy in one menstrual cycle (approximately 20 to 25% in healthy young couples). Assuming a fecundability of 0.25, 98% of couples should conceive within 13 months. Based on this definition, the National Survey of Family Growth reports a 14% rate of infertility in the United States in married women aged 15 to 44. The infertility rate has remained relatively stable over the past 30 years, although the proportion of couples without children has risen, reflecting a trend to delay childbearing. This trend has important implications because of an age-related decrease in fecundability, which begins at age 35 and is exacerbated after age 40.

CAUSES OF INFERTILITY The spectrum of infertility ranges from reduced conception rates or the need for medical intervention to irreversible causes of infertility (*sterility*). Infertility can be attributed primarily to male factors in 25%, female factors in 58%, and is unexplained in about 17% of couples (Fig. 45-1). Not uncommonly, both male and female factors contribute to infertility.

APPROACH TO THE PATIENT

Initial Evaluation In all couples presenting with infertility, the initial evaluation includes discussion of the appropriate timing of intercourse and discussion of modifiable risk factors such as smoking, alcohol, caffeine, and obesity. A description of the range of investigations that may be required and a brief description of infertility treatment options, including adoption, should be reviewed. Initial investigations are focused on determining whether the primary cause of the infertility is male, female, or both. These investigations include a semen analysis in the male, confirmation of ovulation in the female, and, in the majority of situations, documentation of tubal patency in the female. Although frequently used in the past, recent studies have not supported the efficacy of postcoital testing of sperm interaction with cervical mucus as a routine component of initial testing. Strategies for further evaluation are described below and in Chaps. 325 and 326. In some cases, after an extensive evaluation has excluded identifiable male or female causes of infertility, the disorder is classified as unexplained infertility.

Psychological Aspects of Infertility Infertility is invariably associated with psychological stress. In addition to the diagnostic and therapeutic procedures, stress may result from repeated cycles of hope and loss associated with each new procedure or cycle of treatment that does not result in the birth of a child. These feelings are often combined with a sense of isolation from friends and family. Counseling and stress-management techniques should be introduced early in the evaluation of infertility. When extreme, stress can contribute to infertility; for example, stress may impair hypothalamic control of ovulation. Infertility and its treatment do not appear to be associated with long-term psychological sequelae.

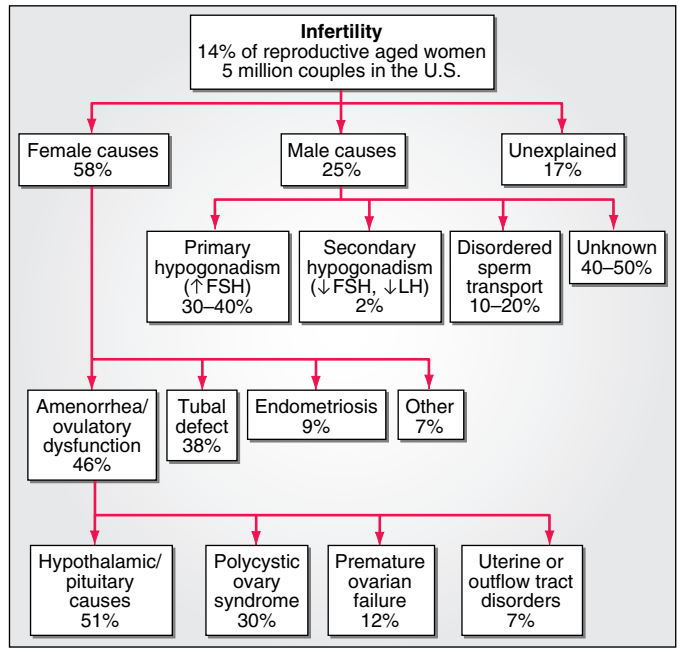

FIGURE 45-1 Causes of infertility. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Female Causes Abnormalities in menstrual function constitute the most common cause of female infertility. These disorders, which include ovulatory dysfunction and abnormalities of the uterus or outflow tract, may present as amenorrhea (absence of menses) or as irregular or short menstrual cycles. A careful history and physical examination and a limited number of laboratory tests will help to determine whether the abnormality is (1) hypothalamic or pituitary [low follicle-stimulating hormone (FSH), luteinizing hormone (LH), and estradiol with or without an increase in prolactin]; (2) polycystic ovarian syndrome (PCOS; irregular cycles and hyperandrogenism in the absence of other causes of androgen excess); (3) ovarian (low estradiol with increased FSH); or (4) uterine or outflow tract abnormality. The frequency of these diagnoses depends on whether the amenorrhea is primary or occurs after normal puberty and menarche (Fig. 45-1). →***The approach to further evaluation of these disorders is described in detail in Chap. 326.***

OVULATORY DYSFUNCTION In women with a history of regular menstrual cycles, *evidence of ovulation* should be sought by using urinary ovulation predictor kits (they reflect the preovulatory gonadotropin surge but do not confirm ovulation), basal body temperature charts, or a mid-luteal phase progesterone level. The mid-luteal phase progesterone increase (usually >3 ng/mL) confirms ovulation and corpus luteum function and is responsible for the rise in basal body temperature [>0.3°C (>0.6°F) for 10 days]. An endometrial biopsy to exclude luteal phase insufficiency is no longer considered an essential part of the infertility workup for most patients. Even in the presence of ovulatory cycles, evaluation of *ovarian reserve* is recommended for women over 35 by measurement of FSH on day 3 of the cycle or in response to clomiphene, an estrogen antagonist (see below). An FSH level <10 IU/mL on cycle day 3 predicts adequate ovarian oocyte reserve. Inhibin B, an ovarian hormone that selectively suppresses FSH, is not of additional benefit in assessment of ovarian reserve.

TUBAL DISEASE Tubal disease may result from pelvic inflammatory disease (PID), appendicitis, endometriosis, pelvic adhesions, tubal surgery, and previous use of an intrauterine device (IUD). How-

ever, a specific cause is not identified in up to 50% of patients with documented tubal factor infertility. Because of the high prevalence of tubal disease, evaluation of tubal patency by hysterosalpingogram or laparoscopy should occur early in the majority of couples with infertility. Subclinical infection with *Chlamydia trachomatis* may be an underdiagnosed cause of tubal infertility and requires the treatment of both partners.

ENDOMETRIOSIS *Endometriosis* is defined as the presence of endometrial glands or stroma outside the endometrial cavity and uterine musculature. Its presence is suggested by a history of dyspareunia (painful intercourse), worsening dysmenorrhea that often begins before menses, or by a thickened rectovaginal septum or deviation of the cervix on pelvic examination. The pathogenesis of the infertility associated with endometriosis is unclear but may involve cytokine effects on the normal endometrium as well as adhesions. Endometriosis is often clinically silent, however, and can only be excluded definitively by laparoscopy.

Male Causes Known causes of male infertility include primary testicular dysfunction, disorders of sperm transport, and hypothalamic-pituitary disease resulting in secondary hypogonadism. However, the etiology is not ascertained in up to half of men with suspected male factor infertility (Fig. 45-1). The key initial diagnostic test is a *semen analysis*. Although 95% confidence limits can be used to define normal semen parameters, data relating sperm counts to fecundability are more useful. Such studies suggest that normal fertility is associated with sperm counts of >48 million/mL, with a motility of >63%, with >12% exhibiting normal morphology, whereas subfertility is seen with sperm counts of <13 million/mL, motility of <32%, and <9% normal morphology. Abnormalities of spermatogenesis may have a genetic component. Y chromosome microdeletions and *POLG* variants are increasingly recognized as a cause of *azoospermia* (absence of sperm) or *oligospermia* (low sperm count). Y chromosome microdeletions have also been identified in a subset of men with elevated FSH levels and idiopathic infertility. Testosterone levels should be measured if the sperm count is low on repeated examination or if there is clinical evidence of hypogonadism. A low testosterone level may result from *primary gonadal deficiency*; in this condition, levels of LH and FSH will be elevated. Less commonly, low testosterone and decreased spermatogenesis result from hypothalamic or pituitary disease, in which case the LH and FSH levels will be low (Chap. 325).

Acquired disorders of the testes are often associated with impaired spermatogenesis with relatively preserved Leydig cell function; thus, testosterone levels may be normal. Such abnormalities include viral orchitis (especially mumps) and other infectious causes such as tuberculosis or sexually transmitted diseases (STDs), chemotherapy (especially the alkylating agents cyclophosphamide and chlorambucil), ionizing radiation, and drugs that may impair fertility directly or through inhibition of testicular androgen production or action. Anabolic androgen abuse should be considered in a well-androgenized man with low gonadotropins and testosterone but a suppressed sperm count. Prolonged elevation of testicular temperature may impair spermatogenesis, e.g., cryptorchidism, after an acute febrile illness or in association with varicocele. A potential role for environmental toxins as a cause of impaired spermatogenesis has been suggested based on an apparent decrease in sperm counts over the past several decades, but a direct cause-and-effect relationship has not been established.

SECONDARY HYPOGONADISM Low gonadotropin levels, associated with low testosterone, may signal the presence of a pituitary macroadenoma or hypothalamic tumor (in both cases prolactin levels may be elevated; Chap. 318) or may be the first presentation of hemochromatosis (Chap. 336) or other systemic illness. Recent studies have identified several genetic causes of gonadotropin-releasing hormone (GnRH) deficiency (*KAL* and *DAX-1*), as well as mutations that lead to isolated gonadotropin deficiency (GnRH receptor, LHβ, FSHβ mutations) (Chap. 318).

DISORDERED SPERM TRANSPORT Patients with low sperm counts and normal hormonal levels may be found to have obstructive abnormalities of the vas deferens or epididymis. The most common causes of vas deferens obstruction are previous vasectomy or accidental ligation during inguinal surgery. Congenital absence of the vas deferens can be diagnosed by a deficiency of fructose in the ejaculate and is often associated with an abnormality of the cystic fibrosis transmembrane regulator (*CFTR*) gene. Young's syndrome, characterized by inspissated secretions, can also preclude normal sperm transport.

TREATMENT

The treatment of infertility should be tailored to the problems unique to each couple. In many situations, including unexplained infertility, mild to moderate endometriosis, and/or borderline semen parameters, a stepwise approach to infertility is optimal, beginning with low-risk interventions and moving to more invasive, higher risk interventions only if necessary. After determination of all infertility factors and their correction, if possible, this approach might include, in increasing order of complexity: (1) expectant management, (2) clomiphene citrate (see below) with or without intrauterine insemination (IUI), (3) gonadotropins with or without IUI, and (4) in vitro fertilization (IVF). The time used to complete the evaluation, correction, and expectant management can be longer in women <30, but this process should be advanced rapidly in women >35. In some situations, expectant management will not be appropriate.

Ovulatory Dysfunction Treatment of ovulatory dysfunction should first be directed at identification of the etiology of the disorder to allow specific management when possible. Dopamine agonists, for example, may be indicated in patients with hyperprolactinemia (Chap. 318); lifestyle modification may be successful in women with low body weight or a history of intensive exercise (Chap. 65).

Medications used for ovulation induction include clomiphene citrate, gonadotropins, and pulsatile GnRH. *Clomiphene citrate* is a nonsteroidal estrogen antagonist that increases FSH and LH levels by blocking estrogen negative feedback at the hypothalamus. The efficacy of clomiphene for ovulation induction is highly dependent on patient selection. It induces ovulation in 70 to 80% of women with PCOS and is the initial treatment of choice in these patients, particularly in conjunction with the use of insulin-sensitizing agents, such as metformin. Clomiphene citrate is less successful in patients with hypogonadotropic hypogonadism.

Gonadotropins are highly effective for ovulation induction in women with hypogonadotropic hypogonadism and PCOS and are used to induce multiple follicular recruitment in unexplained infertility and in older reproductive-aged women. Disadvantages include a significant risk of multiple gestation and the risk of ovarian hyperstimulation, but careful monitoring and a conservative approach to ovarian stimulation reduce these risks. Currently available gonadotropins include urinary preparations of LH and FSH, highly purified FSH, and recombinant FSH. Though FSH is the key component, the addition of some LH (or human chorionic gonadotropin) may improve results, particularly in hypogonadotropic patients.

Pulsatile GnRH is highly effective for restoring ovulation in patients with hypothalamic amenorrhea but is not widely available in the United States. Pregnancy rates are similar to those following the use of gonadotropins, but rates of multiple gestation are lower and there is virtually no risk of ovarian hyperstimulation.

None of these methods are effective in women with premature ovarian failure in whom donor oocyte or adoption are the methods of choice.

Tubal Disease If hysterosalpingography suggests a tubal or uterine cavity abnormality, or if a patient is ≥35 at the time of initial evaluation, laparoscopy with tubal lavage is recommended, often with a hysteroscopy. Although tubal reconstruction may be attempted if tubal disease is identified, IVF is often used instead, as these patients are at increased risk of developing an ectopic pregnancy.

Endometriosis Though 60% of women with minimal or mild endometriosis may conceive within 1 year without treatment, laparoscopic resection or ablation appears to improve conception rates. Medical management of advanced stages of endometriosis is widely used for symptom control but has not been shown to enhance fertility (Chap. 326). In moderate to severe endometriosis, conservative surgery is associated with pregnancy rates of 50 and 39% respectively, compared with rates of 25 and 5% with expectant management alone. In some patients, IVF may be the treatment of choice.

TABLE 45-1 *Effectiveness of Different Forms of Contraception*

Method of Contraception	Theoretical Effectiveness, %[a]	Actual Effectiveness, %[a]	% Continuing Use at 1 Year[b]	Contraceptive Methods Used by U.S. Women[c]

Male Factor Infertility Treatment options for male factor infertility have expanded greatly in recent years. Secondary hypogonadism is highly amenable to treatment with pulsatile GnRH or gonadotropins (Chap. 325). In vitro techniques have provided new opportunities for patients with primary testicular failure and disorders of sperm transport. Choice of initial treatment options depends on sperm concentration and motility. Expectant management should be attempted initially in men with mild male factor infertility (sperm count of 15 to 20 $\times$ 10^6/mL and normal motility). Moderate male factor infertility (10 to 15 $\times$ 10^6/mL and 20 to 40% motility) should begin with IUI alone or in combination with treatment of the female partner with clomiphene or gonadotropins, but it may require IVF with or without intracytoplasmic sperm injection (ICSI). For men with a severe defect (sperm count of $<10 \times 10^6$/mL, 10% motility), IVF with ICSI or donor sperm should be used.

Assisted Reproductive Technologies The development of assisted reproductive technologies (ART) has dramatically altered the treatment of male and female infertility. IVF is indicated for patients with many causes of infertility that have not been successfully managed with more conservative approaches. IVF or ICSI is often the treatment of choice in couples with a significant male factor or tubal disease, whereas IVF using donor oocytes is used in patients with premature ovarian failure and in women of advanced reproductive age. Success rates depend on the age of the woman and the cause of the infertility and are generally 18 to 24% per cycle when initiated in women <40. In women >40, there is a marked decrease in both the number of oocytes retrieved and their ability to be fertilized. Though often effective, IVF is expensive and requires careful monitoring of ovulation induction and invasive techniques, including the aspiration of multiple follicles. IVF is associated with a significant risk of multiple gestation (31% twins, 6% triplets, and 0.2% higher order multiples).

CONTRACEPTION

Though various forms of contraception are widely available, approximately 30% of births in the United States are the result of unintended pregnancy. Teenage pregnancies continue to represent a serious public health problem in the United States, with >1 million unintended pregnancies each year—a significantly greater incidence than in other industrialized nations.

Contraceptive methods are widely used (Table 45-1). Only 15% of couples report having unprotected sexual intercourse in the past 3 months. A reversible form of contraception is used by >50% of couples. Sterilization (in either the male or female) has been employed as a permanent form of contraception by over a third of couples. Pregnancy termination is relatively safe when directed by health care professionals but is rarely the option of choice.

No single contraceptive method is ideal, although all are safer than carrying a pregnancy to term. The effectiveness of a given method of contraception is dependent on the efficacy of the method itself, compliance, and appropriate use. Knowledge of the advantages and disadvantages of each contraceptive is essential for counseling an individual about the methods that are safest and most consistent with his or her lifestyle. Discrepancies between theoretical and actual effectiveness emphasize the importance of patient education and compliance when considering various forms of contraception (Table 45-1).

BARRIER METHODS Barrier contraceptives (such as condoms, diaphragms, and cervical caps) and spermicides are easily available, reversible, and have fewer side effects than hormonal methods. However, their effectiveness is highly dependent on compliance and proper use (Table 45-1). A major advantage of barrier contraceptives is the protection provided against STDs (Chap. 115). Consistent use is associated with a decreased risk of gonorrhea, nongonococcal urethritis, and genital herpes, probably due in part to the concomitant use of spermicides. Condom use also reduces the transmission of HIV infection. Natural membrane condoms may be less effective than latex condoms, and petroleum-based lubricants can degrade condoms and decrease their efficacy for preventing HIV infection. A highly effective female condom, which also provides protection against STDs, was approved in 1994 but has not achieved widespread use.

STERILIZATION Sterilization is the method of birth control most frequently chosen by fertile men and multiparous women >30 (Table 45-1). Sterilization prevents fertilization by surgical interruption of the fallopian tubes in women or the vas deferens in men. Although tubal ligation and vasectomy are potentially reversible, these procedures should be considered permanent and should not be undertaken without careful patient counseling.

Several methods of *tubal ligation* have been developed, all of which are highly effective with a 10-year cumulative pregnancy rate of 1.85 per 100 women. However, when pregnancy does occur, the risk of ectopic pregnancy may be as high as 30%. In addition to prevention of pregnancy, tubal ligation reduces the risk of ovarian cancer, possibly by limiting the upward migration of potential carcinogens.

Vasectomy is an outpatient surgical procedure that has little risk

and is highly effective. The development of azoospermia may be delayed for 2 to 6 months, and other forms of contraception must be used until two sperm-free ejaculations provide proof of sterility.

INTRAUTERINE DEVICES IUDs inhibit pregnancy primarily through a spermicidal effect caused by a sterile inflammatory reaction produced by the presence of a foreign body in the uterine cavity (copper IUDs) or by the release of progestins (Progestasert, Mirena). IUDs provide a high level of efficacy in the absence of systemic metabolic effects, and ongoing motivation is not required to ensure efficacy once the device has been placed. However, only 1% of women in the United States use this method compared to a utilization rate of 15 to 30% in much of Europe and Canada. This relatively low utilization rate continues despite evidence that the newer devices are not associated with increased rates of pelvic infection and infertility, as occurred with earlier devices. Screening for STDs should be performed prior to insertion, and an IUD should not be used in women at high risk for development of STDs or in women at high risk for bacterial endocarditis.

HORMONAL METHODS ■ Oral Contraceptive Pills Because of their ease of use and efficacy, oral contraceptive pills are the most widely used form of hormonal contraception. They act by suppressing ovulation, changing cervical mucus, and altering the endometrium. The current formulations are made from synthetic estrogens and progestins. The estrogen component of the pill consists of ethinyl estradiol or mestranol, which is metabolized to ethinyl estradiol. Multiple synthetic progestins are available. Norethindrone and its derivatives are used in many formulations. Low-dose norgestimate and the more recently developed progestins (desogestrel, gestodene, drospirenone) have a less androgenic profile; levonorgestrel appears to be the most androgenic of the progestins and should be avoided in patients with hyperandrogenic features. The three major formulations of oral contraceptives are: (1) fixed-dose estrogen-progestin combination, (2) phasic estrogen-progestin combination, and (3) progestin only. Combination formulations are administered daily for 3 weeks followed by a week of no medication during which menstrual bleeding generally occurs. Progestin-only pills are administered continuously. There has been recent interest in the development of extended oral contraceptives, reducing the number of episodes of withdrawal bleeding. An oral, trimonthly regimen is currently under investigation in the United States. Preliminary studies indicate that headache is reduced, although there is an early incidence of breakthrough bleeding.

Current doses of ethinyl estradiol range from 20 to 50 μg. However, indications for the 50-μg dose are rare, and the majority of formulations contain 35 μg of ethinyl estradiol. The reduced estrogen and progesterone content in the second- and third-generation pills has decreased both side effects and risks associated with oral contraceptive use (Table 45-2). At the currently used doses, patients must be cautioned not to miss pills due to the potential for ovulation. Side effects, including break-through bleeding, amenorrhea, breast tenderness, and weight gain, are often responsive to a change in formulation.

The microdose progestin-only minipill is less effective as a contraceptive, having a pregnancy rate of 2 to 7 per 100 women-years. However, it may be appropriate for women with cardiovascular disease or for women who cannot tolerate synthetic estrogens.

New Methods A *weekly contraceptive patch* (Ortho Evra) is now available. It has similar efficacy to oral contraceptives and may be associated with less breakthrough bleeding. Approximately 2% of patches fail to adhere, and a similar percentage of women have skin reactions. Efficacy is lower in women >90 kg. A *monthly contraceptive injection* (Lunelle) is also available. This estrogen/progestin combination is highly effective, with a first-year failure rate of <0.2%, but it may be less effective in obese women. Its use is associated with bleeding irregularities that diminish over time. Fertility returns rapidly after discontinuation. A *monthly vaginal ring* (NuvaRing) is now approved for contraceptive use. It is highly effective, with a 12-month failure rate of 0.7%. The device is intended to be left in place during intercourse. If removed during intercourse, it must be reinserted within 3 h. Ovulation returns within the first recovery cycle after discontinuation.

TABLE 45-2 Oral Contraceptives: Contraindications and Disease Risk

I. Contraindications
  A. Absolute
    1. Previous thromboembolic event or stroke
    2. History of an estrogen-dependent tumor
    3. Active liver disease
    4. Pregnancy
    5. Undiagnosed abnormal uterine bleeding
    6. Hypertriglyceridemia
    7. Women over age 35 who smoke heavily (>15 cigarettes per day)
  B. Relative
    1. Hypertension
    2. Women receiving anticonvulsant drug therapy
II. Disease risks
  A. Increased
    1. Coronary heart disease—increased only in smokers > 35; no relation to progestin type
    2. Hypertension—relative risk 1.8 (current users) and 1.2 (previous users)
    3. Venous thrombosis—relative risk ~4; markedly increased with factor V Leiden or prothrombin-gene mutations
    4. Stroke—increased only in combination with hypertension; unclear relation to migraine headache
    5. Cerebral vein thrombosis—relative risk ~13–15; synergistic with prothrombin-gene mutation
    6. Cervical cancer—relative risk 2–4
  B. Decreased
    1. Ovarian cancer—50% reduction in risk
    2. Endometrial cancer—40% reduction in risk
  C. No effect
    1. Breast cancer

Long-Term Contraceptives Long-term progestin administration in the form of Depo-Provera and Norplant (Table 45-1) act primarily by inhibiting ovulation and causing changes in the endometrium and cervical mucus that result in decreased implantation and sperm transport. Depo-Provera requires an intramuscular injection and is effective for 3 months, but return of fertility after discontinuation may be delayed for up to 12 to 18 months. Norplant requires surgical insertion but is effective for up to 5 years afer insertion; fertility is possible shortly after its removal. Amenorrhea, irregular bleeding, and weight gain are the most common adverse effects associated with both injectable forms of contraception. A major advantage of the injectable progestin-based contraceptives is the apparent lack of increased arterial and venous thromboembolic events, but increased gallbladder disease and decreased bone density may result.

POSTCOITAL CONTRACEPTION Postcoital contraceptive methods prevent implantation or cause regression of the corpus luteum and are highly efficacious if used appropriately. Unprotected intercourse without regard to the time of the month carries an 8% incidence of pregnancy, an incidence that can be reduced to 2% by the use of emergency contraceptives within 72 h of unprotected intercourse. Certain oral contraceptive pills can be used within 72 h of unprotected intercourse [Ovral (2 tablets, 12 h apart) and Lo/Ovral (4 tablets, 12 h apart)]. Preven (50 mg ethinyl estradiol and 0.25 mg levonorgestrel) and Plan B (0.75 mg levonorgestrel) are now approved for postcoital contraception. Side effects are common with these high doses of hormones and include nausea, vomiting, and breast soreness. Recent studies suggest that 600 mg mifepristone (RU486), a progesterone receptor antagonist, may be equally as effective or more effective than hormonal regimens, with fewer side effects.

MALE HORMONAL CONTRACEPTION An effective and reversible male contraceptive has long been sought, and surveys indicate that a "male pill" would be acceptable to both men and women. Complete suppression of spermatogenesis is required for acceptable contraception but is not achieved reliably with testosterone alone. However, the combination of a long-acting testosterone preparation with a GnRH antagonist or a

progestin such as norgestral, desonorgestrel, or norethisterone results in effective contraception, suggesting that a male contraceptive may be forthcoming.

46 APPROACH TO THE PATIENT WITH A SKIN DISORDER

Thomas J. Lawley, Kim B. Yancey

The challenge of examining the skin lies in distinguishing normal from abnormal, significant findings from trivial ones, and in integrating pertinent signs and symptoms into an appropriate differential diagnosis. The fact that the largest organ in the body is visible is both an advantage and a disadvantage to those who examine it. It is advantageous because no special instrumentation is necessary and because the skin can be biopsied with little morbidity. However, the casual observer can be misled by a variety of stimuli and overlook important, subtle signs of skin or systemic disease. For instance, the sometimes minor differences in color and shape that distinguish a malignant melanoma (Fig. 46-1) from a benign pigmented nevus (Fig. 46-2) can be difficult to recognize. To aid in the interpretation of skin lesions, a variety of descriptive terms have been developed to characterize cutaneous lesions (Tables 46-1 and 46-2 and Fig. 46-3) and to formulate a differential diagnosis (Table 46-3). For instance, the finding of large numbers of scaling papules, usually indicative of a primary skin disease, places the patient in a different diagnostic category than would hemorrhagic papules, which may indicate vasculitis or sepsis (Figs. 46-4 and 46-5, respectively). It is important to differentiate primary skin lesions from secondary skin changes. If the examiner focuses on linear erosions overlying an area of erythema and scaling, he or she may incorrectly assume that the erosion is the primary lesion and the redness and scale are secondary, while the correct interpretation would be that the patient has a pruritic eczematous dermatitis with erosions caused by scratching.

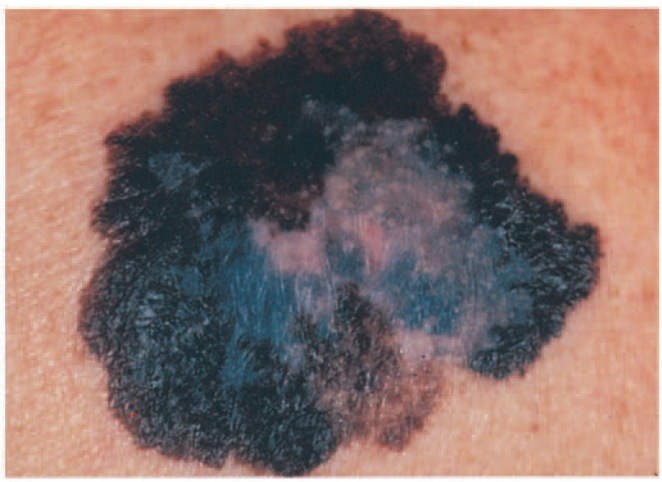

FIGURE 46-1 Superficial spreading melanoma is the most common type of malignant melanoma and demonstrates color variegation (black, blue, brown, pink, and white) and irregular borders.

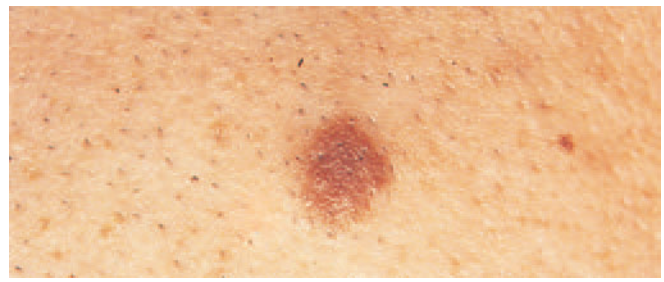

FIGURE 46-2 Nevi are benign proliferations of nevomelanocytes characterized by regularly shaped hyperpigmented macules or papules of a uniform color.

APPROACH TO THE PATIENT

In examining the skin it is usually advisable to assess the patient before taking an extensive history. This way, the entire cutaneous surface is sure to be evaluated, and objective findings can be integrated with relevant historic data. Four basic features of any cutaneous lesion must be noted and considered in the examination of

TABLE 46-1 Descriptions of Primary Skin Lesions

Macule: A flat, colored lesion, <2 cm in diameter, not raised above the surface of the surrounding skin. A "freckle," or ephelid, is a prototype pigmented macule.

Patch: A large (>2 cm), flat lesion with a color different from the surrounding skin. This differs from a macule only in size.

Papule: A small, solid lesion, <0.5 cm in diameter, raised above the surface of the surrounding skin and hence palpable (e.g., a closed comedone, or whitehead, in acne).

Nodule: A larger (0.5–5.0 cm), firm lesion raised above the surface of the surrounding skin. This differs from a papule only in size (e.g., dermal nevus).

Tumor: A solid, raised growth >5 cm in diameter.

Plaque: A large (>1 cm), flat-topped, raised lesion; edges may either be distinct (e.g., in psoriasis) or gradually blend with surrounding skin (e.g., in eczematous dermatitis).

Vesicle: A small, fluid-filled lesion, <0.5 cm in diameter, raised above the plane of surrounding skin. Fluid is often visible, and the lesions are often translucent [e.g., vesicles in allergic contact dermatitis caused by *Toxicodendron* (poison ivy)].

Pustule: A vesicle filled with leukocytes. Note: The presence of pustules does not necessarily signify the existence of an infection.

Bulla: A fluid-filled, raised, often translucent lesion >0.5 cm in diameter.

Cyst: A soft, raised, encapsulated lesion filled with semisolid or liquid contents.

Wheal: A raised, erythematous papule or plaque, usually representing short-lived dermal edema.

Telangiectasia: Dilated, superficial blood vessels.

TABLE 46-2 Common Dermatologic Terms

Lichenification: A distinctive thickening of the skin that is characterized by accentuated skin-fold markings and that feels thick on palpation.
Crust: Dried exudate of body fluids that may be either yellow (serous exudate) or red (hemorrhagic exudate).
Milia: Small, firm, white papules that are filled with keratin (and may in part resemble pustules).
Erosion: Loss of epidermis without an associated loss of dermis.
Ulcer: Loss of epidermis and at least a portion of the underlying dermis.
Excoriations: Linear, angular erosions that may be covered by crust and are caused by scratching.
Atrophy: An acquired loss of substance. In the skin, this may appear as a depression with intact epidermis (i.e., loss of dermal or subcutaneous tissue) or as sites of shiny, delicate, wrinkled lesions (i.e., epidermal atrophy).
Scar: A change in the skin secondary to trauma or inflammation. Sites may be erythematous, hypopigmented, or hypertrophic depending on their age or character. Sites on hair-bearing areas may be characterized by destruction of hair follicles.
Pruritus: A sensation that elicits the desire to scratch. Pruritus is often the predominant symptom of inflammatory skin diseases (e.g., atopic dermatitis, allergic contact dermatitis); it is also commonly associated with xerosis and aged skin. Systemic conditions that can be associated with pruritus include chronic renal disease, cholestasis, pregnancy, malignancy, polycythemia vera, and delusions of parasitosis.

skin: the distribution of the eruption, the type(s) of primary lesion, the shape of individual lesions, and the arrangement of the lesions. In the initial examination it is important that the patient be disrobed as completely as possible. This will minimize chances of missing important individual skin lesions and make it possible to assess the distribution of the eruption accurately. The patient should first be viewed from a distance of about 1.5 to 2 m (4 to 6 ft) so that the general character of the skin and the distribution of lesions can be evaluated. Indeed, distribution of lesions often correlates highly with diagnosis (Fig. 46-6). For example, a hospitalized patient with a generalized erythematous exanthem is more likely to have a drug eruption than is a patient with a similar rash limited to the sun-exposed portions of the face. The presence or absence of lesions on mucosal surfaces should also be determined. Once the distribution of the lesions has been established, the nature of the primary

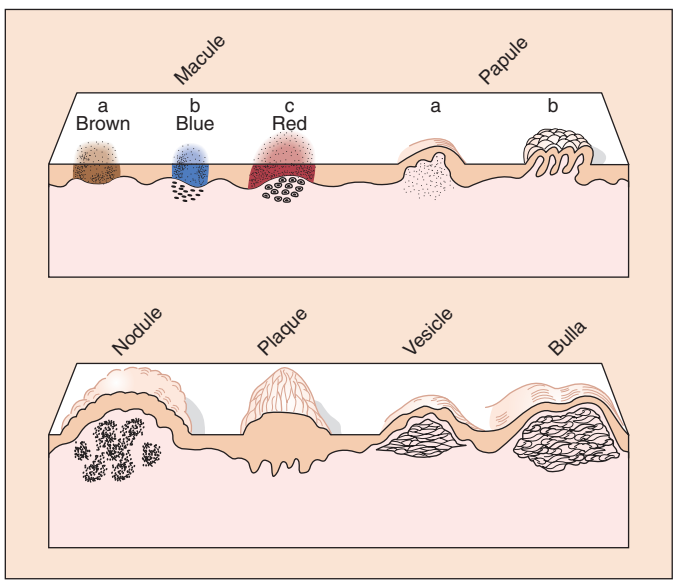

FIGURE 46-3 A schematic representation of several common primary skin lesions (see Table 46-1).

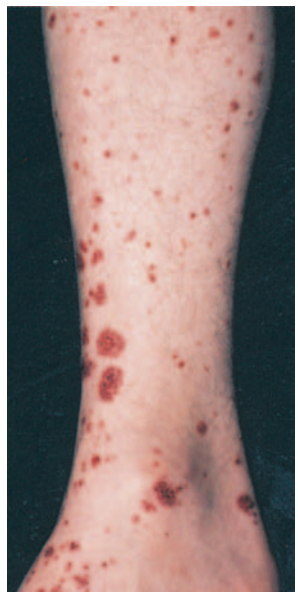

FIGURE 46-4 Palpable purpuric papules on the lower legs are seen in this patient with cutaneous small vessel vasculitis. *(Courtesy of Robert Swerlick, MD.)*

lesion must be determined. Thus, when lesions are distributed on elbows, knees, and scalp, the most likely possibility based solely on distribution is psoriasis or dermatitis herpetiformis (Figs. 46-7 and 46-8, respectively). The primary lesion in psoriasis is a scaly papule that soon forms erythematous plaques covered with a white scale, whereas that of dermatitis herpetiformis is an urticarial papule that quickly becomes a small vesicle. In this manner, identification of the primary lesion directs the examiner toward the proper diagnosis. Secondary changes in skin can also be quite helpful. For example, scale represents excessive epidermis, while crust is the result of a discontinuous epithelial cell layer. Palpation of skin lesions can also yield insight into the character of an eruption. Thus red papules on the lower extremities that blanch with pressure can be a manifestation of many different diseases, but hemorrhagic red papules that do not blanch with pressure indicate palpable purpura characteristic of necrotizing vasculitis (Fig. 46-4).

The shape of lesions is also an important feature. Flat, round, erythematous papules and plaques are common in many cutaneous diseases. However, target-shaped lesions that consist in part of erythematous plaques are specific for erythema multiforme (Fig. 46-9). In the same way, the arrangement of individual lesions is important. Erythematous papules and vesicles can occur in many conditions, but their arrangement in a specific linear array suggests an external etiology such as allergic contact (Fig. 46-10) or primary

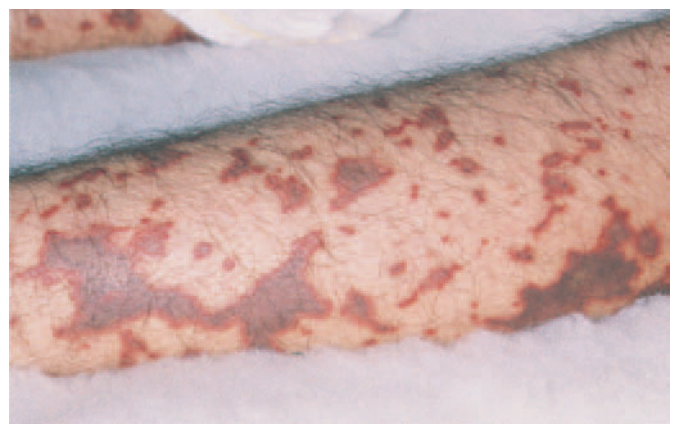

FIGURE 46-5 Fulminant meningococcemia with extensive angular purpuric patches. *(Courtesy of Stephen E. Gellis, MD.)*

TABLE 46-3 *Selected Common Dermatologic Conditions*

Diagnosis	Common Distribution	Usual Morphology
Acne vulgaris	Face, upper back	Open and closed comedones, erythematous papules, pustules, cysts
Rosacea	Blush area of cheeks, nose, forehead, chin	Erythema, telangiectasias, papules, pustules
Seborrheic dermatitis	Scalp, eyebrows, perinasal areas	Erythema with greasy yellow-brown scale
Atopic dermatitis	Antecubital and popliteal fossae; may be widespread	Patches and plaques of erythema, scaling, and lichenification; pruritus
Stasis dermatitis	Ankles, lower legs	Patches of erythema and scaling on background of hyperpigmentation associated with signs of venous insufficiency
Dyshidrotic eczema	Palms, soles, sides of fingers and toes	Deep vesicles
Allergic contact dermatitis	Anywhere	Localized erythema, vesicles, scale, and pruritus (e.g., fingers, earlobes—nickel; dorsal aspect of foot—shoe; exposed surfaces—poison ivy)
Psoriasis	Elbows, knees, scalp, lower back, fingernails (may be generalized)	Papules and plaques covered with silvery scale; nails have pits
Lichen planus	Wrists, ankles, mouth (may be widespread)	Violaceous flat-topped papules and plaques
Keratosis pilaris	Extensor surfaces of arms and thighs, buttocks	Keratotic follicular papules with surrounding erythema
Melasma	Forehead, cheeks, temples, upper lip	Tan to brown patches
Vitiligo	Periorificial, trunk, extensor surfaces of extremities, flexor wrists, axillae	Chalk-white macules
Actinic keratosis	Sun-exposed areas	Skin-colored or red-brown macule or papule with dry, rough, adherent scale
Basal cell carcinoma	Face	Papule with pearly, telangiectatic border on sun-damaged skin
Squamous cell carcinoma	Face, especially lower lip, ears	Indurated and possibly hyperkeratotic lesions often showing ulceration and/or crusting
Seborrheic keratosis	Trunk, face	Brown plaques with adherent, greasy scale; "stuck on" appearance
Folliculitis	Any hair-bearing area	Follicular pustules
Impetigo	Anywhere	Papules, vesicles, pustules, often with honey-colored crusts
Herpes simplex	Lips, genitalia	Grouped vesicles progressing to crusted erosions
Herpes zoster	Dermatomal, usually trunk but may be anywhere	Vesicles limited to a dermatome (often painful)
Varicella	Face, trunk, relative sparing of extremities	Lesions arise in crops and quickly progress from erythematous macules to papules to vesicles to pustules to crusts
Pityriasis rosea	Trunk (Christmas tree pattern); herald patch followed by multiple smaller lesions	Symmetric erythematous patches with a collarette of scale
Tinea versicolor	Chest, back, abdomen, proximal extremities	Scaly hyper- or hypopigmented macules
Candidiasis	Groin, beneath breasts, vagina, oral cavity	Erythematous macerated areas with satellite pustules; white, friable patches on mucous membranes
Dermatophytosis	Feet, groin, beard, or scalp	Varies with site, (e.g., tinea corporis—scaly annular patch)
Scabies	Groin, axillae, between fingers and toes, beneath breasts	Excoriated papules, burrows, pruritus
Insect bites	Anywhere	Erythematous papules with central puncta
Cherry angioma	Trunk	Red, blood-filled papules
Keloid	Anywhere (site of previous injury)	Firm tumor, pink, purple, or brown
Dermatofibroma	Anywhere	Firm red to brown nodule that shows dimpling of overlying skin with lateral compression
Acrochordons (skin tags)	Groin, axilla, neck	Fleshy papules
Urticaria	Anywhere	Wheals, sometimes with surrounding flare; pruritus
Transient acantholytic dermatosis	Trunk, especially anterior chest	Erythematous papules
Xerosis	Extensor extremities, especially legs	Dry, erythematous, scaling patches; pruritus

irritant dermatitis. In contrast, lesions with a generalized arrangement are common and suggest a systemic etiology.

As in other branches of medicine, a complete history should be obtained to emphasize the following features:

1. Evolution of lesions
   a. Site of onset
   b. Manner in which the eruption progressed or spread
   c. Duration
   d. Periods of resolution or improvement in chronic eruptions
2. Symptoms associated with the eruption
   a. Itching, burning, pain, numbness
   b. What, if anything, has relieved symptoms
   c. Time of day when symptoms are most severe
3. Current or recent medications (prescribed as well as over-the-counter)
4. Associated systemic symptoms (e.g., malaise, fever, arthralgias)
5. Ongoing or previous illnesses
6. History of allergies
7. Presence of photosensitivity
8. Review of systems

DIAGNOSTIC TECHNIQUES Many skin diseases can be diagnosed on gross clinical appearance, but sometimes relatively simple diagnostic procedures can yield valuable information. In most instances, they can be performed at the bedside with a minimum of equipment.

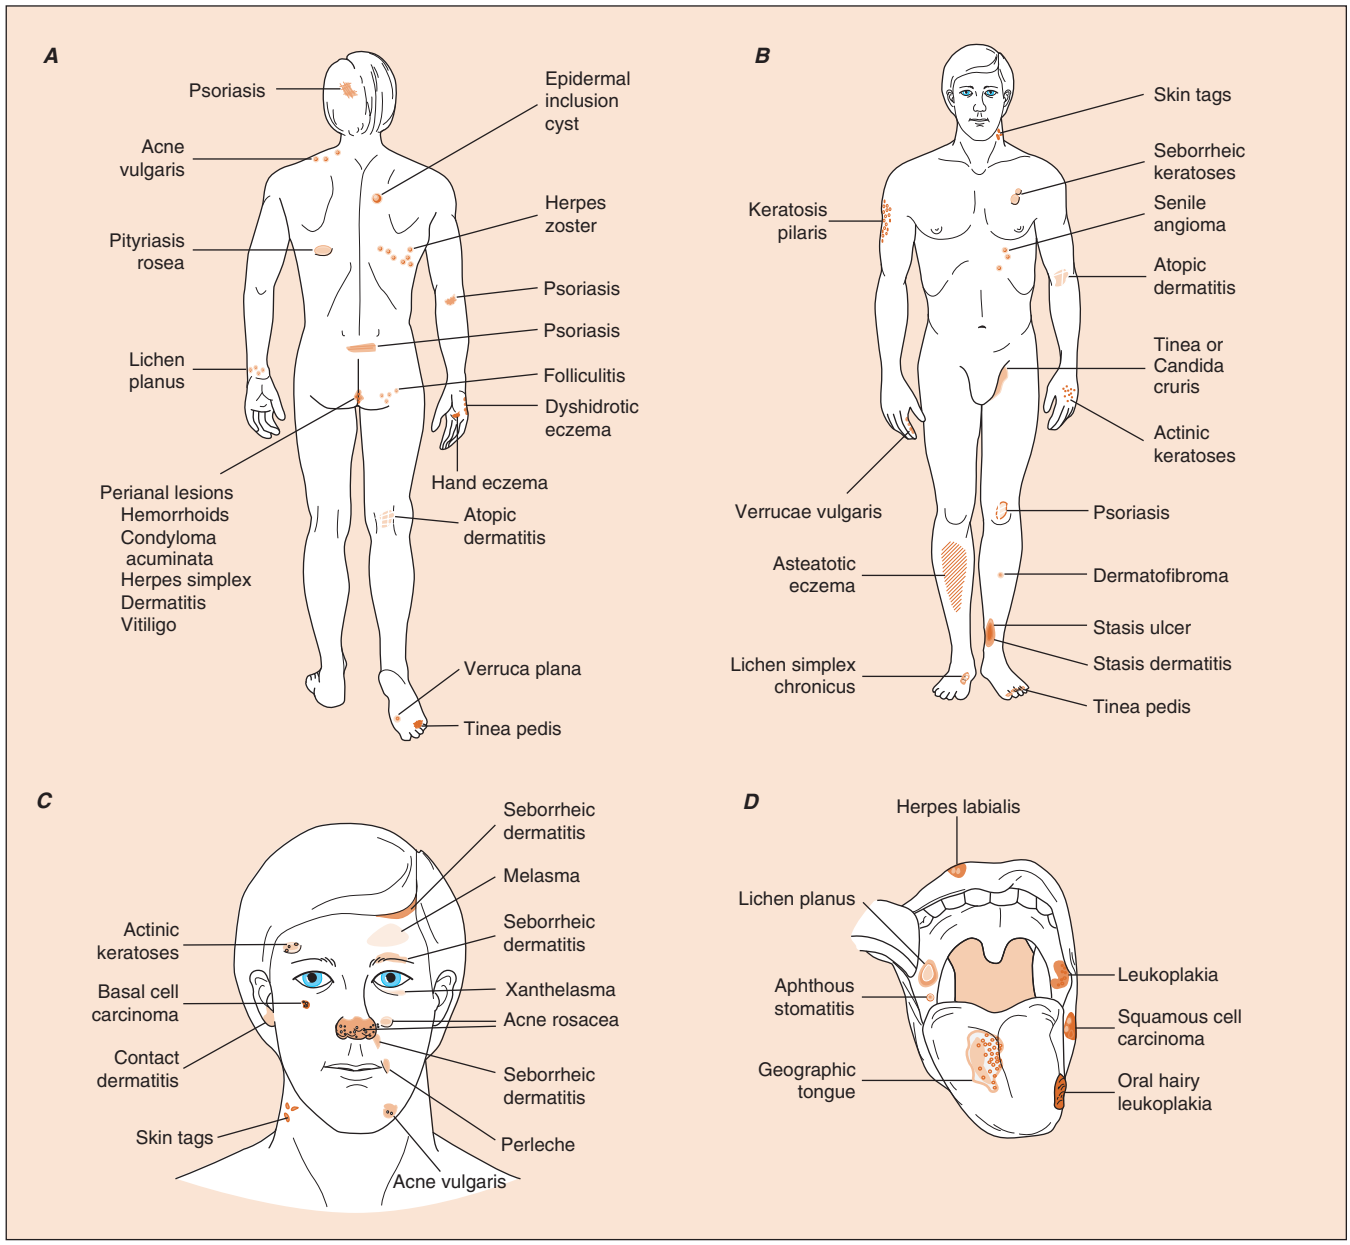

FIGURE 46-6 *A–D.* The distribution of some common dermatologic diseases and lesions.

Skin Biopsy A skin biopsy is a straightforward minor surgical procedure; however, it is important to biopsy a lesion that is most likely to yield diagnostic findings. This decision may require expertise in skin diseases and knowledge of superficial anatomic structures in selected areas of the body. In this procedure, a small area of skin is anesthetized with 1% lidocaine with or without epinephrine. The skin lesion in question can be excised with a scalpel or removed by punch biopsy. In the latter technique, a punch is pressed against the surface of the skin and rotated with downward pressure until it penetrates to the subcutaneous tissue. The circular biopsy is then lifted with forceps, and the bottom is cut with iris scissors. Biopsy sites may or may not need suture closure, depending on size and location.

KOH Preparation A potassium hydroxide (KOH) preparation is performed on scaling skin lesions where a fungal etiology is a possibility. The edge of such a lesion is scraped gently with a scalpel blade, and the removed scale is collected on a glass microscope slide and treated with 1 to 2 drops of a solution of 10 to 20% KOH. KOH dissolves keratin and allows easier visualization of fungal elements. Brief heating of the slide accelerates dissolution of keratin. When the preparation

FIGURE 46-7 Psoriasis is characterized by small and large erythematous plaques with adherent silvery scale.

FIGURE 46-8 Dermatitis herpetiformis manifested by pruritic, grouped vesicles in a typical location. The vesicles are often excoriated and may occur on knees, buttocks, and posterior scalp.

is viewed under the microscope, the refractile hyphae will be seen more easily when the light intensity is reduced and the condenser is lowered. This technique can be utilized to identify hyphae in dermatophyte infections (see Fig. 190-1), pseudohyphae and budding yeast in *Candida* infections (see Fig. 187-1), and fragmented hyphae and spores in tinea versicolor. The same sampling technique can be used to obtain scale for culture of selected pathogenic organisms.

Tzanck Smear A Tzanck smear is a cytologic technique most often used in the diagnosis of herpesvirus infections [simplex or varicella-zoster (see Figs. 164-1 and 164-3). An early vesicle, not a pustule or crusted lesion, is unroofed, and the base of the lesion is scraped gently with a scalpel blade. The material is placed on a glass slide, air-dried, and stained with Giemsa or Wright's stain. Multinucleated epithelial giant cells suggest the presence of herpes, but culture or immunofluorescence testing must be performed to identify the specific virus.

Diascopy Diascopy is designed to assess whether a skin lesion will blanch with pressure as, for example, in determining whether a red lesion is hemorrhagic or simply blood-filled. For instance, urticaria (Fig. 46-11) will blanch with pressure, whereas a purpuric lesion caused by necrotizing vasculitis (Fig. 46-4) will not. Diascopy is performed by pressing a microscope slide or magnifying lens against a lesion and noting the amount of blanching that occurs. Granulomas often have an "apple jelly" appearance on diascopy.

Wood's Light A Wood's lamp generates 360-nm ultraviolet (or "black") light that can be used to aid the evaluation of certain skin

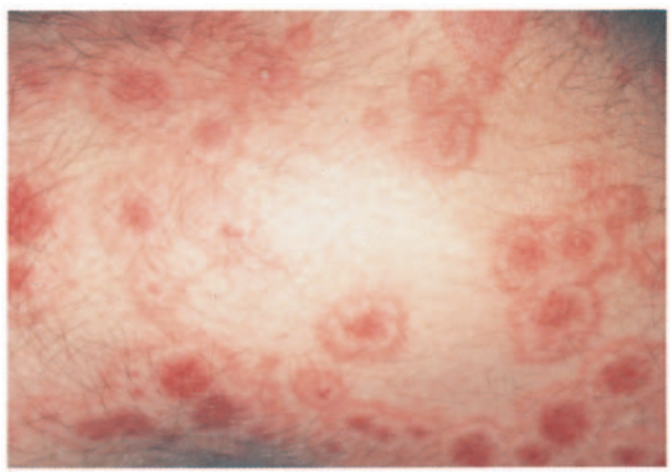

FIGURE 46-9 Erythema multiforme is characterized by multiple erythematous plaques with a target or iris morphology and usually represents a hypersensitivity reaction to drugs or infections (especially herpes simplex virus). *(Courtesy of the Yale Resident's Slide Collection.)*

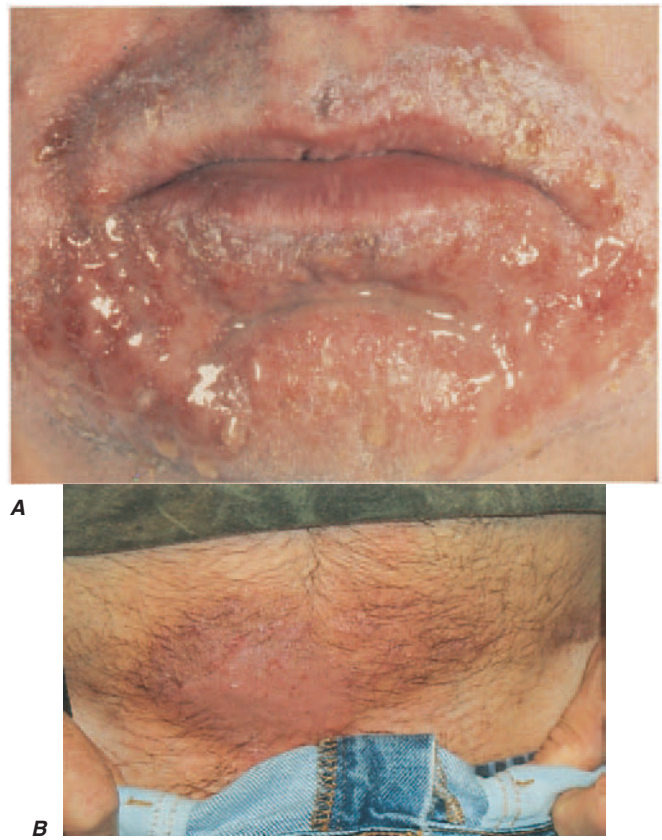

FIGURE 46-10 *A.* Allergic contact dermatitis, acute phase, with sharply demarcated, weeping, eczematous plaques in a perioral distribution. *B.* Allergic contact dermatitis to nickel, chronic phase demonstrating an erythematous, lichenified, weeping plaque on skin chronically exposed to a metal snap. disorders. For example, a Wood's lamp will cause erythrasma (a superficial, intertriginous infection caused by *Corynebacterium minutissimum*) to show a characteristic coral red color, and wounds colonized by *Pseudomonas* to appear pale blue. Tinea capitis caused by certain dermatophytes such as *Microsporum canis* or *M. audouini* exhibits a yellow fluorescence. Pigmented lesions of the epidermis such as freckles are accentuated, while dermal pigment such as postinflammatory hyperpigmentation fades under a Wood's light. Vitiligo (Fig. 46-12)

FIGURE 46-11 Urticaria showing characteristic discrete and confluent, edematous, erythematous papules and plaques.

FIGURE 46-12 Vitiligo in a typical acral distribution demonstrating striking cutaneous depigmentation, as a result of loss of melanocytes.

appears totally white under a Wood's lamp, and previously unsuspected areas of involvement often become apparent. A Wood's lamp may also aid in the demonstration of tinea versicolor and in recognition of ash leaf spots in patients with tuberous sclerosis.

Patch Tests Patch testing is designed to document sensitivity to a specific antigen. In this procedure, a battery of suspected allergens is applied to the patient's back under occlusive dressings and allowed to remain in contact with the skin for 48 h. The dressings are removed, and the area is examined for evidence of delayed hypersensitivity reactions (e.g., erythema, edema, or papulovesicles). This test is best performed by physicians with special expertise in patch testing and is often helpful in the evaluation of patients with chronic dermatitis.

47 ECZEMA, PSORIASIS, CUTANEOUS INFECTIONS, ACNE, AND OTHER COMMON SKIN DISORDERS

Calvin O. McCall, Thomas J. Lawley

ECZEMA AND DERMATITIS

Eczema, or dermatitis, is a reaction pattern that presents with variable clinical and histologic findings and is the final common expression for a number of disorders, including atopic dermatitis, allergic contact and irritant contact dermatitis, dyshidrotic eczema, nummular eczema, lichen simplex chronicus, asteatotic eczema, and seborrheic dermatitis. Primary lesions may include papules, erythematous macules, and vesicles, which can coalesce to form patches and plaques. In severe eczema, secondary lesions from infection or excoriation, marked by weeping and crusting, may predominate. Long-standing dermatitis is often dry and is characterized by thickened, scaling skin (*lichenification*).

ATOPIC DERMATITIS Atopic dermatitis (AD) is the cutaneous expression of the atopic state, characterized by a family history of asthma, hay fever, or dermatitis in up to 70% of patients. Some of the features of atopic eczema are shown in Table 47-1. The prevalence of atopic dermatitis is increasing worldwide, with a point prevalence in Norwegian school children as high as 23%.

The etiology of AD is only partially defined, but there is a clear genetic predisposition. When both parents are affected by AD, over 80% of their children manifest the disease. When only one parent is affected, the prevalence drops to slightly over 50%. Patients with AD may display a variety of immunoregulatory abnormalities including increased IgE synthesis; increased serum IgE; increased specific IgE to foods, aeroallergens, bacteria, and bacterial products; increased expression of CD23 (low-affinity IgE receptor) on monocytes and B cells; and impaired delayed type hypersensitivity reactions.

The clinical presentation often varies with age. Half of patients with AD present within the first year of life, and 80% present by 5 years of age. About 80% ultimately coexpress allergic rhinitis or asthma. The infantile pattern is characterized by weeping inflammatory patches and crusted plaques that occur on the face, neck, and extensor surfaces. The childhood and adolescent pattern is marked by dermatitis of flexural skin, particularly in the antecubital and popliteal fossae (Fig. 47-1). AD may resolve spontaneously, but over half of all individuals affected as children will have dermatitis in adult life. The distribution of lesions may be similar to those seen in childhood. However, adults frequently have localized disease, manifesting as hand eczema or lichen simplex chronicus (see below). In patients with localized disease, AD may be suspected because of a typical personal history, family history, or the presence of cutaneous stigmata of AD such as perioral pallor, an extra fold of skin beneath the lower eyelid (Dennie's line), increased palmar skin markings, and an increased incidence of cutaneous infections, particularly with *Staphylococcus aureus*. Regardless of other manifestations, pruritus is a prominent characteristic of AD and is exacerbated by dry skin. Many of the cutaneous findings in affected patients, such as lichenification, are secondary to rubbing and scratching.

TABLE 47-1 Clinical Features of Atopic Dermatitis

1. Pruritus and scratching
2. Course marked by exacerbations and remissions
3. Lesions typical of eczematous dermatitis
4. Personal or family history of atopy (asthma, allergic rhinitis, food allergies, or eczema)
5. Clinical course lasting longer than 6 weeks

FIGURE 47-1 Atopic dermatitis with hyperpigmentation, lichenification, and scaling in the antecubital fossae. (Courtesy of Robert Swerlick, MD.)

Histologic examination of the skin affected by AD may demonstrate features of acute or chronic dermatitis. Immunopathology shows activated, memory T helper cells. AD skin lesions may also demonstrate IgE-bearing CD1a+ Langerhans cells, and these cells have been implicated in AD disease pathophysiology through mediation of hypersensitivity responses to environmental antigens.

Rx TREATMENT

Therapy of AD should include avoidance of cutaneous irritants, adequate moisturizing, judicious use of topical anti-inflammatory agents, and prompt treatment of secondary infection. Patients should be instructed to bathe using warm, but not hot, water and to limit their use of soap. Immediately after bathing while the skin is still moist, a topical anti-inflammatory agent in a cream or ointment base should be applied to areas of dermatitis, and all other skin areas should be lubricated with a moisturizer. Approximately 30 g of a topical agent is required to cover the entire body surface of an average adult.

Until recently, low- to midpotency topical glucocorticoids were employed in most treatment regimens for AD. Skin atrophy and the potential for systemic absorption, especially with more potent agents, were constant concerns. Two non-glucocorticoid anti-inflammatory agents are now available, tacrolimus ointment and pimecrolimus cream. These agents are macrolide immunosuppressants derived from soil fungi and are approved for use in AD. Reports of broader effectiveness appear in the literature. These agents do not cause skin atrophy and do not suppress the hypothalamic-pituitary-adrenal axis. They may replace topical glucocorticoids in some patients, but they are more costly than generic topical glucocorticoids. The non-steroid agents or low-potency topical glucocorticoids should be selected for use on the face or intertriginous areas to minimize the risk of skin atrophy.

Crusted and weeping skin lesions should be treated with systemic antibiotics with activity against *S. aureus* since secondary infection often exacerbates eczema. The frequency of macrolide-resistant organisms makes the use of penicillinase-resistant penicillins or cephalosporins preferable. Dicloxacillin or cephalexin (250 mg four times daily for 7 to 10 days) is generally adequate to decrease heavy colonization. As an adjunct, the use of triclosan-containing antibacterial washes and intermittent nasal mupirocin may be useful as prophylactic measures. The role of dietary allergens in atopic dermatitis is controversial, and there is little evidence that they play any role outside of infancy.

Control of pruritus is essential for treatment, since AD often represents "an itch that rashes." Antihistamines are most often used to control pruritus, and mild sedation may be responsible for their antipruritic action. Sedation may also limit their usefulness. Unlike their effects in urticaria, nonsedating antihistamines and selective H_2 blockers are of little use in controlling the pruritus of AD.

Treatment with systemic glucocorticoids should be limited to severe exacerbations unresponsive to conservative topical therapy. In the patient with chronic AD, therapy with systemic glucocorticoids will generally clear the skin only briefly, but cessation of the systemic therapy will invariably be accompanied by return, if not worsening, of the dermatitis. Patients who do not respond to conventional therapies should be considered for patch testing to rule out allergic contact dermatitis. Immunotherapy with aeroallergens has not proven useful in AD, unlike its effect in allergic rhinitis and extrinsic asthma.

CONTACT DERMATITIS Contact dermatitis is an inflammatory process in skin caused by an exogenous agent or agents that directly or indirectly injure the skin. This injury may be caused by an inherent characteristic of a compound—irritant contact dermatitis (ICD). An example of ICD would be dermatitis induced by a concentrated acid or base. Agents that cause allergic contact dermatitis (ACD) induce an antigen-specific immune response. The clinical lesions of contact dermatitis may be acute (wet and edematous) or chronic (dry, thickened, and scaly), depending on the persistence of the insult (see Fig. 46-10). The most common presentation of contact dermatitis is hand eczema, and it is frequently related to occupational exposures. Occupation-related contact dermatitis represents a significant proportion of occupation-induced injury, affecting over 60,000 persons annually.

ICD is generally strictly demarcated and often localized to areas of thin skin (eyelids, intertriginous areas) or to areas where the irritant was occluded. Lesions may range from minimal skin erythema to areas of marked edema, vesicles, and ulcers. Chronic low-grade irritant dermatitis is the most common type of ICD, and the most common area of involvement is the hands (see below). The most common irritants encountered are chronic wet work, soaps, and detergents. Treatment should be directed to avoidance of irritants and use of protective gloves or clothing.

ACD is a manifestation of delayed-type hypersensitivity mediated by memory T lymphocytes in the skin. The most common cause of ACD is exposure to plants, especially to members of the family Anacardiaceae, including the genus *Toxicodendrun*. Poison ivy, poison oak, and poison sumac are members of this genus and cause an allergic reaction marked by erythema, vesiculation, and severe pruritus. The eruption is often linear, corresponding to areas where plants have touched the skin. The sensitizing antigen common to these plants is urushiol, an oleoresin containing the active ingredient pentadecylcatechol. The oleoresin may adhere to skin, clothing, tools, and pets, and contaminated articles may cause dermatitis even after prolonged storage. Blister fluid does not contain urushiol and is not capable of inducing skin eruption in exposed subjects. Other allergens may be more difficult to identify, especially if the exposure is chronic and the skin becomes thickened and scaly.

Rx TREATMENT

If ACD is suspected and an offending agent is identified and removed, the eruption will resolve. Usually, treatment with high-potency fluorinated topical glucocorticoids is enough to relieve symptoms while the ACD runs its course. For those patients who require systemic therapy, daily oral prednisone beginning at 1 mg/kg, but usually not exceeding 60 mg/d, is sufficient. It should be tapered over 2 to 3 weeks, and each daily dose given in the morning with food.

Identification of a contact allergen can be a difficult and time-consuming task. Patients with dermatitis unresponsive to conventional therapy or with an unusual and patterned distribution should be suspected of having ACD. They should be questioned carefully regarding occupational exposures, topical medicaments, and oral medications. Common sensitizers include preservatives in topical preparations, nickel sulfate, potassium dichromate, thimerosal, neomycin sulfate, fragrances, formaldehyde, and rubber-curing agents. Patch testing is helpful in identifying these agents, but should not be attempted on patients with widespread active dermatitis or on those taking systemic glucocorticoids.

HAND ECZEMA Hand eczema is a very common, chronic skin disorder. It represents a large proportion of occupation-associated skin disease. It may be associated with other cutaneous disorders such as AD or may occur by itself. Similar to other forms of dermatitis, both exogenous and endogenous factors play important roles in the expression of hand dermatitis. Chronic, excessive exposure to water and detergents may initiate or aggravate this disorder. It may present with dryness and cracking of the skin of the hands as well as with variable amounts of erythema and edema. Often, the dermatitis will begin under rings where water and irritants are trapped. A variant of hand dermatitis, dyshidrotic eczema, presents with multiple, intensely pruritic, small papules and vesicles occurring on the thenar and hypothenar eminences and the sides of the fingers (Fig. 47-2). Lesions tend to occur in crops that slowly form crusts and heal.

The evaluation of a patient with hand eczema should include an assessment of potential occupation-associated exposures. Predominant involvement of the dorsal surface of the hands with sparing of the palmar surface suggests a possible contact dermatitis. The history

FIGURE 47-2 Dyshidrotic eczema, characterized by deep-seated vesicles and scaling on palms and lateral fingers, is often associated with an atopic diathesis.

should be directed to identifying possible irritant or allergen exposures. The use of rubber gloves to protect dermatitic skin is sometimes associated with the development of delayed-type hypersensitivity reactions to agents used for cross-linking rubber. Such reactions can be detected by patch testing. Less commonly, patients may manifest hand dermatitis as a consequence of developing immediate-type hypersensitivity reactions to latex. These are of particular concern since these patients are at risk for anaphylactic reactions. The most sensitive method of detection is the use of scratch testing with latex extract. However, this should be done with extreme caution only in a setting where an anaphylactic reaction can be treated. A latex radioallergosorbent test is available but is only about 60% sensitive.

℞ TREATMENT

Therapy of hand dermatitis is directed toward avoidance of irritants, identification of possible contact allergens, treatment of coexistent infection, and application of topical glucocorticoids. Whenever possible, the hands should be protected by gloves, preferably vinyl. Most patients can be treated with cool moist compresses (dressings) to dry and debride acute inflammatory lesions and to decrease swelling, followed by application of a mid- to high-potency topical glucocorticoid in a cream or ointment base. As with atopic dermatitis, treatment of secondary infection by staphylococci or streptococci is essential for good control. Additionally, patients with hand dermatitis should be examined for dermatophyte infection by KOH preparation and culture (see below).

NUMMULAR ECZEMA Nummular eczema is characterized by circular or oval "coinlike" lesions. Initially, this eruption consists of small edematous papules that become crusted and scaly. The most common locations are on the trunk or the extensor surfaces of the extremities, particularly on the pretibial areas or dorsum of the hands. It occurs more frequently in men and is most commonly seen in middle age. The etiology of nummular eczema is unknown. The treatment of nummular eczema is similar to that for other forms of dermatitis.

LICHEN SIMPLEX CHRONICUS Lichen simplex chronicus may represent the end stage of a variety of pruritic and eczematous disorders. It consists of a well-circumscribed plaque or plaques with lichenified or thickened skin due to chronic scratching or rubbing. Common areas involved include the posterior nuchal region, dorsum of the feet, or ankles. Treatment of lichen simplex chronicus centers around breaking the cycle of chronic itching and scratching, which often occur during sleep. High-potency topical glucocorticoids are helpful in alleviating pruritus in most cases, but in recalcitrant cases, application of topical glucocorticoids under occlusion or intralesional injection of glucocorticoids may be required. Oral antihistamines such as hydroxyzine (10 to 25 mg every 6 h) or tricyclic antidepressants with antihistaminic activity such as doxepin (10 to 25 mg at bedtime) are useful as antipruritics primarily due to their sedating action. Higher doses of these agents may be required, but sedation can become bothersome. Patients need to be counseled regarding driving or operating heavy equipment after taking these medications due to their potentially potent sedative activity.

ASTEATOTIC ECZEMA Asteatotic eczema, also known as *xerotic eczema* or *"winter itch,"* is a mildly inflammatory dermatitis that develops in areas of extremely dry skin, especially during the dry winter months. This form of eczema accounts for a large number of physician visits because of the associated pruritus. Fine cracks and scale, with or without erythema, characteristically develop in areas of dry skin, especially on the anterior surfaces of the lower extremities in elderly patients. Asteatotic eczema responds well to topical moisturizers and the avoidance of cutaneous irritants. Overbathing and the use of harsh soaps exacerbate asteatotic eczema. Moisturizers should be applied to dry skin areas twice daily and always applied to damp skin after bathing. Prescription emollients containing ammonium lactate or urea are useful in patients with extremely dry skin, but they may be associated with skin irritation. Emollients should be applied after leaving the bath or shower to avoid increasing the risk of falling.

STASIS DERMATITIS AND STASIS ULCERATION Stasis dermatitis develops on the lower extremities secondary to venous incompetence and chronic edema. Early findings in stasis dermatitis consist of mild erythema and scaling associated with pruritus. The typical initial site of involvement is the medial aspect of the ankle, often over a distended vein (Fig. 47-3). As the disorder progresses, the dermatitis becomes progressively pigmented, due to chronic erythrocyte extravasation leading to cutaneous hemosiderin deposition. As with other forms of dermatitis, stasis dermatitis may become acutely inflamed, with crusting and exudate. Chronic stasis dermatitis is often associated with dermal fibrosis that is recognized clinically as brawny edema of the skin. Stasis dermatitis is often complicated by secondary infection and contact dermatitis. Severe stasis dermatitis may precede the development of stasis ulcers.

℞ TREATMENT

Patients with stasis dermatitis and stasis ulceration benefit greatly from leg elevation and the routine use of compression stockings with a gradient of at least 30 to 40 mmHg. Stockings providing less compression, such as antiembolism hose, are poor substitutes. Use of emollients and/or midpotency topical glucocorticoids and avoidance of irritants are also helpful in treating stasis dermatitis. Protecting the legs from injury, including scratching, and control of chronic edema are essential to prevent ulcers.

FIGURE 47-3 Stasis dermatitis showing erythematous, scaly, and oozing patches over the lower leg. Several stasis ulcers are also seen in this patient.

FIGURE 47-4 Seborrheic dermatitis showing central facial erythema with overlying greasy, yellowish scale. (Courtesy of Jean Bolognia, MD.)

Stasis ulcers are difficult to treat, and resolution of these lesions is slow. It is extremely important to elevate the affected limb as much as possible. The ulcer should be kept clear of necrotic material by gentle debridement and covered with a semipermeable dressing under pressure. Glucocorticoids should not be applied to ulcers, since they may retard healing. Secondarily infected lesions should be treated with appropriate oral antibiotics, but it should be noted that all ulcers will become colonized with bacteria, and the purpose of antibiotic therapy should not be to clear all bacterial growth. Care must be taken to exclude treatable causes of leg ulcers (hypercoagulation, vasculitis) before beginning the chronic management outlined above.

SEBORRHEIC DERMATITIS Seborrheic dermatitis is a common, chronic disorder, characterized by greasy scales overlying erythematous patches or plaques. The most common location is in the scalp where it may be recognized as severe dandruff. On the face, seborrheic dermatitis affects the eyebrows, eyelids, glabella, and nasolabial folds (Fig. 47-4). Scaling of the external auditory canal is common in seborrheic dermatitis and may be mistaken for a fungal infection (otomycosis). The postauricular areas often become macerated and tender. Additionally, seborrheic dermatitis may develop in the central chest, axilla, groin, submammary folds, and gluteal cleft. Rarely, it may cause a widespread generalized dermatitis.

Seborrheic dermatitis may be evident within the first few weeks of life, and within this context it occurs in the scalp ("cradle cap"), face, or groin. It is rarely seen in children beyond infancy but becomes evident again during adult life. Although it is frequently seen in patients with Parkinson's disease, in those who have had cerebrovascular accidents, and in those with HIV infection, the overwhelming majority of individuals with seborrheic dermatitis have no underlying disorder.

TREATMENT

Treatment with low-potency topical glucocorticoids in conjunction with a topical antifungal agent, such as ketoconazole cream or ciclopirox cream, is often effective. The scalp and beard areas may benefit from shampoos containing coal tar and/or salicylic acid. Shampoos should be left in place 3 to 5 min before rinsing. High-potency topical glucocorticoid solutions (betamethasone or fluocinonide) are effective for control of severe scalp involvement. Fluorinated topical glucocorticoids should not be used on the face since this is often associated with the development of rebound worsening and steroid-induced rosacea or atrophy.

PAPULOSQUAMOUS DISORDERS (Table 47-2)

PSORIASIS Psoriasis is one of the most common dermatologic diseases, affecting up to 2.5% of the world's population. It is a chronic inflammatory skin disorder clinically characterized by erythematous, sharply demarcated papules and rounded plaques, covered by silvery micaceous scale. The skin lesions of psoriasis are variably pruritic. Traumatized areas often develop lesions of psoriasis (Koebner or isomorphic phenomenon). Additionally, other external factors may exacerbate psoriasis including infections, stress, and medications (lithium, beta blockers, and antimalarials).

The most common variety of psoriasis is called *plaque type*. Patients with plaque-type psoriasis will have stable, slowly enlarging plaques, which remain basically unchanged for long periods of time. The most common areas for plaque psoriasis to occur are the elbows, knees, gluteal cleft, and the scalp. Involvement tends to be symmetric. *Inverse psoriasis* affects the intertriginous regions including the axilla, groin, submammary region, and navel; it also tends to affect the scalp, palms, and soles. The individual lesions are sharply demarcated plaques (see Fig. 46-7) but may be moist due to their location. Plaque psoriasis generally develops slowly and runs an indolent course. It rarely remits spontaneously.

Eruptive psoriasis (guttate psoriasis) is most common in children and young adults. It develops acutely in individuals without psoriasis or in those with chronic plaque psoriasis. Patients present with many small erythematous, scaling papules, frequently after upper respiratory tract infection with β-hemolytic streptococci. The differential diagnosis should include pityriasis rosea and secondary syphilis. *Pustular psoriasis* is another variant. Patients may have disease localized to the palms and soles or generalized and associated with fever, malaise, diarrhea, and arthralgias.

About half of all patients with psoriasis have fingernail involvement, appearing as punctate pitting, nail thickening, or subungual hyperkeratosis. About 5 to 10% of patients with psoriasis have associated joint complaints, and these are most often found in patients with fingernail involvement. Although some have the coincident occurrence

TABLE 47-2 *Papulosquamous Disorders*

	Clinical Features	*Other Notable Features*	*Histologic Features*
Psoriasis	Sharply demarcated, erythematous plaques with mica-like scale; predominantly elbows, knees, and scalp; atypical forms may localize to intertriginous areas; eruptive forms may be associated with infection (Reiter's syndrome)	May be aggravated by certain drugs, infection; severe forms seen associated with HIV	Acanthosis, vascular proliferation
Lichen planus	Purple polygonal papules marked by severe pruritus; lacy white markings, especially associated with mucous membrane lesions	Certain drugs may induce: thiazides, antimalarial drugs	Interface dermatitis
Pityriasis rosea	Rash often preceded by herald patch; oval to round plaques with trailing scale; most often affects the trunk, and eruption lines up in skin folds giving a "fir tree"-like appearance; generally spares palms and soles	Variable pruritus; self-limited resolving in 2–8 weeks; may be imitated by secondary syphilis	Pathologic features often nonspecific
Dermatophytosis	Polymorphous appearance depending on dermatophyte, body site, and host response; sharply defined to ill-demarcated scaly plaques with or without inflammation; may be associated with hair loss	KOH preparation may show branching hyphae; culture helpful	Hyphae and neutrophils in stratum corneum

of classic rheumatoid arthritis (Chap. 301), many have joint disease that falls into one of three types associated with psoriasis: (1) asymmetric inflammatory arthritis most commonly involving the distal and proximal interphalangeal joints and less commonly the knees, hips, ankles, and wrists; (2) a seronegative rheumatoid arthritis–like disease; a significant portion of these patients go on to develop a severe destructive arthritis; or (3) disease limited to the spine (psoriatic spondylitis).

The etiology of psoriasis is still poorly understood, but there is clearly a genetic component to the disease. Over 50% of patients with psoriasis report a positive family history. Psoriasis has been linked to HLA-Cw6 and, to a lesser extent, to HLA-DR7. Psoriatic lesions are characterized by infiltration of skin with activated T cells, which appear to have a role in the pathophysiology of psoriasis. Presumably, cytokines from activated T cells elaborate growth factors that stimulate keratinocyte hyperproliferation. Agents that inhibit T cell activation, clonal expansion, or release of proinflammatory cytokines are often effective for the treatment of severe psoriasis.

TREATMENT

Treatment of psoriasis depends on the type, location, and extent of disease. All patients should be instructed to avoid excess drying or irritation of their skin and to maintain adequate cutaneous hydration. Most patients with localized, plaque-type psoriasis can be managed with midpotency topical glucocorticoids, although their long-term use is often accompanied by loss of effectiveness (tachyphylaxis) and atrophy of the skin. A topical vitamin D analogue (calcipotriene) and a retinoid (tazarotene) are also efficacious in the treatment of psoriasis and have largely replaced other topical agents such as coal tar, salicylic acid, and anthralin.

Ultraviolet light, natural or artificial, is an effective therapy for patients with widespread psoriasis. Ultraviolet B (UV-B) light is effective alone, or may be combined with coal tar or anthralin. The combination of the ultraviolet A (UV-A) spectrum with either oral or topical psoralens (PUVA) is also extremely effective for the treatment of psoriasis, but long-term use may be associated with an increased incidence of squamous cell cancer and melanoma of the skin.

Various other agents can be used for severe, widespread psoriatic disease. Oral glucocorticoids should not be used for the treatment of psoriasis due to the potential for developing life-threatening pustular psoriasis when therapy is discontinued. Methotrexate is an effective agent, especially in patients with psoriatic arthritis; however, liver toxicity and bone marrow suppression limit its use. The synthetic retinoid, acitretin, is effective in some patients with severe psoriasis. It is a potent teratogen and should not be used in women of childbearing potential. The evidence implicating psoriasis as a T cell–mediated disorder has directed therapeutic efforts to immunoregulation. Cyclosporine is highly effective in selected patients with severe disease, but nephrotoxicity and hypertension complicate its use. Much attention is currently directed toward the development of biologic agents with more selective immunosuppressive properties and better safety profiles. Etanercept, a tumor necrosis factor α (TNF-α) inhibitor, is now approved for psoriatic arthritis and is in clinical trials for psoriasis. Other agents in clinical trials target TNF-α and other proinflammatory cytokines, T cell activation, and lymphocyte trafficking in an attempt to suppress the inflammation characteristic of psoriasis.

LICHEN PLANUS Lichen planus (LP) is a papulosquamous disorder in which the primary lesions are pruritic, polygonal, flat-topped, violaceous papules. Close examination of the surface of these papules often reveals a network of gray lines (Wickham's striae). The skin lesions may occur anywhere but have a predilection for the wrists, shins, lower back, and genitalia (Fig. 47-5). Involvement of the scalp may lead to hair loss. LP commonly involves mucous membranes, particularly the buccal mucosa, where it can present as a white netlike eruption. Its etiology is unknown, but cutaneous eruptions clinically resembling LP have been observed after administration of numerous drugs, including thiazide diuretics, gold, antimalarials, penicillamine, and phenothiazines, and in patients with skin lesions of chronic graft-versus-host disease. Additionally, LP may be associated with hepatitis C infection. The course of LP is variable, but most patients have spontaneous remissions 6 months to 2 years after the onset of disease. Topical glucocorticoids are the mainstay of therapy.

FIGURE 47-5 Lichen planus showing multiple flat-topped, violaceous papules and plaques. Nail dystrophy as seen in this patient's thumbnail may also be a feature. (Courtesy of Robert Swerlick, MD.)

PITYRIASIS ROSEA Pityriasis rosea (PR) is a papulosquamous eruption of unknown etiology that occurs more commonly in the spring and fall. Its first manifestation is the development of a 2- to 6-cm annular lesion (the herald patch). This is followed in a few days to a few weeks by the appearance of many smaller annular or papular lesions with a predilection to occur on the trunk (Fig. 47-6). The lesions are generally oval, with their long axis parallel to the skin-fold lines. Individual lesions may range in color from red to brown and have a trailing scale. PR shares many clinical features with the eruption of secondary syphilis, but palm and sole lesions are extremely rare in PR and common in secondary syphilis. The eruption tends to be moderately pruritic and lasts 3 to 8 weeks. Treatment is generally directed at alleviating pruritus and consists of oral antihistamines, midpotency topical glucocorticoids, and, in some cases, the use of UV-B phototherapy.

CUTANEOUS INFECTIONS (Table 47-3)

IMPETIGO AND ECTHYMA Impetigo is a common superficial bacterial infection of skin caused by group A β-hemolytic streptococci (Chap.

FIGURE 47-6 Pityriasis rosea in which multiple round to oval erythematous patches with fine central scale are distributed along the skin tension lines on the trunk.

TABLE 47-3 *Common Skin Infections*

	Clinical Features	Etiologic Agent	Treatment
Impetigo	Honey-colored crusted papules, plaques, or bullae	Group A *Streptococcus* and *Staphylococcus aureus*	Systemic or topical antistaphylococcal antibiotics
Dermatophytosis	Inflammatory or noninflammatory annular scaly plaques; may have hair loss; groin involvement spares scrotum; hyphae on KOH preparation	*Trichophyton*, *Epidermophyton*, or *Microsporum* sp.	Topical azoles, systemic griseofulvin, terbinafine, or azoles
Candidiasis	Inflammatory papules and plaques with satellite pustules, frequently in intertriginous areas; may involve scrotum; pseudohyphae on KOH preparation	*Candida albicans* and other *Candida* species	Topical nystatin or azoles; systemic azoles for resistant disease
Tinea versicolor	Hyperpigmented or hypopigmented scaly patches on the trunk; characteristic mixture of hyphae and spores on KOH preparation ("spaghetti and meatballs")	*Malassezia furfur*	Topical selenium sulfide lotion or azoles

121) or *S. aureus* (Chap. 120). The primary lesion is a superficial pustule that ruptures and forms a characteristic yellow-brown honey-colored crust (see Fig. 121-1). Lesions caused by staphylococci may be tense, clear bullae, and this less common form of the disease is called *bullous impetigo*. Lesions may occur on normal skin or in areas already affected by another skin disease. Ecthyma is a variant of impetigo that generally occurs on the lower extremities and causes punched-out ulcerative lesions. Treatment of both ecthyma and impetigo involves gentle debridement of adherent crusts, which is facilitated by the use of soaks and topical antibiotics, in conjunction with appropriate oral antibiotics.

ERYSIPELAS AND CELLULITIS →*See Chap. 110*

DERMATOPHYTOSIS Dermatophytes are fungi that infect skin, hair, and nails and include members of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. Tinea corporis, or infection of the relatively hairless skin of the body (glabrous skin), may have a variable appearance depending on the extent of the associated inflammatory reaction (see Fig. 46-11). It may have the typical annular appearance of "ringworm" or appear as deep inflammatory nodules or granulomas. Involvement of the groin (tinea cruris) is more common in males than females. It presents as a scaling, erythematous eruption that spares the scrotum. Infection of the foot (tinea pedis) is the most common dermatophyte infection and is often chronic; it is characterized by variable erythema, edema, scaling, pruritus, and occasionally vesiculation. Involvement may be widespread or localized, but almost invariably involves the web space between the fourth and fifth toes. Infection of the nails (tinea unguium or onychomycosis) occurs in many patients with tinea pedis and is characterized by opacified, thickened nails and subungual debris. Dermatophyte infection of the scalp (tinea capitis) has returned in epidemic proportions, particularly affecting inner-city children, but it also affects adults. The predominant organism is *T. tonsurans*, which can produce a relatively noninflammatory infection with mild scale and hair loss that is diffuse or localized. Localized disease may be well defined or irregular. *T. tonsurans* can also cause a markedly inflammatory dermatosis with edema and nodules. This latter presentation is a kerion.

The diagnosis of tinea can be made from skin scrapings, nail scrapings, or hair by culture or direct microscopic examination with potassium hydroxide (KOH). Hair, nail scrapings, and scrapings from markedly inflamed skin may fail to show hyphae on direct examination.

℞ TREATMENT

Both topical and systemic therapies may be used to treat dermatophyte infections. Treatment depends on the site involved and the type of infection. Topical therapy is generally effective for uncomplicated tinea corporis, tinea cruris, and limited tinea pedis. It is not effective as a monotherapy for tinea capitis or onychomycosis. Topical imidazoles, triazoles, and allylamines may all be effective topical therapies for dermatophyte infections. Haloprogin, undecylenic acid, ciclopirox olamine, and tolnaftate are also effective, but nystatin is not active against dermatophytes. Topicals are generally applied twice daily, and treatment should continue 1 week beyond clinical resolution of the infection. Tinea pedis often requires longer treatment courses and frequently relapses. Oral antifungal agents may be required for recalcitrant tinea pedis or tinea corporis with a nodular (granulomatous) component.

Oral antifungal agents are required for dermatophyte infections involving the hair and nails and for other infections unresponsive to topical therapy. A fungal etiology should be confirmed by direct microscopic examination or by culture prior to prescribing oral antifungal agents. All of the oral agents may cause hepatotoxicity and should not be used in women who are pregnant or breast-feeding.

Griseofulvin is the only oral agent approved in the United States for dermatophyte infections involving the skin, hair, or nails. Itraconazole and terbinafine are approved for onychomycosis; however, the literature cites multiple examples of their effective use in other dermatophyte infections. When griseofulvin is used, a daily dose of 500 mg of microsized or 350 mg of ultramicrosized griseofulvin administered with a fatty meal is an adequate dose for most dermatophyte infections. Higher doses are required for tinea pedis and onychomycosis. The duration of therapy may be 2 weeks for uncomplicated tinea corporis or as long as 6 to 18 months for nail infections. Due to high relapse rates, griseofulvin is seldom used for nail infections. The usual adult dose of griseofulvin for tinea capitis is 1 g of microsized or 0.5 g of ultramicrosized given daily for 6 to 8 weeks or until cultures are negative. The adjunctive use of topical antifungal agents may be useful, but topical therapy alone is not adequate for tinea capitis. Markedly inflammatory tinea capitis may result in scarring and hair loss, and systemic or topical glucocorticoids may be helpful in preventing these sequelae. Common side effects of griseofulvin include gastrointestinal distress, headache, and urticaria.

Oral itraconazole and terbinafine are approved for onychomycosis. Itraconazole is given as either continuous daily therapy (200 mg/d) or pulses (200 mg twice daily for 1 week per month) administered with food. Fingernails require 2 months of continuous therapy or two pulses. Toenails require 3 months of continuous therapy or three pulses. Itraconazole has the potential for serious interactions with other drugs requiring the P450 enzyme system for metabolism. Terbinafine (250 mg/d) is also effective for onychomycosis. Therapy with terbinafine is continued for 6 weeks for fingernail infections and 12 weeks for toenail infections. Terbinafine has fewer drug-drug interactions, but caution should be used when patients are on multiple medications.

TINEA VERSICOLOR Tinea versicolor is caused by a non-dermatophyte, dimorphic fungus, *Malassezia furfur*, a normal inhabitant of the skin. As the yeast form, it generally does not cause disease (except for folliculitis in certain individuals). However, in some individuals, it converts to the hyphal form and causes characteristic lesions. The ex-

pression of infection is promoted by heat and humidity. The typical lesions consist of oval scaly macules, papules, and patches concentrated on the chest, shoulders, and back but only rarely on the face or distal extremities. On dark skin, they often appear as hypopigmented areas, while on light skin, they are slightly erythematous or hyperpigmented. In some darkly pigmented individuals, they may only appear as scaling patches. A KOH preparation from scaling lesions will demonstrate a confluence of short hyphae and round spores (so-called spaghetti and meatballs). Solutions containing sulfur, salicylic acid, or selenium sulfide will clear the infection if used daily for a week and then intermittently thereafter. Treatment with a single 400-mg oral dose of ketoconazole is also effective.

CANDIDIASIS Candidiasis is a fungal infection caused by a related group of yeasts, whose manifestations may be localized to the skin, or rarely, may be systemic and life-threatening. The causative organism is usually *Candida albicans*, but may also be *C. tropicalis*, *C. parapsilosis*, or *C. krusei*. These organisms are normal saprophytic inhabitants of the gastrointestinal tract but may overgrow (usually due to broad-spectrum antibiotic therapy) and cause disease at a number of cutaneous sites. Other predisposing factors include diabetes mellitus, chronic intertrigo, oral contraceptive use, and cellular immune deficiency. Candidiasis is a very common infection in HIV-infected individuals (Chap. 173). The oral cavity is commonly involved. Lesions may occur on the tongue or buccal mucosa (thrush) and appear as white plaques (see Fig. 46-12). Microscopic examination of scrapings demonstrate both pseudohyphae and yeast forms. Fissured, macerated lesions at the corners of the mouth (perlèche) are often seen in individuals with poorly fitting dentures and may also be associated with candidal infection. Additionally, candidal infections have an affinity for sites that are chronically wet and macerated and may occur around nails (onycholysis and paronychia) and in intertriginous areas. Intertriginous lesions are characteristically edematous, erythematous, and scaly, with scattered "satellite pustules." In males, there is often involvement of the penis and scrotum as well as the inner aspect of the thighs. In contrast to dermatophyte infections, candidal infections are frequently painful and accompanied by a marked inflammatory response. Diagnosis of candidal infection is based upon the clinical pattern and demonstration of yeast on KOH preparation or culture.

Rx TREATMENT

Treatment routinely involves removing any predisposing factors such as antibiotic therapy or chronic wetness and the use of appropriate topical or systemic antifungal therapy. Effective topical agents include nystatin or topical azoles (miconazole, clotrimazole, econazole, or ketoconazole). These agents are generally effective in clearing mucous membrane or glabrous skin involvement in nonimmunosuppressed patients. The associated inflammatory response that often accompanies candidal infection on glabrous skin can be treated with a mild glucocorticoid lotion or cream (2.5% hydrocortisone). Systemic therapy is generally reserved for immunosuppressed patients or individuals with chronic or recurrent disease who fail to respond to or tolerate appropriate topical therapy.

WARTS Warts are cutaneous neoplasms that are caused by papilloma viruses. Approximately 80 different human papilloma viruses (HPV) have been described, and this number will likely increase. Typical verruca vulgaris lesions are sessile, dome-shaped, usually about a centimeter in diameter, and their surface is hyperkeratotic consisting of many small filamentous projections. The HPV that cause typical verruca vulgaris also cause typical plantar warts, flat warts (or verruca plana), and filiform warts in intertriginous areas. Plantar warts are endophytic and are covered by thick keratin. Paring of the wart will generally demonstrate a central core of keratinized debris and punctate bleeding points. Filiform warts are most commonly seen on the face, neck, and skin folds and present as papillomatous lesions on a narrow base. Flat warts are only slightly elevated and have a velvety, nonverrucous surface. They have a propensity for the face, arms, and legs and are often spread by shaving.

Genital warts generally begin as small papillomas that may grow to form large fungating lesions. In women, they may involve either the labia, perineum, or perianal skin. Additionally, the mucosa of the vagina, urethra, and anus can be involved, as well as the cervical epithelium. In men, the lesions often occur initially in the coronal sulcus, but may be seen on the shaft of the penis, the scrotum, perianal skin, or in the urethra.

Within the past decade, appreciable evidence has accumulated that suggests HPV plays a role in the development of neoplasia of the uterine cervix and external genitalia (Chap. 83). HPV types 16 and 18 have been most intensely studied, while recent evidence also implicates other types. Lesions may initially appear as small, flat, velvety, hyperpigmented papules occurring on the genitalia or perianal skin. Histologic examination of biopsies from affected sites may reveal changes associated with typical warts and/or features typical of intraepidermal carcinoma (Bowen's disease). Squamous cell carcinomas associated with HPV infections have also been observed in extragenital skin (Chap. 73). This is most commonly seen in patients immunosuppressed after organ transplantation.

Rx TREATMENT

There are many modalities available to treat warts, but no single therapy is universally effective. Factors that influence the choice of therapy include the location of the wart, extent of disease, the age and immunologic status of the patient, and the patient's desire for therapy. Perhaps the most useful and convenient method for treating warts in almost any location is cryotherapy with liquid nitrogen. Equally effective, but requiring much more patient compliance, is the use of keratolytic agents such as salicylic acid plasters or solutions. For genital warts, in-office application of a podophyllin solution is moderately effective but may be associated with marked local reactions. Prescription preparations of dilute, purified podophyllin are available for home use. Topical imiquimod, a potent inducer of local cytokine release, has also been approved for use in genital warts. Conventional and laser surgical procedures may be required for recalcitrant warts. Recurrence of warts appears to be common to all these modalities.

Treatment of warts, other than anogenital warts, should be tempered by the observation that a majority of warts in normal individuals resolve spontaneously within 1 to 2 years. Also, very few warts are associated with malignancy, and those are usually located in the anogenital region.

HERPES ZOSTER →*See Chap. 164*

ACNE

ACNE VULGARIS Acne vulgaris is a self-limited disorder primarily of teenagers and young adults, although perhaps 10 to 20% of adults may continue to experience some form of the disorder. The permissive factor for the expression of the disease in adolescence is the increase in sebum production by sebaceous glands after puberty. Small cysts, called *comedones*, form in hair follicles due to blockage of the follicular orifice by retention of sebum and keratinous material. The activity of bacteria (*Proprionobacterium acnes*) within the comedones releases free fatty acids from sebum, causes inflammation within the cyst, and results in rupture of the cyst wall. An inflammatory foreign-body reaction develops as a result of extrusion of oily and keratinous debris from the cyst.

The clinical hallmark of acne vulgaris is the comedone, which may be closed (whitehead) or open (blackhead). Closed comedones appear as 1- to 2-mm pebbly white papules, which are accentuated when the

FIGURE 47-7 Acne vulgaris with inflammatory papules, pustules, and comedones. (Courtesy of Kalman Watsky, MD.)

skin is stretched. They are the precursors of inflammatory lesions of acne vulgaris. The contents of closed comedones are not easily expressed. Open comedones, which rarely result in inflammatory acne lesions, have a large dilated follicular orifice and are filled with easily expressible oxidized, darkened, oily debris. Comedones are usually accompanied by inflammatory lesions: papules, pustules, or nodules.

The earliest lesions seen in early adolescence are generally mildly inflamed or noninflammatory comedones on the forehead. Subsequently, more typical inflammatory lesions develop on the cheeks, nose, and chin (Fig. 47-7). The most common location for acne is the face, but involvement of the chest and back is not uncommon. Most disease remains mild and does not lead to scarring. However, a small number of patients develop large inflammatory cysts and nodules, which may drain and result in significant scarring.

Exogenous and endogenous factors can alter the expression of acne vulgaris. Friction and trauma may rupture preexisting microcomedones and elicit inflammatory acne lesions. This is commonly seen with headbands or chin straps of athletic helmets. Application of comedogenic topical agents in cosmetics or hair preparations or chronic topical exposure to certain industrial compounds that are comedogenic may elicit or aggravate acne. Glucocorticoids, applied topically or administered systemically in high doses, may also elicit acne. Other systemic medications such as lithium, isoniazid, halogens, phenytoin, and phenobarbital may produce acneiform eruptions, or aggravate preexisting acne.

℞ TREATMENT

Treatment of acne vulgaris is directed toward elimination of comedones by normalization of follicular keratinization, decreasing sebaceous gland activity, decreasing the population of *P. acnes*, and decreasing inflammation. Acne vulgaris may be treated with either local or systemic medications. Minimal to moderate, pauci-inflammatory disease may respond adequately to local therapy alone. Although areas affected with acne should be kept clean, there is little evidence to suggest that removal of surface oils plays an important role in therapy. Overly vigorous scrubbing may aggravate acne due to mechanical rupture of comedones. Topical agents such as retinoic acid, benzoyl peroxide, or salicylic acid may alter the pattern of epidermal desquamation, preventing the formation of comedones and aiding in the resolution of preexisting cysts. Topical antibacterial agents such as benzoyl peroxide, azelaic acid, topical erythromycin (with or without zinc), or clindamycin are also useful adjuncts to therapy.

Patients with moderate to severe acne with a prominent inflammatory component will benefit from the addition of systemic therapy, such as tetracycline or erythromycin, in doses of 250 to 1000 mg/d. Such antibiotics appear to have an anti-inflammatory effect independent of their antibacterial effect. Female patients who do not respond to oral antibiotics may benefit from hormonal therapy. Women placed on oral contraceptives containing ethinyl estradiol and norgestimate have demonstrated improvement in their acne when compared to a placebo control.

Patients with severe nodulocystic acne unresponsive to the therapies discussed above may benefit from treatment with the synthetic retinoid, isotretinoin. Its use is highly regulated due to its potential for severe adverse events, primarily teratogenicity. Recently there have also been concerns that it is associated with severe depression in some patients. The latter has not been proved. At present, prescribers must receive from the manufacturer training, certification, and stickers to affix to each prescription. These measures are imposed to ensure that all prescribers are familiar with the risks of isotretinoin; that all female patients have two negative pregnancy tests prior to initiating therapy and a negative pregnancy test prior to each refill; and that all patients have been warned about the risks associated with isotretinoin, including depression. Additionally, patients receiving this medication develop extremely dry skin and cheilitis and must be followed for development of hypertriglyceridemia.

ACNE ROSACEA Acne rosacea is an inflammatory disorder predominantly affecting the central face. It is seen almost exclusively in adults, only rarely affecting patients under 30 years of age. Rosacea is seen more often in women, but those most severely affected are men. It is characterized by the presence of erythema, telangiectases, and superficial pustules (Fig. 47-8), but is not associated with the presence of comedones. Rosacea only rarely involves the chest or back.

There is a relationship between the tendency for pronounced facial flushing and the subsequent development of acne rosacea. Often, individuals with rosacea initially demonstrate a pronounced flushing reaction. This may be in response to heat, emotional stimuli, alcohol, hot drinks, or spicy foods. As the disease progresses, the flush persists longer and longer and may eventually become permanent. Papules, pustules, and telangiectases can become superimposed on the persistent flush. Rosacea of very long standing may lead to connective tissue overgrowth, particularly of the nose (rhinophyma). Rosacea may also be complicated by various inflammatory disorders of the eye, including keratitis, blepharitis, iritis, and recurrent chalazion. These ocular problems are potentially sight-threatening and warrant ophthalmologic evaluation.

℞ TREATMENT

Acne rosacea can be treated topically or systemically. Mild disease often responds to topical metronidazole or sodium sulfacetamide. More severe disease requires oral tetracycline in doses ranging from 250 to 1000 mg/d. Residual telangiectasia may respond to laser therapy. Topical glucocorticoids, especially potent agents, should be avoided since chronic use of these preparations may elicit rosacea. Topical therapy of the skin is not effective treatment for ocular disease.

FIGURE 47-8 Acne rosacea with prominent facial erythema, telangiectasia, scattered papules, and small pustules. (Courtesy of Robert Swerlick, MD.)

SKIN DISEASES AND SMALLPOX VACCINATION

Given the potential threat of a bioterrorism attack with smallpox, vaccinations against smallpox are available to the general public, although they are not recommended. Because of a higher incidence of adverse events associated with smallpox vaccination in patients with a history of certain skin diseases, including atopic dermatitis, eczema, severe acne, and psoriasis, such vaccination is contraindicated in patients with these conditions in the absence of a bioterrorism attack and a real or potential exposure to smallpox. In the case of such exposure, the risk of smallpox infection outweighs the risk of adverse events from the vaccine (Chap. 205).

48 SKIN MANIFESTATIONS OF INTERNAL DISEASE

Jean L. Bolognia, Irwin M. Braverman

It is now a generally accepted concept in medicine that the skin can show signs of internal disease. Therefore, in textbooks of medicine one finds a chapter describing in detail the major systemic disorders that can be identified by cutaneous signs. The underlying assumption of such a chapter is that the clinician has been able to identify the disorder in the patient and needs only to read about it in the textbook. In reality, concise differential diagnoses and the identification of these disorders are actually difficult for the nondermatologist because he or she is not well versed in the recognition of cutaneous lesions or their spectrum of presentations. Therefore, the authors of this chapter have decided to cover this particular topic of cutaneous medicine not by discussing individual disorders but by describing and discussing the various presenting clinical signs and symptoms that indicate the presence of these disorders. Concise differential diagnoses will be generated in which the significant diseases will be briefly discussed and distinguished from the more common disorders that have no significance for internal diseases. The latter disorders are reviewed in table form and always need to be excluded when considering the former. For a detailed description of individual diseases, the reader should consult a dermatologic text.

PAPULOSQUAMOUS SKIN LESIONS (Table 48-1) When an eruption is characterized by elevated lesions, papules (<1 cm), or plaques (>1 cm), in association with scale, it is referred to as a *papulosquamous lesion*. The most common papulosquamous diseases—*psoriasis*, *tinea*, *pityriasis rosea*, and *lichen planus*—are primary cutaneous disorders (Chap. 47). When psoriatic lesions are accompanied by arthritis, the possibility of psoriatic arthritis or *Reiter's disease* should be considered. A history of oral ulcers, conjunctivitis, uveitis, and/or urethritis points to the latter diagnosis. In *guttate psoriasis* there is an acute onset of small, widely scattered, uniform lesions, often in association with a streptococcal infection. Lithium, beta blockers, HIV infection, and a rapid taper of systemic glucocorticoids are also known to exacerbate psoriasis.

Whenever the diagnosis of pityriasis rosea or lichen planus is made, it is important to review the patient's medications because the eruption can be treated by simply discontinuing the offending agent. Pityriasis rosea–like drug eruptions are seen most commonly with beta blockers, angiotensin-converting enzyme (ACE) inhibitors, gold, and metronidazole, while the drugs that can produce a lichenoid eruption include gold, antimalarials, thiazides, quinidine, phenothiazines, sulfonylureas, and ACE inhibitors. Lichen planus–like lesions are also observed in chronic graft-versus-host disease.

In its early stages, *cutaneous T cell lymphoma* (CTCL) may be confused with ezcema or psoriasis, but it often fails to respond to the appropriate therapy for those inflammatory diseases. CTCL can develop within lesions of large-plaque parapsoriasis and is suggested by an increase in the thickness of the lesions. The diagnosis of CTCL is established by skin biopsy in which collections of atypical T lymphocytes are found in the epidermis and dermis. As the disease progresses, cutaneous tumors and lymph node involvement may appear.

In *secondary syphilis* there are scattered red-brown papules with thin scale. The eruption often involves the palms and soles and can resemble pityriasis rosea. Associated findings are helpful in making the diagnosis and include annular plaques on the face, nonscarring alopecia, condyloma lata (broad-based and moist), and mucous patches as well as lymphadenopathy, malaise, fever, headache, and myalgias. The interval between the primary chancre and the secondary stage is usually 4 to 8 weeks, and spontaneous resolution without appropriate therapy is seen.

TABLE 48-3 *Erythroderma (Primary Cutaneous Disorders)*

	Initial Lesions	Location of Initial Lesions	Other Findings	Diagnostic Aids	Treatment
Psoriasis[a]	Pink-red, silvery scale, sharply demarcated	Elbows, knees, scalp, presacral area	Nail dystrophy, arthritis, pustules	Skin biopsy	Oral retinoid ± PUVA; UV-B; methotrexate; cyclosporine; monoclonal antibodies
Dermatitis[a]					
Atopic	Acute: Erythema, fine scale, crust, indistinct borders Chronic: Lichenification (increased skin markings)	Antecubital and popliteal fossae, neck, hands	Pruritus Family history of atopy, including asthma, allergic rhinitis or conjunctivitis, and atopic dermatitis Rule out secondary infection with *S. aureus* Rule out superimposed irritant contact dermatitis	Skin biopsy	Topical glucocorticoids, tacrolimus, pimecrolimus, tar, and antipruritics; oral antihistamines; open wet dressings; UV-B + UV-A; PUVA; oral/IM glucocorticoids; cyclosporine Topical or oral antibiotics
Stasis	Erythema, crusting, excoriations	Lower extremities	Pruritus, lower extremity edema History of venous ulcers, thrombophlebitis, and/or cellulitis Rule out cellulitis Rule out superimposed contact dermatitis, e.g., topical neomycin	Skin biopsy	Topical glucocorticoids; open; wet dressings; leg elevation; pressure stockings
Contact	Local: Erythema, crusting, vesicles, and bullae	Depends on offending agent	Irritant—onset often within hours Allergic—delayed-type hypersensitivity; lag time of 48 h	Patch testing	Remove irritant or allergen; topical glucocorticoids; oral antihistamines; oral/IM glucocorticoids
	Systemic: Erythema, fine scale, crust	Generalized	Patient has history of allergic contact dermatitis to topical agent and then receives systemic medication that is structurally related, e.g., ethylenediamine, (topical) aminophylline (IV)	Patch testing	Same as local
Seborrheic	Pink-red, greasy scale	Scalp, nasolabial folds, eyebrows, intertriginous zones	Flares with stress, HIV infection Associated with Parkinson's disease	Skin biopsy	Topical glucocorticoids and imidazoles
Pityriasis rubra pilaris	Orange-red, perifollicular papules	Generalized, but characteristic "skip" areas of normal skin	Wax-like keratoderma Rule out cutaneous T cell lymphoma	Skin biopsy	Isotretinoin or acitretin; methotrexate

[a] Discussed in detail in Chap. 47.
Note: PUVA, *p*soralens + *u*ltraviolet *A* irradiation; UV-B, *u*ltraviolet *B*; UV-A, *u*ltraviolet *A*; IM, intramuscular; IV, intravenous.

buminemia, and high-output cardiac failure. The major etiologies of erythroderma are (1) cutaneous diseases such as psoriasis and dermatitis (Table 48-3); (2) drugs; (3) systemic diseases, most commonly CTCL; and (4) idiopathic. In the first three groups, the location and description of the initial lesions, prior to the development of the erythroderma, aid in the diagnosis. For example, a history of red scaly plaques on the elbows and knees would point to psoriasis. It is also important to examine the skin carefully for a migration of the erythema and associated secondary changes such as pustules or erosions. Migratory waves of erythema studded with superficial pustules are seen in *pustular psoriasis*.

Drug-induced erythroderma (exfoliative dermatitis) may begin as a morbilliform eruption (Chap. 50) or may arise as diffuse erythema. Fever and peripheral eosinophilia often accompany the eruption, and occasionally there is an associated allergic interstitial nephritis. A number of drugs can produce an erythroderma, including penicillins, sulfonamides, carbamazepine, phenytoin, gold, allopurinol, and captopril. While reactions to anticonvulsants can lead to a pseudolymphoma syndrome (with adenopathy, hepatitis, and circulating atypical lymphocytes), reactions to allopurinol may be accompanied by hepatitis, gastrointestinal bleeding, and nephropathy.

The most common malignancy that is associated with erythroderma is CTCL; in some series, up to 25% of the cases of erythroderma were due to CTCL. The patient may progress from isolated plaques and tumors, but more commonly the erythroderma is present throughout the course of the disease (Sézary syndrome). In the Sézary syndrome, there are circulating atypical T lymphocytes, pruritus, and lymphadenopathy. In cases of erythroderma where there is no apparent cause (idiopathic), longitudinal follow-up is mandatory to monitor for the possible development of CTCL. There have been isolated case reports of erythroderma secondary to some solid tumors—lung, liver, prostate, thyroid, and colon—but it is usually in a late stage of the disease.

ALOPECIA (Table 48-4) The two major forms of alopecia are scarring and nonscarring. In *scarring alopecia* there are associated fibrosis, inflammation, and loss of hair follicles. A smooth scalp with a decreased number of follicular openings is usually observed clinically, but in some cases the changes are seen only in biopsy specimens from the affected areas. In *nonscarring alopecia* the hair shafts are gone, but the hair follicles are preserved, explaining the reversible nature of nonscarring alopecia.

The most common causes of nonscarring alopecia include *telogen effluvium*, *androgenetic alopecia*, *alopecia areata*, *tinea capitis*, and *traumatic alopecia* (Table 48-5). In women with androgenetic alopecia, an elevation in circulating levels of androgens may be seen as a result of ovarian or adrenal gland dysfunction. When there are

TABLE 48-4 Causes of Alopecia

I. Nonscarring alopecia

  2. Lichen planus
  3. Folliculitis decalvans
  4. Linear scleroderma (morphea)
  5. Traumatic alopecia[a]
- B. Systemic diseases
  1. Lupus erythematosus
  2. Sarcoidosis
  3. Cutaneous metastases

[a] Also referred to as follicular degeneration.

signs of virilization, such as a deepened voice and enlarged clitoris, the possibility of an ovarian or adrenal gland tumor should be considered.

Exposure to various drugs can also cause diffuse hair loss, usually by inducing a telogen effluvium. An exception is the anagen effluvium observed with antimitotic agents such as daunorubicin. Alopecia is a side effect of the following drugs: warfarin, heparin, propylthiouracil, carbimazole, vitamin A, isotretinoin, acitretin, lithium, beta blockers, colchicine, and amphetamines. Fortunately, spontaneous regrowth usually follows discontinuation of the offending agent.

Less commonly, nonscarring alopecia is associated with *lupus erythematosus* and *secondary syphilis*. In systemic lupus there are two forms of alopecia—one is scarring secondary to discoid lesions (see below) and the other is nonscarring. The latter form may be diffuse and involve the entire scalp, or it may be localized to the frontal scalp and result in multiple short hairs ("lupus hairs"). Scattered, poorly circumscribed patches of alopecia with a "moth-eaten" appearance are a manifestation of the secondary stage of syphilis. Diffuse thinning of the hair is also associated with hypothyroidism and hyperthyroidism (Table 48-4).

Scarring alopecia is more frequently the result of a primary cutaneous disorder such as *lichen planus*, *folliculitis decalvans*, *cutaneous lupus*, or *linear scleroderma* (*morphea*) than it is a sign of systemic disease. Although the scarring lesions of *discoid lupus* can be seen in patients with systemic lupus, in the majority of cases the disease process is limited to the skin. Less common causes of scarring alopecia include *sarcoidosis* (see "Papulonodular Skin Lesions," below) and *cutaneous metastases*.

In the early phases of discoid lupus, lichen planus, and folliculitis decalvans, there are circumscribed areas of alopecia. Fibrosis and subsequent loss of follicles are observed primarily in the center of the individual lesions, while the inflammatory process is most prominent at the periphery. The areas of active inflammation in discoid lupus are erythematous with scale, whereas the areas of previous inflammation are often hypopigmented with a rim of hyperpigmentation. In lichen planus the peripheral perifollicular macules are usually violet-colored. Complete examination of the skin and oral mucosa combined with a biopsy and direct immunofluorescence microscopy will aid in distinguishing these two entities. The peripheral active lesions in folliculitis decalvans are follicular pustules; these patients can develop a reactive arthritis.

FIGURATE SKIN LESIONS (Table 48-6) In *figurate eruptions*, the lesions form rings and arcs that are usually erythematous but can be skin-colored to brown. Most commonly, they are due to primary cutaneous diseases such as *tinea*, *urticaria*, *erythema annulare centrifugum*, and *granuloma annulare* (Chaps. 47 and 49). An underlying systemic illness is found in a second, less common group of migratory annular erythemas. It includes *erythema gyratum repens*, *erythema migrans*, *erythema marginatum*, and *necrolytic migratory erythema*.

In erythema gyratum repens, one sees hundreds of mobile concentric arcs and wavefronts that resemble the grain in wood. A search for an underlying malignancy is mandatory in a patient with this eruption. Erythema migrans is the cutaneous manifestation of Lyme disease, which is caused by the spirochete *Borrelia burgdorferi*. In the initial stage (3 to 30 days after tick bite), a single annular lesion is usually seen, which can expand to $\geq$10 cm in diameter. Within several days, approximately half the patients develop multiple smaller erythematous lesions at sites distant from the bite. Associated symptoms include fever, headache, photophobia, myalgias, arthralgias, and malar rash. Erythema marginatum is seen in patients with rheumatic fever, primarily on the trunk. Lesions are pink-red in color, flat to mildly elevated, and transient.

There are additional cutaneous diseases that present as annular eruptions but lack an obvious migratory component. Examples include *CTCL*, *annular cutaneous lupus* (also referred to as *subacute lupus*), *secondary syphilis*, and *sarcoidosis* (see "Papulonodular Skin Lesions," below).

ACNE (Table 48-7) In addition to *acne vulgaris* and *acne rosacea*, the two major forms of acne (Chap. 47), there are drugs and systemic diseases that can lead to acneiform eruptions (Table 48-7).

Patients with the *carcinoid syndrome* have episodes of flushing of the head, neck, and sometimes the trunk. Resultant skin changes of the face, in particular telangiectasias, may mimic the clinical appearance of acne rosacea.

PUSTULAR LESIONS *Acneiform eruptions* (see "Acne," above) and *folliculitis* represent the most common pustular dermatoses. An important consideration in the evaluation of follicular pustules is a determination of the associated pathogen, e.g., normal flora, *Staphylococcus aureus*, *Pityrosporum*. Noninfectious forms of folliculitis include HIV-associated eosinophilic folliculitis and folliculitis secondary to drugs such as glucocorticoids and lithium. Administration of high-dose oral glucocorticoids can result in a widespread eruption of follicular pustules on the trunk, characterized by lesions in the same stage of development. With regard to underlying systemic diseases, nonfollicular-based pustules are a characteristic component of pustular psoriasis and can be seen in septic emboli of bacterial or fungal origin (see "Purpura," below).

TELANGIECTASIAS (Table 48-8) In order to distinguish the various types of telangiectasias, it is important to examine the shape and configuration of the dilated blood vessels. *Linear telangiectasias* are seen on the face of patients with *actinically damaged skin* and *acne rosacea* and they are found on the legs of patients with *venous hypertension* and *essential telangiectasia*. Patients with an unusual form of *mastocytosis* (telangiectasia macularis eruptiva perstans) and the *carcinoid syndrome* (see "Acne," above) also have linear telangiectasias. Lastly, linear telangiectasias are found in areas of cutaneous inflammation. For example, lesions of discoid lupus frequently have telangiectasias within them.

Poikiloderma is a term used to describe a patch of skin with (1) reticulated hypo- and hyperpigmentation, (2) wrinkling secondary to epidermal atrophy, and (3) telangiectasias. Poikiloderma does not imply a single disease entity—although becoming less common, it is seen in skin damaged by *ionizing radiation*, as well as in patients with autoimmune connective tissue diseases, primarily *dermatomyositis* (DM).

In *scleroderma*, the dilated blood vessels have a unique configuration and are known as *mat telangiectasias*. The lesions are broad macules that usually measure 2 to 7 mm in diameter but occasionally are larger. Mats have a polygonal or oval shape, and their erythematous color may be uniform or the result of delicate telangiectasias. The most common locations for mat telangiectasias are the face, oral mucosa, and hands—peripheral sites that are prone to intermittent ischemia. The CREST (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) variant of scleroderma

(Chap. 303) is associated with a chronic course and anticentromere antibodies. Mat telangiectasias are an important clue to the diagnosis of the CREST syndrome as well as systemic scleroderma, for they may be the only cutaneous finding.

Periungual telangiectasias are pathognomonic signs of the three major autoimmune connective tissue diseases—*lupus erythematosus*, *scleroderma*, and *DM*. They are easily visualized by the naked eye and occur in at least two-thirds of these patients. In both DM and lupus there is associated nailfold erythema, and in DM the erythema is often accompanied by "ragged" cuticles and fingertip tenderness. Under 10× magnification, the blood vessels in the nailfolds of lupus patients are tortuous and resemble "glomeruli," whereas in scleroderma and DM there is a loss of capillary loops and those that remain are markedly dilated.

In *hereditary hemorrhagic telangiectasia* (Osler-Rendu-Weber disease), the lesions usually appear during adulthood and are most commonly seen on the mucous membranes, face, and distal extremities, including under the nails. They represent arteriovenous (AV) malformations of the dermal microvasculature, are dark red in color, and are usually slightly elevated. When the skin is stretched over an individual lesion, an eccentric punctum with radiating legs is seen. Although the degree of systemic involvement varies in this autosomal dominant disease (due to mutations in either the endoglin or activin receptor–like kinase gene), the major symptoms are recurrent epistaxis and gastrointestinal bleeding. The fact that these mucosal telangiectasias are actually AV communications helps to explain their tendency to bleed.

TABLE 48-5 *Nonscarring Alopecia (Primary Cutaneous Disorders)*

	Clinical Characteristics	*Pathogenesis*	*Treatment*
Telogen effluvium	Diffuse shedding of normal hairs Follows either major stress (high fever, severe infection) or change in hormones (post partum) Reversible without treatment	Stress causes the normally asynchronous growth cycles of individual hairs to become synchronous; therefore, large numbers of growing (anagen) hairs simultaneously enter the dying (telogen) phase	Observation; discontinue any drugs that have alopecia as a side effect; must exclude underlying metabolic causes, e.g., hypothyroidism, hyperthyroidism
Androgenetic alopecia	Miniaturization of hairs along the midline of the scalp Recession of the anterior scalp line in men and some women	Increased sensitivity of affected hairs to the effects of testosterone Increased levels of circulating androgens (ovarian or adrenal source in women)	If no evidence of hyperandrogen state, then topical minoxidil ± tretinoin; finasteride[a]; hair transplant
Alopecia areata	Well-circumscribed, circular areas of hair loss, 2–5 cm in diameter In extensive cases, coalescence of lesions and/or involvement of other hair-bearing surfaces of the body Pitting of the nails	The germinative zones of the hair follicles are surrounded by T lymphocytes Occasional associated diseases: hyperthyroidism, hypothyroidism, vitiligo, Down's syndrome	Topical anthralin; intralesional glucocorticoids; topical contact sensitizers
Tinea	Varies from scaling with minimal hair loss to discrete patches with "black dots" (broken hairs) to boggy plaque with pustules (kerion)	Invasion of hairs by dermatophytes, most commonly *Trichophyton tonsurans*	Oral griseofulvin or terbinafine plus 2.5% selenium sulfide or ketoconazole shampoo; examine family members
Traumatic alopecia	Broken hairs Irregular outline	Traction with curlers, rubber bands, braiding Exposure to heat or chemicals Mechanical pulling (trichotillomania)	Discontinuation of offending hair style or chemical treatments; trichotillomania may require hair clipping and observation of shaved hairs or biopsy for diagnosis, followed by psychotherapy

[a] To date, FDA-approved for men.

HYPOPIGMENTATION (Table 48-9) Disorders of hypopigmentation are classified as either diffuse or localized. The classic example of *diffuse hypopigmentation* is *oculocutaneous albinism* (OCA). The most common forms are due to mutations in the tyrosinase gene (type I) or the *P* gene (type II); patients with type IA OCA have a total lack of enzyme activity. At birth, different forms of OCA can appear similar—white hair, gray-blue eyes, and pink-white skin. However, the patients with no tyrosinase activity maintain this phenotype, whereas those with decreased activity or *P* gene mutations will acquire some pigmentation of the eyes, hair, and skin as they age. The degree of pigment formation is also a function of racial background, and the pigmentary dilution is readily apparent when patients are compared to their first-degree relatives. The ocular findings in OCA correlate with the degree of hypopigmentation and include decreased visual acuity, nystagmus, photophobia, and monocular vision.

The differential diagnosis of *localized hypomelanosis* includes the following primary cutaneous disorders: *idiopathic guttate hypomelanosis*, *postinflammatory hypopigmentation*, *tinea (pityriasis) versicolor*, *vitiligo*, *chemical leukoderma*, *nevus depigmentosus* (see below), and *piebaldism* (Table 48-9). In this group of diseases, the areas of involvement are macules or patches with a decrease or absence of pigmentation. Patients with vitiligo also have an increased incidence of several autoimmune disorders, including hypothyroidism, Graves' disease, pernicious anemia, Addison's disease, uveitis, alopecia areata, chronic mucocutaneous candidiasis, and the polyglandular autoimmune syndromes (types I and II). Diseases of the thyroid gland are the most frequently associated disorders, occurring in up to 30% of patients with vitiligo. Circulating autoantibodies are often found, and the most common ones are antithyroglobulin, antimicrosomal, and antiparietal cell antibodies.

There are three systemic diseases that should be considered in a patient with skin findings suggestive of vitiligo—*Vogt-Koyanagi-Harada syndrome*, *scleroderma*, and *melanoma-associated leukoderma*. A history of aseptic meningitis, nontraumatic uveitis, tinnitus, hearing loss, and/or dysacousis points to the diagnosis of the Vogt-Koyanagi-Harada syndrome. In these patients, the face and scalp are the most common locations of pigment loss. The vitiligo-like leukoderma seen in patients with scleroderma has a clinical resemblance to idiopathic vitiligo that has begun to repigment as a result of treatment; that is, perifollicular macules of normal pigmentation are seen within areas of depigmentation. The basis of this leukoderma is unknown;

[a] Becoming less common.

there is no evidence of inflammation in areas of involvement, but it can resolve if the underlying connective tissue disease becomes inactive. In contrast to idiopathic vitiligo, melanoma-associated leukoderma often begins on the trunk, and its appearance should prompt a search for metastatic disease. The possibility exists that the destruction of normal melanocytes is the result of an immune response against malignant melanocytes.

There are two systemic disorders that may have the cutaneous findings of piebaldism (Table 48-10). They are *Hirschsprung's disease* and *Waardenburg's syndrome*. A possible explanation for both disorders is an abnormal embryonic migration or survival of two neural crest–derived elements, one of them being melanocytes and the other myenteric ganglion cells (Hirschsprung's disease) or auditory nerve cells (Waardenburg's syndrome). The latter syndrome is characterized by congenital sensorineural hearing loss, dystopia canthorum (lateral displacement of the inner canthi but normal interpupillary distance), heterochromic irises, and a broad nasal root, in addition to the piebaldism. Patients with Waardenburg's syndrome have been shown to have mutations in two genes that encode DNA-binding proteins, *PAX-3* and *MITF*, while patients with Hirschsprung's disease and white spotting have mutations in one of three genes—endothelin 3, endothelin B receptor, and *SOX-10*.

In *tuberous sclerosis*, the earliest cutaneous sign is an ash leaf spot. These lesions are often present at birth and are usually multiple; however, detection may require Wood's lamp examination, especially in fair-skinned individuals. The pigment within them is reduced but not absent. The average size is 1 to 3 cm, and the common shapes are polygonal and lance-ovate. Examination of the patient for additional cutaneous signs such as adenoma sebaceum (multiple angiofibromas of the face), ungual and gingival fibromas, fibrous plaques of the forehead, and connective tissue nevi (shagreen patches) is recommended. It is important to remember that an ash leaf spot on the scalp will result in *poliosis*, which is a circumscribed patch of gray-white hair. Internal manifestations include seizures, mental retardation, central nervous system (CNS) and retinal hamartomas, renal angiomyolipomas, and cardiac rhabdomyomas. The latter can be detected in up to 60% of children (<18 years) with tuberous sclerosis by echocardiography.

Nevus depigmentosus is a stable, well-circumscribed hypomelanosis that is present at birth. There is usually a single circular or rectangular lesion, but occasionally the nevus has a segmental or whorled pattern. It is important to distinguish this more common entity from ash leaf spots especially when there are multiple lesions. In *hypomelanosis of Ito*, swirls and streaks of hypopigmentation run parallel to one another in a pattern that resembles a marble cake. Lesions may progress or regress with time, and in up to a third of patients, associated abnormalities are found including in the musculoskeletal system (asymmetry), the CNS (seizures and mental retardation), and the eyes (strabismus and hypertelorism). Chromosomal mosaicism has been de-

TABLE 48-10 *Hypopigmentation (Primary Cutaneous Disorders, Localized)*

	Clinical Characteristics	*Wood's Lamp Examination (UV-A; Peak = 365 nm)*	*Skin Biopsy Specimen*	*Pathogenesis*	*Treatment*
Idiopathic guttate hypomelanosis	Common; acquired; 1 to 4 mm in diameter Shins and extensor forearms	Less enhancement than vitiligo	Abrupt decrease in epidermal melanin content	Possible somatic mutations as a reflection of aging; UV exposure	None
Postinflammatory hypopigmentation	Can develop within active lesions, as in subacute lupus, or after the lesion fades, as in dermatitis	Depends on particular disease Usually less enhancement than in vitiligo	Type of inflammatory infiltrate depends on specific disease	Block in transfer of melanin from melanocytes to keratinocytes could be secondary to edema or decrease in contact time Destruction of melanocytes if inflammatory cells attack basal layer	Treat underlying inflammatory disease
Tinea (pityriasis) versicolor	Common disorder Upper trunk and neck Shawl-like distribution Young adults Macules have fine white scale when scratched	Golden fluorescence	Hyphae and budding yeast in stratum corneum	Invasion of stratum corneum by the yeast *Pityrosporum* Yeast is lipophilic and produces C_9 and C_{11} dicarboxylic acids, which in vitro inhibit tyrosinase	Selenium sulfide 2.5%; topical imidazoles; oral imidazoles or triazoles
Vitiligo	Acquired; progressive Symmetric areas of complete pigment loss Periorificial—around mouth, nose, eyes, nipples, umbilicus, anus Other areas—flexor wrists, extensor distal extremities Segmental form is less common—unilateral, dermatomal-like	More apparent Chalk-white	Absence of melanocytes Mild inflammation	Possible autoimmune phenomenon that results in destruction of melanocytes—humoral and/or cellular Alternative hypothesis is self-destruction of melanocytes and circulating antibodies or cytotoxic T cells as a secondary phenomenon	Topical glucocorticoids; UV-B; PUVA; transplants; depigmentation if widespread
Chemical leukoderma	Similar appearance to vitiligo Often begins on hands Satellite lesions in areas not exposed to chemicals	More apparent Chalk-white	Decreased number or absence of melanocytes	Exposure to chemicals that selectively destroy melanocytes, in particular phenols and catechols (germicides; adhesives) Release of cellular antigens and activation of circulating lymphocytes may explain satellite phenomenon	Avoid exposure to offending agent, then treat as vitiligo
Piebaldism	Autosomal dominant Congenital, stable White forelock Areas of hypomelanosis contain normally pigmented and hyperpigmented macules of various sizes Symmetric involvement of central forehead, ventral trunk, and mid regions of upper and lower extremities	Enhancement of leukoderma and hyperpigmented macules	Hypomelanotic areas—few to no melanocytes	Defect in migration of melanoblasts from neural crest to ventral skin or failure of melanoblasts to survive or differentiate in these areas Mutations within the c-*kit* proto-oncogene that encodes the tyrosine kinase receptor for mast/stem cell growth factor	None; occasionally transplants

Note: PUVA, *p*soralens + *u*ltra*v*iolet *A* irradiation; UV-B, *u*ltra*v*iolet B.

tected in these patients; this lends support to the hypothesis that the pattern is the result of the migration of two clones of primordial melanocytes, each with a different pigment potential.

Localized areas of decreased pigmentation are commonly seen as a result of cutaneous inflammation (Table 48-10) and have been observed in the skin overlying active lesions of sarcoidosis (see "Papulonodular Skin Lesions," below) as well as in CTCL. Cutaneous infections also present as disorders of hypopigmentation, and in *tuberculoid leprosy* there are a few asymmetric patches of hypomelanosis that have associated anesthesia, anhidrosis, and alopecia. Biopsy specimens of the palpable border show dermal granulomas that contain rare, if any, *Mycobacterium leprae* organisms.

HYPERPIGMENTATION (Table 48-11) Disorders of hyperpigmentation are also divided into two groups—localized and diffuse. The localized forms are due to an epidermal alteration, a proliferation of melanocytes, or an increase in pigment production. Both seborrheic keratoses and acanthosis nigricans belong to the first group. *Seborrheic keratoses* are common lesions, but in one clinical setting they are a sign of systemic disease, and that setting is the sudden appearance of multiple lesions, often with an inflammatory base and in association with acrochordons (skin tags) and acanthosis nigricans. This is termed the *sign of Leser-Trélat* and signifies an internal malignancy. *Acanthosis nigricans* can also be a reflection of an internal malignancy, most commonly of the gastrointestinal tract, and it appears as velvety hy-

[d] Late 1980s.

perpigmentation, primarily in flexural areas. In the majority of patients, acanthosis nigricans is associated with obesity and insulin resistance, but it may be a reflection of an endocrinopathy such as acromegaly, Cushing's syndrome, the Stein-Leventhal syndrome, or insulin-resistant diabetes mellitus (type A, type B, and lipoatrophic forms).

A proliferation of melanocytes results in the following pigmented lesions: *lentigo*, *melanocytic nevus*, and *melanoma* (Chap. 73). In an adult, the majority of lentigines are related to sun exposure, which explains their distribution. However, in the Peutz-Jeghers and LEOPARD [*l*entigines; *E*CG abnormalities, primarily conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis and subaortic valvular stenosis; *a*bnormal genitalia (cryptorchidism, hypospadias); *r*etardation of growth; and *d*eafness (sensorineural)] syndromes, lentigines do serve as a clue to systemic disease. In *LEOPARD syndrome*, hundreds of lentigines develop during childhood and are scattered over the entire surface of the body. The lentigines in patients with *Peutz-Jeghers syndrome* are located primarily around the nose and mouth, on the hands and feet, and within the oral cavity. While the pigmented macules on the face may fade with age, the oral lesions persist. However, similar intraoral lesions are also seen in Addison's disease and as a normal finding in darkly pigmented individuals. Patients with this autosomal dominant syndrome (due to mutations in a novel serine threonine kinase gene) have multiple benign polyps of the gastrointestinal tract, testicular tumors, and an increased risk of developing gastrointestinal (primarily colon), breast, and gynecologic cancers.

Lentigines are also seen in association with cardiac myxomas and have been described in two syndromes whose findings overlap: *LAMB* (*l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi) *syndrome* and *NAME* [*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, and *e*phelides (freckles)] *syndrome*. These patients can also have evidence of endocrine overactivity in the form of Cushing's syndrome, acromegaly, or sexual precocity (Carney complex).

The third type of localized hyperpigmentation is due to a local increase in pigment production, and it includes *ephelides* and café au lait macules (CALM). The latter are most commonly associated with two disorders—neurofibromatosis (NF) and McCune-Albright syndrome. *CALM* are flat, uniformly light brown in color, and can vary in size from 0.5 to 12 cm. Approximately 80% of adult patients with *type I NF* will have six or more CALM measuring $\geq$1.5 cm in diameter. Additional findings are discussed in the section on neurofibromas (see "Papulonodular Skin Lesions," below). In comparison with NF, the CALM in patients with *McCune-Albright syndrome* [polyostotic fibrous dysplasia with precocious puberty in females due to mosaicism for an activating mutation in a G protein ($G_s\alpha$) gene] are usually larger, more irregular in outline, and tend to respect the midline. CALM have also been associated with pulmonary stenosis (Watson syndrome), tuberous sclerosis, the LEOPARD syndrome, and multiple endocrine neoplasia (MEN), but a few such lesions can be found in normal individuals.

In incontinentia pigmenti, dyskeratosis congenita, and bleomycin pigmentation, the areas of localized hyperpigmentation form a pattern—swirled in the first, reticulated in the second, and flagellate in the third. In *dyskeratosis congenita*, atrophic reticulated hyperpigmentation is seen on the neck, thighs, and trunk and is accompanied by nail dystrophy, pancytopenia, and leukoplakia of the oral and anal mucosa. The latter often develops into squamous cell carcinoma. In addition to the flagellate pigmentation (linear streaks) on the trunk, patients receiving bleomycin often have hyperpigmentation on the elbows, knees, and small joints of the hand.

Localized hyperpigmentation is seen as a side effect of several other *systemic medications*, including those that produce fixed drug reactions [phenolphthalein, nonsteroidal anti-inflammatory drugs (NSAIDs), sulfonamides, and barbiturates] and those that can complex with melanin (antimalarials). Fixed drug eruptions recur in the same location as circular areas of erythema that can become bullous and then resolve as brown macules. The eruption usually appears within hours of administration of the offending agent, and common locations include the genitalia, extremities, and perioral region. Chloroquine and hydroxychloroquine produce gray-brown to blue-black discoloration of the shins, hard palate, and face, while blue macules can be seen on the lower extremities and in sites of inflammation with prolonged minocycline administration. Estrogen in oral contraceptives can induce melasma—symmetric brown patches on the face, especially the cheeks, upper lip, and forehead. Similar changes are seen in pregnancy, in patients receiving phenytoin, and in the adult form of Gaucher's disease. In the latter group there is also hyperpigmentation of the distal lower extremities.

In the diffuse forms of hyperpigmentation, the darkening of the skin may be of equal intensity over the entire body or may be accentuated in sun-exposed areas. The causes of diffuse hyperpigmentation can be divided into four groups—endocrine, metabolic, autoimmune, and drugs. The endocrinopathies that frequently have associated hyperpigmentation include *Addison's disease*, *Nelson syndrome*, and *ectopic ACTH syndrome*. In these diseases, the increased pigmentation is diffuse but is accentuated in the palmar creases, sites of friction,

scars, and the oral mucosa. An overproduction of the pituitary hormones α-MSH (melanocyte-stimulating hormone) and ACTH can lead to an increase in melanocyte activity. These peptides are products of the proopiomelanocortin gene and exhibit homology; e.g., α-MSH and ACTH share 13 amino acids. A minority of the patients with Cushing's disease or hyperthyroidism have generalized hyperpigmentation.

The metabolic causes of hyperpigmentation include *porphyria cutanea tarda* (PCT), *hemochromatosis*, *vitamin B_{12} deficiency*, *folic acid deficiency*, *pellagra*, *malabsorption*, and *Whipple's disease*. In patients with PCT (see "Vesicles/Bullae," below), the skin darkening is seen in sun-exposed areas and is a reflection of the photoreactive properties of porphyrins. The increased level of iron in the skin of patients with hemochromatosis stimulates melanin pigment production and leads to the classic bronze color. Patients with pellagra have a brown discoloration of the skin, especially in sun-exposed areas, as a result of nicotinic acid (niacin) deficiency. In the areas of increased pigmentation, there is a thin varnish-like scale. These changes are also seen in patients who are vitamin B_6 deficient, have functioning carcinoid tumors (increased consumption of niacin), or take isoniazid. Approximately 50% of the patients with Whipple's disease have an associated generalized hyperpigmentation in association with diarrhea, weight loss, arthritis, and lymphadenopathy. A diffuse slate-blue color is seen in patients with melanosis secondary to metastatic melanoma. Although there is a debate as to whether the color is due to single-cell metastases in the dermis or to a widespread deposition of melanin resulting from the high concentration of circulating melanin precursors, there is more evidence to support the latter.

Of the autoimmune diseases associated with diffuse hyperpigmentation, *biliary cirrhosis* and *scleroderma* are the most common, and occasionally both disorders are seen in the same patient. The skin is dark brown in color, especially in sun-exposed areas. In biliary cirrhosis the hyperpigmentation is accompanied by pruritus, jaundice, and xanthomas, whereas in scleroderma it is accompanied by sclerosis of the extremities, face, and, less commonly, the trunk. Additional clues to the diagnosis of scleroderma are telangiectasias, calcinosis cutis, Raynaud's phenomenon, and distal ulcerations (see "Telangiectasias," above). The differential diagnosis of cutaneous sclerosis with hyperpigmentation includes the POEMS [*p*olyneuropathy; *o*rganomegaly (liver, spleen, lymph nodes); *e*ndocrinopathies (impotence, gynecomastia); *M*-protein; and *s*kin changes] syndrome. The skin changes include hyperpigmentation, skin thickening, hypertrichosis, and angiomas.

Diffuse hyperpigmentation that is due to drugs or metals can result from one of several mechanisms—induction of melanin pigment formation, complexing of the drug or its metabolites to melanin, and deposits of the drug in the dermis. Busulfan; cyclophosphamide; long-term, high-dose ACTH; and inorganic arsenic induce pigment production. Complexes containing melanin or hemosiderin plus the drug or its metabolites are seen in patients receiving chlorpromazine and minocycline. The sun-exposed skin as well as the conjunctivae of patients on long-term, high-dose chlorpromazine can become blue-gray in color. Patients taking minocycline may develop a diffuse blue-gray, muddy appearance in sun-exposed areas in addition to pigmentation of the mucous membranes, teeth, nails, bones, and thyroid. Administration of amiodarone can result in both a phototoxic eruption (exaggerated sunburn) and/or a brown or blue-gray discoloration of sun-exposed skin. Biopsy specimens of the latter show yellow-brown granules in dermal macrophages, which represent intralysosomal accumulations of lipids, amiodarone, and its metabolites. Actual deposits of a particular drug or metal in the skin are seen with silver (argyria), where the skin appears blue-gray in color; gold (chrysiasis), where the skin has a brown to blue-gray color; and clofazimine, where the skin appears reddish brown. The associated hyperpigmentation is accentuated in sun-exposed areas, and discoloration of the eye is seen with gold (sclerae) and clofazimine (conjunctivae).

VESICLES/BULLAE (Table 48-12) Depending on their size, cutaneous blisters are referred to as *vesicles* (<0.5 cm) or *bullae* (>0.5 cm). The primary blistering disorders include *pemphigus vulgaris*, *pemphigus foliaceus*, *pemphigus erythematosus*, *paraneoplastic pemphigus*, *bullous pemphigoid*, *gestational pemphigoid*, *cicatricial pemphigoid*, *epidermolysis bullosa acquisita*, *linear IgA disease*, and *dermatitis herpetiformis* (Chap. 49).

TABLE 48-12 Causes of Vesicles/Bullae

I. Primary cutaneous diseases
- A. Primary blistering diseases (autoimmune)
  1. Pemphigus[a]
  2. Bullous pemphigoid[b]
  3. Gestational pemphigoid[b]
  4. Cicatricial pemphigoid[b]
  5. Dermatitis herpetiformis[b,c]
  6. Linear IgA disease[b]
  7. Epidermolysis bullosa acquisita[b,d]
- B. Secondary blistering diseases

  5. Bullous dermatosis of hemodialysis[b]
- D. Ischemia
  1. Coma bullae

[a] Intraepidermal.
[b] Subepidermal.
[c] Associated with gluten enteropathy.
[d] Associated with inflammatory bowel disease.
[e] Also systemic.
[f] In adults, associated with renal failure and immunocompromised state.

Vesicles and bullae are also seen in *contact dermatitis*, both allergic and irritant forms (Chap. 47). When there is a linear arrangement of vesicular lesions, an exogenous cause should be suspected. Bullous disease secondary to the ingestion of drugs can take one of several forms, including phototoxic eruptions, isolated bullae, toxic epidermal necrolysis (TEN), and erythema multiforme major (Chap. 50). Clinically, phototoxic eruptions resemble an exaggerated sunburn with diffuse erythema and bullae in sun-exposed areas. The most commonly associated drugs are thiazides, doxycycline, sulfonamides, NSAIDs, and psoralens. The development of a phototoxic eruption is dependent on the doses of both the drug and ultraviolet (UV)-A irradiation.

Toxic epidermal necrolysis is characterized by bullae that arise on widespread areas of erythema and then slough. This results in large areas of denuded skin. The associated morbidity, such as sepsis, and mortality are relatively high and are a function of the extent of epidermal necrosis. In addition, these patients may also have involvement of the mucous membranes and intestinal tract. Drugs are the primary cause of TEN, and the most common offenders are phenytoin, barbiturates, sulfonamides, penicillins, and NSAIDs. Severe acute graft-versus-host disease (grade 4) can also resemble TEN.

In *erythema multiforme* (EM), the primary lesions are pink-red macules and edematous papules, the centers of which may become vesicular. The clue to the diagnosis of EM, as opposed to a drug-induced morbilliform exanthem, is the development of a "dusky" violet color or petechiae in the center of the lesions. Target or iris lesions are also characteristic of EM and arise as a result of active centers and borders in combination with centrifugal spread. However, iris lesions need not be present to make the diagnosis of EM.

EM has been subdivided into two major groups: (1) herpes simplex virus (HSV)-associated and (2) EM major due to drugs or *Mycoplasma pneumoniae*. Involvement of the mucous membranes (oral, nasal, oc-

ular, and genital) is seen more commonly in the latter form. Hemorrhagic crusts of the lips are characteristic of EM major as well as herpes simplex, pemphigus vulgaris, and paraneoplastic pemphigus. Fever, malaise, myalgias, sore throat, and cough may precede or accompany the eruption. The lesions of EM usually resolve over 3 to 6 weeks but may be recurrent, especially when due to HSV.

Induction of EM major is most often due to drugs, especially sulfonamides, phenytoin, barbiturates, penicillins, and carbamazepine. In addition to HSV (in which lesions appear 7 to 12 days after the viral eruption), EM can also follow vaccinations, radiation therapy, and exposure to environmental toxins.

In addition to primary blistering disorders and hypersensitivity reactions, bacterial and viral infections can lead to vesicles and bullae. The most common infectious agents are herpes simplex (Chap. 163), herpes varicella-zoster (Chap. 164), and staphylococci (Chap. 120).

Staphylococcal scalded-skin syndrome (SSSS) and *bullous impetigo* are two blistering disorders associated with staphylococcal (phage group II) infection. In SSSS, the initial findings are redness and tenderness of the central face, neck, trunk, and intertriginous zones. This is followed by short-lived flaccid bullae and a slough or exfoliation of the superficial epidermis. Crusted areas then develop, characteristically around the mouth. SSSS is distinguished from TEN by the following features: younger age group, more superficial site of blister formation, no oral lesions, shorter course, less morbidity and mortality, and an association with staphylococcal exfoliative toxin ("exfoliatin"), not drugs. A rapid diagnosis of SSSS versus TEN can be made by a frozen section of the blister roof or exfoliative cytology of the blister contents. In SSSS the site of staphylococcal infection is usually extracutaneous (conjunctivitis, rhinorrhea, otitis media, pharyngitis, tonsillitis), and the cutaneous lesions are sterile, whereas in bullous impetigo the skin lesions are the site of infection. Impetigo is more localized than SSSS and usually presents with honey-colored crusts. Occasionally, superficial purulent blisters also form. *Cutaneous emboli* from gram-negative infections may present as isolated bullae, but the base of the lesion is purpuric or necrotic, and it may develop into an ulcer (see "Purpura," below).

Several metabolic disorders are associated with blister formation, including diabetes mellitus, renal failure, and porphyria. Local hypoxia secondary to decreased cutaneous blood flow can also produce blisters, which explains the presence of bullae over pressure points in comatose patients (coma bullae). In *diabetes mellitus*, tense bullae with clear viscous fluid arise on normal skin. The lesions can be as large as 6 cm in diameter and are located on the distal extremities. There are several types of porphyria, but the most common form with cutaneous findings is *PCT*. In sun-exposed areas (primarily the face and hands), the skin is very fragile, and trauma leads to erosions and tense vesicles. These lesions then heal with scarring and formation of milia; the latter are firm, 1- to 2-mm white or yellow papules that represent epidermoid inclusion cysts. Associated findings can include hypertrichosis of the lateral malar region (men) or face (women) and, in sun-exposed areas, hyperpigmentation and firm sclerotic plaques. An elevated level of urinary uroporphyrins confirms the diagnosis and is due to a decrease in uroporphyrinogen decarboxylase activity. Precipitating agents include alcohol, iron, chlorinated hydrocarbons, hepatitis C infection, and hepatomas.

The differential diagnosis of PCT includes (1) *porphyria variegata*—the skin signs of PCT plus the systemic findings of acute intermittent porphyria; it has a diagnostic plasma porphyrin fluorescence emission at 626 nm; (2) *drug-induced bullous photosensitivity* (pseudoporphyria)—the clinical and histologic findings are similar to PCT, but porphyrins are normal; etiologic agents include naproxen, furosemide, tetracycline, and nalidixic acid; (3) *bullous dermatosis of hemodialysis*—the same appearance as PCT, but porphyrins are usually normal or occasionally borderline elevated; patients have chronic renal failure and are on hemodialysis; (4) PCT associated with hepatomas, hepatic carcinomas, and hemodialysis; and (5) *epidermolysis bullosa acquisita* (Chap. 49).

EXANTHEMS (Table 48-13) Exanthems are characterized by an acute generalized eruption. The two most common presentations are erythematous macules and papules (morbilliform) and confluent blanching erythema (scarlatiniform). *Morbilliform* eruptions are usually due to either drugs or viral infections. For example, up to 5% of the patients receiving penicillins, sulfonamides, phenytoin, or gold will develop a maculopapular eruption. Accompanying signs may include pruritus, fever, eosinophilia, and transient lymphadenopathy. Similar maculopapular eruptions are seen in the classic childhood viral exanthems, including (1) *rubeola* (measles)—a prodrome of coryza, cough, and conjunctivitis followed by Koplik's spots on the buccal mucosa; the eruption begins behind the ears, at the hairline, and on the forehead and then spreads down the body, often becoming confluent; (2) *rubella*—it begins on the forehead and face and then spreads down the body; it resolves in the same order and is associated with retroauricular and suboccipital lymphadenopathy; and (3) *erythema infectiosum* (fifth disease)—erythema of the cheeks is followed by a reticulated pattern on extremities; it is secondary to a parvovirus B19 infection, and an associated arthritis is seen in adults.

Both measles and rubella are seen in unvaccinated young adults, and an atypical form of measles is seen in adults immunized with either killed measles vaccine or killed vaccine followed in time by live vaccine. In contrast to classic measles, the eruption of atypical measles begins on the palms, soles, wrists, and knuckles, and the lesions may become purpuric. The patient with atypical measles can have pulmonary involvement and be quite ill. Rubelliform and roseoliform eruptions are also associated with *Epstein-Barr virus* (5 to 15% of patients), *echovirus*, *coxsackievirus*, and *adenovirus* infections. Detection of specific IgM antibodies or fourfold elevations in IgG antibodies allows the proper diagnosis. Occasionally, a maculopapular drug eruption is a reflection of an underlying viral infection. For example, about 95% of the patients with infectious mononucleosis who are given ampicillin will develop a rash.

Of note, early in the course of infections with *Rickettsia* and meningococcus, prior to the development of purpura, the lesions may be erythematous macules and papules. This is also the case in chickenpox prior to the development of vesicles. Maculopapular eruptions are associated with early *HIV infection*, early secondary *syphilis*, *typhoid fever*, and *acute graft-versus-host disease*. In the last, lesions frequently begin on the palms and soles; the macular rose spots of typhoid fever involve primarily the anterior trunk.

The prototypic *scarlatiniform* eruption is seen in *scarlet fever* and is due to an erythrotoxin produced by group A β-hemolytic streptococcal infections, most commonly pharyngitis. This eruption is characterized by diffuse erythema, which begins on the neck and upper trunk, and red follicular puncta. Additional findings include a white

TABLE 48-13 Causes of Exanthems

  E. Kawasaki's disease
II. Scarlatiniform
  A. Scarlet fever
  B. Toxic shock syndrome
  C. Kawasaki's disease

strawberry tongue (white coating with red papillae) followed by a red strawberry tongue (red tongue with red papillae); petechiae of the palate; a facial flush with circumoral pallor; linear petechiae in the antecubital fossae; and desquamation of the involved skin, palms, and soles 5 to 20 days after onset of the eruption. A similar desquamation of the palms and soles is seen in toxic shock syndrome (TSS), Kawasaki's disease, and after severe febrile illnesses. Certain strains of staphylococci also produce an erythrotoxin that leads to the same clinical findings as in streptococcal scarlet fever, except that the antistreptolysin O titers are not elevated.

In *toxic shock syndrome*, staphylococcal (phage group I) infections produce an exotoxin (TSST-1) that causes the fever and rash, as well as enterotoxins. Initially, the majority of cases were reported in menstruating women who were using tampons. However, other sites of infection, including wounds and vaginitis, can lead to TSS. The diagnosis of TSS is based on clinical criteria (Chap. 120), and three of these involve mucocutaneous sites (diffuse erythema of the skin, desquamation of the palms and soles 1 to 2 weeks after onset of illness, and involvement of the mucous membranes). The latter is characterized as hyperemia of the vagina, oropharynx, or conjunctivae. Similar systemic findings have been described in *streptococcal toxic shock–like syndrome* (Chap. 121), and although an exanthem is seen less often than in TSS due to a staphylococcal infection, the underlying infection is often in the soft tissue.

The cutaneous eruption in *Kawasaki's disease* (mucocutaneous lymph node syndrome) (Chap. 121) is polymorphous, but the two most common forms are morbilliform and scarlatiniform. Additional mucocutaneous findings include bilateral conjunctival injection; erythema and edema of the hands and feet followed by desquamation; and diffuse erythema of the oropharynx, red strawberry tongue, and erosions with crusting on the lips. This clinical picture can resemble TSS and scarlet fever, but clues to the diagnosis of Kawasaki's disease are cervical lymphadenopathy, lip erosions, and thrombocytosis. The most serious associated systemic finding in this disease is coronary aneurysm secondary to arteritis. Aneurysms may lead to sudden death, primarily within the first 30 days of the illness. Scarlatiniform eruptions are also seen in the early phase of SSSS (see "Vesicles/Bullae," above) and as reactions to drugs.

URTICARIA (Table 48-14) *Urticaria* (hives) are transient lesions that are composed of a central wheal surrounded by an erythematous halo. Individual lesions are round, oval, or figurate and are often pruritic. Acute and chronic urticaria have a wide variety of allergic etiologies and reflect edema in the dermis. Urticarial lesions can also be seen in patients with mastocytosis (urticaria pigmentosa), hyperthyroidism, and juvenile rheumatoid arthritis (JRA). In JRA, the lesions coincide with the fever spike, are transient, and are due to dermal infiltrates of neutrophils.

The common *physical urticarias* include dermographism, solar urticaria, cold urticaria, and cholinergic urticaria. Patients with *dermographism* exhibit linear wheals following minor pressure or scratching of the skin. It is a common disorder, affecting ~5% of the population.

TABLE 48-14 Causes of Urticaria

I. Primary cutaneous disorders
  A. Acute and chronic urticaria[a]
  B. Physical urticaria
    1. Dermatographism
    2. Solar urticaria[b]
    3. Cold urticaria[b]
    4. Cholinergic urticaria[b]
  C. Angioedema (hereditary and acquired)[b]
II. Systemic diseases
  A. Urticarial vasculitis
  B. Hepatitis B or C infection
  C. Serum sickness
  D. Angioedema (hereditary and acquired)

[a] A small minority develop anaphylaxis.
[b] Also systemic.

Solar urticaria characteristically occurs within minutes of sun exposure and is a skin sign of one systemic disease—erythropoietic protoporphyria. In addition to the urticaria, these patients have subtle pitted scarring of the nose and hands. *Cold urticaria* is precipitated by exposure to the cold, and therefore exposed areas are usually affected. In some cases, the disease is associated with abnormal circulating proteins—more commonly cryoglobulins and less commonly cryofibrinogens and cold agglutinins. Additional systemic symptoms include wheezing and syncope, thus explaining the need for these patients to avoid swimming in cold water. *Cholinergic urticaria* is precipitated by heat, exercise, or emotion and are characterized by small wheals with relatively large flares. They are occasionally associated with wheezing.

Whereas urticaria are the result of dermal edema, subcutaneous edema leads to the clinical picture of *angioedema*. Sites of involvement include the eyelids, lips, tongue, larynx, and gastrointestinal tract as well as the subcutaneous tissue. Angioedema occurs alone or in combination with urticaria, including urticarial vasculitis and the physical urticarias. Both acquired and hereditary (autosomal dominant) forms of angioedema occur (Chap. 298), and in the latter, urticaria is rarely, if ever, seen.

Urticarial vasculitis is an immune complex disease that may be confused with simple urticaria. In contrast to simple urticaria, individual lesions tend to last longer than 24 h and usually develop central petechiae that can be observed even after the urticarial phase has resolved. The patient may also complain of burning rather than pruritus. On biopsy, there is a leukocytoclastic vasculitis of the small blood vessels. Although many cases of urticarial vasculitis are idiopathic in origin, it can be a reflection of an underlying systemic illness such as lupus erythematosus, Sjögren's syndrome, or hereditary complement deficiency. There is a spectrum of urticarial vasculitis that ranges from purely cutaneous to multisystem involvement. The most common systemic signs and symptoms are arthralgias and/or arthritis, nephritis, and crampy abdominal pain, with asthma and chronic obstructive lung disease seen less often. Hypocomplementemia occurs in one- to two-thirds of patients, even in the idiopathic cases. Urticarial vasculitis can also be seen in patients with *hepatitis B* and *hepatitis C* infections, *serum sickness*, and *serum sickness–like illnesses*.

PAPULONODULAR SKIN LESIONS (Table 48-15) In the *papulonodular diseases*, the lesions are elevated above the surface of the skin and may coalesce to form plaques. The location, consistency, and color of the lesions are the keys to their diagnosis; this section is organized on the basis of color.

White Lesions In *calcinosis cutis* there are firm white to white-yellow papules with an irregular surface. When the contents are expressed, a chalky white material is seen. *Dystrophic calcification* is seen at sites of previous inflammation or damage to the skin. It develops in acne scars as well as on the distal extremities of patients with scleroderma and in the subcutaneous tissue and intermuscular fascial planes in DM. The latter is more extensive and is more commonly seen in children. An elevated calcium phosphate product, most commonly due to secondary hyperparathyroidism in the setting of renal failure, can lead to nodules of *metastatic calcinosis cutis*, which tend to be subcutaneous and periarticular. These patients can also develop calcification of muscular arteries and subsequent ischemic necrosis (calciphylaxis).

Skin-Colored Lesions There are several types of skin-colored lesions, including epidermoid inclusion cysts, lipomas, rheumatoid nodules, neurofibromas, angiofibromas, neuromas, and adnexal tumors such as tricholemmomas. Both *epidermoid inclusion cysts* and *lipomas* are very common mobile subcutaneous nodules—the former are rubbery and compressible and drain cheeselike material (sebum and keratin) if incised. Lipomas are firm and somewhat lobulated on palpation. When extensive facial epidermoid inclusion cysts develop in childhood or there is a family history of such lesions, the patient should be examined for other signs of Gardner syndrome, including osteomas and desmoid

TABLE 48-15 Papulonodular Skin Lesions According to Color Groups

Note: MEN, multiple endocrine neoplasia.

tumors. *Rheumatoid nodules* are firm, 0.5- to 4-cm nodules that tend to localize around pressure points, especially the elbows. They are seen in approximately 20% of patients with rheumatoid arthritis and 6% of patients with Still's disease. Biopsies of the nodules show palisading granulomas. Similar lesions that are smaller and shorter-lived are seen in rheumatic fever.

Neurofibromas (benign Schwann cell tumors) are soft papules or nodules that exhibit the "button-hole" sign, that is, they invaginate into the skin with pressure in a manner similar to a hernia. Single lesions are seen in normal individuals, but multiple neurofibromas, usually in combination with six or more CALM measuring >1.5 cm (see "Hyperpigmentation," above), axillary freckling, and multiple Lisch nodules, are seen in von Recklinghausen's disease (NF type I; Chap. 359). In some patients the neurofibromas are localized and unilateral due to somatic mosaicism.

Angiofibromas are firm, pink to skin-colored papules that measure from 3 mm to several centimeters in diameter. When they are located on the central cheeks (adenoma sebaceum), the patient has tuberous sclerosis or MEN syndrome, type 1. The former is an autosomal disorder due to mutations in two different genes, and the associated findings are discussed in the section on ash leaf spots as well as in Chap. 359.

Neuromas (benign proliferations of nerve fibers) are also firm, skin-colored papules. They are more commonly found at sites of amputation and as rudimentary supernumerary digits. However, when there are multiple neuromas on the eyelids, lips, distal tongue, and/or oral mucosa, the patient should be investigated for other signs of the MEN syndrome, type 2b. Associated findings include marfanoid habitus, protuberant lips, intestinal ganglioneuromas, and medullary thyroid carcinoma (>75% of patients; Chap. 330).

Adnexal tumors are derived from pluripotential cells of the epidermis that can differentiate toward hair, sebaceous, apocrine, or eccrine glands or remain undifferentiated. *Basal cell carcinomas* (BCCs) are examples of adnexal tumors that have little or no evidence of differentiation. Clinically, they are translucent papules with rolled borders, telangiectasias, and central erosion. BCCs commonly arise in sun-damaged skin of the head and neck. When a patient has multiple BCCs, especially prior to age 30, the possibility of the nevoid basal cell carcinoma syndrome should be raised. It is inherited as an autosomal dominant trait and is associated with jaw cysts, palmar and plantar pits, frontal bossing, medulloblastomas, and calcification of the falx cerebri and diaphragma sellae. *Tricholemmomas* are also skin-colored adnexal tumors but differentiate toward hair follicles and can have a wartlike appearance. The presence of multiple tricholemmomas on the face and cobblestoning of the oral mucosa points to the diagnosis of Cowden's disease (multiple hamartoma syndrome) due to mutations in the *PTEN* gene. Internal organ involvement (in decreasing order of frequency) includes fibrocystic disease and carcinoma of the breast, adenomas and carcinomas of the thyroid, and gastrointestinal polyposis. Keratoses of the palms, soles, and dorsa of the hands are also seen.

Pink Lesions The cutaneous lesions associated with primary systemic *amyloidosis* are pink in color and translucent. Common locations are the face, especially the periorbital and perioral regions, and flexural areas. On biopsy, homogeneous deposits of amyloid are seen in the dermis and in the walls of blood vessels; the latter lead to an increase in vessel wall fragility. As a result, petechiae and purpura develop in clinically normal skin as well as in lesional skin following minor trauma, hence the term *pinch purpura*. Amyloid deposits are also seen in the striated muscle of the tongue and result in macroglossia.

Even though specific mucocutaneous lesions are rarely seen in secondary amyloidosis and are present in only about 30% of the patients with primary amyloidosis, a rapid diagnosis of systemic amyloidosis can be made by an examination of abdominal subcutaneous fat. By special staining, deposits are seen around blood vessels or individual fat cells in 40 to 50% of patients. There are also three forms of amyloidosis that are limited to the skin and that should not be construed as cutaneous lesions of systemic amyloidosis. They are macular amyloidosis (upper back), lichenoid amyloidosis (usually lower extremities), and nodular amyloidosis. In macular and lichenoid amyloidosis, the deposits are composed of altered epidermal keratin. Recently, macular and lichenoid amyloidosis have been associated with MEN syndrome, type 2a.

Patients with *multicentric reticulohistiocytosis* also have pink-colored papules and nodules on the face and mucous membranes as well as on the extensor surface of the hands and forearms. They have a polyarthritis that can mimic rheumatoid arthritis clinically. On histologic examination, the papules have characteristic giant cells that are not seen in biopsies of rheumatoid nodules. Pink to skin-colored papules that are firm, 2 to 5 mm in diameter, and often in a linear arrangement are seen in patients with *papular mucinosis*. This disease is also referred to as *lichen myxedematosus* or *scleromyxedema*. The latter name comes from the brawny induration of the face and extremities that may accompany the papular eruption. Biopsy specimens of the

papules show localized mucin deposition, and serum protein electrophoresis demonstrates a monoclonal spike of IgG, usually with a λ light chain.

Yellow Lesions Several systemic disorders are characterized by yellow-colored cutaneous papules or plaques—hyperlipidemia (xanthomas), gout (tophi), diabetes (necrobiosis lipoidica), pseudoxanthoma elasticum, and Torre syndrome (sebaceous tumors). Eruptive xanthomas are the most common form of *xanthomas*, and are associated with hypertriglyceridemia (types I, III, IV, and V). Crops of yellow papules with erythematous halos occur primarily on the extensor surfaces of the extremities and the buttocks, and they spontaneously involute with a fall in serum triglycerides. Increased β-lipoproteins (primarily types II and III) result in one or more of the following types of xanthoma: xanthelasma, tendon xanthomas, and plane xanthomas. Xanthelasma are found on the eyelids, whereas tendon xanthomas are frequently associated with the Achilles and extensor finger tendons; plane xanthomas are flat and favor the palmar creases, face, upper trunk, and scars. Tuberous xanthomas are frequently associated with hypertriglyceridemia, but they are also seen in patients with hypercholesterolemia (type II) and are found most frequently over the large joints or hand. Biopsy specimens of xanthomas show collections of lipid-containing macrophages (foam cells).

Patients with several disorders, including biliary cirrhosis, can have a secondary form of hyperlipidemia with associated tuberous and planar xanthomas. However, patients with myeloma have *normolipemic flat xanthomas*. This latter form of xanthoma may be $\geq$12 cm in diameter and is most frequently seen on the upper trunk or side of the neck. It is important to note that the most common setting for eruptive xanthomas is uncontrolled diabetes mellitus. The least specific sign for hyperlipidemia is xanthelasma, because at least 50% of the patients with this finding have normal lipid profiles.

In *tophaceous gout* there are deposits of monosodium urate in the skin around the joints, particularly those of the hands and feet. Additional sites of *tophi* formation include the helix of the ear and the olecranon and prepatellar bursae. The lesions are firm, yellow in color, and occasionally discharge a chalky material. Their size varies from 1 mm to 7 cm, and the diagnosis can be established by polarization of the aspirated contents of a lesion. Lesions of *necrobiosis lipoidica* are found primarily on the shins (90%), and patients can have diabetes mellitus or develop it subsequently. Characteristic findings include a central yellow color, atrophy (transparency), telangiectasias, and an erythematous border. Ulcerations can also develop within the plaques. Biopsy specimens show necrobiosis of collagen, granulomatous inflammation, and obliterative endarteritis.

In *pseudoxanthoma elasticum* (PXE) there is an abnormal deposition of calcium on the elastic fibers of the skin, eye, and blood vessels. In the skin, the flexural areas such as the neck, axillae, antecubital fossae, and inguinal area are the primary sites of involvement. Yellow papules coalesce to form reticulated plaques that have an appearance similar to that of plucked chicken skin. In severely affected skin, hanging, redundant folds develop. Biopsy specimens of involved skin show swollen and irregularly clumped elastic fibers with deposits of calcium. In the eye, the calcium deposits in Bruch's membrane lead to angioid streaks and choroiditis; in the arteries of the heart, kidney, gastrointestinal tract, and extremities, the deposits lead to angina, hypertension, gastrointestinal bleeding, and claudication, respectively. Long-term administration of D-penicillamine can lead to PXE-like skin changes as well as elastic fiber alterations in internal organs.

Adnexal tumors that have differentiated toward sebaceous glands include sebaceous adenoma, sebaceous carcinoma, and sebaceous hyperplasia. Except for sebaceous hyperplasia, which is commonly seen on the face, these tumors are fairly rare. Patients with Torre syndrome have one or more *sebaceous adenoma(s)*, and they can also have sebaceous carcinomas and sebaceous hyperplasia as well as keratoacanthomas. The internal manifestations of Torre syndrome include *multiple* carcinomas of the gastrointestinal tract (primarily colon) as well as cancers of the larynx, genitourinary tract, and endometrium.

Red Lesions Cutaneous lesions that are red in color have a wide variety of etiologies; in an attempt to simplify their identification, they will be subdivided into papules, papules/plaques, and subcutaneous nodules. Common red papules include *arthropod bites* and *cherry hemangiomas*; the latter are small, bright-red, dome-shaped papules that represent benign proliferation of capillaries. In patients with AIDS, the development of multiple red hemangioma-like lesions points to bacillary angiomatosis, and biopsy specimens show clusters of bacilli that stain positive with the Warthin-Starry stain; the pathogens have been identified as *Bartonella henselae* and *B. quintana*. Disseminated visceral disease is seen primarily in immunocompromised hosts but can occur in immunocompetent individuals.

Multiple *angiokeratomas* are seen in Fabry's disease, an X-linked recessive lysosomal storage disease that is due to a deficiency of α-galactosidase A. The lesions are red to red-blue in color and can be quite small in size (1 to 3 mm), with the most common location being the lower trunk. Associated findings include chronic renal failure, peripheral neuropathy, and corneal opacities (cornea verticillata). Electron photomicrographs of angiokeratomas and clinically normal skin demonstrate lamellar lipid deposits in fibroblasts, pericytes, and endothelial cells that are diagnostic of this disease. Widespread acute eruptions of erythematous papules are discussed in the section on exanthems.

There are several infectious diseases that present as erythematous papules or nodules in a sporotrichoid pattern, that is, in a linear arrangement along the lymphatic channels. The two most common etiologies are *Sporothrix schenckii* (sporotrichosis) and *M. marinum* (atypical mycobacteria). The organisms are introduced as a result of trauma, and a primary inoculation site is often seen in addition to the lymphatic nodules. Additional causes include *Nocardia*, *Leishmania*, and other dimorphic fungi; culture of lesional tissue will aid in the diagnosis.

The diseases that are characterized by erythematous plaques with scale are reviewed in the papulosquamous section, and the various forms of dermatitis are discussed in the section on erythroderma. Additional disorders in the differential diagnosis of red papules/plaques include *erysipelas*, *polymorphous light eruption* (PMLE), *lymphocytoma cutis*, *cutaneous lupus*, *lymphoma cutis*, and *leukemia cutis*. The first three diseases represent primary cutaneous disorders. PMLE is characterized by erythematous papules and plaques in a primarily sun-exposed distribution—dorsum of the hand, extensor forearm, and face. Lesions follow exposure to UV-B and/or UV-A, and in northern latitudes PMLE is most severe in the late spring and early summer. A process referred to as "hardening" occurs with continued UV exposure, and the eruption fades, but in temperate climates it will recur in the spring. PMLE must be differentiated from cutaneous lupus, and this is accomplished by histologic examination and direct immunofluorescence of the lesions. Lymphocytoma cutis (pseudolymphoma) is a *benign* polyclonal proliferation of lymphocytes in the skin that presents as infiltrated pink-red to red-purple papules and plaques; it must be distinguished from lymphoma cutis.

Several types of red plaques are seen in patients with systemic *lupus*, including (1) erythematous urticarial plaques across the cheeks and nose in the classic butterfly rash; (2) erythematous discoid lesions with fine or "carpet-tack" scale, telangiectasias, central hypopigmentation, peripheral hyperpigmentation, follicular plugging, and atrophy located on the face, scalp, external ears, arms, and upper trunk; and (3) psoriasiform or annular lesions of subacute lupus with hypopigmented centers located on the face, extensor arms, and upper trunk. Additional cutaneous findings include (1) a violaceous flush on the face and V of the neck; (2) urticarial vasculitis (see "Urticaria," above); (3) lupus panniculitis (see below); (4) diffuse alopecia; (5) alopecia secondary to discoid lesions; (6) periungual telangiectasias and erythema; (7) EM-like lesions that may become bullous; and (8) distal ulcerations secondary to Raynaud's phenomenon, vasculitis, or livedoid vasculopathy. Patients with only discoid lesions usually have the

form of lupus that is limited to the skin. However, 2 to 10% of these patients eventually develop systemic lupus. Direct immunofluorescence of involved skin shows deposits of IgG or IgM and C3 in a granular distribution along the dermal-epidermal junction.

In *lymphoma cutis* there is a proliferation of malignant lymphocytes or histiocytes in the skin, and the clinical appearance resembles that of lymphocytoma cutis—infiltrated pink-red to red-purple papules and plaques. Lymphoma cutis can occur anywhere on the surface of the skin, whereas the sites of predilection for lymphocytomas include the malar ridge, tip of the nose, and earlobes. Patients with non-Hodgkin's lymphomas have specific cutaneous lesions more often than those with Hodgkin's disease, and occasionally, the skin nodules precede the development of extracutaneous non-Hodgkin's lymphoma or represent the only site of involvement. Arcuate lesions are sometimes seen in lymphoma and lymphocytoma cutis as well as in CTCL. *Leukemia cutis* has the same appearance as lymphoma cutis, and specific lesions are seen more commonly in monocytic leukemias than in lymphocytic or granulocytic leukemias. Cutaneous chloromas (granulocytic sarcomas) may precede the appearance of circulating blasts in acute nonlymphocytic leukemia and, as such, represent a form of aleukemic leukemia cutis.

Common causes of erythematous subcutaneous nodules include inflamed epidermoid inclusion cysts, acne cysts, and furuncles. *Panniculitis*, an inflammation of the fat, also presents as subcutaneous nodules and is frequently a sign of systemic disease. There are several forms of panniculitis, including erythema nodosum, erythema induratum/nodular vasculitis, lupus profundus, lipomembranous lipodermatosclerosis, α_1-antitrypsin deficiency, facticial, and fat necrosis secondary to pancreatic disease. Except for erythema nodosum, these lesions may break down and ulcerate or heal with a scar. The shin is the most common location for the nodules of erythema nodosum, whereas the calf is the most common location for lesions of erythema induratum. In erythema nodosum the nodules are initially red but then develop a blue color as they resolve. Patients with erythema nodosum but no underlying systemic illness can still have fever, malaise, leukocytosis, arthralgias, and/or arthritis. However, the possibility of an underlying illness should be excluded, and the most common associations are streptococcal infections, upper respiratory infections, sarcoidosis, and inflammatory bowel disease. The less common associations include tuberculosis, histoplasmosis, coccidioidomycosis, psittacosis, drugs (oral contraceptives, sulfonamides, aspartame, bromides, iodides), cat-scratch fever, and infections with *Yersinia*, *Salmonella*, and *Chlamydia*.

Erythema induratum and nodular vasculitis share a similar histology and were thought to represent the clinical spectrum of a single entity; subsequently they have been separated, with the latter idiopathic and the former associated with the presence of *M. tuberculosis* DNA by polymerase chain reaction (PCR) in 25 to 70% of patients. The lesions of lupus profundus are found primarily on the upper arms and buttocks (sites of abundant fat) and are seen in both the cutaneous and systemic forms of lupus. The overlying skin may be normal, erythematous, or have the changes of discoid lupus. The subcutaneous fat necrosis that is associated with pancreatic disease is presumably secondary to circulating lipases and is seen in patients with pancreatic carcinoma as well as in patients with acute and chronic pancreatitis. In this disorder there may be an associated arthritis, fever, and inflammation of visceral fat. Histologic examination of deep incisional biopsy specimens will aid in the diagnosis of the particular type of panniculitis.

Subcutaneous erythematous nodules are also seen in *cutaneous polyarteritis nodosa* (PAN) and as a manifestation of *systemic vasculitis*, e.g., systemic PAN, allergic granulomatosis, or Wegener's granulomatosis (Chap. 306). Cutaneous PAN presents with painful subcutaneous nodules and ulcers within a red-purple, netlike pattern of livedo reticularis. The latter is due to slowed blood flow through the superficial horizontal venous plexus. The majority of lesions are found on the lower extremity, and while arthralgias and myalgias may accompany cutaneous PAN, there is no evidence of systemic involvement. In both the cutaneous and systemic forms of vasculitis, skin biopsy specimens of the associated nodules will show the changes characteristic of a vasculitis; the size of the vessel involved will depend on the particular disease.

Red-Brown Lesions The cutaneous lesions in *sarcoidosis* (Chap. 309) are classically red to red-brown in color, and with diascopy (pressure with a glass slide) a yellow-brown residual color is observed that is secondary to the granulomatous infiltrate. The waxy papules and plaques may be found anywhere on the skin, but the face is the most common location. Usually there are no surface changes, but occasionally the lesions will have scale. Biopsy specimens of the papules show "naked" granulomas in the dermis, i.e., granulomas surrounded by a minimal number of lymphocytes. Other cutaneous findings in sarcoidosis include annular lesions with an atrophic or scaly center, papules within scars, hypopigmented macules and papules, alopecia, acquired ichthyosis, erythema nodosum, and lupus pernio (see below).

The differential diagnosis of sarcoidosis includes foreign-body granulomas produced by chemicals such as beryllium and zirconium, late secondary syphilis, and *lupus vulgaris*. Lupus vulgaris is a form of cutaneous tuberculosis that is seen in previously infected and sensitized individuals. There is often underlying active tuberculosis elsewhere, usually in the lungs or lymph nodes. At least 90% of the lesions occur in the head and neck area and are red-brown plaques with a yellow-brown color on diascopy. Secondary scarring and squamous cell carcinomas can develop within the plaques. Cultures or PCR analysis of the lesions should be done because it is rare for the acid-fast stain to show bacilli within the dermal granulomas.

Sweet's syndrome is characterized by red to red-brown plaques and nodules that are frequently painful and occur primarily on the head, neck, and upper extremities. The patients also have fever, neutrophilia, and a dense dermal infiltrate of neutrophils in the lesions. In approximately 10% of the patients there is an associated malignancy, most commonly acute nonlymphocytic leukemia. Sweet's syndrome has also been reported with lymphoma, chronic leukemia, myeloma, myelodysplastic syndromes, and solid tumors (primarily of the genitourinary tract). The differential diagnosis includes neutrophilic eccrine hidradenitis and atypical forms of pyoderma gangrenosum. Extracutaneous sites of involvement include joints, muscles, eye, kidney (proteinuria, occasionally glomerulonephritis), and lung (neutrophilic infiltrates). The idiopathic form of Sweet's syndrome is seen more often in women, following a respiratory tract infection.

A generalized distribution of red-brown macules and papules is seen in the form of mastocytosis known as *urticaria pigmentosa* (Chap. 298). Each lesion represents a collection of mast cells in the dermis, with hyperpigmentation of the overlying epidermis. Stimuli such as rubbing cause these mast cells to degranulate, and this leads to the formation of localized urticaria (Darier's sign). Additional symptoms can result from mast cell degranulation and include headache, flushing, diarrhea, and pruritus. Mast cells also infiltrate various organs such as the liver, spleen, and gastrointestinal tract in up to 30 to 50% of patients with urticaria pigmentosa, and accumulations of mast cells in the bones may produce either osteosclerotic or osteolytic shadows on radiographs. In the majority of these patients, however, the internal involvement remains fairly static. A subtype of chronic leukocytoclastic vasculitis, *erythema elevatum diutinum* (EED), also presents with papules that are red-brown in color. The papules coalesce into plaques on the extensor surfaces of knees, elbows, and the small joints of the hand. Flares of EED have been associated with streptococcal infections.

Blue Lesions Lesions that are blue in color are the result of either vascular ectasias and tumors or melanin pigment in the dermis. *Venous lakes* (ectasias) are compressible dark-blue lesions that are found commonly in the head and neck region. *Venous malformations* are also compressible blue papules and nodules that can occur anywhere on the body, including the oral mucosa. When there are multiple rather

than single congenital lesions, the patient may have the blue rubber bleb syndrome or Mafucci's syndrome. Patients with the blue rubber bleb syndrome also have vascular anomalies of the gastrointestinal tract that may bleed, whereas patients with Mafucci's syndrome have associated dyschondroplasia and osteochondromas. *Blue nevi* (moles) are seen when there are collections of pigment-producing nevus cells in the dermis. These benign papular lesions are dome-shaped and occur most commonly on the dorsum of the hand or foot.

Violaceous Lesions Violaceous papules and plaques are seen in *lupus pernio*, *lymphoma cutis*, and *cutaneous lupus*. Lupus pernio is a particular type of sarcoidosis that involves the tip of the nose and the earlobes, with lesions that are violaceous in color rather than red-brown. This form of sarcoidosis is associated with involvement of the upper respiratory tract. The plaques of lymphoma cutis and cutaneous lupus may be red or violaceous in color and were discussed above.

Purple Lesions Purple-colored papules and plaques are seen in vascular tumors, such as *Kaposi's sarcoma* (Chap. 173) and *angiosarcoma*, and when there is extravasation of red blood cells into the skin in association with inflammation, as in *palpable purpura* (see "Purpura," below). Patients with congenital or acquired AV fistulas and venous hypertension can develop purple papules on the lower extremities that can resemble Kaposi's sarcoma clinically and histologically; this condition is referred to as pseudo-Kaposi sarcoma (acral angiodermatitis). Angiosarcoma is found most commonly on the scalp and face of elderly patients or within areas of chronic lymphedema and presents as purple papules and plaques. In the head and neck region the tumor often extends beyond the clinically defined borders and may be accompanied by facial edema.

Brown and Black Lesions Brown- and black-colored papules are reviewed in "Hyperpigmentation," above.

Cutaneous Metastases These are discussed last because they can have a wide range of colors. Most commonly they present as either firm, skin-colored subcutaneous nodules or firm, red to red-brown papulonodules. The lesions of lymphoma cutis range from pink-red to plum in color, whereas metastatic melanoma can be pink, blue, or black in color. Cutaneous metastases develop from hematogenous or lymphatic spread and are most often due to the following primary carcinomas: in men, lung, colon, melanoma, and oral cavity; and in women, breast, colon, and lung. These metastatic lesions may be the initial presentation of the carcinoma, especially when the primary site is the lung, kidney, or ovary.

PURPURA (Table 48-16) *Purpura* are seen when there is an extravasation of red blood cells into the dermis and, as a result, the lesions do not blanch with pressure. This is in contrast to those erythematous or violet-colored lesions that are due to localized vasodilatation—they do blanch with pressure. Purpura (≥3 mm) and petechiae (≤2 mm) are divided into two major groups, palpable and nonpalpable. The most frequent causes of *nonpalpable* petechiae and purpura are primary cutaneous disorders such as *trauma*, *solar purpura*, and *capillaritis*. Less common causes are *steroid purpura* and *livedoid vasculitis* (see "Ulcers," below). Solar purpura are seen primarily on the extensor forearms, while glucocorticoid purpura secondary to potent topical steroids or endogenous or exogenous Cushing's syndrome can be more widespread. In both cases there is alteration of the supporting connective tissue that surrounds the dermal blood vessels. In contrast, the petechiae that result from capillaritis are found primarily on the lower extremities. In capillaritis there is an extravasation of erythrocytes as a result of perivascular lymphocytic inflammation. The petechiae are bright red, 1 to 2 mm in size, and scattered within annular or coin-shaped yellow-brown macules. The yellow-brown color is caused by hemosiderin deposits within the dermis.

Systemic causes of nonpalpable purpura fall into several categories, and those secondary to clotting disturbances and vascular fragility will be discussed first. The former group includes *thrombocytopenia* (Chap. 101), *abnormal platelet function* as is seen in uremia, and *clotting factor defects*. The initial site of presentation for thrombocytopenia-induced petechiae is the distal lower extremity. Capillary fragility leads to nonpalpable purpura in patients with systemic *amyloidosis* (see "Papulonodular Skin Lesions," above), disorders of collagen production such as *Ehlers-Danlos syndrome*, and *scurvy*. In scurvy there are flattened corkscrew hairs with surrounding hemorrhage on the lower extremities, in addition to gingivitis. Vitamin C is a cofactor for lysyl hydroxylase, an enzyme involved in the posttranslational modification of procollagen that is necessary for cross-link formation.

In contrast to the previous group of disorders, the purpura seen in the following group of diseases are associated with thrombi formation within vessels. It is important to note that these thrombi are demonstrable in skin biopsy specimens. This group of disorders includes disseminated intravascular coagulation (DIC), monoclonal cryoglobulinemia, thrombotic thrombocytopenic purpura, and reactions to warfarin. DIC is triggered by several types of infection (gram-negative, gram-positive, viral, and rickettsial) as well as by tissue injury and neoplasms. Widespread purpura and hemorrhagic infarcts of the distal extremities are seen. Similar lesions are found in purpura fulminans, which is a form of DIC associated with fever and hypotension that occurs more commonly in children following an infectious illness such as varicella, scarlet fever, or an upper respiratory tract infection. In both disorders, hemorrhagic bullae can develop in involved skin.

Monoclonal cryoglobulinemia is associated with multiple myeloma, Waldenström's macroglobulinemia, lymphocytic leukemia, and lymphoma. Purpura, primarily of the lower extremities, and hemorrhagic infarcts of the fingers and toes are seen in these patients. Exacerbations of disease activity can follow cold exposure or an increase in serum viscosity. Biopsy specimens show precipitates of the cryoglobulin within dermal vessels. Similar deposits have been found in the lung, brain, and renal glomeruli. Patients with *thrombotic thrombocytopenic purpura* can also have hemorrhagic infarcts as a result of intravascular thromboses. Additional signs include thrombocytopenic purpura, fever, and microangiopathic hemolytic anemia (Chap. 93).

Administration of *warfarin* can result in painful areas of erythema that become purpuric and then necrotic with an adherent black eschar. This reaction is seen more often in women and in areas with abundant subcutaneous fat—breasts, abdomen, buttocks, thighs, and calves. The erythema and purpura develop between the third and tenth day of therapy, most likely as a result of a transient imbalance in the levels of

TABLE 48-16 Causes of Purpura

I. Primary cutaneous disorders
  A. Nonpalpable
    1. Trauma
    2. Solar purpura
    3. Steroid purpura
    4. Capillaritis
    5. Livedoid vasculitis[a]
II. Systemic diseases
  A. Nonpalpable
    1. Clotting disturbances
      a. Thrombocytopenia (including ITP)
      b. Abnormal platelet function
      c. Clotting factor defects
    2. Vascular fragility
      a. Amyloidosis
      b. Ehlers-Danlos syndrome
      c. Scurvy
    3. Thrombi
      a. Disseminated intravascular coagulation
      b. Monoclonal cryoglobulinemia
      c. Thrombotic thrombocytopenic purpura
      d. Warfarin reaction
    4. Emboli
      a. Cholesterol
      b. Fat
    5. Possible immune complex
      a. Gardner-Diamond syndrome (autoerythrocyte sensitivity)
      b. Waldenström's hypergammaglobulinemic purpura
  B. Palpable
    1. Vasculitis
      a. Leukocytoclastic vasculitis
      b. Polyarteritis nodosa
    2. Emboli[b]
      a. Acute meningococcemia
      b. Disseminated gonococcal infection
      c. Rocky Mountain spotted fever
      d. Ecthyma gangrenosum

[a] Also associated with systemic diseases.
[b] Bacterial, fungal, or parasitic.
Note: ITP, idiopathic thrombocytopenic purpura.

anticoagulant and procoagulant vitamin K–dependent factors. Continued therapy does not exacerbate preexisting lesions, and patients with an inherited or acquired deficiency of protein C are at increased risk for this particular reaction as well as for purpura fulminans.

Purpura secondary to *cholesterol emboli* are usually seen on the lower extremities of patients with atherosclerotic vascular disease. They often follow anticoagulant therapy or an invasive vascular procedure such as an arteriogram but also occur spontaneously from disintegration of atheromatous plaques. Associated findings include livedo reticularis, gangrene, cyanosis, subcutaneous nodules, and ischemic ulcerations. Multiple step sections of the biopsy specimen may be necessary to demonstrate the cholesterol clefts with the vessels. Petechiae are also an important sign of *fat embolism* and occur primarily on the upper body 2 to 3 days after a major injury. By using special fixatives, the emboli can be demonstrated in biopsy specimens of the petechiae. Emboli of tumor or thrombus are seen in patients with atrial myxomas and marantic endocarditis.

In the *Gardner-Diamond syndrome* (autoerythrocyte sensitivity), female patients develop large ecchymoses within areas of painful, warm erythema. Intradermal injections of autologous erythrocytes or phosphatidyl serine derived from the red cell membrane can reproduce the lesions in some patients; however, there are instances where a reaction is seen at an injection site of the forearm but not in the midback region. The latter has led some observers to view Gardner-Diamond syndrome as a cutaneous manifestation of severe emotional stress. *Waldenström's hypergammaglobulinemic purpura* is a chronic disorder characterized by petechiae on the lower extremities. There are circulating complexes of IgG–anti-IgG molecules, and exacerbations are associated with prolonged standing or walking.

Palpable purpura are further subdivided into vasculitic and embolic. In the group of vasculitic disorders, *leukocytoclastic vasculitis* (LCV), also known as *allergic* or *small-vessel vasculitis*, is the one most commonly associated with palpable purpura (Chap. 306). Underlying etiologies include drugs (e.g., antibiotics), infections (e.g., hepatitis C), and connective tissue diseases. *Henoch-Schönlein purpura* is a subtype of acute LCV that is seen primarily in children and adolescents following an upper respiratory infection. The majority of lesions are found on the lower extremities and buttocks. Systemic manifestations include fever, arthralgias (primarily of the knees and ankles), abdominal pain, gastrointestinal bleeding, and nephritis. Direct immunofluorescence examination shows deposits of IgA within dermal blood vessel walls. In *polyarteritis nodosa*, specific cutaneous lesions result from a vasculitis of arterial vessels rather than postcapillary venules as in LCV. The arteritis leads to ischemia of the skin, and this explains the irregular outline of the purpura (see below).

Several types of infectious emboli can give rise to palpable purpura. These embolic lesions are usually *irregular* in outline as opposed to the lesions of LCV, which are *circular* in outline. The irregular outline is indicative of a cutaneous infarct, and the size corresponds to the area of skin that received its blood supply from that particular arteriole or artery. The palpable purpura in LCV are circular because the erythrocytes simply diffuse out evenly from the postcapillary venules as a result of inflammation. Infectious emboli are most commonly due to gram-negative cocci (meningococcus, gonococcus), gram-negative rods (Enterobacteriaceae), and gram-positive cocci (*Staphylococcus*). Additional causes include *Rickettsia* and, in immunocompromised patients, *Candida* and opportunistic fungi.

The embolic lesions in *acute meningococcemia* are found primarily on the trunk, lower extremities, and sites of pressure, and a gunmetal-gray color often develops within them. Their size varies from 1 mm to several centimeters, and the organisms can be cultured from the lesions. Associated findings include a preceding upper respiratory tract infection, fever, meningitis, DIC, and, in some patients, a deficiency of the terminal components of complement. In *disseminated gonococcal infection* (arthritis-dermatitis syndrome), a small number of papules and vesicopustules with central purpura or hemorrhagic necrosis are found on the distal extremities. Additional symptoms include arthralgias, tenosynovitis, and fever. To establish the diagnosis, a Gram stain of these lesions should be performed. *Rocky Mountain spotted fever* is a tick-borne disease that is caused by *R. rickettsii*. A several-day history of fever, chills, severe headache, and photophobia precedes the onset of the cutaneous eruption. The initial lesions are erythematous macules and papules on the wrists, ankles, palms, and soles. With time, the lesions spread centripetally and become purpuric.

Lesions of *ecthyma gangrenosum* begin as edematous, erythematous papules or plaques and then develop central purpura and necrosis. Bullae formation also occurs in these lesions, and they are frequently found in the girdle region. The organism that is classically associated with ecthyma gangrenosum is *Pseudomonas aeruginosa*, but other gram-negative rods such as *Klebsiella*, *Escherichia coli*, and *Serratia* can produce similar lesions. In immunocompromised hosts, the list of potential pathogens is expanded to include *Candida* and opportunistic fungi.

ULCERS The approach to the patient with a cutaneous ulcer is outlined in Table 48-17. →***Peripheral vascular diseases of the extremities are reviewed in Chap. 232, as is Raynaud's phenomenon.***

Livedoid vasculitis (atrophie blanche) represents a combination of a vasculopathy with intravascular thrombosis. Purpuric lesions and livedo reticularis are found in association with painful ulcerations of the lower extremities. These ulcers are often slow to heal, but when they do, irregularly shaped white scars are formed. The majority of cases are secondary to venous hypertension, but possible underlying illnesses include cryofibrinogenemia and disorders of hypercoagulability, e.g., the antiphospholipid syndrome (Chaps. 102 and 300).

In *pyoderma gangrenosum*, the border of the ulcers has a characteristic appearance of an undermined necrotic violaceous edge and a peripheral erythematous halo. The ulcers often begin as pustules that then expand rather rapidly to a size as large as 20 cm. Although these lesions are most commonly found on the lower extremities, they can arise anywhere on the surface of the body, including sites of trauma (pathergy). An estimated 30 to 50% of cases are idiopathic, and the

most common associated disorders are ulcerative colitis and Crohn's disease. Less commonly, it is associated with chronic active hepatitis, seropositive rheumatoid arthritis, acute and chronic granulocytic leukemia, polycythemia vera, and myeloma. Additional findings in these patients, even those with idiopathic disease, are cutaneous anergy and a benign monoclonal gammopathy. Because the histology of pyoderma gangrenosum is nonspecific, the diagnosis is made clinically by excluding less common causes of similar-appearing ulcers such as necrotizing vasculitis, Meleney's ulcer (synergistic infection at a site of trauma or surgery), dimorphic fungi, cutaneous amebiasis, spider bites, and facticial. In the myeloproliferative disorders, the ulcers may be more superficial with a pustulobullous border, and these lesions provide a connection between classic pyoderma gangrenosum and acute febrile neutrophilic dermatosis (Sweet's syndrome).

FEVER AND RASH The major considerations in a patient with a fever and a rash are inflammatory diseases versus infectious diseases. In the hospital setting, the most common scenario is a patient who has a drug rash plus a fever secondary to an underlying infection. However, it should be emphasized that a drug reaction can lead to both a cutaneous eruption and a fever ("drug fever"). Additional inflammatory diseases that are often associated with a fever include pustular psoriasis, erythroderma, and Sweet's syndrome. Lyme disease, secondary syphilis, and viral and bacterial exanthems (see "Exanthems," above) are examples of infectious diseases that produce a rash and a fever. Lastly, it is important to determine whether or not the cutaneous lesions represent septic emboli (see "Purpura," above). Such lesions usually have evidence of ischemia in the form of purpura, necrosis, or impending necrosis (gunmetal-gray color). In the patient with thrombocytopenia, however, purpura can be seen in inflammatory reactions such as morbilliform drug eruptions and infectious lesions.

49 IMMUNOLOGICALLY MEDIATED SKIN DISEASES

Kim B. Yancey, Thomas J. Lawley

A number of immunologically mediated skin diseases and immunologically mediated systemic disorders with cutaneous manifestations are now recognized as distinct entities with consistent clinical, histologic, and immunopathologic findings. Many of these disorders are due to autoimmune mechanisms. Clinically, they are characterized by morbidity (pain, pruritus, disfigurement) and in some instances by mortality (largely due to loss of epidermal barrier function and/or secondary infection). The major features of the more common immunologically mediated skin diseases are summarized in this chapter (Table 49-1).

PEMPHIGUS VULGARIS Pemphigus vulgaris (PV) is a blistering skin disease seen predominantly in elderly patients. Patients with PV have an increased incidence of the HLA-DR4 and -DRw6 serologically defined haplotypes. This disorder is characterized by the loss of cohesion between epidermal cells (a process termed *acantholysis*) with the resultant formation of intraepidermal blisters. Clinical lesions of PV typically consist of flaccid blisters on either normal-appearing or erythematous skin. These blisters rupture easily, leaving denuded areas that may crust and enlarge peripherally (Fig. 49-1). Substantial portions of the body surface may be denuded in severe cases. Manual pressure to the skin of these patients may elicit the separation of the epidermis (Nikolsky's sign). This finding, while characteristic of PV, is not specific to this disorder and is also seen in toxic epidermal necrolysis, Stevens-Johnson syndrome, and a few other skin diseases. Lesions in PV typically present on the oral mucosa, scalp, face, neck, axilla, and trunk. In most patients, lesions begin in the mouth; involvement of other mucosal surfaces (e.g., pharyngeal, laryngeal, esophageal, conjunctival, vulval, or rectal) can occur in severe disease. Pruritus may be a feature of early pemphigus lesions; extensive denudation may be associated with severe pain. Lesions usually heal without scarring, except at sites complicated by secondary infection or mechanically induced dermal wounds. Nonetheless, postinflammatory hyperpigmentation is usually present at sites of healed lesions for some time.

Biopsies of early lesions demonstrate intraepidermal vesicle formation secondary to loss of cohesion between epidermal cells (i.e., acantholytic blisters). Blister cavities contain acantholytic epidermal cells, which appear as round homogeneous cells containing hyperchromatic nuclei. Basal keratinocytes remain attached to the epidermal basement membrane, hence blister formation is within the suprabasal portion of the epidermis. Lesional skin may contain focal collections of intraepidermal eosinophils within blister cavities; dermal alterations are slight, often limited to an eosinophil-predominant leukocytic infiltrate. Direct immunofluorescence microscopy of lesional or intact patient skin shows deposits of IgG on the surface of keratinocytes; in contrast, deposits of complement components are typically found in lesional but not uninvolved skin. Deposits of IgG on keratinocytes are derived from circulating autoantibodies directed against cell-surface antigens. Circulating autoantibodies can be demonstrated in 80 to 90% of PV patients by indirect immunofluorescence microscopy; monkey esophagus is the optimal substrate for these studies. Patients with PV have IgG autoantibodies directed against *desmogleins* (Dsgs), transmembrane desmosomal glycoproteins that belong to the cadherin supergene family of calcium-dependent adhesion molecules. Such autoantibodies can now be precisely quantitated by enzyme-linked immunosorbent assay (ELISA). Most patients with early PV (i.e., only mucosal involvement) have only anti-Dsg3 autoantibodies; most patients with advanced disease (i.e., involvement of skin and mucosa) have both anti-Dsg3 and anti-Dsg1 autoantibodies. Recent studies have shown that the anti-Dsg autoantibody profile in these patients' sera as well as the tissue distribution of Dsg3 and Dsg1 determine the site of blister formation in patients with pemphigus. Experimental studies have also shown that these autoantibodies are pathogenic (i.e., responsible for blister formation) and that their titer correlates with disease activity.

PV can be life-threatening. Prior to the availability of glucocorticoids, the mortality ranged from 60 to 90%; the current mortality is approximately 5%. Common causes of morbidity and mortality are infection and complications of treatment with glucocorticoids. Bad prognostic factors include advanced age, widespread involvement, and the requirement for high doses of glucocorticoids (with or without other immunosuppressive agents) for control of disease. The course of PV in individual patients is variable and difficult to predict. Some patients achieve remission (40% of patients in some series), but others may require long-term treatment or succumb to complications of their disease or its treatment. The mainstay of treatment is systemic glucocorticoids. Patients with moderate to severe disease are usually started on prednisone, 60 to 80 mg/d. If new lesions continue to appear

TABLE 49-1 *Immunologically Mediated Blistering Diseases*

Disease	Clinical	Histology	Immunopathology	Autoantigens[a]
Pemphigus foliaceus	Crusts and shallow erosions on scalp, central face, upper chest, and back	Acantholytic blister formed in superficial layer of epidermis	Cell surface deposits of IgG on keratinocytes	Dsg1
Pemphigus vulgaris	Flaccid blisters, denuded skin, oromucosal lesions	Acantholytic blister formed in suprabasal layer of epidermis	Cell surface deposits of IgG on keratinocytes	Dsg3 (plus Dsg1 in patients with skin involvement)
Bullous pemphigoid	Large tense blisters on flexor surfaces and trunk	Blister formed in subepidermal region; usually eosinophil-rich infiltrate	Linear band of IgG and/or C3 in epidermal BMZ[a]	BPAG1, BPAG2
Pemphigoid gestationis	Pruritic, urticarial plaques, rimmed by vesicles and bullae on the trunk and extremities	Teardrop-shaped, subepidermal blisters in dermal papillae; eosinophil-rich infiltrate	Linear band of C3 in epidermal BMZ	BPAG2 (plus BPAG1 in some patients)
Linear IgA disease	Pruritic small papules on extensor surfaces; occasionally larger, arciform blisters	Subepidermal blister with neutrophils in dermal papillae	Linear band of IgA in epidermal BMZ	BPAG2 (see text for specific details)
Cicatricial pemphigoid	Erosive and/or blistering lesions of mucous membranes and possibly the skin; scarring of some sites	Subepidermal blister that may or may not include a leukocytic infiltrate	Linear band of IgG, IgA, and/or C3 in epidermal BMZ	BPAG2, laminin 5, or others
Epidermolysis bullosa acquisita	Blisters, erosions, scars, and milia on sites exposed to trauma; widespread, inflammatory, tense blisters may be seen initially	Subepidermal blister that may or may not include a leukocytic infiltrate	Linear band of IgG and/or C3 in epidermal BMZ	Type VII collagen
Dermatitis herpetiformis	Extremely pruritic small papules and vesicles on elbows, knees, buttocks, and posterior neck	Subepidermal blister with neutrophils in dermal papillae	Granular deposits of IgA in dermal papillae	Epidermal transglutaminase

[a] Autoantigens bound by these patients' autoantibodies are defined as follows: Dsg1, desmoglein 1; Dsg3, desmoglein 3; BPAG1, bullous pemphigoid antigen 1; BPAG2, bullous pemphigoid antigen 2; BMZ, basement membrane zone.

after 1 to 2 weeks of treatment, the dose may need to be increased. Many regimens combine an immunosuppressive agent with systemic glucocorticoids for control of PV. The most frequently used are either azathioprine (1 to 2 mg/kg per day), or mycophenolate mofetil (20 to 35 mg/kg per day), cyclophosphamide (1 to 2 mg/kg per day). It is important to bring severe or progressive disease under control quickly to lessen the severity and/or duration of this disorder.

PEMPHIGUS FOLIACEUS Pemphigus foliaceus (PF) is distinguished from PV by several features. In PF, acantholytic blisters are located high within the epidermis, usually just beneath the stratum corneum. Hence PF is a more superficial blistering disease than PV. The distribution of lesions in the two disorders is much the same, except that in PF mucous membranes are almost always spared. Patients with PF rarely demonstrate intact blisters but rather exhibit shallow erosions associated with erythema, scale, and crust formation. Mild cases of PF resemble severe seborrheic dermatitis; severe PF may cause extensive exfoliation. Sun exposure (ultraviolet irradiation) may be an aggravating factor. A blistering skin disease endemic to south central Brazil known as *fogo selvagem*, or *Brazilian pemphigus*, is clinically, histologically, and immunopathologically indistinguishable from PF.

Patients with PF have immunopathologic features in common with PV. Specifically, direct immunofluorescence microscopy of perilesional skin demonstrates IgG on the surface of keratinocytes. As in PV, patients with PF frequently have circulating IgG autoantibodies against keratinocyte cell surface antigens. Guinea pig esophagus is the optimal substrate for indirect immunofluorescence microscopy studies of sera from patients with PF. In PF, autoantibodies are directed against Dsg1, a 160-kDa desmosomal cadherin. As noted for PV, the autoantibody profile in patients with PF (i.e., anti-Dsg1) and the normal tissue distribution of this autoantigen (i.e., low expression in oral mucosa) is thought to account for the distribution of lesions in this disease.

Although pemphigus has been associated with several autoimmune diseases, its association with thymoma and/or myasthenia gravis is particularly notable. To date, more than 30 cases of thymoma and/or myasthenia gravis have been reported in association with pemphigus, usually with PF. Patients may also develop pemphigus as a consequence of drug exposure. The most frequently implicated agent is penicillamine; other offenders include captopril, rifampin, piroxicam, penicillin, and phenobarbital. Drug-induced pemphigus usually resembles PF rather than PV; autoantibodies in these patients have the same antigenic specificity as they do in other pemphigus patients. In most patients, lesions resolve following discontinuation of the drug; however, some patients require treatment with systemic glucocorticoids and/or immunosuppressive agents.

PF is generally a far less severe disease than PV and carries a better prognosis. Localized disease can be treated conservatively with topical or intralesional glucocorticoids; more active cases can usually be controlled with systemic glucocorticoids.

PARANEOPLASTIC PEMPHIGUS Paraneoplastic pemphigus (PNP) is an autoimmune acantholytic mucocutaneous disease associated with an occult or confirmed neoplasm. Patients with PNP typically show painful mucosal erosive lesions in association with papulosquamous eruptions that often progress to blisters. Palm and sole involvement is common in these patients and raises the possibility that prior reports of neoplasia-associated erythema multiforme actually may have represented unrecognized cases of PNP. Biopsies of lesional skin from these patients show varying combinations of acantholysis, keratinocyte necrosis, and vacuolar-interface dermatitis. Direct immunofluorescence microscopy of patient skin shows deposits of IgG and complement on the surface

B

FIGURE 49-1 *A.* Pemphigus vulgaris demonstrating flaccid bullae that are easily ruptured, resulting in multiple erosions and crusted plaques. *B.* Pemphigus vulgaris almost invariably involves the oral mucosa and may present with erosions involving the gingiva, buccal mucosa, palate, posterior pharynx, or the tongue. (*B*, Courtesy of Robert Swerlick, MD.)

of keratinocytes and (variably) similar immunoreactants in the epidermal basement membrane zone. Patients with PNP have IgG autoantibodies against cytoplasmic proteins that are members of the plakin family (e.g., desmoplakins I and II, bullous pemphigoid antigen 1, envoplakin, periplakin, and plectin) and cell-surface proteins that are members of the cadherin family (e.g., Dsg3). Because immunoadsorption of anti-Dsg3 IgG is sufficient to eliminate the ability of PNP sera to induce blisters in an experimental passive transfer animal model, these particular autoantibodies are thought to play the key pathogenic role in blister formation in these patients.

Although PNP is generally resistant to conventional therapies (i.e., those used to treat PV), patients may improve (or even remit) following resection of underlying neoplasms. The predominant neoplasms associated with this disorder are non-Hodgkin's lymphoma, chronic lymphocytic leukemia, Castleman's disease, thymoma, and spindle cell tumors.

BULLOUS PEMPHIGOID Bullous pemphigoid (BP) is an autoimmune subepidermal blistering disease usually seen in the elderly. Lesions typically consist of tense blisters on either normal-appearing or erythematous skin (Fig. 49-2). The lesions are usually distributed over the lower abdomen, groin, and flexor surface of the extremities; oral mucosal lesions are found in 10 to 40% of patients. Pruritus may be nonexistent or severe. As lesions evolve, tense blisters tend to rupture and be replaced by flaccid lesions or erosions with or without surmounting crust. Nontraumatized blisters heal without scarring. The major histocompatibility complex class II allele HLA-DQβ1*0301 is prevalent in patients with BP. Despite isolated reports, several studies have shown that patients with BP do not have an increased incidence of malignancy in comparison with appropriately age- and gender-matched controls.

While biopsies of early lesional skin demonstrate subepidermal blisters, the histologic features depend on the character of the particular lesion. Lesions on normal-appearing skin generally show a sparse perivascular leukocytic infiltrate with some eosinophils; conversely, biopsies of inflammatory lesions typically show an eosinophil-rich infiltrate within the papillary dermis at sites of vesicle formation and in perivascular areas. In addition to eosinophils, cell-rich lesions also contain mononuclear cells and neutrophils. It is not always possible to distinguish BP from other subepidermal blistering diseases by routine histologic techniques.

Immunopathologic studies have broadened our understanding of this disease and aided its diagnosis. Direct immunofluorescence microscopy of normal-appearing perilesional skin shows linear deposits of IgG and/or C3 in the epidermal basement membrane. The sera of approximately 70% of these patients contain circulating IgG autoantibodies that bind the epidermal basement membrane of normal human skin in indirect immunofluorescence microscopy. An even higher percentage of patients shows reactivity to the epidermal side of 1 *M* NaCl split skin [an alternative immunofluorescence microscopy test substrate that is commonly used to distinguish circulating IgG anti-basement membrane autoantibodies in patients with BP from those in patients with similar, yet different, subepidermal blistering diseases (e.g., epidermolysis bullosa acquisita, see below)]. No correlation exists between the titer of these autoantibodies and disease activity. In BP, circulating autoantibodies recognize 230- and 180-kDa hemidesmosome-associated proteins in basal keratinocytes [i.e., bullous pemphigoid antigen (BPAG)1 and BPAG2, respectively]. Autoantibodies are thought to develop against these antigens (more specifically, initially against BPAG2), deposit in situ, and activate complement that subsequently produces dermal mast cell degranulation and granulocyte-rich infiltrates that cause tissue damage and blister formation.

BP may persist for months to years, with exacerbations or remissions. Although extensive involvement may result in widespread erosions and compromise cutaneous integrity, the mortality rate is rela-

FIGURE 49-2 Bullous pemphigoid with tense vesicles and bullae on erythematous, urticarial bases. (Courtesy of the Yale Resident's Slide Collection.)

tively low. Nonetheless, deaths may occur in elderly and/or debilitated patients. The mainstay of treatment is systemic glucocorticoids. Patients with local or minimal disease can sometimes be controlled with topical glucocorticoids alone; patients with more extensive lesions generally respond to systemic glucocorticoids either alone or in combination with immunosuppressive agents. Patients will usually respond to prednisone, 40 to 60 mg/d. In some instances, azathioprine (1 to 2 mg/kg per day), mycophenolate mofetil (20 to 35 mg/kg per day), or cyclophosphamide (1 to 2 mg/kg per day) are necessary adjuncts.

PEMPHIGOID GESTATIONIS Pemphigoid gestationis (PG), also known as *herpes gestationis*, is a rare, nonviral, subepidermal blistering disease of pregnancy and the puerperium. PG may begin during any trimester of pregnancy or present shortly after delivery. Lesions are usually distributed over the abdomen, trunk, and extremities; mucous membrane lesions are rare. Skin lesions in these patients may be quite polymorphic and consist of erythematous urticarial papules and plaques, vesiculopapules, and/or frank bullae. Lesions are almost always very pruritic. Severe exacerbations of PG frequently occur after delivery, typically within 24 to 48 h. PG tends to recur in subsequent pregnancies, often beginning earlier during such gestations. Brief flare-ups of disease may occur with resumption of menses and may develop in patients later exposed to oral contraceptives. Occasionally, infants of affected mothers demonstrate transient skin lesions.

Biopsies of early lesional skin show teardrop-shaped subepidermal vesicles forming in dermal papillae in association with an eosinophil-rich leukocytic infiltrate. Differentiation of PG from other subepidermal bullous diseases by light microscopy is often difficult. However, direct immunofluorescence microscopy of perilesional skin from PG patients reveals the immunopathologic hallmark of this disorder—linear deposits of C3 in the epidermal basement membrane zone. These deposits develop as a consequence of complement activation produced by low titer IgG anti-basement membrane zone autoantibodies. Recent studies have shown that the majority of PG sera contain autoantibodies that recognize BPAG2, the same 180-kDa hemidesmosome-associated protein that is targeted by autoantibodies in patients with BP—a subepidermal bullous disease that resembles PG morphologically, histologically, and immunopathologically.

The goals of therapy in patients with PG are to prevent the development of new lesions, relieve intense pruritus, and care for erosions at sites of blister formation. Most patients require treatment with moderate doses of daily glucocorticoids (i.e., 20 to 40 mg of prednisone) at some point in their course. Mild cases (or brief flare-ups) may be controlled by vigorous use of potent topical glucocorticoids. Although PG was once thought to be associated with an increased risk of fetal morbidity and mortality, the best evidence now suggests that these infants are only at increased risk of being slightly premature or "small for dates." Current evidence suggests that there is no difference in the incidence of uncomplicated live births in PG patients treated with systemic glucocorticoids and in those managed more conservatively. If systemic glucocorticoids are administered, newborns are at risk for development of reversible adrenal insufficiency.

DERMATITIS HERPETIFORMIS Dermatitis herpetiformis (DH) is an intensely pruritic, papulovesicular skin disease characterized by lesions symmetrically distributed over extensor surfaces (i.e., elbows, knees, buttocks, back, scalp, and posterior neck) (see Fig. 46-8). The primary lesion in this disorder is a papule, papulovesicle, or urticarial plaque. Because pruritus is prominent, patients may present with excoriations and crusted papules but no observable primary lesions. Patients sometimes report that their pruritus has a distinctive burning or stinging component; the onset of such local symptoms reliably heralds the development of distinct clinical lesions 12 to 24 h later. Almost all DH patients have an associated, usually subclinical, gluten-sensitive enteropathy (Chap. 275), and more than 90% express the HLA-B8/DRw3 and HLA-DQw2 haplotypes. DH may present at any age, including childhood; onset in the second to fourth decades is most common. The disease is typically chronic.

Biopsy of early lesional skin reveals neutrophil-rich infiltrates within dermal papillae. Neutrophils, fibrin, edema, and microvesicle formation at these sites are characteristic of early disease. Older lesions may demonstrate nonspecific features of a subepidermal bulla or an excoriated papule. Because the clinical and histologic features of this disease can be variable and resemble other subepidermal blistering disorders, the diagnosis is confirmed by direct immunofluorescence microscopy of normal-appearing perilesional skin. Such studies demonstrate granular deposits of IgA (with or without complement components) in the papillary dermis and along the epidermal basement membrane zone. IgA deposits in the skin are unaffected by control of disease with medication; however, these immunoreactants may diminish in intensity or disappear in patients maintained for long periods on a strict gluten-free diet (see below). Patients with DH have granular deposits of IgA in their epidermal basement membrane zone and should be distinguished from individuals with linear IgA deposits at this site (see below).

Although most DH patients do not report overt gastrointestinal symptoms or have laboratory evidence of malabsorption, biopsies of small bowel usually reveal blunting of intestinal villi and a lymphocytic infiltrate in the lamina propria. As is true for patients with celiac disease, this gastrointestinal abnormality can be reversed by a gluten-free diet. Moreover, if maintained, this diet alone may control the skin disease and eventuate in clearance of IgA deposits from these patients' epidermal basement membrane zone. Subsequent gluten exposure in such patients alters the morphology of their small bowel, elicits a flare-up of their skin disease, and is associated with the reappearance of IgA in their epidermal basement membrane zone. As in patients with celiac disease, dietary gluten sensitivity in patients with DH is associated with IgA anti-endomysial autoantibodies that target tissue transglutaminase. Recent studies suggest that patients with DH also have high-avidity IgA autoantibodies against epidermal transglutaminase and that the latter is co-localized with granular deposits of IgA in the papillary dermis of DH patients. Patients with DH also have an increased incidence of thyroid abnormalities, achlorhydria, atrophic gastritis, and antigastric parietal cell antibodies. These associations likely relate to the high frequency of the HLA-B8/DRw3 haplotype in these patients, since this marker is commonly linked to autoimmune disorders. The mainstay of treatment of DH is dapsone, a sulfone. Patients respond rapidly (24 to 48 h) to dapsone (50 to 200 mg/d) but require careful pretreatment evaluation and close follow-up to ensure that complications are avoided or controlled. All patients on more than 100 mg/d dapsone will have some hemolysis and methemoglobinemia. These are expected pharmacologic side effects of this agent. Gluten restriction can control DH and lessen dapsone requirements; this diet must rigidly exclude gluten to be of maximal benefit. Many months of dietary restriction may be necessary before a beneficial result is achieved. Good dietary counselling by a trained dietitian is essential.

LINEAR IGA DISEASE Linear IgA disease, once considered a variant form of dermatitis herpetiformis, is actually a separate and distinct entity. Clinically, these patients may resemble patients with typical cases of DH, BP, or other subepidermal blistering diseases. Lesions typically consist of papulovesicles, bullae, and/or urticarial plaques, predominantly on extensor (as seen in "classic" DH), central, or flexural sites. Oral mucosal involvement occurs in some patients. Severe pruritus resembles that in patients with DH. Patients with linear IgA disease do not have an increased frequency of the HLA-B8/DRw3 haplotype or an associated enteropathy and hence are not candidates for a gluten-free diet.

The histologic alterations in early lesions may be virtually indistinguishable from those in DH. However, direct immunofluorescence microscopy of normal-appearing perilesional skin reveals linear deposits of IgA (and often C3) in the epidermal basement membrane zone. Most patients with linear IgA disease demonstrate circulating IgA anti-basement membrane autoantibodies against epitopes in the

extracellular domain of BPAG2, a transmembrane protein found in hemidesmosomes of basal keratinocytes. These patients generally respond to treatment with dapsone, 50 to 200 mg/d.

EPIDERMOLYSIS BULLOSA ACQUISITA EBA is a rare, noninherited, polymorphic, chronic, subepidermal blistering disease. (The inherited form is discussed in Chap. 342.) Patients with classic or noninflammatory EBA have blisters on noninflamed skin, atrophic scars, milia, nail dystrophy, and oral lesions. Because lesions generally occur at sites exposed to minor trauma, classic EBA is considered to be a mechanobullous disease. Other patients with EBA have widespread inflammatory, scarring, and bullous lesions that resemble severe BP. Inflammatory EBA may evolve into the classic, noninflammatory form of this disease. Rare patients present with lesions that predominate on mucous membranes. The HLA-DR2 haplotype is found with increased frequency in EBA patients. Recent studies suggest that EBA is often associated with inflammatory bowel disease (especially Crohn's disease).

The histology of lesional skin varies depending on the character of the lesion being studied. Noninflammatory bullae show subepidermal blisters with a sparse leukocytic infiltrate and resemble those in patients with porphyria cutanea tarda. Inflammatory lesions consist of a subepidermal blister and neutrophil-rich leukocytic infiltrates in the superficial dermis. EBA patients have continuous deposits of IgG (and frequently C3 as well as other complement components) in a linear pattern within the epidermal basement membrane zone. Ultrastructurally, these immunoreactants are found in the sublamina densa region in association with anchoring fibrils, wheat stack–like structures that extend from the lamina densa into the underlying papillary dermis. Approximately 50% of EBA patients have circulating IgG anti-basement membrane autoantibodies directed against type VII collagen—the collagen species that comprises anchoring fibrils. Such IgG autoantibodies bind the dermal side of 1 *M* NaCl split skin (in contrast to IgG autoantibodies in patients with BP that bind either epidermal or both sides of this indirect immunofluorescence microscopy test substrate).

Treatment of EBA is generally unsatisfactory. Some patients with inflammatory EBA may respond to systemic glucocorticoids, either alone or in combination with immunosuppressive agents. Other patients (especially those with neutrophil-rich inflammatory lesions) may respond to dapsone. The chronic, noninflammatory form of this disease is largely resistant to treatment, although some patients may respond to cyclosporine or intravenous immunoglobulin.

CICATRICIAL PEMPHIGOID Cicatricial pemphigoid (CP) is a rare, acquired, subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring of at least some sites of involvement. Immunopathologically, perilesional mucosa and skin of patients with CP demonstrate in situ deposits of immunoreactants in epithelial basement membranes. Common sites of involvement include the oral mucosa (especially the gingiva) and conjunctiva; other sites that may be affected include the nasopharyngeal, laryngeal, esophageal, urogenital, and rectal mucosa. Skin lesions (present in about one-third of patients) tend to predominate on the scalp, face, and upper trunk and generally consist of a few scattered erosions or tense blisters on an erythematous or urticarial base. CP is typically a chronic and progressive disorder. Serious complications may arise as a consequence of ocular, laryngeal, esophageal, or urogenital lesions. Erosive conjunctivitis may result in shortened fornices, symblephara, ankyloblepharon, entropion, corneal opacities, and (in severe cases) blindness. Similarly, erosive lesions of the larynx may cause hoarseness, pain, and tissue loss that if unrecognized and untreated may eventuate in complete destruction of the airway. Esophageal lesions may result in stenosis and/or strictures that may place patients at risk for aspiration. Strictures may also complicate urogenital involvement.

Biopsies of lesional tissue generally demonstrate subepithelial vesiculobullae and a mononuclear leukocytic infiltrate. Neutrophils and eosinophils may be seen in biopsies of early lesions; older lesions may demonstrate a scant leukocytic infiltrate and fibrosis. Direct immunofluorescence microscopy of perilesional tissue typically demonstrates deposits of IgG, IgA, and/or C3 in these patients' epithelial basement membranes. Because many of these patients show no evidence of circulating anti-basement membrane autoantibodies, testing of perilesional skin is important diagnostically. Although CP was once thought to be a single nosologic entity, it is now largely regarded as a disease phenotype that may develop as a consequence of an autoimmune reaction against a variety of different molecules in epithelial basement membranes (e.g., BPAG2, laminin 5, type VII collagen, and other antigens yet to be completely defined). Treatment of CP is largely dependent upon sites of involvement. Due to potentially severe complications, ocular, laryngeal, esophageal, and/or urogenital involvement require aggressive systemic treatment with dapsone, prednisone, or the latter in combination with another immunosuppressive agent (e.g., azathioprine, mycophenolate mofetil, or cyclophosphamide) or intravenous immunoglobulin. Less threatening forms of the disease may be managed with topical or intralesional glucocorticoids.

AUTOIMMUNE SYSTEMIC DISEASES WITH PROMINENT CUTANEOUS FEATURES

DERMATOMYOSITIS The cutaneous manifestations of dermatomyositis (Chap. 369) are often distinctive but at times may resemble those of systemic lupus erythematosus (SLE) (Chap. 300), scleroderma (Chap. 303), or other overlapping connective tissue diseases (Chap. 303). The extent and severity of cutaneous disease may or may not correlate with the extent and severity of the myositis. The cutaneous manifestations of dermatomyositis are similar whether the disease appears in childhood or old age, except that calcification of subcutaneous tissue is a common late sequela in childhood dermatomyositis.

The cutaneous signs of dermatomyositis may precede or follow the development of myositis by weeks to years. Cases lacking muscle involvement (i.e., dermatomyositis sine myositis) have also been reported. The most common manifestation is a purple-red discoloration of the upper eyelids, sometimes associated with scaling ("heliotrope" erythema; Fig. 49-3) and periorbital edema. Erythema on the cheeks and nose in a "butterfly" distribution may resemble the eruption in SLE. Erythematous or violaceous scaling patches are common on the upper anterior chest, posterior neck, scalp, and the extensor surfaces of the arms, legs, and hands. Erythema and scaling may be particularly prominent over the elbows, knees, and the dorsal interphalangeal joints. Approximately one-third of patients have violaceous, flat-topped papules over the dorsal interphalangeal joints that are pathognomonic of dermatomyositis (Gottron's sign or Gottron's papules; Fig. 49-4). These lesions can be contrasted with the erythema and scaling

FIGURE 49-3 Dermatomyositis Periorbital violaceous erythema characterizes the classic heliotrope rash. (Courtesy of James Krell, MD.)

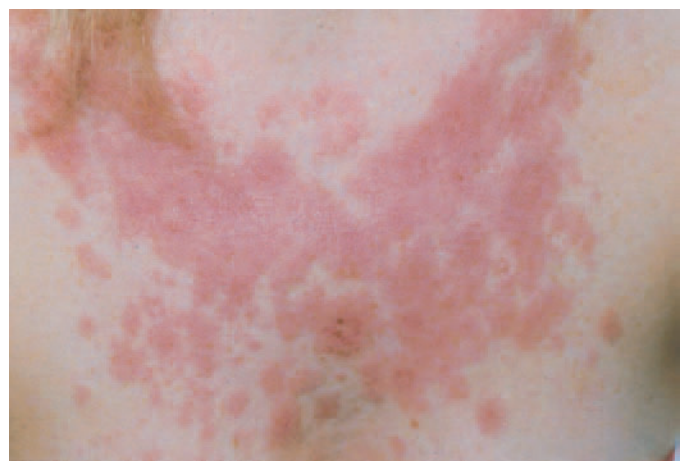
FIGURE 49-4 Dermatomyositis often involves the hands as erythematous flat-topped papules over the knuckles (Gottron's sign) and periungual telangiectasias.

on the dorsum of the fingers in some patients with SLE, which spares the skin over the interphalangeal joints. Periungual telangiectasia may be prominent, and a lacy or reticulated erythema may be associated with fine scaling on the extensor surfaces of the thighs and upper arms. Other patients, particularly those with long-standing disease, develop areas of hypopigmentation, hyperpigmentation, mild atrophy, and telangiectasia known as *poikiloderma*. Poikiloderma is rare in both SLE and scleroderma and thus can serve as a clinical sign that distinguishes dermatomyositis from these two diseases. Cutaneous changes may be similar in scleroderma and dermatomyositis and may include thickening and binding down of the skin of the hands (sclerodactyly) as well as Raynaud's phenomenon. However, the presence of severe muscle disease, Gottron's papules, heliotrope erythema, and poikiloderma serve to distinguish patients with dermatomyositis. Skin biopsy of erythematous, scaling lesions of dermatomyositis may reveal only mild nonspecific inflammation but sometimes may show changes indistinguishable from those found in SLE, including epidermal atrophy, hydropic degeneration of basal keratinocytes, edema of the upper dermis, and a mild mononuclear cell infiltrate. Direct immunofluorescence microscopy of lesional skin is usually negative, although granular deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone have been described in some patients. Treatment should be directed at the systemic disease. In the few instances where adjunctive cutaneous therapy is desirable, topical glucocorticoids are sometimes useful. These patients should avoid exposure to ultraviolet irradiation and use photoprotective measures such as sunscreens.

LUPUS ERYTHEMATOSUS The cutaneous manifestations of lupus erythematosus (LE) (Chap. 300) can be divided into acute, subacute, and chronic types. *Acute cutaneous LE* is characterized by erythema of the nose and malar eminences in a "butterfly" distribution (Fig. 49-5). The erythema is often sudden in onset, accompanied by edema and fine scale, and correlated with systemic involvement. Patients may have widespread involvement of the face as well as erythema and scaling of the extensor surfaces of the extremities and upper chest. These acute lesions, while sometimes evanescent, usually last for days and are often associated with exacerbations of systemic disease. Skin biopsy of acute lesions may show only a sparse dermal infiltrate of mononuclear cells and dermal edema. In some instances, cellular infiltrates around blood vessels and hair follicles are notable, as is hydropic degeneration of basal cells of the epidermis. Direct immunofluorescence microscopy of lesional skin frequently reveals deposits of immunoglobulin(s) and complement in the epidermal basement membrane zone. Treatment is aimed at control of systemic disease; photoprotection in this, as well as in other forms of LE, is very important.

Subacute cutaneous lupus erythematosus (SCLE) is characterized by a widespread photosensitive, nonscarring eruption. About half of these patients have SLE in which severe renal and central nervous system involvement is uncommon. SCLE may present as a papulosquamous eruption that resembles psoriasis or annular lesions that resemble those seen in erythema multiforme. In the papulosquamous form, discrete erythematous papules arise on the back, chest, shoulders, extensor surfaces of the arms, and the dorsum of the hands; lesions are uncommon on the face, flexor surfaces of the arms, and below the waist. The slightly scaling papules tend to merge into large plaques, some with a reticulate appearance. The annular form involves the same areas and presents with erythematous papules that evolve into oval, circular, or polycyclic lesions. The lesions of SCLE are more widespread but have less tendency for scarring than do lesions of discoid LE. Skin biopsy reveals a dense mononuclear cell infiltrate around hair follicles and blood vessels in the superficial dermis, combined with hydropic degeneration of basal cells in the epidermis. Direct immunofluorescence microscopy of lesional skin reveals deposits of immunoglobulin(s) in the epidermal basement membrane zone in about half these cases. A particulate pattern of IgG deposition around basal keratinocytes has recently been associated with SCLE. Most SCLE patients have anti-Ro antibodies. Local therapy is usually unsuccessful, and most patients require treatment with aminoquinoline antimalarials. Low-dose therapy with oral glucocorticoids is sometimes necessary; photoprotective measures against both ultraviolet B and A wavelengths are very important.

A



B

FIGURE 49-5 *A*. Systemic lupus erythematosus showing prominent, scaly, malar erythema. Involvement of other sun-exposed sites is also common. *B*. Acute LE on the upper chest demonstrating brightly erythematous and slightly edematous papules and plaques. (*B*, Courtesy of Robert Swerlick, MD.)

Discoid lupus erythematosus (DLE) is characterized by discrete lesions, most often on the face, scalp, or external ears. The lesions are erythematous papules or plaques with a thick, adherent scale that occludes hair follicles (follicular plugging). When the scale is removed, its underside will show small excrescences that correlate with the openings of hair follicles and is termed a "carpet tack" appearance. This finding is relatively specific for DLE. Long-standing lesions develop central atrophy, scarring, and hypopigmentation but frequently have erythematous, sometimes raised borders at the periphery (Fig. 49-6). These lesions persist for years and tend to expand slowly. Only 5 to 10% of patients with DLE meet the American Rheumatism Association criteria for SLE. However, typical discoid lesions are frequently seen in patients with SLE. Biopsy of DLE lesions shows hyperkeratosis, follicular plugging, and atrophy of the epidermis; hydropic degeneration of basal keratinocytes; and a mononuclear cell infiltrate adjacent to epidermal, adnexal, and microvascular basement membranes. Direct immunofluorescence microscopy demonstrates immunoglobulin(s) and complement deposits at the basement membrane zone in about 90% of cases. Treatment is focused on control of local cutaneous disease and consists mainly of photoprotection and topical or intralesional glucocorticoids. If local therapy is ineffective, use of aminoquinoline antimalarials may be indicated.

SCLERODERMA AND MORPHEA The skin changes of scleroderma (Chap. 303) usually begin on the hands, feet, and face, with episodes of recurrent nonpitting edema. Sclerosis of the skin begins distally on the fingers (sclerodactyly) and spreads proximally, usually accompanied by resorption of bone of the fingertips, which may have punched out ulcers, stellate scars, or areas of hemorrhage (Fig. 49-7). The fingers may actually shrink in size and become sausage-shaped, and since the fingernails are usually unaffected, the nails may curve over the end of the fingertips. Periungual telangiectasias are usually present, but periungual erythema is rare. In advanced cases, the extremities show contractures and calcinosis cutis. Facial involvement includes a smooth, unwrinkled brow, taut skin over the nose, shrinkage of tissue around the mouth, and perioral radial furrowing (Fig. 49-8). Matlike telangiectasias are often present, particularly on the face and hands. Involved skin feels indurated, smooth, and bound to underlying structures; hyperpigmentation and hypopigmentation are also often present. Raynaud's phenomenon, i.e., cold-induced blanching, cyanosis, and reactive hyperemia, is present in almost all patients and can precede development of scleroderma by many years. The combination of calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia has been termed the *CREST syndrome*. Anticentromere antibodies have been reported in a very high percentage of patients with the CREST syndrome but in only a small minority of patients with scleroderma. Skin biopsy reveals thickening of the dermis and homogenization of collagen bundles. Direct immunofluorescence microscopy of lesional skin is usually negative.

FIGURE 49-7 Scleroderma showing acral sclerosis and focal digital ulcers.

Morphea, which has been called *localized scleroderma*, is characterized by localized thickening and sclerosis of skin, usually affecting young adults or children. Morphea begins as erythematous or flesh-colored plaques that become sclerotic, develop central hypopigmentation, and demonstrate an erythematous border. In most cases, patients have one or a few lesions, and the disease is termed *localized morphea*. In some patients, widespread cutaneous lesions may occur, without systemic involvement. This form is called *generalized morphea*. Most patients with morphea do not have autoantibodies. Skin biopsy of morphea is indistinguishable from that of scleroderma. Linear scleroderma is a limited form of disease that presents in a linear, bandlike distribution and tends to involve deep as well as superficial layers of skin. Scleroderma and morphea are usually quite resistant to therapy. For this reason, physical therapy to prevent joint contractures and to maintain function is employed and is often helpful.

Diffuse fasciitis with eosinophilia is a clinical entity that can sometimes be confused with scleroderma. There is usually the sudden onset of swelling, induration, and erythema of the extremities frequently following significant physical exertion. The proximal portions of extremities (arms, forearms, thighs, legs) are more often involved than are the hands and feet. While the skin is indurated, it is usually not bound down as in scleroderma; contractures may occur early second-

FIGURE 49-6 Violaceous, hyperpigmented, atrophic plaques, often with evidence of follicular plugging, which may result in scarring, are characteristic of discoid lupus erythematosus.

FIGURE 49-8 Scleroderma characterized by typical expressionless, mask-like facies.

ary to fascial involvement. The latter may also cause muscle groups to be separated (i.e., the "groove sign") and veins to appear depressed (i.e., sunken veins). These skin findings are accompanied by peripheral blood eosinophilia, increased erythrocyte sedimentation rate, and sometimes hypergammaglobulinemia. Deep biopsy of affected areas of skin reveals inflammation and thickening of the deep fascia overlying muscle. An inflammatory infiltrate composed of eosinophils and mononuclear cells is usually found. Patients with eosinophilic fasciitis appear to be at increased risk to develop bone marrow failure or other hematologic abnormalities. While the ultimate course of eosinophilic fasciitis is uncertain, many patients respond favorably to treatment with prednisone in doses ranging from 40 to 60 mg/d.

The *eosinophilia-myalgia syndrome*, a disorder reported in epidemic numbers in 1989 and linked to ingestion of L-tryptophan manufactured by a single company in Japan, is a multisystem disorder characterized by debilitating myalgias and absolute eosinophilia in association with varying combinations of arthralgias, pulmonary symptoms, and peripheral edema. In a later phase (i.e., 3 to 6 months after initial symptoms), these patients often develop localized scleroderma-tous skin changes, weight loss, and/or neuropathy (Chap. 303). The precise cause of this syndrome, which may resemble other sclerotic skin conditions, is unknown. However, the implicated lots of L-tryptophan contained the contaminant 1,1-ethylidene bis[tryptophan]. This contaminant may be pathogenic or a marker for another substance that provokes the disorder.

50 CUTANEOUS DRUG REACTIONS

Olivier M. Chosidow, Robert S. Stern, Bruce U. Wintroub

Cutaneous reactions are among the most frequent adverse reactions to drugs. Prompt recognition of these reactions, drug withdrawal, and appropriate therapeutic interventions can minimize toxicity. This chapter focuses on adverse cutaneous reactions to drugs other than topical agents and reviews the incidence, patterns, and pathogenesis of cutaneous reactions to drugs and other therapeutic agents.

USE OF PRESCRIPTION DRUGS IN THE UNITED STATES More than 1.5 billion prescriptions for 60,000 drug products, which include over 2000 different active agents, are dispensed each year in the United States. Hospital inpatients alone annually receive about 120 million courses of drug therapy, and half of adult Americans receive prescription drugs on a regular outpatient basis. Many additional patients use over-the-counter medicines that may cause adverse cutaneous reactions.

INCIDENCE OF CUTANEOUS REACTIONS Although adverse drug reactions are common, it is difficult to ascertain their incidence, seriousness, and ultimate health effects. Available information comes from evaluations of hospitalized patients, epidemiologic surveys, premarketing studies, and voluntary reporting, most notably to the U.S. Food and Drug Administration's Medwatch System. In a systematic literature review of cutaneous reactions to drugs, the reaction rates varied from 0 to 8% and were highest for antibiotics (Table 50-1). In a series of 48,005 inpatients over a 20-year period, morbilliform rash (91%) and urticaria (6%) were the most frequent skin reactions.

The relative risk of Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), perhaps the most important severe cutaneous reactions, has been quantified in an international case control study and case series. Sulfonamide antibiotics, allopurinol, amine antiepileptic drugs (phenytoin and carbamazepine), lamotrigine, and the oxicam nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with the highest risk of these reactions.

TABLE 50-1 *Cutaneous Reactions to Drugs Received by at Least 1000 Patients (BCDSP)[a]*

Drug	Reactions, No.	Recipients, No.	Rate, %	95% Confidence Interval
Amoxicillin	63	1225	5.1	3.9–6.4
Ampicillin	215	4763	4.5	3.9–5.1
Co-trimoxazole	46	1235	3.7	2.7–4.8
Semisynthetic penicillins	41	1436	2.9	2.0–3.7
Red blood cells	67	3386	2.0	1.5–2.4
Penicillin G	68	4204	1.6	1.2–2.0
Cephalosporins	27	1781	1.5	0.9–2.1
Gentamicin	13	1277	1.0	0.5–1.6

PATHOGENESIS OF DRUG REACTIONS

Untoward cutaneous responses to drugs can arise as a result of immunologic or nonimmunologic mechanisms. Immunologic reactions require activation of host immunologic pathways and are designated *drug allergy*. Drug reactions occurring through nonimmunologic mechanisms may be due to activation of effector pathways, overdosage, cumulative toxicity, side effects, ecologic disturbance, interactions between drugs, metabolic alterations, exacerbation of preexisting dermatologic conditions, or inherited protein or enzyme deficiencies. It is often not possible to specify the responsible drug or pathogenic mechanism because the skin responds to a variety of stimuli through a limited number of reaction patterns. The mechanism of many drug reactions is unknown.

IMMUNOLOGIC DRUG REACTIONS Drugs frequently elicit an immune response, but only a small number of individuals experience clinical hypersensitivity reactions. For example, most patients exposed to penicillin develop demonstrable antibodies to penicillin but do not manifest drug reactions when exposed to penicillin. Multiple factors determine the capacity of a drug to elicit an immune response, including the molecular characteristics of the drug and host effects.

Increases in *molecular* size and complexity are associated with increased immunogenicity, and macromolecular drugs such as protein or peptide hormones are highly antigenic. Most drugs are small organic molecules <1000 Da in size, and the capacity of such small molecules to elicit an immune response depends on their ability to act as haptens, i.e., to form stable, usually covalent, bonds with tissue macromolecules, an extremely rare event.

Route of administration of a drug or simple chemical can influence the nature of the *host* immune response. For example, topical application of antigens tends to induce delayed hypersensitivity, and exposure to antigens via oral or nasal cavities stimulates production of secretory immunoglobins, IgA and IgE, and occasionally IgM. Frequency of sensitization through intravenous administration of drugs varies, but anaphylaxis is a more likely consequence with this route of exposure than following oral administration.

The degree of drug exposure and individual variability in absorption and metabolism of a given agent may alter immunogenic load. The variable degree of in vivo acetylation of hydralazine provides a

clinical example of this phenomenon. Hydralazine produces a lupus-like syndrome associated with antinuclear antibody formation more frequently in patients who acetylate the drug slowly. Frequent high-dose and interrupted courses of therapy are also important risk factors for development of drug allergy.

Pathogenesis of Allergic Drug Reactions ■ *IGE-DEPENDENT REACTIONS* IgE-dependent drug reactions are usually manifest in the skin and gastrointestinal, respiratory, and cardiovascular systems (Chap. 298). Primary symptoms and signs include pruritus, urticaria, nausea, vomiting, cramps, bronchospasm, and laryngeal edema and, on occasion, anaphylactic shock with hypotension and death. Immediate reactions may occur within minutes of drug exposure, and accelerated reactions occur hours or days after drug administration. Accelerated reactions are usually urticarial and may include laryngeal edema. Penicillin and related drugs are the most frequent causes of IgE-dependent reactions. Release of chemical mediators such as histamine, adenosine, leukotrienes, prostaglandins, platelet-activating factor, enzymes, and proteoglycans from sensitized tissue, mast cells, or circulating basophilic leukocytes results in vasodilation and edema. Release is triggered when polyvalent drug protein conjugates cross-link IgE molecules fixed to sensitized cells. The clinical manifestations are determined by interaction of the released chemical mediator with its target organ, i.e., skin, respiratory, gastrointestinal, and/or cardiovascular systems. Certain routes of administration favor different clinical patterns (i.e., oral route: gastrointestinal effects; intravenous route: circulatory effects).

IMMUNE-COMPLEX–DEPENDENT REACTIONS Serum sickness is produced by circulating immune complexes and is characterized by fever, arthritis, nephritis, neuritis, edema, and an urticarial, papular, or purpuric rash (Chap. 306). The syndrome requires an antigen that remains in the circulation for prolonged periods so that when antibody is synthesized, circulating antigen-antibody complexes are formed. Serum sickness was first described following administration of foreign sera, but drugs are now the usual cause. Drugs that produce serum sickness include the penicillins, sulfonamides, thiouracils, cholecystographic dyes, phenytoin, aminosalicylic acid, heparin, and antilymphocyte globulin. Cephalosporin administration in febrile children is associated with a high risk of a clinically similar reaction, but the mechanism of this reaction is unknown. In classic serum sickness, symptoms develop 6 days or more after exposure to a drug, the latent period representing the time needed to synthesize antibody. The antibodies responsible for immune-complex–dependent drug reactions are largely of the IgG or IgM class. Vasculitis, a relatively rare cutaneous complication of drugs, may also be a result of immune complex deposition (Chap. 306).

CYTOTOXICITY AND DELAYED HYPERSENSITIVITY Cytotoxicity and delayed hypersensitivity mechanisms may be important in the etiology of morbilliform exanthema, hypersensitivity syndrome, SJS, or TEN, but this is not proven. Systemic manifestations occur frequently. The antigen may be the drug or its metabolites, and it is likely that different T lymphocyte populations are activated. T_H1 type cells will lead to the production of interleukin (IL)-2 and interferon (IFN)-γ and subsequent activation of cytotoxic T cells. In early lesions of morbilliform exanthema or TEN, histopathologic studies have shown expression of HLA-DR and intercellular adhesion molecule (ICAM)-1 by keratinocytes, CD4 cells (in the dermis), and CD8 T cells (in the epidermis) and apoptosis of keratinocytes (facilitated by tumor necrosis factor α, perforin, and granzyme secretion, and *fas*-ligand expression). T_H2 type cells produce cytokines such as IL-5 and eotaxin, which may be involved in hypersensitivity syndrome (see below).

NONIMMUNOLOGIC DRUG REACTIONS Nonimmunologic mechanisms are responsible for the majority of drug reactions; however, only the most important mechanisms will be discussed.

Nonimmunologic Activation of Effector Pathways Drug reactions may result from nonimmunologic activation of effector pathways by three mechanisms: First, drugs may release mediators directly from mast cells and basophils and present as anaphylaxis, urticaria, and/or angioedema. Urticarial anaphylactic reactions induced by opiates, polymyxin B, tubocurarine, radiocontrast media, and dextrans may occur by this mechanism. Second, drugs may activate complement in the absence of antibody. This is an additional mechanism through which radiocontrast media may act. Third, drugs such as aspirin and other NSAIDs may alter pathways of arachidonic acid metabolism and induce urticaria.

Phototoxicity Phototoxic reactions may be drug-induced or may occur in metabolic disorders in which a photosensitizing chemical is overproduced. A phototoxic reaction occurs when enough chromophore (drug or metabolic product) absorbs sufficient radiation to cause a reaction or interaction with target tissue. Drug-induced phototoxic reactions can occur on first exposure. Phototoxic injury is usually manifest as a photodistributed dermatitis.

Exacerbation of Preexisting Diseases A variety of agents can exacerbate preexisting diseases. For example, lithium can exacerbate acne and psoriasis in a dose-dependent manner. Beta-blocking agents and IFN-α may induce psoriasis. Withdrawal of glucocorticoids can exacerbate psoriasis or atopic dermatitis.

Inherited Enzyme or Protein Deficiencies Specific genetically determined defects in the ability of an individual to detoxify toxic reactive drug metabolites may predispose such individuals to the development of severe drug reactions, especially hypersensitivity syndrome, and perhaps TEN associated with use of sulfonamides and anticonvulsants. However, in a prospective cohort of 136 HIV-infected patients treated with sulfonamides, no association of drug eruption with acetylation genotype or glutathione levels was found.

Alterations of Immunologic Status Alterations in patients' immunologic status may also modify the risk of cutaneous reactions. Bone marrow transplant patients, HIV-infected persons, and persons with Epstein-Barr virus infection are at higher risk of developing cutaneous reactions to drugs. Skin reactions to trimethoprim-sulfamethoxazole are seen in about a third of HIV-infected users of this drug, but desensitization can be accomplished. Dapsone, trimethoprim alone, and amoxicillin-clavulanate are also frequent causes of drug eruptions in HIV-infected patients. The advent of highly active antiretroviral therapy (HAART) may have decreased the risk of cutaneous reactions in HIV patients (Chap. 173).

A CLINICAL CLASSIFICATION OF CUTANEOUS DRUG REACTIONS

URTICARIA/ANGIOEDEMA *Urticaria* is a skin reaction characterized by pruritic, red wheals. Lesions may vary from a small point to a large area. Individual lesions rarely last more than 24 h. When deep dermal and subcutaneous tissues are also swollen, this reaction is known as *angioedema*. Angioedema may involve mucous membranes and may be part of a life-threatening anaphylactic reaction. Urticarial lesions, along with pruritus and morbilliform (or maculopapular) eruptions, are among the most frequent types of cutaneous reactions to drugs.

Drug-induced urticaria may be caused by three mechanisms: an IgE-dependent mechanism, circulating immune complexes (serum sickness), and nonimmunologic activation of effector pathways. IgE-dependent urticarial reactions usually occur within 36 h but can occur within minutes. Reactions occurring within minutes to hours of drug exposure are termed *immediate reactions*, whereas those that occur 12 to 36 h after drug exposure are designated *accelerated reactions*. Immune-complex–induced urticaria associated with serum sickness usually occurs from 6 to 12 days after first exposure. In this syndrome, the urticarial eruption may be accompanied by fever, hematuria, arthralgias, hepatic dysfunction, and neurologic symptoms.

Certain drugs, such as NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, and radiographic dyes, may induce urticarial reactions, angioedema, and anaphylaxis in the absence of drug-specific antibody. Although ACE inhibitors, aspirin, penicillin, and blood products are the most frequent causes of urticarial eruptions, urticaria

has been observed in association with nearly all drugs. Drugs may also cause chronic urticaria, which lasts more than 6 weeks. Aspirin frequently exacerbates this problem.

The treatment of urticaria or angioedema depends on the severity of the reaction and the rate at which it is evolving. In severe cases, especially with respiratory or cardiovascular compromise, epinephrine is the mainstay of therapy, but its effect is reduced in patients using beta blockers. For more seriously affected patients, treatment with systemic glucocorticoids, sometimes intravenously administered, are helpful. In addition to drug withdrawal, for patients with only cutaneous symptoms and without symptoms of angioedema or anaphylaxis, oral antihistamines are usually sufficient.

PHOTOSENSITIVITY ERUPTIONS Photosensitivity eruptions are usually most marked in sun-exposed areas but may extend to sun-protected areas. The mechanism of photosensitivity eruptions is almost always phototoxicity. Phototoxic reactions are also most marked in sun-exposed areas, resemble sunburn, and can occur with first exposure to a drug. Their severity depends on the tissue level of the drug, the extent of exposure to light, and the efficiency of the photosensitizer (Chap. 51).

Common orally administered photosensitizing drugs include many fluoroquinolones and doxycycline. Other drugs less frequently encountered are chlorpromazine, other tetracyclines, thiazides, and at least two NSAIDs (ibuprofen and naproxen). The majority of the common photosensitizing drugs have action spectrums in the long-wave ultraviolet A (UV-A) range. Photosensitive reactions abate with removal of either the drug or ultraviolet radiation. Because UV-A and visible light, which trigger these reactions, are not easily absorbed by nonopaque sunscreens and are transmitted through window glass, these reactions may be difficult to block.

Photosensitivity reactions are treated by avoiding exposure to ultraviolet light (sunlight), use of high-potency sunscreens which block UV-A light, and treating the reaction as one would a sunburn. Rarely, individuals develop persistent reactivity to light, necessitating long-term avoidance of sun exposure.

PIGMENTATION CHANGES Drugs, either systemic or topical, may cause a variety of pigmentary changes in the skin. Oral contraceptives may induce melasma. Long-term minocycline or perfloxacin may cause blue-gray pigmentation, while amiodarone causes a more purple coloration. Long-term high-dose phenothiazine results in gray-brown pigmentation of sun-exposed areas. Numerous cancer chemotherapeutic agents may be associated with pigmentation. Bleomycin, busulphan, daunorubicin, cyclophosphamide, hydroxyurea, and methotrexate pigmentation changes may also occur in mucous membranes (busulphan), nails (zidovudine), hair, and teeth. Gold may cause blue-gray pigmentation in light-exposed areas.

VASCULITIS Cutaneous necrotizing vasculitis often presents as palpable purpuric lesions that may be generalized or limited to the lower extremities or other dependent areas (Chap. 306). Urticarial lesions, ulcers, and hemorrhagic blisters also occur. Vasculitis may involve other organs, including the liver, kidney, brain, and joints. Drugs are only one cause of vasculitis, with infection and collagen vascular disease responsible for the majority of cases.

Propylthiouracil induces a cutaneous vasculitis that is accompanied by leukopenia and splenomegaly. Direct immunofluorescent changes in these lesions suggest immune-complex deposition. Drugs implicated in vasculitic eruptions include allopurinol, thiazides, sulfonamides, penicillin, and some NSAIDs.

HYPERSENSITIVITY SYNDROME Initially described with phenytoin, hypersensitivity syndrome presents as an erythematous eruption that may become purpuric or lichenoid and is accompanied by many of the following features: fever, facial and periorbital edema, tender generalized lymphadenopathy, leukocytosis (often with atypical lymphocytes and eosinophils), hepatitis, and sometimes nephritis or pneumonitis. The cutaneous reaction usually begins 2 to 8 weeks after the drug is begun and may resolve with drug cessation. However, symptoms may persist for several weeks, especially hepatitis. With phenytoin, an increased risk of this syndrome is associated with an inherited deficiency of epoxide hydrolase, an enzyme required for metabolism of a toxic intermediate arene oxide that is formed during metabolism of phenytoin by the cytochrome P450 system. This explains why the eruption recurs with rechallenge, and cross-reactions among aromatic anticonvulsants, including phenytoin, carbamazepine, and barbiturates, are frequent. The role of human herpes virus (HHV)-6 infection is still unclear. Other drugs causing this syndrome include lamotrigine, minocycline, dapsone, allopurinol, sulfonamides, and abacavir and zalcitabine in HIV-infected patients. Mortality as high as 10% has been reported. In life-threatening situations such as hepatitis, systemic glucocorticoids (prednisone, 0.5 to 1.0 mg/kg) seems to reduce symptoms. Topical high-potency glucocorticoids may be helpful too. In all cases, urgent withdrawal of the suspected drug is required.

WARFARIN NECROSIS OF THE SKIN This rare reaction occurs usually between the third and tenth days of therapy with warfarin derivatives, usually in women. Lesions are sharply demarcated, erythematous, indurated, and purpuric and may resolve or progress to form large, irregular, hemorrhagic bullae with eventual necrosis and slow-healing eschar formation.

Development of the syndrome is unrelated to drug dose or underlying condition. Favored sites are breasts, thighs, and buttocks. The course is not altered by discontinuation of the drug after onset of the eruption. Similar reactions have been associated with heparin. Warfarin reactions are associated with protein C deficiency. Protein C is a vitamin K–dependent protein with a shorter half-life than other clotting proteins and is in part responsible for control of fibrinolysis. Since warfarin inhibits synthesis of vitamin K–dependent coagulation factors, warfarin anticoagulation in heterozygotes for protein C deficiency causes a precipitous fall in circulating levels of protein C, permitting hypercoagulability and thrombosis in the cutaneous microvasculature, with consequent areas of necrosis. Heparin-induced necrosis may have clinically similar features but is probably due to heparin-induced platelet aggregation with subsequent occlusion of blood vessels.

Warfarin-induced cutaneous necrosis is treated with vitamin K and heparin. Vitamin K reverses the effects of warfarin, and heparin acts as an anticoagulant. Treatment with protein C concentrates may also be helpful in individuals with deficiencies of protein C, the predisposing factor for development of these reactions.

MORBILLIFORM REACTIONS Morbilliform or maculopapular eruptions are the most common of all drug-induced reactions, often start on the trunk or areas of pressure or trauma, and consist of erythematous macules and papules that are frequently symmetric and may become confluent. Involvement of mucous membranes, palms, and soles is variable; the eruption may be associated with moderate to severe pruritus and fever.

The pathogenesis is unclear. A hypersensitivity mechanism has been suggested, although these reactions do not always recur following drug rechallenge. Diagnosis is rarely assisted by laboratory or patch testing; differentiation from viral exanthem is the principal differential diagnostic consideration. Unless the suspect drug is essential it should be discontinued. Occasionally these eruptions may decrease or fade with continued use of the responsible drug.

Morbilliform reactions usually develop within 1 week of initiation of therapy and last 1 to 2 weeks; however, reactions to some drugs, especially penicillin and drugs with long half-lives, may begin more than 2 weeks after therapy has begun and last as long as 2 weeks after therapy has ceased.

Morbilliform eruptions are usually treated by discontinuing the suspect medications symptomatically. Oral antihistamines, emollients, and soothing baths are useful for treatment of pruritus. Short courses of potent topical glucocorticoids can reduce inflammation and symptoms and are probably helpful. Systemic glucocorticoid treatment is rarely indicated.

FIXED DRUG REACTIONS These reactions are characterized by one or more sharply demarcated, erythematous lesions in which hyperpigmentation results after resolution of the acute inflammation; with rechallenge, the lesion recurs in the same (i.e., "fixed") location. Lesions often involve the lips, hands, legs, face, genitalia, and oral mucosa and cause burning. Most patients have multiple lesions. Patch testing is useful to establish the etiology. Fixed drug eruptions have been associated with phenolphthalein, sulfonamides, tetracyclines, phenylbutazone, NSAIDs, and barbiturates. Although cross-sensitivity appears to occur between different tetracycline compounds, cross-sensitivity was not elicited when different sulfonamide compounds were administered to patients as part of provocation testing.

LICHENOID DRUG ERUPTIONS A lichenoid cutaneous reaction, clinically and morphologically indistinguishable from lichen planus, is associated with a variety of drugs and chemicals. Eosinophils are more common when the reaction is drug-induced. Gold and antimalarials are most often associated with this eruption. Sulfomamides, thiazides, and antihypertensive agents, including beta blockers and captopril, have also been reported to cause lichenoid reactions.

PUSTULAR ERUPTIONS Acute generalized exanthematous pustulosis (AGEP) is often associated with exposure to drugs, most notably antibiotics. Usually beginning on the face or intertriginous areas, small nonfollicular pustules overlying erythematous and edematous skin may coalesce and lead to superficial ulceration. Fever is present, and differentiating this eruption from TEN in its initial stages may be difficult. AGEP often begins within a few days of initiating drug treatment.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS SJS and TEN are terms that, most believe, describe the same drug-induced disorder, which is characterized by blisters and epidermal detachment resulting from epidermal necrosis in the absence of substantial dermal inflammation. The term *SJS* is now used to describe patients with blisters developing on dusky or purpuric macules in which total percent body surface area blistering and eventual detachment is $<10\%$. The term *SJS/TEN* is used to describe patients with 10 to 30% detachment, and *TEN* is used to describe patients with $>30\%$ detachment. Erythema multiforme (EM) is a third term which, in the past, was used to describe patients now designated as having SJS. EM is now used by most to describe patients with typical "target" lesions resulting as a reaction to infection, most commonly from herpes simplex virus.

SJS, SJS/TEN, and TEN patients initially present with acute symptoms, painful skin lesions, fever $>39°C$ (102.2°F), sore throat, and visual impairment resulting from mucous membrane and ocular lesions. Intestinal and pulmonary involvement are associated with a poor prognosis, as are a greater extent of epidermal detachment and older age. About 5% of SJS and 30% of TEN affected persons die from their disease. Drugs that most commonly cause SJS, SJS/TEN, or TEN are sulfonamides, lamotrigine, aromatic anticonvulsants, and oxicam NSAIDs. Many treatments affecting immune responses or cytokines have been advocated, but none have been shown to be efficacious in well-controlled trials. Because drug-induced epidermal apoptosis has been proposed as a possible pathogenesis, intravenous immunoglobulin (IVIG) has been used recently by some with success in the absence of side effects or additional toxicity. At this time, the best results come from early diagnosis, immediate discontinuation of any suspected drug, and supportive therapy, paying close attention to ocular complications, often in burn units or intensive care units.

DRUGS OF SPECIAL INTEREST

PENICILLIN The incidence of cutaneous reactions to penicillin is about 1%. About 85% of cutaneous reactions to penicillin are morbilliform, and about 10% are urticaria or angioedema.

IgG, IgM, and IgE antibodies can be produced; IgG and IgM antipenicillin antibodies play a role in the development of hemolytic anemia, whereas anaphylaxis and serum sickness appear to be due to IgE antibodies in serum.

In patients with suspected IgE-mediated reactions to penicillin for whom future treatment is anticipated, accurate tests for sensitization are available. Current practice is to perform skin testing with a commercially available penicilloyl determinant preparation (Pre-pen, Kremers-Urban) and with fresh penicillin and, if possible, with another source of minor (nonpenicilloyl) determinants such as aged or base-treated penicillin. Antibodies to minor determinants are common in patients experiencing anaphylaxis, but testing with major determinants alone detects most patients at risk for anaphylaxis.

About one-fourth of patients with positive history of penicillin allergy have a positive skin test, while 6% (3 to 10%) with no history of penicillin sensitivity demonstrate a positive skin response to penicillin. Administering penicillin to those patients with a positive skin test produces reactions in a high proportion (50 to 100%); conversely, only a few patients (0.5%) with a negative skin test react to the drug, and reactions tend to be mild and to occur late. Since a false-negative skin test may occur during or just after an acute reaction, testing should be performed either prospectively or several months after a suspected reaction. As many as 80% of patients lose anaphylactic sensitivity and IgE antibody after several years. Radioallergosorbent tests and other in vitro tests offer no advantage over properly performed skin testing. Some cross-reactivity between penicillin and nonpenicillin β-lactam antibiotics (e.g., cephalosporins) occurs, but the majority of penicillin-allergic patients will tolerate cephalosporins. Persons who have negative skin tests to penicillin rarely develop reactions to cephalosporins.

In the face of a positive clinical history of penicillin reaction, another drug should be chosen. If this is not feasible or prudent (e.g., in a pregnant patient with syphilis or with enterococcal endocarditis), skin testing with penicillin is warranted. If skin tests are negative, cautious administration of penicillin is acceptable, although some recommend desensitization of such patients if the reaction was likely to be IgE-mediated. In those with positive skin tests, desensitization is mandatory if therapeutic use of β-lactam antibiotics is to be undertaken. Various protocols are available, including oral and parenteral approaches. Oral desensitization appears to have lower risk of serious anaphylactic reactions during desensitization. However, desensitization carries the risk of anaphylaxis regardless of how it is performed. After desensitization, many patients experience non-life-threatening IgE-mediated untoward reactions to penicillin during their course of therapy. Desensitization is not effective in those with exfoliative dermatitis or morbilliform reactions due to penicillin.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS NSAIDs, including aspirin and indomethacin (indometacin), cause two broad categories of allergic-like symptoms in susceptible individuals: (1) approximately 1% of persons experience urticaria or angioedema, and (2) about half as many (0.5%) experience rhinosinusitis and asthma; however, about 10% of adults with asthma and one-third of individuals with nasal polyposis and sinusitis may respond adversely to aspirin.

Urticaria/angioedema may be delayed up to 24 h and may occur at any age. The rhinosinusitis-asthma syndrome generally develops within 1 h of drug administration. In young patients, the reaction pattern often begins as watery rhinorrhea, which can be complicated by nasal and sinus infection, and polyposis, bloody discharge, and nasal eosinophilia. In many individuals with this syndrome, asthma that can be life-threatening eventually ensues whenever NSAIDs are subsequently ingested, and symptoms may persist despite avoidance of these drugs. Proof of the association of symptoms and NSAID use requires either clear-cut history of symptoms following drug ingestion or an oral challenge. For the latter to be performed with relative safety, (1) asthma must be under good control, (2) the procedure must be conducted in a hospital setting by experienced personnel capable of recognizing and treating acute respiratory responses, and (3) the challenge should begin with very low doses (i.e., not >30 mg) of aspirin and increase every 1 to 2 h in doubling doses as tolerated to 650 mg.

While cross-reactivity between NSAIDs is common, it is not im-

munologic, and patients who are sensitive to NSAIDs cannot be identified by assessment of IgE antibody to aspirin, lymphocyte sensitization, or in vitro immunologic testing.

RADIOCONTRAST MEDIA Large numbers of patients are exposed to radiocontrast agents. High-osmolality radiocontrast media are about five times more likely to induce urticaria (1%) or anaphylaxis than newer low-osmolality media. Severe reactions are rare with either type of contrast media. About one-third of those with mild reactions to previous exposure rereact on reexposure. In most cases, these reactions are probably not immunologic. Pretreatment with prednisone and diphenhydramine reduces reaction rates. Persons with a reaction to a high-osmolality contrast media should be given low-osmolality media if later contrast studies are required.

ANTICONVULSANTS Of the anticonvulsants, the single orally administered agent with the highest risk of severe adverse cutaneous reactions is the antiseizure medicine lamotrigine. Older anticonvulsants, including phenytoin and carbamazepine, are also associated with many types of severe reactions and a high incidence of less severe reactions, particularly in children. In addition to SJS, TEN, and the hypersensitivity syndrome discussed above, the aromatic anticonvulsants can induce a pseudolymphoma syndrome and induce gingival hyperplasia.

SULFONAMIDES Sulfonamides have perhaps the highest risk of causing cutaneous eruptions and are the drugs most frequently implicated in SJS and TEN. The combination of sulfamethoxazole and trimethoprim frequently induces adverse cutaneous reactions in patients with AIDS (Chap. 173). Desensitization is often successful in AIDS patients with morbilliform eruptions but does not work in AIDS patients who manifest erythroderma, fever, or a bullous reaction in response to their earlier sulfonamide exposure.

VANCOMYCIN Vancomycin causes two unusual but recognizable cutaneous reactions: Linear IgA bullous dermatosis and "red man syndrome." The first is an autoimmune disorder characterized by pruritic vesiculobullous skin lesions favoring the trunk, proximal extremities, and acral region. When the syndrome is drug-induced, most cases have been associated with vancomycin, but a variety of other drugs have been reported to cause the same clinical picture.

The red man syndrome occurs during rapid intravenous infusion of vancomycin. This is thought to be a histamine-related anaphylactoid reaction characterized by flushing, diffuse maculopapular eruption, hypotension, and, in rare cases, cardiac arrest.

AGENTS USED IN CANCER CHEMOTHERAPY Since many agents used in cancer chemotherapy inhibit cell division, rapidly proliferating elements of the skin, including hair, mucous membranes, and appendages, are sensitive to their effects; as a result, stomatitis and alopecia are among the most frequent dose-dependent side effects of chemotherapy. Various nail abnormalities have been described: onycholysis, dystrophy, Beau's lines, white lines, and pigmentation. Sterile cellulitis and phlebitis and ulceration of pressure areas occur with many of these agents. Also reported is acral erythema, which begins with dysesthesia followed by redness and a painful edematous eruption of the palms and soles; it is caused by cytarabin, doxorubicin, methotrexate, and 5-fluorouracil. Urticaria, angioedema, and exfoliative dermatitis have also been seen, as has local and diffuse hyperpigmentation.

GLUCOCORTICOIDS Both systemic and topical glucocorticoids cause a variety of skin changes, including acneiform eruptions, atrophy, striae, and other stigmata of Cushing's syndrome, and in sufficiently high doses can retard wound healing. Patients using glucocorticoids are at higher risk for bacterial, yeast, and fungal skin infections that may be misinterpreted as drug eruptions but are instead drug side effects.

CYTOKINE THERAPY Alopecia is a common complication of IFN-α. Induction or exacerbation of various immune-mediated disorders (psoriasis, lichen planus, lupus erythematosus) has been also reported with this agent. IFN-β injection has been associated with local necrosis of the skin. Granulocyte colony-stimulating factor may induce various neutrophilic dermatosis, including Sweet's syndrome, pyoderma gangrenosum, neutrophilic eccrine hidradenitis, and vasculitis, and can exacerbate psoriasis.

IL-2 is associated with frequent cutaneous reactions including exanthema, facial edema, xerosis, and pruritus. Cases of pemphigus vulgaris, linear IgA disease, psoriasis, and vitiligo have also been described in association with this drug.

ANTIMALARIAL AGENTS Antimalarial agents are used as therapy for several skin diseases, including the skin manifestations of lupus and polymorphous light eruption, but they can also induce cutaneous reactions. Although also used to treat porphyria cutanea tarda at low doses, in patients with asymptomatic porphyria cutanea tarda, higher doses of chloroquine increase porphyrin levels to such an extent that they may exacerbate the disease.

Pigmentation disturbances, including black pigmentation of the face, mucous membranes, and pretibial and subungual areas, occur with antimalarials. Quinacrine (mepacrine) causes generalized, cutaneous yellow discoloration.

GOLD Chrysotherapy has been associated with a variety of dose-related dermatologic reactions (including maculopapular eruptions), which can develop as long as 2 years after initiation of therapy and require months to resolve. Erythema nodosum, psoriasiform dermatitis, vaginal pruritus, eruptions similar to those of pityriasis rosea, hyperpigmentation, and lichenoid eruptions resembling those seen with antimalarial agents have been reported. After a cutaneous reaction, it is sometimes possible to reinstitute gold therapy at lower doses without recurrence of the dermatitis.

DIAGNOSIS OF DRUG REACTIONS

Possible causes of an adverse reaction can be assessed as definite, probable, possible, or unlikely based on six variables: (1) previous experience with the drug in the general population, (2) alternative etiologic candidates, (3) timing of events, (4) drug levels or evidence of overdose, (5) patient reaction to drug discontinuation, and (6) patient reaction to rechallenge.

PREVIOUS EXPERIENCE Tables of relative reaction rates are available and are useful to assess the likelihood that a given drug is responsible for a given cutaneous reaction. The specific morphologic pattern of a drug reaction, however, may modify these reaction rates by increasing or decreasing the likelihood that a given drug is responsible for a given reaction. For example, since fixed eruptions due to drugs are more often seen with barbiturates than with penicillin, a fixed drug reaction in a patient taking both types of agents is more likely to be due to the barbiturate, even though penicillins have a higher overall drug reaction rate.

ALTERNATIVE ETIOLOGIC CANDIDATES A cutaneous eruption may be due to exacerbation of preexisting disease or to development of new disease unrelated to drugs. For example, a patient with psoriasis may have a flare-up of disease coincidental with administration of penicillin for streptococcal infection; in this case, infection is a more likely cause for the flare-up than drug reaction.

TIMING OF EVENTS Most drug reactions of the skin occur within 1 to 2 weeks of initiation of therapy. Hypersensitivity syndrome may occur later (up to 8 weeks) after initiating drug therapy. Fixed drug reactions and generalized exanthematous pustulosis often occur earlier (within 48 h), as do reactions of all types in persons with prior sensitization to that drug or a cross-sensitizing agent.

DRUG LEVELS Some cutaneous reactions are dependent on dosage or cumulative toxicity. For example, lichenoid dermatoses due to gold administration appear more often in patients taking high doses.

DISCONTINUATION Most adverse cutaneous reactions to drugs remit with discontinuation of the suspected agent. A reaction is considered unlikely to be drug-related if improvement occurs while the drug is

TABLE 50-2 *Clinical and Laboratory Findings Associated with More Serious Drug-Induced Cutaneous Clinical Findings*

Cutaneous
- Confluent erythema
- Facial edema or central facial involvement
- Skin pain
- Palpable purpura
- Skin necrosis
- Blisters or epidermal detachment
- Positive Nikolsky's sign
- Mucous membrane erosions
- Urticaria
- Swelling of tongue

General
- High fever [temperature >40°C (>104°F)]
- Enlarged lymph nodes
- Arthralgias or arthritis
- Shortness of breath, wheezing, hypotension

Laboratory results
- Eosinophil count >1000/μL
- Lymphocytosis with atypical lymphocytes
- Abnormal liver function tests

continued or if a patient fails to improve after stopping the drug and appropriate therapy.

RECHALLENGE Rechallenge provides the most definitive information concerning adverse cutaneous reactions to drugs, since a reaction failing to recur on rechallenge with a drug is unlikely to be due to that agent. Rechallenge is usually impractical, however, because the need to ensure patient safety and comfort outweighs the value of the possible information derived from rechallenge.

Of special importance is the rapid recognition of reactions that may become serious or life-threatening. Table 50-2 lists clinical and laboratory features that, if present, suggest the reaction may be serious. Table 50-3 provides key features of the most serious adverse cutaneous reactions.

DIAGNOSIS OF DRUG ALLERGY

Tests for IgE responses include in vivo and in vitro methods, but such tests are available for only a limited number of drugs, including penicillins and cephalosporins, some peptide and protein drugs (insulin, xenogeneic sera), and some agents used for general anesthesia. In vivo testing is accomplished by prick puncture and/or by intradermal skin testing. A wheal-and-flare response 2 × 2 mm greater than that seen with a saline control within 20 min is considered indicative of IgE-mediated mast cell degranulation, provided (1) the patient is not dermographic, (2) the drug does not nonspecifically degranulate mast cells, (3) the drug concentration is not high enough to be irritating, and (4) the buffer itself does not cause wheal-and-flare responses.

Skin testing with major and minor determinants of penicillins or cephalosporins has proved useful for identifying patients at risk of anaphylactic reactions to these agents. However, skin tests themselves carry a small risk of anaphylaxis. Negative skin tests do not rule out IgE-mediated reactivity, and the risk of anaphylaxis in response to

TABLE 50-3 *Clinical Features of Selected Severe Cutaneous Reactions Often Induced by Drugs*

Diagnosis	*Mucosal Lesions*	*Typical Skin Lesions*	*Frequent Signs and Symptoms*	*Alternative Causes not Related to Drugs*
Stevens-Johnson syndrome	Erosions usually at ≥two sites	Small blisters on dusky purpuric macules or atypical targets; rare areas of confluence; detachment ≤10% of body surface area	10–30% of cases involve fever	
Toxic epidermal necrolysis[a]	Erosions usually at ≥two sites	Individual lesions like those seen in Stevens-Johnson syndrome; confluent erythema; outer layer of epidermis separates readily from basal layer with lateral pressure; large sheet of necrotic epidermis; total detachment of >30% of body surface area	Nearly all cases involve fever, "acute skin failure," leukopenia	
Hypersensitivity syndrome	Infrequent	Severe exanthematous rash (may become purpuric), exfoliative dermatitis	30–50% of cases involve fever, lymphadenopathy, hepatitis, nephritis, carditis, eosinophilia, atypical lymphocytes	Cutaneous lymphoma
Acute generalized exanthematous pustulosis	About 50% erosions mouth, tongue	Initially nonfollicular small pustules overlying edematous erythema, sometimes leading to superficial ulcers	Fever, burning, pruritus, facial swelling, leukocytosis, hypocalcemia	Infection
Serum sickness or reactions resembling serum sickness	Absent	Morbilliform lesions, sometimes with urticaria	Fever, arthralgias	Infection
Anticoagulant-induced necrosis	Infrequent	Erythema then purpura and necrosis, especially of fatty areas	Pain in affected areas	Disseminated intravascular coagulopathy, septicemia
Angioedema	Often involved	Urticaria or swelling of central part of face	Respiratory distress, cardiovascular collapse	Insect stings, foods

[a] Overlap of Stevens-Johnson syndrome and toxic epidermal necrolysis with features of both and attachment of 10 to 30% of body surface area may occur.

penicillin administration in patients with negative skin tests is about 1%; about two-thirds of patients with a positive skin test and history of a previous adverse reaction to penicillin experience an allergic response on rechallenge. Skin tests may be negative in allergic patients receiving antihistamines or in those whose allergy is to determinants not present in the test reagent. Although less well studied, similar techniques can identify patients who are sensitive to protein drugs and to agents such as gallamine and succinylcholine. Most other drugs are small molecules, and skin testing with them is unreliable.

There are no generally available and reliable tests for assessing causality of non-IgE-mediated reactions, except possibly patch tests for assessment of fixed drug reactions. Therefore, diagnosis usually relies on clinical factors rather than test results.

51 PHOTOSENSITIVITY AND OTHER REACTIONS TO LIGHT

David R. Bickers

SOLAR RADIATION Sunlight is the most visible and obvious source of comfort in the environment. The sun provides the beneficial effects of warmth and vitamin D synthesis; however, acute and chronic sun exposure also have pathologic consequences. Few effects of sun exposure beyond those affecting the skin have been identified, but cutaneous exposure to sunlight is the major cause of human skin cancer and can exert immunosuppressive effects as well.

The sun's energy reaching the earth's surface is limited to components of the ultraviolet (UV), the visible, and portions of the infrared spectra. The cutoff at the short end of the UV is at approximately 290 nm; this is due primarily to stratospheric ozone formed by highly energetic ionizing radiation, thereby preventing penetration to the earth's surface of the shorter, more energetic, potentially more harmful wavelengths of solar radiation. Indeed, concern about destruction of the ozone layer by chlorofluorocarbons released into the atmosphere has led to international agreements to reduce production of these chemicals.

Measurements of solar flux indicate that there is a twentyfold regional variation in the amount of energy at 300 nm that reaches the earth's surface. This variability relates to seasonal effects; the path of sunlight transmission through ozone and air; the altitude (4% increase for each 300 m of elevation); the latitude (increasing intensity with decreasing latitude); and the amount of cloud cover, fog, and pollution.

The major components of the photobiologic action spectrum capable of affecting human skin include the UV and visible wavelengths between 290 and 700 nm. In addition, the wavelengths beyond 700 nm in the infrared spectrum primarily emit heat and under certain circumstances may exacerbate the pathologic effects of energy in the UV and visible spectra.

The UV spectrum reaching the earth represents $<10\%$ of total incident solar energy and is arbitrarily divided into two major segments: UV-B, and UV-A. This includes the wavelengths between 290 and 400 nm. UV-B consists of wavelengths between 290 and 320 nm. This portion of the photobiologic action spectrum is the most efficient in producing redness or erythema in human skin and hence is sometimes known as the "sunburn spectrum." UV-A represents those wavelengths between 320 and 400 nm and is approximately 1000-fold less efficient in producing skin redness than is UV-B.

The wavelengths between 400 and 700 nm are visible to the human eye. The photon energy in the visible spectrum is not capable of damaging human skin in the absence of a photosensitizing chemical. Without the absorption of energy by a molecule there can be no photosensitivity. Thus the *absorption spectrum* of a molecule is defined as the range of wavelengths absorbed by it, whereas the *action spectrum* for an effect of incident radiation is defined as the range of wavelengths that evoke the response.

Photosensitivity occurs when a photon-absorbing chemical (chromophore) present in the skin absorbs incident energy, becomes excited, and transfers the absorbed energy to various structures or to oxygen.

UV RADIATION (UVR) AND SKIN STRUCTURE AND FUNCTION Skin consists of two major compartments: the outer epidermis, a stratified squamous epithelium, and the underlying dermis rich in matrix proteins such as collagen and elastin. Both of these compartments are susceptible to damage from sun exposure. The epidermis and the dermis contain several chromophores capable of absorbing incident solar energy including nucleic acids, proteins, and lipids. The outermost epidermal layer, the stratum corneum, is a major absorber of UV-B, and $<10\%$ of incident UV-B wavelengths penetrate through the epidermis to the dermis. Approximately 3% of radiation below 300 nm, 20% of radiation below 360 nm, and 33% of short visible radiation reaches the basal cell layer in untanned human skin. In contrast, UV-A readily penetrates to the dermis and is capable of altering structural and matrix proteins that contribute to the aged appearance of chronically sun-exposed skin, particularly in individuals of light complexion.

Epidermal DNA, predominantly in keratinocytes, absorbs UV-B and undergoes structural changes including the formation of cyclobutane dimers and 6,4-photoproducts. These structural changes are potentially mutagenic and can be repaired by mechanisms that result in their recognition and excision and the reestablishment of normal base sequences. The efficient repair of these structural aberrations is crucial, since individuals with defective DNA repair are at high risk for the development of cutaneous cancer. For example, patients with xeroderma pigmentosum (XP), an autosomal recessive disorder, are characterized by variably deficient repair of UV-induced photoproducts, and their skin phenotype often manifests the dry, leathery appearance of prematurely photoaged skin as well as basal cell and squamous cell carcinomas and melanoma in the first two decades of life. Studies in mice using knockout gene technology have verified the importance of functional genes regulating these repair pathways in preventing the development of UV-induced cancer. Furthermore, incorporation of a bacterial DNA repair enzyme, T4N5 endonuclease, into liposomes in a product applied to skin of patients with XP selectively removes cyclobutane pyrimidine dimers and reduces the degree of solar damage and skin cancer.

Cutaneous Optics and Chromophores Chromophores are endogenous or exogenous chemical components that can absorb physical energy. Endogenous chromophores are of two types: (1) chemicals that are normal components of skin, including nucleic acids, proteins, lipids, and 7-dehydrocholesterol, the precursor of vitamin D; and (2) chemicals, such as porphyrins, synthesized elsewhere in the body that circulate in the bloodstream and diffuse into the skin. Normally, only trace amounts of porphyrins are present in the skin, but in selected diseases known as the porphyrias (Chap. 337), increased amounts are released into the circulation from the bone marrow and the liver and are trans-

ported to the skin, where they absorb incident energy both in the Soret band, around 400 nm (short visible), and to a lesser extent in the red portion of the visible spectrum (580 to 660 nm). This results in the generation of reactive oxygen species that can mediate structural damage to the skin, manifest as erythema, edema, urticaria, or blister formation.

Acute Effects of Sun Exposure The acute effects of skin exposure to sunlight include sunburn and vitamin D synthesis.

SUNBURN This painful skin condition is caused predominantly by UV-B. Generally speaking, an individual's ability to tolerate sunlight is inversely proportional to the degree of melanin pigmentation. Melanin, a complex tyrosine polymer, is synthesized in specialized epidermal dendritic cells known as melanocytes and is packaged into *melanosomes* that are transferred via dendritic process into *keratinocytes*, thereby providing photoprotection and simultaneously darkening the skin. Sun-induced melanogenesis is a consequence of increased tyrosinase activity in melanocytes that in turn may be due to a combination of eicosanoid and endothelin-1 release. The Fitzpatrick classification of human skin is a function of the efficiency of the epidermal-melanin unit and can usually be ascertained by asking an individual two questions: (1) Do you burn after sun exposure? and (2) Do you tan after sun exposure? The answers to these questions permit division of the population into six skin types varying from type I (always burn, never tan) to type VI (never burn, always tan) (Table 51-1).

Sunburn is due to vasodilatation of dermal blood vessels. There is a lag in time between skin exposure to sunlight and the development of visible redness (usually 4 to 12 h), suggesting that an epidermal chromophore causes delayed production and/or release of vasoactive mediator(s), or cytokines, that diffuse to the dermal vasculature to evoke vasodilatation.

The action spectrum for sunburn erythema includes the UV-B and UV-A. Photons in the UV-B are at least 1000-fold more efficient than photons in the UV-A in evoking the response. However, UV-A may contribute to sunburn erythema at midday when much more UV-A than UV-B is present in the solar spectrum. UV-induced activation of nuclear factor-κB (NF-κB)-dependent gene transactivation can augment release of several proinflammatory cytokines including interleukin (IL) 1B, 1L-6, vascular endothelial growth factor, and tumor necrosis factor α. Local accumulation of these cytokines occurs in sunburned skin. It is of interest that nonsteroidal anti-inflammatory drugs can reduce sunburn erythema, perhaps by blocking I-κB kinase 2, the enzyme essential for nuclear translocation of cytosolic NF-κB.

VITAMIN D PHOTOCHEMISTRY Cutaneous exposure to UV-B causes photolysis of epidermal 7-dehydrocholesterol converting it to pre-vitamin D_3, which then undergoes a temperature-dependent isomerization to form the stable hormone vitamin D_3. This compound then diffuses to the dermal vasculature and circulates systemically where it is converted to the functional hormone 1,25-dihydroxy vitamin D_3 [$1,25(OH)_2D_3$]. Vitamin D metabolites from the circulation or those produced in the skin itself can augment epidermal differentiation signaling. Aging substantially decreases the ability of human skin to photocatalytically produce vitamin D_3. This, coupled with the widespread use of sunscreens that filter out UV-B, has led to concern that vitamin D deficiency may become a significant clinical problem in the elderly. Nonetheless, at least one double-blind placebo-controlled trial has shown that a broad-spectrum sunscreen applied topically for several months has no significant effect on measured plasma vitamin D metabolites.

Chronic Effects of Sun Exposure: Nonmalignant The clinical features of photodamaged sun-exposed skin consist of wrinkling, blotchiness, and telangiectasia and a roughened, irregular, "weather-beaten" leathery appearance. Whether this photoaging represents accelerated chronologic aging or a separate and distinct process is not clear.

Within chronically sun-exposed epidermis, there is thickening (acanthosis) and morphologic heterogeneity within the basal cell layer. Higher but irregular melanosome content may be present in some keratinocytes, indicating prolonged residence of the cells in the basal cell layer. These structural changes may help to explain the leathery texture and the blotchy discoloration of sun-damaged skin.

The dermis and its connective tissue matrix are the major site for sun-associated chronic damage, manifest as solar elastosis, a massive increase in thickened irregular masses of abnormal elastic fibers. Collagen fibers are also abnormally clumped in the deeper dermis of sun-damaged skin. The chromophore(s), the action spectra, and the specific biochemical events orchestrating these changes are only partially understood. Chronologically aged, sun-protected skin and photoaged skin share important molecular features including connective tissue damage, elevated matrix metalloproteinase levels, and reduced collagen production.

Chronic Effects of Sun Exposure: Malignant One of the major known consequences of chronic skin exposure to sunlight is nonmelanoma skin cancer. The two types of nonmelanoma skin cancer are *basal cell carcinoma* and *squamous cell carcinoma* (Chap. 73). There are three major steps for cancer induction: initiation, promotion, and progression. Exposure of human skin to sunlight results in *initiation*, a step whereby structural (mutagenic) changes in DNA evoke an irreversible alteration in the target cell (*keratinocyte*) that begins the tumorigenic process. Exposure to a tumor initiator such as UV-B is believed to be a necessary but not sufficient step in the malignant process, since initiated skin cells not exposed to tumor promoters do not generally develop tumors. The second stage in tumor development is *promotion*, a multistep process whereby chronic exposure to sunlight evokes epigenetic changes that culminate in the clonal expansion of initiated cells and cause the development, over many years, of premalignant growths known as *actinic keratoses*, a minority of which may progress to form skin cancer. Based on extensive studies it seems clear that UV-B is a *complete carcinogen*, meaning that it can act as both a tumor initiator and a promoter.

The third and final step in the malignant process is *malignant conversion* of benign precursors into malignant lesions, a process thought to require additional genetic alterations in already transformed cells. Skin carcinogenesis is thought to be caused by the accumulation of mutations in the tumor suppressor gene p53 as a result of UV-induced DNA damage. Indeed both human and murine UV-induced skin cancers have unique p53 mutations (C $\rightarrow$ T and CC $\rightarrow$ TT transitions) that are present in the majority of these lesions. Studies have shown that sunscreens can substantially reduce the frequency of these signature mutations in p53 and can dramatically inhibit the induction of tumors. The p53 mutations are present in normal human skin, in actinic keratoses, and in nonmelanoma skin cancers including basal cell and squamous cell carcinomas.

Basal cell carcinomas also manifest mutations in the tumor-suppressor gene known as *patched*, which results in activation of hedgehog signaling, and enhanced activity of *smoothened*, which in turn causes downstream activation of transcription factors that augment cell proliferation. Thus, these tumors can manifest mutations in both p53 and in *patched*.

Sun exposure causes nonmelanoma and melanoma cancers of the skin, although the evidence is far more direct for its role in nonmelanoma (basal cell and squamous cell carcinoma) than in melanoma.

Approximately 80% of nonmelanoma skin cancers develop on exposed body area, including the face, the neck, and the hands. Major risk factors include male sex, childhood sun exposures, older age, fair skin, and residence at latitudes closer to the equator. Whites of darker complexions (e.g., Hispanics) have one-tenth the risk of developing such cancers compared to fair-skinned individuals. Blacks are at substantially reduced risk for all forms of skin cancer. One million individuals in the United States develop nonmelanoma skin cancer annually, and the lifetime risk for a fair-skinned individual to develop such a neoplasm is estimated at approximately 15%. A consensus exists that the incidence of nonmelanoma skin cancer in the population is increasing at the rate of 2 to 3% per year, for unknown reasons.

The relationship of sun exposure to melanoma development is less clear-cut, but suggestive evidence supports an association. Melanomas occasionally develop by the teenage years, indicating that the latent period for tumor growth is less than that of nonmelanoma skin cancer. Melanomas are among the most rapidly increasing of all human malignancies (Chap. 73). Epidemiologic studies of immigrant populations of similar ethnic stock indicate that individuals born in one area or who migrate to the same locale before age 10 have higher age-specific melanoma rates than individuals arriving later. It is thus reasonable to conclude that life in a sunny climate from birth or early childhood increases the risk of melanoma. In general, risk does not correlate with cumulative sun exposure but may relate to the duration and extent of exposure in childhood.

Meta-analysis of 17 case-control studies in patients with melanoma concluded that the protective effect of sunscreens against this type of tumor could not be substantiated. Since no prospective studies are available to address this issue, it seems reasonable to recommend that patients at risk for melanoma utilize photoprotection such as sun avoidance, high sun protective factor (SPF) sunscreens, and protective clothing.

Immunologic Effects Exposure to solar radiation suppresses both local and systemic immune responses. The action spectrum for UV-induced immunosuppression closely mimics the absorption spectrum of urocanic acid. UV-induced *trans-cis* isomerization of urocanic acid in the stratum corneum leads to its systemic absorption and consequent immunosuppressive effects. Furthermore administration of modest doses of UV-B to human skin reduces the degree of allergic sensitization to the potent contact allergen, dinitrochlorobenzene. This is associated with depletion of epidermal Langerhans cells.

Higher doses of UV-radiation evoke diminished immunologic responses to antigens introduced either epicutaneously or intracutaneously at sites distant from the irradiated site. These suppressed responses are also associated with the induction of antigen-specific suppressor T lymphocytes and may be mediated by as yet undefined factors that are released from epidermal cells at the irradiated site. One important consequence of chronic sun exposure and the concomitant immunosuppression is enhanced risk of skin cancer. Perhaps the most graphic demonstration of the role of immunosuppression in enhancing the risk of nonmelanoma skin cancer has come from studies of patients receiving organ transplantation who are on chronic immunosuppressive antirejection drug regimens. More than 50% of transplant patients develop basal and squamous cell carcinomas, and these cancers are the most common malignancy arising in renal transplant recipients. These patients require close periodic monitoring and rigorous photoprotection using sunscreens, protective clothing, and sun avoidance.

PHOTOSENSITIVITY DISEASES The diagnosis of photosensitivity requires a careful history to define the duration of the signs and symptoms, the length of time between exposure to sunlight and the development of subjective complaints, and visible changes in the skin. The age of onset can also be a helpful clue; for example, the acute photosensitivity of erythropoietic protoporphyria almost always begins in childhood, whereas the chronic photosensitivity of porphyria cutanea tarda (PCT) typically begins in the fourth and fifth decades. A history of exposure to topical and systemic drugs and chemicals may provide important clues. Many classes of drugs can cause photosensitivity on the basis of either phototoxicity or photoallergy. Fragrances such as musk ambrette that were previously present in numerous cosmetic products are also potent photosensitizers.

Examination of the skin may also offer important clues. Anatomic areas that are naturally protected from direct sunlight such as the hairy scalp, the upper eyelids, the retroauricular areas, and the infranasal and submental regions may be spared, whereas exposed areas show characteristic features of the pathologic process. These anatomic localization patterns are often helpful, but not infallible, in making the diagnosis. For example, airborne contact sensitizers that are blown onto the skin may produce dermatitis that can be difficult to distinguish from photosensitivity, despite the fact that such material may trigger skin reactivity in areas shielded from direct sunlight.

Many dermatologic conditions may be caused or aggravated by sunlight (Table 51-2). The role of light in evoking these responses may be dependent on genetic abnormalities ranging from well-described defects in DNA repair that occur in XP to the inherited abnormalities in heme synthesis that characterize the porphyrias. In certain photosensitivity diseases, the chromophore has been identified, whereas in the majority, the energy-absorbing agent is unknown.

Polymorphous Light Eruption After sunburn, the most common type of photosensitivity disease is *polymorphous light eruption* (PLE), the mechanism of which is unknown. Many affected individuals never seek medical attention because the condition is often transient, becoming manifest each spring with initial sun exposure but then subsiding spontaneously with continuing exposure, a phenomenon known as "hardening." The major manifestations of PLE include pruritic (often intensely so) erythematous papules that may coalesce into plaques in

a patchy distribution on exposed areas of the trunk and forearms. The face is usually less seriously involved.

The diagnosis can be confirmed by skin biopsy and by performing phototest procedures in which skin is exposed to multiple erythema doses of UV-A and UV-B. The action spectrum for PLE is usually within these portions of the solar spectrum.

Treatment of this PLE includes the use of sunscreens and the induction of hardening by the cautious administration of artificial UV-B and/or UV-A radiation for 2 to 3 weeks in the spring.

Phototoxicity and Photoallergy These photosensitivity disorders are related to the topical or systemic administration of drugs and other chemicals. Both reactions require the absorption of energy by a drug or chemical resulting in the production of an excited-state photosensitizer that can transfer its absorbed energy to a bystander molecule or to molecular oxygen, thereby generating tissue-destructive chemical species.

Phototoxicity is a nonimmunologic reaction caused by drugs and chemicals, a few of which are listed in Table 51-3. The usual clinical manifestations include erythema resembling a sunburn reaction that quickly desquamates, or "peels," within several days. In addition, edema, vesicles, and bullae may occur.

Photoallergy is much less common and is distinct in that the immune system participates in the pathologic process. The excited-state photosensitizer may create highly unstable haptenic free radicals that bind covalently to macromolecules to form a functional antigen capable of evoking a delayed hypersensitivity response. Some of the drugs and chemicals that produce photoallergy are listed in Table 51-4. The clinical manifestations typically differ from those of phototoxicity in that an intensely pruritic eczematous dermatitis tends to predominate and evolves into lichenified, thickened, "leathery" changes in sun-exposed areas. A small subset (perhaps 5 to 10%) of patients with photoallergy may develop a persistent exquisite hypersensitivity to light even when the offending drug or chemical is identified and eliminated, a condition known as *persistent light reaction*.

A very uncommon type of persistent photosensitivity is known as *chronic actinic dermatitis*. These patients are typically elderly men with a long history of preexisting allergic contact dermatitis or photosensitivity. They are usually exquisitely sensitive to UV-B, UV-A, and visible wavelengths.

Diagnostic confirmation of phototoxicity and photoallergy can often be obtained using phototest procedures. In patients with suspected phototoxicity, determining the minimal erythema dose (MED) while the patient is exposed to a suspected agent and then repeating the MED after discontinuation of the agent may provide a clue to the causative drug or chemical. Photopatch testing can be performed to confirm the diagnosis of photoallergy. This is a simple variant of ordinary patch testing in which a series of known photoallergens is applied to the skin in duplicate and one set is irradiated with a suberythema dose of UV-A. Development of eczematous changes at sites exposed to sensitizer and light is a positive result. The characteristic abnormality in patients with persistent light reaction is a diminished threshold to erythema evoked by UV-B. Patients with chronic actinic dermatitis usually manifest a broad spectrum of UV hyperresponsiveness and require rigorous photoprotection for relief of their symptoms.

The management of drug photosensitivity involves first and foremost the elimination of exposure to the chemical agents responsible for the reaction and minimization sun exposure. The acute symptoms of phototoxicity may be ameliorated by cool, moist compresses, topical glucocorticoids, and systemically administered NSAIDs. In severely affected individuals, a rapidly tapered course of systemic glucocorticoids may be useful. Judicious use of analgesics may be necessary.

Photoallergic reactions require a similar management approach. Furthermore, patients with persistent light reaction and chronic actinic dermatitis must be meticulously protected against light exposure. In selected patients in whom chronic systemic high-dose glucocorticoids pose unacceptable risks, it may be necessary to employ cytotoxic agents such as azathioprine or cyclophosphamide.

Porphyria The porphyrias (Chap. 337) are a group of diseases that have in common inherited or acquired derangements in the synthesis of heme. Heme is an iron-chelated tetrapyrrole or porphyrin, and the nonmetal chelated porphyrins are potent photosensitizers that absorb light intensely in both the short (400 to 410 nm) and the long (580 to 650 nm) portions of the visible spectrum.

Heme cannot be reutilized and must be continuously synthesized, and the two body compartments with the largest capacity for its production are the bone marrow and the liver. Accordingly, the porphyrias originate in one or the other of these organs, with the end result of excessive endogenous production of potent photosensitizing porphyrins. The porphyrins circulate in the bloodstream and diffuse into the skin, where they absorb solar energy, become photoexcited, generate reactive oxygen species, and evoke cutaneous photosensitivity. The mechanism of porphyrin photosensitization is known to be photodynamic, or oxygen-dependent, and is mediated by reactive oxygen species such as singlet oxygen and superoxide anions.

Porphyria cutanea tarda is the most common type of human porphyria and is associated with decreased activity of the enzyme uroporphyrinogen decarboxylase associated with a number of gene mutations. There are two basic types of PCT: (1) the sporadic or acquired type, generally seen in individuals ingesting ethanol or receiving estrogens; and (2) the inherited type, in which there is autosomal dominant transmission of deficient enzyme activity. Both forms are associated with increased hepatic iron stores.

In both types of PCT, the predominant feature is a chronic photosensitivity characterized by increased fragility of sun-exposed skin, particularly areas subject to repeated trauma such as the dorsa of the hands, the forearms, the face, and the ears. The predominant skin lesions are vesicles and bullae that rupture, producing moist erosions, often with a hemorrhagic base, that heal slowly with crusting and

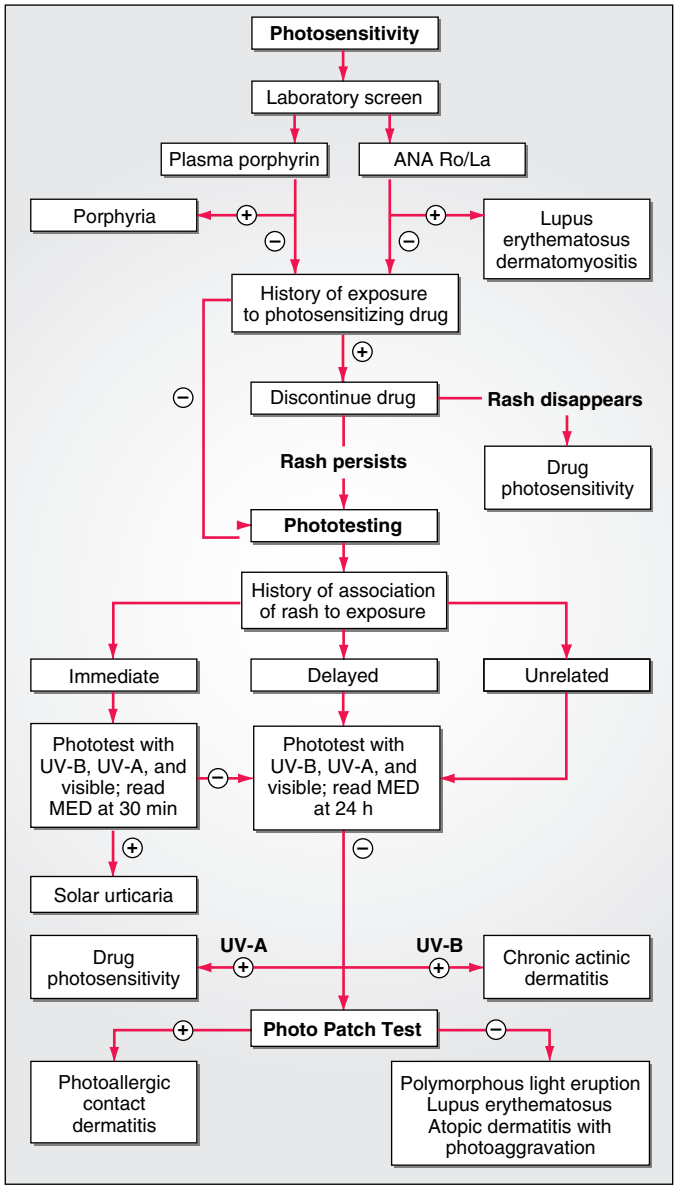

FIGURE 51-1 An algorithm for the diagnosis of a patient with photosensitivity.

purplish discoloration of the affected skin. Hypertrichosis, mottled pigmentary change, and scleroderma-like induration are associated features. Biochemical confirmation of the diagnosis can be obtained by measurement of urinary porphyrin excretion, plasma porphyrin assay, and by assay of erythrocyte and/or hepatic uroporphyrinogen decarboxylase. Multiple mutations of the uroporphyrinogen decarboxylase gene have been identified in human populations, including exon skipping and base substitutions. Some patients with PCT have associated mutations in the *HFE* gene linked to hemochromatosis. This could contribute to the iron overload seen in PCT, although iron status as measured by serum ferritin, iron levels, and transferrin saturation is no different from that in PCT patients without *HFE* mutations. Prior hepatitis C infection appears to be an independent risk factor for PCT.

Treatment of PCT consists of repeated phlebotomies to diminish the excessive hepatic iron stores and/or intermittent low doses of the antimalarial drugs chloroquine and hydroxychloroquine. Long-term remission of the disease can be achieved if the patient eliminates exposure to porphyrinogenic agents.

Erythropoietic protoporphyria originates in the bone marrow and is due to a decrease in the mitochondrial enzyme ferrochelatase secondary to numerous gene mutations. The major clinical features include an acute photosensitivity characterized by subjective burning and stinging of exposed skin that often develops during or just after exposure. There may be associated skin swelling and, after repeated episodes, a waxlike scarring.

The diagnosis is confirmed by demonstration of elevated levels of free erythrocyte protoporphyrin. Detection of increased plasma protoporphyrin helps to differentiate lead poisoning and iron-deficiency anemia, in both of which elevated erythrocyte protoporphyrin levels occur in the absence of cutaneous photosensitivity and of elevated plasma protoporphyrin levels.

Treatment consists of reducing sun exposure and the oral administration of the carotenoid β-carotene, which is an effective scavenger of free radicals. This drug increases tolerance to sun exposure in many affected individuals, although it has no effect on deficient ferrochelatase.

An algorithm for managing patients with photosensitivity is illustrated in Fig. 51-1.

PHOTOPROTECTION Since photosensitivity of the skin results from exposure to sunlight, it follows that absolute avoidance of the sun would eliminate these disorders. Unfortunately, contemporary life-styles make this an impractical alternative for most individuals, and this has led to a search for better approaches to photoprotection.

Natural photoprotection is provided by structural proteins in the epidermis, particularly keratins and melanin. The amount of melanin and its distribution in cells is genetically regulated, and individuals of darker complexion (skin types IV to VI) are at decreased risk for the development of acute sunburn and cutaneous malignancy.

Other forms of photoprotection include clothing and sunscreens. Clothing constructed of tightly woven sun-protective fabrics, irrespective of color, affords substantial protection. Wide-brimmed hats, long sleeves, and trousers all reduce direct exposure. Sunscreens are now considered to be over-the-counter drugs and category I ingredients are recognized by the U.S. Food and Drug Administration (FDA) as monographed and safe and effective. These are listed in Table 51-5. Sunscreens are rated for their photoprotective effect by their SPF. The SPF is simply a ratio of the time required to produce sunburn erythema with and without sunscreen application. The monograph stipulates that sunscreens must be rated on a scale ranging from minimal (SPF $\lessapprox$2 and $\gtrapprox$12) to moderate (SPF $\lessapprox$12 and $\gtrapprox$30) to high (SPF $\geq$30, labeled as 30+). No SPF number >30 can be placed on the label.

In addition to light absorption, a critical determinant of the sustained photoprotective effect of sunscreens is their water-resistance. The FDA monograph has also defined strict testing criteria for sunscreens making this claim.

Some degree of photoprotection can also be achieved by limiting the time of exposure during the day. Since the majority of an individual's total lifetime sun exposure may occur by the age of 18, it is important to educate parents and young children about the hazards of

sunlight. Simply eliminating exposure at midday will substantially reduce lifetime UV-B exposure.

PHOTOTHERAPY AND PHOTOCHEMOTHERAPY UV can also be used therapeutically. The administration of UV-B alone or in combination with topically applied agents can induce remissions of psoriasis and atopic dermatitis.

Photochemotherapy in which topically applied or systemically administered psoralens are combined with UV-A (PUVA) is also effective in treating psoriasis and in the early stages of cutaneous T cell lymphoma and vitiligo. Psoralens are tricyclic furocoumarins that, when intercalated into DNA and exposed to UV-A, form adducts with pyrimidine bases and eventually form DNA cross-links. These structural changes are thought to decrease DNA synthesis and relate to the improvement that occurs in psoriasis. The reason that PUVA photochemotherapy is effective in cutaneous T cell lymphoma is not clear.

In addition to its effects on DNA, PUVA photochemotherapy also stimulates melanin synthesis, and this provides the rationale for its use in the depigmenting disease vitiligo. Oral 8-methoxypsoralen and UV-A appear to be most effective in this regard, but as many as 100 treatments extending over 12 to 18 months may be required to promote satisfactory repigmentation.

Not surprisingly the major side effects of long-term UV-B phototherapy and PUVA photochemotherapy mimic those seen in individuals with chronic sun exposure and include skin dryness, actinic keratoses, and an increased risk of melanoma and nonmelanoma skin cancer. Despite these risks, the therapeutic index of these modalities continues to be excellent.

52 ANEMIA AND POLYCYTHEMIA

John W. Adamson, Dan L. Longo

HEMATOPOIESIS AND THE PHYSIOLOGIC BASIS OF RED CELL PRODUCTION *Hematopoiesis* is the process by which the formed elements of the blood are produced. The process is regulated through a series of steps beginning with the pluripotent hematopoietic stem cell. Stem cells are capable of producing red cells, all classes of granulocytes, monocytes, platelets, and the cells of the immune system. Commitment of the stem cell to the specific cell lineages appears not to be regulated by known exogenous growth factors or cytokines. Rather, stem cells develop into differentiated cell types through incompletely defined molecular events that are intrinsic to the stem cell itself. Following lineage commitment (or differentiation), hematopoietic progenitor and precursor cells come increasingly under the regulatory influence of growth factors and hormones. For red cell production, erythropoietin (EPO) is the regulatory hormone. EPO is required for the maintenance of committed erythroid progenitor cells that, in the absence of the hormone, undergo programmed cell death (*apoptosis*). The regulated process of red cell production is *erythropoiesis*, and its key elements are illustrated in Fig. 52-1.

In the bone marrow, the first morphologically recognizable erythroid precursor is the pronormoblast. This cell can undergo 4 to 5 cell divisions that result in the production of 16 to 32 mature red cells. With increased EPO production, or the administration of EPO as a drug, early progenitor cell numbers are amplified and, in turn, give rise to increased numbers of erythrocytes. The regulation of EPO production itself is linked to O_2 transport.

In mammals, O_2 is transported to tissues bound to the hemoglobin contained within circulating red cells. The mature red cell is 8 μm in diameter, anucleate, discoid in shape, and extremely pliable in order to traverse the microcirculation successfully; its membrane integrity is maintained by the intracellular generation of ATP. Normal red cell production results in the daily replacement of 0.8 to 1% of all circulating red cells in the body. The average red cell lives 100 to 120 days. The machinery responsible for red cell production is called the *erythron*. The erythron is a dynamic organ made up of a rapidly proliferating pool of marrow erythroid precursor cells and a large mass of mature circulating red blood cells. The size of the red cell mass reflects the balance of red cell production and destruction. The physiologic basis of red cell production and destruction provides an understanding of the mechanisms that can lead to anemia.

The physiologic regulator of red cell production, the glycoprotein hormone EPO, is produced and released by peritubular capillary lining cells within the kidney. These cells are highly specialized epithelial-like cells. A small amount of EPO is produced by hepatocytes. The fundamental stimulus for EPO production is the availability of O_2 for tissue metabolic needs. Impaired O_2 delivery to the kidney can result from a decreased red cell mass (*anemia*), impaired O_2 loading of the hemoglobin molecule (*hypoxemia*), or, rarely, impaired blood flow to the kidney (renal artery stenosis). EPO governs the day-to-day production of red cells, and ambient levels of the hormone can be measured in the plasma by sensitive immunoassays—the normal level being 10 to 25 U/L. When the hemoglobin concentration falls below 100 to 120 g/L (10 to 12 g/dL), plasma EPO levels increase in proportion to the severity of the anemia. In circulation, EPO has a half-clearance time of 6 to 9 h. EPO acts by binding to specific receptors on the surface of marrow erythroid precursors, inducing them to proliferate and to mature. Under the stimulus of EPO, red cell production

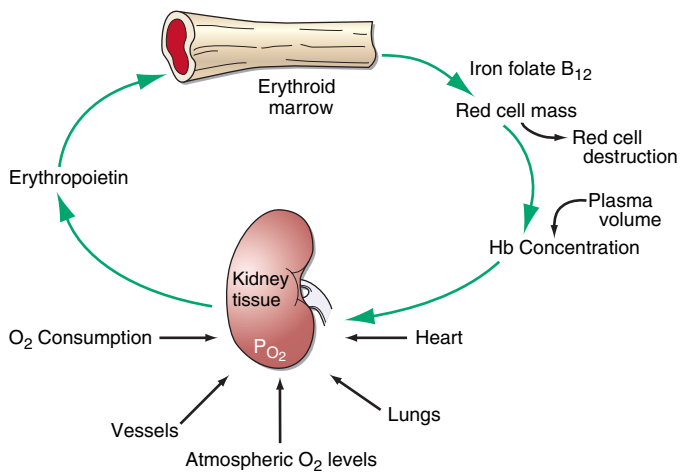

FIGURE 52-1 The physiologic regulation of red cell production by tissue oxygen tension. Hb, hemoglobin.

can increase four- to fivefold within a 1- to 2-week period but only in the presence of adequate nutrients, especially iron. The functional capacity of the erythron, therefore, requires normal renal production of EPO, a functioning erythroid marrow, and an adequate supply of substrates for hemoglobin synthesis. A defect in any of these key components can lead to anemia. Generally, anemia is recognized in the laboratory when a patient's hemoglobin level or hematocrit is reduced below an expected value (the normal range). The likelihood and severity of anemia are defined based on the deviation of the patient's hemoglobin/hematocrit from values expected for age- and sex-matched normal subjects. The lower ranges of distribution of hemoglobin/hematocrit values for adult males and females are shown in Fig. 52-2. The hemoglobin concentration in adults has a Gaussian distribution. The mean hematocrit value for adult males is 47% (± SD 7) and that for adult females is 42% (± 5). Any single hematocrit or hemoglobin value carries with it a likelihood of associated anemia. Thus, a hematocrit of ≤39% in an adult male or <35% in an adult female has only about a 25% chance of being normal. Suspected low hemoglobin or hematocrit values are more easily interpreted if there are historic values for the same patient for comparison.

The critical elements of erythropoiesis—EPO production, iron availability, the proliferative capacity of the bone marrow, and effective maturation of red cell precursors—are used for the initial classification of anemia (see below).

ANEMIA

CLINICAL PRESENTATION OF ANEMIA ■ Signs and Symptoms Anemia is most often recognized by abnormal screening laboratory tests. Patients less commonly present with advanced anemia and its attendant signs and symptoms. Acute anemia is nearly always due to blood loss or hemolysis. If blood loss is mild, enhanced O_2 delivery is achieved through changes in the O_2-hemoglobin dissociation curve mediated by a decreased pH or increased CO_2 (*Bohr effect*). With acute blood loss, hypovolemia dominates the clinical picture and the hematocrit and hemoglobin levels do not reflect the volume of blood lost. Signs of vascular instability appear with acute losses of 10 to 15% of the total blood volume. In such patients, the issue is not anemia but hypotension and decreased organ perfusion. When >30% of the blood volume is lost suddenly, patients are unable to compensate with the usual mechanisms of vascular contraction and changes in regional blood flow. The patient prefers to remain supine and will show postural hypotension and tachycardia if upright. If the volume of blood lost is >40% (i.e., >2 L in the average-sized adult), signs of hypovolemic shock including confusion, dyspnea, diaphoresis, hypotension, and tachycardia appear (Chap. 93). Such patients have significant deficits in vital organ perfusion and require immediate volume replacement.

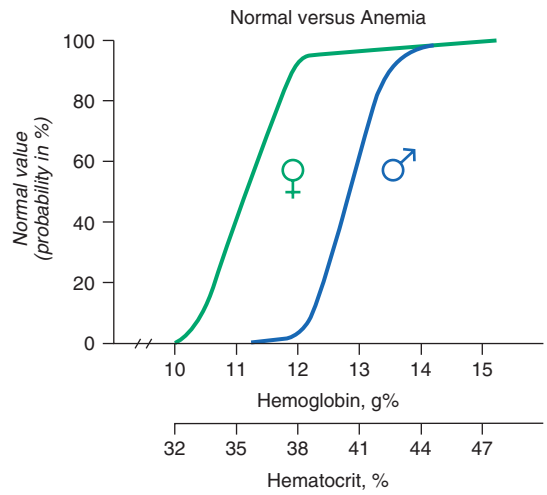

FIGURE 52-2 The probability that a particular hemoglobin or hematocrit value is abnormal is different in men and women.

With acute hemolytic disease, the signs and symptoms depend on the mechanism that leads to red cell destruction. Intravascular hemolysis with release of free hemoglobin may be associated with acute back pain, free hemoglobin in the plasma and urine, and renal failure. Symptoms associated with more chronic or progressive anemia depend on the age of the patient and the adequacy of blood supply to critical organs. Symptoms associated with moderate anemia include fatigue, loss of stamina, breathlessness, and tachycardia (particularly with physical exertion). However, because of the intrinsic compensatory mechanisms that govern the O_2-hemoglobin dissociation curve, the gradual onset of anemia—particularly in young patients—may not be associated with signs or symptoms until the anemia is severe [hemoglobin <70 to 80 g/L (7 to 8 g/dL)]. When anemia develops over a period of days or weeks, the total blood volume is normal to slightly increased and changes in cardiac output and regional blood flow help compensate for the overall loss in O_2-carrying capacity. Changes in the position of the O_2-hemoglobin dissociation curve account for some of the compensatory response to anemia. With chronic anemia, intracellular levels of 2,3-bisphosphoglycerate rise, shifting the dissociation curve to the right and facilitating O_2 unloading. This compensatory mechanism can only maintain normal tissue O_2 delivery in the face of a 20 to 30 g/L (2 to 3 g/dL) deficit in hemoglobin concentration. Finally, further protection of O_2 delivery to vital organs is achieved by the shunting of blood away from organs that are relatively rich in blood supply, particularly the kidney, gut, and skin.

Certain disorders are commonly associated with anemia. Chronic inflammatory states (e.g., infection, rheumatoid arthritis) are associated with mild to moderate anemia, whereas lymphoproliferative disorders, such as chronic lymphocytic leukemia and certain other B cell neoplasms, may be associated with autoimmune hemolysis.

APPROACH TO THE PATIENT

The evaluation of the patient with anemia requires a careful history and physical examination. Nutritional history related to drugs or alcohol intake and family history of anemia should always be assessed. Certain geographic backgrounds and ethnic origins are associated with an increased likelihood of an inherited disorder of the hemoglobin molecule or intermediary metabolism. Glucose-6-phosphate dehydrogenase deficiency and certain hemoglobinopathies are seen more commonly in those of Middle Eastern or African origin. Other information that may be useful includes exposure to certain toxic agents or drugs and symptoms related to other disorders commonly associated with anemia. These include

TABLE 52-2 *Red Blood Cell Indices*

Index	Normal Value
Mean cell volume (MCV) = (hematocrit × 10)/(red cell count × 10^6)	90 ± 8 fL
Mean cell hemoglobin (MCH) = (hemoglobin × 10)/(red cell count × 10^6)	30 ± 3 pg
Mean cell hemoglobin concentration = (hemoglobin × 10)/hematocrit, or MCH/MCV	33 ± 2%

symptoms and signs such as bleeding, fatigue, malaise, fever, weight loss, night sweats, and other systemic symptoms. Clues to the mechanisms of anemia may be provided on physical examination by findings of infection, blood in the stool, lymphadenopathy, splenomegaly, or petechiae. Splenomegaly and lymphadenopathy suggest an underlying lymphoproliferative disease, while petechiae suggest platelet dysfunction. Past laboratory measurements may be helpful to determine a time of onset.

In the anemic patient, physical examination may demonstrate a forceful heartbeat, strong peripheral pulses, and a systolic "flow" murmur. The skin and mucous membranes may be pale if the hemoglobin is <80 to 100 g/L (8 to 10 g/dL). This part of the physical examination should focus on areas where vessels are close to the surface such as the mucous membranes, nail beds, and palmar creases. If the palmar creases are lighter in color than the surrounding skin when the hand is hyperextended, the hemoglobin level is usually <80 g/L (8 g/dL).

Laboratory Evaluation Table 52-1 lists the tests used in the initial workup of anemia. A routine complete blood count (CBC) is required as part of the evaluation and includes the hemoglobin, hematocrit, and red cell indices: the mean cell volume (MCV) in femtoliters, mean cell hemoglobin (MCH) in picograms per cell, and mean concentration of hemoglobin per volume of red cells (MCHC) in grams per liter (non-SI: grams per deciliter). The red cell indices are calculated as shown in Table 52-2, and the normal variations in the hemoglobin and hematocrit with age are shown in Table 52-3. A number of physiologic factors affect the normal CBC values including age, gender, pregnancy, smoking, and altitude. High-normal hemoglobin values may be seen in men and women who live at altitude or smoke heavily. Hemoglobin elevations due to smoking reflect normal compensation due to the displacement of O_2 by CO in hemoglobin binding. Other important information is provided by the reticulocyte count and measurements of iron supply including *serum iron*, *total iron-binding capacity* (TIBC; an indirect measure of the transferrin level), and *serum ferritin*. Marked alterations in the red cell indices usually reflect disorders of maturation or iron deficiency. Clinical laboratories also provide a description of both the red and white cells, a white cell differential count, and the platelet count. In patients with severe anemia and abnormalities in red blood cell morphology, a bone marrow aspirate or biopsy may be important to assist in the diagnosis. Other tests of value in the diagnosis of specific anemias are discussed in chapters on specific disease states.

The components of the CBC also help in the classification of anemia. *Microcytosis* is reflected by a lower than normal MCV (<80), whereas high values (>100) reflect *macrocytosis*. The MCH and MCHC reflect defects in hemoglobin synthesis (*hypochromia*). Automated cell counters describe the red cell volume distribution width (RDW). The MCV (representing the peak of the distribution curve) is insensitive to the appearance of small populations of macrocytes or microcytes. An experienced laboratory technician will be able to identify minor populations of large or small cells or hypochromic cells before the red cell indices change.

TABLE 52-3 *Changes in Normal Hemoglobin/Hematocrit Values with Age and Pregnancy*

Age/Sex	Hemoglobin g/dL	Hematocrit %
At birth	17	52
Childhood	12	36
Adolescence	13	40
Adult man	16 (±2)	47 (±6)
Adult woman (menstruating)	13 (±2)	40 (±6)
Adult woman (postmenopausal)	14 (±2)	42 (±6)
During pregnancy	12 (±2)	37 (±6)

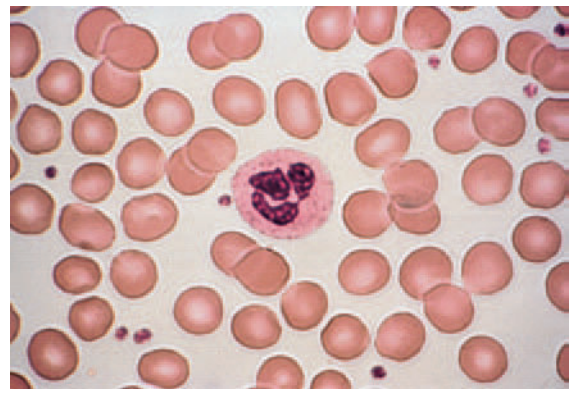

FIGURE 52-3 Normal blood smear (Wright's stain). High-power field showing normal red cells, a neutrophil, and a few platelets. (*From Hillman and Ault.*)

PERIPHERAL BLOOD SMEAR The peripheral blood smear provides important information about defects in red cell production. As a complement to the red cell indices, the blood smear also reveals variations in cell size (*anisocytosis*) and shape (*poikilocytosis*). The degree of anisocytosis usually correlates with increases in the RDW or the range of cell sizes. Poikilocytosis suggests a defect in the maturation of red cell precursors in the bone marrow or fragmentation of circulating red cells. The blood smear may also reveal *polychromasia*—red cells that are slightly larger than normal and grayish blue in color on the Wright-Giemsa stain. These cells are reticulocytes that have been prematurely released from the bone marrow, and their color represents residual amounts of ribosomal RNA. These cells appear in circulation in response to EPO stimulation or to architectural damage of the bone marrow (fibrosis, infiltration of the marrow by malignant cells, etc.) that results in their disordered release from the marrow. The appearance of nucleated red cells, Howell-Jolly bodies, target cells, sickle cells, and others may provide clues to specific disorders (see Figs. 52-3 to 52-11).

RETICULOCYTE COUNT An accurate reticulocyte count is key to the initial classification of anemia. Normally, reticulocytes are red cells

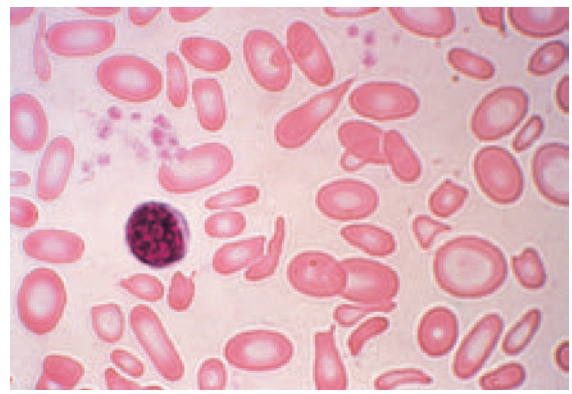

FIGURE 52-4 Severe iron-deficiency anemia. Microcytic and hypochromic red cells smaller than the nucleus of a lymphocyte associated with marked variation in size (anisocytosis) and shape (poikilocytosis). (*From Hillman and Ault.*)

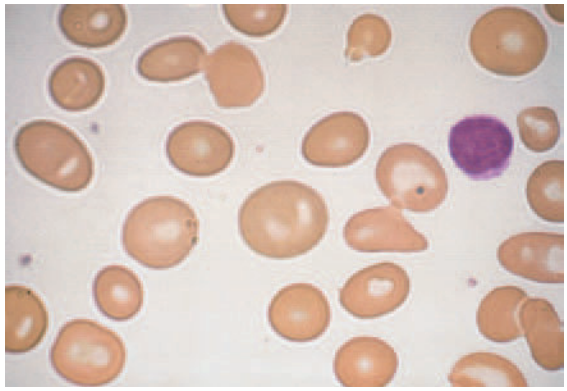

FIGURE 52-5 Macrocytosis. Red cells are larger than a small lymphocyte and well hemoglobinized. Often macrocytes are oval-shaped, so-called macroovalocytes.

FIGURE 52-6 Howell-Jolly bodies. In the absence of a functional spleen, nuclear remnants are not culled from the red cells and remain as small homogeneously staining blue inclusions on Wright stain. (*From Hillman and Ault.*)

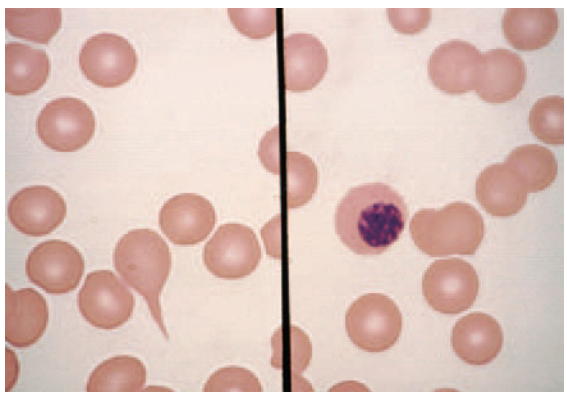

FIGURE 52-7 Red cell changes in myelofibrosis. The left panel shows a teardrop-shaped cell. The right panel shows a nucleated red cell. These forms are seen in myelofibrosis with extramedullary hematopoiesis.

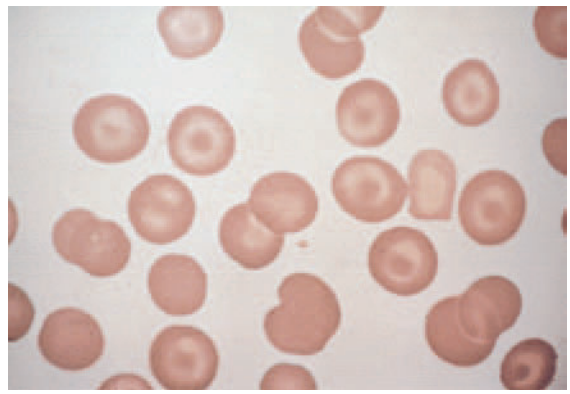

FIGURE 52-8 Target cells. Target cells have a bull's-eye appearance and are seen in thalassemia and in liver disease. (*From Hillman and Ault.*)

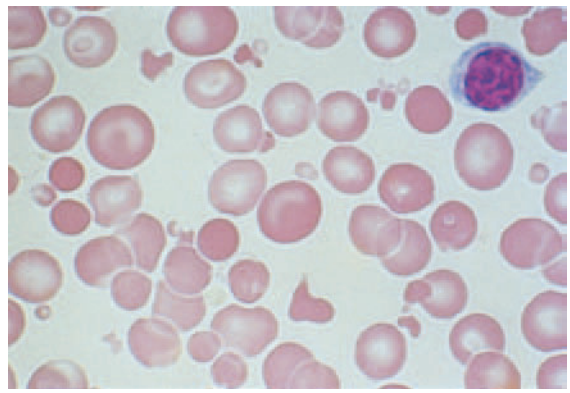

FIGURE 52-9 Red cell fragmentation. Red cells may become fragmented in the presence of foreign bodies in the circulation such as mechanical heart valves or in the setting of thermal injury. (*From Hillman and Ault.*)

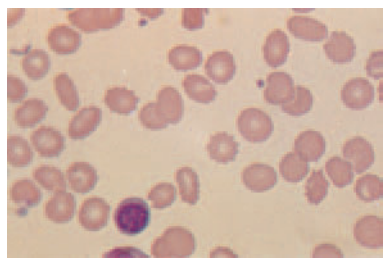

FIGURE 52-10 Uremia. The red cells in uremia may acquire numerous, regularly spaced, small spiny projections. Such cells, called burr cells or echinocytes, are readily distinguishable from irregularly spiculated acanthocytes shown in Fig. 52-11.

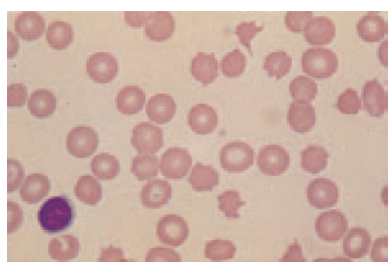

FIGURE 52-11 Spur cells. Spur cells are recognized as distorted red cells containing several irregularly distributed thornlike projections. Cells with this morphologic abnormality are also called acanthocytes. (*Courtesy of Elaine Jaffe, MD.*)

that have been recently released from the bone marrow. They are identified by staining with a supravital dye that precipitates the residual ribosomal RNA (Fig. 52-12). These precipitates appear as blue or black punctate spots. This residual RNA is metabolized over the first 24 to 36 h of the reticulocyte's lifespan in circulation. Normally, the reticulocyte count ranges from 1 to 2% and reflects the daily replacement of 0.8 to 1.0% of the circulating red cell population. A reticulocyte count provides a reliable measure of red cell production.

In the initial classification of anemia, the patient's reticulocyte count is compared with the expected reticulocyte response. In general, if the EPO and erythroid marrow responses to moderate anemia [hemoglobin <100 g/L (10 g/dL)] are intact, the red cell production rate increases to two to three times normal within 10 days following the onset of anemia. In the face of established anemia, a reticulocyte response less than two to three times normal indicates an inadequate marrow response.

In order to use the reticulocyte count to estimate marrow response, two corrections are necessary. The first correction adjusts the reticulocyte count based on the reduced number of circulating red cells. With anemia, the percentage of reticulocytes may be increased while the absolute number is unchanged. To correct for this effect, the reticulocyte percentage is multiplied by the ratio of the patient's hemoglobin or hematocrit to the expected hemoglobin/

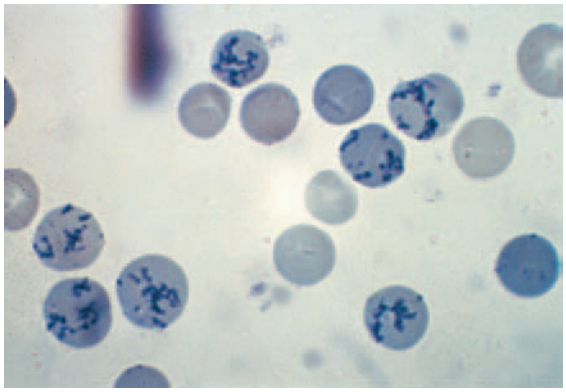

FIGURE 52-12 Reticulocytes. Methylene blue stain demonstrates residual RNA in newly made red cells. (*Courtesy of Elaine Jaffe, MD.*)

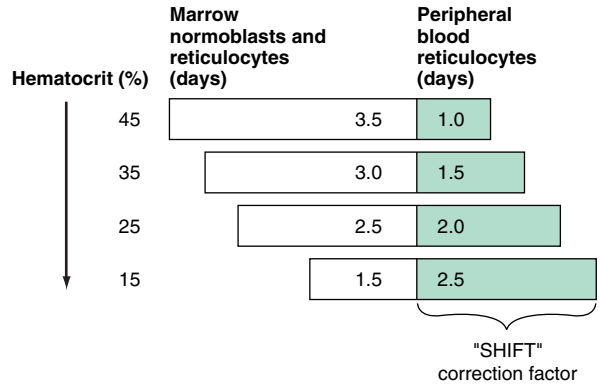

FIGURE 52-13 Correction of reticulocyte count based on level of anemia and the circulatory life span of prematurely released reticulocytes. Erythroid cells take about 4.5 days to mature. At normal hematocrit levels, they are released to the circulation with about 1 day left as reticulocytes. However, with different levels of anemia, erythroid cells are released from the marrow prematurely. Most patients come to clinical attention with hematocrits in the mid-20s and thus, a correction factor of 2 is commonly used because the observed reticulocytes will live for 2 days in the circulation before losing their RNA.

hematocrit for the age and gender of the patient (Table 52-4). This provides an estimate of the reticulocyte count corrected for anemia. In order to convert the corrected reticulocyte count to an index of marrow production, a further correction is required, depending on whether some of the reticulocytes in circulation have been released from the marrow prematurely. For this second correction, the peripheral blood smear is examined to see if there are polychromatophilic macrocytes present. These cells, representing prematurely released reticulocytes, are referred to as "shift" cells, and the relationship between the degree of shift and the necessary shift correction factor is shown in Fig. 52-13. The correction is necessary because these prematurely released cells survive as reticulocytes in circulation for >1 day, thereby providing a falsely high estimate of daily red cell production. If polychromasia is increased, the reticulocyte count, already corrected for anemia, should be divided again by a factor of 2 to account for the prolonged reticulocyte maturation time. The second correction factor varies from 1 to 3 depending on the severity of anemia. In general, a correction of 2 is commonly used. An appropriate correction is shown in Table 52-4. If polychromatophilic cells are not seen on the blood smear, the second correction is not required. The now doubly corrected reticulocyte count is the *reticulocyte production index*, and it provides an estimate of marrow production relative to normal.

Premature release of reticulocytes is normally due to increased EPO stimulation. However, if the integrity of the bone marrow release process is lost through tumor infiltration, fibrosis, or other disorders, the appearance of nucleated red cells or polychromatophilic macrocytes should still invoke the second reticulocyte correction. The shift correction should always be applied to a patient with anemia and a very high reticulocyte count to provide a true index of effective red cell production. Patients with severe chronic hemolytic anemia may increase red cell production as much as six- to sevenfold. This measure alone, therefore, confirms the fact that the patient has an appropriate EPO response, a normally functioning bone marrow, and sufficient iron available to meet the demands for new red cell formation. If the reticulocyte production index is <2 in the face of established anemia, a defect in erythroid marrow proliferation or maturation must be present.

TESTS OF IRON SUPPLY AND STORAGE The laboratory measurements that reflect the availability of iron for hemoglobin synthesis include the serum iron, the TIBC, and the percent transferrin saturation. The percent transferrin saturation is derived by dividing the serum iron level (× 100) by the TIBC. The normal serum iron ranges from 9 to 27 μmol/L (50 to 150 μg/dL), while the normal TIBC is 54 to 64 μmol/L (300 to 360 μg/dL); the transferrin saturation ranges from 25 to 50%. A diurnal variation in the serum iron leads to a variation in the percent transferrin saturation. The serum ferritin is used to evaluate total-body iron stores. Adult males have serum ferritin levels that average about 100 μg/L, corresponding to iron stores of about 1 g. Adult females have lower serum ferritin levels averaging 30 μg/L, reflecting lower iron stores. A serum ferritin level of 10 to 15 μg/L represents depletion of body iron stores. However, ferritin is also an acute-phase reactant and, in the presence of acute or chronic inflammation, may rise severalfold above baseline levels. As a rule, a serum ferritin >200 μg/L means there is at least some iron in tissue stores.

BONE MARROW EXAMINATION A bone marrow aspirate and smear or a needle biopsy may be useful in the diagnosis of a marrow disorder such as myelofibrosis, a red cell maturation defect, or an infiltrative disease (Figs. 52-14 to 52-16). The increase or decrease of one cell lineage (myeloid vs. erythroid) compared to another is obtained by a differential count of nucleated cells in a bone marrow smear [the myeloid/erythroid (M/E) ratio]. A patient with a hypoproliferative anemia (see below) and a reticulocyte production index <2 will demonstrate an M/E ratio of 2 or 3:1. In contrast, patients with hemolytic disease and a production index >3 will have an M/E ratio of at least 1:1. Maturation disorders are identified from the discrepancy between the M/E ratio and the reticulocyte production

TABLE 52-4 Calculation of Reticulocyte Production Index

Correction #1 for anemia:
This correction produces the corrected reticulocyte count
In a person whose reticulocyte count is 9%, hemoglobin 7.5 g/dL, hematocrit 23%, the absolute reticulocyte count = 9 × (7.5/15)[or ×(23/45)] = 4.5%
Correction #2 for longer life of prematurely released reticulocytes in the blood:
This correction produces the reticulocyte production index
In a person whose reticulocyte count is 9%, hemoglobin 7.5 gm/dL, hematocrit 23%, the reticulocyte production index =

$$9 \times \frac{(7.5/15)(\text{hemoglobin correction})}{2\ (\text{maturation time correction})} = 2.25$$

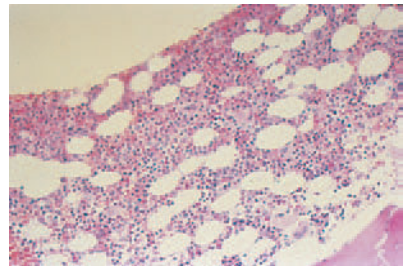

FIGURE 52-14 Normal bone marrow. This is a low-power view of a section of normal marrow stained with hematoxylin and eosin (H&E). Note that the nucleated cellular elements account for about 40 to 50% and the fat (clear areas) accounts for about 50 to 60% of the area. (*Courtesy of Elaine Jaffe, MD.*)

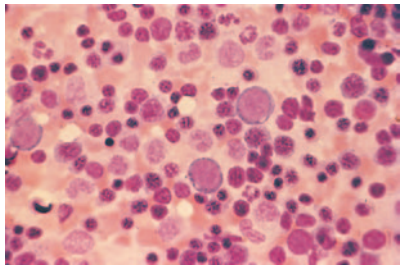

FIGURE 52-15 Erythroid hyperplasia. This marrow shows an increase in the fraction of cells in the erythroid lineage as might be seen when a normal marrow compensates for acute blood loss or hemolysis. The M/E ratio is about 1:1.

index (see below). Either the marrow smear or biopsy can be stained for the presence of iron stores or iron in developing red cells. The storage iron is in the form of ferritin or *hemosiderin*. On carefully prepared bone marrow smears, small ferritin granules can normally be seen in 20 to 40% of developing erythroblasts. Such cells are called *sideroblasts*.

Other Laboratory Measurements Additional laboratory tests may be of value in confirming specific diagnoses. →***For details of these tests and how they are applied in individual disorders, see Chaps. 90 to 94.***

DEFINITION AND CLASSIFICATION OF ANEMIA ■ Initial Classification of Anemia

Classifying an anemia according to the functional defect in red cell production helps organize the subsequent use of laboratory studies. The three major classes of anemia are: (1) marrow production defects (*hypoproliferation*), (2) red cell maturation defects (*ineffective erythropoiesis*), and (3) decreased red cell survival (*blood loss/hemolysis*). This functional classification of anemia then guides the selection of specific clinical and laboratory studies designed to complete the differential diagnosis and to plan appropriate therapy. The classification is shown in Fig. 52-17. A hypoproliferative anemia is typically seen with a low reticulocyte production index together with little or no change in red cell morphology (a normocytic, normochromic anemia) (Chap. 90). Maturation disorders typically have a slight to moderately elevated reticulocyte production index that is accompanied by either macrocytic (Chap. 92) or microcytic (Chaps. 90, 91) red cell indices. Increased red blood cell destruction secondary to hemolysis results in an increase in the reticulocyte production index to at least three times normal (Chap. 93), provided sufficient iron is available for hemoglobin synthesis. Hemorrhagic anemia does not typically result in production indices of more than 2.5 times normal because of the limitations placed on expansion of the erythroid marrow by iron availability.

In the first branch point of the classification of anemia, a reticulocyte production index >2.5 indicates that hemolysis is most likely. A reticulocyte production index <2 indicates either a hypoproliferative anemia or maturation disorder. The latter two possibilities can often be distinguished by the red cell indices, by examination of the peripheral blood smear, or by a marrow examination. If the red cell indices are normal, the anemia is almost certainly hypoproliferative in nature. Maturation disorders are characterized by ineffective red cell production and a low reticulocyte production index. Bizarre red cell shapes—macrocytes or hypochromic microcytes—are seen on the peripheral blood smear. With a hypoproliferative anemia, no erythroid hyperplasia is noted in the marrow, whereas patients with ineffective red cell production have erythroid hyperplasia and an M/E ratio <1:1.

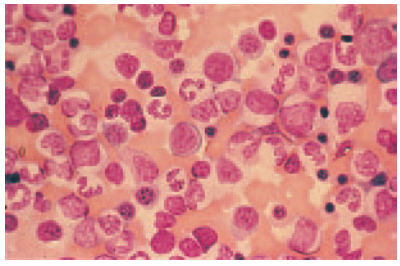

FIGURE 52-16 Myeloid hyperplasia. This marrow shows an increase in the fraction of cells in the myeloid or granulocytic lineage as might be seen in a normal marrow responding to infection. The M/E ratio is >3:1.

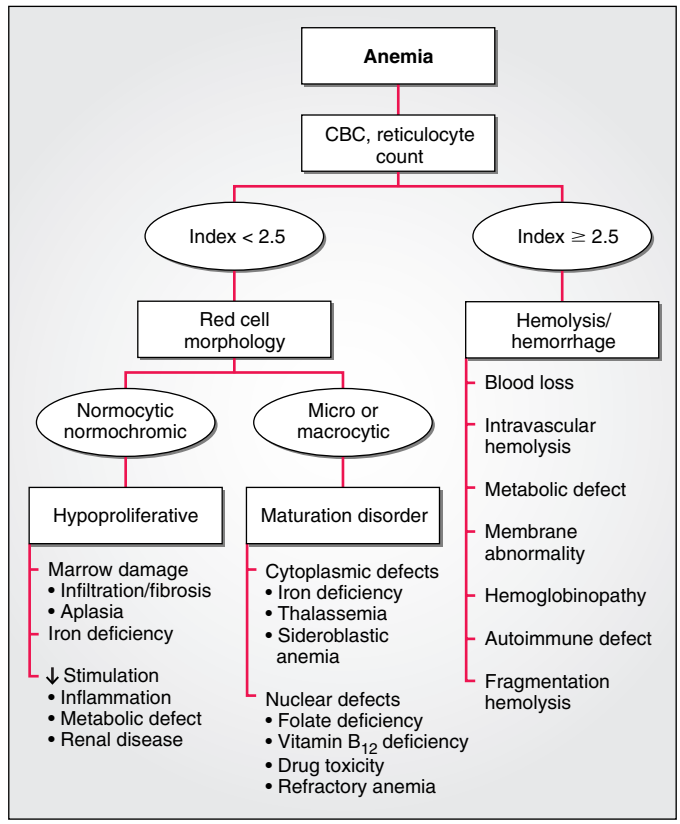

FIGURE 52-17 The physiologic classification of anemia. CBC, complete blood count.

Hypoproliferative Anemias At least 75% of all cases of anemia are hypoproliferative in nature. A hypoproliferative anemia reflects absolute or relative marrow failure in which the erythroid marrow has not proliferated appropriately for the degree of anemia. The majority of hypoproliferative anemias are due to mild to moderate iron deficiency or inflammation. A hypoproliferative anemia can result from marrow damage, iron deficiency, or inadequate EPO stimulation. The last may reflect impaired renal function, suppression of EPO production by inflammatory cytokines such as interleukin 1, or reduced tissue needs for O_2 from metabolic disease such as hypothyroidism. Only occasionally is the marrow unable to produce red cells at a normal rate, and this is most prevalent in patients with renal failure. In general, hypoproliferative anemias are characterized by normocytic, normochromic red cells, although microcytic, hypochromic cells may be observed with mild iron deficiency or long-standing chronic inflammatory disease. The key laboratory tests in distinguishing between the various forms of hypoproliferative anemia include the serum iron and iron-binding capacity, evaluation of renal and thyroid function, a marrow biopsy or aspirate to detect marrow damage or infiltrative disease, and serum ferritin to assess iron stores. Occasionally, an iron stain of the marrow will be needed to determine the pattern of iron distribution. Patients with the anemia of acute or chronic inflammation show a distinctive pattern of serum iron (low), TIBC (normal or low), percent transferrin saturation (low), and serum ferritin (normal or high). A distinct pattern of results is noted in mild to moderate iron deficiency (low serum iron, high TIBC, low percent transferrin saturation, low serum ferritin) (Chap. 90). Marrow damage by a drug, infiltrative disease such as leukemia or lymphoma, or marrow aplasia can usually be diagnosed from the peripheral blood and bone marrow morphology. With infiltrative disease or fibrosis, a marrow biopsy will likely be required.

Maturation Disorders The presence of anemia with an inappropriately low reticulocyte production index, macro- or microcytosis on smear,

and abnormal red cell indices suggests a maturation disorder. Maturation disorders are divided into two categories: nuclear maturation defects, associated with macrocytosis and abnormal marrow development, and cytoplasmic maturation defects, associated with microcytosis and hypochromia usually from defects in hemoglobin synthesis. The low reticulocyte production index is a reflection of the ineffective erythropoiesis that results from the destruction within the marrow of developing erythroblasts. Marrow morphology shows an M/E ratio of <1:1, diagnostic of erythroid hyperplasia.

Nuclear maturation defects result from vitamin B_{12} or folic acid deficiency, drug damage, or myelodysplasia. Drugs that interfere with cellular DNA metabolism, such as methotrexate or alkylating agents, can produce a nuclear maturation defect. Alcohol, alone, is also capable of producing macrocytosis and a variable degree of anemia, but this is usually associated with coincident folic acid deficiency. Measurements of folic acid and vitamin B_{12} are key not only in identifying the specific vitamin deficiency but also because they reflect different pathogenetic mechanisms.

Cytoplasmic maturation defects result from severe iron deficiency or abnormalities in globin or heme synthesis. Iron deficiency occupies an unusual position in the classification of anemia. If the iron-deficiency anemia is mild to moderate, erythroid marrow proliferation is decreased and the anemia is classified as hypoproliferative. However, if the anemia is severe and prolonged, the erythroid marrow will become hyperplastic despite the inadequate iron supply, and the anemia will be classified as ineffective erythropoiesis with a cytoplasmic maturation defect. In either case, a reduced reticulocyte production index, microcytosis, and a classic pattern of iron values make the diagnosis clear and easily distinguish iron deficiency from other cytoplasmic maturation defects such as the thalassemias. Defects in heme synthesis, in contrast to globin synthesis, are less common and may be acquired or inherited (Chap. 337). Acquired abnormalities are usually associated with myelodysplasia, may lead to either a macro- or microcytic anemia, and are frequently associated with mitochondrial iron loading. In these cases, iron is taken up by the mitochondria of the developing erythroid cell but not incorporated into heme. The iron-encrusted mitochondria surround the nucleus of the erythroid cell, forming a ring. Based on the distinctive finding of so-called ringed sideroblasts on the marrow iron stain, patients are diagnosed as having a sideroblastic anemia—almost always reflecting myelodysplasia. Again, studies of iron parameters are helpful in the differential diagnosis and management of these patients.

Blood Loss/Hemolytic Anemia In contrast to anemias associated with an inappropriately low reticulocyte production index, blood loss or hemolysis is associated with red cell production indices ≥2.5 times normal. The stimulated erythropoiesis is reflected in the blood smear by the appearance of increased numbers of polychromatophilic macrocytes. A marrow examination is rarely indicated if the reticulocyte production index is increased appropriately. The red cell indices are typically normocytic or slightly macrocytic, reflecting the increased number of reticulocytes. Acute blood loss is not associated with an increased reticulocyte production index because of the time required to increase EPO production and, subsequently, marrow proliferation. Subacute blood loss may be associated with modest reticulocytosis. Anemia from chronic blood loss presents more often as iron deficiency than with the picture of increased red cell production.

The evaluation of blood loss anemia is usually not difficult. Most problems arise when a patient presents with an increased red cell production index from an episode of acute blood loss that went unrecognized. The cause of the anemia and increased red cell production may not be obvious. The confirmation of a recovering state may require observations over a period of 2 to 3 weeks, during which the hemoglobin concentration will be seen to rise and the reticulocyte production index fall.

Hemolytic disease, while dramatic, is among the least common forms of anemia. The ability to sustain a high reticulocyte production index reflects the ability of the erythroid marrow to compensate for hemolysis and the efficient recycling of iron from the destroyed red cells to support new hemoglobin synthesis. The level of response will depend on the severity of the anemia and the nature of the underlying disease process.

Hemoglobinopathies, such as sickle cell disease and the thalassemias, present a mixed picture. The reticulocyte index may be high but is inappropriately low for the degree of marrow erythroid hyperplasia (Chap. 91).

Hemolytic anemias present in different ways. Some appear suddenly as an acute, self-limited episode of intravascular or extravascular hemolysis, a presentation pattern often seen in patients with autoimmune hemolysis or with inherited defects of the Embden-Meyerhof pathway or the glutathione reductase pathway. Patients with inherited disorders of the hemoglobin molecule or red cell membrane generally have a lifelong clinical history typical of the disease process. Those with chronic hemolytic disease, such as hereditary spherocytosis, may actually present not with anemia but with a complication stemming from the prolonged increase in red cell destruction such as aplastic crisis, symptomatic bilirubin gallstones, or splenomegaly.

The differential diagnosis of an acute or chronic hemolytic event requires the careful integration of family history, pattern of clinical presentation, and a number of highly specific laboratory studies (Chap. 93). Some of the more common congenital hemolytic anemias may be identified from the red cell morphology, a routine laboratory test such as hemoglobin electrophoresis, or a screen for red cell enzymes. Acquired defects in red cell survival are often immunologically mediated and require a direct or indirect antiglobulin test or a cold agglutinin titer to detect the presence of hemolytic antibodies or complement-mediated red cell destruction.

TREATMENT

An overriding principle is to initiate treatment of mild to moderate anemia only when a specific diagnosis is made. Rarely, in the acute setting, anemia may be so severe that red cell transfusions are required before a specific diagnosis is made. Whether the anemia is of acute or gradual onset, the selection of the appropriate treatment is determined by the documented cause(s) of the anemia. Often, the cause of the anemia may be multifactorial. For example, a patient with severe rheumatoid arthritis who has been taking anti-inflammatory drugs may have a hypoproliferative anemia associated with chronic inflammation as well as chronic blood loss associated with intermittent gastrointestinal bleeding. In every circumstance, it is important to evaluate the patient's iron status fully before and during the treatment of any anemia. ***→Transfusion is discussed in Chap. 99; iron therapy is discussed in Chap. 90; treatment of megaloblastic anemia is discussed in Chap. 92; treatment of other entities is discussed in their respective chapters (sickle cell anemia, Chap. 91; hemolytic anemias, Chap. 93; aplastic anemia and myelodysplasia, Chap. 94).***

Therapeutic options for the treatment of anemias have expanded dramatically during the past 25 years. Blood component therapy is available and safe. Recombinant EPO as an adjunct to anemia management has transformed the lives of patients with chronic renal failure on dialysis. Improvements in the management of sickle cell crises and sickle cell anemia also have occurred. Eventually, patients with inherited disorders of globin synthesis or mutations in the globin gene, such as sickle cell disease, may benefit from the successful introduction of targeted genetic therapy (Chap. 59).

POLYCYTHEMIA

Polycythemia is defined as an increase in circulating red blood cells above normal. This increase may be real or only apparent because of a decrease in plasma volume (spurious or relative). The term *erythrocytosis* may be used interchangeably with polycythemia, but some draw a distinction between them; erythrocytosis implies documentation of increased red cell mass, whereas polycythemia refers to any

increase in red cells. Often patients with polycythemia are detected through an incidental finding of elevated hemoglobin or hematocrit levels. Concern that the hemoglobin level may be abnormally high is usually triggered at 170 g/L (17 g/dL) for men and 150 g/L (15 g/dL) for women. Hematocrit levels >50% in men or >45% in women may be abnormal. Hematocrits >60% in men and >55% in women are almost invariably associated with increased red cell mass.

Historic features useful in the differential diagnosis include smoking history; living at high altitude; or a history of congenital heart disease, peptic ulcer disease, sleep apnea, chronic lung disease, or renal disease.

Patients with polycythemia may be asymptomatic or experience symptoms related to the increased red cell mass or an underlying disease process that leads to increased red cell production. The dominant symptoms from increased red cell mass are related to hyperviscosity and thrombosis (both venous and arterial), because the blood viscosity increases logarithmically at hematocrits >55%. Manifestations range from digital ischemia to Budd-Chiari syndrome with hepatic vein thrombosis. Abdominal thromboses are particularly common. Neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances may occur. Hypertension is often present. Patients with *polycythemia vera* may have aquagenic pruritus and symptoms related to hepatosplenomegaly. Patients may have easy bruising, epistaxis, or bleeding from the gastrointestinal tract. Patients with hypoxemia may develop cyanosis on minimal exertion or have headache, impaired mental acuity, and fatigue.

The physical examination usually reveals a ruddy complexion. Splenomegaly favors polycythemia vera as the diagnosis (Chap. 95). The presence of cyanosis or evidence of a right-to-left shunt suggests congenital heart disease presenting in the adult, particularly tetralogy of Fallot or Eisenmenger syndrome (Chap. 218). Increased blood viscosity raises pulmonary artery pressure; hypoxemia can lead to increased pulmonary vascular resistance. Together these factors can produce cor pulmonale.

Polycythemia can be spurious (related to a decrease in plasma volume; Gaisbock's syndrome), primary, or secondary in origin. The secondary causes are all associated with increases in EPO levels: either a physiologically adapted appropriate elevation based on tissue hypoxia (lung disease, high altitude, CO poisoning, high-affinity hemoglobinopathy) or an abnormal overproduction (renal cysts, renal artery stenosis, tumors with ectopic EPO production). A rare familial form of polycythemia is associated with normal EPO levels but hyperresponsive EPO receptors due to mutations.

APPROACH TO THE PATIENT

As shown in Fig. 52-18, the first step is to document the presence of an increased red cell mass using the principle of isotope dilution by administering ^{51}Cr-labeled autologous red blood cells to the patient and sampling blood radioactivity over a 2-h period. If the red cell mass is normal (<36 mL/kg in men, <32 mL/kg in women), the patient has spurious polycythemia. If the red cell mass is increased (>36 mL/kg in men, >32 mL/kg in women), serum EPO levels should be measured. If EPO levels are low or unmeasurable, the patient most likely has polycythemia vera. Ancillary tests that support this diagnosis include elevated white blood cell count, increased absolute basophil count, thrombocytosis, elevated leukocyte alkaline phosphatase levels, and elevated serum vitamin B_{12} and vitamin B_{12}–binding protein levels.

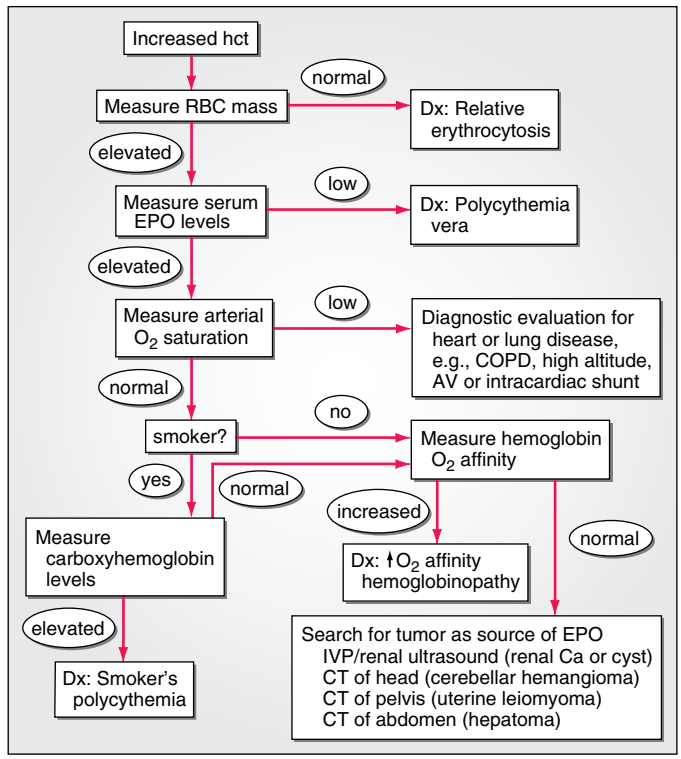

FIGURE 52-18 An approach to diagnosing patients with polycythemia. RBC, red blood cell; EPO, erythropoietin; COPD, chronic obstructive pulmonary disease; AV, atrioventricular; IVP, intravenous pyelogram; CT, computed tomography.

If serum EPO levels are elevated, one attempts to distinguish whether the elevation is a physiologic response to hypoxia or is related to autonomous production. Patients with low arterial O_2 saturation (<92%) should be further evaluated for the presence of heart or lung disease, if they are not living at high altitude. Patients with normal O_2 saturation who are smokers may have elevated EPO levels because of CO displacement of O_2. If carboxyhemoglobin (COHb) levels are high, the diagnosis is smoker's polycythemia. Such patients should be urged to stop smoking. Those who cannot stop smoking require phlebotomy to control their polycythemia. Patients with normal O_2 saturation who do not smoke either have an abnormal hemoglobin that does not deliver O_2 to the tissues (evaluated by finding elevated O_2-hemoglobin affinity) or have a source of EPO production that is not responding to the normal feedback inhibition. Further workup is dictated by the differential diagnosis of EPO-producing neoplasms. Hepatoma, uterine leiomyoma, and renal cancer or cysts are all detectable with abdominopelvic computed tomography scans. Cerebellar hemangiomas may produce EPO, but they nearly always present with localizing neurologic signs and symptoms rather than polycythemia-related symptoms.

53 BLEEDING AND THROMBOSIS

Robert I. Handin

Hemorrhage, intravascular thrombosis, and embolism are common clinical manifestations of many diseases. The normal hemostatic system limits blood loss by precisely regulated interactions between components of the vessel wall, blood platelets, and plasma proteins. However, when disease or trauma damages large arteries and veins, excessive bleeding may occur, despite a normal hemostatic system. Less frequently, hemorrhage is caused by an inherited or acquired disorder of the hemostatic machinery itself. A large number of bleeding disorders have been identified.

In addition, unregulated activation of the hemostatic system may cause thrombosis and embolism, which can reduce blood flow to critical organs such as the brain and myocardium. Although we understand less about the pathophysiology of thrombosis than of hemostatic failure, certain patient groups have been identified that are particularly prone to thrombosis and embolism. These include patients who (1) are immobilized after surgery, (2) have chronic congestive heart failure, (3) have atherosclerotic vascular disease, (4) have a malignancy, or (5) are pregnant. Most of these "thrombosis-prone" patients have inherited or acquired "hypercoagulable" or "prethrombotic" disorders.

Certain information in the patient's history, such as the mode of onset and sites of bleeding, a family bleeding tendency, and a record of drug ingestion, helps establish the correct diagnosis. Physical examination can identify bleeding in the skin or joint deformities due to previous hemarthroses. Ultimately, however, bleeding disorders are diagnosed by laboratory tests. General screening tests are used first, to document a systemic disorder, and are then supplemented by specific tests of coagulation protein or platelet function to arrive at an accurate diagnosis.

The hypercoagulable or prethrombotic patient can also be identified by a careful history. Three important clues to this diagnosis are: (1) repeated episodes of thromboembolism without an obvious predisposing condition, (2) a family history of thrombosis, and (3) well-documented thromboembolism in adolescents and young adults. All of the known inherited prethrombotic disorders can be diagnosed with specific immunologic, functional, or genetic tests.

NORMAL HEMOSTASIS

Accurate diagnosis and treatment of patients with either bleeding or thrombosis require knowledge of the pathophysiology of hemostasis. The process can be divided into primary and secondary components and is initiated when trauma, surgery, or disease disrupts the vascular endothelial lining and blood is exposed to subendothelial connective tissue. *Primary hemostasis* is the name given to the process of platelet plug formation at sites of injury. It occurs within seconds of injury and is of prime importance in stopping blood loss from capillaries, small arterioles, and venules (Fig. 53-1). *Secondary hemostasis* consists of the reactions of the plasma coagulation system that result in fibrin formation. It requires several minutes for completion. The fibrin strands that are produced strengthen the primary hemostatic plug. This reaction is particularly important in larger vessels and prevents bleeding from recurring hours or days after the injury. Although presented here as separate events, primary and secondary hemostasis are closely linked. For example, activated platelets accelerate plasma coagulation, and products of the plasma coagulation reaction, such as thrombin, induce platelet activation.

Effective primary hemostasis requires three critical events—platelet adhesion, granule release, and platelet aggregation. Within a few seconds of injury, platelets adhere to collagen fibrils in vascular subendothelium by at least two collagen receptors, glycoprotein (Gp) Ia/IIa, a member of the integrin family, and GpVI. GpVI binding of collagen transduces signals that activate platelets through the Fc receptor (FcRγ). As shown in Fig. 53-2, this interaction with collagen is stabilized by the von Willebrand factor (vWF), an adhesive glycoprotein that allows platelets to remain attached to the vessel wall despite the high shear forces generated within the vascular lumen. The vWF accomplishes this task by forming a link between a platelet receptor site on Gp Ib/IX and collagen fibrils. The adherent, activated platelets then release preformed granule constituents and generate de novo mediators like those depicted in Fig. 53-1.

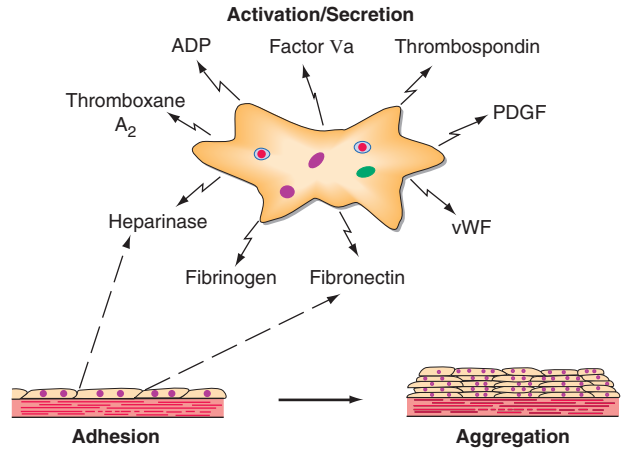

FIGURE 53-1 Schematic presentation of the major events in primary hemostasis. The first event is platelet adhesion, the interaction of platelets with a nonplatelet surface such as vascular subendothelium. This is followed by platelet activation and secretion. Some of the products secreted by platelets are depicted. Abbreviations: ADP, adenosine diphosphate; PDGF, platelet-derived growth factor; vWF, von Willebrand factor. The final event is the binding of activated platelets to the adherent monolayer in the process of platelet aggregation.

As in other cells, platelet activation and secretion are regulated by changes in the level of cyclic nucleotides, the influx of calcium, hydrolysis of membrane phospholipids, and phosphorylation of critical

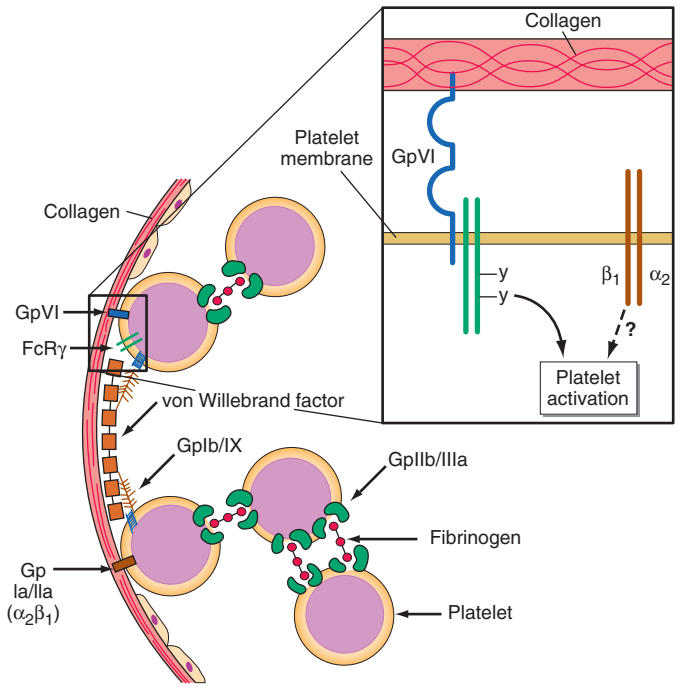

FIGURE 53-2 The molecular basis of platelet adhesion and aggregation. Adhesion of platelets to vascular subendothelium is facilitated by the interaction of two platelet collagen receptors, GpIa/IIa ($\alpha_2\beta_1$) integrin and GpVI with collagen. The binding of collagen to GpVI causes it to interact with FcRγ, which is phosphorylated and transduces activation signals in the platelet. Adhesion is stabilized by the von Willebrand factor, which forms a bridge between collagen fibrils in the vessel wall and receptors on platelet glycoprotein Ib/IX (GpIb/IX). In a similar manner, platelet aggregation is mediated by fibrinogen, which links adjacent platelets via receptors on the platelet glycoprotein IIb/IIIa complex (GpIIb/IIIa, α_1b/β_3).

intracellular proteins. The relevant pathways are depicted in Figs. 53-3, 53-4, and 53-5. The binding of agonists such as epinephrine, collagen, or thrombin to platelet surface receptors activates two membrane enzymes—phospholipase C and phospholipase A_2. These enzymes catalyze the release of arachidonic acid from two of the major membrane phospholipids, phosphatidylinositol and phosphatidylcholine. Initially, a small quantity of the released arachidonic acid is converted to thromboxane A_2 (TXA_2), which, in turn, can activate phospholipase C. The formation of TXA_2 from arachidonic acid is mediated by the enzyme cyclooxygenase (Fig. 53-3). This enzyme is inhibited by aspirin and nonsteroidal anti-inflammatory drugs. Inhibition of TXA_2 synthesis is a cause of mild bleeding in some patients and is the same way some antithrombotic drugs work.

A finely balanced mechanism controls the rate and extent of platelet activation (Fig. 53-3). TXA_2, a platelet product of arachidonic acid, stimulates platelet activation and secretion. In contrast, prostacyclin, an endothelial cell product of arachidonic acid metabolism, inhibits platelet activation by raising intraplatelet levels of cyclic adenosine monophosphate. In addition, endothelial cells have an ecto-ADPase on their surface that hydrolyzes the platelet agonist adenosine diphosphate (ADP) and limits its effects.

Platelet signal transduction pathways are complex (Fig. 53-4). Potential platelet-activating agents bind to a surface receptor that initiates a cascade of signaling events. The four major classes of receptors are: (1) GpIb/IX complex that binds vWF; (2) integrin family receptors [GpIIB/IIIa ($\alpha IIb\beta_3$) binds fibrinogen; GpIa/IIa ($\alpha_2\beta_1$) binds collagen]; (3) seven membrane-spanning "serpentine" receptors that bind thrombin (PAR1) or TXA_2; and (4) GpVI/FcγRIIa that binds collagen. Signaling induces calcium flux and leads to remodeling of the cytoskeleton, change in shape, formation of filopodia, and granule release. These changes allow the platelet to adhere to substrata and form intravascular aggregates in concert with platelet and matrix glycoproteins such as collagen, vWF, and fibrinogen. The details of the guanine nucleotide–dependent reactions are shown in Fig. 53-5.

Following activation, platelets secrete their granule contents into plasma. Endoglycosidases and a heparin-cleaving enzyme are released from lysosomes; calcium, serotonin, and ADP are released from the dense granules; and several proteins, including vWF, fibronectin, thrombospondin, the platelet-derived growth factor (PDGF), and a heparin-neutralizing protein (platelet factor 4), are released from α granules. Released ADP binds to purinergic receptors, which, when activated, change the conformation of the GpIIb/IIIa complex so that it binds fibrinogen, linking adjacent platelets into a hemostatic plug (Fig. 53-2). The platelet-specific purinergic receptor P_2Y_{12} is the principal activating receptor on the platelet. Released PDGF stimulates the growth and migration of fibroblasts and smooth-muscle cells within the vessel wall, an important part of the repair process.

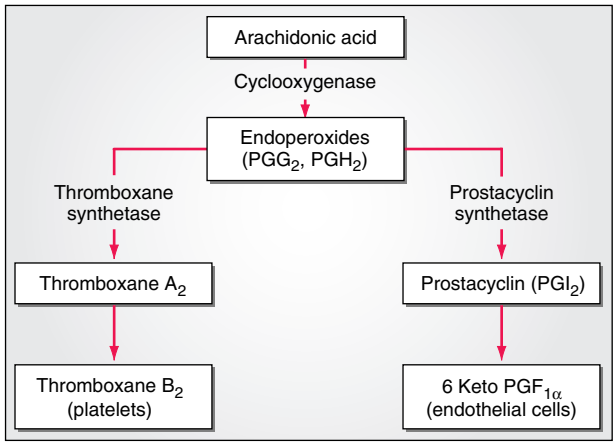

FIGURE 53-3 Generation of thromboxane A_2 in platelets and prostacyclin (PGI_2) in endothelial cells.

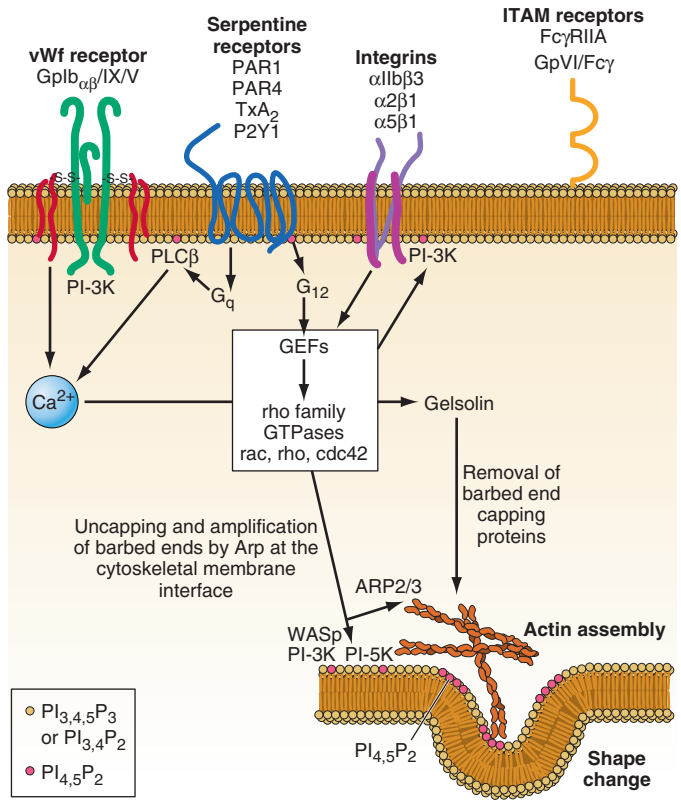

FIGURE 53-4 Platelet signal transduction overview. Actin assembly, platelet shape change, granule secretion, and the activation of some receptors are regulated by the level of intracellular calcium, the activity of guanosine triphosphatases (GTPases), and the synthesis of polyphosphoinositides. The best understood signal transduction pathway involves the multimembrane-spanning or serpentine receptors that include as agonists thrombin and thromboxane A_2. As shown, the receptors couple to downstream signaling molecules via heterotrimeric G proteins. For example, thrombin binding to PAR1 leads to the phosphorylation and dissociation of the Gq trimer complex, the activation of phospholipase Cβ (PLCβ), the hydrolysis of membrane phosphatidylinositol 4,5-bisphosphate ($PI_{4,5}P_2$) to inositol 1,4,5-triphosphate (IP_3), and diacylglycerol (DAG). IP_3 binds to receptors on the smooth endoplasmic reticulum to release calcium into the cytosol. Calcium then activates gelsolin, which fragments actin filaments and mediates the activation of myosin II by myosin light chain kinase (MLCK). At the same time trimeric guanosine triphosphatase (GTPase) G_{12} is activated, leading to the stimulation of guanine exchange factors (GEFs) that activate small GTPases of the rhoA family. GTP-rac activates downstream effectors including the lipid kinases phosphoinositide 5-kinase (PI-5K) and phosphoinositide 3-kinase (PI-3K). Activation of other receptors, as shown in the figure, induces other signal transduction pathways with parallel but distinct effects. Stimulation of receptors such as GpVI and FcγRIIA, which contain an immunoreceptor tyrosine-based activation motif (ITAM), increases tyrosine phosphorylation of these receptors, the tyrosine kinase Syk, the adaptor SLP76, and PLCγ. Phosphorylation activates PLCγ to hydrolyze lipids, which, in turn, promote calcium release and actin assembly. These are two of the complex signaling pathways leading to platelet activation. *[From JH Hartwig, JE Italiano, Jr, in RI Handin et al (eds), Blood: Principles and Practice of Hematology, 2d ed. Philadelphia, Lippincott Williams & Wilkins, 2003, pp 1062–1079; with permission.]*

As the primary hemostatic plug is being formed, plasma coagulation proteins are activated to initiate secondary hemostasis. An overall picture of the coagulation scheme, including the role of various inhibitors, is shown in Fig. 53-6. In the classic view of coagulation, four reactions have been defined (Fig. 53-7) that culminate in the production of enough thrombin to convert a small amount of plasma fibrinogen to fibrin. Each of the reactions requires the formation of a surface-bound complex and the conversion of inactive precursor proteins into active proteases by limited proteolysis, and each is regulated by both plasma and cellular cofactors and calcium.

In *reaction 1*, the intrinsic, or contact, phase of coagulation, three plasma proteins, Hageman factor (factor XII), high-molecular-weight kininogen (HMWK), and prekallikrein (PK), form a complex on vascular subendothelial collagen. After binding to HMWK, factor XII is slowly converted to an active protease (XIIa), which then activates PK to kallikrein and factor XI to XIa. Kallikrein accelerates the conversion

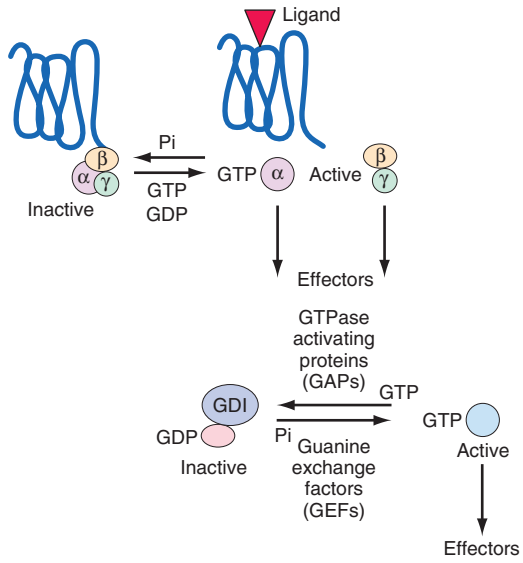

FIGURE 53-5 A more detailed look at G protein activation and inactivation—a key step in platelet and other cellular signal transduction pathways. G proteins exist as inactive membrane-bound heterotrimeric (α,β,γ) complexes. Binding of ligand to one of the multimembrane-spanning (usually 7 passes through the membrane) receptors leads to the conversion of the inactive guanosine diphosphate (GDP) form of the G protein complex to the active guanosine triphosphate (GTP) form that then dissociates into the GTP-α and the β,γ subunits. The dissociated subunits go on to mediate downstream events as shown in Fig. 53-4. GTP-activating proteins (GAPs) convert GTP to GDP, which then favors reassociation of the subunits to form the inactive heterotrimer. GDP dissociation inhibitors (GDI) maintain the α-GDP complex in an inactive state. The released Pi is then added to the low-molecular-weight small G proteins in the cytosol by the guanine nucleotide exchange factors (GEFs). The active forms of these low-molecular-weight G proteins also effect downstream events shown in Fig. 53-4. *[From JH Hartwig, JE Italiano, Jr, in RI Handin et al (eds), Blood: Principles and Practice of Hematology, 2d ed. Philadelphia, Lippincott William & Wilkins, 2003, pp 1062–1079; with permission.]*

of XII to XIIa, while XIa participates in subsequent coagulation reactions. An alternative mechanism for the activation of factor XI may exist, as patients who are deficient in either factor XII, HMWK, or PK have apparently normal hemostasis and no clinical bleeding.

Reaction 2 provides a second pathway to initiate coagulation by activating factor VII to a protease. In this extrinsic, or tissue factor–dependent, pathway, a complex is formed between factor VII, calcium, and tissue factor, a ubiquitous lipoprotein present in cellular membranes and exposed by cellular injury. The tissue factor–VII pathway

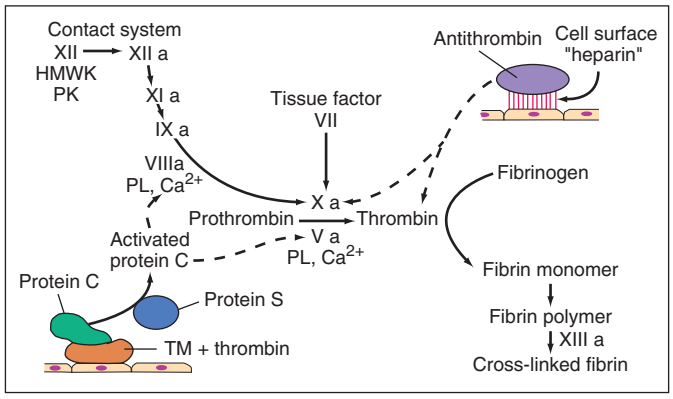

FIGURE 53-6 A schematic diagram of some of the clinically important coagulation reactions. The unactivated or precursor proteins are indicated by roman numerals, and the active form by the addition of a lowercase "a"—a standard convention. Other abbreviations: HMWK, high-molecular-weight kininogen; PK, prekallikrein; PL, phospholipid; TM, thrombomodulin; Ca^{2+}, calcium. There are two independent activation pathways, the contact system and the tissue factor–mediated, or extrinsic, system. They merge at the point of factor X activation and lead to the generation of thrombin, which converts fibrinogen into fibrin. These reactions are regulated by antithrombin, which forms complexes with all of the coagulation protein serine proteases except factor VII, and by the protein C–protein S system, which inactivates factors V and VIII.

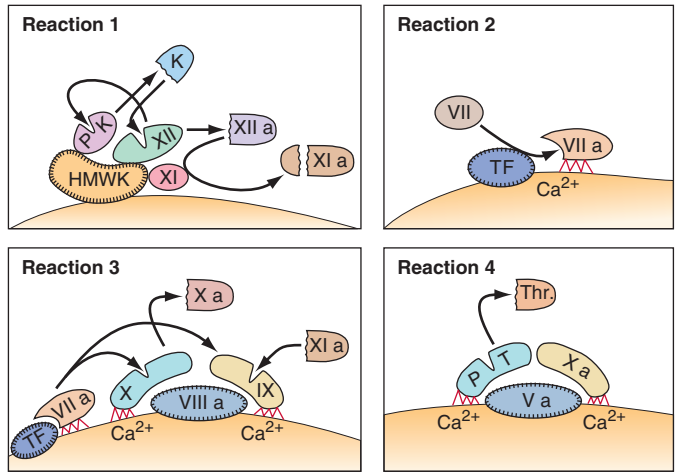

FIGURE 53-7 The major coagulation reactions are subdivided and depicted in schematic form to emphasize their similarity. They all rely on the formation of surface-bound enzyme-cofactor complexes. Abbreviations: PK, prekallikrein; K, kallikrein; HMWK, high-molecular-weight kininogen; TF, tissue factor; Ca^{2+}, calcium; PT, prothrombin; Thr, thrombin. By convention, other coagulation factors are indicated by roman numerals, with a lowercase "a" appended to indicate their active form. The ^^^ is used to indicate the Gla (di-γ-carboxyglutamic acid)–containing domains of factors VII, IX, X, Xa, and PT, which bind calcium and phospholipid. Hatching is used to indicate proteins that adhere to surfaces by hydrophobic interaction.

is continuously active and makes a major contribution to basal coagulation; indeed, it seems to be the major way to initiate coagulation. Factor VII and three other coagulation proteins—factors II (prothrombin), IX, and X—require calcium and vitamin K for biologic activity. These proteins are synthesized in the liver, where a vitamin K–dependent carboxylase catalyzes a unique posttranslational modification that adds a second carboxyl group to certain glutamic acid residues. Pairs of these di-γ-carboxyglutamic acid (Gla) residues bind calcium, which alters protein comformation for binding to phospholipid surfaces and confers biologic activity. Inhibition of this modification by vitamin K antagonists (e.g., warfarin) is the basis of one of the most common forms of anticoagulant therapy.

In *reaction 3*, factor X is activated by the proteases generated in the two previous reactions. In one reaction, a calcium- and lipid-dependent complex is formed between factors VIII, IX, and X. Within this complex, factor IX is first converted to IXa by factor XIa that was generated within the intrinsic pathway (reaction 1). Factor X is then activated by factor IXa in concert with factor VIII. Alternatively, both factors IX and X can be activated more directly by factor VIIa, generated via the extrinsic pathway (reaction 2). Activation of factors IX and X provides a link between the intrinsic and extrinsic coagulation pathways (Fig. 53-6).

Reaction 4, the final step, converts prothrombin to thrombin in the presence of factor V, calcium, and phospholipid. Although prothrombin conversion can take place on various natural and artificial phospholipid-rich surfaces, it proceeds several thousand times faster on the surface of activated platelets or endothelial cells. Thrombin has multiple functions in hemostasis. Although its principal role in hemostasis is the conversion of fibrinogen to fibrin, it also activates factors V, VIII, and XIII and stimulates platelet aggregation and secretion. Following the release of fibrinopeptides A and B from the α and β chains of fibrinogen, the modified molecule, now called *fibrin monomer*, polymerizes into an insoluble gel. The fibrin polymer is then stabilized by the cross-linking of individual chains by factor XIIIa, a plasma transglutaminase (Fig. 53-6).

Although the classic view of coagulation had clinical utility, it left several important questions unanswered: (1) Why does factor XII deficiency dramatically prolong partial thromboplastin time (PTT) but not cause bleeding? (2) Why is there heterogeneity in the bleeding symptoms of patients with factor XI deficiency? (3) Why do deficiencies in factors VIII or IX produce such dramatic bleeding even though

the "extrinsic" pathway remains intact? Activation of factors IX and X by the tissue factor–VIIa complex is thought to play a major role in the initiation of hemostasis. Once coagulation is initiated by this interaction, the tissue factor pathway inhibitor (TFPI) blocks the pathway, and elements of the intrinsic pathway, particularly factors VIII and IX, become the dominant regulators of thrombin generation. This step in the pathway explains why factor XII–deficient patients are asymptomatic and why factor XI–deficient patients have only a mild to moderate bleeding diathesis (Fig. 53-8).

Clot lysis and vessel repair begin immediately after the formation of the definitive hemostatic plug. Three potential activators of the fibrinolytic system are Hageman factor fragments; urinary plasminogen activator (uPA), or urokinase; and tissue plasminogen activator (tPA). The principal physiologic activators, tPA and uPA, diffuse from endothelial cells and convert plasminogen, adsorbed to the fibrin clot, into plasmin (Fig. 53-9). Plasmin then degrades fibrin polymer into small fragments, which are cleared by the monocyte-macrophage scavenger system. Although plasmin can also degrade fibrinogen, the reaction remains localized because (1) tPA and some forms of uPA activate plasminogen more effectively when it is adsorbed to fibrin clots; (2) any plasmin that enters the circulation is rapidly bound and neutralized by the α_2 plasmin inhibitor (patients who lack this factor have unchecked fibrinolysis and bleed); and (3) endothelial cells release a plasminogen activator inhibitor (PAI) 1, which blocks the action of tPA.

Only a small quantity of each coagulation enzyme is converted to its active form. As a consequence, the hemostatic plug does not propagate beyond the site of injury. Precise regulation is important, since each milliliter of blood contains enough clotting material to clot all the fibrinogen in the body in 10 to 15 s. Blood fluidity is maintained by the flow of blood, the adsorption of coagulation factors to surfaces and their trapping in the emerging clot, and by multiple inhibitors in plasma. These factors reduce the concentration of these potent enzymes and cofactors and reduce reaction rates. Antithrombin, proteins C and S, and TFPI are important inhibitors that maintain blood fluidity.

These inhibitors have distinct modes of action. Antithrombin forms complexes with all serine protease coagulation factors except factor VII (Fig. 53-6). Rates of complex formation are accelerated by heparin and heparin-like molecules on the surface of the endothelial cells. Heparin's ability to accelerate antithrombin activity is the basis for its anticoagulant action. Protein C is converted to an active protease by thrombin after it is bound to an endothelial cell protein called *thrombomodulin*. Activated protein C then inactivates the two plasma cofactors V and VIII by limited proteolysis, which slows down two critical coagulation reactions. Protein C may also stimulate the release

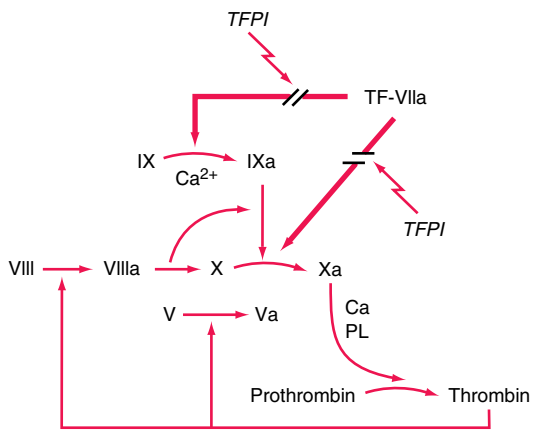

FIGURE 53-8 The contribution of the tissue factor–VIIa complex (TF-VIIa) and tissue factor pathway inhibitor (TFPI) to coagulation. Initial activation of factor IX by TF-VIIa compensates for deficiencies in the early factors, e.g., factors XII and XI. The subsequent inhibition of TF-VIIa by TFPI makes sustained activation of factor X by IXa and VIIIa critical for normal hemostasis. PL, phospholipid.

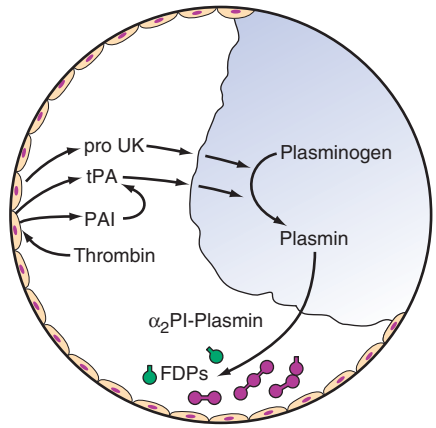

FIGURE 53-9 A schematic diagram of the fibrinolytic pathway. Tissue plasminogen activator (tPA) is released from endothelial cells, enters the fibrin clot, and activates plasminogen to plasmin. Any free plasmin is complexed with α_2 plasmin inhibitor (α_2PI). Fibrin is degraded to low-molecular-weight fragments, fibrin degradation products (FDPs).

of tPA from endothelial cells. The inhibitory function of protein C is enhanced by protein S. Reduced levels of antithrombin or proteins C and S, or dysfunctional forms of these molecules, result in a hypercoagulable or prethrombotic state. In addition, a particularly common heritable defect associated with a hypercoagulable state is the presence of a form of factor V (factor V Leiden) that is resistant to protein C inhibition. Between 20 and 50% of patients with unexplained venous thromboembolism have this defect.

Blood coagulation is not uniform throughout the body. The composition of the blood clot varies with the site of injury. Hemostatic plugs or thrombi that form in veins where blood flow is slow are rich in fibrin and trapped red blood cells and contain relatively few platelets. They are often called *red thrombi* because of their appearance in surgical and pathologic specimens. The friable ends of these red thrombi, which most often form in leg veins, can break off and embolize to the pulmonary circulation. Conversely, clots that form in arteries under conditions of high flow are predominantly composed of platelets and have little fibrin. These *white thrombi* may readily dislodge from the arterial wall and embolize to distant sites, causing temporary or permanent ischemia. These clots are a particularly common cause of embolism in the cerebral and retinal circulation, where they may lead to transient neurologic dysfunction (transient ischemic attacks), including temporary monocular blindness (amaurosis fugax), or to strokes. In addition, most episodes of myocardial infarction are due to thrombi that form after the rupture of atherosclerotic plaques within diseased coronary arteries. Hemostatic plugs, which are a physiologic response to injury, are very similar to pathologic thrombi. Thrombosis has been described as coagulation occurring in the wrong place or at the wrong time.

CLINICAL EVALUATION

HISTORY Certain elements of the history are particularly useful in determining whether bleeding is caused by an underlying hemostatic disorder or by a local anatomic defect. One clue is a history of bleeding following common hemostatic stresses such as dental extraction, childbirth, or minor surgery. Bleeding that is sufficiently severe to require a blood transfusion merits special attention. A family history of bleeding and bleeding from multiple sites that cannot be linked to trauma or surgery also suggest a systemic disorder. Since bleeding can be mild, lack of a family history of bleeding does not exclude an inherited hemostatic disorder.

Bleeding from a platelet disorder is usually localized to superficial sites such as the skin and mucous membranes, comes on immediately after trauma or surgery, and is readily controlled by local measures (Table 53-1). In contrast, bleeding from plasma coagulation defects occurs hours or days after injury and is unaffected by local therapy. Such bleeding most often occurs in deep subcutaneous tissues, muscles, joints, or body cavities. A thorough history may establish the presence of a hemostatic disorder and guide initial laboratory testing.

PHYSICAL EXAMINATION The most common site to observe bleeding is in the skin and mucous membranes. Collections of blood in the skin

TABLE 53-1 *Differences in the Clinical Manifestations of Disorders of Primary and Secondary Hemostasis*

Manifestations	Defects of Primary Hemostasis (Platelet Defects)	Defects of Secondary Hemostasis (Plasma Protein Defects)
Onset of bleeding after trauma	Immediate	Delayed—hours or days
Sites of bleeding	Superficial—skin, mucous membranes, nose, gastrointestinal and genitourinary tracts	Deep—joints, muscle, retroperitoneum
Physical findings	Petechiae, ecchymoses	Hematomas, hemarthroses
Family history	Autosomal dominant	Autosomal or X-linked recessive
Response to therapy	Immediate; local measures effective	Requires sustained systemic therapy

are called *purpura* and may be subdivided on the basis of the site of bleeding in the skin. Small pinpoint hemorrhages into the dermis due to the leakage of red cells through capillaries are called *petechiae* and are characteristic of platelet disorders—in particular, severe thrombocytopenia. Larger subcutaneous collections of blood due to leakage of blood from small arterioles and venules are called *ecchymoses* (common bruises) or, if somewhat deeper and palpable, *hematomas*. They are also common in patients with platelet defects and result from minor trauma. Dilated capillaries, or *telangiectasia*, may cause bleeding without any hemostatic defect. In addition, the loss of connective tissue support for capillaries and small veins that accompanies aging increases the fragility of superficial vessels, such as those on the dorsum of the hand, leading to extravasation of blood into subcutaneous tissue—*senile purpura*. Menorrhagia is sometimes a serious problem in women with severe thrombocytopenia or platelet dysfunction. Some patients with primary hemostatic defects, especially von Willebrand's disease, may have recurrent gastrointestinal hemorrhage, often associated with angiodysplasia, a common vascular malformation in the gastrointestinal tract.

Bleeding into body cavities, the retroperitoneum, or joints is a common manifestation of plasma coagulation defects. Repeated joint bleeding may cause synovial thickening, chronic inflammation, and fluid collections and may erode articular cartilage and lead to chronic joint deformity and limited mobility. Joint deformities are particularly common in patients with deficiencies of factors VIII and IX, the two sex-linked coagulation disorders referred to as the *hemophilias*. For unclear reasons, hemarthroses are much less common in patients with other plasma coagulation defects. Blood collections in various body cavities or soft tissues can cause secondary necrosis of tissues or nerve compression. Retroperitoneal hematomas can cause femoral nerve compression, and large collections of poorly coagulated blood in soft tissues occasionally mimic malignant growths—the *pseudotumor syndrome*. Two of the most life-threatening sites of bleeding are in the oropharynx, where bleeding can compromise the airway, and in the central nervous system. Intracerebral hemorrhage is one of the leading causes of death in patients with severe coagulation disorders. Because of their need for plasma and factor concentrates derived from multiple donors, many patients with hemophilia were infected with HIV before effective testing of donors was in place. HIV infection can induce thrombocytopenia and exacerbate bleeding in hemophilia patients.

LABORATORY TESTS The most important screening tests of the primary hemostatic system are (1) a bleeding time (a sensitive measure of platelet function), and (2) a platelet count. The latter correlates well with the propensity to bleed. The normal platelet count is 150,000 to 450,000/μL of blood. As long as the count is >100,000/μL, patients are usually asymptomatic and the bleeding time remains normal. Platelet counts of 50,000 to 100,000/μL cause mild prolongation of the bleeding time; bleeding occurs only from severe trauma or other stress. Patients with platelet counts <50,000/μL have easy bruising, manifested by skin purpura after minor trauma and bleeding after mucous membrane surgery. Patients with a platelet count <20,000/μL have an appreciable incidence of spontaneous bleeding, usually have petechiae, and may have intracranial or other spontaneous internal bleeding. The major causes of thrombocytopenia are outlined in Table 53-2.

TABLE 53-2 *Causes of Thrombocytopenia*

- Decreased marrow production of megakaryocytes
  - Marrow infiltration with tumor, fibrosis
  - Marrow failure—aplastic, hypoplastic anemias, drug effects
- Splenic sequestration of circulating platelets
  - Splenic enlargement due to tumor infiltration
  - Splenic congestion due to portal hypertension
- Increased destruction of circulating platelets
  - Nonimmune destruction
    - Vascular prostheses, cardiac valves
    - Disseminated intravascular coagulation
    - Sepsis
    - Vasculitis
  - Immune destruction
    - Autoantibodies to platelet antigens
    - Drug-associated antibodies
    - Circulating immune complexes (systemic lupus erythematosus, viral agents, bacterial sepsis)

Patients with qualitative platelet abnormalities have a normal platelet count and a prolonged bleeding time (Table 53-3). The bleeding time is ascertained by making a small, superficial skin incision and timing the duration of blood flow from the wounded area. With careful standardization, bleeding time is a reliable and sensitive test of platelet function. A template or an automated scalpel controls the length and depth of the incision (usually 1 mm deep by 9 mm long), and a sphygmomanometer inflated to 40 mmHg distends the capillary bed of the forearm uniformly. The bleeding time test must be performed by an experienced technician, as small differences in technique have a big effect on outcome. Any patient with a bleeding time >10 min has an increased risk of bleeding, but the risk does not become great until the bleeding time is >15 or 20 min. As shown in Fig. 53-10, the relationship between the platelet count and the bleeding time is roughly linear. When a defect in primary hemostasis is uncovered, specialized testing is needed to determine the cause of the platelet dysfunction (Table 53-3). A precise diagnosis is important in determining the proper treatment. Occasional patients with a strong history of bleeding, particularly those with mild von Willebrand's disease, may have a normal bleeding time when initially tested, owing to cyclical variations in the level of the vWF. Repeated testing may be necessary to establish an accurate diagnosis. Bleeding time is not an effective screening test for preoperative patients.

Plasma coagulation function is readily assessed with the PTT, pro-

TABLE 53-3 *Primary Hemostatic (Platelet) Disorders*

- Defects of platelet adhesion
  - von Willebrand's disease
  - Bernard-Soulier syndrome (absence or dysfunction of GpIb/IX)
- Defects of platelet aggregation
  - Glanzmann's thrombasthenia (absence or dysfunction of GpIIb/IIIa)

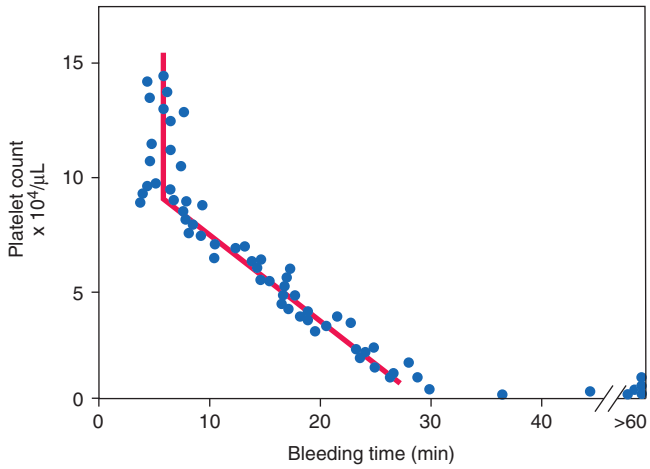

FIGURE 53-10 The relationship between the platelet count and the bleeding time. *(From LA Harker, Hemostasis Manual, 2d ed. Philadelphia, FA Davis Company, 1974.)*

thrombin time (PT), thrombin time (TT), and quantitative fibrinogen determination (Fig. 53-6, Table 53-4). The PTT screens the intrinsic limb of the coagulation system and tests for the adequacy of factors XII, HMWK, PK, XI, IX, and VIII. The PT screens the extrinsic or tissue factor–dependent pathway. Both tests also evaluate the common coagulation pathway involving all the reactions that occur after the activation of factor X. Prolongation of the PT and PTT that does not resolve after the addition of normal plasma suggests a coagulation inhibitor. A specific test for the conversion of fibrinogen to fibrin is needed when both the PTT and PT are prolonged—either a TT or a clottable fibrinogen level can be employed. When abnormalities are noted in any of the screening tests, more specific coagulation factor assays can be ordered to determine the nature of the defect.

Several rare coagulation abnormalities may be missed as they do not affect these screening tests: factor XIII deficiency, α_2 plasmin inhibitor deficiency, PAI-1 deficiency (PAI-1 is the major inhibitor of plasminogen activators), and Scott's syndrome, a platelet coagulant defect. A test for factor XIII–dependent fibrin cross-linking, like clot solubility in 5 *M* urea, should be ordered when the PT and PTT are both normal but the history of bleeding is strong. The fibrinolytic system can be assessed by measuring the rate of clot lysis with the euglobulin lysis or whole blood clot lysis tests and by measuring the levels of α_2 plasmin inhibitor and PAI-1. Scott's syndrome can be detected by measuring the serum PT, which assesses the amount of residual prothrombin.

Conditions associated with thrombosis are listed in Table 53-5. Patients suspected of having a hypercoagulable or prethrombotic disorder on the basis of clinical information should be tested with specific assays to screen for the known defects. Currently available tests can identify 50 to 60% of the cases of familial or recurrent venous thrombosis.

Inhibitor syndromes or circulating anticoagulants are usually due to antibodies that impair coagulation factor activity. They are an infrequent cause of bleeding and require specialized diagnostic testing. Inhibitors are likely when screening test abnormalities cannot be reversed by adding normal plasma to patient plasma. Antibodies against specific coagulation factors may develop in: (1) postpartum women, (2) patients with autoimmune disorders such as systemic lupus erythematosus (SLE), (3) patients taking drugs such as penicillin and streptomycin, and (4) otherwise healthy elderly individuals. In addition, between 10 to 20% of patients with severe hemophilia who have received multiple plasma infusions develop inhibitory antibodies. Some patients, especially those with SLE, may also have a nonspecific form of anticoagulant antibody that interferes with phospholipid binding of coagulation factors and prolongs the PT and PTT but does not cause clinical bleeding. The presence of the lupus anticoagulant may increase the risk of thromboembolism and may cause placental infarction, recurrent midtrimester abortion, and venous and arterial thrombosis. The lupus-like anticoagulant is one manifestation of the anticardiolipin antibody syndrome. Patients may have anticardiolipin antibodies that do not prolong the PTT, but they still have an increased risk of thrombosis. Occasionally, patients develop inhibitors that are not antibodies. For example, several patients with clinical bleeding have been found to have circulating mucopolysaccharides that have heparin-like activity.

TABLE 53-4 Relationship between Secondary Hemostatic Disorders and Coagulation Test Abnormalities

Prolonged partial thromboplastin time (PTT)
No clinical bleeding—factors XII, HMWK, PK
Mild or rare bleeding—factor XI
Frequent, severe bleeding—factors VIII and IX
Prolonged prothrombin time (PT)
Factor VII deficiency
Vitamin K deficiency—early
Warfarin anticoagulant ingestion
Prolonged PTT and PT
Factor II, V, or X deficiency
Vitamin K deficiency—late
Warfarin anticoagulant ingestion
Prolonged thrombin time (TT)
Mild or rare bleeding—afibrinogenemia
Frequent, severe bleeding—dysfibrinogenemia
Heparin-like inhibitors or heparin administration
Prolonged PT and/or PTT not corrected with normal plasma
Specific or nonspecific inhibitor syndromes
Clot solubility in 5 *M* urea
Factor XIII deficiency
Inhibitors or defective cross-linking
Rapid clot lysis
α_2 plasmin inhibitor

Abbreviations: HMWK, high-molecular-weight kininogen; PK, prekallikrein.

TABLE 53-5 Thrombotic Disorders

Inherited
Defective inhibition of coagulation factors
Factor V Leiden (resistant to inhibition by activated protein C)
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Prothrombin gene mutation (G20210A)
Impaired clot lysis
Dysfibrinogenemia
Plasminogen deficiency
tPA deficiency
PAI-1 excess
Uncertain mechanism
Homocystinuria - ? endothelial damage
Acquired
Diseases or syndromes
Lupus anticoagulant/anticardiolipin antibody syndrome
Malignancy
Myeloproliferative disorder
Thrombotic thrombocytopenic purpura
Estrogen treatment
Hyperlipidemia
Diabetes mellitus
Hyperviscosity
Nephrotic syndrome
Congestive heart failure
Paroxysmal nocturnal hemoglobinuria
Physiologic states
Pregnancy (especially postpartum)
Obesity
Postoperative state
Immobilization
Old age

54 ENLARGEMENT OF LYMPH NODES AND SPLEEN

Patrick H. Henry, Dan L. Longo

This chapter is intended to serve as a guide to the evaluation of patients who present with enlargement of the lymph nodes (*lymphadenopathy*) or the spleen (*splenomegaly*). Lymphadenopathy is a rather common clinical finding in primary care settings, whereas palpable splenomegaly is less so.

LYMPHADENOPATHY

Lymphadenopathy may be an incidental finding in patients being examined for various reasons or it may be a presenting sign or symptom of the patient's illness. The physician must eventually decide whether the lymphadenopathy is a normal finding or one that requires further study, up to and including biopsy. Soft, flat, submandibular nodes (<1 cm) are often palpable in healthy children and young adults, and healthy adults may have palpable inguinal nodes of up to 2 cm, which are considered normal. Further evaluation of these normal nodes is not warranted. In contrast, if the physician believes the node(s) to be abnormal, then pursuit of a more precise diagnosis is needed.

APPROACH TO THE PATIENT

Lymphadenopathy may be a primary or secondary manifestation of numerous disorders, as shown in Table 54-1. Many of these disorders are infrequent causes of lymphadenopathy. Analysis of lymphadenopathy in primary care practice has shown that more than two-thirds of patients have nonspecific causes or upper respiratory illnesses (viral or bacterial), and <1% have a malignancy. In one study, researchers reported that 186 of 220 patients (84%) referred for evaluation of lymphadenopathy had a "benign" diagnosis. The remaining 34 patients (16%) had a malignancy (lymphoma or metastatic adenocarcinoma). Of the 186 patients with benign lymphadenopathy, 63% (112) had a nonspecific or reactive etiology (no causative agent found), and the remainder had a specific cause demonstrated, most commonly infectious mononucleosis, toxoplasmosis, or tuberculosis. Thus, the vast majority of patients with lymphadenopathy will have a nonspecific etiology requiring few diagnostic tests.

Clinical Assessment The physician will be aided in the pursuit of an explanation for the lymphadenopathy by a careful medical history, physical examination, selected laboratory tests, and perhaps an excisional lymph node biopsy.

The *medical history* should reveal the setting in which lymphadenopathy is occurring. Symptoms such as sore throat, cough, fever, night sweats, fatigue, weight loss, or pain in the nodes should be sought. The patient's age, sex, occupation, exposure to pets, sexual behavior, and use of drugs such as diphenylhydantoin are other important historic points. For example, children and young adults usually have benign (i.e., nonmalignant) disorders, such as viral or bacterial upper respiratory infections, infectious mononucleosis, toxoplasmosis, and, in some countries, tuberculosis, which account for the observed lymphadenopathy. In contrast, after age 50 the incidence of malignant disorders increases and that of benign disorders decreases.

The *physical examination* can provide useful clues such as the extent of lymphadenopathy (localized or generalized), size of nodes, texture, presence or absence of nodal tenderness, signs of inflammation over the node, skin lesions, and splenomegaly. A thorough ear, nose, and throat (ENT) examination is indicated in adult patients with cervical adenopathy and a history of tobacco use. Localized or regional adenopathy implies involvement of a single anatomic area. Generalized adenopathy has been defined as involvement of three or more noncontiguous lymph node areas. Many of the causes of lymphadenopathy (Table 54-1) can produce localized *or* generalized adenopathy, so this distinction is of limited

TABLE 54-1 Diseases Associated with Lymphadenopathy

1. Infectious diseases
   a. Viral—infectious mononucleosis syndromes (EBV, CMV), infectious hepatitis, herpes simplex, herpesvirus-6, varicella-zoster virus, rubella, measles, adenovirus, HIV, epidemic keratoconjunctivitis, vaccinia, herpesvirus-8
   b. Bacterial—streptococci, staphylococci, cat-scratch disease, brucellosis, tularemia, plague, chancroid, melioidosis, glanders, tuberculosis, atypical mycobacterial infection, primary and secondary syphilis, diphtheria, leprosy
   c. Fungal—histoplasmosis, coccidioidomycosis, paracoccidioidomycosis
   d. Chlamydial—lymphogranuloma venereum, trachoma
   e. Parasitic—toxoplasmosis, leishmaniasis, trypanosomiasis, filariasis
   f. Rickettsial—scrub typhus, rickettsialpox
2. Immunologic diseases
   a. Rheumatoid arthritis
   b. Juvenile rheumatoid arthritis
   c. Mixed connective tissue disease
   d. Systemic lupus erythematosus
   e. Dermatomyositis
   f. Sjögren's syndrome
   g. Serum sickness
   h. Drug hypersensitivity—diphenylhydantoin, hydralazine, allopurinol, primidone, gold, carbamazepine, etc.
   i. Angioimmunoblastic lymphadenopathy
   j. Primary biliary cirrhosis
   k. Graft-vs.-host disease
   l. Silicone-associated
3. Malignant diseases
   a. Hematologic—Hodgkin's disease, non-Hodgkin's lymphomas, acute or chronic lymphocytic leukemia, hairy cell leukemia, malignant histiocytosis, amyloidosis
   b. Metastatic—from numerous primary sites
4. Lipid storage diseases—Gaucher's, Niemann-Pick, Fabry, Tangier
5. Endocrine diseases—hyperthyroidism
6. Other disorders
   a. Castleman's disease (giant lymph node hyperplasia)
   b. Sarcoidosis
   c. Dermatopathic lymphadenitis
   d. Lymphomatoid granulomatosis
   e. Histiocytic necrotizing lymphadenitis (Kikuchi's disease)
   f. Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
   g. Mucocutaneous lymph node syndrome (Kawasaki's disease)
   h. Histiocytosis X
   i. Familial mediterranean fever
   j. Severe hypertriglyceridemia
   k. Vascular transformation of sinuses
   l. Inflammatory pseudotumor of lymph node

Note: EBV, Epstein-Barr virus; CMV, cytomegalovirus.

utility in the differential diagnosis. Nevertheless, generalized lymphadenopathy is frequently associated with nonmalignant disorders such as infectious mononucleosis [Epstein-Barr virus (EBV) or cytomegalovirus (CMV)], toxoplasmosis, AIDS, other viral infections, systemic lupus erythematosus (SLE), and mixed connective tissue disease. Acute and chronic lymphocytic leukemias and malignant lymphomas also produce generalized adenopathy in adults.

The site of localized or regional adenopathy may provide a useful clue about the cause. Occipital adenopathy often reflects an infection of the scalp, and preauricular adenopathy accompanies conjunctival infections and cat-scratch disease. The most frequent site of regional adenopathy is the neck, and most of the causes are benign—upper respiratory infections, oral and dental lesions, infectious mononucleosis, other viral illnesses. The chief malignant causes include metastatic cancer from head and neck, breast, lung, and thyroid primaries. Enlargement of supraclavicular and scalene nodes is always abnormal. Because these nodes drain regions of the lung and retroperitoneal space, they can reflect either lymphomas, other cancers, or infectious processes arising in these areas. Virchow's node is an enlarged left supraclavicular node infiltrated with metastatic cancer from a gastrointestinal primary. Metastases to supraclavicular nodes also occur from lung, breast, testis, or ovarian cancers. Tuberculosis, sarcoidosis, and toxoplasmosis are nonneoplastic causes of supraclavicular adenopathy. Axillary adenopathy is usually due to injuries or localized infections of the ipsilateral upper extremity. Malignant causes include melanoma or lymphoma and, in women, breast cancer. Inguinal lymphadenopathy is usually secondary to infections or trauma of the lower extremities and may accompany sexually transmitted diseases such as lymphogranuloma venereum, primary syphilis, genital herpes, or chancroid. These nodes may also be involved by lymphomas and metastatic cancer from primary lesions of the rectum, genitalia, or lower extremities (melanoma).

The size and texture of the lymph node(s) and the presence of pain are useful parameters in evaluating a patient with lymphadenopathy. Nodes <1.0 cm^2 in area (1.0×1.0 cm or less) are almost always secondary to benign, nonspecific reactive causes. In one retrospective analysis of younger patients (9 to 25 years) who had a lymph node biopsy, a maximum diameter of >2 cm served as one discriminant for predicting that the biopsy would reveal malignant or granulomatous disease. Another study showed that a lymph node size of 2.25 cm^2 (1.5 cm $\times$ 1.5 cm) was the best discriminating limit for distinguishing malignant or granulomatous lymphadenopathy from other causes of lymphadenopathy. Patients with node(s) ≤ 1.0 cm^2 should be observed after excluding infectious mononucleosis and/or toxoplasmosis unless there are symptoms and signs of an underlying systemic illness.

The texture of lymph nodes may be described as soft, firm, rubbery, hard, discrete, matted, tender, movable, or fixed. Tenderness is found when the capsule is stretched during rapid enlargement, usually secondary to an inflammatory process. Some malignant diseases such as acute leukemia may produce rapid enlargement and pain in the nodes. Nodes involved by lymphoma tend to be large, discrete, symmetric, rubbery, firm, mobile, and nontender. Nodes containing metastatic cancer are often hard, nontender, and nonmovable because of fixation to surrounding tissues. The coexistence of splenomegaly in the patient with lymphadenopathy implies a systemic illness such as infectious mononucleosis, lymphoma, acute or chronic leukemia, SLE, sarcoidosis, toxoplasmosis, cat-scratch disease, or other less common hematologic disorders. The patient's story should provide helpful clues about the underlying systemic illness.

Nonsuperficial presentations (thoracic or abdominal) of adenopathy are usually detected as the result of a symptom-directed diagnostic workup. Thoracic adenopathy may be detected by routine chest roentgenography or during the workup for superficial adenopathy. It may also be found because the patient complains of a cough or wheezing from airway compression; hoarseness from recurrent laryngeal nerve involvement; dysphagia from esophageal compression; or swelling of the neck, face, or arms secondary to compression of the superior vena cava or subclavian vein. The differential diagnosis of mediastinal and hilar adenopathy includes primary lung disorders and systemic illnesses that characteristically involve mediastinal or hilar nodes. In the young, mediastinal adenopathy is associated with infectious mononucleosis and sarcoidosis. In endemic regions, histoplasmosis can cause unilateral paratracheal lymph node involvement that mimics lymphoma. Tuberculosis can also cause unilateral adenopathy. In older patients, the differential diagnosis includes primary lung cancer (especially among smokers), lymphomas, metastatic carcinoma (usually lung), tuberculosis, fungal infection, and sarcoidosis.

Enlarged intraabdominal or retroperitoneal nodes are usually malignant. Although tuberculosis may present as mesenteric lymphadenitis, these masses usually contain lymphomas or, in young men, germ cell tumors.

Laboratory Investigation The laboratory investigation of patients with lymphadenopathy must be tailored to elucidate the etiology suspected from the patient's history and physical findings. One study from a family practice clinic evaluated 249 younger patients with "enlarged lymph nodes, not infected" or "lymphadenitis." No laboratory studies were obtained in 51%. When studies were performed, the most common were a complete blood count (33%), throat culture (16%), chest x-ray (12%), or monospot test (10%). Only eight patients (3%) had a node biopsy, and half of those were normal or reactive. The complete blood count can provide useful data for the diagnosis of acute or chronic leukemias, EBV or CMV mononucleosis, lymphoma with a leukemic component, pyogenic infections, or immune cytopenias in illnesses such as SLE. Serologic studies may demonstrate antibodies specific to components of EBV, CMV, HIV, and other viruses; *Toxoplasma gondii*; *Brucella*; etc. If SLE is suspected, then antinuclear and anti-DNA antibody studies are warranted.

The chest x-ray is usually negative, but the presence of a pulmonary infiltrate or mediastinal lymphadenopathy would suggest tuberculosis, histoplasmosis, sarcoidosis, lymphoma, primary lung cancer, or metastatic cancer and demands further investigation.

A variety of imaging techniques [computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, color Doppler ultrasonography] have been employed to differentiate benign from malignant lymph nodes, especially in patients with head and neck cancer. CT and MRI are comparably accurate (65 to 90%) in the diagnosis of metastases to cervical lymph nodes. Ultrasonography has been used to determine the long (L) axis, short (S) axis, and a ratio of long to short axis in cervical nodes. An L/S ratio of <2.0 has a sensitivity and a specificity of 95% for distinguishing benign and malignant nodes in patients with head and neck cancer. This ratio has greater specificity and sensitivity than palpation or measurement of either the long or the short axis alone.

The indications for lymph node biopsy are imprecise, yet it is a valuable diagnostic tool. The decision to biopsy may be made early in a patient's evaluation or delayed for up to 2 weeks. Prompt biopsy should occur if the patient's history and physical findings suggest a malignancy; examples include a solitary, hard, nontender cervical node in an older patient who is a chronic user of tobacco; supraclavicular adenopathy; and solitary or generalized adenopathy that is firm, movable, and suggestive of lymphoma. If a primary head and neck cancer is suspected as the basis of a solitary, hard cervical node, then a careful ENT examination should be performed. Any mucosal lesion that is suspicious for a primary neoplastic process should be biopsied first. If no mucosal lesion is detected, an excisional biopsy of the largest node should be performed. Fine-needle aspiration should not be performed as the first

diagnostic procedure. Most diagnoses require more tissue than such aspiration can provide, and it often delays a definitive diagnosis. Fine-needle aspiration should be reserved for thyroid nodules and for confirmation of relapse in patients whose primary diagnosis is known. If the primary physician is uncertain about whether to proceed to biopsy, consultation with a hematologist or medical oncologist should be helpful. In primary care practices, <5% of lymphadenopathy patients will require a biopsy. That percentage will be considerably larger in referral practices, i.e., hematology, oncology, or otolaryngology (ENT).

Two groups have reported algorithms that they claim will identify more precisely those lymphadenopathy patients who should have a biopsy. Both reports were retrospective analyses in referral practices. The first study involved patients 9 to 25 years of age who had a node biopsy performed. Three variables were identified that predicted those young patients with peripheral lymphadenopathy who should undergo biopsy; lymph node size >2 cm in diameter and abnormal chest x-ray had positive predictive value, whereas recent ENT symptoms had negative predictive values. The second study evaluated 220 lymphadenopathy patients in a hematology unit and identified five variables [lymph node size, location (supraclavicular or nonsupraclavicular), age (>40 years or <40 years), texture (nonhard or hard), and tenderness] that were utilized in a mathematical model to identify those patients requiring a biopsy. Positive predictive value was found for age >40 years, supraclavicular location, node size >2.25 cm^2, hard texture, and lack of pain or tenderness. Negative predictive value was evident for age <40 years, node size <1.0 cm^2, nonhard texture, and tender or painful nodes. Ninety-one percent of those who required biopsy were correctly classified by this model. Since both of these studies were retrospective analyses and one was limited to young patients, it is not known how useful these models would be if applied prospectively in a primary care setting.

Most lymphadenopathy patients do not require a biopsy, and at least half require no laboratory studies. If the patient's history and physical findings point to a benign cause for lymphadenopathy, then careful follow-up at a 2- to 4-week interval can be employed. The patient should be instructed to return for reevaluation if the node(s) increase in size. Antibiotics are not indicated for lymphadenopathy unless there is strong evidence of a bacterial infection. Glucocorticoids should not be used to treat lymphadenopathy because their lympholytic effect obscures some diagnoses (lymphoma, leukemia, Castleman's disease) and they contribute to delayed healing or activation of underlying infections. An exception to this statement is the life-threatening pharyngeal obstruction by enlarged lymphoid tissue in Waldeyer's ring that is occasionally seen in infectious mononucleosis.

SPLENOMEGALY

STRUCTURE AND FUNCTION OF THE SPLEEN The spleen is a reticuloendothelial organ that has its embryologic origin in the dorsal mesogastrium at about 5 weeks' gestation. It arises in a series of hillocks, migrates to its normal adult location in the left upper quadrant (LUQ), and is attached to the stomach via the gastrolienal ligament and to the kidney via the lienorenal ligament. When the hillocks fail to unify into a single tissue mass, accessory spleens may develop in around 20% of persons. The function of the spleen has been elusive. Galen believed it was the source of "black bile" or melancholia, and the word *hypochondria* (literally, beneath the ribs) and the idiom "to vent one's spleen" attest to the beliefs that the spleen had an important influence on the psyche and emotions. In humans, its normal physiologic roles seem to be the following:

1. Maintenance of quality control over erythrocytes in the red pulp by removal of senescent and defective red blood cells. The spleen accomplishes this function through a unique organization of its parenchyma and vasculature (Fig. 54-1).
2. Synthesis of antibodies in the white pulp.

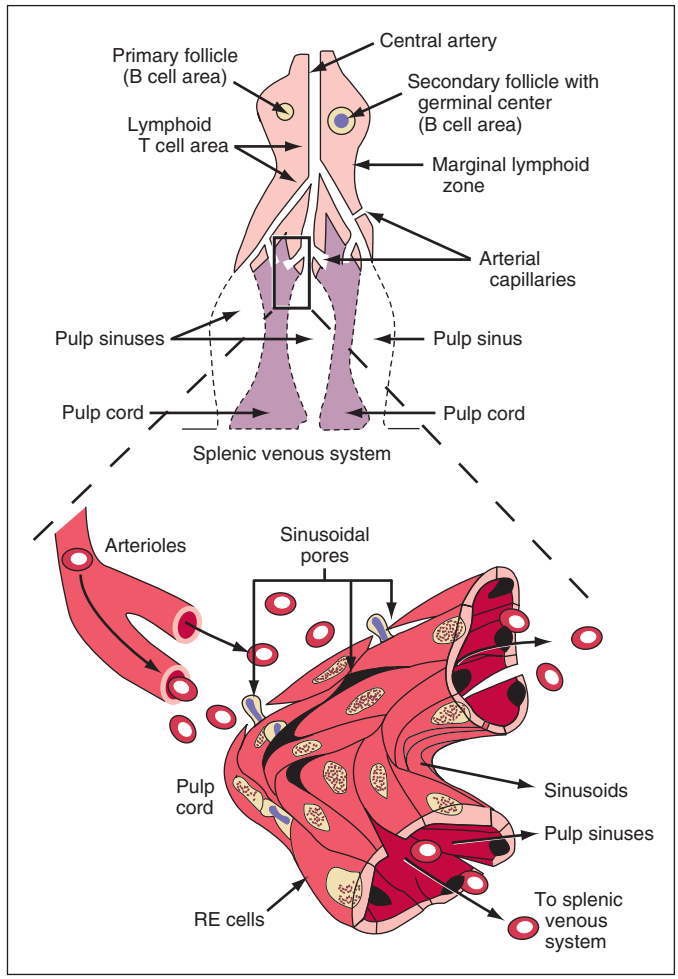

FIGURE 54-1 Schematic spleen structure. The spleen comprises many units of red and white pulp centered around small branches of the splenic artery, called central arteries. White pulp is lymphoid in nature and contains B cell follicles, a marginal zone around the follicles, and T cell–rich areas sheathing arterioles. The red pulp areas include pulp sinuses and pulp cords. The cords are dead ends. In order to regain access to the circulation, red blood cells must traverse tiny openings in the sinusoidal lining. Stiff, damaged, or old red cells cannot enter the sinuses. *(Top portion of figure from CA Janeway et al: Immunobiology, 5th edition, New York, Garland, 2001; Bottom portion of figure from RS Hillman, KA Ault: Hematology in Clinical Practice. New York, McGraw-Hill, 1995.)*

3. The removal of antibody-coated bacteria and antibody-coated blood cells from the circulation.

An increase in these normal functions may result in splenomegaly.

The spleen is composed of red pulp and white pulp, which are Malpighi's terms for the red blood–filled sinuses and reticuloendothelial cell–lined cords and the white lymphoid follicles arrayed within the red pulp matrix. The spleen is in the portal circulation. The reason for this is unknown but may relate to the fact that lower blood pressure allows less rapid flow and minimizes damage to normal erythrocytes. Blood flows into the spleen at a rate of about 150 mL/min through the splenic artery, which ultimately ramifies into central arterioles. Some blood goes from the arterioles to capillaries and then to splenic veins and out of the spleen, but the majority of blood from central arterioles flows into the macrophage-lined sinuses and cords. The blood entering the sinuses reenters the circulation through the splenic venules, but the blood entering the cords is subjected to an inspection of sorts. In order to return to the circulation, the blood cells in the cords must squeeze through slits in the cord lining to enter the sinuses that lead to the venules. Old and damaged erythrocytes are less deformable and are retained in the cords, where they are destroyed and their components

recycled. Red cell inclusion bodies such as parasites, nuclear residua (Howell-Jolly bodies), or denatured hemoglobin (Heinz bodies) are pinched off in the process of passing through the slits, a process called *pitting*. The culling of dead and damaged cells and the pitting of cells with inclusions appear to occur without significant delay since the blood transit time through the spleen is only slightly slower than in other organs.

The spleen is also capable of assisting the host in adapting to its hostile environment. It has at least three adaptational functions: (1) clearance of bacteria and particulates from the blood, (2) the generation of immune responses to certain invading pathogens, and (3) the generation of cellular components of the blood under circumstances in which the marrow is unable to meet the needs (i.e., extramedullary hematopoiesis). The latter adaptation is a recapitulation of the blood-forming function the spleen plays during gestation. In some animals, the spleen also serves a role in the vascular adaptation to stress because it stores red blood cells (often hemoconcentrated to higher hematocrits than normal) under normal circumstances and contracts under the influence of β-adrenergic stimulation to provide the animal with an autotransfusion and improved oxygen-carrying capacity. However, the normal human spleen does not sequester or store red blood cells and does not contract in response to sympathetic stimuli. The normal human spleen contains approximately one-third of the total body platelets and a significant number of marginated neutrophils. These sequestered cells are available when needed to respond to bleeding or infection.

APPROACH TO THE PATIENT

Clinical Assessment The most common *symptoms* produced by diseases involving the spleen are pain and a heavy sensation in the LUQ. Massive splenomegaly may cause early satiety.Pain may result from acute swelling of the spleen with stretching of the capsule, infarction, or inflammation of the capsule. For many years, it was believed that splenic infarction was clinically silent, which at times is true. However, Soma Weiss, in his classic 1942 report of the self-observations by a Harvard medical student on the clinical course of subacute bacterial endocarditis, documented that severe LUQ and pleuritic chest pain may accompany thromboembolic occlusion of splenic blood flow. Vascular occlusion, with infarction and pain, is commonly seen in children with sickle cell crises. Rupture of the spleen, either from trauma or infiltrative disease that breaks the capsule, may result in intraperitoneal bleeding, shock, and death. The rupture itself may be painless.

A palpable spleen is the major *physical sign* produced by diseases affecting the spleen and suggests enlargement of the organ. The normal spleen is said to weigh <250 g, decreases in size with age, normally lies entirely within the rib cage, has a maximum cephalocaudad diameter of 13 cm by ultrasonography or maximum length of 12 cm and/or width of 7 cm by radionuclide scan, and is usually not palpable. However, a palpable spleen was found in 3% of 2200 asymptomatic, male, freshman college students. Follow-up at 3 years revealed that 30% of those students still had a palpable spleen without any increase in disease prevalence. Ten-year follow-up found no evidence for lymphoid malignancies. Furthermore, in some tropical countries (e.g., New Guinea) the incidence of splenomegaly may reach 60%. Thus, the presence of a palpable spleen does not always equate with presence of disease. Even when disease is present, splenomegaly may not reflect the primary disease but rather a reaction to it. For example, in patients with Hodgkin's disease, only two-thirds of the palpable spleens show involvement by the cancer.

Physical examination of the spleen utilizes primarily the techniques of palpation and percussion. Inspection may reveal a fullness in the LUQ that descends on inspiration, a finding associated with a massively enlarged spleen. Auscultation may reveal a venous hum or a friction rub.

Palpation can be accomplished by bimanual palpation, ballotment, and palpation from above (Middleton maneuver). For bimanual palpation, which is at least as reliable as the other techniques, the patient is supine with flexed knees. The examiner's left hand is placed on the lower rib cage and pulls the skin toward the costal margin, allowing the fingertips of the right hand to feel the tip of the spleen as it descends while the patient inspires slowly, smoothly, and deeply. Palpation is begun with the right hand in the left lower quadrant with gradual movement toward the left costal margin, thereby identifying the lower edge of a massively enlarged spleen. When the spleen tip is felt, the finding is recorded as centimeters below the left costal margin at some arbitrary point, i.e., 10 to 15 cm, from the midpoint of the umbilicus or the xiphisternal junction. This allows other examiners to compare findings or the initial examiner to determine changes in size over time. Bimanual palpation in the right lateral decubitus position adds nothing to the supine examination.

Percussion for splenic dullness is accomplished with any of three techniques described by Nixon, Castell, or Barkun:

1. *Nixon's method*: The patient is placed on the right side so that the spleen lies above the colon and stomach. Percussion begins at the lower level of pulmonary resonance in the posterior axillary line and proceeds diagonally along a perpendicular line toward the lower midanterior costal margin. The upper border of dullness is normally 6 to 8 cm above the costal margin. Dullness >8 cm in an adult is presumed to indicate splenic enlargement.
2. *Castell's method*: With the patient supine, percussion in the lowest intercostal space in the anterior axillary line (8th or 9th) produces a resonant note if the spleen is normal in size. This is true during expiration or full inspiration. A dull percussion note on full inspiration suggests splenomegaly.
3. *Percussion of Traube's semilunar space*: The borders of Traube's space are the sixth rib superiorly, the left midaxillary line laterally, and the left costal margin inferiorly. The patient is supine with the left arm slightly abducted. During normal breathing, this space is percussed from medial to lateral margins, yielding a normal resonant sound. A dull percussion note suggests splenomegaly.

Studies comparing methods of percussion and palpation with a standard of ultrasonography or scintigraphy have revealed sensitivity of 56 to 71% for palpation and 59 to 82% for percussion. Reproducibility among examiners is better for palpation than percussion. Both techniques are less reliable in obese patients or patients who have just eaten. Thus, the physical examination techniques of palpation and percussion are imprecise at best. It has been suggested that the examiner perform percussion first and, if positive, proceed to palpation; if the spleen is palpable, then one can be reasonably confident that splenomegaly exists. However, not all LUQ masses are enlarged spleens; gastric or colon tumors and pancreatic or renal cysts or tumors can mimic splenomegaly.

The presence of an enlarged spleen can be more precisely determined, if necessary, by liver-spleen radionuclide scan, CT, MRI, or ultrasonography. The latter technique is the current procedure of choice for routine assessment of spleen size (normal = a maximum cephalocaudad diameter of 13 cm) because it has high sensitivity and specificity and is safe, noninvasive, quick, mobile, and less costly. Nuclear medicine scans are accurate, sensitive, and reliable but are costly, require greater time to generate data, and utilize immobile equipment. They have the advantage of demonstrating accessory splenic tissue. CT and MRI provide accurate determination of spleen size, but the equipment is immobile and the procedures are expensive. MRI appears to offer no advantage over CT. Changes in spleen structure such as mass lesions, infarcts, inhomogeneous infiltrates, and cysts are more readily assessed by CT, MRI, or ultrasonography. None of these techniques is very reliable in the detection of patchy infiltration (e.g., Hodgkin's disease).

Differential Diagnosis Many of the diseases associated with splenomegaly are listed in Table 54-2. They are grouped according to the presumed basic mechanisms responsible for organ enlargement:

1. Hyperplasia or hypertrophy related to a particular splenic function such as reticuloendothelial hyperplasia (work hypertrophy) in diseases such as hereditary spherocytosis or thalassemia syndromes that require removal of large numbers of defective red blood cells; immune hyperplasia in response to systemic infection (infectious mononucleosis, subacute bacterial endocarditis) or to immunologic diseases (immune thrombocytopenia, SLE, Felty's syndrome).

2. Passive congestion due to decreased blood flow from the spleen in conditions that produce portal hypertension (cirrhosis, Budd-Chiari syndrome, congestive heart failure).

3. Infiltrative diseases of the spleen (lymphomas, metastatic cancer, amyloidosis, Gaucher's disease, myeloproliferative disorders with extramedullary hematopoiesis).

The differential diagnostic possibilities are much fewer when the spleen is "massively enlarged," that is, it is palpable more than 8 cm below the left costal margin or its drained weight is ≥1000 g (Table 54-3). The vast majority of such patients will have non-Hodgkin's lymphoma, chronic lymphocytic leukemia, hairy cell leukemia, chronic myelogenous leukemia, myelofibrosis with myeloid metaplasia, or polycythemia vera.

TABLE 54-2 Diseases Associated with Splenomegaly Grouped by Pathogenic Mechanism

ENLARGEMENT DUE TO INCREASED DEMAND FOR SPLENIC FUNCTION
Reticuloendothelial system hyperplasia (for removal of defective erythrocytes)
Spherocytosis
Early sickle cell anemia
Ovalocytosis
Thalassemia major
Hemoglobinopathies
Paroxysmal nocturnal hemoglobinuria
Nutritional anemias
Immune hyperplasia
Response to infection (viral, bacterial, fungal, parasitic)
Infectious mononucleosis
AIDS
Viral hepatitis
Cytomegalovirus
Subacute bacterial endocarditis
Bacterial septicemia
Congenital syphilis
Splenic abscess
Tuberculosis
Histoplasmosis
Malaria
Leishmaniasis
Trypanosomiasis
Ehrlichiosis
Disordered immunoregulation
Rheumatoid arthritis (Felty's syndrome)
Systemic lupus erythematosus
Collagen vascular diseases
Serum sickness
Immune hemolytic anemias
Immune thrombocytopenias
Immune neutropenias
Drug reactions
Angioimmunoblastic lymphadenopathy
Sarcoidosis
Thyrotoxicosis (benign lymphoid hypertrophy)
Interleukin 2 therapy
Extramedullary hematopoiesis
Myelofibrosis
Marrow damage by toxins, radiation, strontium
Marrow infiltration by tumors, leukemias, Gaucher's disease

ENLARGEMENT DUE TO ABNORMAL SPLENIC OR PORTAL BLOOD FLOW
Cirrhosis
Hepatic vein obstruction
Portal vein obstruction, intrahepatic or extrahepatic
Cavernous transformation of the portal vein
Splenic vein obstruction
Splenic artery aneurysm
Hepatic schistosomiasis
Congestive heart failure
Hepatic echinococcosis
Portal hypertension (any cause including the above): "Banti's disease"
INFILTRATION OF THE SPLEEN
Intracellular or extracellular depositions
Amyloidosis
Gaucher's disease
Niemann-Pick disease
Tangier disease
Hurler's syndrome and other mucopolysaccharidoses
Hyperlipidemias
Benign and malignant cellular infiltrations
Leukemias (acute, chronic, lymphoid, myeloid, monocytic)
Lymphomas
Hodgkin's disease
Myeloproliferative syndromes (e.g., polycythemia vera)
Angiosarcomas
Metastatic tumors (melanoma is most common)
Eosinophilic granuloma
Histiocytosis X
Hamartomas
Hemangiomas, fibromas, lymphangiomas
Splenic cysts
UNKNOWN ETIOLOGY
Idiopathic splenomegaly
Berylliosis
Iron-deficiency anemia

Laboratory Assessment The major laboratory abnormalities accompanying splenomegaly are determined by the underlying systemic illness. Erythrocyte counts may be normal, decreased (thalassemia major syndromes, SLE, cirrhosis with portal hypertension), or increased (polycythemia vera). Granulocyte counts may be normal, decreased (Felty's syndrome, congestive splenomegaly, leukemias), or increased (infections or inflammatory disease, myeloproliferative disorders). Similarly, the platelet count may be normal, decreased when there is enhanced sequestration or destruction of platelets in an enlarged spleen (congestive splenomegaly, Gaucher's disease, immune thrombocytopenia), or increased in the myeloproliferative disorders such as polycythemia vera.

The complete blood count may reveal cytopenia of one or more blood cell types, which should suggest *hypersplenism*. This condition is characterized by splenomegaly, cytopenia(s), normal or hyperplastic bone marrow, and a response to splenectomy. The latter characteristic is less precise because reversal of cytopenia, particularly granulocytopenia, is sometimes not sustained after splenectomy. The cytopenias result from increased destruction of the cellular elements secondary to reduced flow of blood through enlarged and congested cords (congestive splenomegaly) or to immune-mediated mechanisms. In hypersplenism, various cell types usually have normal morphology on the peripheral blood smear, although the red cells may be spherocytic due to loss of surface area during their longer transit through the enlarged spleen. The increased marrow production of red cells should be reflected as an increased reticulocyte production index, although the value may be less than expected due to increased sequestration of reticulocytes in the spleen.

The need for additional laboratory studies is dictated by the differential diagnosis of the underlying illness of which splenomegaly is a manifestation.

SPLENECTOMY Splenectomy is infrequently performed for diagnostic purposes, especially in the absence of clinical illness or other diagnostic tests that suggest underlying disease. More often splenectomy is performed for staging the extent of disease in patients with Hodgkin's disease, for symptom control in patients with massive splenomegaly, for disease control in patients with traumatic splenic rupture, or for correction of cytopenias in patients with hypersplenism or immune-mediated destruction of one or more cellular blood elements.

TABLE 54-3 Diseases Associated with Massive Splenomegaly[a]

Chronic myelogenous leukemia	Gaucher's disease
Lymphomas	Chronic lymphocytic leukemia
Hairy cell leukemia	Sarcoidosis
Myelofibrosis with myeloid metaplasia	Autoimmune hemolytic anemia
Polycythemia vera	Diffuse splenic hemangiomatosis

[a] The spleen extends greater than 8 cm below left costal margin and/or weighs more than 1000 g.

Splenectomy is necessary for routine staging of patients with Hodgkin's disease only in those with clinical stage I or II disease in whom radiation therapy alone is contemplated as the treatment. Noninvasive staging of the spleen in Hodgkin's disease is not a sufficiently reliable basis for treatment decisions because one-third of normal-sized spleens will be involved with Hodgkin's disease and one-third of enlarged spleens will be tumor-free. Although splenectomy in chronic myelogenous leukemia does not affect the natural history of disease, removal of the massive spleen usually makes patients significantly more comfortable and simplifies their management by significantly reducing transfusion requirements. Splenectomy is an effective secondary or tertiary treatment for two chronic B cell leukemias, hairy cell leukemia and prolymphocytic leukemia, and for the very rare splenic mantle cell or marginal zone lymphoma. Splenectomy in these diseases may be associated with significant tumor regression in bone marrow and other sites of disease. Similar regressions of systemic disease have been noted after splenic irradiation in some types of lymphoproliferative disease, especially chronic lymphocytic leukemia and prolymphocytic leukemia. This has been termed the *abscopal effect*. Such systemic tumor responses to local therapy directed at the spleen suggest that there may be some hormone or growth factor produced by the spleen that affects tumor cell proliferation, but this conjecture is not yet substantiated. A common therapeutic indication for splenectomy is traumatic or iatrogenic splenic rupture. In a fraction of patients with splenic rupture, peritoneal seeding of splenic fragments can lead to *splenosis*—the presence of multiple rests of spleen tissue not connected to the portal circulation. This ectopic spleen tissue may cause pain or gastrointestinal obstruction, as in endometriosis. A large number of hematologic, immunologic, and congestive causes of splenomegaly can lead to destruction of one or more cellular blood elements. In the majority of such cases, splenectomy can correct the cytopenias, particularly anemia and thrombocytopenia. In a large series of patients seen in two tertiary care centers, the indication for splenectomy was diagnostic in 10% of the patients, therapeutic in 44%, staging for Hodgkin's disease in 20%, and incidental to another procedure in 26%. Perhaps the only contraindication to splenectomy is the presence of marrow failure, in which the enlarged spleen is the only source of hematopoietic tissue.

The absence of the spleen has minimal long-term effects on the hematologic profile. In the immediate postsplenectomy period, there may be some leukocytosis (up to 25,000/μL) and thrombocytosis (up to $1 \times 10^6/\mu$L), but within 2 to 3 weeks, blood cell counts and survival of each cell lineage are usually normal. The chronic manifestations of splenectomy are marked variation in size and shape of erythrocytes (anisocytosis, poikilocytosis) and the presence of Howell-Jolly bodies (nuclear remnants), Heinz bodies (denatured hemoglobin), basophilic stippling, and an occasional nucleated erythrocyte in the peripheral blood. When such erythrocyte abnormalities appear in a patient whose spleen has not been removed, one should suspect splenic infiltration by tumor that has interfered with its normal culling and pitting function.

The most serious consequence of splenectomy is increased susceptibility to bacterial infections, particularly those with capsules such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and some gram-negative enteric organisms. Patients under age 20 years are particularly susceptible to overwhelming sepsis with *S. pneumoniae*, and the overall actuarial risk of sepsis in patients who have had their spleens removed is about 7% in 10 years. The case-fatality rate for pneumococcal sepsis in splenectomized patients is 50 to 80%. About 25% of patients without spleens will develop a serious infection at some time in their life. The frequency is highest within the first 3 years after splenectomy. About 15% of the infections are polymicrobial, and lung, skin, and blood are the most common sites. No increased risk of viral infection has been noted in patients who have no spleen. The susceptibility to bacterial infections relates to the inability to remove opsonized bacteria from the bloodstream and a defect in making antibodies to T cell–independent antigens such as the polysaccharide components of bacterial capsules. Pneumococcal vaccine (23-valent polysaccharide vaccine) should be administered to all patients 2 weeks before elective splenectomy. The Advisory Committee on Immunization Practices recommends that even splenectomized patients receive pneumococcal vaccine with a repeat vaccination 5 years later. Efficacy has not been proven in this setting, and the recommendation discounts the possibility that administration of the vaccine may actually lower the titer of specific pneumococcal antibodies. A more effective pneumococcal vaccine that involves T cells in the response is in development. The vaccine to *Neisseria meningitidis* should also be given to patients in whom elective splenectomy is planned. No other vaccines are routinely recommended in this setting.

Splenectomized patients should be educated to consider any unexplained fever as a medical emergency. Prompt medical attention with evaluation and treatment of suspected bacteremia may be lifesaving. Routine chemoprophylaxis with oral penicillin can result in the emergence of drug-resistant strains and is not recommended.

In addition to an increased susceptibility to bacterial infections, splenectomized patients are also more susceptible to the parasitic disease babesiosis. The splenectomized patient should avoid areas where the parasite *Babesia* is endemic (e.g., Cape Cod, MA).

Surgical removal of the spleen is an obvious cause of hyposplenism. Patients with sickle cell disease often suffer from autosplenectomy as a result of splenic destruction by the numerous infarcts associated with sickle cell crises during childhood. Indeed, the presence of a palpable spleen in a patient with sickle cell disease after age 5 suggests a coexisting hemoglobinopathy, e.g., thalassemia or hemoglobin C. In addition, patients who receive splenic irradiation for a neoplastic or autoimmune disease are also functionally hyposplenic. The term *hyposplenism* is preferred to *asplenism* in referring to the physiologic consequences of splenectomy because asplenia is a rare, specific, and fatal congenital abnormality in which there is a failure of the left side of the coelomic cavity (which includes the splenic anlagen) to develop normally. Infants with asplenia have no spleens, but that is the least of their problems. The right side of the developing embryo is duplicated on the left so there is liver where the spleen should be, there are two right lungs, and the heart comprises two right atria and two right ventricles.

55 DISORDERS OF GRANULOCYTES AND MONOCYTES

Steven M. Holland, John I. Gallin

Leukocytes are the major cells comprising inflammatory and immune responses and include neutrophils, T and B lymphocytes, natural killer (NK) cells, monocytes, eosinophils, and basophils. These cells have specific functions, such as antibody production by B lymphocytes or destruction of bacteria by neutrophils, but in no single infectious disease is the exact role of the cell types completely established. Thus, whereas neutrophils are classically thought to be critical to host defense against bacteria, they may also play important roles in defense against viral infections.

The blood delivers leukocytes to the various tissues from the bone marrow, where they are produced. Normal blood leukocyte counts are 4.3 to 10.8 $\times$ 10^9/L with neutrophils representing 45 to 74% of the cells, bands 0 to 4%, lymphocytes 16 to 45%, monocytes 4 to 10%, eosinophils 0 to 7%, and basophils 0 to 2%. The various leukocytes are derived from a common stem cell in the bone marrow. Three-fourths of the nucleated cells of bone marrow are committed to the production of leukocytes. Leukocyte maturation in the marrow is under the regulatory control of a number of different factors, known as colony-stimulating factors and interleukins (ILs). Because an alteration in the number and type of leukocytes is often associated with disease processes, total white blood count (WBC) (cells per microliter) and differential counts are informative. The lymphocytes and basophils are discussed in Chaps. 295 and 298, respectively. This chapter focuses on the neutrophils, monocytes, and eosinophils.

NEUTROPHILS

MATURATION Important events in neutrophil life are summarized in Fig. 55-1. In normal humans, neutrophils are produced only in the bone marrow. The minimum number of stem cells necessary to support hematopoiesis is estimated to be 400 to 500. Human blood monocytes, tissue macrophages, and stromal cells produce colony-stimulating factors, hormones required for the growth of monocytes and neutrophils in the bone marrow. The hematopoietic system not only produces enough neutrophils ($\sim$1.3 $\times$ 10^{11} cells per 80-kg person per day) to carry out physiologic functions but also has a large reserve stored in the marrow, which can be mobilized in response to inflammation or infection. An increase in the number of blood neutrophils is called *neutrophilia*, and the presence of immature cells is termed a *shift to the left*. A decrease in the number of blood neutrophils is called *neutropenia*.

Neutrophils and monocytes evolve from pluripotent stem cells under the influence of cytokines and colony-stimulating factors (Fig. 55-2). The proliferation phase through the metamyelocyte takes about 1 week, while the maturation phase from metamyelocyte to mature neutrophil takes another week. The myeloblast is the first recognizable precursor cell and is followed by the *promyelocyte*. The promyelocyte evolves when the classic lysosomal granules, called the *primary*, or *azurophil, granules*, are produced. The primary granules contain hydrolases, elastase, myeloperoxidase, cathepsin G, cationic proteins, and bactericidal/permeability-increasing protein, which is important for killing gram-negative bacteria. Azurophil granules also contain *defensins*, a family of cysteine-rich polypeptides with broad antimicrobial activity against bacteria, fungi, and certain enveloped viruses. The promyelocyte divides to produce the *myelocyte*, a cell responsible for the synthesis of the *specific*, or *secondary, granules*, which contain unique (specific) constituents such as lactoferrin, vitamin B_{12}–binding protein, membrane components of the nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase required for hydrogen peroxide production, histaminase, and receptors for certain chemoattractants and adherence-promoting factors (CR3) as well as receptors for the basement membrane component, laminin. The secondary granules do not contain acid hydrolases and therefore are not classic lysosomes. Packaging of secondary granule contents during myelopoiesis is controlled by CCAAT/enhancer binding protein-ε. Secondary granule contents are readily released extracellularly, and their mobilization is important in modulating inflammation. During the final stages of maturation no cell division occurs, and the cell passes through the metamyelocyte stage and then to the band neutrophil with a sausage-shaped nucleus (Fig. 55-3). As the band cell matures, the nucleus assumes a lobulated configuration. The nucleus of neutrophils normally contains up to four segments (Fig. 55-4). Excessive segmentation (more than five nuclear lobes) may be a manifestation of folate or vitamin B_{12} deficiency (Fig. 92-4). The Pelger-Hüet anomaly (Fig. 55-5), an infrequent dominant benign inherited trait, results in neutrophils with distinctive bilobed nuclei that must be distinguished from band forms. The physiologic role of the multilobed nucleus of neutrophils is unknown, but it may allow great deformation of neutrophils during migration into tissues at sites of inflammation.

In severe acute bacterial infection, prominent neutrophil cytoplasmic granules, called *toxic granulations*, are occasionally seen. Toxic granulations are immature or abnormally staining azurophil granules. Cytoplasmic inclusions, also called *Döhle bodies* (Fig. 55-3), can be seen during infection and are fragments of ribosome-rich endoplasmic reticulum. Large neutrophil vacuoles are often present in acute bacterial infection and probably represent pinocytosed (internalized) membrane.

Neutrophils are heterogeneous in function. Monoclonal antibodies have been developed that recognize only a subset of mature neutrophils. The meaning of neutrophil heterogeneity is not known.

The morphology of eosinophils and basophils is shown in Fig. 55-6.

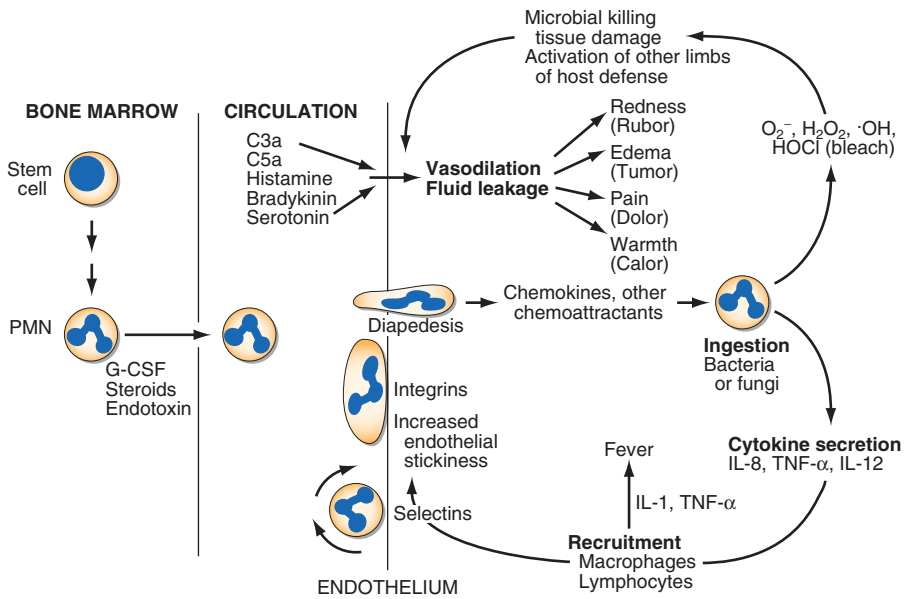

FIGURE 55-1 Schematic events in neutrophil production, recruitment, and inflammation. The four cardinal signs of inflammation (rubor, tumor, calor, dolor) are indicated, as are the interactions of neutrophils with other cells and cytokines. PMN, polymorphonuclear leukocytes; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; TNF-α, tumor necrosis factor.

Cell	Stage	Surface Markers[a]	Characteristics
	MYELOBLAST	CD33, CD13, CD15	Prominent nucleoli
	PROMYELOCYTE	CD33, CD13, CD15	Large cell Primary granules appear
	MYELOCYTE	CD33, CD13, CD15, CD14, CD11b	Secondary granules appear
	METAMYELOCYTE	CD33, CD13, CD15, CD14, CD11b	Kidney bean–shaped nucleus
	BAND FORM	CD33, CD13, CD15, CD14, CD11b CD10, CD16	Condensed, band–shaped nucleus
	NEUTROPHIL	CD33, CD13, CD15, CD14, CD11b CD10, CD16	Condensed, multilobed nucleus

[a]CD= Cluster Determinant; Nucleolus; Primary granule; Secondary granule.

FIGURE 55-2 Stages of neutrophil development are schematically shown. G-CSF and GM-CSF are critical to this process. Identifying cellular characteristics and specific cell-surface markers are listed for each maturational stage.

MARROW RELEASE AND CIRCULATING COMPARTMENTS Specific signals, including IL -1, tumor necrosis factor-α (TNF-α), the colony-stimulating factors, complement fragments, and perhaps other cytokines, mobilize leukocytes from the bone marrow and deliver them to the blood in an unstimulated state. Under normal conditions, ~90% of the neutrophil pool is in the bone marrow, 2 to 3% in the circulation, and the remainder in the tissues (Fig. 55-7).

The circulating pool exists in two dynamic compartments: one freely flowing and one marginated. The freely flowing pool is about one-half the neutrophils in the basal state and is composed of those cells that are in the blood and not in contact with the endothelium. Marginated leukocytes are those that are in close physical contact with the endothelium (Fig. 55-8). In the pulmonary circulation, where an extensive capillary bed (~1000 capillaries per alveolus) exists, margination occurs because the capillaries are about the same size as a mature neutrophil. Therefore, neutrophil fluidity and deformability are necessary to make the transit through the pulmonary bed. Increased neutrophil rigidity and decreased deformability lead to augmented neutrophil trapping and margination in the lung. In contrast, in the systemic postcapillary venules, margination is mediated by the interaction of specific cell-surface molecules. *Selectins* are glycoproteins expressed on neutrophils and endothelial cells, among others, that cause a low-affinity interaction, resulting in "rolling" of the neutrophil along the endothelial surface. On neutrophils, the molecule L-selectin [cluster determinant (CD) 62L] binds to glycosylated proteins on endothelial cells [e.g., glycosylation-dependent cell adhesion molecule (GlyCAM1) and CD34]. Glycoproteins on neutrophils, most importantly sialyl-Lewis^x (SLe^x, CD15s), are targets for binding of selectins expressed on endothelial cells [E-selectin (CD62E) and P-selectin (CD62P)] and other leukocytes. In response to chemotactic stimuli from injured tissues (e.g., complement product C5a, leukotriene B_4, IL-8) or bacterial products [e.g., *N*-formylmethionylleucylphenylalanine (f-metleuphe)], neutrophil adhesiveness increases, and the cells "stick" to the endothelium through *integrins*. The integrins are leukocyte glycoproteins that exist as complexes of a common CD18 β chain with CD11a (LFA-1), CD11b (also called either Mac-1, CR3, or the C3bi receptor), and CD11c (p150,95). CD11a/CD18 and CD11b/CD18 bind to specific endothelial receptors [intercellular adhesion molecules (ICAM) 1 and 2.]

On cell stimulation, L-selectin is shed; receptors for chemoattractants and opsonins are mobilized; and the phagocytes orient toward the chemoattractant source in the extravascular space, increase their motile activity (chemokinesis), and migrate directionally (chemotaxis) into tissues. The process of migration into tissues is called *diapedesis* and involves the crawling of neutrophils between postcapillary endothelial cells that open junctions between adjacent cells to permit leukocyte passage. Diapedesis involves platelet/endothelial cell adhesion molecule (PECAM) 1 (CD31), which is expressed on both the emigrating leukocyte and the endothelial cells. The endothelial responses (increased blood flow from increased vasodilation and permeability) are mediated by anaphylatoxins (e.g., C3a and C5a) as well as vasodilators such as histamine, bradykinin, serotonin, nitric oxide, vascular endothelial growth factor (VEGF), and prostaglandins E and I. Cytokines regulate some of these processes [e.g., TNF-α induction of VEGF, interferon (IFN) γ inhibition of prostaglandin E.

In the healthy adult, most neutrophils leave the body by migration through the mucous membrane of the gastrointestinal tract. Normally, neutrophils spend a short time in the circulation (half-life, 6 to 7 h). Senescent neutrophils are cleared from the circulation by macrophages in the lung and spleen. Once in the tissues, neutrophils release enzymes, such as collagenase and elastase, that help establish abscess cavities. Neutrophils ingest pathogenic materials that have been opsonized by IgG and C3b. Fibronectin and the tetrapeptide tuftsin facilitate phagocytosis.

With phagocytosis comes a burst of oxygen consumption and activation of the hexose-monophosphate shunt. A membrane-associated NADPH oxidase, consisting of membrane and cytosolic components, is assembled and catalyzes the reduction of oxygen to superoxide anion, which is then converted to hydrogen peroxide and other toxic oxygen products (e.g., hydroxyl radical). Hydrogen peroxide + chloride + neutrophil myeloperoxidase generate hypochlorous acid (bleach), hypochlorite, and chlorine. These products oxidize and halogenate microorganisms and tumor cells and, when uncontrolled, can damage host tissue. Strongly cationic proteins, defensins, and probably

FIGURE 55-3 Neutrophil band with Döhle body. The neutrophil with a sausage-shaped nucleus in the center of the field is a band form. Döhle bodies are discrete, blue-staining nongranular areas found in the periphery of the cytoplasm of the neutrophil in infections and other toxic states. They represent aggregates of rough endoplasmic reticulum.

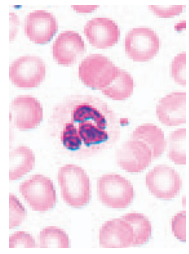

FIGURE 55-4 Normal granulocyte. The normal granulocyte has a segmented nucleus with heavy, clumped chromatin; fine neutrophilic granules are dispersed throughout the cytoplasm.

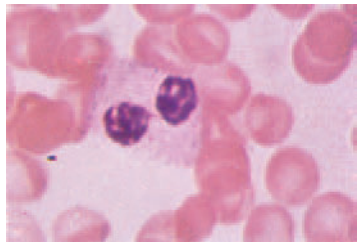

FIGURE 55-5 Pelger-Hüet anomaly. In this benign disorder, the majority of granulocytes are bilobed. The nucleus frequently has a spectacle-like, or "pince-nez," configuration.

nitric oxide also participate in microbial killing. Other enzymes, such as lysozyme and acid proteases, help digest microbial debris. After 1 to 4 days in tissues neutrophils die. The apoptosis of neutrophils is also cytokine-regulated; granulocyte colony-stimulating factor (G-CSF) and IFN-γ prevent their death. Under certain conditions, such as in delayed-type hypersensitivity, monocyte accumulation occurs within 6 to 12 h of initiation of inflammation. Neutrophils, monocytes, microorganisms in various states of digestion, and altered local tissue cells make up the inflammatory exudate, pus. Myeloperoxidase confers the characteristic green color to pus and may participate in turning off the inflammatory process by inactivating chemoattractants and immobilizing phagocytic cells.

Neutrophils respond to certain cytokines [IFN-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-8] and produce cytokines and chemotactic signals [TNF-α, IL-8, macrophage inflammatory protein (MIP) 1] that modulate the inflammatory response. In the presence of fibrinogen, f-metleuphe or leukotriene B_4 induces IL-8 production by neutrophils, providing autocrine amplification of inflammation. *Chemokines* (chemoattractant cytokines) are small proteins produced by many different cell types, including endothelial cells, fibroblasts, epithelial cells, neutrophils, and monocytes, that regulate neutrophil and monocyte recruitment and activation. The chemokines transduce their signals through heterotrimeric G protein–linked receptors that have seven cell membrane–spanning domains, the same type of cell-surface receptor that mediates the response to the classic chemoattractants f-metleuphe and C5a. Four major groups of chemokines are recognized based on the cysteine structure near the N terminus: C, CC, CXC, and CXXXC. The CXC cytokines such as IL-8 mainly attract neutrophils; CC chemokines such as MIP-1 attract lymphocytes, monocytes, eosinophils, and basophils; the C chemokine lymphotactin is T cell tropic; the CXXXC chemokine fractalkine attracts neutrophils, monocytes, and T cells. These molecules and their receptors not only regulate the trafficking and activation of inflammatory cells, but chemokine receptors serve as co-receptors for HIV infection (Chap. 173) and have a role in atherogenesis.

NEUTROPHIL ABNORMALITIES A defect in the neutrophil life cycle can lead to dysfunction and compromised host defenses. Inflammation is often depressed, and the clinical result is often recurrent and severe bacterial and fungal infections. Aphthous ulcers of mucous membranes (gray ulcers without pus) and gingivitis and periodontal disease suggest a phagocytic cell disorder. Patients with congenital phagocyte defects can have infections within the first few days of life. Skin, ear, upper and lower respiratory tract, and bone infections are common. Sepsis and meningitis are rare. In some disorders the frequency of infection is variable, and patients can go for months or even years without major infection. Aggressive management of these congenital diseases has extended the life span of patients well beyond 30 years.

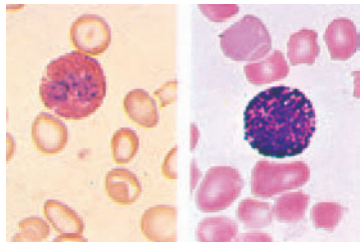

FIGURE 55-6 Normal eosinophil and basophil. The eosinophil contains large, bright orange granules and usually a bilobed nucleus. The basophil contains large purple-black granules that fill the cell and obscure the nucleus.

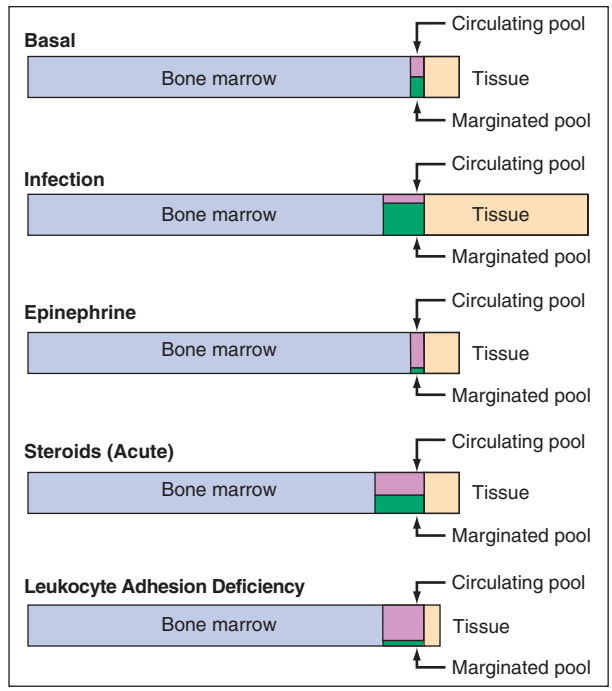

FIGURE 55-7 Schematic neutrophil distribution and kinetics between the different anatomic and functional pools.

Neutropenia The consequences of absent neutrophils are dramatic. Susceptibility to infectious diseases increases sharply when neutrophil counts fall below 1000 cells/μL. When the absolute neutrophil count (ANC; band forms and mature neutrophils combined) falls to $<$500 cells/μL, control of endogenous microbial flora (e.g., mouth, gut) is impaired; when the ANC is $<$200/μL, the inflammatory process is absent. Neutropenia can be due to depressed production, increased peripheral destruction, or excessive peripheral pooling. A falling neutrophil count or a significant decrease in the number of neutrophils below steady-state levels, together with a failure to increase neutrophil counts in the setting of infection or other challenge, requires investigation. Acute neutropenia, such as that caused by cancer chemotherapy, is more likely to be associated with increased risk of infection than neutropenia of long duration (months to years) that reverses in response to infection or carefully controlled administration of endotoxin (see "Laboratory Diagnosis," below).

Some causes of inherited and acquired neutropenia are listed in Table 55-1. The most common neutropenias are iatrogenic, resulting from the use of cytotoxic or immunosuppressive therapies for malignancy or control of autoimmune disorders. These drugs cause neutropenia because they result in decreased production of rapidly growing progenitor (stem) cells of the marrow. Certain antibiotics such as chloramphenicol, trimethoprim-sulfamethoxazole, flucytosine, vidarabine, and the antiretroviral drug zidovudine may cause neutropenia by inhibiting proliferation of myeloid precursors. The marrow suppression is generally dose-related and dependent on continued administration of the drug. Recombinant human G-CSF usually reverses this form of neutropenia.

Another important mechanism for iatrogenic neutropenia is the effect of drugs that serve as immune haptens and sensitize neutrophils or neutrophil precursors to immune-mediated peripheral destruction. This form of drug-induced neutropenia can be seen within 7 days of exposure to the drug; with previous drug exposure, resulting in preexisting antibodies, neutropenia may occur a few hours after administration of the drug. Although any drug can cause this form of neutropenia, the most frequent causes are commonly used antibiotics, such as sulfa-containing compounds, penicillins, and cephalosporins. Fever and eosinophilia may also be associated with drug reactions, but

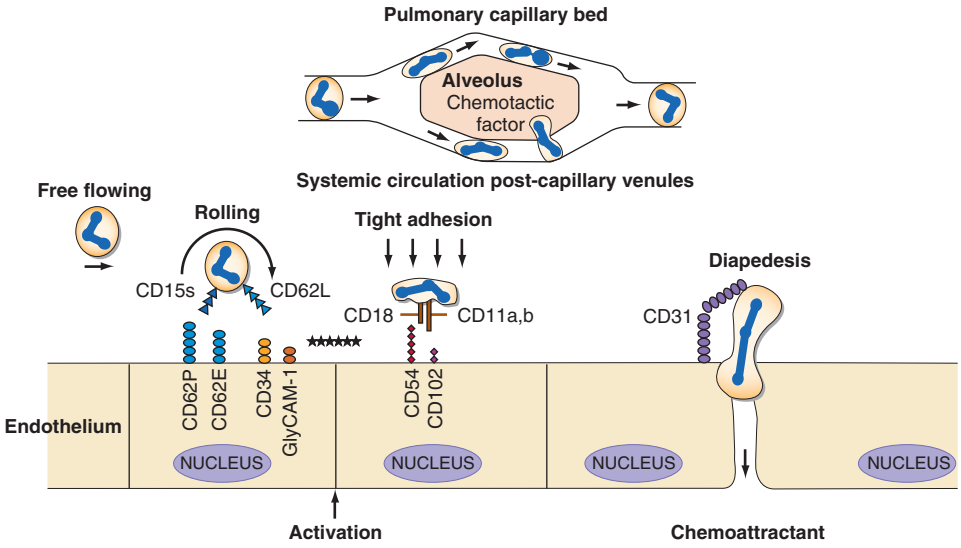

FIGURE 55-8 Neutrophil travel through the pulmonary capillaries is dependent on neutrophil deformability. Neutrophil rigidity (e.g., caused by C5a) enhances pulmonary trapping and response to pulmonary pathogens in a way that is not so dependent upon cell-surface receptors. Intraalveolar chemotactic factors, such as those caused by certain bacteria (e.g., *Streptococcus pneumoniae*) lead to diapedesis of neutrophils from the pulmonary capillaries into the alveolar space. Neutrophil interaction with the endothelium of the systemic postcapillary venules is dependent on molecules of attachment. The neutrophil "rolls" along the endothelium using selectins: neutrophil CD15s (sialyl-Lewis^x) binds to CD62E (E-selectin) and CD62P (P-selectin) on endothelial cells; CD62L (L-selectin) on neutrophils binds to CD34 and other molecules (e.g., GlyCAM-1) expressed on endothelium. Chemokines or other activation factors stimulate integrin-mediated "tight adhesion": CD11a/CD18 (LFA-1) and CD11b/CD18 (Mac-1, CR3) bind to CD54 (ICAM-1) and CD102(ICAM-2) on the endothelium. Diapedesis occurs between endothelial cells: CD31 (PECAM-1) expressed by the emigrating neutrophil interacts with CD31 expressed at the endothelial cell-cell junction.

often these signs are not present. Drug-induced neutropenia can be severe, but discontinuation of the sensitizing drug is sufficient for recovery, which is usually seen within 5 to 7 days and is complete by 10 days. Readministration of the sensitizing drug should be avoided, since abrupt neutropenia will often result. For this reason, diagnostic challenge should be avoided.

Autoimmune neutropenias caused by circulating antineutrophil antibodies are another form of acquired neutropenia that results in increased destruction of neutrophils. Acquired neutropenia may also be seen with viral infections, including infection with HIV. Acquired neutropenia may be cyclic in nature, occurring at intervals of several weeks. Acquired cyclic or stable neutropenia may be associated with an expansion of large granular lymphocytes (LGL), which may be T cells, NK cells, or NK-like cells. Patients with LGL lymphocytosis may have moderate blood and bone marrow lymphocytosis, neutropenia, polyclonal hypergammaglobulinemia, splenomegaly, rheumatoid arthritis, and absence of lymphadenopathy. Such patients may have a chronic and relatively stable course. Recurrent bacterial infections are frequent. Benign and malignant forms of this syndrome occur. In some patients, a spontaneous regression has occurred even after 11 years, suggesting an immunoregulatory defect as the basis for at least one form of the disorder. Glucocorticoids, cyclosporine, IFN-α, and nucleosides such as 2-chlorodeoxyadenosine each have induced remission.

Hereditary Neutropenias Hereditary neutropenias are rare and may manifest in early childhood as a profound constant neutropenia or agranulocytosis. Congenital forms of neutropenia include Kostmann's syndrome (neutrophil count $< 100/\mu L$), which is often fatal; more benign severe chronic neutropenia (neutrophil count of 300 to 1500/μL) due to mutations in neutrophil elastase; the cartilage-hair hypoplasia syndrome due to mutations in the mitochondrial RNA-processing endoribonuclease, RMRP; Shwachman-Diamond syndrome associated with pancreatic insufficiency due to mutations in the Shwachman-Bodian-Diamond syndrome gene, *SBDS*; myelokathexis, a congenital disorder characterized by neutrophil degeneration, hypersegmentation, and myeloid hyperplasia in the marrow associated with decreased expression of bcl-X_L in myeloid precursors and accelerated apoptosis due to mutations in the chemokine receptor CXCR4; and neutropenias associated with other immune defects (X-linked agammaglobulinemia, ataxia telangiectasia, IgA deficiency). Mutations in the G-CSF receptor on chromosome 1 associated with poor response to G-CSF can develop in severe congenital neutropenia and are linked to myeloid malignancy. Hereditary cyclic neutropenia, an autosomal dominant trait, is typically diagnosed in infancy and is characterized by a remarkably regular 3-week cycle. Hereditary cyclic neutropenia actually is cyclic hematopoiesis, also due to mutations in the neutrophil elastase gene. Glucocorticoids and G-CSF blunt the cycling in some patients.

Maternal factors can be associated with neutropenia in the newborn. Transplacental transfer of IgG directed against antigens on fetal neutrophils can result in peripheral destruction. Drugs (e.g., thiazides) ingested during pregnancy can cause neutropenia in the newborn by either depressed production or peripheral destruction.

The presence of immunoglobulin directed toward neutrophils is seen in Felty's syndrome—a triad of rheumatoid arthritis, splenomegaly, and neutropenia (Chap. 301). Patients with Felty's syndrome who respond to splenectomy with an increase in their neutrophil count also have lower postoperative serum neutrophil-binding IgG. Some of these patients have neutropenia associated with an increased number of LGL. Splenomegaly with peripheral trapping and destruction of neutrophils is also seen in lysosomal storage diseases and in portal hypertension.

Neutrophilia Neutrophilia results from increased neutrophil production, increased marrow release, or defective margination (Table 55-2). The most important acute cause of neutrophilia is infection. Neutrophilia from acute infection represents both increased production and increased marrow release. Increased production is also associated with chronic inflammation and certain myeloproliferative diseases. In-

TABLE 55-1 Causes of Neutropenia

Decreased Production
Drug-induced—alkylating agents (nitrogen mustard, busulfan, chlorambucil, cyclophosphamide); antimetabolites (methotrexate, 6-mercaptopurine, 5-flucytosine); noncytotoxic agents [antibiotics (chloramphenicol, penicillins, sulfonamides), phenothiazines, tranquilizers (meprobamate), anticonvulsants (carbamazepine), antipsychotics (clozapine), certain diuretics, anti-inflammatory agents, antithyroid drugs, many others]
Hematologic diseases—idiopathic, cyclic neutropenia, Chédiak-Higashi syndrome, aplastic anemia, infantile genetic disorders (see text)
Tumor invasion, myelofibrosis
Nutritional deficiency—vitamin B_{12}, folate (especially alcoholics)
Infection—tuberculosis, typhoid fever, brucellosis, tularemia, measles, infectious mononucleosis, malaria, viral hepatitis, leishmaniasis, AIDS
Peripheral Destruction
Antineutrophil antibodies and/or splenic or lung trapping
Autoimmune disorders—Felty's syndrome, rheumatoid arthritis, lupus erythematosus
Drugs as haptens—aminopyrine, α-methyldopa, phenylbutazone, mercurial diuretics, some phenothiazines
Wegener's granulomatosis
Peripheral Pooling (Transient Neutropenia)
Overwhelming bacterial infection (acute endotoxemia)
Hemodialysis
Cardiopulmonary bypass

TABLE 55-2 *Causes of Neutrophilia*

Increased Production
Idiopathic
Drug-induced—glucocorticoids
Infection—bacterial, fungal, sometimes viral
Inflammation—thermal injury, tissue necrosis, myocardial and pulmonary infarction, hypersensitivity states, collagen vascular diseases
Myeloproliferative diseases—myelocytic leukemia, myeloid metaplasia, polycythemia vera
Increased Marrow Release
Glucocorticoids
Acute infection (endotoxin)
Inflammation—thermal injury
Decreased or Defective Margination
Drugs—epinephrine, glucocorticoids, nonsteroidal anti-inflammatory agents
Stress, excitement, vigorous exercise
Leukocyte adhesion deficiency type 1 (integrin β chain, CD18); leukocyte adhesion deficiency type 2 (selectin ligand, CD15s, sialyl-Lewis^x)
Miscellaneous
Metabolic disorders—ketoacidosis, acute renal failure, eclampsia, acute poisoning
Drugs—lithium
Other—metastatic carcinoma, acute hemorrhage or hemolysis

creased marrow release and mobilization of the marginated leukocyte pool are induced by glucocorticoids. Release of epinephrine, as with vigorous exercise, excitement, or stress, will demarginate neutrophils in the spleen and lungs and double the neutrophil count in minutes. Leukocytosis with cell counts of 10,000 to 25,000/μL occurs in response to infection and other forms of acute inflammation and results from both release of the marginated pool and mobilization of marrow reserves. Persistent neutrophilia with cell counts of $\geq$30,000 to 50,000/μL is called a *leukemoid reaction*, a term often used to distinguish this degree of neutrophilia from leukemia. In a leukemoid reaction, the circulating neutrophils are usually mature and not clonally derived.

Abnormal Neutrophil Function Inherited and acquired abnormalities of phagocyte function are listed in Table 55-3. The resulting diseases are best considered in terms of the functional defects of adherence, chemotaxis, and microbicidal activity. The distinguishing features of the important inherited disorders of phagocyte function are shown in Table 55-4.

DISORDERS OF ADHESION Two types of leukocyte adhesion deficiency (LAD) have been described. Both are autosomal recessive traits and result in the inability of neutrophils to exit the circulation to sites of infection, leading to leukocytosis and increased susceptibility to infection (Fig. 55-8). Patients with LAD 1 have mutations in CD18, the common component of the integrins LFA-1, Mac-1, and p150,95, leading to a defect in tight adhesion between neutrophils and the endothelium. The heterodimer formed by CD18/CD11b (Mac-1) is also the receptor for the complement-derived opsonin C3bi (CR3). The CD18 gene is located on distal chromosome 21q. Variable expression of the defect determines the severity of clinical disease. Complete lack of expression of the leukocyte integrins results in severe phenotype in which inflammatory stimuli do not increase the expression of leukocyte integrins on neutrophils or activated T and B cells. Neutrophils (and monocytes) from patients with LAD 1 adhere poorly to endothelial cells and protein-coated surfaces and exhibit defective spreading, aggregation, and chemotaxis. Patients with LAD 1 have recurrent bacterial and fungal infections involving skin, oral and genital mucosa, and respiratory and intestinal tracts; persistent leukocytosis (neutrophil counts of 15,000 to 20,000/μL) because cells do not marginate; and, in severe cases, a history of delayed separation of the umbilical stump. Infections, especially of the skin, may become necrotic with progressively enlarging borders, slow healing, and development of dysplastic scars. The most common bacteria are *Staphylococcus aureus* and enteric gram-negative bacteria. LAD 2 is caused by an abnormality of fucosylation of SLe^x(CD15s), the ligand on neutrophils that interacts with selectins on endothelial cells. It is now also known as *congenital disorder of glycosylation IIc* (CDGIIc).

DISORDERS OF NEUTROPHIL GRANULES The most common neutrophil defect is myeloperoxidase deficiency, a primary granule defect inherited as an autosomal recessive trait; the incidence is ~1 in 2000 persons. Isolated myeloperoxidase deficiency is not associated with clinically compromised defenses, presumably because other defense systems such as hydrogen peroxide generation are amplified. Microbicidal activity of neutrophils is delayed but not absent. Myeloperoxidase deficiency may make other acquired host defense defects more serious. An acquired form of myeloperoxidase deficiency occurs in myelomonocytic leukemia and acute myeloid leukemia.

Chédiak-Higashi syndrome (CHS) is a rare disease with autosomal recessive inheritance due to defects in the lysosomal transport protein LYST, encoded by the gene *CHS1* at 1q42. This protein is required for normal packaging and disbursement of granules. Neutrophils (and all cells containing lysosomes) from patients with CHS characteristically have large granules (Fig. 55-9). Patients with CHS have an increased number of infections resulting from many bacterial agents. CHS neutrophils and monocytes have impaired chemotaxis and abnormal rates of microbial killing due to slow rates of fusion of the lysosomal granules with phagosomes. NK cell function is also impaired.

TABLE 55-3 *Types of Granulocyte and Monocyte Disorders*

	Cause of Indicated Dysfunction		
Function	*Drug-Induced*	*Acquired*	*Inherited*
Adherence-aggregation	Aspirin, colchicine, alcohol, glucocorticoids, ibuprofen, piroxicam	Neonatal state, hemodialysis	Leukoctye adhesion deficiency types 1 and 2
Deformability		Leukemia, neonatal state, diabetes mellitus, immature neutrophils	
Chemokinesis-chemotaxis	Glucocorticoids (high dose), auranofin, colchicine (weak effect), phenylbutazone, naproxen, indomethacin, interleukin 2	Thermal injury, malignancy, malnutrition, periodontal disease, neonatal state, systemic lupus erythematosus, rheumatoid arthritis, diabetes mellitus, sepsis, influenza virus infection, herpes simplex virus infection, acrodermatitis enteropathica, AIDS	Chédiak-Higashi syndrome, neutrophil-specific granule deficiency, hyper IgE–recurrent infection (Job's) syndrome (in some patients), Down syndrome, α-mannosidase deficiency, severe combined immunodeficiency, Wiskott-Aldrich syndrome
Microbicidal activity	Colchicine, cyclophosphamide, glucocorticoids (high dose), TNF-α blocking antibodies	Leukemia, aplastic anemia, certain neutropenias, tuftsin deficiency, thermal injury, sepsis, neonatal state, diabetes mellitus, malnutrition, AIDS	Chédiak-Higashi syndrome, neutrophil-specific granule deficiency, chronic granulomatous disease, defects in IFN-γ/IL-12 axis

TABLE 55-4 *Inherited Disorders of Phagocyte Function: Differential Features*

Clinical Manifestations	Cellular or Molecular Defects	Diagnosis
CHRONIC GRANULOMATOUS DISEASES (70% X-LINKED, 30% AUTOSOMAL RECESSIVE)		
Severe infections of skin, ears, lungs, liver, and bone with catalase-positive microorganisms such as *S. aureus*, *Burkholderia cepacia*, *Aspergillus* spp., *Chromobacterium violaceum*; often hard to culture organism; excessive inflammation with granulomas, frequent lymph node suppuration; granulomas can obstruct GI or GU tracts; gingivitis, aphthous ulcers, seborrheic dermatitis	No respiratory burst due to the lack of one of four NADPH oxidase subunits in neutrophils, monocytes, and eosinophils	NBT or DHR test; no superoxide and H_2O_2 production by neutrophils; immunoblot for NADPH oxidase components; genetic detection
CHÉDIAK-HIGASHI SYNDROME (AUTOSOMAL RECESSIVE)		
Recurrent pyogenic infections, especially with *S. aureus*; many patients get lymphoma-like illness during adolescence; periodontal disease; partial oculocutaneous albinism, nystagmus, progressive peripheral neuropathy, mental retardation in some patients	Reduced chemotaxis and phagolysosome fusion, increased respiratory burst activity, defective egress from marrow, abnormal skin window; defect in LYST	Giant primary granules in neutrophils and other granule-bearing cells (Wright's stain); genetic detection
SPECIFIC GRANULE DEFICIENCY (AUTOSOMAL RECESSIVE?)		
Recurrent infections of skin, ears, and sinopulmonary tract; delayed wound healing; decreased inflammation; bleeding diathesis	Abnormal chemotaxis, impaired respiratory burst and bacterial killing, failure to upregulate chemotactic and adhesion receptors with stimulation, defect in transcription of granule proteins; defect in cEPB-ε	Lack of secondary (specific) granules in neutrophils (Wright's stain), no neutrophil-specific granule contents (i.e., lactoferrin), no defensins, platelet α granule abnormality; genetic detection
MYELOPEROXIDASE DEFICIENCY (AUTOSOMAL RECESSIVE)		
Clinically normal except in patients with underlying disease such as diabetes mellitus; then candidiasis or other fungal infections	No myeloperoxidase due to pre- and posttranslational defects	No peroxidase in neutrophils; genetic detection
LEUKOCYTE ADHESION DEFICIENCY (AUTOSOMAL RECESSIVE)		
Type 1: Delayed separation of umbilical cord, sustained neutrophilia, recurrent infections of skin and mucosa, gingivitis, periodontal disease	Impaired phagocyte adherence, aggregation, spreading, chemotaxis, phagocytosis of C3bi-coated particles; defective production of CD18 subunit common to leukocyte integrins	Reduced phagocyte surface expression of the CD18-containing integrins with monoclonal antibodies against LFA-1 (CD18/CD11a), Mac-1 or CR3 (CD18/CD11b), p150,95 (CD18/CD11c); genetic detection
Type 2: Mental retardation, short stature, Bombay (hh) blood phenotype, recurrent infections, neutrophilia	Impaired phagocyte rolling along endothelium	Reduced phagocyte surface expression of Sialyl-Lewis^x, with monoclonal antibodies against CD15s; genetic detection
PHACOCYTE ACTIVATION DEFECTS (X-LINKED AND AUTOSOMAL RECESSIVE)		
NEMO deficiency: mild hypohidrotic ectodermal dysplasia; broad based immune defect: pyogenic and encapsulated bacteria, viruses, *Pneumocystis*, mycobacteria; X-linked	Impaired phagocyte activiation by IL-1, IL-18, TLR, CD40, TNF-α leading to problems with inflammation and antibody production	Poor in vitro response to endotoxin; lack of NF-κB activation; genetic detection
IRAK4 deficiency: susceptibility to pyogenic bacteria such as staphylococci, streptococci, clostridia; resistant to mycobacteria; autosomal recessive	Impaired phagocyte activation by endotoxin through TLR and other pathways; TNF-α signaling preserved	Poor in vitro response to endotoxin; lack of NF-κB activation by endotoxin; genetic detection
HYPER IGE–RECURRENT INFECTION SYNDROME (AUTOSOMAL DOMINANT) (JOB'S SYNDROME)		
Eczematoid or pruritic dermatitis, "cold" skin abscesses, recurrent pneumonias with *S. aureus* with bronchopleural fistulae and cyst formation, mild eosinophilia, mucocutaneous candidiasis, characteristic facies, restrictive lung disease, scoliosis, delayed primary dental deciduation	Reduced chemotaxis in some patients, reduced suppressor T cell activity	Clinical features, involving lungs, skeleton, and immune system; serum IgE $>$ 2000 IU/mL
MYCOBACTERIA SUSCEPTIBILITY (AUTOSOMAL DOMINANT AND RECESSIVE FORMS)		
Severe local or disseminated infections with bacille Calmette-Guérin (BCG), nontuberculous mycobacteria, salmonella, histoplasmosis, poor granuloma formation	Inability to kill intracellular organisms due to low IFN-γ production; mutations in IFN-γ receptors, IL-12 receptor, IL-12 p40, STAT-1, NEMO	Low or very high levels of IFN-γ receptor 1; functional assays of cytokine production and response; genetic detection

Abbreviations: GI, gastrointestinal; GU, genitourinary; NADPH, nicotinamide-adenine dinucleotide phosphate, NBT, nitroblue tetrazolium (dye test), DHR, dihydrorhodamine (oxidation test); LYST, lysosomal transport protein; cEBP-ε, CCAAT/enhancer binding protein-ε; NEMO, NF-κB essential modulator; TLR, Toll-like receptor; IL, interleukin; TNF, tumor necrosis factor; IRAK4, IL-1 receptor–associated kinase protein-ε, NEMO 4; IFN, interferon.

Specific granule deficiency is a rare autosomal recessive disease in which the production of secondary granules and their contents, as well as the primary granule component defensins, is defective. The defect in bacterial killing leads to severe bacterial infections. One type of specific granule deficiency is due to a mutation in the CCAAT/enhancer binding protein-ε, a regulator of expression of granule components.

CHRONIC GRANULOMATOUS DISEASE Chronic granulomatous disease (CGD) is a group of disorders of granulocyte and monocyte oxidative metab-

FIGURE 55-9 Chédiak-Higashi syndrome. In this disorder, the granulocytes contain huge cytoplasmic granules formed from aggregation and fusion of azurophilic and specific granules. Large abnormal granules are found in other granule-containing cells throughout the body.

olism. Although CGD is rare, with an incidence of 1 in 200,000 individuals, it is an important model of defective neutrophil oxidative metabolism. Most often CGD is inherited as an X-linked recessive trait; 30% of patients inherit the disease in an autosomal recessive pattern. Mutations in the genes for the four proteins that assemble at the plasma membrane account for all patients with CGD. Two proteins (a 91-kDa protein, abnormal in X-linked CGD, and a 22-kDa protein, absent in one form of autosomal recessive CGD) form the heterodimer cytochrome b-558 in the plasma membrane. Two other proteins (47 and 67 kDa, abnormal in the other autosomal recessive forms of CGD) are cytoplasmic in origin and interact with the cytochrome after cell activation to form NADPH oxidase, required for hydrogen peroxide production. Leukocytes from patients with CGD have severely diminished hydrogen peroxide production. The genes involved in each of the defects have been cloned and sequenced and the chromosome locations identified. Patients with CGD characteristically have increased numbers of infections due to catalase-positive microorganisms (organisms that destroy their own hydrogen peroxide). When patients with CGD become infected, they often have extensive inflammatory reactions, and lymph node suppuration is common despite the administration of appropriate antibiotics. Aphthous ulcers and chronic inflammation of the nares are often present. Granulomas are frequent and can obstruct the gastrointestinal or genitourinary tracts. The excessive inflammation probably reflects failure to degrade chemoattractants and antigens, leading to persistent neutrophil accumulation. Impaired killing of intracellular microorganisms by macrophages may lead to persistent cell-mediated immune activation and granuloma formation. Autoimmune complications such as immune thrombocytopenic purpura (ITP) and juvenile rheumatoid arthritis (JRA) are also increased in CGD. In addition, discoid lupus is more common in X-linked carriers.

DISORDERS OF PHAGOCYTE ACTIVATION Phagocytes depend on cell-surface stimulation to induce signals that evoke multiple levels of the inflammatory response, including cytokine synthesis, chemotaxis, and antigen presentation. Mutations affecting the major pathway that signals through NF-κB have been noted in patients with a variety of infection susceptibility syndromes. If the defects are at a very late stage of signal transduction, in the protein critical for NF-κB activation known as the NF-κB essential modulator (NEMO), then affected males develop ectodermal dysplasia and severe immune deficiency with susceptibility to bacteria, fungi, mycobacteria, and viruses. If the defect in NF-κB activation is closer to the signaling source, in the IL-1 receptor–associated kinase 4 (IRAK4), then children have a marked suceptibility to pyogenic infections early in life but develop resistance to infection later.

MONONUCLEAR PHAGOCYTES

The mononuclear phagocyte system is composed of monoblasts, promonocytes, and monocytes in addition to the structurally diverse tissue macrophages that make up what was previously referred to as the reticuloendothelial system. Macrophages are long-lived phagocytic cells capable of many of the functions of neutrophils. They are also secretory cells that participate in many immunologic and inflammatory processes distinct from neutrophils. Monocytes leave the circulation by diapedesis more slowly than neutrophils and have a half-life in the blood of 12 to 24 h.

After blood monocytes arrive in the tissues, they differentiate into macrophages ("big eaters") with specialized functions suited for specific anatomic locations. Macrophages are particularly abundant in capillary walls of the lung, spleen, liver, and bone marrow, where they function to remove microorganisms and other noxious elements from the blood. Alveolar macrophages, liver Kupffer cells, splenic macrophages, peritoneal macrophages, bone marrow macrophages, lymphatic macrophages, brain microglial cells, and dendritic macrophages all have specialized functions. Macrophage-secreted products include lysozyme, neutral proteases, acid hydrolases, arginase, complement components, enzyme inhibitors (plasmin, α_2-macroglobulin), binding proteins (transferrin, fibronectin, transcobalamin II), nucleosides, and cytokines (TNF-α; IL-1, -8, -12, and -18). IL-1 (Chaps. 16 and 295) has many functions, including initiating fever in the hypothalamus, mobilizing leukocytes from the bone marrow, and activating lymphocytes and neutrophils. TNF-α is a pyrogen that duplicates many of the actions of IL-1 and plays an important role in the pathogenesis of gram-negative shock (Chap. 254). TNF-α stimulates production of hydrogen peroxide and related toxic oxygen species by macrophages and neutrophils. In addition, TNF-α induces catabolic changes that contribute to the profound wasting (cachexia) associated with many chronic diseases.

Other macrophage-secreted products include reactive oxygen and nitrogen metabolites, bioactive lipids (arachidonic acid metabolites and platelet-activating factors), chemokines, colony-stimulating factors, and factors stimulating fibroblast and vessel proliferation. Macrophages help regulate the replication of lymphocytes and participate in the killing of tumors, viruses, and certain bacteria (*Mycobacterium tuberculosis* and *Listeria monocytogenes*). Macrophages are key effector cells in the elimination of intracellular microorganisms. Their ability to fuse to form giant cells that coalesce into granulomas in response to some inflammatory stimuli is important in the elimination of intracellular microbes and is under the control of IFN-γ. Nitric oxide induced by IFN-γ is an important effector against intracellular parasites, including tuberculosis and *Leishmania*.

Macrophages play an important role in the immune response (Chap. 295). They process and present antigen to lymphocytes and secrete cytokines that modulate and direct lymphocyte development and function. Macrophages participate in autoimmune phenomena by removing immune complexes and other substances from the circulation. Polymorphisms in macrophage receptors for immunoglobulin (FcγRII) determine suceptibility to some infections and autoimmune diseases. In wound healing, they dispose of senescent cells, and they contribute to atheroma development. Macrophage elastase mediates development of emphysema from cigarette smoking.

DISORDERS OF THE MONONUCLEAR PHAGOCYTE SYSTEM Many disorders of neutrophils extend to mononuclear phagocytes. Thus, drugs that suppress neutrophil production in the bone marrow can cause monocytopenia. Transient monocytopenia occurs after stress or glucocorticoid administration. Monocytosis is associated with tuberculosis, brucellosis, subacute bacterial endocarditis, Rocky Mountain spotted fever, malaria, and visceral leishmaniasis (kala azar). Monocytosis also occurs with malignancies, leukemias, myeloproliferative syndromes, hemolytic anemias, chronic idiopathic neutropenias, and granulomatous diseases such as sarcoidosis, regional enteritis, and some collagen vascular diseases. Patients with LAD, hyperimmunoglobulin E–recurrent infection (Job's) syndrome, CHS, and CGD all have defects in the mononuclear phagocyte system.

Monocyte cytokine production or response is impaired in some patients with disseminated nontuberculous mycobacterial infection who are not infected with HIV. Genetic defects in the pathways regulated by IFN-γ and IL-12 lead to impaired killing of intracellular bacteria, mycobacteria, salmonellae, and certain viruses (Fig. 55-10).

Certain viral infections impair mononuclear phagocyte function. For example, influenza virus infection causes abnormal monocyte chemotaxis. Mononuclear phagocytes can be infected by HIV using

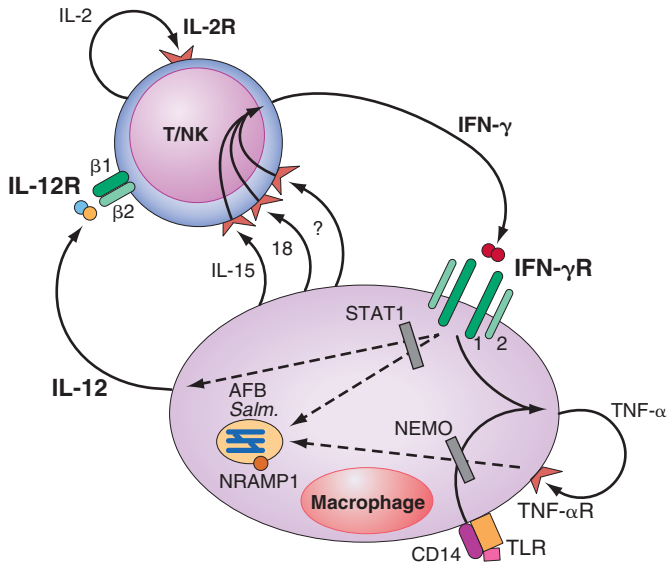

FIGURE 55-10 Lymphocyte-macrophage interactions underlying resistance to mycobacteria and other intracellular parasites such as *Salmonella*. *Mycobacteria* infect macrophages, leading to the production of IL-12, which activates T or NK cells through its receptor, leading to production of IL-2 and IFN-γ. IFN-γ acts through its receptor on macrophages to upregulate TNF-α and IL-12 and kill intracellular parasites. Mutant forms of the cytokines and receptors shown in large type have been found in severe cases of nontuberculous mycobacterial infection and salmonellosis.

CCR5, the chemokine receptor that acts as a co-receptor with CD4 for HIV. T lymphocytes produce IFN-γ, which induces FcR expression and phagocytosis and stimulates hydrogen peroxide production by mononuclear phagocytes and neutrophils. In certain diseases, such as AIDS, IFN-γ production may be deficient, while in other diseases, such as T cell lymphomas, excessive release of IFN-γ may be associated with erythrophagocytosis by splenic macrophages.

Gain-of-function mutations in the TNF-α receptor cause TNF-α receptor–associated periodic syndromes (TRAPS) that are characterized by recurrent fever in the absence of infection, due to persistent stimulation of the TNF-α receptor. Administration of the TNF-α antagonists infliximab, etanercept, and adalimumab has been associated with severe infections such as tuberculosis.

Monocytopenia occurs with acute infections, with stress, and after treatment with glucocorticoids. Monocytopenia also occurs in aplastic anemia, hairy cell leukemia, acute myeloid leukemia, and as a direct result of myelotoxic drugs.

EOSINOPHILS

Eosinophils and neutrophils share similar morphology, many lysosomal constituents, phagocytic capacity, and oxidative metabolism. Eosinophils express a specific chemoattractant receptor and respond to a specific chemokine, eotaxin. Little is known about the role of eosinophils. Eosinophils are much longer lived than neutrophils, and unlike neutrophils, tissue eosinophils can recirculate. During most infections, eosinophils are not important. However, in invasive helminthic infections, such as hookworm, schistosomiasis, strongyloidiasis, toxocariasis, trichinosis, filariasis, echinococcosis, and cysticercosis, the eosinophil plays a central role in host defense. Eosinophils are associated with bronchial asthma, cutaneous allergic reactions, and other hypersensitivity states.

The distinctive feature of the red-staining (Wright's stain) eosinophil granule is its crystalline core consisting of an arginine-rich protein (major basic protein) with histaminase activity, important in host defense against parasites. Eosinophil granules also contain a unique eosinophil peroxidase that catalyzes the oxidation of many substances by hydrogen peroxide and may facilitate killing of microorganisms.

Eosinophil peroxidase, in the presence of hydrogen peroxide and halide, initiates mast cell secretion in vitro and thereby promotes inflammation. Eosinophils contain cationic proteins, some of which bind to heparin and reduce its anticoagulant activity. Eosinophil-derived neurotoxin and eosinophil cationic protein are ribonucleases that can kill respiratory syncytial virus. Eosinophil cytoplasm contains Charcot-Leyden crystal protein, a hexagonal bipyramidal crystal first observed in a patient with leukemia and then in sputum of patients with asthma; this protein is lysophospholipase and may function to detoxify certain lysophospholipids.

Several factors enhance the eosinophil's function in host defense. T cell–derived factors enhance the ability of eosinophils to kill parasites. Mast cell–derived eosinophil chemotactic factor of anaphylaxis (ECFa) increases the number of eosinophil complement receptors and enhances eosinophil killing of parasites. Eosinophil colony-stimulating factors (e.g., IL-5) produced by macrophages increase eosinophil production in the bone marrow and activate eosinophils to kill parasites.

EOSINOPHILIA Eosinophilia is the presence of >500 eosinophils per microliter of blood and is common in many settings besides parasite infection. Significant tissue eosinophilia can occur without an elevated blood count. A common cause of eosinophilia is allergic reaction to drugs (iodides, aspirin, sulfonamides, nitrofurantoin, penicillins, and cephalosporins). Allergies such as hay fever, asthma, eczema, serum sickness, allergic vasculitis, and pemphigus are associated with eosinophilia. Eosinophilia also occurs in collagen vascular diseases (e.g., rheumatoid arthritis, eosinophilic fasciitis, allergic angiitis, and periarteritis nodosa) and malignancies (e.g., Hodgkin's disease; mycosis fungoides; chronic myelogenous leukemia; and cancer of the lung, stomach, pancreas, ovary, or uterus), as well as in Job's syndrome and CGD. Eosinophilia is commonly present in the helminthic infections. IL-5 is the dominant eosinophil growth factor. Therapeutic administration of the cytokines IL-2 and GM-CSF frequently leads to transient eosinophilia. The most dramatic hypereosinophilic syndromes are Loeffler's syndrome, tropical pulmonary eosinophilia, Loeffler's endocarditis, eosinophilic leukemia, and idiopathic hypereosinophilic syndrome (50,000 to 100,000/μL).

The idiopathic hypereosinophilic syndrome represents a heterogeneous group of disorders with the common feature of prolonged eosinophilia of unknown cause and organ system dysfunction, including the heart, central nervous system, kidneys, lungs, gastrointestinal tract, and skin. The bone marrow is involved in all affected individuals, but the most severe complications involve the heart and central nervous system. Clinical manifestations and organ dysfunction are highly variable. Eosinophils are found in the involved tissues and likely cause tissue damage by local deposition of toxic eosinophil proteins such as eosinophil cationic protein and major basic protein. In the heart, the pathologic changes lead to thrombosis, endocardial fibrosis, and restrictive endomyocardiopathy. The damage to tissues in other organ systems is similar. Some cases are due to mutations involving the platelet derived growth factor receptor and these are extremely sensitive to the tyrosine kinase inhibitor imatinib. Glucocorticoids may also induce remission. In patients who do not respond to glucocorticoids, a cytotoxic agent such as hydroxyurea has been used successfully to lower the peripheral blood eosinophil counts and to improve the prognosis markedly. IFN-α is also effective in some patients, including those unresponsive to hydroxyurea. Aggressive medical and surgical approaches are used to manage patients with cardiovascular complications.

The *eosinophilia-myalgia syndrome* is a multisystem disease with prominent cutaneous, hematologic, and visceral manifestations that frequently evolves into a chronic course and can occasionally be fatal. The syndrome is characterized by eosinophilia (eosinophil count > 1000/μL) and generalized disabling myalgias without other recognized causes. Eosinophilic fasciitis, pneumonitis, and myocarditis; neuropathy culminating in respiratory failure; and encephalopathy may occur. The disease is caused by ingesting contaminants in L-tryptophan–containing products. Eosinophils, lymphocytes, macro-

phages, and fibroblasts accumulate in the affected tissues, but their role in pathogenesis is unclear. Activation of eosinophils and fibroblasts and the deposition of eosinophil-derived toxic proteins in affected tissues may contribute. IL-5 and transforming growth factor β have been implicated as potential mediators. Treatment is withdrawal of products containing L-tryptophan and the administration of glucocorticoids. Most patients recover fully, remain stable, or show slow recovery, but the disease can be fatal in up to 5% of patients.

EOSINOPENIA Eosinopenia occurs with stress, such as acute bacterial infection, and after treatment with glucocorticoids. The mechanism of eosinopenia of acute bacterial infection is unknown but is independent of endogenous glucocorticoids, since it occurs in animals after total adrenalectomy. There is no known adverse effect of eosinopenia.

HYPERIMMUNOGLOBULIN E-RECURRENT INFECTION SYNDROME

The hyperimmunoglobulin E–recurrent infection (HIE) syndrome, or Job's syndrome, is a rare multisystem disease in which the immune system, bone, teeth, lung, and skin are affected. Abnormal chemotaxis is a variable feature. The molecular basis for this syndrome is not known, but some cases show autosomal dominant transmission with linkage to 4q. Patients with this syndrome have characteristic facies with broad nose, kyphoscoliosis and osteoporosis, and eczema. The primary teeth erupt normally but do not deciduate, often requiring extraction. Patients develop recurrent sinopulmonary and cutaneous infections that tend to be much less inflamed than appropriate for the degree of infection and have been referred to as "cold abscesses." A high degree of suspicion is required to diagnose infections in these patients, who may appear well despite extensive disease. The cold abscesses have been considered a reflection of too few phagocytes arriving too late, perhaps due to a lymphocyte factor inhibiting chemotaxis. However, the chemotactic defect in these patients is variable, and the fundamental basis for the impaired defenses is complex and poorly defined.

LABORATORY DIAGNOSIS AND MANAGEMENT

Initial studies of WBC and differential and often a bone marrow examination may be followed by assessment of bone marrow reserves (steroid challenge test), marginated circulating pool of cells (epinephrine challenge test), and marginating ability (endotoxin challenge test) (Fig. 55-7). In vivo assessment of inflammation is possible with a Rebuck skin window test or an in vivo blister assay, which measures the ability of leukocytes and inflammatory mediators to accumulate locally in the skin. In vitro tests of phagocyte aggregation, adherence, chemotaxis, phagocytosis, degranulation, and microbicidal activity (for *S. aureus*) may help pinpoint cellular or humoral lesions. Deficiencies of oxidative metabolism are detected with either the nitroblue tetrazolium (NBT) dye test or the dihydrorhodamine (DHR) oxidation test. These tests are based on the ability of products of oxidative metabolism to alter the oxidation states of reporter molecules so that they can be detected microscopically (NBT) or by flow cytometry (DHR). Qualitative studies of superoxide and hydrogen peroxide production may further define neutrophil oxidative function.

Patients with leukopenias or leukocyte dysfunction often have delayed inflammatory responses. Therefore, clinical manifestations may be minimal despite overwhelming infection, and unusual infections must always be suspected. Early signs of infection demand prompt, aggressive culturing for microorganisms, use of antibiotics, and surgical drainage of abscesses. Prolonged courses of antibiotics are often required. In patients with CGD, prophylactic antibiotics (trimethoprim-sulfamethoxazole) and antifungals (itraconazole) markedly diminish the frequency of life-threatening infections. Short courses of glucocorticoids may relieve gastrointestinal or genitourinary tract obstruction by granulomas in patients with CGD. Recombinant human IFN-γ, which nonspecifically stimulates phagocytic cell function, reduces the frequency of infections in patients with CGD by 70% and reduces the severity of infection. This effect of IFN-γ in CGD is additive to the effect of prophylactic antibiotics. The recommended dose is 50 μg/m^2 subcutaneously three times weekly. IFN-γ has also been used successfully in the treatment of leprosy, nontuberculous mycobacteria, and visceral leishmaniasis.

Rigorous oral hygiene reduces but does not eliminate the discomfort of gingivitis, periodontal disease, and aphthous ulcers; chlorhexidine mouthwash and tooth brushing with a hydrogen peroxide–sodium bicarbonate paste helps many patients. Oral antifungal agents (fluconazole) have reduced mucocutaneous candidiasis in patients with Job's syndrome. Androgens, glucocorticoids, lithium, and immunosuppressive therapy have been used to restore myelopoiesis in patients with neutropenia due to impaired production. Recombinant G-CSF is useful in the management of certain forms of neutropenia due to depressed neutrophil production, especially those related to cancer chemotherapy. Patients with chronic neutropenia with evidence of a good bone marrow reserve need not receive prophylactic antibiotics. Patients with chronic or cyclic neutrophil counts $< 500/\mu$L may benefit from prophylactic antibiotics and G-CSF during periods of neutropenia. Oral trimethoprim-sulfamethoxazole (160/800 mg) twice daily can prevent infection. Increased numbers of fungal infections are not seen in patients with CGD on this regimen. Oral quinolones such as levofloxacin and ciprofloxacin are alternatives.

In the setting of cytotoxic chemotherapy with severe, persistent neutropenia, trimethoprim-sulfamethoxazole prevents *Pneumocystis carinii* pneumonia. These patients, and patients with phagocytic cell dysfunction, should avoid heavy exposure to airborne soil, dust, or decaying matter (mulch, manure), which are often rich in *Nocardia* and the spores of *Aspergillus* and other fungi. Restriction of activities or social contact has no proven role in reducing risk of infection.

Cure of some congenital phagocyte defects is possible by bone marrow transplantation (Chap. 100). However, complications of bone marrow transplantation are still serious, and with rigorous medical care many patients with phagocytic disorders can go for years without a life-threatening infection. The identification of specific gene defects in patients with LAD 1, CGD, and other immunodeficiencies has led to gene therapy trials in a number of genetic white cell disorders.

PART III GENETICS AND DISEASE

56 PRINCIPLES OF HUMAN GENETICS

J. Larry Jameson, Peter Kopp

IMPACT OF GENETICS ON MEDICAL PRACTICE

The beginning of the new millennium was marked by the announcement that the vast majority of the human genome has been sequenced. This milestone in the exploration of the human genome was preceded by numerous conceptual and technological advances. They include, among others, the elucidation of the DNA double-helix structure, the discovery of restriction enzymes and the polymerase chain reaction (PCR), the development and automatization of DNA sequencing, and the generation of genetic and physical maps by the Human Genome Project (HGP). The consequences of this wealth of knowledge for the practice of medicine are profound, but the integration of genetics into the everyday practice of medicine remains challenging. To date, the most significant impact of genetics has been to enhance our understanding of disease etiology and pathogenesis. In the near term, we can expect an increasing role for genetics in the diagnosis, prevention, and treatment of disease (Chaps. 58 and 59).

Genetics has traditionally been viewed through the window of relatively rare single-gene diseases. Taken together, these rare disorders account for up to 10% of pediatric admissions and childhood mortality. It is, however, increasingly apparent that virtually every medical condition with the exception of simple trauma has a genetic component. As is often evident from a patient's family history, many common disorders such as hypertension, heart disease, asthma, diabetes mellitus, and mental illnesses are significantly influenced by the genetic background. These polygenic or multifactorial disorders involve the contributions of many different genes, as well as environmental factors, that can modify disease risk (Chap. 58). Cancer has a genetic basis since it results from acquired somatic mutations in genes controlling growth and differentiation (Chap. 68). In addition, the development of many cancers is associated with a hereditary predisposition. The prevalence of genetic diseases, combined with their severity and chronic nature, imposes a great financial, social, and emotional burden on society.

Genetics has historically focused on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down syndrome) or monosomy X (Turner syndrome) can be diagnosed using cytogenetics (Chap. 57). Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) are diagnosed using biochemical analyses. Recent advances in DNA diagnostics have extended the field of genetics to include virtually all medical specialties. In cardiology, for example, the molecular basis of inherited cardiomyopathies and ion channel defects that predispose to arrhythmias is being defined (Chaps. 214 and 221). In neurology, genetics has unmasked the pathophysiology of a startling number of neurodegenerative disorders (Chap. 345). Hematology has evolved dramatically, from its incipient genetic descriptions of hemoglobinopathies to the current understanding of the molecular basis of red cell membrane defects, clotting disorders, and thrombotic disorders (Chaps. 91 and 102). It is now abundantly clear that neoplasia and the acquisition of metastatic potential can be described in genetic terms (Chaps. 68 and 69).

New concepts derived from genetic studies can sometimes clarify the pathogenesis of disorders that were previously opaque. For example, although many different genetic defects can cause peripheral neuropathies, disruption of the normal folding of the myelin sheath is frequently a common final pathway (Chap. 364). Several genetic causes of obesity appear to converge on a physiologic pathway that involves products of the proopiomelanocortin polypeptide and the MC4R receptor, thus identifying a key mechanism for appetite control (Chap. 64). A similar situation is emerging for genetically distinct forms of Alzheimer's disease, several of which lead to the formation of neurofibrillary tangles (Chap. 350). Increasingly, the identification of defective genes can pinpoint cellular pathways involved in key physiologic processes. Examples include identification of the cystic fibrosis conductance regulator (*CFTR*) gene, the Duchenne muscular dystrophy (*DMD*) gene, which encodes dystrophin, and the fibroblast growth factor receptor-3 (*FGFR3*) gene, which is responsible for achondroplastic dwarfism. Similarly, transgenic (over)expression, and targeted gene "knockout" and "knockin" models help to unravel the physiologic function of genes. Genetic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites. In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing, enhanced our understanding of pathophysiology, and is beginning to open new avenues for therapy, including gene and cellular therapy (Chap. 59).

The astounding rate at which new genetic information is being generated creates a major challenge for physicians, health care providers, and basic investigators. The terminology and techniques used for discovery evolve continuously. Much genetic information presently resides in computer databases or is being published in basic science journals. Databases provide easy access to the expanding information about the human genome, genetic disease, and genetic testing (Table 56-1). For example, several thousand monogenic disorders are summarized in a large, continuously evolving compendium, referred to as the *Online Mendelian Inheritance in Man* (OMIM) catalog (Table 56-1). The ongoing refinement of bioinformatics is simplifying the access to this seemingly daunting onslaught of new information.

APPROACH TO THE PATIENT

For the practicing clinician, the family history remains an essential step in recognizing the possibility of a hereditary component. When taking the history, it is useful to draw a detailed pedigree of the first-degree relatives (e.g., parents, siblings, and children), since they share 50% of genes with the patient. Standard symbols for pedigrees are depicted in Fig. 56-1. The family history should include information about ethnic background, age, health status, and (infant) deaths. Next, the physician should explore whether there is a family history of the same or related illnesses to the current problem. An inquiry focused on commonly occurring disorders such as cancers, heart disease, and diabetes mellitus should follow. Because of the possibility of age-dependent expressivity and penetrance, the family history may need updating. If the findings suggest a genetic disorder, the clinician will have to assess whether some of the patient's relatives may be at risk of carrying or transmitting the disease. In this circumstance, it is useful to confirm and extend the pedigree based on input from several family members. This information may form the basis for carrier detection, genetic counseling, early intervention, and prevention of a disease in relatives of the index patient (Chap. 59).

In instances where a diagnosis at the molecular level may be relevant, the physician will have to identify an appropriate laboratory that can perform the test. If a disease-causing mutation is expected in all cells due to germline transmission, DNA can be collected from any tissue, most commonly nucleated blood cells. In the case of somatic mutations, which are limited to a neoplastic

tissue, an adequate sample of this lesion is used for extraction of DNA or RNA. For the detection of pathogens, the material to be analyzed will vary and may include blood, cerebrospinal fluid, solid tissues, sputum, or fluid obtained through bronchioalveolar lavage.

CHROMOSOMES AND DNA REPLICATION

ORGANIZATION OF DNA INTO CHROMOSOMES ■ Size of the Human Genome

The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1 to 22) and the X and Y sex chromosomes. Adult cells are diploid, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and divided into two daughter cells (Chap. 57).

The human genome is estimated to contain about 30,000 to 40,000 genes, a smaller number than initially predicted, that are divided among the 23 chromosomes. A *gene* is a functional unit that is regulated by transcription (see below) and encodes a product, either RNA or protein, that exerts activity within or outside the cell. Historically, genes were identified because they conferred specific traits that are

transmitted from one generation to the next. Increasingly, they are characterized based on expression in various tissues. The number of genes greatly underestimates the complexity of genetic expression, as single genes can generate multiple spliced mRNA products, which are translated into proteins that are subject to complex posttranslational modification, such as phosphorylation. *Proteomics* is an emerging field focused on protein variation and function.

Human DNA consists of about 3 billion base pairs (bp) of DNA per haploid genome. DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). Not all DNA encodes genes. In fact, genes account for only about 10 to 15% of DNA. Much of the remaining DNA consists of highly repetitive sequences, the function of which is poorly understood. These repetitive DNA regions, along with nonrepetitive sequences that do not encode genes, may serve a structural role in the packaging of DNA into chromatin (DNA bound to histone proteins) and chromosomes (Fig. 56-2). If only 10% of DNA is expressed and there are 30,000 genes, the average gene site would be about 10 kb in length. Although many genes are about this size, the range is quite broad. For example, some genes are only a few hundred bp, whereas others, like the *DMD* gene, are extraordinarily large (2 Mb).

Structure of DNA Each gene is composed of a linear polymer of DNA. DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired to cytosine, by hydrogen bond interactions that span the double helix. DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, at least in comparison to RNA or proteins. The double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. As described below, complementarity also allows the transmission of genetic information from DNA → RNA → protein (Fig. 56-3). Messenger RNA (mRNA) is encoded by the so-called sense or coding strand of the DNA double helix and is translated into proteins by ribosomes.

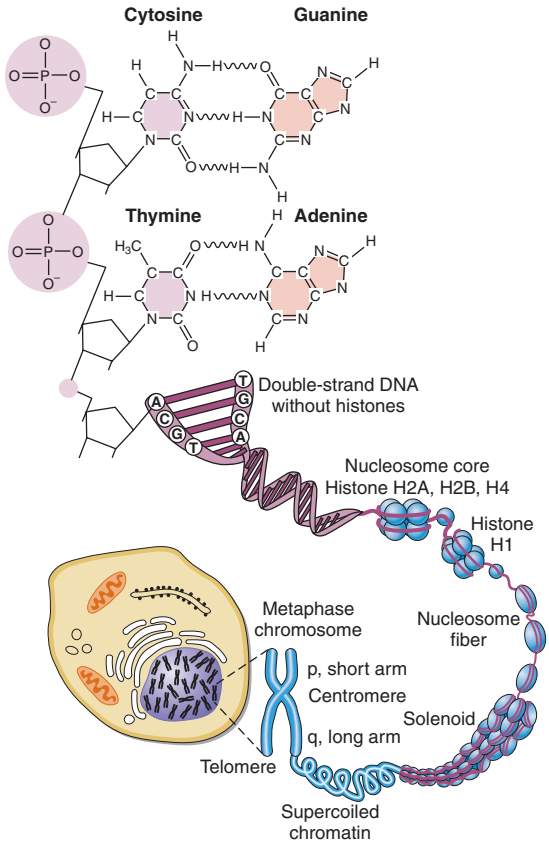

FIGURE 56-2 Structure of chromatin and chromosomes. Chromatin is composed of double-strand DNA that is wrapped around histone and nonhistone proteins forming nucleosomes. The nucleosomes are further organized into solenoid structures. Chromosomes assume their characteristic structure, with short (p) and long (q) arms at the metaphase stage of the cell cycle.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4^3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal, such as initiation and stop of translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

REPLICATION OF DNA AND MITOSIS Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by mitosis, allowing the diploid ($2n$) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo meiosis, a process that enables the reduction of the diploid ($2n$) set of chromosomes to the haploid state ($1n$) (Chap. 57).

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle (Chap. 69). After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The process of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly predispose to neoplasia because of the rapid acquisition of additional mutations (Chap. 68). After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell (see Fig. 57-3). After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid ($2n$) state.

ASSORTMENT AND SEGREGATION OF GENES DURING MEIOSIS Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids ($2n \rightarrow 4n$) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues (Fig. 56-4). Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2^{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recombination, and the independent segregation of chromosomes, provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells ($2n$), the two chromatids of each chromosome separate during a second

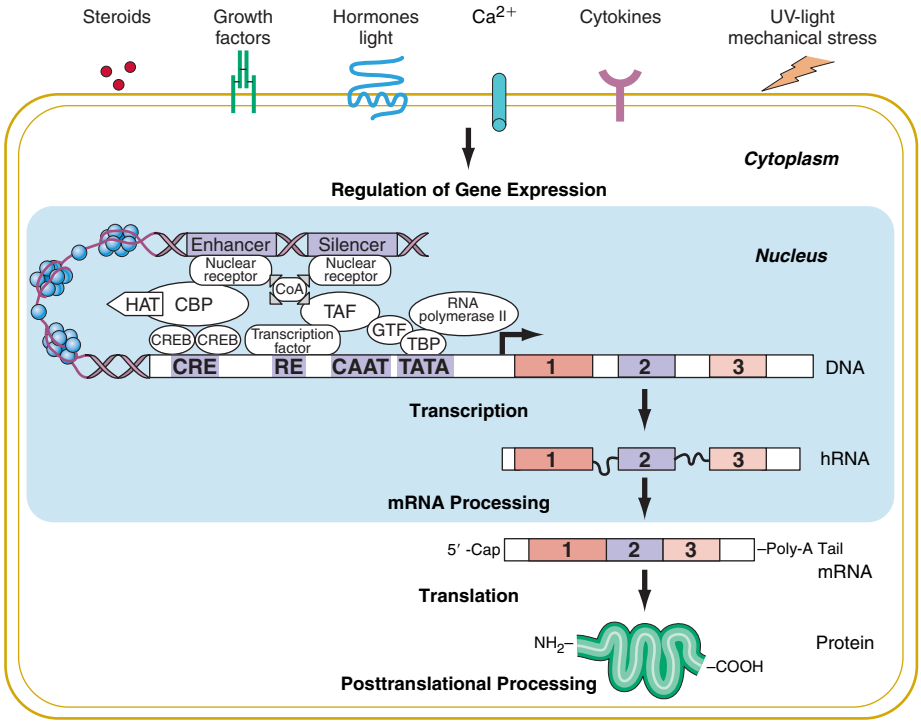

FIGURE 56-3 Flow of genetic information. Multiple extracellular signals activate intracellular signal cascades that result in altered regulation of gene expression through the interaction of transcription factors with regulatory regions of genes. RNA polymerase transcribes DNA into RNA that is processed to mRNA by excision of intronic sequences. The mRNA is translated into a polypeptide chain to form the mature protein after undergoing posttranslational processing. HAT, histone acetyl transferase; CBP, CREB-binding protein; CREB, cyclic AMP response element–binding protein; CRE, cyclic AMP responsive element; CoA, Co activator; TAF, TBP-associated factors; GTF, general transcription factors; TBP, TATA-binding protein; TATA, TATA box; RE, response element; NH_2, aminoterminus; COOH, carboxyterminus.

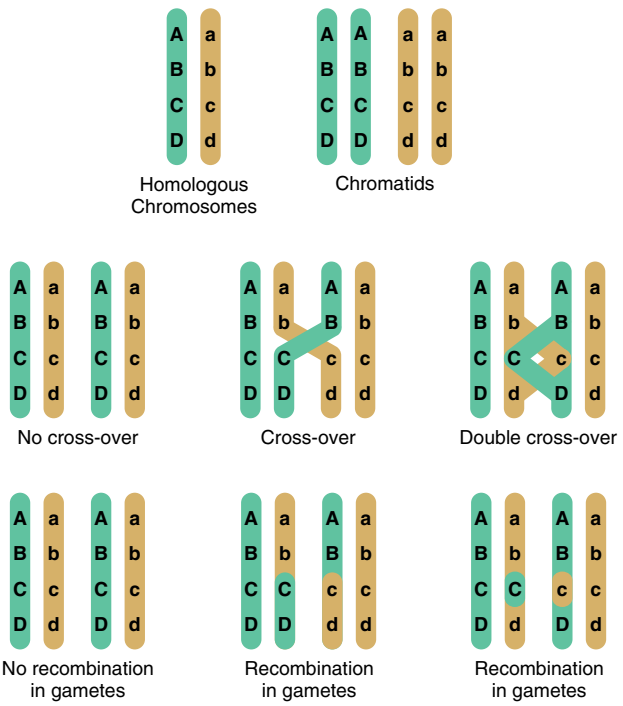

FIGURE 56-4 Crossing-over and genetic recombination. During chiasma formation, either of the two sister chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination occurs through crossing-over and results in recombinant and nonrecombinant chromosome segments in the gametes. Together with the random segregation of the maternal and paternal chromosomes, recombination contributes to genetic diversity and forms the basis of the concept of linkage.

meiotic division to yield four gametes with a haploid state ($1n$). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state ($2n$) in the zygote.

REGULATION OF GENE EXPRESSION

Mechanisms that regulate gene expression play a critical role in the function of genes. The new field of *functional genomics* is based on the concept that understanding gene regulation and function will provide a better understanding of physiology and offer novel therapeutic opportunities. The transcription of genes is controlled primarily by *transcription factors* that bind to DNA sequences in the regulatory regions of genes. As described below, mutations in transcription factors cause a significant number of genetic disorders. Gene expression is also influenced by *epigenetic events*, such as X-inactivation and imprinting, processes in which DNA methylation is associated with the silencing (i.e., suppression) of expression. Several genetic disorders, such as Prader-Willi syndrome (neonatal hypotonia, developmental delay, obesity, short stature, and hypogonadism) and Albright hereditary osteodystrophy (resistance to parathyroid hormone, short stature, brachydactyly, resistance to other hormones in certain subtypes), exhibit the consequences of genomic imprinting. Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it should be emphasized that gene expression requires a series of steps, including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 56-3).

STRUCTURE OF GENES A gene product is usually a protein but can occasionally consist of RNA that is not translated. *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing (Fig. 56-3).

The gene locus also includes regions that are necessary to control its expression. The regulatory regions most commonly involve sequences upstream (5′) of the transcription start site, although there are also examples of control elements within introns or downstream of the coding regions of a gene. The upstream regulatory regions are also referred to as the *promoter*. The minimal promoter usually consists of a TATA box (which binds TATA-binding protein, TBP) and initiator sequences that enhance the formation of an active transcription complex. A gene may generate various transcripts through the use of alternative promoters and/or alternative splicing of exons, mechanisms that contribute to the enormous diversity of proteins and their functions. Transcriptional termination signals reside downstream, or 3′, of a gene. Specific sequences, such as the AAUAAA sequence at the 3′ end of the mRNA, designate the site for polyadenylation (poly-A tail), a process that influences mRNA transport to the cytoplasm, stability, and translation efficiency. A rigorous test of the regulatory region boundaries involves expressing a gene in a transgenic animal to determine whether the isolated DNA flanking sequences are sufficient to recapitulate the normal developmental, tissue-specific, and signal-responsive features of the endogenous gene. This has been accomplished for only a few genes; there are many examples in which large genomic fragments only partially reconstitute normal gene regulation in vivo, implying the presence of distant regulatory sequences. This approach is critical to our understanding of mechanisms that regulate genes and

is also relevant for gene therapy strategies that require normal gene regulation (Chap. 59).

As genes are dissected with greater resolution, the number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15 to 20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors such as CAAT box/enhancer binding protein (C/EBP), cyclic AMP response element–binding (CREB) protein, selective promoter factor 1 (Sp-1), or activator protein 1 (AP-1). However, factors involved in cell-specific expression may also bind to these sequences. For example, basic helix-loop-helix (bHLH) proteins bind to E-boxes in the promoters of myogenic genes, and steroidogenic factor 1 (SF-1) binds to a specific recognition site in the regulatory region of multiple steroidogenic enzyme genes. Key regulatory elements may also reside at some distance from the proximal promoter. The globin and the immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner that is dependent on developmental state, cell type, and numerous extracellular stimuli. As described below, the transcription factors that bind to DNA actually represent only the first level of regulatory control. Other proteins—*coactivators* and *co-repressors*—interact with the DNA-binding transcription factors to generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways, including phosphorylation and acetylation. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template.

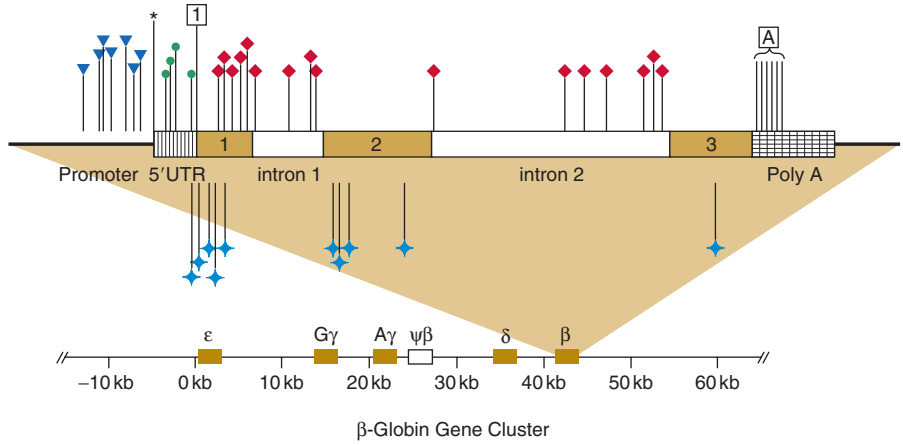

FIGURE 56-5 Point mutations causing β-thalassemia as example of allelic heterogeneity. The β-globin gene is located in the globin gene cluster. Point mutations can be located in the promoter, the CAP site, the 5′-untranslated region, the initiation codon, each of the three exons, the introns, or the polyadenylation signal. Many mutations introduce missense or nonsense mutations, whereas others cause defective RNA splicing. Not shown here are deletion mutations of the β-globin gene or larger deletions of the globin locus that can also result in thalassemia. ▼, Promoter mutations; *, CAP site; •, 5′UTR; 1, Initiation codon; ♦, Defective RNA processing; ✦, Missense and nonsense mutations; A, Poly A signal.

Mutations can occur in all domains of a gene (Fig. 56-5). A point mutation occurring within the coding region leads to an amino acid substitution if the codon is altered. Point mutations that introduce a premature stop codon result in a truncated protein. Large deletions may affect a portion of a gene or an entire gene, whereas small deletions and insertions alter the reading frame if they do not represent a multiple of three bases. These "frameshift" mutations lead to an entirely altered carboxy terminus. Mutations occurring in regulatory or intronic regions may result in altered expression or splicing of genes. Examples are shown in Fig. 56-6.

TRANSCRIPTIONAL ACTIVATION AND REPRESSION Every gene is controlled uniquely, whether in its spatial or temporal pattern of expression or in its response to extracellular signals. It is estimated that transcription factors account for about 30% of expressed genes. A growing number of identified genetic diseases involve transcription factors (Table 56-2). The MODY (maturity-onset diabetes of the young) disorders are representative of this group of diseases; mutations in several different islet cell–specific transcription factors cause various forms of MODY (Chap. 323).

Transcriptional activation can be divided into three main mechanisms:

1. Events that alter chromatin structure can enhance the access of transcription factors to DNA. For example, histone acetylation opens chromatin structure and is correlated with transcriptional activation.
2. Posttranslational modifications of transcription factors, such as phosphorylation, can induce the assembly of active transcription complexes. As an example, phosphorylation of CREB protein on serine 133 induces a conformational change that allows the recruitment of CREB-binding protein (CBP), a factor that integrates the actions of many transcription factors, including proteins, with histone acetyltransferase activity.
3. Transcriptional activators can displace a repressor protein. This mechanism is particularly common during development when the pattern of transcription factor expression changes dynamically.

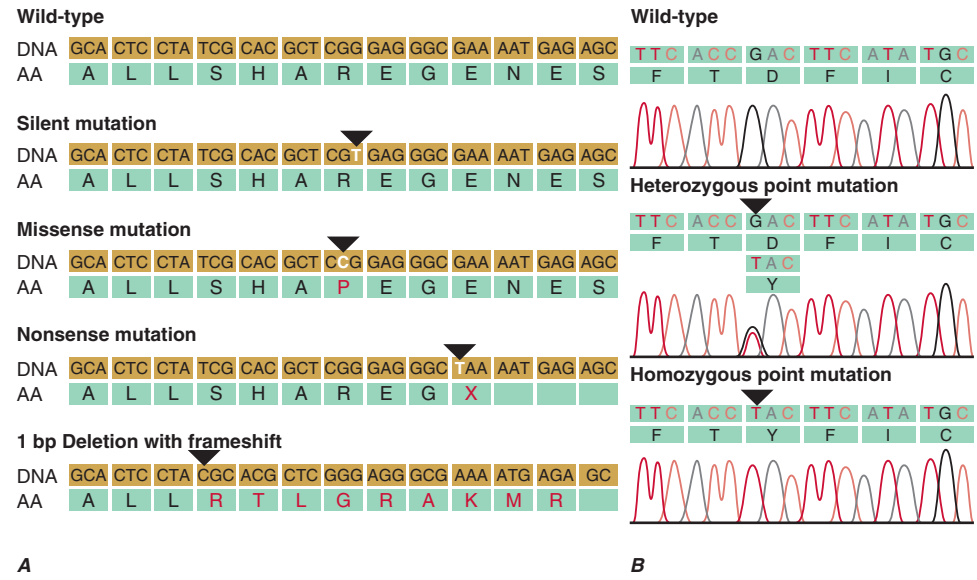

FIGURE 56-6 *A*. Examples of mutations. The coding strand is shown with the encoded amino acid sequence. *B*. Chromatograms of sequence analyses after amplification of genomic DNA by polymerase chain reaction.

TABLE 56-2 *Selected Examples of Diseases Caused by Mutations and Rearrangements in Transcription Factor Classes*

Transcription Factor Class	Example	Associated Disorder
Nuclear receptors	Androgen receptor	Complete or partial androgen insensitivity (recessive missense mutations) Spinobulbar muscular atrophy (CAG repeat expansion)
Zinc finger proteins	WT-1	WAGR syndrome: Wilm's tumor, aniridia, genitourinary malformations, mental retardation
Basic helix-loop-helix	MITF	Waardenburg syndrome type 2A
Homeobox	IPF1	Maturity onset of diabetes mellitus type 4 (heterozygous mutation/haploinsufficiency) Pancreatic agenesis (homozygous mutation)
Leucine zipper	Retina leucine zipper (NRL)	Autosomal dominant retinitis pigmentosa
High- mobility group (HMG) proteins	SRY	Sex-reversal
Forkhead	HNF4α, HNF1α, HNF1β	Maturity-onset of diabetes mellitus types 1, 3, 5
Paired box	PAX-3	Waardenburg syndrome types 1 and 3
T-box	TBX-5	Holt-Oram syndrome (thumb anomalies, atrial or ventricular septum defects, phocomelia)
Cell cycle control proteins	P53	Li-Fraumeni syndrome, other cancers
Coactivators	CREB binding protein (CBP)	Rubenstein-Taybi syndrome
General transcription factors	TATA-binding protein (TBP)	Spinocerebellar ataxia 17 (CAG expansion)
Transcription elongation factor	VHL	von Hippel-Lindau syndrome (renal cell carcinoma, pheochromocytoma, pancreatic tumors, hemangioblastomas) Autosomal dominant inheritance, somatic inactivation of second allele
Runt	CBFA2	Familial thrombocytopenia with propensity to acute myelogenous leukemia
Chimeric proteins due to translocations	PML—RAR	Acute promyelocytic leukemia t(15;17)(q22;q11.2-q12) translocation

Abbreviations: SRY, sex determining region Y; HNF, hepatocyte nuclear factor; CREB (cAMP responsive element binding) binding protein; VHL, von Hippel-Lindau; PML, promyelocytic leukemia; RAR, retinoic acid receptor.

Of course, these mechanisms are not mutually exclusive, and most genes are activated by some combination of these events.

Suppression of gene expression is as important as gene activation in the control of cell differentiation and function. Some mechanisms of repression are the corollary of activation. For example, repression is often associated with histone deacetylation or protein dephosphorylation. For nuclear hormone receptors, transcriptional silencing involves the recruitment of repression complexes that contain histone deacetylase activity. Aberrant expression of repressor proteins is sometimes associated with neoplasia. The t(15;17) chromosomal translocation that occurs in promyelocytic leukemia fuses the *PML* gene to a portion of the retinoic acid receptor α (*RAR* α) gene (Table 56-2). This event causes unregulated transcriptional repression in a manner that precludes normal cellular differentiation. The addition of the RAR ligand, retinoic acid, activates the receptor, thereby relieving repression and allowing cells to differentiate and ultimately undergo apoptosis. This mechanism has therapeutic importance as the addition of retinoic acid to treatment regimens induces a higher remission rate in patients with promyelocytic leukemia (Chap. 96).

CLONING AND SEQUENCING DNA

Since the mid-1970s, eight Nobel prizes have been awarded for research that led, directly or indirectly, to major methodological advances and to profound insights into genetics. Examples include the discoveries of reverse transcriptase, restriction enzymes, plasmid cloning vectors, DNA sequencing, and PCR. A description of recombinant DNA techniques, the methodology used for the manipulation, analysis, and characterization of DNA segments, is beyond the scope of this chapter. As these methods are widely used in genetics and molecular diagnostics, however, it is useful to review briefly some of the fundamental principles of cloning and DNA sequencing.

CLONING OF GENES *Cloning* refers to the creation of a recombinant DNA molecule that can be propagated indefinitely. The ability to clone genes and cDNAs therefore provides a permanent and renewable source of these reagents. Cloning is essential for DNA sequencing, nucleic acid hybridization studies, expression of recombinant proteins, and other recombinant DNA procedures.

The cloning of DNA involves the insertion of a DNA fragment into a cloning vector, followed by the propagation of the recombinant DNA in a host cell. The most straightforward cloning strategy involves inserting a DNA fragment into bacterial plasmids. Plasmids are small, autonomously replicating, circular DNA molecules that propagate separately from the chromosome in bacterial cells. The process of DNA insertion relies heavily on the use of restriction enzymes, which cleave DNA at highly specific sequences (usually 4 to 6 bp in length). Restriction enzymes generate complementary, cohesive sequences at the ends of the DNA fragment, which allow them to be efficiently ligated to the plasmid vector. Because plasmids contain genes that confer resistance to antibiotics, their presence in the host cell can be used for selection and DNA amplification.

A variety of vectors (e.g., plasmids, phage, bacterial, or yeast artificial chromosomes) are used for cloning. Many of these are used for creating *libraries*, a term that refers to a collection of DNA clones. A genomic library represents an array of clones derived from genomic DNA. These overlapping DNA fragments represent the entire genome and can ultimately be arranged according to their linear order. cDNA libraries reflect clones derived from mRNA, typically from a particular tissue source. Thus, a cDNA library from the heart contains copies of mRNA expressed specifically in cardiac myocytes, in addition to those that are expressed ubiquitously. For this reason, a heart cDNA library will be enriched with cardiac-specific gene products and will differ from cDNA libraries generated from liver or pituitary mRNAs. As an example of the complexity of a genomic library, consider that the human genome contains 3×10^9 bp and the average genomic insert in a λ phage library is about 10^4 bp. Therefore, it requires at least 3×10^5 clones to represent all genomic DNA. Specific clones are isolated from the several hundred thousand clones by using DNA hybridization.

With completion of the HGP, all human genes have been cloned and sequenced. As a result, many of these cloning procedures are now unnecessary or greatly facilitated by the extensive information concerning DNA markers and the sequence of DNA (see below).

NUCLEIC ACID HYBRIDIZATION Nucleic acid *hybridization* is a fundamental principle in molecular biology that takes advantage of the fact that the two complementary strands of nucleic acids bind, or *hybridize*, to one another with very high specificity. The goal of hybridization is to

detect specific nucleic acid (DNA or RNA) sequences in a complex background of other sequences. This technique is used for Southern blotting, Northern blotting, and for screening libraries (see above). Further adaptation of hybridization techniques has led to the development of microarray DNA chips.

Southern Blot Southern blotting is used to analyze whether genes have been deleted or rearranged. It is also used to detect restriction fragment length polymorphisms (RFLPs). Genomic DNA is digested with restriction endonucleases and separated by gel electrophoresis. Individual fragments can then be transferred to a membrane and detected after hybridization with specific radioactive DNA probes. Because single base-pair mismatches can disrupt the hybridization of short DNA probes (oligonucleotides), a variation of the Southern blot, termed *oligonucleotide-specific hybridization* (OSH), uses short oligonucleotides to distinguish normal from mutant genes.

Northern Blot Northern blots are used to analyze patterns and levels of gene expression in different tissues. In a northern blot, mRNA is separated on a gel and transferred to a membrane, and specific transcripts are detected using radiolabeled DNA as a probe. This technique is rapidly being supplanted by more sensitive and comprehensive methods such as reverse transcriptase (RT)–PCR and gene expression arrays on DNA chips (see below).

Microarray Technology A rapidly evolving approach to genome-scale studies consists of *microarrays*, or *DNA chips*. These approaches consist of thousands of synthetic nucleic acid sequences aligned on thin glass or silicon surfaces. Fluorescently labeled test sample DNA or RNA is hybridized to the chip, and a computerized scanner detects sequence matches. Microarrays allow the detection of variations in DNA sequence and are used for mutational analysis and genotyping. Alternatively, the expression pattern of large numbers of mRNA transcripts can be determined by hybridization of RNA samples to cDNA or genomic microarrays. This method has tremendous potential in the era of functional genomics (e.g., a comprehensive analysis of gene expression profiles). As one example, microarrays can be used to develop genetic fingerprints of different types of malignancies, providing information useful for classification, pathophysiology, prognosis, and treatment.

THE POLYMERASE CHAIN REACTION The PCR, introduced in 1985, has revolutionized the way DNA analyses are performed and has become a cornerstone of molecular biology and genetic analysis. In essence, PCR provides a rapid way of cloning (amplifying) specific DNA fragments in vitro (Fig. 56-7). Exquisite specificity is conferred by the use of PCR primers, which are designed for a given DNA sequence. The geometric amplification of the DNA after multiple cycles yields remarkable sensitivity. As a result, PCR can be used to amplify DNA from very small samples, including single cells. These properties also allow DNA amplification from a variety of tissue sources including blood samples, biopsies, surgical or autopsy specimens, or cells from hair or saliva. PCR can also be used to study mRNA. In this case, the enzyme RT is first used to convert the RNA to DNA, which can then be amplified by PCR. This procedure, commonly known as *RT-PCR*, is useful as a quantitative measure of gene expression.

PCR provides a key component of molecular diagnostics. It provides a strategy for the rapid amplification of DNA (or mRNA) to search for mutations by a wide array of techniques, including DNA sequencing. PCR is also used for the amplification of highly polymorphic di- or trinucleotide repeat sequences, which allow various polymorphic alleles to be traced in genetic linkage or association studies. PCR is increasingly used to diagnose various microbial pathogens.

DNA SEQUENCING DNA sequencing is now an automated procedure. Although many protocols exist, the most commonly used strategy is based on the Sanger method in which dideoxynucleotides are used to randomly terminate DNA polymerization at each of the four bases (A,G,T,C). After separating the array of terminated DNA fragments using high-resolution gel or capillary electrophoresis, it is possible to deduce the DNA sequence by examining the progression of fragment lengths generated in each of the four nucleotide reactions. The use of fluorescently labeled dideoxynucleotides allows automated detection of the different bases and direct computer analysis of the DNA sequence (Fig. 56-6). Efforts are underway to develop faster, more cost-effective DNA sequencing technologies. These include the use of mass spectrometry; detection of fluorescently labeled bases in flow cytometry; direct reading of the DNA sequence by scanning, tunneling, or atomic force microscopy; and sequence analysis using DNA chips.

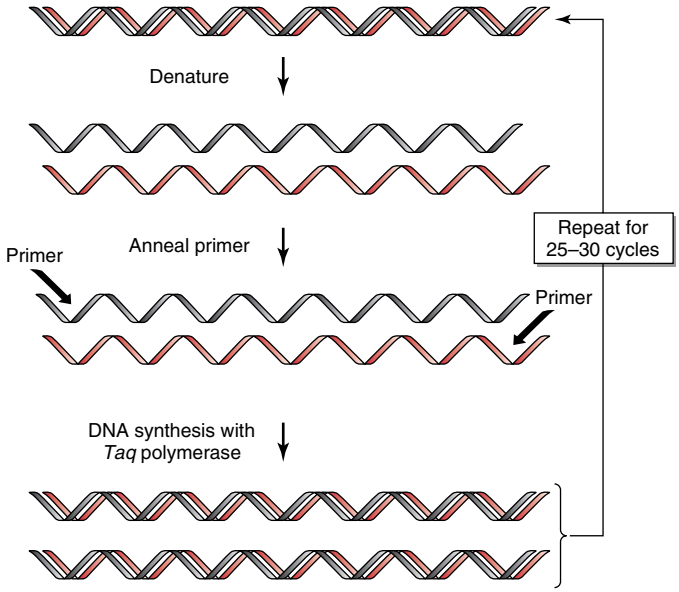

FIGURE 56-7 Polymerase chain reaction. The polymerase chain reaction (PCR) generates multiple copies of a DNA segment. After denaturing the double-stranded (ds) DNA, complementary synthetic oligonucleotide primers of about 20 bp are annealed on each side of the fragment of interest. A heat-stable polymerase then extends the oligonucleotides and synthesizes the complementary strand. This cycle is repeated 25 to 30 times. The number of DNA-amplified DNA segments is thus doubled after every PCR cycle.

TRANSGENIC MICE AS MODELS OF GENETIC DISEASE

Several organisms have been studied extensively as genetic models, including *Mus musculus* (mouse), *Drosophila melanogaster* (fruit fly), *Caenorhabditis elegans* (nematode), *Saccharomyces cerevisiae* (baker's yeast), and *Escherichia coli* (colonic bacterium). The ability to use these evolutionarily distant organisms as genetic models that are relevant to human physiology reflects a surprising conservation of genetic pathways and gene function. Transgenic mouse models have been particularly valuable, because many human and mouse genes exhibit similar structure and function, and because manipulation of the mouse genome is relatively straightforward compared to those of other mammalian species.

Transgenic strategies in mice can be divided into two main approaches: (1) expression of a gene by random insertion into the genome, and (2) deletion or targeted mutagenesis of a gene by homologous recombination with the native endogenous gene (knockout, knockin) (Fig. 56-8; Table 56-3). Transgenic mice are generated by pronuclear injection of foreign DNA into fertilized mouse oocytes and subsequent transfer into the oviduct of pseudopregnant foster mothers.

Transgenic expression of genes can be useful for studying disorders that are sensitive to gene dosage. Overexpression of *PMP22*, for example, mimics a common duplication of this gene in type IA Charcot-Marie-Tooth disease (Chap. 364). Duplication of the *PMP22* gene results in high levels of expression of peripheral myelin protein 22, and this dosage effect is responsible for the demyelinating neuropathy. Expression of the Y chromosome–specific gene, *SRY*, in XX females demonstrates that *SRY* is sufficient to induce the formation of testes. This finding confirms the pathogenic role of *SRY* translocations to the

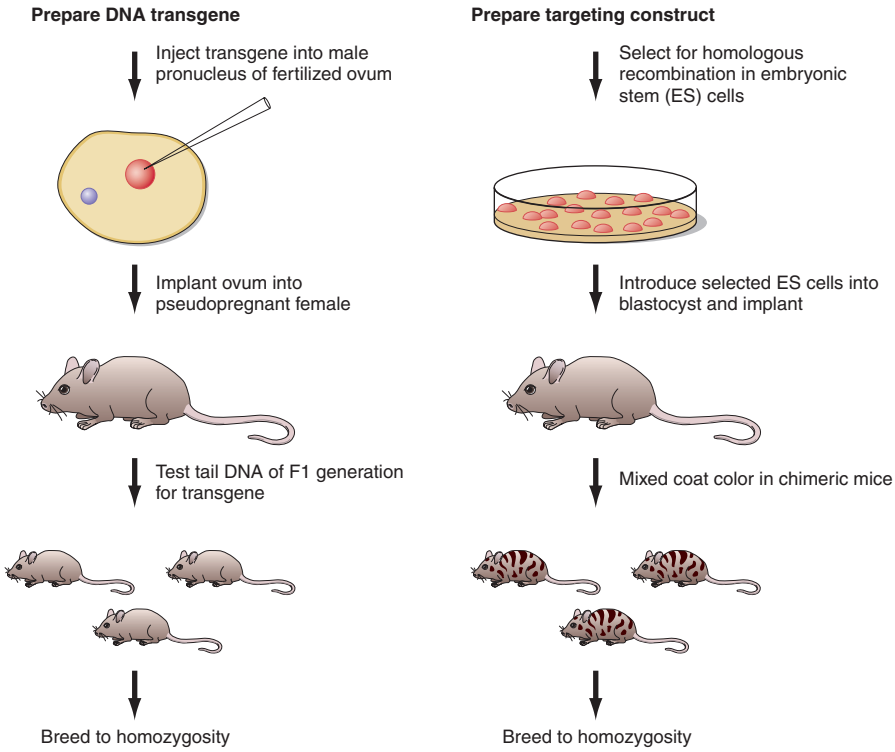

FIGURE 56-8 Transgenic mouse models. *Left*. Transgenic mice are generated by pronuclear injection of foreign DNA into fertilized mouse oocytes and subsequent transfer into the oviduct of pseudopregnant foster mothers. *Right*. For targeted mutagenesis (gene knockout/knockin), embryonic stem (ES) cells are transfected with the targeted (mutagenized) transgene. The transgene undergoes homologous recombination with the wild-type gene. After selection, positive ES cells are introduced into blastocysts and implanted into foster mothers. Chimeric mice can be identified based on the mixed coat color of the offspring. Heterozygous mice are bred to obtain mice homozygous for the mutant allele.

X chromosome in sex-reversed XX females. Huntington disease is an autosomal dominant disorder caused by expansion of a CAG trinucleotide repeat that encodes a polyglutamine tract. Targeted deletion of the Huntington disease (*HD*) gene does not induce the neurologic disorder. On the other hand, transgenic expression of the entire gene or of the first exon containing the expanded polyGlu repeat is sufficient to cause many features of the neurologic disorder, indicating a gain-of-function property for the expanded polyGlu-containing protein. Transgenic strategies can also be used as a precursor to gene therapy. Expression of dystrophin, the protein that is deleted in Duchenne muscular dystrophy, partially corrects the disorder in a mouse model of Duchenne's. Targeted expression of oncogenes has been valuable to study mechanisms of neoplasia and to generate immortalized cell lines. For example, expression of the simian virus 40 (SV40) large T antigen under the direction of the insulin promoter induces the formation of islet cell tumors.

The creation of gene knockout and knockin models takes advantage of the fact that a segment of DNA can be substituted by another that is identical (homologous), or nearly identical, by recombination. This permits integration of deletions that disrupt the gene (knockout) or selected mutations (knockin) into the target gene of choice. The transgene is introduced into embryonic stem (ES) cells by transfection and, after selection of cells with an integrated transgene, the positive ES cells are introduced into blastocysts and implanted into foster mothers. Chimeric mice can be identified based on the mixed coat color of the offspring. Heterozygous mice are bred to obtain mice homozygous for the mutant allele. This is particularly useful for genes that would be lethal if deleted universally or during early development. The list of genes that have been modified by this approach is very large.

Many of these knockouts do not have an apparent phenotype, either because of redundant functions of the other genes or because the phenotype is subtle. For example, deletion of the hypoxanthine phosphoribosyltransferase (HPRT) gene (*Hprt*) does not cause characteristic features of Lesch-Nyhan syndrome in mice because of their reliance on adenine phosphoribosyltransferase (APRT) in the purine salvage pathway. Deletion of the retinoblastoma (*Rb*) gene does not lead to retinoblastoma or other tumors that characterize the human syndrome. These examples underscore the fact that the functions of genes, and their interactions with genetic background and the environment, are not necessarily identical in mice and humans. On the other hand, the deletion of many genes provides a remarkably faithful model of human disorders. In addition to clarifying pathophysiology, these models facilitate the development of therapies, both genetic and pharmaceutical.

Many variations of these basic approaches now exist that allow genes to be expressed or deleted in specific cell types, at different times during development, or at varying levels. Consequently, transgenic technology has emerged as a powerful strategy for defining the physiologic effects of deleting or overexpressing a gene, as well as providing unique genetic models for dissecting pathophysiology or testing therapies. In addition to transgenic animal models, naturally occurring mutations in mice and other species continue to provide fundamental insights into human disease. A compendium of natural and transgenic animal models is provided in continuously evolving databases (Table 56-1).

Human pluripotential *stem cells* have recently been developed, and, consistent with their potential for self-renewal, these cell lines express high levels of telomerase, an enzyme that is essential for allowing repeated replication of the ends of eukaryotic chromosomes. Although much remains to be learned about the properties of pluripotential stem cells, they may prove useful for transplantation, drug testing, or for other purposes (Chap. 59).

IMPLICATIONS OF THE HUMAN GENOME PROJECT

The HGP was initiated in the mid-1980s as an ambitious effort to characterize the human genome, culminating in a complete DNA sequence. The initial main goals were (1) creation of genetic maps, (2) development of physical maps, and (3) determination of the complete human DNA sequence. Some analogies help in appreciating the scope of the HGP. The 23 pairs of human chromosomes encode approximately 30,000 to 40,000 genes. The total length of DNA is about 3 billion bp, which is nearly 1000-fold greater than that of the *E. coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine*.

THE GENETIC MAP Given the size and complexity of the human genome, initial efforts aimed at developing genetic maps to provide orientation and to delimit where a gene of interest may be located. A *genetic map* describes the order of genes and defines the position of a gene relative to other loci on the same chromosome. It is constructed by assessing how frequently two markers are inherited together (e.g., *linked*) by association studies. Distances of the genetic map are expressed in recombination units, or centimorgans (cM). One cM corresponds to a recombination frequency of 1% between two polymorphic markers; 1 cM corresponds to approximately 1 Mb of DNA (Fig. 56-4). Any polymorphic sequence variation can be useful for mapping purposes. Examples of polymorphic markers include variable number of tandem repeats (VNTRs), RFLPs, microsatellite repeats, and single nucleotide polymorphisms (SNPs); the latter two methods are now used predominantly because of the high density of markers and because they are

amenable to automated procedures. Current efforts aim at creating high quality, dense SNP maps and haplotype maps (e.g., linear arrangements of alleles) of the human genome through the identification of as many as 500,000 SNPs. These variations, which are amenable to automated analysis with DNA chips, will greatly facilitate association and linkage studies for the elucidation of the complex interactions among multiple genes and life-style factors in multifactorial disorders. SNP patterns may ultimately become useful for the prediction of disease predisposition and pharmacogenomics.

THE PHYSICAL MAP Cytogenetics and chromosomal banding techniques provide a relatively low-resolution microscopic view of genetic loci. Physical maps indicate the position of a locus or gene in absolute values. Sequence-tagged sites (STSs) are used as a standard unit for physical mapping and serve as sequence-specific landmarks for arranging overlapping cloned fragments in the same order as they occur in the genome. These overlapping clones allow the characterization of contiguous DNA sequences, commonly referred to as *contigs*. This approach led to high-resolution physical maps by cloning the whole genome into overlapping fragments and has been essential for the identification of disease-causing genes by positional cloning. The complete DNA sequence of each chromosome, now already complete for several chromosomes and as draft for the whole genome, provides the highest resolution physical map.

TABLE 56-3 *Genetic Modified Animals*

Commonly Used Description	*Technical Principle*	*Remarks*
Transgenic	Pronuclear injection of transgene	Commonly used Genomic DNA or cDNA constructs Random integration of transgene Variable copy numbers of transgene Variable expression in each individual founder Gain of function models due to overexpression using tissue-specific promoters Loss of function models using antisense and dominant negative transgenes Inducible expression possible (Tetracycline, ecdysone) Applicable to several species
(Targeted) Knockout	Substitution of functional gene with inactive gene by homologous recombination in embryonic stem cells	Predominantly used in mice Tissue-specific knockout possible (Cre/lox) Absence of phenotype possible due to redundancy
(Targeted) Knockin	Introduction of subtle mutation(s) into gene by substitution of endogenous gene with gene carrying a specific mutation. Homologous recombination in embryonic stem cells	Predominantly used in mice Can accurately model human disease
Forward genetics	Mutations created randomly by ENU (N-ethyl-N-nitrourea)	Selection of phenotype followed by genetic characterization Useful for cloning of novel genes
Cloning	Introduction of nucleus into enucleated eggs (nuclear transfer)	Successful in several mammalian species including sheep (Dolly), mice, cows, monkeys Cloning of genetically identical individuals May affect life span Ethical concerns

STATUS OF DNA SEQUENCING The primary focus of the HGP was to obtain DNA sequence for the entire human genome as well as model organisms. Although the prospect of determining the complete sequence of the human genome seemed daunting several years ago, technical advances in DNA sequencing and bioinformatics led to the completion of a draft human sequence in June 2000, well in advance of the original goal year of 2003. The whole genomes of more than 800 organisms have been sequenced partially or completely. They include, among others, eukaryotes such as man and mouse; *S. cerevisiae*, *C. elegans*, and *D. melanogaster*; bacteria (e.g., *E. coli*); and archeae, viruses, organelles (mitochondriae, chloroplasts), and plants (e.g., *Arabidopsis thaliana*). For the human genome, the current goal is now to achieve 99.99% (1 error in 10,000 bp) accuracy. This level of accuracy is important for many reasons, including efforts to determine the degree of DNA sequence variation in the population. Comparisons of the DNA sequence from multiple individuals or populations will allow assessments of genetic variance in the human population. Another goal is to develop a complete set of full-length human cDNAs and to define their locations on the physical map.

CURRENT DIRECTIONS ARISING FROM THE HGP The primary goals of the HGP have been achieved, but there are numerous remaining challenges, including (1) refining the sequence information and solving ambiguities, (2) establishing catalogs of sequence variations and SNPs, (3) characterizing the expression pattern of thousands of genes simultaneously in order to detect differences between various tissues in health and disease (*functional genomics*), (4) identifying the genes that play critical roles in the development of polygenic and multifactorial disorders, and (5) developing large-scale analyses of protein expression (*proteomics*).

ETHICAL ISSUES Implicit in the HGP is the idea and hope that identifying disease-causing genes can lead to improvements in diagnosis, prognosis, and treatment. It is estimated that most individuals harbor several serious recessive genes. However, completion of the human genome sequence, determination of the association of genetic defects with disease, and studies of genetic variation raise many new issues with implications for the individual and mankind. The controversies concerning the cloning of mammals and the establishment of human embryonic stem cells underscore the relevance of these questions. Moreover, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause multiple endocrine neoplasia (MEN) type 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present, the identification of an Alzheimer or Huntington disease gene does not alter therapy. Genetic test results can generate anxiety in affected individuals and family members, and there is the possibility of discrimination on the basis of the test results. Most genetic disorders are likely to fall into an intermediate category where the opportunity for prevention or treatment is significant but limited (Chap. 58). For these reasons, the scientific components of the HGP have been paralleled by efforts to examine ethical and legal implications as new issues arise. About 5% of the HGP budget had been allocated to studies addressing the ethical, legal, and social implications associated with the increasing knowledge about the human genome and the genetic basis of disease.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction is known to be at increased risk of coronary heart disease. In such cases, it is clear that the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fi-

brosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information. We can anticipate similar efforts, whether based on genotypes or other markers of genetic predisposition, to be applied to many disorders. One confounding aspect of the rapid expansion of information is that our ability to make clinical predictions often lags behind genetic advances. For example, when genes that predispose to breast cancer, such as *BRCA1*, are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or their families, there is a great need for more information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it imperative for physicians and other health care professionals to become more informed about genetics, and to provide advice and counseling in conjunction with trained genetic counselors (Chap. 58). The application of screening and prevention strategies will therefore require intensive patient and physician education, changes in health care financing, and legislation to protect patient's rights.

TRANSMISSION OF GENETIC DISEASE

ORIGINS AND TYPES OF MUTATIONS A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences. Some mutations may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Mutations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, mutations can occur during embryogenesis or in somatic tissues. Mutations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events, heritable changes that do not involve changes in gene sequence (e.g., altered DNA methylation), may influence gene expression or facilitate genetic damage. With the exception of triplet nucleotide repeats, which can expand (see below), mutations are usually stable.

Mutations are structurally diverse—they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes (Chap. 57). Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness (Chap. 25). Mutations involving single nucleotides are referred to as *point mutations* (Fig. 56-6). Substitutions are called *transitions* if a purine is replaced by another purine base (A ↔ G) or if a pyrimidine is replaced by another pyrimidine (C ↔ T). Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes. *Polymorphisms* are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype. Often they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code, although it is possible that some might alter mRNA stability, translation, or the amino acid sequence. These types of silent base substitutions and SNPs are encountered frequently during genetic testing and must be distinguished from true mutations that alter protein expression or function. Small nucleotide deletions or insertions cause a shift of the codon reading frame (*frameshift)*. Most commonly, reading frame alterations result in an abnormal protein segment of variable length before termination of translation occurs at a stop codon (*nonsense mutation*) (Fig. 56-6). Mutations in intronic sequences or in exon junctions may destroy or create splice donor or splice acceptor sites. Mutations may also be found in the regulatory sequences of genes, resulting in reduced gene transcription.

Mutation Rates As noted before, mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of about 10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only about 20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves about 30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased (Chap. 57). Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are $\sim 10^{-5}$ to 10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling, as a new mutation can be transmitted to the affected individual but does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

Unequal Crossing-Over Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 56-4). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over (Chap. 318). The *GH* gene is a member of a large gene cluster that includes a growth hormone variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly prone to undergo recombination and, consequently, gene duplication or deletion. On the other hand, duplication of the *PMP22* gene because of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease (Chap. 364). Unequal crossing-over resulting in deletion of *PMP22* causes a distinct neuropathy called *hereditary liability to pressure palsy* (Chap. 364).

Glucocorticoid-remediable aldosteronism (GRA) is caused by a rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11β-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95% identical, predisposing to gene duplication and deletion by unequal crossing-over. The rearranged gene product contains the regulatory regions of 11β-hydroxylase fused to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)-dependent zona fasciculata of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension (Chap. 321).

Gene conversion refers to a nonreciprocal exchange of homologous genetic information; it is probably more common than generally rec-

ognized. In human genetics, gene conversion has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A*) is adjacent to a nonfunctional pseudogene. Many of the nucleotide substitutions that are found in the *CYP21A* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the pseudogene, suggesting gene conversion as a mechanism of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

Insertions and Deletions Though many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events suggests that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene appear to be hot spots for deletions.

Errors in DNA Repair Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders (Chap. 69). Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway (Chap. 73). Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. More than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum. This finding is consistent with the earlier classification of this disease into different complementation groups in which normal function is rescued by the fusion of cells derived from two different forms of xeroderma pigmentosum.

Ataxia telangiectasia causes large telangiectatic lesions of the face, cerebellar ataxia, immunologic defects, and hypersensitivity to ionizing radiation (Chap. 352). The discovery of the ataxia telangiectasia mutated (*ATM*) gene reveals that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and a strong predisposition to develop aplastic anemia and acute myelogenous leukemia (Chap. 96). Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. At least eight different complementation groups have been identified, and several loci and genes associated with Fanconi's anemia have been mapped or cloned.

HNPCC is caused by mutations in one of several different mismatch repair (MMR) genes including MutS homologue 2 (*MSH2*) and MutL homologue 1 (*MLH1*) (Chap. 77). These enzymes are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. This syndrome is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk (Chap. 58). Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

CpG and Dipyrimidine Sequences Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light–induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of mutation. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C → T transition (or G → A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. Many of the *MSH2* mutations in HNPCC, for example, involve CpG sequences. In addition to the fact that certain types of mutations (C → T or G → A) are relatively common, the nature of the genetic code also results in overrepresentation of certain amino acid substitutions.

Unstable DNA Sequences *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of mental retardation. Other disorders arising from a similar mechanism include Huntington disease (Chap. 350), X-linked spinobulbar muscular atrophy (Chap. 353), and myotonic dystrophy (Chap. 368) (Table 56-4). Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

FUNCTIONAL CONSEQUENCES OF MUTATIONS Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant, i.e., they result in phenotypic alterations when a single allele is affected. Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (e.g., carrying two different mutant alleles) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient to maintain a normal phenotype. Haploinsufficiency is a commonly observed mechanism in diseases associated with mutations in transcription factors (Table 56-2). Remarkably, the clinical features among patients with an identical mutation in a transcription factor often vary significantly. One mechanism underlying this variability consists in the influence of modifying genes. Haploinsufficiency can also affect the expression of rate-limiting enzymes. For example, haploinsufficiency in enzymes involved in heme synthesis can cause porphyrias (Chap. 337).

An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1* gene in dosage-sensitive sex-reversal (Chap. 328). Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta (Chap. 342); (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance, a disorder in which inactivated thyroid hormone receptor binds to target genes and functions as an antagonist of normal receptors (Chap. 320); or (3) a mutant protein can be cytotoxic as in α_1 antitrypsin deficiency (Chap. 242) or autosomal dominant neurohypophyseal diabetes insipidus (Chap. 319), in which the

TABLE 56-4 *Selected Trinucleotide Repeat Disorders*

Disease	Locus	Repeat	Triplet Length Normal/Disease	Inheritance	Gene Product
X-Chromosomal spinobulbar muscular atrophy (SBMA)	Xq11-q12	CAG	11–34/40–62	XR	Androgen receptor
Fragile X-syndrome (FRAXA)	Xq27.3	CGG	6–50/200–300	XR	FMR-1 protein

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

GENOTYPE AND PHENOTYPE ■ Alleles, Genotypes, and Haplotypes An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as *alleles*. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring the adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations in a gene that clearly alter its function. The common Glu → Val sickle cell mutation (E6V) in the *β-globin* gene and the δF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), he or she can have only two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting such identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity. If the alleles are different, the individual is *heterozygous* at this locus (Fig. 56-6). If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus. Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination, if the crossover event occurs between the alleles (Fig. 56-4). As an example, various alleles at the histocompatibility locus antigen (HLA) on chromosome 6p are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close vicinity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases.

Allelic Heterogeneity *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the β-globin locus can cause β-thalassemia (Fig. 56-5). In essence, allelic heterogeneity reflects the fact that many different mutations are capable of altering protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include: (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, as these can differ in each patient.

Phenotypic Heterogeneity *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., different mutations in the same gene). For example, mutations in the *myosin VIIIA* gene can result in four distinct clinical disorders: (1) autosomal recessive deafness DFNB2, (2) autosomal dominant nonsyndromic deafness DFNA11, (3) Usher 1B syndrome [congenital deafness, retinitis pigmentosa (Fig. 56-9)], and (4) an atypical variant of Usher's syndrome.

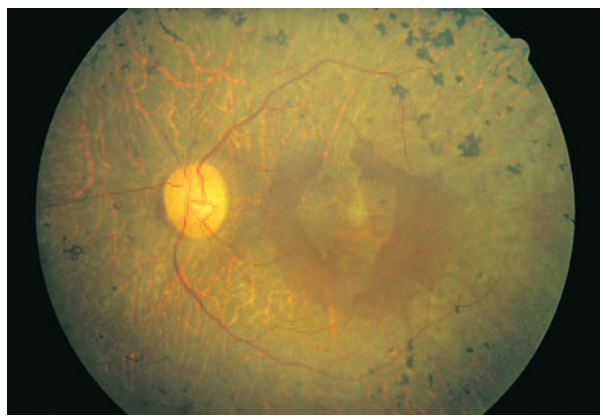

FIGURE 56-9 Retinitis pigmentosa with black clumps of pigment in the retinal periphery, known as "bone spicules." There is also atrophy of the retinal pigment epithelium, making the vasculature of the choroid easily visible.

Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon syndrome (craniofacial synostosis), or Pfeiffer syndrome (acrocephalopolysyndactyly).

TABLE 56-5 *Selected Examples of Locus Heterogeneity*

Phenotype	Gene	Chromosomal Location	Protein
Familial hypertrophic cardiomyopathy			
Genes encoding for sarcomeric proteins	*MYH7*	14q12	Myosin heavy chain beta
	TNNT2	1q2	Troponin-T2
	TPM1	15q22.1	Tropomyosin α
	MYBPC3	11p11q	Myosin binding protein C
	TNNI3	19q13.4	Troponin 1
	MYL3	3p	Myosin light chain 3
	MYL2	12q23-24.3	Myosin light chain 2
	TTN	2q24.3	Cardiac titin
	ACTC	15q11	Cardiac alpha actin
	MYH6	14q1	Myosin heavy chain alpha
	TNNC1	3p21.3-3p14.3	Cardiac troponin C
Nonsarcomeric proteins	*MTT1*	Mitochondrial	tRNA isoleucine and tRNA glycine
	PRKAG2	7q35-q36	AMP-activated protein kinase γ2 subunit
	DMPK	19q13	Myotonin protein kinase (myotonic dystrophy)
	FRDA	9q13	Frataxin (Friedreich ataxia)
Polycystic kidney disease			
	PKD1	16p13.3-13.12	Polycystin 1 (AD)
	PKD2	4q21.-23	Polycystin 2 (AD)
	PKHD1	6p21.1-p12	Fibrocystin (AR)
Familial breast cancer			
BRCA1	*BRCA1*	17q21	BRCA1 (RNA polymerase II component)
BRCA2	*BRCA2*	13q12.3	BRCA2

Locus or Nonallelic Heterogeneity and Phenocopies *Nonallelic or locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci (Table 56-5). This often occurs when more than one gene product produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes (Chap. 342). The effects of inactivating mutations in these two genes are similar because the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner (Chap. 368). Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene as well as the fact that the phenotype is expressed in hemizygous males because they have only a single copy of the X chromosome. Dystrophin is associated with a large group of additional proteins that form the membrane-associated cytoskeleton in muscle. Mutations in several components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin also cause allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne or the less severe Becker muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer dementia (Chap. 350). Children born with activating mutations of the thyroid-stimulating hormone receptor (TSH-R) exhibit goiter and thyrotoxicosis similar to that seen in neonatal Graves' disease, which is caused by the transfer of maternal autoantibodies to the fetus (Chap. 320). As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

Variable Expressivity and Incomplete Penetrance It is not uncommon for the same genetic mutation to cause a phenotypic spectrum illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a complex disorder (e.g., MEN), the severity of the disorder (e.g., sickle cell anemia), or the age of disease onset (e.g., Alzheimer dementia). MEN-1 illustrates several of these features. Families with this autosomal dominant disorder develop tumors of the parathyroid gland, endocrine pancreas, and the pituitary gland (Chap. 330). However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable expression reflects the influence of modifier genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake (Chap. 336), and the course of phenylketonuria is affected by exposure to phenylalanine in the diet (Chap. 343). Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, as one cannot always predict the course of disease, even when the mutation is known.

Penetrance refers to the proportion of individuals with a mutant genotype that express the phenotype. If all carriers of a mutant express the phenotype, penetrance is complete, whereas it is said to be *incomplete* or *reduced* if some individuals do not have any features of the phenotype. Dominant conditions with incomplete penetrance are characterized by skipping of generations with unaffected carriers transmitting the mutant gene. For example, hypertrophic obstructive cardiomyopathy (HCM) caused by mutations in the *myosin-binding protein C* gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation (Chap. 221). Patients who have the mutation but no evidence of the disease can still transmit the disorder to subsequent generations. In many conditions with postnatal onset, the proportion of gene carriers who are affected varies with age. When describing penetrance, one has to therefore specify age. For

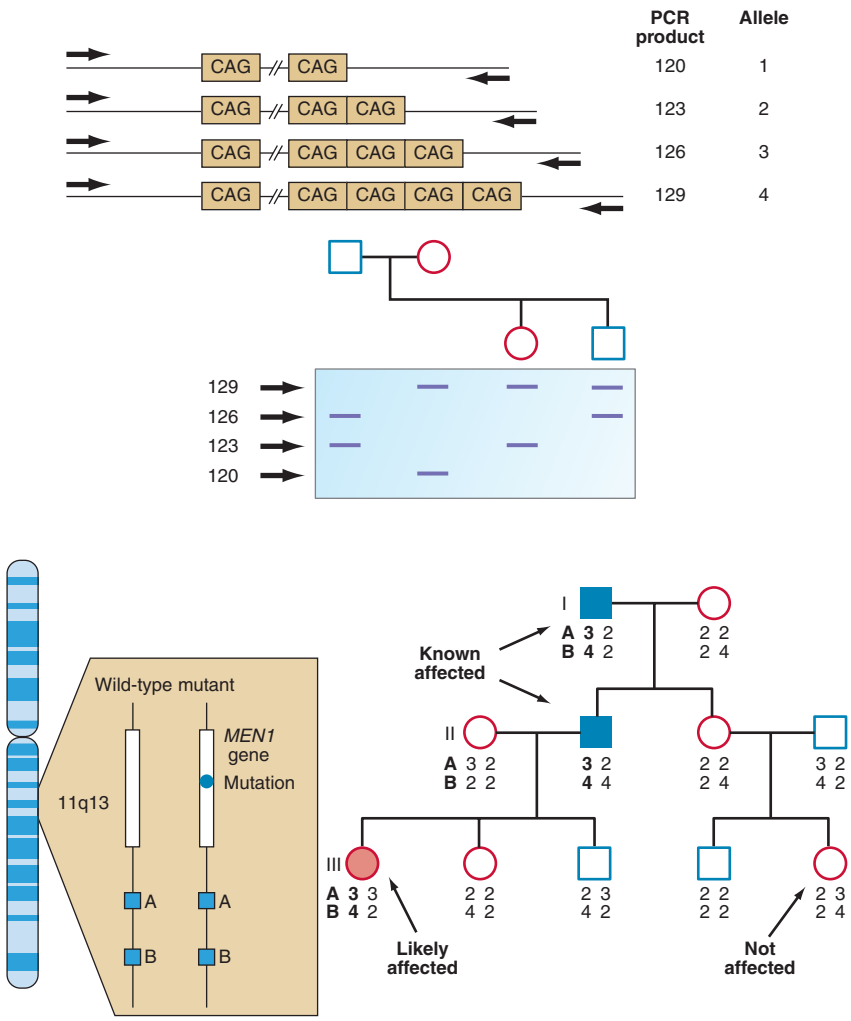

FIGURE 56-10 CAG repeat length and linkage analysis in multiple endocrine neoplasia type 1. *Upper panel.* Detection of different alleles using polymorphic microsatellite markers. The example depicts a CAG trinucleotide repeat. PCR with primers flanking the polymorphic region results in products of variable length, depending on the number of CAG repeats. After characterization of the alleles in the parents, transmission of the paternal and maternal alleles can be determined. *Lower panel.* Genotype analysis using microsatellite markers in a family with multiple endocrine neoplasia type 1. Two microsatellite markers, A and B, are located in close proximity to the *MEN1* gene on chromosome 11q13. For each individual, the A and B alleles have been determined. Based on this analysis, the genotype A3,B4 is linked to the disease because it occurs in the two affected individuals I-1 and II-1 but not in unaffected siblings. Because the disease allele is linked to A3,B4 within the affected family, it is likely that the individual III-1 is a carrier of the mutated *MEN1* gene. Although III-5 also has the A3,B4 genotype, she has inherited the allele from her unaffected father (II-4), who is not related to the original family. The A3,B4 genotype is only associated with MEN-1 in the original family, but not in the general population. Therefore, individual III-5 is not at risk for developing the disease.

example, for disorders such as Huntington disease or familial amyotrophic lateral sclerosis, which present late in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease (see below). For example, in patients with Albright hereditary osteodystrophy, mutations in the Gsα subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother (Chap. 334).

Sex-Influenced Phenotypes Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation (Chap. 102). On the other hand, some females heterozygous for the X-linked lipid storage defect caused by α-galactosidase A deficiency (Fabry disease) experience mild manifestations of painful neuropathy, as well as other features of the disease (Chap. 340). Because only males have a Y chromosome, mutations in genes such as *SRY*, which causes male-to-female sex-reversal, or *DAZ* (deleted in azoospermia), which causes abnormalities of spermatogenesis, are unique to males (Chap. 328).

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys (Chap. 325). The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Homozygous inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired (Chap. 325). In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTH stimulation of the adrenal gland leads to increased production of androgenic precursors (Chap. 321). In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females (Chap. 336).

GENETIC LINKAGE *Genetic linkage* refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of linkage: (1) when two genes are close together on a chromosome, they are usually transmitted together, unless a recombination event separates them (Fig. 56-4); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are further apart are more likely to undergo a recombination event than genes that are very close together. The detection of chromosomal loci that segregate with a disease by linkage can be used to identify the gene responsible for the disease (*positional cloning*) and to predict the odds of disease gene transmission in genetic counseling.

Polymorphisms are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist between any two unrelated individuals and the probability that the sequence at such loci will differ on the two homologous chromosomes is high (often >70 to 90%). These sequence variations include VNTRs, short tandem repeats (STRs), and SNPs. Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be measured readily using PCR (Fig. 56-10). Charac-

terization of SNPs, using DNA chips, provides a promising means for rapid analysis of genetic variation and linkage. Although this sequence variation usually has no apparent functional consequence, it provides much of the basis for variation in genetic traits.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to determine the genotype or haplotype of DNA samples from one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination events and therefore receive a higher linkage score. Linkage is expressed as a lod (logarithm of odds) score—the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of −2 is consistent with the absence of linkage.

An example of the use of linkage analysis is shown in Fig. 56-10. In this case, the gene for the autosomal dominant disorder, MEN-1, is known to be located on chromosome 11q13. Using positional cloning, the *MEN1* gene was identified and shown to encode menin, a tumor suppressor. Affected individuals inherit a mutant form of the *MEN1* gene, predisposing them to certain types of tumors (parathyroid, pituitary, pancreatic islet) (Chap. 330). In the tissues that develop a tumor, a "second hit" occurs in the normal copy of the *MEN1* gene. This somatic mutation may be a point mutation, a microdeletion, or loss of a chromosomal fragment (detected as loss of heterozygosity, LOH). Within a given family, linkage to the *MEN1* gene locus can be assessed without necessarily knowing the specific mutation in the *MEN1* gene. Using polymorphic STRs that are close to the *MEN1* gene, one can assess transmission of the different *MEN1* alleles and compare this pattern to development of the disorder to determine which allele is associated with risk of MEN-1. In the pedigree shown, the affected grandfather in generation I carries alleles 3 and 4 on the chromosome with the mutated *MEN1* gene and alleles 2 and 2 on his other chromosome 11. Consistent with linkage of the 3/4 genotype to the *MEN1* locus, his son in generation II is affected, whereas his daughter (who inherits the 2/2 genotype from her father) is unaffected. In the third generation, transmission of the 3/4 genotype indicates risk of developing MEN-1, assuming that no genetic recombination between the 3/4 alleles and the *MEN1* gene has occurred. After a specific mutation in the *MEN1* gene is identified within a family, it is possible to track transmission of the mutation itself, thereby eliminating uncertainty caused by recombination.

CHROMOSOMAL DISORDERS Chromosomal or cytogenetic disorders are caused by numerical or structural aberrations in chromosomes. Deviations in chromosome number are common causes of abortions, developmental disorders, and malformations. *Contiguous gene syndromes*, i.e., large deletions affecting several genes, have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different patients, a systematic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region. →***For discussion of disorders of chromosome number and structure, see Chap. 57.***

MONOGENIC MENDELIAN DISORDERS Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The continuously updated OMIM catalog lists several thousand of these disorders and provides information about the clinical phenotype, molecular basis, allelic variants, and pertinent animal models (Table 56-1). The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols (Fig. 56-1). The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated in Fig. 56-11. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-chromosomal. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked. Genetic testing is now available for many of these disorders and plays an increasingly important role in clinical medicine (Chap. 58).

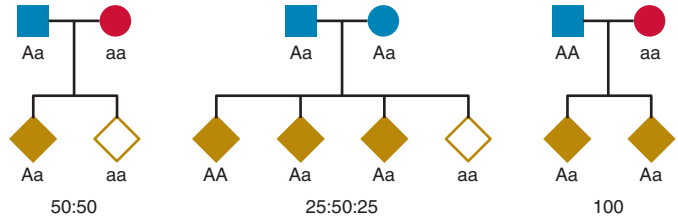

FIGURE 56-11 Segregation of alleles. Segregation of genotypes in the offspring of parents with one dominant (A) and one recessive (a) allele. The distribution of the parental alleles to their offspring depends on the combination present in the parents.

Autosomal Dominant Disorders Autosomal dominant disorders assume particular relevance because mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is loss of gene function, in dominant disorders there are various disease mechanisms, many of which are unique to the function of the genetic pathway involved.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes (Fig. 56-12*A*). Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an affected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent. De novo germline mutations occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. As noted before, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is approximately 37 years, whereas fathers who transmit the disease by inheritance have an average age of about 30 years.

Autosomal Recessive Disorders The clinical expression of autosomal recessive disorders is more uniform than in autosomal dominant disorders. Most mutated alleles lead to a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. In an autosomal recessive disease, the affected individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and often occur in the context of parental consanguinity. The relatively high frequency of certain recessive disorders, such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below). Though heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes (Chap. 91).

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the off-

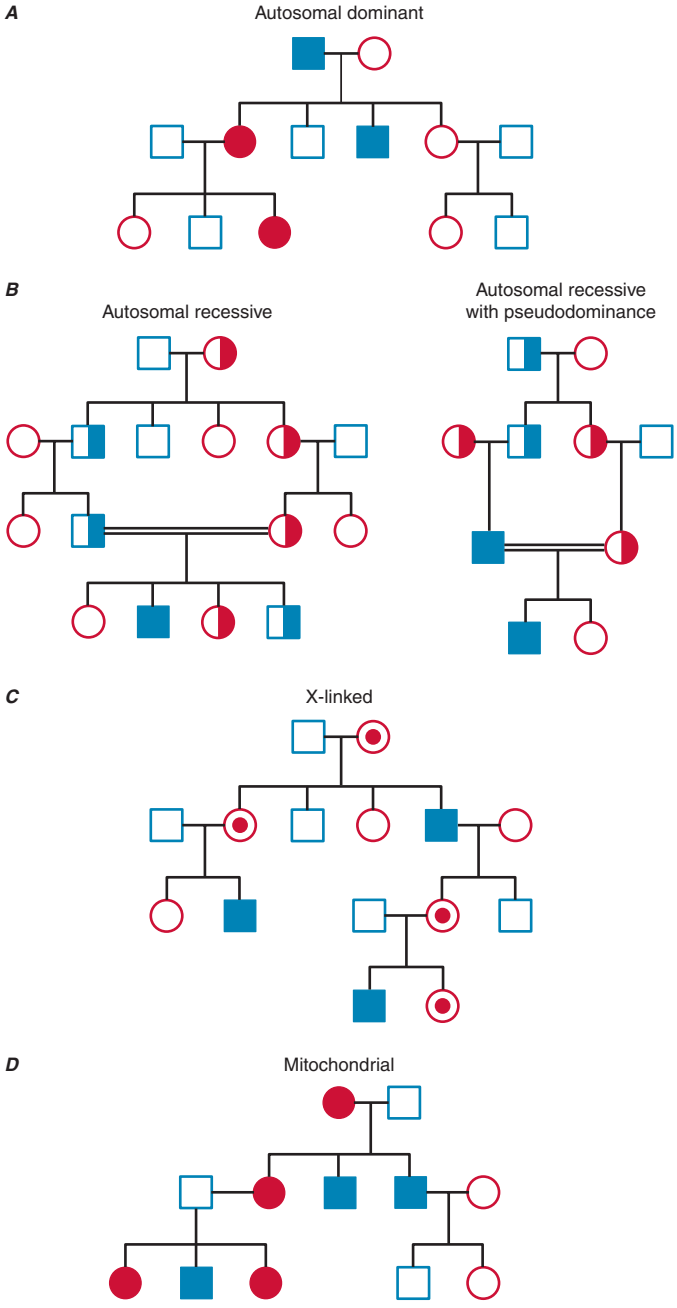

FIGURE 56-12 Dominant, recessive, X-linked, and mitochondrial (matrilinear) inheritance.

spring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles (Fig. 56-12*B*). In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-Linked Disorders Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission, and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele (Fig. 56-12*C*). The risk of developing disease due to a mutant X-chromosomal gene differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* or *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation (see below).

Y-Linked Disorders Only a few genes are known on the Y chromosome. One such gene, the sex-region determining Y factor (*SRY*), or testis-determining factor (*TDF*), is crucial for normal male development. Normally there is infrequent exchange of sequences on the Y chromosome with the X chromosome. Because the *SRY* region is closely adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology, a crossing-over occasionally involves the *SRY* region. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes (Chap. 328). Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

EXCEPTIONS TO SIMPLE MENDELIAN INHERITANCE PATTERNS ■ Mitochondrial Disorders Mendelian inheritance refers to the transmission of genes encoded by DNA contained in the nuclear chromosomes. In addition, each mitochondrion contains several copies of a circular chromosome. The mitochondrial DNA (mtDNA) is small (16.5 kb) and encodes transfer and ribosomal RNAs, and 13 proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome does not recombine and is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. A noncoding region of the mitochondrial chromosome, referred to as D-loop, is highly polymorphic. This property, together with the absence of mtDNA recombination, makes it a valuable tool for studies tracing human migration and evolution, and it is also used for specific forensic applications.

Inherited mitochondrial disorders are transmitted in a matrilineal fashion; all children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children (Fig. 56-12*D*). Alterations in the mtDNA affecting enzymes required for oxidative phosphorylation lead to reduction of ATP supply, generation of free radicals, and induction of apoptosis. Several syndromic disorders arising from mutations in the mitochondrial genome are known in humans and they affect both protein-coding and tRNA genes (Tables 56-1 and 56-6). The broad clinical spectrum often involves (cardio)myopathies and encephalopathies because of the high dependence of these tissues on oxidative phosphorylation. The age of onset and the clinical course are highly variable because of the unusual mechanisms of mtDNA, which replicates independently from nuclear DNA. During cell replication, the proportion of wild-type and mutant mitochondria can drift among different cells and tissues. The resulting heterogeneity in the proportion of mitochondria with and without a mutation is referred to as *heteroplasmia* and underlies the phenotypic variability that is characteristic of mitochondrial diseases.

Acquired somatic mutations in mitochondria are thought to be involved in several age-dependent degenerative disorders affecting predominantly muscle and the peripheral and central nervous system (e.g., Alzheimer's and Parkinson's disease). Establishing that a mtDNA alteration is causal for a clinical phenotype is challenging because of the high degree of polymorphism in mtDNA and the phenotypic variability characteristic of these disorders. Certain pharmacologic treatments may have an impact on mitochondria and/or their function. For

TABLE 56-6 Selected Mitochondrial Diseases

Disease/Syndrome	MIM #
MELAS syndrome: mitochondrial myopathy with encephalopathy, lactic acidosis, and stroke	540000 540050
Leber's optic atrophy: hereditary optical neuropathy	535000
Kearns-Sayre syndrome (KSS): ophthalmoplegia, pigmental degeneration of the retina, cardiomyopathy	530000
MERRF syndrome: myoclonic epilepsy and ragged red fibers	545030
Maternally inherited myopathy and cardiomyopathy (MMC)	590050
Neurogenic muscular weakness with ataxia and retinitis pigmentosa (NARP)	551500
Progressive external ophthalmoplegia (CEOP)	258470
Pearson syndrome (PEAR): bone marrow and pancreatic failure	557000
Autosomal dominant inherited mitochondrial myopathy with mitochondrial deletion (ADMIMY)	157640
Somatic mutations in cytochrome *b* gene: exercise intolerance, lactic acidosis, complex III deficiency, muscle pain, ragged-red fibers	

example, treatment with the antiretroviral compound azidothymidine (AZT) causes an acquired mitochondrial myopathy through depletion of muscular mtDNA.

Mosaicism Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from non-disjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner syndrome (Chap. 328). Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein α ($G_s\alpha$) that occur early in development (Chap. 334). The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, growth hormone–secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules (Chap. 326).

X-Inactivation, Imprinting, and Uniparental Disomy According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. Nonetheless, there are important exceptions to this rule. X-inactivation prevents the expression of most genes on one of the two X-chromosomes in every cell of a female. Gene inactivation also occurs on selected chromosomal regions of autosomes. This phenomenon, referred to as *genomic imprinting*, leads to preferential expression of an allele depending on its parental origin. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman syndrome (Chap. 57). Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, mental retardation, short stature, and hypogonadotropic hypogonadism. Deletions in the Prader-Willi syndrome occur exclusively on the paternal chromosome 15. In contrast, patients with Angelman syndrome, characterized by mental retardation, seizures, ataxia, and hypotonia, have deletions at the same site of chromosome 15; however, they are located on the maternal chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but by the inheritance of either two maternal chromosomes (Prader-Willi syndrome) or two paternal chromosomes (Angelman syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented, as it is difficult to examine levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies (Chap. 57). Hydatidiform mole contains a normal number of diploid chromosomes, but they are all of paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor II (IGF-II) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS) (Chap. 68). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilm's tumor. Normally, only the paternally derived copy of the *IGF-II* gene is active and the maternal copy is inactive. Imprinting of the *IGF-II* gene is regulated by *H19*, which encodes an RNA transcript that is not translated into protein. Disruption or lack of *H19* methylation leads to a relaxation of *IGF-II* imprinting and expression of both alleles. Heritable changes in gene expression not associated with DNA sequence alterations are referred to as *epigenetic effects*; these changes are increasingly recognized to play a role in human diseases and possibly in aging as well.

Somatic Mutations Cancer can be defined as a genetic disease at the cellular level (Chap. 68). Cancers are monoclonal in origin, indicating that they have arisen from a single precursor cell with one or several mutations in genes controlling growth and/or differentiation. These acquired somatic mutations are restricted to the tumor and its metastases and are not found in the surrounding normal tissue. The molecular alterations include dominant gain-of-function mutations in oncogenes, recessive loss-of-function mutations in tumor supressor genes and DNA repair genes, gene amplification, and chromosome rearrangements. Rarely, a single mutation in certain genes may be sufficient to transform a normal cell into a malignant cell. In most cancers, however, the development of a malignant phenotype requires several genetic alterations for the gradual progression from a normal cell to a cancerous cell, a phenomenon termed *multistep carcinogenesis* (Chaps. 68 and 69).

In many cancer syndromes, there is an inherited *predisposition* to tumor formation. In these instances, a germline mutation is inherited in an autosomal dominant fashion. This germline alteration affects one allele of an autosomal tumor suppressor gene. If the second allele is inactivated by a somatic mutation in a given cell, this will lead to neoplastic growth (two-hit model, or Knudson hypothesis). Thus, the defective allele in the germline is transmitted in a dominant pattern, though tumorigenesis results from a recessive loss of the tumor suppressor gene in an affected tissue. The classic example to illustrate this phenomenon is retinoblastoma, which can occur as a sporadic or hereditary tumor. In sporadic retinoblastoma, both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events. In hereditary retinoblastoma, one mutated or deleted *RB* allele is inherited in an autosomal dominant manner and the second allele is inactivated by a subsequent somatic mutation. This two-hit model applies to other inherited cancer syndromes such as MEN-1 (Chap. 330) and neurofibromatosis type 2 (Chap. 358).

Nucleotide Repeat Expansion Disorders Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold (Table 56-4). The repeats are sometimes located within the coding region of the genes, as in Huntington disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA, Kennedy syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington disease, for example, there is a correlation between age of onset and length of the triplet codon expansion (Chap. 350). Anticipation has also been doc-

TABLE 56-7 *Genetic Approaches for Identifying Disease Genes*

Method	Indications and Advantages	Limitations
Linkage analysis	Analysis of monogenic traits Suitable for genome scan Control population not required Useful for multifactorial disorders in isolated populations	Difficult to collect large informative pedigrees Difficult to obtain sufficient statistical power for complex traits
Allele-sharing methods		
Affected sib and relative pair analyses	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders Suitable for genome scan	Difficult to collect sufficient number of subjects Difficult to obtain sufficient statistical power for complex traits
Sib pair analysis	Control population not required if allele frequencies are known Statistical power can be increased by including parents and relatives	
Association studies		
Case-control studies Linkage disequilibrium Transmission distortion test	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders Suitable for testing specific allelic variants of known candidate loci Does not necessarily need relatives	Requires large sample size and matched control population False-positive results in the absence of suitable control population

umented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 56-4). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be tenfold greater in muscle tissue than in lymphocytes (Chap. 368).

POPULATION GENETICS AND ASSOCIATION STUDIES ■ Overview of Population Genetics In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes of alleles in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency, if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographical regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malarial infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Though homozygosity for the sickle cell gene is associated with severe anemia and sickle crises (Chap. 91), heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

Allelic Association and Linkage Disequilibrium There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model (see above) or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies (Table 56-7). *Allelic association* refers to a situation in which the frequency of an allele is significantly increased or decreased in a particular disease. Linkage and association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls, or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently in combination than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. In Fig. 56-13, a mutation, Z, has occurred at a susceptibility locus where the normal allele is Y. The mutation is in close proximity to a genetic polymorphism with allele A or B. With time, the chromosomes carrying the A and Z alleles accumulate and represent 10% of the chromosomes in the population. The fact that the disease susceptibility gene, Z, is found preferentially, or exclusively, in association with the A allele illustrates linkage disequilibrium. Though not all chromosomes carrying the A allele carry the disease gene, the A allele is associated with an increased risk because of its possible association with the Z allele. This model implies that it may be possible in the future to identify Z directly to provide a more accurate prediction of disease susceptibility. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci, in this case A and Z, are tightly linked.

POLYGENIC DISEASE AND COMPLEX GENETIC TRAITS ■ Approach to Polygenic and Multifactorial Disease The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by genetic background, environmental factors, and lifestyle (Table 56-8). A trait is called *polygenic* if multiple genes are thought to contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifying genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, plays an important role in polygenic traits that require the simultaneous presence of variations in multiple genes in order to result in a pathologic phenotype. Gene-environment interactions are relevant for many monogenic and polygenic disorders. In phenylketonuria, the phenotypic expression of the disease depends not only on the presence

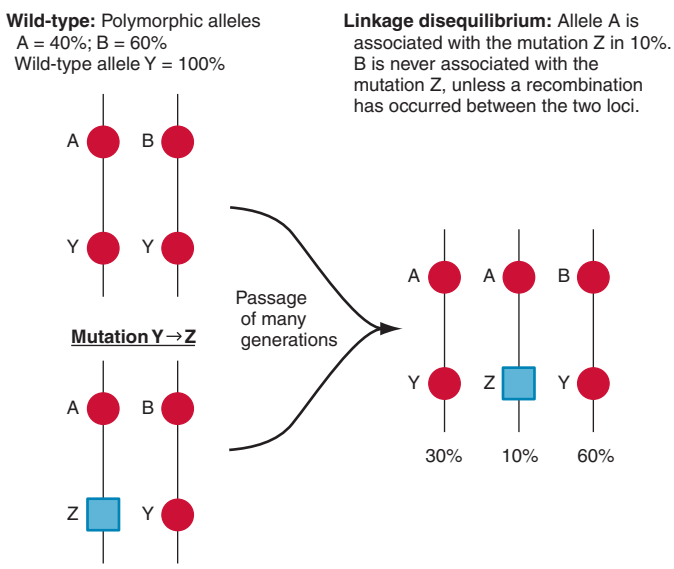

FIGURE 56-13 Linkage disequilibrium.

TABLE 56-8 *Genes and Loci Involved in Mono- and Polygenic Forms of Diabetes and Hypertension*

Disorder	Genes or Susceptibility Locus	Chromosomal Location	Other Factors
DIABETES MELLITUS			
Monogenic forms of diabetes			
MODY 1	HNF4α (hepatocyte nuclear factor 4α)	20q12-q13.1	
MODY 1	GCK (glucokinase)	7p15-p13	
MODY 1	HNF1α (hepatocyte nuclear factor 1α)	12q24.2	
MODY 1	IPF1 (insulin promoter factor 1)	13q12.1	
MODY 5 (Renal cysts, diabetes)	HNF1β (hepatocyte nuclear factor 1β)	17cen-q21.3	
MODY 6	NeuroD1 (neurogenic differention factor 1)	2q32	
Loci and genes associated with susceptibility for diabetes mellitus type 2	Genes and loci identified by linkage/association studies		Diet
	CPN10 (Calpain-10)	2q37.3	Energy expenditure
	1q, 3q, 8p, 12q, 20q	1q, 3q, 8p, 12q, 20q	Obesity
	"Candidate genes" with possible contribution		
	Peroxisome proliferator receptor gamma	3p25	
	Insulin	11p15	
	Sulfonylurea receptor	11p15.1	
	IPF1 (insulin promoter factor 1)	13q12.1	
	IRS-1 (insulin receptor substrate)	2q36	
	KCNJ11 (ATP-sensitive K channel Kir6.2)	11p15.1	
	AMP1 (adiponectin)	3q27	
	PGC-1	6p21.3-p21.1	
HYPERTENSION			
Monogenic forms			
Apparent mineralocorticoid excess	11-Ketoreductase		
Glucocorticoid-remediable HTN	CYP11B1 (unequal crossover with CYP11B2)		
Glucocorticoid-remediable HTN	CYP11B2 (unequal crossover with CYP11B1)		
17-alpha hydroxylase deficiency	17α hydroxylase		
Liddle's syndrome	SCNN1B		
Liddle's syndrome	SCNN1G		
Pseudohypoaldosteronism type II	WNK1		
Pseudohypoaldosteronism type II	WNK4		
Early onset HTN (AD)	MR		
Early onset HTN (AD)	BBS2		
Bardet-Biedl syndrome type 2	BBS4		
Loci and genes associated with susceptibility for essential hypertension	Loci identified by linkage/association studies		Salt intake

	Angiotensin receptor 1	3q21-25	
	G-protein subunit 3	12p13	

of the mutation in the phenylalanine hydroxylase gene but also on the exposure to the amino acid phenylalanine (Chap. 343). Type 2 diabetes mellitus provides a paradigm for considering a multifactorial disorder, as genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis (Chap. 323). The identification of genetic variations and environmental factors that either predispose or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches (Chap. 58). The study of rare monogenic diseases may provide insight into genetic and molecular mechanisms that are subsequently of importance for the understanding of complex diseases. For example, the identification of the insulin promoter factor 1 in maturity-onset of diabetes type 4 defined it as a *candidate gene* in the pathogenesis of diabetes mellitus type 2 (Tables 56-2 and 56-8). Genome scans have identified various loci that may be associated with susceptibility to development of diabetes mellitus in certain populations. Efforts to identify susceptibility genes require very large sample sizes, and positive results may depend on ethnicity, ascertainment criteria, and statistical analysis. Association studies analyzing the potential influence of (biologically functional) SNPs and SNP haplotypes on a particular phenotype are a promising approach for the detection of involved genes.

APPROACH TO THE PATIENT

Identifying the Disease-Causing Gene *Genomic medicine* aims to enhance the quality of medical care through the use of genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein (e.g., hemoglobin, apoprotein E), mRNA, or DNA. However, technological advances have made DNA analysis particularly useful because it can be readily applied to all but the largest genes (Fig. 56-14).

DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the ΔF508 mutation with a frequency of $\sim$70% in northern Europe, is feasible and seems to be effective. One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the disease can be caused by $>$600 other mutations. The search for these less common mutations would substantially increase costs but not the effectiveness of the screening program as a whole. Occupational screening programs aim to detect

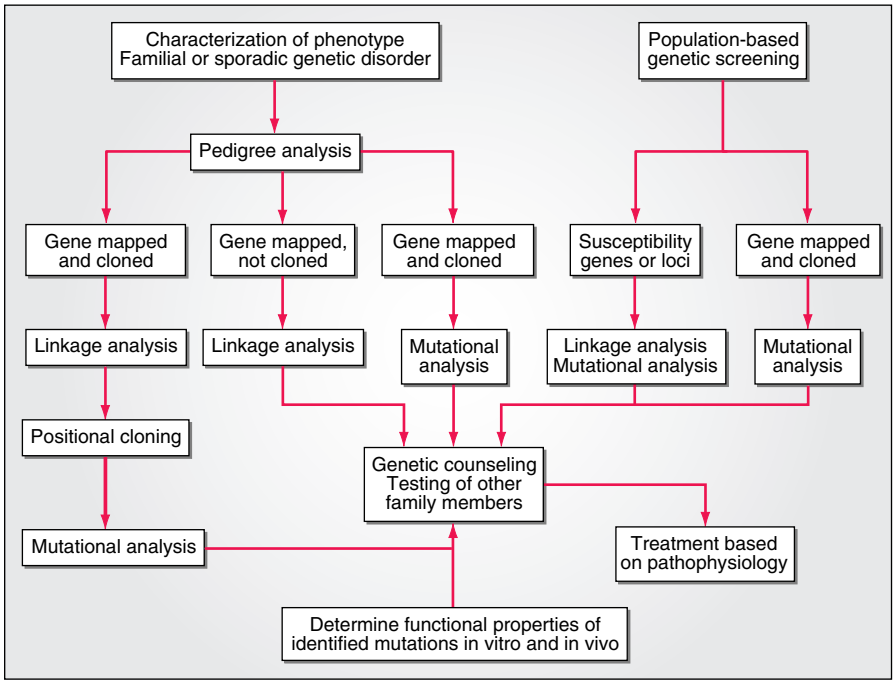

FIGURE 56-14 Approach to genetic disease.

individuals with increased risk for certain professional activities (e.g., α_1 antitrypsin deficiency and smoke or dust exposure).

MUTATIONAL ANALYSES DNA sequence analysis is increasingly used as a diagnostic tool and has significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders (Chap. 58). Numerous techniques are available for the detection of mutations (Table 56-9). In a very broad sense, one can distinguish between techniques that allow for screening the absence or presence of known mutations (screening mode) or techniques that definitively characterize mutations. Analyses of large alterations in the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), and Southern blotting (Chap. 57).

More discrete sequence alterations rely heavily on the use of the PCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. Screening for point mutations can be performed by numerous methods (Table 56-9); most are based on the recognition of mismatches between nucleic acid duplexes, electrophoretic separation of single- or double-stranded DNA, or sequencing of DNA fragments amplified by PCR. DNA sequencing can be performed directly on PCR products or on fragments cloned into plasmid vectors amplified in bacterial host cells.

RT-PCR may be useful to detect absent or reduced levels of mRNA expression due to a mutated allele. Protein truncation tests (PTT) can be used to detect the broad array of mutations that result in premature termination of a polypeptide during its synthesis. The isolated cDNA is transcribed and translated in vitro, and the proteins are analyzed by gel electrophoresis. Comparison of electrophoretic mobility with the wild-type protein allows detection of truncated mutants.

The majority of traditional diagnostic methods are gel-based. Novel technologies for the analysis of mutations, genetic mapping, and mRNA expression profiles are in rapid development. DNA chip technologies allow hybridization of DNA or RNA to hundreds of thousands of probes simultaneously. Microarrays are being used clinically for mutational analysis of several human disease genes, as well as for the identification of viral sequence variations. Together with the knowledge gained from the HGP, these technologies provide the foundation to expand from a focus on single genes to analyses at the scale of the genome.

TABLE 56-9 *Methods Used for the Detection of Mutations*

Method	Principle	Type of Mutation Detected
COMMONLY USED TECHNIQUES		
Cytogenic analysis	Unique visual appearance of various chromosomes	Numerical or structural abnormalities in chromosomes
Fluorescent in situ hybridization (FISH)	Hybridization to chromosomes with fluorescently labeled probes	Numerical or structural abnormalities in chromosomes
Southern blot	Hybridization with genomic probe or cDNA probe after digestion of high molecular DNA	Large deletion, insertion, rearrangement, expansions of triplet repeat, amplification
Polymerase chain reaction (PCR)	Amplification of DNA segment	Expansion of triplet repeats, variable number of tandem repeats (VNTR), gene rearrangements, translocations; prepare DNA for other mutation methods
Reverse transcriptase PCR (RT-PCR)	Reverse transcription, amplification of DNA segment → absence or reduction of mRNA transcription	Analyze expressed mRNA (cDNA) sequence; detect loss of expression
DNA sequencing	Direct sequencing of PCR products Sequencing of DNA segments cloned into plasmid vectors	Point mutations, small deletions, and insertions
Restriction fragment polymorphism (RFLP)	Detection of altered restriction pattern of genomic DNA (Southern blot) or PCR products	Point mutations, small deletions, and insertions
OTHER TECHNIQUES		
Single-strand conformational polymorphism (SSCP)	PCR of DNA segment: Mutations result in conformational change and altered mobility	Point mutations, small deletions, and insertions
Denaturing gradient gel electrophoresis (DGGE)	PCR of DNA segment: Mutations result in conformational change and altered mobility	Point mutations, small deletions, and insertions
RNAse cleavage	Cleavage of mismatch between mutated and wild type sequence	Point mutations, small deletions, and insertions
Oligonucleotide specific hybridization (OSH)	Hybridization of PCR products to wild type or mutated oligonucleotides immobilized on chips or slides	Point mutations, small deletions, and insertions
Microarrays	Hybridization of PCR products to wild type or mutated oligonucleotides	Point mutations, small deletions, and insertions
Protein truncation test (PTT)	Transcription/translation of cDNA isolated from tissue sample	Mutations leading to premature truncations

A general algorithm for the approach to mutational analysis is outlined in Fig. 56-14. The importance of a detailed clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations is labor intensive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Prenatal diagnosis of numerous genetic diseases in instances with a high risk for certain disorders is now possible by direct DNA analysis. *Amniocentesis* involves the removal of a small amount of amniotic fluid, usually at 16 weeks of gestation. Cells can be collected and submitted for karyotype analyses, FISH, and mutational analysis of selected genes. The main indications for amniocentesis include advanced maternal age above age 35, abnormal serum triple marker test (α-fetoprotein, β human chorionic gonadotropin, pregnancy-associated plasma protein A, or unconjugated estriol), a family history of chromosomal abnormalities, or a Mendelian disorder amenable to genetic testing. Prenatal diagnosis can also be performed by *chorionic villus sampling* (CVS), in which a small amount of the chorion is removed by a transcervical or transabdominal biopsy. Chromosomes and DNA obtained from these cells can be submitted for cytogenetic and mutational analyses. CVS can be performed earlier in gestation (weeks 9 to 12) than amniocentesis, an aspect that may be of relevance when termination of pregnancy is a consideration. Later in pregnancy, beginning at about 18 weeks of gestation, percutaneous umbilical blood sampling (PUBS) permits collection of fetal blood for lymphocyte culture and analysis. In combination with in vitro fertilization (IVF) techniques, it is even possible to perform genetic diagnoses in a single cell removed from the four- to eight-cell embryo or to analyze the first polar body from an oocyte. Preconceptual diagnosis thereby avoids therapeutic abortions but is extremely costly and labor intensive. Lastly, it has to be emphasized that excluding a specific disorder by any of these approaches is never equivalent to the assurance of having a normal child.

Mutations in certain cancer susceptibility genes, such as *BRCA1* and *BRCA2*, may identify individuals with an increased risk for the development of malignancies and result in risk-reducing interventions. The detection of mutations is an important diagnostic and prognostic tool in leukemias and lymphomas. The demonstration of the presence or absence of mutations and polymorphisms is also relevant for the rapidly evolving field of pharmacogenomics, including the identification of differences in drug treatment response or metabolism as a function of genetic background. For example, the thiopurine drugs 6-mercaptopurine and azathioprine are commonly used cytotoxic and immunosuppressive agents. They are metabolized by thiopurine methyltransferase (TPMT), an enzyme with variable activity associated with genetic polymorphisms in 10% of Caucasians and complete deficiency in about 1/300 individuals. Patients with intermediate or deficient TPMT activity are at risk for excessive toxicity, including fatal myelosuppression. Characterization of these polymorphisms allows mercaptopurine doses to be modified based on TPMT genotype. Pharmacogenomics may increasingly permit individualized drug therapy, improve drug effectiveness, reduce adverse side effects, and provide cost-effective pharmaceutical care.

57 CHROMOSOME DISORDERS

Terry Hassold, Stuart Schwartz

In humans, the normal diploid number of chromosomes is 46, consisting of 22 pairs of autosomal chromosomes (numbered 1 to 22 in decreasing size) and one pair of sex chromosomes (XX in females and XY in males). The genome is estimated to contain between 30,000 and 40,000 genes. Even the smallest autosome contains between 200 and 300 genes. Not surprisingly, duplications or deletions of chromosomes, or even small chromosome segments, have profound consequences on normal gene expression, leading to severe developmental and physiologic abnormalities.

Deviations in number or structure of the 46 human chromosomes are astonishingly common, despite severe deleterious consequences. Chromosomal disorders occur in an estimated 10 to 25% of all pregnancies. They are the leading cause of fetal loss and, among pregnancies surviving to term, the leading known cause of birth defects and mental retardation.

In recent years, the practice of cytogenetics has shifted from conventional cytogenetic methodology to a union of cytogenetic and molecular techniques. Formerly the province of research laboratories, fluorescence in situ hybridization (FISH) and related molecular cytogenetic technologies have been incorporated into everyday practice in clinical laboratories. As a result, there is an increased appreciation of the importance of "subtle" constitutional cytogenetic abnormalities, such as microdeletions and imprinting disorders, as well as previously recognized translocations and disorders of chromosome number.

VISUALIZING CHROMOSOMES

CONVENTIONAL CYTOGENETIC ANALYSIS In theory, chromosome preparations can be obtained from any actively dividing tissue by causing the cells to arrest in metaphase, the stage of the cell cycle when chromosomes are maximally condensed. In practice, only a small number of tissues are used for routine chromosome analysis: amniocytes or chorionic villi for prenatal testing, and blood, bone marrow, or skin fibroblasts for postnatal studies. Samples of blood, bone marrow, and chorionic villi can be processed using short-term culture techniques that yield results in 1 to 3 days. Analysis of other tissue types typically involves long-term cell culture, requiring 1 to 3 weeks of processing before cytogenetic analysis is possible.

Cells are isolated at metaphase or prometaphase, and treated chemically or enzymatically to reveal chromosome "bands" (Fig. 57-1). Analysis of the number of chromosomes in the cell, and the distribution of bands on individual chromosomes, allows the identification of numerical or structural abnormalities. This strategy is useful for characterizing the normal chromosome complement and determining the incidence and types of major chromosome abnormalities.

Each human chromosome contains two specialized structures: a centromere and two telomeres. The centromere, or primary constriction, divides the chromosome into short (p) and long (q) arms and is responsible for the segregation of chromosomes during cell division.

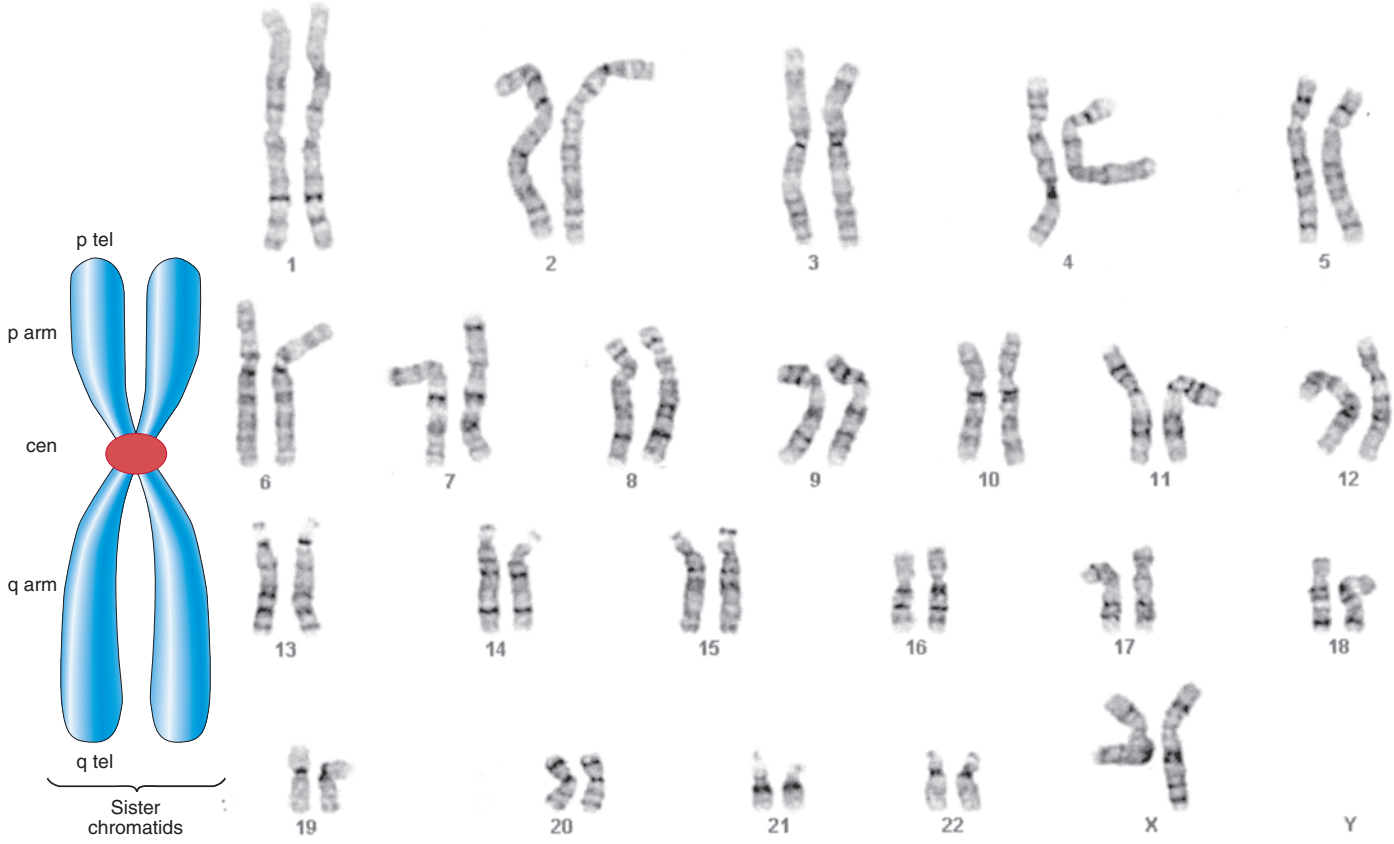

FIGURE 57-1 *A.* An idealized human chromosome, showing the centromere (cen), long (q) and short (p) arms, and telomeres (tel). *B.* A G-banded human karyotype from a normal (46,XX) female.

The telomeres, or chromosome ends, "cap" the p and q arms and are important for allowing DNA replication at the ends of the chromosomes. Prior to DNA replication, each chromosome consists of a single chromatid copy of the DNA double helix. After DNA replication and continuing until the time of cell division (including metaphase, when chromosomes are typically visualized), each chromosome consists of two identical sister chromatids (Fig. 57-1).

MOLECULAR CYTOGENETICS The introduction of FISH methodologies in the late 1980s revolutionized the field of cytogenetics. In principle, FISH is similar to other DNA-DNA hybridization methodologies. The probe is labeled with a hapten, such as biotin or digoxigenin, to allow detection with a fluorophore (e.g., FITC or rhodamine). After the hybridization step, the specimen is counter-stained and the preparations are visualized with a fluorescence microscope.

Types of FISH Probes A variety of probes are available for use with FISH, including chromosome-specific paints (chromosome libraries), repetitive probes, and single-copy probes (Fig. 57-2). Chromosome libraries hybridize to sequences that span the entirety of the chromosome from which they are derived and, as a result, they can be used to "paint" individual chromosomes.

Repetitive probes recognize amplified DNA sequences present in chromosomes. The most common are α-satellite DNA probes that are complementary to DNA sequences found at the centromeric regions of all human chromosomes. A vast number of *single-copy probes* are now available as a result of the human genome project. These probes can be as small as 1 kb, though normally they are much larger and are packaged into cosmids (40 kb), bacterial artificial chromosomes (BACs) or P1 clones (100 to 200 kb), or yeast artificial chromosomes (YACs) (1 to 2 Mb). Many are available commercially, including probes for a variety of microdeletion syndromes and for subtelomeric regions of individual chromosomes.

Applications of FISH The majority of FISH applications involve hybridization of one or two probes of interest as an adjunctive procedure to conventional chromosomal banding techniques. In this regard, FISH can be utilized to identify specific chromosomes, characterize de novo duplications or deletions, and clarify subtle chromosomal rearrangements. Its greatest utilization, however, is in the detection of microdeletions (see below). Though conventional cytogenetic studies can detect some microdeletions, initial detection and/or confirmation with FISH is essential. In fact, since appropriate FISH probes have become available, detection of microdeletion syndromes has increased significantly.

In addition to metaphase FISH, cells can be analyzed at a variety of stages. Interphase analysis, for example, can be used to make a rapid diagnosis in instances when metaphase chromosome preparations are not yet available (e.g., amniotic fluid interphase analysis). Interphase analysis also increases the number of cells available for examination, allows for investigation of nuclear organization, and provides results when cells do not progress to metaphase. One specialized type of interphase analysis involves the application of FISH to paraffin-embedded sections, thereby preserving the architecture of the tissue.

The use of interphase FISH has increased recently, especially for analyses of amniocentesis samples. These studies are performed on uncultured amniotic fluid, typically using DNA probes specific for the chromosomes most commonly identified in trisomies (chromosomes 13, 18, 21, and the X and Y). These studies can be performed rapidly (24 to 72 h) and will ascertain about 60% of the abnormalities detected prenatally. Another area in which interphase analysis is routinely utilized is cancer cytogenetics (Chap. 68). Many site-specific translocations are associated with specific types of malignancies. For example, there are probes available for both the Abelson (Abl) oncogene and breakpoint cluster region (bcr) involved in chronic myelogenous leukemia (CML); these probes are labeled in red and green, respectively; the fusion of these genes in CML combines the fluorescent colors and appears as a yellow hybridization signal.

In addition to standard metaphase and interphase FISH analyses, a number of enhanced techniques have been developed for specific types

of analysis, including multicolor FISH techniques, reverse painting, comparative genomic hybridization, and fiber FISH. *Spectral karyotyping* (SKY) and multicolor FISH (m-FISH) techniques use combinatorially labeled probes that create a unique color for individual chromosomes. This technology is useful in the identification of unknown chromosome material (such as markers of duplications) but is most commonly used with the complex rearrangements seen in cancer specimens.

Comparative genomic hybridization (CGH) is a method that can be used only when DNA is available from a specimen of interest. The entire DNA specimen from the sample of interest is labeled in one color (e.g., green), and the normal control DNA specimen is indicated by another color (e.g., red). These are mixed in equal amounts and hybridized to normal metaphase chromosomes. The red-to-green ratio is analyzed by a computer program, which determines where the DNA of interest may have gains or losses of material. This technique is useful in the analysis of tumors, particularly in those cases where cytogenetic analysis is not possible.

Fiber FISH is a technique in which chromosomes are mechanically stretched, using one of a variety of different methods. It provides a higher resolution of analysis than conventional FISH.

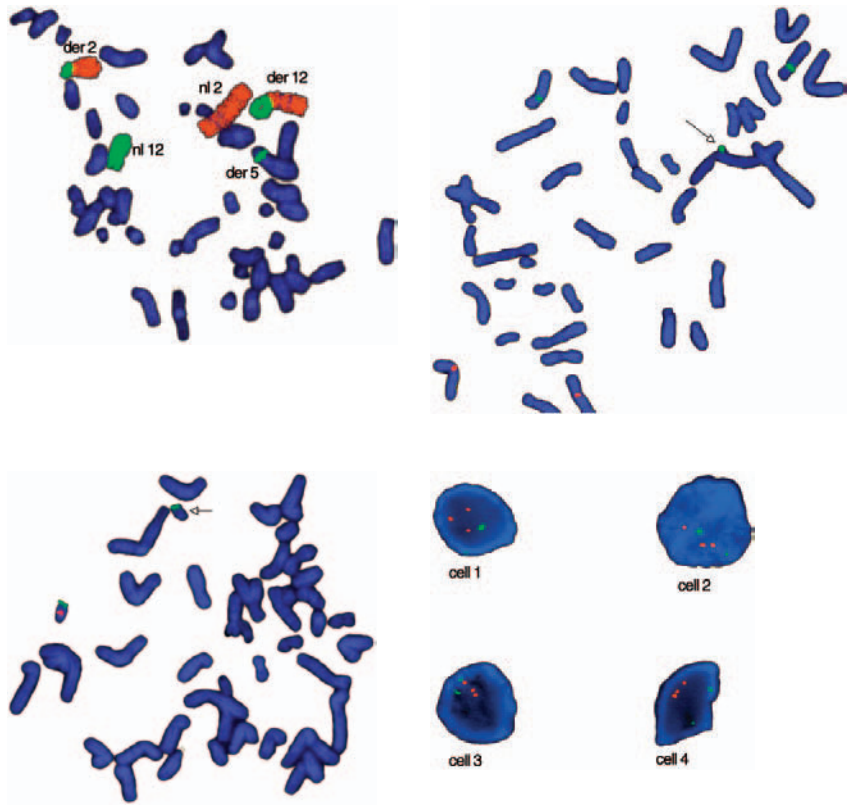

FIGURE 57-2 Examples of different applications of fluorescence in situ hybridization (FISH) to human metaphase and interphase preparations. Top left, chromosome-specific "paint" probes demonstrating hybridization to normal chromosomes 2 (red) and 12 (green), as well as indicating a translocation between the short arm of chromosome 12 and the long arm of chromosome 2. This hybridization also demonstrates that some of the short arm of chromosome 12 has been inserted into the short arm of chromosome 5. Top right, a repetitive DNA probe specific for centromeric α-satellite sequences on chromosome 7 (red) and chromosome 10 (green) hybridizes to the centromeric region of the appropriate chromosomes, as well as to a marker chromosome derived from chromosome 10. Bottom left, two-color FISH used to detect a microdeletion of chromosome 22 associated with velocardiofacial (VCF) syndrome. A probe for ARSA (a locus on the distal portion of chromosome 22, visualized as a green signal) is observed on both chromosomes. However, a probe for TUPLE1 (a locus within the VCF region of chromosome 22, visualized in red) hybridizes only to the normal chromosome. The arrow points to the deleted chromosome. Bottom right, interphase FISH using chromosome 13 (green) and chromosome 21 (red) unique sequence probes on interphase cells from direct amniotic fluid preparations. In each of the four interphase cells, three chromosome 21 signals are observed, indicating the presence of trisomy 21 in the fetus.

INDICATIONS FOR CYTOGENETIC ANALYSIS

Primary indications for karyotypic analysis vary according to the developmental stage/age of the conceptus/individual under investigation. One especially important application is in prenatal diagnosis (particularly for pregnancies involving older women), assaying for chromosomal abnormalities in either chorionic villi of first-trimester fetuses or amniotic fluid of second-trimester fetuses. Tissue specimens from spontaneously aborted fetuses or stillbirths can also be examined for chromosome abnormalities. Interphase cytogenetics (using FISH) is increasingly being used to study individual blastomeres of preimplantation embryos (with in vitro fertilization-derived pregnancies). This makes it possible to detect aneuploid or structurally unbalanced embryos or, in the case of sex-linked disorders, to identify male conceptuses; such embryos would not be used to initiate pregnancies.

Among infants and children, peripheral blood is examined, most often in individuals with specific phenotypic abnormalities. For example, karotypic analysis can be used for the confirmation or exclusion of a specific chromosomal syndrome (e.g., trisomy 21); in patients with unexplained psychomotor retardation with or without dysmorphic features; in cases of monogenic disorders associated with mental retardation and/or dysmorphic features; and with abnormalities of sexual differentiation and development.

In adults, peripheral blood can be examined in patients with infertility or recurrent miscarriages, since chromosome abnormalities can lead to meiotic arrest or to genetically unbalanced gametes. An important branch of cytogenetics is concerned with analyses of bone marrow, unstimulated peripheral blood, and lymph nodes of tumors, as chromosomal abnormalities are a common correlate of leukemia, lymphoma, and solid tumors (Chap. 68).

CYTOGENETIC TESTING IN PRENATAL DIAGNOSIS The vast majority of prenatal diagnostic studies are performed to rule out a chromosomal abnormality, but cells may also be propagated for biochemical studies or molecular analyses of DNA. Three procedures are used to obtain samples for prenatal diagnosis: amniocentesis, chorionic villus sampling (CVS), and fetal blood sampling. Amniocentesis is the most common procedure and is routinely performed at 15 to 17 weeks of gestation. On some occasions, early amniocentesis at 12 to 14 weeks is performed to expedite results, although less fluid is obtained at this time. Early amniocentesis carries a greater risk of spontaneous abortion or fetal injury but provides results at an earlier stage of pregnancy.

The vast majority of amniocenteses are performed in the context of advanced maternal age, the best-known correlate of trisomy (see below). Additional reasons for amniocentesis referral include an abnormal "triple- or quad-marker assay" and/or detection of ultrasound abnormalities. In this assay, levels of human chorionic gonadotropin, α-fetoprotein, and unconjugated estriol (and, in the quad assay, inhibin) in the maternal serum are quantified and used to adjust the maternal age-predicted risk of a trisomy 21 or trisomy 18 fetus. Specific ultrasound abnormalities, when detected at midtrimester, can also be associated with chromosomal defects. When a nonspecific ultrasound abnormality is present, the estimated risk of a chromosomal defect is approximately 16%. Associations of chromosomal abnormalities and specific types of abnormal ultrasound findings are listed in Table 57-1.

CVS is the second most common procedure for genetic prenatal diagnosis. Because this procedure is routinely performed at about 10

TABLE 57-1 Frequency of Chromosome Abnormalities, Identified on the Basis of Abnormal Ultrasound Findings

Ultrasound Finding	Chromosomal Abnormalities (Frequency)	
	Average, %	Range in Different Studies, %
Abnormal ultrasound (nonspecific)	16	13–35
Omphalocele	39	26–54
Cystic hygroma	68	46–78
Congenital heart disease	30	8–40
Choroid plexus cyst	5	4–10

to 12 weeks of gestation, it allows for an earlier detection of abnormalities and a safer pregnancy termination, if desired. CVS is a relatively safe procedure (spontaneous abortions, <0.5 to 1%). Because there is an increased association of limb defects when the procedure is performed earlier (<10 weeks of gestation), CVS is applicable during a narrow time frame of gestation. CVS involves the use of a catheter inserted transvaginally; approximately 25 mg of villi are aspirated from the chorion frondosum (the fetal portion of the placenta). By adding colchicine directly to the rapidly dividing cytotrophoblasts, results can be obtained within 24 to 48 h. Findings from these procedures should be confirmed by analyses of cultured mesenchymal cells, as they are more reliably derived from the fetus.

Percutaneous umbilical blood sampling (PUBS) is a method for obtaining fetal blood during the second and third trimesters of pregnancy. PUBS is usually performed when ultrasound abnormalities are detected late in the second trimester. PUBS is also used when cytogenetic results from amniocentesis need clarification, such as in the detection of mosaicism.

CHROMOSOME ABNORMALITIES

CHROMOSOMES IN CELL DIVISION To understand the etiology of chromosome abnormalities, it is important to review the movement of chromosomes during cell division. In somatic tissues, chromosomes are replicated during the S-phase of the cell cycle, so that each replicated chromosome consists of two identical sister chromatids. When the cell enters mitosis, each of the 46 chromosomes align on the metaphase plate, with the centomeres co-oriented toward opposite spindle poles (Fig. 57-3). At anaphase the sister chromatids separate, with each of the daughter cells receiving one sister chromatid from each of the 46 chromosomes.

Chromosome segregation is more complicated in germ cell division, since the number of chromosomes must be reduced from 46 to 23 in the mature sperm and eggs. This is accomplished by two rounds of division—meiosis I and meiosis II (Fig. 57-3). In meiosis I, homologous chromosomes pair and exchange genetic material, then align on the metaphase plate, and finally separate from one another. Thus, by the end of meiosis I, only 23 of the original 46 chromosomes are represented in each of the two daughter cells. Meiosis II quickly follows meiosis I and is essentially a "haploid mitosis," involving separation of the sister chromatids in each of the 23 chromosomes.

Although the fundamentals of meiosis are the same in males and females, there are important distinctions, particularly in the timing of meiotic divisions. In males, meiosis begins with puberty and continues throughout the individual's lifetime. In females, meiosis begins prenatally, with oocytes proceeding through the first stages of meiosis I but arresting at mid-prophase. At the time of birth, the first meiotic division is suspended in oocytes. Only after ovulation many years later do oocytes complete meiosis I and proceed to the metaphase stage of meiosis II; if fertilized, the oocyte then completes the second meiotic division. Thus, in females, the first meiotic division takes at least 10 to 15 years and as many as 40 to 45 years to complete. Maternal age-related increases in the incidence of trisomy are likely the consequence of this protracted process of cell division.

INCIDENCE AND TYPES OF CHROMOSOME ABNORMALITIES Errors in meiosis, or in early cleavage divisions, occur with extraordinary frequency. At least 10 to 25% of all pregnancies, for example, involve chromosomally abnormal conceptions. A large proportion of these terminate in the earliest stages of pregnancy, many of which go unrecognized. Nevertheless, even among clinically recognized pregnancies, nearly 10% of fetuses are chromosomally unbalanced. For the three types of clinically recognized pregnancies—spontaneous abortions, stillbirths, and livebirths—the frequencies of different chromosomal abnormalities are summarized in Table 57-2. The most common abnormalities are numerical, involving fetuses with additional (trisomy) or missing (monosomy) chromosomes, or those with one (triploidy) or two (tetraploidy) additional sets of chromosomes. Structural chromosome abnormalities are much less common, although several of the most important clinical chromosomal disorders involve structural rearrangements (see below).

By far the most common abnormality is trisomy, which is identified in approximately 25% of spontaneous abortions and 0.3% of newborns. Trisomies for all chromosomes have now been identified in embryos or fetuses, but there is considerable variation in frequency for various chromosomes. For example, trisomy 16 is extraordinarily common, accounting for about one-third of all trisomies in spontaneous abortions, whereas trisomies 1, 5, 11, and 19 have been identified less often. Available evidence suggests two reasons for this variation: (1) some chromosomes (e.g., chromosome 16) are more likely to segregate abnormally or undergo nondisjunction during meiosis than are others; and (2) the potential for development varies widely among different trisomic conditions, with some being eliminated very early in gestation, others surviving to the time of clinical pregnancy recognition, and some (e.g., trisomies 13, 18, and 21 and sex chromosome trisomies) being compatible with survival to term.

CHROMOSOMAL SYNDROMES

While most chromosomally abnormal conceptions perish in utero, several conditions are compatible with survival to term. The best-char-

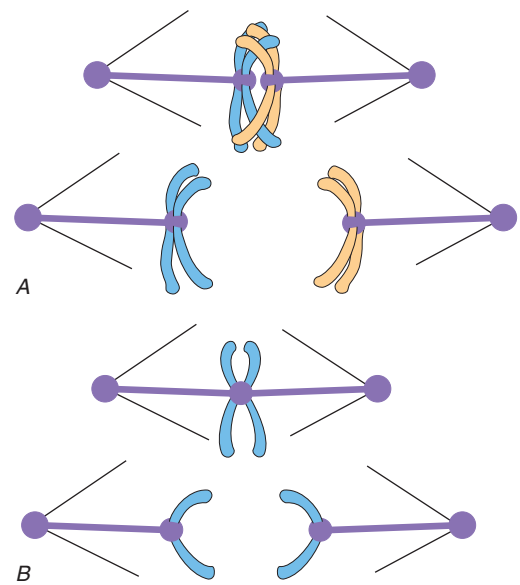

FIGURE 57-3 Chromosome segregation in meiosis. *A*. In meiosis I, each of the 23 pairs of chromosomes finds its "partner," or homologue, and exchanges genetic material (recombines) with it. At metaphase, each homologous pair aligns on the equatorial plate; at anaphase, each member of the homologous pair segregates from its partner. Thus, at the end of meiosis I, each daughter cell contains 23 chromosomes, with each chromosome consisting of two sister chromatids. *B*. In meiosis II, each chromosome aligns on the metaphase plate, and at anaphase, each of the two sister chromatids divide from one another. Thus, at the end of meiosis II, each daughter cell (e.g., the oocyte or spermatocyte) contains 23 chromosomes, with each chromosome consisting of one sister chromatid. In mitosis, the chromosomes behave exactly as they do in meiosis II, except that somatically dividing cells contain 46 chromosomes, not the 23 that are present in the meiosis II cell.

acterized of these are numerical abnormalities involving loss or gain of individual chromosomes, and abnormalities resulting from unbalanced translocations. FISH and other molecular studies have led to the identification of two "new" types of chromosome abnormalities, commonly referred to as microdeletion syndromes and imprinting syndromes.

TABLE 57-2 *Frequency and Distribution of Chromosome Abnormalities in Different Types of Clinically Recognizable Pregnancies*

Chromosome Abnormality	Frequency of Abnormality			Probability of Surviving to Term, %
	Spontaneous Abortion	Stillbirth	Livebirth	
Trisomy, all	25.1	4.0	0.3	5
+13, 18, 21	4.5	2.7	0.14	15
+16	7.5	—	—	0

Triploidy	6.4	0.2	—	0
Tetraploidy	2.4	—	—	0
Structural abnormality	2.0	0.8	0.3	45
Total abnormalities	50.0	5.1	0.6	5

NUMERICAL ABNORMALITIES Virtually all types of numerical abnormalities are eliminated prenatally, so that only those involving small, gene-poor autosomes or the sex chromosomes are identified with any frequency among liveborns. Clinically, the most important of these is trisomy 21, the most frequent cause of Down syndrome. Depending on the maternal age structure of the population and the utilization of prenatal testing, the incidence of trisomy 21 ranges from 1/600 to 1/1000 live births, making it the most common chromosome abnormality in live-born individuals. Like most trisomies, the incidence of trisomy 21 is highly correlated with maternal age, increasing from about 1/1500 live births for women 20 years of age to 1/30 for women 45 years of age and older.

In addition to trisomy 21, only two other autosomal trisomies, 13 and 18, occur with any frequency in livebirths. Incidence rates for trisomies 13 and 18 in livebirths are 1/20,000 and 1/10,000, respectively. Unlike trisomy 21, which is associated with near-normal life expectancy, both trisomies 13 and 18 are associated with death in infancy, typically occurring during the first year of life.

Three sex chromosome trisomies—the 47,XXX, 47,XXY (Klinefelter syndrome), and 47,XYY conditions—are quite common, with each occurring in about 1/2000 newborns. Of all the trisomic conditions, these three have the fewest phenotypic complications. In fact, with the exception of infertility in Klinefelter syndrome (Chap. 328), it is likely that most individuals with such trisomic conditions would go undetected. The additional Y chromosome in the 47,XYY condition is small and contains only a few genes. Most Y-linked genes are involved in testicular development or spermatogenesis. Thus, dosage imbalance of Y-linked genes has relatively little effect on other developmental processes. The 47,XYY genotype is associated with increased height. Its role in antisocial behavior, postulated initially because of an increased prevalence among some penalized populations, is unclear.

For the 47,XXX and 47,XXY conditions, the situation is different—the X chromosome contains over 1000 genes, many of them essential for normal development. How, then, are 47,XXX and 47,XXY individuals spared from the catastrophic consequences of dosage imbalance? The answer lies in the biology of X chromosome gene expression. In normal females, one of the chromosomes undergoes *X inactivation* in somatic cells. The inactivation of the paternal or maternal X chromosome occurs randomly in each somatic cell and thereby serves as a mechanism of dosage compensation, ensuring that males and females have equal expression of most X-linked genes. The inactivation process occurs at the blastocyst stage of development; prior to this, both X chromosomes are active. In addition, not all X-linked genes are inactivated. Some genes on the X chromosome "escape" the inactivating mechanism and are expressed from both X chromosomes. In disorders such as Klinefelter syndrome, some genes may be expressed from both X chromosomes, resulting in its phenotypic features.

As a rule, monosomic conditions are incompatible with fetal development and, consequently, autosomal monosomies are only rarely identified in spontaneous abortions and are not found among live-born individuals. In fact, the only monosomy compatible with live birth is the 45,X condition, which causes Turner syndrome. The 45,X chromosome constitution occurs with surprisingly high frequency, present in at least 1 to 2% of all pregnancies. More than 99% of all 45,X conceptions are spontaneously aborted. Thus, live-born individuals with a 45,X chromosome constitution represent a rare group of survivors. The 45,X phenotype is mild, presumably because the second copy of many X chromosomal genes is normally inactivated. Nonetheless, Turner syndrome causes gonadal dysgenesis, resulting in infertility and failure to undergo secondary sexual development, along with a number of other phenotypic features (Chap. 328). Several other structural abnormalities of the X chromosome such as deletions, isochromosome X, or ring chromosomes can cause Turner syndrome. Mosaicism, including 45,X/45,XX, 45X/45,XXX, 45,X/45,XY, and others, also occurs (see below) and contributes to the phenotypic spectrum in Turner syndrome.

Because numerical abnormalities originate in meiosis (Table 57-3), affected individuals have missing or extra chromosomes in all cells. In a small proportion of cases, a mitotic nondisjunctional event occurs at an early stage in an individual with an initially normal chromosome constitution. Alternatively, a "normalizing" mitotic nondisjunctional event may result in a normal chromosome complement in some cells of an embryo. In either case, the embryo is a mosaic, with some cells bearing a normal chromosome constitution and others an aneuploid number of chromosomes. The phenotypic consequences are difficult to predict because they depend on the timing of nondisjunction and the distribution of normal and abnormal cells in different tissues. Nevertheless, mosaicism may lead to clinical abnormalities indistinguishable from those of nonmosaic individuals; for example, nearly 5% of all cases of Down syndrome involve individuals with mosaic trisomy 21, and about 15% of individuals with Turner syndrome are mosaic for various sex chromosomal constitutions as described above.

The Origin and Etiology of Numerical Abnormalities Over the past decade, a number of studies have used DNA polymorphisms to investigate the

origin of different types of chromosome abnormalities (Fig. 57-4). The most thoroughly investigated types have been numerical abnormalities (Table 57-3). Sex chromosome monosomy usually results from loss of the paternal sex chromosome, regardless of whether the conception is live-born or spontaneously aborted.

Trisomies show remarkable variation in parental origin. For example, paternal nondisjunction is responsible for nearly 50% of 47,XXY but only 5 to 10% of cases of trisomies 13, 14, 15, 21, and 22; it is rarely, if ever, the source of the additional chromosome in trisomy 16. Similarly, there is considerable variability in the meiotic stage of origin. For example, all cases of trisomy 16 may be due to meiosis I errors, whereas for trisomy 21, one-third of cases are associated with meiosis II errors, and for trisomy 18, the majority of cases are apparently due to meiosis II nondisjunction. In spite of this variation in parental and meiotic origin, nondisjunction at maternal meiosis I appears to be the most common source of trisomy.

Maternal Age and Trisomy The association between increasing maternal age and trisomy is the most important etiologic factor in congenital chromosomal disorders. Among women under the age of 25, approximately 2% of all clinically recognized pregnancies are trisomic; by the age of 36, however, this figure increases to 10% and by the age of 42, to over 33% (Fig. 57-5). This association between maternal age and trisomy is exerted without respect to race, geography, or socioeconomic factors and likely affects segregation of all chromosomes.

Despite the importance of increasing age, little is known about the mechanism by which aging leads to abnormal chromosomal segregation. As noted above, it is thought to originate in maternal meiosis I

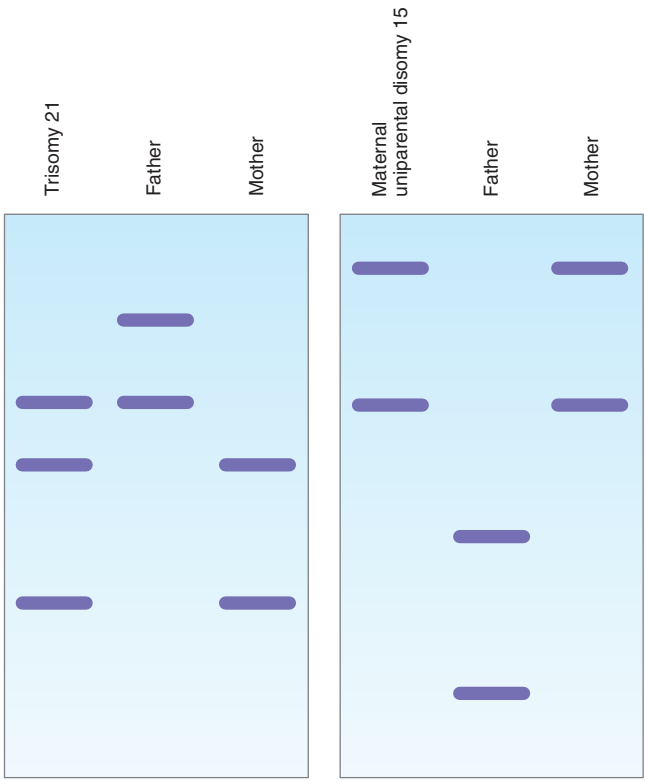

FIGURE 57-4 Use of DNA technology to determine the origin of chromosome abnormalities. *A*. Analysis of a chromosome 21–specific DNA polymorphism demonstrates that the trisomic individual received two chromosomes 21 from his mother and one from his father; thus, the extra chromosome 21 resulted from an error in oogenesis. *B*. Inheritance of a chromosome 15–specific DNA polymorphism in an individual with Prader-Willi syndrome (PWS). The affected individual has received two maternal, but no paternal, chromosomes 15; thus, the individual is said to have maternal uniparental disomy 15, a common cause of PWS.

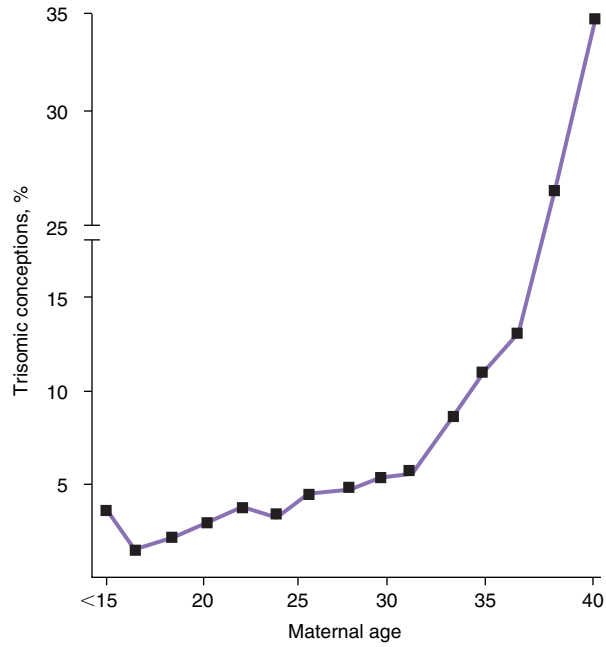

FIGURE 57-5 Estimated maternal age-adjusted rates of trisomy among all clinically recognized pregnancies (e.g., spontaneous abortions, stillbirths, and livebirths). Among women in their forties, over 25% of all pregnancies are estimated to involve a trisomic conception; the vast majority of these spontaneously abort, with only trisomies 13, 18, and 21 and sex chromosome trisomies surviving to term with any appreciable frequency.

owing to the protracted time to completion (often ≥40 years) in females, and recent studies suggest that it may be associated with alterations in meiotic crossing-over. In trisomy 21, for example, crossover patterns appear to be similarly abnormal in younger and older mothers of trisomic conceptions. Thus, it has been suggested that two distinct steps, or "hits," may be involved in maternal age-related nondisjunction. The first hit, which is age independent, involves the establishment of a "vulnerable" crossover configuration in the fetal oocyte; the second hit, which is age dependent, involves abnormal processing of the vulnerable bivalent structure at metaphase I. If this model is correct, it suggests that the nondisjunctional process is the same in younger and older women, but it occurs more frequently with aging, possibly because of age-dependent degradation of meiotic proteins.

STRUCTURAL CHROMOSOME ABNORMALITIES Structural rearrangements involve breakage and reunion of chromosomes. Although less common than numerical abnormalities, they present additional challenges from a genetic counseling standpoint. This is because structural abnormalities, unlike numerical abnormalities, can be present in "balanced" form in clinically normal individuals but transmitted in "unbalanced" form to progeny, thereby resulting in a hereditary form of chromosome abnormality.

Rearrangements may involve exchanges of material between different chromosomes (translocations) or loss, gain, or rearrangements of individual chromosomes (e.g., deletions, duplications, inversions, rings, or isochromosomes). Of particular clinical importance are *translocations*, which involve two basic types: Robertsonian and reciprocal. Robertsonian rearrangements are a special class of translocation, in which the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) join together, generating a fusion chromosome that contains virtually all of the genetic material of the original two chromosomes. If the Robertsonian translocation is present in unbalanced form, a monosomic or trisomic conception ensues. For example, approximately 3% of Down syndrome cases are attributable to unbalanced Robertsonian translocations, most often involving chromosomes 14 and 21. In this instance, the affected individual has 46 chromosomes, including one structurally normal chromosome 14, two structurally normal chromosomes 21, and one fusion 14/21 chromosome. This effect leads to a normal diploid dosage for chromosome 14 and to

a triplication of chromosome 21, thus resulting in Down syndrome. Similarly, a small proportion of individuals with trisomy 13 syndrome are clinically affected because of an unbalanced Robertsonian translocation.

Reciprocal translocations involve mutual exchanges between any two chromosomes. In this circumstance, the phenotypic consequences associated with unbalanced translocations depend on the location of the breakpoints, which dictate the amount of material that has been "exchanged" between the two chromosomes. Because most reciprocal translocations involve unique sets of breakpoints, it is difficult to predict the phenotypic consequences in any one situation. In general, severity is determined by the amount of excess or missing chromosome material in individuals with unbalanced translocations.

In addition to rearrangements between chromosomes, there are several examples of intrachromosome structural abnormalities. The most common and deleterious of these involve loss of chromosome material due to deletions. The two best-characterized deletion syndromes, Wolf-Hirschhorn syndrome and cri-du-chat syndrome, result from loss of relatively small chromosomal segments on chromosomes 4p and 5p, respectively. Nonetheless, each is associated with multiple congenital anomalies, developmental delays, profound retardation, and reduced lifespan.

TABLE 57-4 *Some Commonly Identified Microdeletion and Microduplication Syndromes*

Syndrome	Cytogenetic Location	Principal Features	Imprinting Effects
Langer-Giedion syndrome	8q24.1 (del)	Sparse hair, bulbous nose, variable mental retardation	No
WAGR complex	11p13 (del)	Wilms' tumor, aniridia, genitourinary disorders, mental retardation	No
Beckwith-Wiedemann syndrome	11p15 (dup)	Macrosomia, macroglossia, omphalocoele	Yes, occasionally associated with "paternal uniparental disomy" (see text)
Retinoblastoma	13q14.11 (del)	Retinoblastoma due to homozygous loss of functional RB allele	No obvious effect, although abnormal RB allele more likely to be paternal
Prader-Willi syndrome	15q11-13 (del)	Obesity, hypogonadism, mental retardation	Yes; prototypic imprinting disorder (see text)
Angelman syndrome	15q11-13 (del)	Ataxic gait	With Prader-Willi syndrome, prototypic imprinting disorder (see text)
α-Thalassemia and mental retardation	16p13.3 (del)	α-thalassemia and mental retardation, due to deletion of distal 16p, including α-globin locus	No
Smith-Magenis syndrome	17p11.2 (del)	Brachycephaly, midface hypoplasia, mental retardation	No
Miller-Dieker syndrome	17p13 (del)	Dysmorphic facies, lissencephaly	No
Charcot-Marie-Tooth syndrome type 1A	17p11.2 (dup)	Progressive neuropathy due to microduplication	No
DiGeorge syndrome/ velocardiofacial syndrome	22q11 (del)	Abnormalities of third and fourth branchial arches	No

Microdeletion Syndromes The term *contiguous gene syndrome* refers to genetic disorders that mimic a combination of single gene disorders. They result from the deletion of a small number of tightly clustered genes. Because some are too small to be detected cytogenetically, they are termed microdeletions. The application of molecular techniques has led to the identification of at least 18 of these microdeletion syndromes (Table 57-4). Some of the more common ones include the Wilms' tumor–aniridia complex (WAGR), Miller Dieker syndrome (MDS), and velocardiofacial (VCF) syndrome. WAGR is characterized by mental retardation and involvement of multiple organs, including kidney (Wilm's tumor), eye (aniridia), and the genitourinary system. The cytogenetic abnormality involves a deletion of a part of the short arm of chromosome 11 (11p13), which typically is detectable on well-banded chromosome preparations. In MDS, a disorder characterized by mental retardation, dysmorphic faces, and lissencephaly, the deletion involves chromosome 17 (17p13). Using FISH, 17p deletions have been detected in over 90% of patients with MDS as well as in 20% of cases of isolated lissencephaly.

Deletions involving the long arm of chromosome 22 (22q11) are the most common microdeletions identified to date, present in approximately 1/3000 newborns. VCF syndrome, the most commonly associated syndrome, consists of learning disabilities or mild mental retardation, palatal defects, a hypoplastic aloe nasi and long nose, and congenital heart defects (conotruncal defect). Some individuals with 22q11 deletion are more severely affected and present with DiGeorge syndrome, which involves abnormalities in the development of the third and fourth branchial arches leading to thymic hypoplasia, parathyroid hypoplasia, and conotruncal heart defects. In approximately 30% of these cases, a deletion at 22q11 can be detected with high-resolution banding; by combing conventional cytogenetics, FISH, and molecular detection techniques (i.e., Southern blotting or polymerase chain reaction analyses), these rates improve to over 90%. Additional studies have demonstrated a surprisingly high frequency of 22q11 deletions in individuals with nonsyndromic conotruncal defects. Approximately 10% of individuals with a 22q11 deletion inherited it from a parent with a similar deletion.

Smith-Magenis syndrome involves a microdeletion localized to the proximal region of the short arm of chromosome 17 (17p11.2). Affected individuals have mental retardation, dysmorphic facial features, delayed speech, peripheral neuropathy, and behavior abnormalities. Most of these deletions can be detected with cytogenetic analysis, although FISH is available to confirm these findings. In contrast, William syndrome, a chromosome 7 (7q11.23) microdeletion, cannot be diagnosed with standard or high-resolution analysis; it is only detectable utilizing FISH or other molecular methods. William syndrome involves a deletion of the elastin gene and is characterized by mental retardation, dysmorphic features, a gregarious personality, premature aging, and congenital heart disease (usually supravalvular aortic stenosis).

In addition to microdeletion syndromes, there is now at least one well-described microduplication syndrome, Charcot-Marie-Tooth type 1A (CMT1A). This is a nerve conduction disease previously thought to be transmitted as a simple autosomal dominant disorder. Recent molecular studies have demonstrated that affected individuals are heterozygous for duplication of a small region of chromosome 17 (17p11.2-12). Although it is not yet clear why increased gene dosage would result in CMT1A, the inheritance pattern is explained by the fact that one-half of the offspring of affected individuals inherit the duplication-carrying chromosome.

IMPRINTING DISORDERS Two other microdeletion syndromes, Prader-Willi syndrome (PWS) and Angelman syndrome (AS), exhibit parent-of-origin, or "imprinting," effects. For many years, it has been known that cytogenetically detectable deletions of chromosome 15 occur in a proportion of patients with PWS, as well as in those with AS. This

seemed curious, as the clinical manifestations of the two syndromes are very dissimilar. PWS is characterized by obesity, hypogonadism, and mild to moderate mental retardation, whereas AS is associated with microcephaly, ataxic gait, seizures, inappropriate laughter, and severe mental retardation. New insight into the pathogenesis of these disorders has been provided by the recognition that parental origin of the deletion determines which phenotype ensues: if the deletion is paternal, the result is PWS, whereas if the deletion is maternal, the result is AS (Fig. 57-2).

This scenario is complicated further by the recognition that not all individuals with PWS or AS carry the chromosome 15 deletion. For such individuals, the parental origin of the chromosome 15 region is again the important determinant. In PWS, for example, nondeletion patients invariably have two maternal and no paternal chromosomes 15 [maternal uniparental disomy (UPD)], whereas for some nondeletion AS patients the reverse is true (paternal UPD). This indicates that at least some genes on chromosome 15 are differently expressed, depending on which parent contributed the chromosome. Additionally, this means that normal fetal development requires the presence of one maternal and one paternal copy of chromosome 15.

Approximately 70% of PWS cases are due to paternal deletions of 15q11-q13, whereas 25% are due to maternal UPD, and about 5% are caused by mutations in a chromosome 15 imprinting center. In AS, 75% of cases are due to maternal deletions, and only 2% are due to paternal UPD. The remaining cases are presumably caused by imprinting mutations (5%), or mutations in the *UBE3A* gene, which is associated with AS. The UPD cases are mostly caused by meiotic nondisjunction resulting in trisomy 15, subsequently followed by a normalizing mitotic nondisjunction event ("trisomy rescue") resulting in two normal chromosomes 15, both from the same parent. *UBE3A* is the only maternally imprinted gene known in the critical region of chromosome 15. However, several paternally imprinted genes, or expressed-sequence tags (ESTs), have been identified, including *ZNF127*, *IPW*, *SNRPN*, *SNURF*, *PAR1*, and *PAR5*.

Chromosomal regions that behave in the manner observed in PWS and AS are said to be *imprinted*. This phenomenon is involved in differential expression of certain genes on different chromosomes. Chromosome 11 is one of these with an imprinted region, since it is known that a small proportion of individuals with the Beckwith-Wiedemann overgrowth syndrome have two paternal but no maternal copies of this chromosome.

ACQUIRED CHROMOSOME ABNORMALITIES IN CANCER (See also Chap. 68 for detailed discussion of cancer genetics)

In addition to the constitutional cytogenetic chromosomal abnormalities that are present at birth, somatic chromosomal changes can be acquired later in life and are often associated with malignant conditions. As with constitutional abnormalities, somatic changes can include the net loss of chromosomal material (due to a deletion or loss of a chromosome), net gain of material (duplication or gain of a chromosome), and relocation of DNA sequences (translocation). Cytogenetic changes have been particularly well studied in (1) leukemias, e.g., Philadelphia chromosome translocation in CML [t(9;22)(q34.1;q11.2)]; and (2) lymphomas, e.g., translocations of *MYC* in Burkitt's [t(8;14)(q24;q32)]. These and other translocations are useful for diagnosis, classification, and prognosis. Analyses of cytogenetic changes are also useful in certain solid tumors. For example, a complex karyotype with Wilms' tumor, diploidy in medulloblastoma, and Her-2/neu amplification in breast cancer are poor prognostic signs.

58 THE PRACTICE OF GENETICS IN CLINICAL MEDICINE

Susan Miesfeldt, J. Larry Jameson

IMPLICATIONS OF MOLECULAR GENETICS FOR INTERNAL MEDICINE

The field of medical genetics has traditionally focused on chromosomal abnormalities (Chap. 57) and Mendelian disorders (Chap. 56). However, there is genetic susceptibility to many common adult-onset diseases including atherosclerosis, hypertension, autoimmune diseases, diabetes mellitus, Alzheimer disease, psychiatric disorders, and many forms of cancer. Genetic contributions to these common disorders involve more than the ultimate expression of an illness; these genes can also influence the severity of infirmity, response to treatment, and progression of disease.

The primary care clinician is now faced with the role of recognizing and counseling patients at risk for a number of genetically influenced illnesses. Among the greater than 30,000 genes in the human genome, it is estimated that each of us harbors several potentially deleterious mutations. Fortunately, many of these alterations are recessive and clinically silent. An even greater number, however, represent genetic variants that alter disease susceptibility or severity. Genetic medicine is changing the way diseases are classified, enhancing our understanding of pathophysiology, providing practical information concerning drug metabolism and therapeutic responses, and allowing for individualized screening and health care management programs. In view of these changes, the physician must integrate personal medical history, family history, and diagnostic molecular testing into the overall care of individual patients and their families. In addition, the internist has an important role in educating patients about the indications, benefits, risks, and limitations of genetic testing in the management of a number of diverse diseases. This is a difficult task as scientific advances in genetic medicine, and media attention to these advances, have outpaced the translation of these discoveries into standards of clinical care.

COMMON ADULT-ONSET GENETIC DISORDERS

MULTIFACTORIAL INHERITANCE The risk for many adult-onset disorders reflects the combined effects of genetic factors at multiple loci that may function independently, or in combination with other genes or environmental factors. Our understanding of the genetic basis of these disorders is incomplete, despite the clear recognition of genetic susceptibility. In type 2 diabetes mellitus, for example, the concordance rate in monozygotic twins ranges between 50 and 90%. Diabetes or impaired glucose tolerance occurs in 40% of siblings and in 30% of the offspring of an affected individual. Despite the fact that diabetes affects 5% of the population and exhibits a high degree of heritability, there are only a few examples of genetic mutations (most of which are rare) that might account for the familial nature of the disease. They include certain mitochondrial DNA disorders (Chap. 56), mutations in a cascade of genes that control pancreatic islet cell development and function (*HNF4α*, *HNF1α*, *IPF1*, *glucokinase*), insulin receptor mutations, and others (Chap. 323). Obesity and other factors that contribute to insulin resistance represent major risk factors for type 2 diabetes.

Current models for the genetic basis of type 2 diabetes propose the involvement of more than a dozen genes: some genes influence pancreatic islet cell development or function; others modulate glucose sensing; and an important group determine insulin sensitivity, either directly by affecting insulin signaling or indirectly by regulating body weight or composition. Superimposed on this genetic background are environmental influences such as diet, exercise, pregnancy, and medications.

Identifying these susceptibility genes is a formidable task. Nonetheless, a reasonable goal for this type of disease is to identify genes that increase (or decrease) disease risk by a factor of two or more. For common diseases such as diabetes or heart disease, this level of risk has important implications for health. Much the same way that cholesterol is currently used as a biochemical marker of cardiovascular risk, we can anticipate the development of genetic panels with similar predictive power. Tests for a large number of genetic disorders are available; a website (www.genetests.org) lists various laboratories that perform specific tests. The advent of DNA-sequencing chips represents an important technical advance that promises to make large-scale testing more feasible (Chap. 56). The decision whether or not to perform a genetic test for a particular inherited adult-onset disorder, such as hemochromatosis, multiple endocrine neoplasia (MEN) type 1, prolonged QT syndrome, or Huntington disease, is complex; it depends on the clinical features of the disorder, the desires of the patient and family, and whether the results of genetic testing will alter medical decision-making or treatment (see below).

THE FAMILY HISTORY Pending further advances in genetic testing, the key to assessing the inherited risk for common adult-onset diseases rests in the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination. For example, a history of multiple family members with early-onset coronary artery disease, glucose intolerance, and hypertension should suggest increased risk for genetic, and perhaps environmental, predisposition to insulin resistance (Chap. 323). Individual patients with this family history should be monitored for the possible development of hypertension, diabetes, and hyperlipidemia. They should be counseled about the importance of avoiding additional risk factors such as obesity and cigarette smoking.

Family history should be recorded in the form of a pedigree which greatly assists the assessment of risk in the individual patient (Chap. 56). At a minimum, pedigrees should convey health-related data on all first-degree relatives and selected second-degree relatives, including grandparents. When pedigrees appear to suggest an inherited disease, they should be extended to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the pedigree, the number of unaffected relatives, and the types of diagnoses within the family. For example, a woman with two first-degree relatives with breast cancer is at greater risk for a Mendelian disorder if she has a total of three female first-degree relatives than if she has a total of ten female first-degree relatives. Additional variables that should be documented in the pedigree include the age at diagnosis of each affected family member, present age of all family members, the presence or absence of nonhereditary risk factors among those affected with diseases, and the finding of multiple diseases in an individual patient. For instance, a woman with a history of both colon cancer and endometrial cancer is at risk for hereditary nonpolyposis colon cancer (HNPCC) regardless of her family history.

When assessing the personal and family history, the physician should be alert to a younger age of disease onset than is usually seen in the general population. A 30-year-old with acute myocardial infarction should be considered at risk for a hereditary trait, even if there is no family history of premature coronary artery disease (Chap. 224). The absence of the nonhereditary risk factors typically associated with a disease also raises the prospect of genetic risk factors. A personal or family history of deep-vein thrombosis, in the absence of known nongenetic risk factors, suggests a hereditary thrombotic disorder (Chap. 102). The physical examination may also provide important clues concerning the risk for a specific inherited disorder. A patient with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. Some adult-onset disease-causing mutations are more prevalent in certain ethnic groups. For instance, >2% of the Ashkenazi population carry one of three specific mutations in the *BRCA1* or *BRCA2* genes. The prevalence of the factor V Leiden allele ranges from 3 to 7% in Caucasians but is much less common in Africans or Asians.

Recall of family history is sometimes inaccurate. This is especially so when the history is remote and families become more dispersed. It can be helpful to ask patients to fill out family history forms before or after their visits, as this provides them with an opportunity to contact relatives. Attempts should be made to confirm the illnesses reported in the family history before making important, and in certain circumstances, irreversible management decisions. This process is often labor intensive and ideally involves interviews of additional family members or reviewing medical records, autopsy reports, and death certificates.

Nongenetic factors associated with disease risk should also be reviewed in full, including occupation, diet, living conditions, and social habits. For example, patients at hereditary risk for heart disease should be questioned about tobacco use, diet, exercise, and lipid levels. Patients should also be asked about their health screening and prevention behaviors, as well as medication use. These nonhereditary factors contribute to the assessment of overall risk and represent an important focus for disease prevention.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that *disease penetrance* is incomplete for most multifactorial genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian pattern of inheritance, as not all family members carrying the disease-associated alleles will manifest a clinical disorder. Furthermore, genes associated with some of these disorders often exhibit *variable expression* of disease. For example, the breast cancer–associated gene *BRCA1* can predispose to several different malignancies in the same family, including cancers of the breast, ovary, and prostate (Chap. 68). For common diseases such as breast cancer, some family members without the disease-causing mutation may also develop breast cancer, representing another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated in Fig. 58-1. In this example, the proband, a 36-year-old woman, has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset, as well as the co-occurrence of breast and ovarian cancer in this family, suggests the possibility of an inherited alteration in *BRCA1* or *BRCA2*. It is unclear though—without genetic testing—whether her father inherited such a mutation and transmitted it to her. After appropriate genetic counseling of the proband and her family, one approach to DNA analysis in this family is to test the potentially affected 42-year-old living cousin for the presence of a *BRCA1* or *BRCA2* mutation. If a mutation is found, then it is possible to test for this particular alteration in the proband and other family members, if they so desire. In the example shown, if the proband's father has the *BRCA1* mutation, there is a 50:50 probability that the mutation has been transmitted to her, and genetic testing can be used to establish the absence or presence of this particular risk factor.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to assure that the correct clinical diagnosis has been made, whether based on family history, characteristic physical findings, or biochemical testing. Careful clinical assessment can define the *phenotype*, thereby preventing unnecessary testing and directing testing towards the most probable candidate genes. Many disorders exhibit the feature of *locus heterogeneity*, which refers to the fact that mutations in different genes can

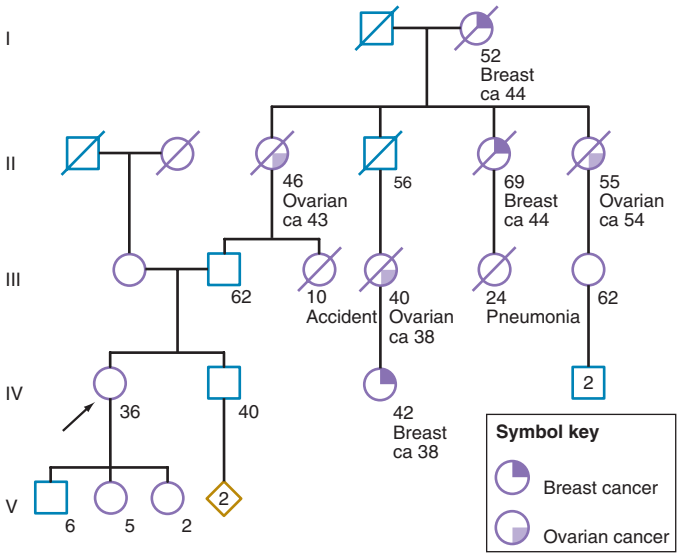

FIGURE 58-1 A 36-year-old woman (arrow) seeks consultation because of her family history of cancer. The patient expresses concern that the multiple cancers in her relatives imply an inherited predisposition to develop cancer. The family history is recorded and records of the patient's relatives confirm the reported diagnoses.

cause phenotypically similar disorders. For example, osteogenesis imperfecta (Chap. 342), long QT syndrome (Chap. 214), muscular dystrophy (Chap. 368), homocystinuria (Chap. 343), retinitis pigmentosa (Chap. 25) and hereditary predisposition to colon cancer (Chap. 77) or breast cancer (Chap. 76) can each be caused by mutations in distinct genes. The pattern of disease transmission, clinical course, and treatment may differ significantly, depending on which gene is affected. In these cases, the choice of which genes to test is often determined by unique clinical features, the relative prevalence of mutations in various genes, or test availability.

Like all laboratory tests, there are limitations to the accuracy and interpretation of genetic tests. In addition to technical errors, genetic tests are often designed to detect only the most common mutations. In this case, a negative result must be qualified by the possibility that the individual may have a mutation that is not included in the test.

In addition to molecular testing for established disease, genetic testing for susceptibility to chronic disease is being increasingly integrated into the practice of medicine. In most cases, however, the discovery of disease-associated genes has greatly outpaced studies that assess clinical outcomes and the impact of interventions. Until such evidence-based studies are available, predictive molecular testing must be approached with caution and should be offered only to patients who have been adequately counseled and have provided informed consent (Fig. 58-2). In the majority of cases, genetic testing should be offered only to individuals with a suggestive personal or family medical history or in the context of a clinical trial.

Predictive genetic testing falls into two distinct categories. *Presymptomatic testing* applies to diseases where a specific genetic alteration is associated with a near 100% likelihood of developing disease. In contrast, *predisposition testing* predicts a risk for disease that is less than 100%. For example, presymptomatic testing is available for those at risk for Huntington's disease, whereas predisposition testing is considered for those at risk for hereditary breast cancer. It is important to note that, for the majority of adult-onset, multifactorial genetic disorders, testing is purely predictive. Test results cannot reveal with confidence whether, when, or how the disease will manifest itself. For example, not everyone with the apolipoprotein E allele ($\epsilon 4$) will develop Alzheimer's disease, and individuals without this genetic marker can still develop the disorder (Chap. 350).

Molecular analysis is generally more informative if testing is initiated in a symptomatic family member, since the identification of a mutation can direct the testing of other at-risk family members (whether they are symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the mutation found in the affected family member can be informed that they are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing on the mutation to their children. On the other hand, asymptomatic family members who test positive for the known mutation must be informed that they are at increased risk for disease development and for transmitting the mutation to their children.

A negative test result is interpreted differently when no genetic mutation is found in a symptomatic family member. In this difficult circumstance, the test performed on a given gene may not detect all mutations in that gene (false negative) or the individual may have a mutation in a different disease-associated gene that was not tested.

Clinicians providing pretest counseling and education should assess the patient's ability to cope with test results. Individuals who demonstrate signs and symptoms of emotional distress should have their psychosocial needs addressed before proceeding with molecular testing. Generally, genetic testing should not be offered at a time of personal crisis or acute illness within the family. Patients will derive more benefit from test results if they are emotionally able to comprehend and absorb the information. It is important to assess patients' preconceived notions of their personal likelihood of disease in preparing pretest educational strategies. Often, patients harbor unwarranted fear or denial of their likelihood of genetic risk.

Genetic testing has the potential of affecting the way individual family members relate to one another, both negatively and positively. As a result, patients addressing the option of molecular testing must consider how test results might impact their relationships with rela-

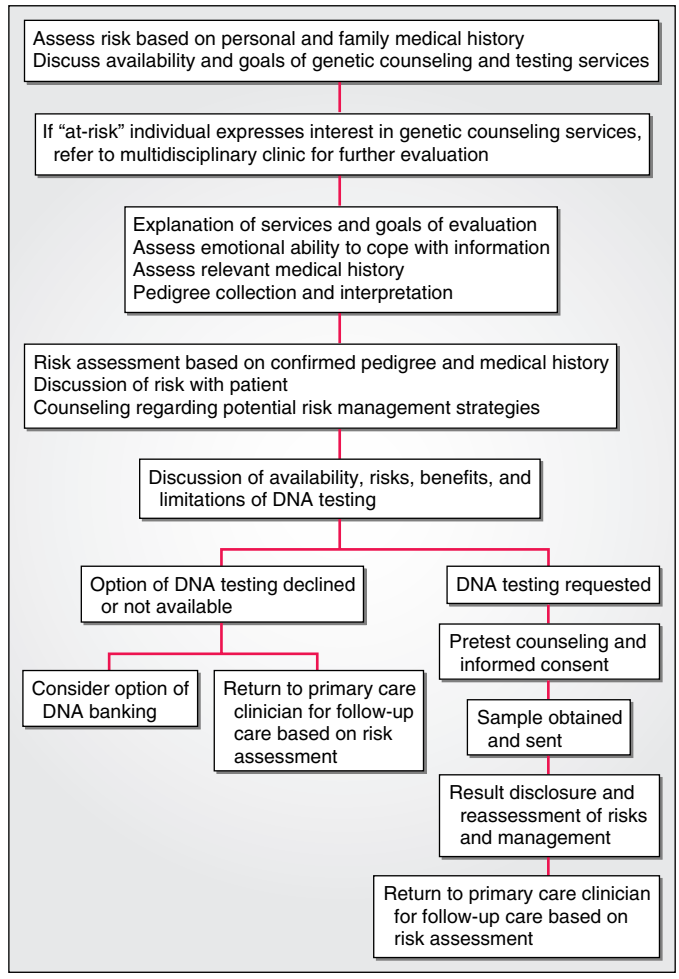

FIGURE 58-2 Algorithm for genetic counseling and testing.

tives, spouses, and friends. In families with a known genetic mutation, those who test positive must consider the impact of their carrier status on their present and future lifestyles; those who test negative may manifest *survivor guilt*. Family members are likely to differ in their emotional and social responses to the same information. Counseling should also address the potential consequences of test results on relationships with a spouse or child. Parents who are found to have a disease-associated mutation often express considerable anxiety and despair as they address the issue of risk to their children.

When a condition does not manifest until adulthood, clinicians will be faced with the question of whether at-risk children should be offered molecular testing and, if so, at what age. Although the matter is debated, several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions are not preventable and, consequently, such information can pose significant psychosocial risk to the child. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may manifest early in life, especially when management options are available. For example, children at risk for familial adenomatous polyposis (FAP), associated with alterations in the *APC* gene, may develop polyps as early as their teens, and progression to an invasive cancer can occur by their twenties. Likewise, children at risk for MEN type 2, which is caused by mutations in the *RET* proto-oncogene, may develop medullary thyroid cancer early in childhood, and the issue of prophylactic thyroidectomy should be addressed with the parents of children with documented mutations (Chap. 330).

INFORMED CONSENT When the issue of testing is addressed, patients should be strongly encouraged to involve other relatives in the decision-making process, as molecular diagnostics will likely have an impact on the entire family. Informed consent for molecular testing begins with detailed education and counseling. The patient must fully understand the risks, benefits, and limitations of undergoing the analysis. Informed consent should include a written document, drafted clearly and concisely in a language and format that is comprehensible to the patient, who should be made aware of the disposition of test results. Informed consent should also include a discussion of the mechanics of testing. Most molecular testing for hereditary disease involves DNA-based analysis of peripheral blood. In the majority of circumstances, test results should be given only to the individual, in person, and with a support person in the room.

Because molecular testing of an asymptomatic individual often allows prediction of future risk, the patient should understand any potential long-term medical, psychological, and social implications of this decision. In the United States, legislation affecting this area is still evolving, and it is important to explore with the patient the potential impact that test results may have on employment, as well as future health, and disability and life insurance coverage.

Patients should understand that alternatives to molecular analysis remain available if they decide not to proceed with this option. They should also be notified that testing is available in the future if they are not currently prepared to undergo analysis. The option of DNA banking should be presented so that samples are readily available for future use by family members, if needed. DNA banking is a particularly valuable option for those individuals who are not expected to survive their illness and cannot immediately proceed with testing.

FOLLOW-UP CARE AFTER TESTING Depending on the nature of the genetic disorder, posttest interventions may include (1) cautious surveillance and appropriate health care screening, (2) specific medical interventions, (3) chemoprevention, (4) risk avoidance, and (5) referral to support services. For example, patients with known pathologic mutations in *BRCA1* or *BRCA2* are offered intensive screening as well as the option of prophylactic mastectomy and/or oophorectomy. In addition, such women may be eligible for preventive treatment with tamoxifen, or enrollment in a chemoprevention clinical trial. In contrast, those at known risk for Huntington's disease are offered continued follow-up and supportive services, including physical and occupational therapy, and social services or support groups, as indicated. Specific interventions will change as translational research continues to enhance our understanding of these genetic diseases and as more is learned about the functions of the proteins involved.

Individuals who test negative for a mutation in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a woman who finds that she does not carry the disease-associated mutation in *BRCA2* previously discovered in her family must be reminded that she still requires the same breast cancer screening recommended for the general population.

GENETIC COUNSELING AND EDUCATION

Genetic counseling should be distinguished from genetic testing and screening, even though genetic counselors are often involved in issues related to testing. Genetic counseling refers to *a communication process that deals with human problems associated with the occurrence or risk of a genetic disorder in a family*. Genetic risk assessment is complex and often involves elements of uncertainty. Counseling therefore includes genetic education as well as psychosocial counseling. Genetic counselors may be called upon by other health care professionals (or by individual patients and families) to address a broad range of issues directly and indirectly involved with genetic disease (Table 58-1). The role of the genetic counselor includes the following:

- Gather and document a detailed family history
- Educate the patient about general genetic principles related to disease risk, both for themselves and others in their family
- Assess and enhance the patient's ability to cope with the genetic information offered
- Discuss how nongenetic factors may relate to the ultimate expression of disease
- Address medical management issues
- Assist in determining the role of genetic testing for the individual and family
- Ensure that the patient is aware of the risks, benefits, and limitations of the various genetic testing options
- Assist the patient, family and referring physician in the interpretation of the test results
- Refer the patient and other at-risk family members for additional medical and support services, if necessary.

The complexity of genetic counseling and the broad scope of genetic diseases have led to the development of specialized, multidisciplinary clinics designed to provide broad-based support and medical care for those at risk and their family members. Such specialty clinics are well established in the areas of cancer and neurodegenerative disorders. The multidisciplinary teams are often composed of medical geneticists, specialist physicians, genetic counselors, nurses, psychologists, social workers, and biomedical ethicists who work together to consider difficult diagnostic, treatment, and testing decisions. Such a format also provides primary care physicians with invaluable support and assistance as they follow and treat at-risk patients.

The approach to genetic counseling has important ethical, social, and financial implications. Philosophies related to genetic counseling vary widely by country and center. In North American centers, for

TABLE 58-1 Indications for Genetic Counseling

Advanced maternal (>35) or paternal (>50) age
Consanguinity
Previous history of a child with birth defects or a genetic disorder
Personal or family history suggestive of a genetic disorder
High-risk ethnic groups; known carriers of genetic alterations
Documented genetic alteration in a family member
Ultrasound or prenatal testing suggesting a genetic disorder

TABLE 58-2 *Examples of Genetic Testing and Possible Interventions*

Genetic Disorder	Inheritance	Genes	Interventions
ONCOLOGY			
Hereditary nonpolyposis colon cancer	AD	*MSH2, MLH1, MSH6, PMS1, PMS2*	Early cancer screening
Familial adenomatous polyposis	AD	*APC*	Nonsteroidal anti-inflammatory drugs Early endoscopic screening Colectomy
Familial breast and ovarian cancer	AD	*BRCA1, BRCA2*	Estrogen receptor antagonists Early screening by exams and mammography Consider prophylactic surgery
Familial melanoma	AD	*CDKN2A*	Avoid UV light Screening and biopsies
Basal cell nevus syndrome	AD	*PTCH*	Avoid UV light Screening and biopsies
HEMATOLOGY			
Factor V Leiden	AD	*F5*	Avoid thrombogenic risk factors and oral contraceptives
Hemophilia A	XL	*F8C*	Factor VIII replacement
Hemophilia B	XL	*F9*	Factor IX replacement Possible gene therapy
Glucose-6-PO4 dehydrogenase deficiency	XL	*G6PD*	Avoid oxidant drugs
CARDIOVASCULAR			
Hypertrophic cardiomyopathy	AD	*MYH7, MYBPC3, TNNT2, TPM1*	Echocardiographic screening Early pharmacologic intervention
Long QT syndrome	AD	*KCNQ1, KCNH2, SCN5A, LQT4, KCNE1, KCNE2*	Electrocardiographic screening and electrophysiologic testing Early pharmacologic intervention Possible implantable cardioverter defibrillator
Marfan syndrome	AD	*FBN1*	Echocardiographic screening Prophylactic beta blockers
GASTROINTESTINAL			
Familial Mediterranean fever	AR	*MEFV*	Colchicine treatment
Hemochromatosis	AR	*HFE*	Phlebotomy
PULMONARY			
α-1 Antitrypsin deficiency	AR	*PI*	Avoid smoking Avoid occupational and environmental toxins
Primary pulmonary hypertension	AD	*BMPR2*	Treatment with pulmonary vasodilators
RENAL			
Polycystic kidney disease	AD	*PKD1*	Prevent hypertension Prevent urinary tract infections Kidney transplantation
Nephrogenic diabetes insipidus	XL, AR	*AVPR2, AQP2*	Fluid replacement Thiazides, amiloride
ENDOCRINE			
Neurohypophyseal diabetes insipidus	AD	*AVP*	Replace vasopressin
Maturity onset diabetes of the young	AD	Multiple genes	Screen and treat for diabetes
Familial hypocalciuric hypercalcemia	AD	*CASR*	Avoid parathyroidectomy
Kallmann syndrome	XL	*KAL*	Induce puberty with hormone replacement
Multiple endocrine neoplasia type 2	AD	*RET*	Prophylactic thyroidectomy Screen for pheochromocytoma and hyperparathyroidism
21-Hydroxylase deficiency	AR	*CYP21*	Glucocorticoid and mineralocorticoid treatment
NEUROLOGIC			
Malignant hyperthermia	AD	*RYR1*	Avoid precipitating anesthetics
Hyperkalemic periodic paralysis	AD	*SCN4A*	Acetazolamide
Adrenoleukodystrophy	XL	*ABCD1*	Possible bone marrow transplant for severe childhood CNS form
Duchenne and Becker muscular dystrophy	XL	*DMD*	Glucocorticoids Possible future myoblast transfer
Familial Parkinson's disease	AD	*SNCA, PARK2*	Amantadine, anticholinergics, levodopa, monoamine oxidase B inhibitors
Wilson's disease	AR	*ATP7B*	D-Penicillamine treatment

Abbreviations: AD, autosomal dominant; AR, autosomal recessive: CNS, central nervous system; XL, X-linked

example, counseling is generally offered in a nondirective manner, wherein patients learn to understand how their values factor into a particular medical decision. Nondirective counseling is particularly appropriate when there are no data demonstrating a clear benefit associated with a particular intervention or when an intervention is considered experimental. For example, nondirective genetic counseling is employed when a person is deciding whether or not to undergo genetic testing for Huntington's disease (Chap. 350). At this time, there is no

clear benefit (in terms of medical outcome) to an at-risk individual undergoing genetic testing for this disease, as its course cannot be altered by therapeutic interventions. However, testing can have an important impact on this individual's perception of the future and his or her interpersonal relationships and plans for reproduction. Therefore, the decision to pursue testing rests on the individual's belief system and values. On the other hand, a more directive approach is appropriate when a condition can be treated. In a family with FAP, colon cancer screening and prophylactic colectomy should be recommended for known *APC* mutation carriers. The counselor and clinician following this family must ensure that the at-risk family members have access to the resources necessary to adhere to these recommendations.

Genetic education is central to an individual's ability to make an informed decision regarding testing options and treatment. Although genetic counselors represent one source of genetic education, other health care providers also need to contribute to patient education. Patients at risk for genetic disease should understand fundamental medical genetic principles and terminology relevant to their situation. This includes the concept of genes, how they are transmitted, and how they confer hereditary disease risk. An adequate knowledge of patterns of inheritance will allow patients to understand the probability of disease risk for themselves and other family members. It is also important to impart the concepts of disease penetrance and expression. For most complex adult-onset genetic disorders, asymptomatic patients should be advised that a positive test result does not always translate into future disease development. In addition, the role of nongenetic factors, such as environmental exposures, must be discussed in the context of multifactorial disease risk and disease prevention. Finally, patients should understand the natural history of the disease as well as the potential options for intervention, including screening, prevention, and—in certain circumstances—pharmacologic treatment or prophylactic surgery.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC RISK FOR DISEASE

Specific treatments are now available for an increasing number of genetic disorders, whether identified through population-based screening or directed testing (Table 58-2). Although the strategies for therapeutic interventions are best developed for childhood hereditary metabolic diseases, these principles are making their way into the diagnosis and management of adult-onset disorders. Hereditary hemochromatosis illustrates many of the issues raised by the availability of genetic screening in the adult population. For instance, it is relatively common (approximately 1 in 200 individuals of northern European descent are homozygous), and its complications are potentially preventable through phlebotomy (Chap. 336). The identification of the *HFE* gene, mutations of which are associated with this syndrome, has sparked interest in the use of DNA-based testing for presymptomatic diagnosis of the disorder. However, up to one-third of individuals who are homozygous for the *HFE* mutation do not have evidence of iron overload. Consequently, in the absence of a positive family history, current recommendations include phenotypic screening for evidence of iron overload followed by genetic testing. Whether genetic screening for hemochromatosis will someday be coupled to assessment of phenotypic expression awaits further studies. In contrast to the issue of population screening, it is important to test and counsel other family members when the diagnosis of hemochromatosis has been made in a proband. Testing allows the physician to exclude family members who are not at risk. It also permits presymptomatic detection of iron overload and the institution of treatment (phlebotomy) before the development of organ damage.

Preventive measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syndrome, associated with ventricular arrythmias, allows early electrocardiographic testing and the use of prophylactic antiarrythmic therapy, overdrive pacemakers, or defibrillators (Chap. 214). Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration (Chap. 221). Likewise, individuals with Marfan syndrome can be treated with beta blockers and monitored for the development of aortic aneurysms (Chap. 231). Individuals with α_1 antitrypsin deficiency can be strongly counseled to avoid cigarette smoking and exposure to environmental pulmonary and hepatotoxins. Various host genes influence the pathogenesis of certain infectious diseases in humans, including HIV (Chap. 173). The factor V Leiden allele increases risk of thrombosis (Chap. 53). Approximately 3% of the worldwide population is heterozygous for this mutation. Moreover, it is found in up to 25% of patients with recurrent deep-vein thrombosis or pulmonary embolism. Women who are heterozygous or homozygous for this allele should therefore avoid the use of oral contraceptives and receive heparin prophylaxis after surgery or trauma.

The field of pharmacogenomics seeks to identify genes that alter drug metabolism or confer susceptibility to toxic drug reactions. Examples include succinylcholine sensitivity, malignant hyperthermia, dihydropyrimidine dehydrogenase deficiency, the porphyrias, and glucose-6-phosphase dehydrogenase (G6PD) deficiency.

As noted above, the identification of genes that increase the risk of specific types of neoplasia is rapidly changing the management of many cancers. Identifying family members with mutations that predispose to FAP or hereditary nonpolyposis colon cancer (HNPCC) can lead to recommendations of early cancer screening or prophylactic surgery (Chap. 77). Similar principles apply to familial forms of melanoma, basal cell carcinoma, and cancers of the breast, ovary, and thyroid gland. It should be recognized, however, that most cancers harbor several distinct genetic abnormalities by the time they acquire invasive or metastatic potential (Chaps. 68 and 69). Consequently, the major impact of genetic testing in these cases is to allow more intensive clinical screening, as it remains very challenging to predict disease penetrance, expression, or the clinical course of these diseases.

Although genetic diagnosis of these and other disorders is only beginning to be used in the clinical setting, predictive testing holds the promise of allowing earlier and more targeted interventions that can reduce the morbidity and mortality associated with these disorders. We can expect the availability of genetic tests to expand rapidly. A critical challenge for physicians and other health care providers is to keep pace with these advances in genetic medicine and to implement testing judiciously. Meeting this goal will enhance patient care through adequate counseling, directed testing, and appropriate interventions, with the ultimate objective being the reduction of morbidity and mortality from genetic diseases.

59 STEM CELL AND GENE TRANSFER IN CLINICAL MEDICINE

David Bodine, J. Larry Jameson, Ron McKay

Gene therapy uses gene replacement to repair or treat disease. *Stem cell replacement* involves the administration of pluripotent, renewable cells to organs irreversibly damaged by disease. The disciplines of gene and cell therapy are now converging, offering unique opportunities to translate new knowledge of genetics and stem cell biology into the clinical setting. The technical, safety, and ethical challenges of these new treatment approaches are substantial, but their enormous promise provides strong incentive for ongoing research.

GENE TRANSFER IN CLINICAL MEDICINE

METHODS OF GENE TRANSFER Approaches to gene transfer can be divided broadly into: (1) ex vivo, in which genes are transferred into cells that are subsequently introduced into the patient; or (2) in vivo, in which genes are introduced directly into tissues, some of which are not readily accessible for ex vivo approaches. Ex vivo approaches are amenable to combining gene transfer with stem cell replacement (see below). In vivo gene transfer approaches have found relatively few clinical applications because of problems with targeting and regulating gene expression, maintaining gene expression, and avoiding toxicity.

Techniques for transferring genes include viral vectors and nonviral methods. *Viral vectors* take advantage of the fact that viruses enter cells efficiently and already contain genes that facilitate expression in host cells. In addition, some viruses such as retroviruses, lentiviruses, and adeno-associated viruses (AAVs) integrate genes into the host genome, facilitating long-term expression. However, technical limitations with viral production, the carrying capacity for the transferred gene, and the requirement for cell replication for effective integration (e.g., retroviruses) have hampered applications using these viruses. Nonetheless, viruses currently provide the best approach for long-lasting genetic modifications, as might be applied to stem cells or somatic cells. Adenoviruses have been widely used because they are easily produced in high titer, infect both quiescent and dividing cells, and can accommodate up to 10 kb of DNA. However, DNA transferred by adenoviruses is episomal (does not integrate into the host genome), resulting in relatively short-term gene expression over several weeks. The current generation of adenoviruses induces variable cytotoxicity and elicits immune responses—features that are useful for cytotoxic gene therapy but not for gene replacement.

Nonviral gene transfer includes the use of liposomes, electroporation, particle-mediated uptake, and direct uptake of naked DNA or oligonucleotides. Although these methods are relatively simple to perform and introduce minimal toxicity, they are much less efficient than viral-mediated approaches.

CHALLENGES ASSOCIATED WITH GENE THERAPY Gene therapy can be defined as the introduction of genes into cells or tissues with the goal of modifying the function of the tissue or producing a protein product beneficial for normal physiology. Potential applications of gene therapy are summarized in Table 59-1. Progress in gene therapy has been slow, reflecting substantial hurdles as investigators move closer to clinical applications. A few examples of potential applications highlight the status of this field and illustrate the requirements for successful gene therapy.

Significant therapeutic benefit can be achieved by the delivery of a single protein—insulin—to the patient with *diabetes mellitus*. In this case, the protein is secreted and can therefore be delivered extracellularly. The ability to produce recombinant human insulin has been a major advance. However, effective intensive insulin therapy remains difficult to achieve because of the exquisite regulation needed for dynamic metabolic responses to meals, exercise, and environmental stresses (Chap. 323). Clearly, much benefit would be gained if the insulin gene could be replaced and regulated normally. Although the gene has been cloned, and its regulatory elements have been characterized, insulin regulation requires multiple features of the normal pancreatic islet beta cell, including metabolic sensing mechanisms, an array of specific transcription factors that regulate the insulin gene, specialized protein-processing enzymes and secretory granules, and various channels that depolarize in response to metabolic signals. Thus, insulin gene therapy will not be successful in the absence of critical cellular features that recapitulate the function of the beta cell.

In contrast to insulin, where the goal is to secrete the protein for actions elsewhere in the body, many proteins function within a particular cell type, significantly complicating the delivery problem. For example, patients with *sickle cell anemia* or *β-thalassemia* have mutations in their β-globin genes (Chap. 91). In this case, one must introduce the replacement genes into specific cells and ensure regulated and sustained expression. The initial delivery and the long-term expression of the introduced gene are two distinct problems. Even if β-hemoglobin is expressed and regulated successfully in a red cell, the cell itself will only last for several weeks. Successful treatment there-

TABLE 59-1 Examples of Disorders Potentially Amenable to Gene Therapy

Disease	Gene Therapy Strategy
Inherited disorders	**Gene addition**
Cystic fibrosis	Express CFTR in pulmonary system and/or GI tract
Familial hypercholesterolemia	Express LDL receptor in liver
Hemophilias A and B	Express factor VIII or IX and secrete in circulation
Thalassemia	Express normal globin in red blood cells
Immunodeficiencies	Express deficient genes, such as adenosine deaminase
Metabolic disorders	Express missing enzymes or transporters
Duchenne's muscular dystrophy	Express mutant dystrophin protein in muscle cells
Retinitis pigmentosa (recessive)	Express normal protein in retina
	Gene correction
Lesch-Nyhan	Modify hypoxanthine phosphoribosyl transferase locus
Retinitis pigmentosa (dominant)	Correct missense mutation
Sickle cell disease	Correct β-globin mutation
Cystic fibrosis	Correct ΔF508 mutation in pulmonary system
Cardiovascular diseases	**Modify vascular biology**
Coronary artery restenosis	Block cell proliferation in vessel wall
Peripheral vascular disease	Induce angiogenesis
Hypertension	Express genes (e.g., tissue kallikrein) to induce vasodilation
Cancer	**Multiples approaches**
Many types	Express immunostimulants in or near malignant cells
	Express toxic genes in tumor cells (e.g., HSV-TK)
	Express genes to protect from chemotherapy in normal cells
Infectious diseases	
Viral diseases	Express genes that block viral replication or function, including ribozymes, decoys, dominant negative proteins
Many	Express antigens as recombinant vaccines
Miscellaneous	
Rheumatoid arthritis	Express anti-inflammatory cytokines in joints
Parkinson's disease	Express genes required for L-dopa synthesis in striatum
Neurodegenerative disease	Express neurotrophic factors

Note: CFTR, cystic fibrous transmembrane regulator; GI, gastrointestinal; LDL, low-density lipoprotein; HSV, herpes simplex virus; TK, thymidine kinase.

fore requires that the therapeutic genes be introduced into long-lived cells that can be renewed continuously to restore normal erythrocytes. Again, it is important to combine gene replacement or correction in the context of the normal host cell, in this case, an erythroblast.

Cystic fibrosis is caused by mutations in the cystic fibrosis transmembrane regulator (CFTR), a protein that regulates epithelial cell transport of Na^+ and Cl^- in the lung, gastrointestinal tract, sweat glands, and genitourinary system (Chap. 241). Gene delivery of the CFTR is more straightforward, in principle, as regulation of its expression level is less critical. The first attempt at gene therapy for cystic fibrosis was performed in 1993 using adenovirus-mediated transfer of the CFTR. This vector provides high level expression and is particularly effective for delivery to the lung. However, adenoviral expression is transient and induces immune responses that can limit subsequent viral administration. No clinical efficacy was demonstrated in the initial trials. Other viral delivery approaches are under investigation, but the challenge remains to target expression to particular tissues and to introduce the gene into a renewable population of cells.

The delivery of toxic, or suicide, genes to cancer cells is one of the most active areas of gene therapy research. Particularly for localized tumors, such as brain tumors or endocrine tumors, it may be possible to deliver highly toxic genes such as diphtheria toxin to tumor cells. For some tumor types, specific promoters can be used to express the toxic gene selectively in the cancer cell. Viruses have also been designed to replicate selectively in cells that lack certain tumor-suppressor genes, such as p53. An advantage of gene therapy for cancer cells is that long-term expression is not required. On the other hand, like chemotherapy or radiotherapy, gene therapy approaches must kill tumor cells with high efficacy without introducing significant toxicity. One novel approach is designed to increase the immunogenicity of tumors by expressing foreign antigens or cytokines that might increase endogenous immune responses.

FACTOR IX REPLACEMENT IN HEMOPHILIA B: POTENTIAL PARADIGM FOR GENE REPLACEMENT An excellent candidate for somatic gene therapy is hemophilia B, an X-linked blood clotting disorder caused by a deficiency of factor IX (Chap. 102). Factor IX is normally produced in the liver and secreted into the circulation. Clotting times can be corrected with <5% of the normal levels of factor IX; thus, low levels of factor IX should be sufficient for clinical benefit. The factor IX gene has been inserted into AAV vectors and introduced into muscle and liver cells. AAVs can be produced at high enough titers that the factor IX gene can be transferred to relatively large numbers of cells. Wild-type AAV has no known pathology, and the AAV particle does not provoke significant inflammatory or immune responses. Studies of AAV-mediated factor IX gene transfer in canine and murine models lacking factor IX have shown efficacy, although correction of the clotting abnormality is transient because inhibitory antibodies against human factor IX are generated in these species.

In an initial human clinical trial, AAV–factor IX was injected at multiple sites in a skeletal muscle that could be excised in the event of an unanticipated adverse event. At moderate doses of vector, factor IX expression and low levels of circulating factor IX were detected. The patients had decreased need for supplemental factor IX injections, but no significant decrease in clotting time was observed.

A different strategy has been employed to express factor VIII in dermal fibroblasts of patients with hemophilia A. Factor VIII was expressed under control of the fibronectin promoter and transferred ex vivo to dermal fibroblasts. The genetically modified cells were injected into the omentum. In four of six patients, plasma levels of factor VIII increased but then declined, probably because the cells were not renewable. This ex vivo approach represents a combination of gene transfer and cellular therapy.

CHARACTERISTICS OF STEM CELLS

The use of stem cell therapy addresses several of the shortcomings of gene therapy, including the need to express genes in specific types of host cells, such as erythrocytes or neurons, and the need to regulate gene expression in response to physiologic signals. Recent advances in stem cell biology greatly enhance the prospects for applying cell therapy (Table 59-2).

Although murine embryonic stem cells (ESCs) have been studied for many years, human ESCs were successfully cultured in vitro only in 1998. *Stem cells* are the undifferentiated progenitors that can develop into highly specialized cells that form the various organs. Stem cells vary in their replicative capacity and in their differentiation potential. A convenient classification of stem cells is as follows:

1. *Totipotent stem cells* can form a placenta and can develop into a complete embryo. These features are characteristic of the cells derived from the first few divisions of the fertilized oocyte.
2. *Pluripotent stem cells* are capable of forming tissues derived from all three major germline layers—endoderm, mesoderm, and ectoderm. These features are exhibited by making chimeras in which ESCs are injected into a blastocyst to become integrated into all tissues in the animal. Cells derived from the inner cell mass of the blastocyst will divide in culture indefinitely, retain a stable genome, and maintain the potential to contribute to all tissues. Common use of the term *embryonic stem cells* refers to lines with these characteristics.
3. *Multipotent stem cells* are the progenitors of cells in particular tissues. Tissues such as bone marrow, skin, intestinal tract, and liver have tremendous regenerative potential and continuously renew their cell populations. In these cases, the multipotent stem cells give rise to multiple cell types characteristic of a particular tissue.

Embryonic germ cells (EGCs) can be derived from the precursors of the germ line. Unlike totipotent ESCs, EGCs cannot be incorporated into the inner cell mass. However, cell lines established from the developing germ cells form chimeras and, like ESCs, contribute to all tissue lines of the embryo.

Stem cells are self-renewing while at the same time generating daughter cells that are more differentiated. The expression of telomerase, an enzyme critical for maintaining the telomeres, is consistent with the self-renewing feature of stem cells. Microarray studies, which examine patterns of gene expression, have identified several hundred genes that are shared by various types of stem cells. For continuous

TABLE 59-2 *Potential Applications of Stem Cell Therapy*

Disease	Stem Cell Therapy Goal
Hematologic disorders	
Leukemias	Replace marrow; graft vs tumor
Multiple myeloma	Replace marrow; graft vs tumor
Sickle cell anemia	Replace or correct erythrocytes
Autoimmune diseases	
Systemic lupus erythematosus	Reconstitute immune system
Crohn disease	Reconstitute immune system
Immune deficiency disorders	
Severe combined immune deficiency	Gene correction in immune cells
Wiscott-Aldrich	Gene correction in immune cells
Cardiovascular diseases	
Myocardial ischemia	Replace ischemic cardiomyocytes
Hepatic disease	
Hepatic failure	Replace or regenerate hepatocytes
Metabolic disorders	
Diabetes	Replace pancreatic islets or induce beta cell differentiation
Osteoporosis	Regenerate bone
Gaucher disease	Express glucocerebrosidase in macrophages
Musculoskeletal disorders	
Duchenne muscular dystrophy	Replace myoblasts
Neurologic disorders	
Parkinson's disease	Replace dopamine-producing neurons

renewal, some daughter cells must remain undifferentiated, while others become committed and generate more differentiated cells (Fig. 59-1).

The ability of ESCs to become incorporated into the germ line has allowed the genome of mouse ESCs to be manipulated in culture before being introduced into blastocysts to form chimeric mice (Chap. 56). Because these mice contain germ cells derived from the cultured ESCs, some animals born in the second generation are derived entirely from the cultured and manipulated ESCs. The genetic manipulation of ESCs has made the mouse a very useful model organism for studying the effects of targeted mutagenesis (gene knock-out or knock-in). Access to cultured ESCs offers the potential for differentiation into multiple tissue types, including cells of the blood, brain, and other tissues.

Emerging evidence indicates that adult tissues previously thought to have little or no plasticity, such as the central nervous system (CNS) and heart, do have some regenerative potential, implying the presence of stem cells, or the ability to attract and adopt circulating stem cells (Fig. 59-2). Thus, most adult tissues appear to contain stem cells, but the characteristics of these so-called adult stem cells are highly variable and appear to depend on the tissue of origin as well as on the mesenchymal niche in which the cells are located. The hematopoietic system, gastrointestinal tract, and skin exemplify highly regenerative tissues in which stem cell populations have been partially characterized.

HEMATOPOIETIC STEM CELLS (See also Chap. 100)

Hematopoietic stem cells (HSCs) provide a relatively well-studied model of adult stem cells. Although HSCs are used routinely for bone marrow transplantation, the technology is complex to implement in part because the stem cells do not grow in culture. An additional difficulty is that the stem cell property is not a stable feature but is dependent on signals derived from other cells that provide a *stem cell niche*. Adherent mesenchymal cells in the bone marrow contain a second class of stem cell, called a *stromal stem cell* or a *mesenchymal stem cell*, which is capable of generating mesodermal cells such as connective tissue or muscle. Adherent cells from the bone marrow can be expanded for long periods to generate yet another stem cell with the potential to form many other cell types, including liver, endothelial, and neural cells. This *mesenchymal adult progenitor cell* may also have the potential to form the various cell types of the blood. The implication is that the bone marrow mesenchyme can generate a pluripotent stem cell that is similar to ESCs, at least in some ways.

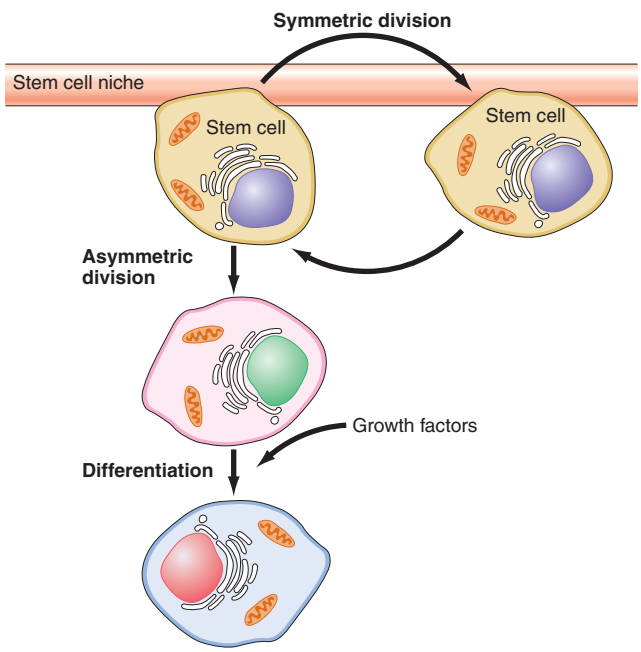

FIGURE 59-1 Stem cells have the capacity for self-renewal through symmetric division or they can generate daughter cells that enter specific differentiation pathways, usually in response to extrinsic cell contacts or growth factor signals.

All blood cells, as well as vascular endothelial cells, are derived from a common progenitor termed the *hemangioblast*. Adoptive transfer of these cells demonstrates that the myeloid and lymphoid cells of a recipient are derived from the donor. Moreover, bone marrow from primary recipients can be transplanted into secondary and tertiary recipients, demonstrating that HSCs can self-renew.

HEMATOPOIETIC STEM CELL DIFFERENTIATION Bone marrow cells cultured in semi-solid medium give rise to colonies of a specific hematopoietic lineage, such as red cells [the colony forming unit (CFU) erythroid (CFU-E)], granulocytes (CFU-G), monocytes (CFU-M), or B cells (CFU-B). Less common are cells that give rise to multiple different cell types such as the colony-forming unit granulocyte, erythroid, macrophage (CFU-GEM). Current models predict that as pluripotent stem cells proliferate, they become progressively committed to fewer hematopoietic lineages and eventually to a single lineage. The differentiation of stem cells appears to involve the ordered sequential expression of transcription factors that dictate lineage. For example, the Gata-1 transcription factor is required for the terminal differentiation of erythroid and megakaryocytic cells, whereas the Gata-2 factor is required for proliferation of the most primitive multilineage hematopoietic cells. Interleukin (IL) receptor signaling (IL-7Rα and the common chain, γc) and the JAK3 kinase are critical for the production of both T and B cells.

HEMATOPOIETIC STEM CELL ENRICHMENT Repopulation assays with limiting numbers of mouse bone marrow cells have shown that the number of HSCs is at least 100-fold lower than the frequency of colony-forming cells. Fluorescence-activated cell sorting using monoclonal antibodies against cell surface proteins has allowed the separation of HSCs from cells that cannot repopulate irradiated mice. Most methods begin with the removal of bone marrow cells expressing markers associated with a specific lineage of peripheral blood cells. Lineage negative (Lin−) cells, which comprise <5% of bone marrow cells, are enriched for colony-forming cells and can repopulate irradiated mice, whereas Lin+ cells have no colony-forming cells. HSCs among the Lin− cells are positively identified by the expression of the c-*kit* receptor and the Ly-6 antigen known as Sca-1. Lin− c-*kit*+ Sca-1+ cells are highly enriched for HSCs as well as for cells capable of generating T and B cells (common lymphoid progenitors). The common lymphoid progenitors express the IL-7 receptor α-chain, whereas HSCs are IL-7Rα−. Lin− c-*kit*+ Sca-1+ IL-7Rα− cells represent the most highly enriched population of mouse HSCs.

Surrogate assays have been developed for the study of human HSCs. The long term culture initiating cell assay is an in vitro system in which single human bone marrow cells are placed on a layer of bone marrow–derived fibroblasts and endothelial cells. Some of these cells can be placed onto new feeder cells where they continue to produce colony-forming cells, indicating both proliferation and self-renewal.

The most widely used in vivo surrogate assays for human HSCs involve the injection of human hematopoietic cells into genetically immune-deficient mice. The simplest model uses mice homozygous for the severe combined immune deficiency (*scid*) mutation, a deletion of the p350 DNA-dependent kinase gene that causes a failure of T and B cell development. The NOD strain of mice is deficient in natural killer cells, and NOD mice homozygous for the *scid* mutation (NOD/SCID) are good hosts for human hematopoietic cells. Human cells engraft in these animals, and their progeny can be detected in the bone marrow for ≥12 weeks after transplantation. Using these and other models, human HSCs have been shown to be Lin− and express the CD34 antigen. Lin− CD34+ cells can be further enriched for HSCs by sorting for cells that express Thy-1 and do not express CD38. Lin− CD34+ Thy-1+ CD38− cells are highly enriched for HSCs and are present at a frequency of <0.02% in human bone marrow.

Human and mouse HSCs share the ability to export the vital dyes

Hoechst 33342 and/or Rhodamine 123 efficiently. Dye export from HSCs is controlled by Bcrp, a member of the ATP-binding cassette transporter protein family that is expressed at high levels in HSCs. The ability to export Hoechst 33342 and Rhodamine 123 is shared by stem cells in other adult tissues, suggesting a common behavior of stem cells.

GENETIC MODIFICATION OF STEM CELLS

Stem cells are the ideal targets for gene therapy approaches. Because stem cells are able to self-renew, gene insertion into stem cells followed by engraftment into the patient should lead to a lifetime supply of corrected cells. In organs where cells are constantly lost and replaced, such as the hematopoietic and epithelial systems, introduction of a gene into a cell that cannot self-renew would require repeated treatments. The ability of stem cells to proliferate and differentiate into different types of mature cells ensures that the correct cell type will have the transferred gene. A problem is that most genes whose function needs to be replaced in disease states are expressed mainly in terminally differentiated cells and are not normally expressed in stem cells.

A variety of methods have been developed to transfer new genetic material into cells, including direct injection of DNA and gene transfer by viruses such as adenovirus, AAV or various RNA tumor viruses. Because RNA tumor viruses integrate into the genome of the target cell, they are currently the method of choice for stem cell gene transfer. The retroviruses have been modified such that most viral proteins are deleted, leaving only sequences important for viral integration. Recombinant virus vectors replace the protein-encoding sequences with a gene of interest. Because packaging sequences are deleted, the viruses do not replicate. The first recombinant RNA viral vectors were based on the Moloney murine leukemia viruses (MMuLV) but transduction efficiencies were very low (<1% of human cells). Although strategies to enhance MMuLV titers, attachment, and integration are ongoing, other retroviruses, such as vesicular stomatitis virus (VSV) and lentivirus, appear more promising. After the RNA virus genome enters the cell, it is converted into DNA by reverse transcriptase packaged with the RNA genome. Integration into the host genome occurs only during cell division. Thus, strategies to recruit cells into the cell cycle (e.g., transforming growth factor β antibodies) or to extend the G_1 to S-phase transition (e.g., antisense p27KIP-1 oligonucleotides) appear to enhance viral integration into stem cells.

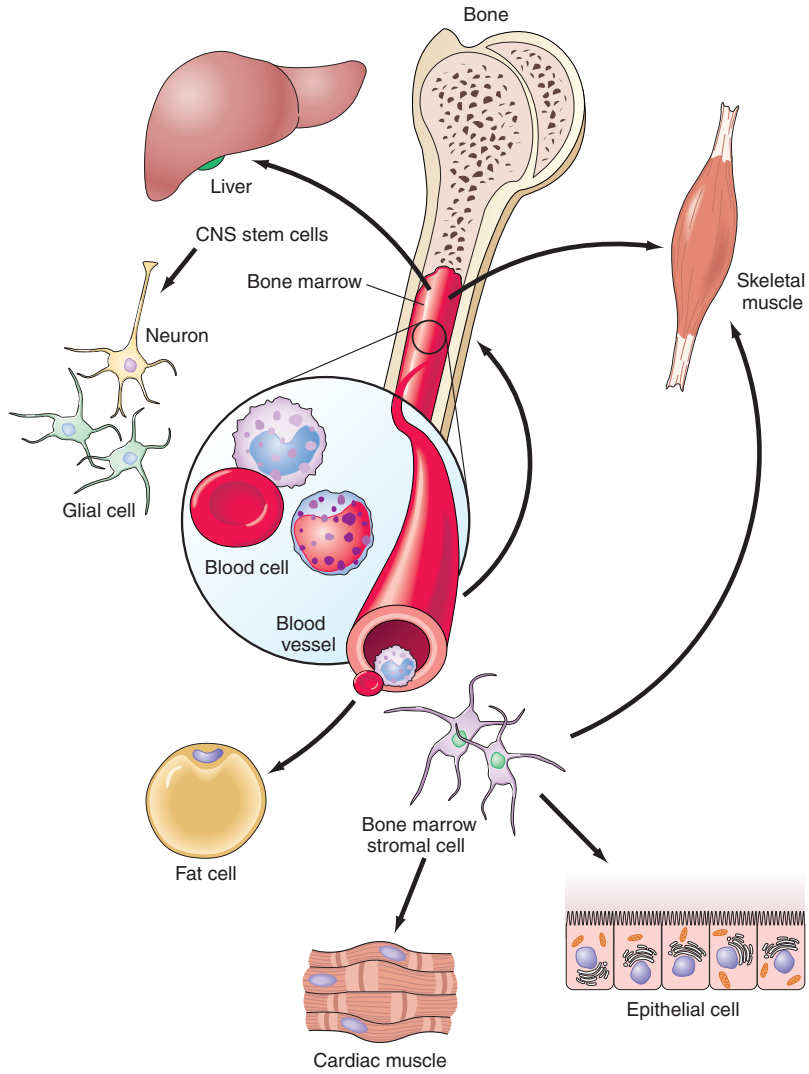

FIGURE 59-2 Plasticity of adult stem cells. CNS, central nervous system. [*Adapted from NIH Guide on Stem Cells: Scientific Promise and Future, 2001 (http://www.nih.gov/news/stemcell/scireport.htm.)*]

HEMATOPOIETIC STEM CELL GENE THERAPY ■ Bone Marrow Transplantation

This is used in thousands of patients yearly and is an example of cell therapy (Chap. 100). The success of bone marrow transplantation reflects the fact that the many cell types of the blood are derived from progenitor stem cells. Bone marrow transplantation is used to treat numerous acquired (aplastic anemia, myelodysplasia, leukemia, and lymphoma) and inherited (immune deficiencies, thalassemia, and sickle cell disease) hematologic and immunologic diseases. Ongoing studies are examining its applicability in selected autoimmune disorders such as refractory systemic lupus erythematosus and Crohn disease. Genetic modification of HSCs may achieve certain therapeutic goals (e.g., resistance to chemotherapy) or allow correction of a genetic defect.

Severe Combined Immune Deficiencies (SCID) This causes defects in both T and B lymphocyte production. Patients with SCID do not have cell-mediated or humoral immune responses and are subject to chronic life-threatening infections. The two most common forms of SCID are adenosine deaminase (ADA) deficiency (ADA-SCID) and deficiency of the X-linked IL-2 receptor γ-chain (γc, X-SCID) (Chap. 297). Bone marrow transplantation from an MHC-matched related donor is the treatment of choice and is effective in about 70 to 80% of patients.

Because the gene defects are known, ADA-SCID and X-SCID patients without a matched donor are excellent candidates for stem cell gene therapy. The first human gene therapy trial was performed in 1991. T lymphocytes from two ADA-deficient patients receiving ADA enzyme therapy were expanded and transduced with a retrovirus vector containing the ADA gene. Between 2 and 10% of the transduced T cells expressed the transferred gene and were reinfused into the patients. Clinical improvements, including positive responses to vaccinations, were documented in both patients despite the gradual disappearance of transduced cells to background levels over the next 5 years. In 2000, the first successful stem cell gene therapy was reported. Cord blood CD34+ cells from X-SCID newborns transduced with a γc retrovirus vector were reinfused into the patients. Approximately 98% of circulating T lymphocytes and 1% of circulating B lymphocytes contained the γc vector, compared to <0.1% of myeloid cells, demonstrating in vivo selection. The patients responded to clinical vaccinations and have been living at home without supportive care. Unfortunately, two recipients of marrow transduced with a γc retrovirus vector have developed a clinical disorder that resembles leukemia, and further studies have been suspended.

Wiscott-Aldrich Syndrome (WAS) This is an X-linked T lymphocyte disorder that can be accompanied by platelet dysfunction. Bone marrow transplantation can cure WAS, and in vivo selection for corrected cells has been demonstrated in several clinically normal WAS patients with

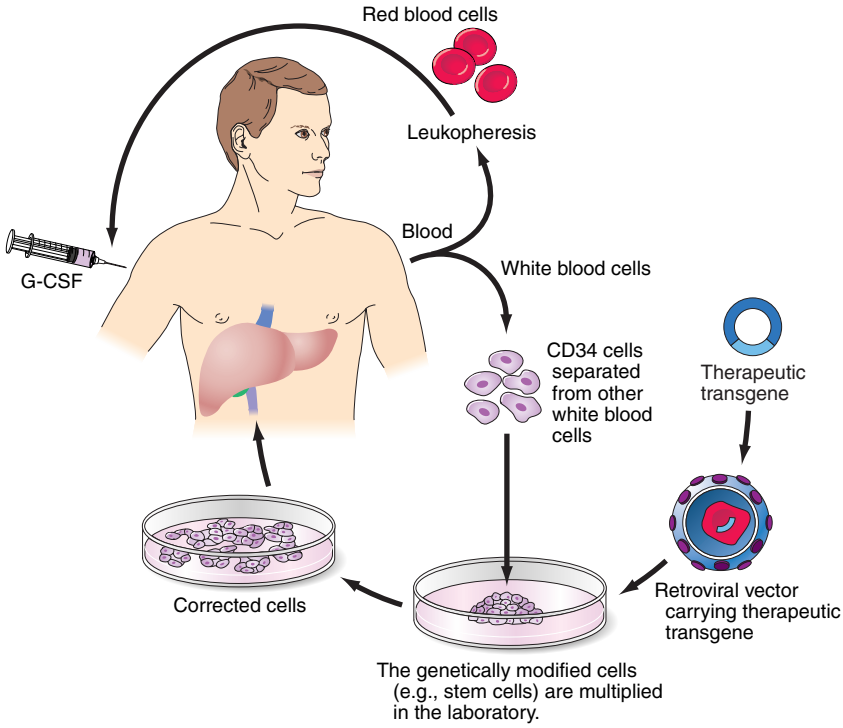

FIGURE 59-3 Strategy for introducing a therapeutic gene into hematopoietic stem cells to be used for autologous transplantation. [*Adapted from Pittsburgh Gaucher Disease Diagnosis and Treatment Program (http://gaucher.mgh.harvard.edu/centers/Pitt.html.)*]

reversion mutations. At present, the low rates of human HSC transduction are not sufficient to treat diseases of granulocytes (chronic granulomatous disease), monocytes (Gaucher disease), or red cells (thalassemia, sickle cell disease), as there is no evidence for in vivo selection of corrected cells.

Gaucher Disease (See also Chap. 340) This is a lysosomal storage disease caused by genetic deficiency of lysosomal glucocerebrosidase. Clinical manifestations reflect the accumulation of lipid-laden macrophages, referred to as *Gaucher cells*, in bone, liver, spleen, and other viscera. Macrophage-targeted enzyme replacement therapy has proven highly effective in Gaucher disease. Trials are currently underway to harvest a patient's HSCs, insert a normal copy of the gene encoding glucocerebrosidase using retroviruses, and return the modified cells to the patient (Fig. 59-3). This strategy represents a potential paradigm for disorders in which stem cells can be modified and reconstituted into normal tissues.

EMBRYONIC AND SOMATIC STEM CELL TECHNOLOGY IN MEDICINE

CARDIOVASCULAR SYSTEM The high incidence of cardiac disease has made regeneration of damaged cardiac muscle of great interest. Skeletal myoblasts can improve function in the damaged heart, but it is not clear if these cells confer long-term benefit. Myocardium has some regenerative capacity; pluripotent cells hone into areas of damaged myocardium. In men who receive heart transplants from female donors, XY-derived host cells are found in the donor tissue, particularly in regions of injury. Stem cells with the potential to generate cardiac tissue have been isolated from the bone marrow. In mouse models, labeled ESCs are incorporated into ischemic regions of the heart and reconstitute vascular and connective tissue as well as cardiac myocytes, and they express a number of highly specific cardiac markers. These findings imply that local factors, perhaps produced in response to injury, induce specific patterns of cellular differentiation.

LIVER The liver is capable of extensive regeneration. In most cases, regeneration is not caused by rare stem cells but rather by the rapid division of differentiated hepatocytes. Hepatocytes can be transplanted serially from one animal to another, demonstrating their extensive proliferative potential in vivo. It has been difficult, however, to establish conditions for long-term growth in vitro. When hepatocytes are inadequate for regeneration, less abundant stem cells in the liver become activated. The term *oval cell* is often used to refer to stem cells in the liver, but other pluripotent cells also appear capable of liver regeneration. For example, hepatocytes may be generated from cell populations enriched for HSCs as demonstrated by engraftment into animals with an otherwise fatal deficiency in liver function. Pluripotent cells derived from the bone marrow and capable of long-term culture can differentiate into liver cells in vitro. There is also evidence that HSCs can fuse with hepatocytes to generate new liver cells. ESCs can also generate liver cells.

PANCREATIC ISLETS The liver and pancreas share a number of developmental transcription factors and growth factors but ultimately diverge into distinct organs containing highly specialized cells. The pancreas is composed of two distinct cell types, the exocrine and endocrine cells. The islets of Langerhans contain the beta cells, which secrete insulin. Improvements in islet transplantation and immunosuppression regimens have resulted in some patients being free of exogenous insulin administration. However, the number of donor islets is very limited. Expansion of the beta cell population in vivo or in vitro would be useful. Stem cells in the adult pancreas reside near the pancreatic ducts and are competent to differentiate into the endocrine cell types. Self-assembling structures similar to pancreatic islets can be derived from ESCs. These embryonic stem–derived cells secrete insulin in response to glucose. An alternative approach involves attempts to alter the differentiation program of hepatic progenitor cells by introducing pancreas-specific transcription factors, such as PDX-1, using adenoviruses. In mouse models, PDX-1 induces a small fraction of liver cells to produce insulin and some of these cells appear to cycle and maintain a beta cell–like phenotype. Although much work remains to characterize and improve these models, early findings suggest that stem cell plasticity may offer a means to increase the population of insulin-producing cells.

NERVOUS SYSTEM The peripheral nervous system (PNS) is generated by an epithelial to mesenchymal transition that occurs in the neural crest. The precursor cells of the PNS are flexible and can give rise to progeny with multiple fates. *PNS stem cells* with somewhat different properties can be found in adult as well as fetal animals.

The many complex cell types of the CNS are generated from epithelial precursors that are not committed to specific fates. *CNS stem cells* can be expanded in tissue culture and generate the three major cell types of the brain: neurons, astrocytes, and oligodendrocytes. Multipotent cells can be obtained in large numbers from both the developing and adult brain. Neurons generated by fetal and adult CNS stem cells form functional excitatory and inhibitory synapses.

Although many types of neurons exist in the brain, the idea that the brain is derived from stem cells has stimulated attempts to exploit the regenerative potential of stem cell therapy to treat neurologic disease in the adult brain.

Parkinson's Disease Transplantation of fetal brain tissue may provide benefit to patients with Parkinson's disease. Dopamine neurons that are functional and long lasting can be obtained by grafting the tissue of the ventral fetal midbrain into the dorsal striatum. Raclopride is a drug that binds to dopamine receptors and radioactive raclopride can be imaged in the human brain using position emission tomography scanning. The displacement of raclopride has been used to show that grafted midbrain neurons release dopamine. This is one of several types of data supporting the idea of transplantation in Parkinson's disease.

The current procedures also have limitations. For optimal effects, the tissue from several fetal brains must be used; as the tissue must be at a specific stage in development, the logistics are difficult. Unexplained adverse reactions have been noted, and efficacy is hard to predict. ESCs offer a potential solution to the problem of variable tissue sources as they expand for long periods in tissue culture and can differentiate through midbrain precursors into dopamine secreting neurons. *Nuclear transfer* represents another approach in which an ESC can be generated from an oocyte after replacing its nucleus with one from a host somatic cell. Preliminary studies show that these ntESCs also readily form dopamine neurons.

Both ESC-derived and normal midbrain neurons express receptors for glial derived neurotrophic factor (GDNF). Gene therapy data in monkeys suggest that GDNF delivery may provide clinical benefit in Parkinson's patients. Clinical trials with GDNF are now underway.

ESCs can also be differentiated into cells similar to motor neurons, which degenerate in amyotrophic lateral sclerosis. ESCs can also be used as a source for large numbers of oligodendrocytes, a cell type that is lost in multiple sclerosis.

New neurons are not normally produced in most regions of the adult CNS. However, large numbers of new neurons are produced in the adult dentate gyrus of the hippocampus and the olfactory bulb. Pyramidal neurons can be regenerated in the CA1 region of the hippocampus and the cerebral cortex. New neurons are also generated in the adult striatum. Thus, endogenous precursors may be capable of regenerating neurons after injury to the adult nervous system.

ETHICAL ISSUES

Gene and stem cell therapies raise ethical and socially contentious issues that must be addressed in parallel with the scientific and medical opportunities. Our society has great diversity with respect to religious beliefs, concepts of individual rights, tolerance for uncertainty and risk, and boundaries for how scientific interventions should be used to alter the outcome of disease. In the United States, the federal government has authorized research using existing human ESC lines but has restricted the use of federal funds for developing new human ESC lines. Studies of the characteristics of these existing lines, including whether they are stable over time, are ongoing.

In considering ethical issues associated with the use of stem cells, it is helpful to draw from experience with other scientific advances, such as organ transplantation, recombinant DNA technology, implantation of mechanical devices, neuroscience and cognitive research, in vitro fertilization, and prenatal genetic testing. From these and other precedents, we learn the importance of understanding and testing fundamental biology in the laboratory setting and in animal models before applying new techniques in carefully controlled clinical trials. When these trials occur, they must include full informed consent and have careful oversight by external review groups.

Ultimately, there will be medical interventions that are scientifically feasible but ethically or socially unacceptable to some members of a society. Since genetic research raises fundamentally difficult questions of identity, it has raised deep fears about our ability to assure justice, access, and safety in genetic medicine. Health care providers and experts with backgrounds in ethics, law, and sociology must help guard against the premature or inappropriate application of gene or stem cell therapies, and the inappropriate use of vulnerable population groups. On the other hand, these therapies offer important new strategies for the treatment of otherwise irreversible disorders. An open dialogue between the scientific community, physicians, patients and their advocates, lawmakers, and the lay population is critically important to raise and address important ethical issues and to balance the benefits and risks associated with gene and stem cell transfer.

60 NUTRITIONAL REQUIREMENTS AND DIETARY ASSESSMENT

Johanna Dwyer

Nutrients are substances that are not synthesized in the body in sufficient amounts and therefore must be supplied by the diet. Nutrient requirements for groups of healthy persons have been defined on the basis of experimental evidence. For good health we require energy-providing nutrients (protein, fat, and carbohydrate), vitamins, minerals, and water. Specific nutrient requirements include 9 essential amino acids, several fatty acids, 4 fat-soluble vitamins, 10 water-soluble vitamins, and choline. Several inorganic substances, including 4 minerals, 7 trace minerals, 3 electrolytes, and the ultratrace elements, must also be supplied in the diet.

The required amounts of the essential nutrients differ by age and physiologic state. Conditionally essential nutrients are not required in the diet but must be supplied to individuals who do not synthesize them in adequate amounts, such as those with genetic defects, those having pathologic states with nutritional implications, and developmentally immature infants. Many organic phytochemicals and zoochemicals present in foods have various health effects. For example, dietary fiber has beneficial effects on gastrointestinal function.

ESSENTIAL NUTRIENT REQUIREMENTS

ENERGY For weight to remain stable, energy intake must match energy output. The major components of energy output are resting energy expenditure (REE) and physical activity; minor sources include the energy cost of metabolizing food (thermic effect of food or specific dynamic action) and shivering thermogenesis (e.g., cold-induced thermogenesis). The average energy intake is about 2800 kcal/d for American men and about 1800 kcal/d for American women, though these estimates vary with body size and activity level. Formulas for estimating REE are useful for assessing the energy needs of an individual whose weight is stable. Thus, for males, REE = 900 + 10*w*, and for females, REE = 700 + 7*w*, where *w* is weight in kilograms. The calculated REE is then adjusted for physical activity level by multiplying by 1.2 for sedentary, 1.4 for moderately active, or 1.8 for very active individuals. The final figure provides an estimate of total caloric needs in a state of energy balance. →***For further discussion of energy balance in health and disease, see Chap. 62.***

PROTEIN Dietary protein consists of both essential and nonessential amino acids that are required for protein synthesis, whereas certain amino acids can also be used for energy and gluconeogenesis. The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine/cystine, phenylalanine/tyrosine, threonine, tryptophan, and valine. When energy intake is inadequate, protein intake must be increased, since ingested amino acids are diverted into pathways of glucose synthesis and oxidation. In extreme energy deprivation, protein-calorie malnutrition may ensue (Chap. 62).

For adults, the recommended dietary allowance (RDA) for protein is about 0.6 g/kg desirable body weight per day, assuming that energy needs are met and that the protein is of relatively high biologic value. Current recommendations for a healthy diet call for at least 10 to 14% of calories from protein. Biologic value tends to be highest for animal proteins, followed by proteins from legumes (beans), cereals (rice, wheat, corn), and roots. Combinations of plant proteins that complement one another in biologic value or combinations of animal and plant proteins can increase biologic value and lower total protein requirements.

Protein needs increase during growth, pregnancy, lactation, and rehabilitation during treatment of malnutrition. The tolerance to dietary protein is decreased in renal insufficiency and liver failure. Normal protein intake can precipitate encephalopathy in patients with cirrhosis of the liver or worsen uremia in those with renal failure.

FAT AND CARBOHYDRATE Fats are a concentrated source of energy and constitute on average 34% of calories in U.S. diets. However, for optimal health, fat intake should total no more than 30% of calories. Saturated fat and trans-fat should be limited to <10% of calories, and polyunsaturated fats to <10% of calories, with monounsaturated fats comprising the remainder of fat intake. At least 55% of total calories should be derived from carbohydrates. The brain requires about 100 g/d of glucose for fuel; other tissues use about 50 g/d. Over time, adaptations in carbohydrate needs are possible in hypocaloric states. For example, reduced insulin levels lead to adipose tissue breakdown and cause the body to burn more fatty acids. However, some tissues (e.g., brain and red blood cells) rely on glucose supplied either exogenously or from muscle proteolysis (Chap. 324).

WATER For adults, 1 to 1.5 mL water per kcal of energy expenditure is sufficient under usual conditions to allow for normal variations in physical activity, sweating, and solute load of the diet. Water losses include 50 to 100 mL/d in the feces, 500 to 1000 mL/d by evaporation or exhalation, and, depending on the renal solute load, ≥1000 mL/d in the urine. If external losses increase, intakes must increase accordingly to avoid underhydration. Fever increases water losses by approximately 200 mL/d per °C; diarrheal losses vary but may be as great as 5 L/d in severe diarrhea. Heavy sweating and vomiting also increase water losses. When renal function is normal and solute intakes are adequate, the kidneys can adjust to increased water intake by excreting up to 18 L/d of excess water (Chap. 319). However, obligatory urine outputs can compromise hydration status when there is inadequate intake or when losses increase in disease or kidney damage.

Infants have high requirements for water because of their large ratio of surface area to volume, the limited capacity of the immature kidney to handle high renal solute loads, and their inability to communicate their thirst. Increased water needs during pregnancy are low, perhaps an additional 30 mL/d. During lactation, milk production increases water requirements so that approximately 1000 mL/d of additional water is needed, or 1 mL for each mL of milk produced. Special attention must be paid to the water needs of the elderly, who have reduced total body water and blunted thirst sensation, and may be taking diuretics.

OTHER NUTRIENTS See Chap. 61 for detailed description of vitamins and trace minerals.

DIETARY REFERENCE INTAKES AND RECOMMENDED DIETARY ALLOWANCES

Fortunately, human life and well-being can be maintained within a fairly wide range for most nutrients. However, the capacity for adaptation is not infinite—too much, as well as too little, intake of a nutrient may have adverse effects or alter the health benefits conferred by another nutrient. Therefore, benchmark recommendations on nutrient intakes have been developed to guide clinical practice. These quantitative estimates of nutrient intakes are collectively referred to as the *dietary reference intakes* (DRIs). The DRIs supplant the *recommended daily allowances* (RDAs), the single reference values used in the United States since 1989. DRIs include the *estimated average requirement* (EAR) for nutrients, as well as three other reference values used for dietary planning for individuals: the RDA, the *adequate intake*

(AI), and the tolerable *upper level* (UL). The current DRIs for vitamins and elements are provided in Tables 60-1 and 60-2, respectively.

ESTIMATED AVERAGE REQUIREMENT When florid dietary deficiency diseases such as rickets, scurvy, xerophthalmia, and protein-calorie malnutrition were common, nutrient adequacy was assumed by the absence of clinical signs of a dietary deficiency disease. Later, it was determined that biochemical and other changes were evident long before the clinical deficiency became apparent. Consequently, criteria of adequacy are now based on biologic markers when they are available. Current efforts focus on the amount of a nutrient that reduces the risk of chronic degenerative diseases. Priority is given to sensitive biochemical, physiologic, or behavioral tests that reflect early changes in regulatory processes or maintenance of body stores of nutrients.

The EAR is the amount of a nutrient estimated to be adequate for half of the healthy individuals of a specific age and sex. The types of evidence and criteria used to establish nutrient requirements vary by nutrient, age, and physiologic group. The EAR is not an effective estimate of nutrient adequacy in individuals because it is a median requirement for a group; 50% of individuals in a group fall below the requirement and 50% fall above it. Thus, a person with a usual intake at the EAR has a 50% risk of an inadequate intake. For these reasons, other standards, described below, are more useful for clinical purposes.

RECOMMENDED DIETARY ALLOWANCES The RDA is the average daily dietary intake level that meets the nutrient requirements of nearly all healthy persons of a specific sex, age, life stage, or physiologic condition (such as pregnancy or lactation). The RDA is the nutrient-intake goal for planning diets of individuals.

The RDA is defined statistically as 2 standard deviations (SD) above the EAR to ensure that the needs of any given individual are met. The RDAs are used to formulate food guides such as the U.S. Department of Agriculture (USDA) Food Guide Pyramid for individuals, to create food exchange lists for therapeutic diet planning, and as a standard for describing the nutritional content of processed foods and nutrient supplements. The nutrient content in a food is stated by weight or as a percent of the daily value (DV), a variant of the RDA

Note: This table presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all individuals (97 to 98%) in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

[a] As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. To calculate RAEs from retinol equivalents (REs) of provitamin A carotenoids in foods, divide the REs by 2. For preformed vitamin A in foods or supplements and for provitamin A carotenoids in supplements, 1 RE = 1 RAE.

[b] As calciferol. 1 μg calciferol = 40 IU vitamin D.

[c] In the absence of adequate exposure to sunlight.

[d] As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the *2S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[e] As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

[f] As dietary folate equivalents (DFEs). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g] Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h] Because 10 to 30% of older people may malabsorb food-bound B_{12}, it is advisable for those >50 years to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}.

[i] In view of evidence linking inadequate folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j] It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

that, for an adult, represents the highest RDA for an adult consuming 2000 kcal/d.

The risk of dietary inadequacy increases as intake falls further below the RDA. However, the RDA is an overly generous criterion for evaluating nutrient adequacy. For example, by definition the RDA exceeds the actual requirements of all but about 2 to 3% of the population. Therefore, many people whose intake falls below the RDA may still be getting enough of the nutrient.

ADEQUATE INTAKE It is not possible to set an RDA for some nutrients that do not have an established EAR. In this circumstance, the AI is based on observed, or experimentally determined, approximations of nutrient intakes in healthy people. In the DRIs established to date, AIs rather than RDAs are proposed for infants up to age 1 year, as well as for calcium, chromium, vitamin D, fluoride, manganese, pantothenic acid, biotin, and choline for persons of all ages.

TOLERABLE UPPER LEVELS OF NUTRIENT INTAKE Excessive nutrient intake can disturb body functions and cause acute, progressive, or permanent disabilities. The tolerable UL is the highest level of chronic nutrient intake (usually daily) that is unlikely to pose a risk of adverse health effects for most of the population. Data on the adverse effects of large amounts of many nutrients are unavailable or too limited to establish a UL. Therefore, the lack of a UL does *not* mean that the risk of adverse effects from high intake is nonexistent. Healthy individuals derive no established benefit from consuming nutrient levels above the RDA or AI. Individual nutrients in foods that most people eat rarely reach levels that exceed the UL. However, nutritional supplements provide more concentrated amounts of nutrients per dose and, as a result, pose a potential risk of toxicity. Nutrient supplements are labeled with "supplement facts" that express the amount of nutrient in absolute units or as the percent of the DV provided per recommended serving size. Total nutrient consumption, including both food and supplements, should not exceed RDA levels.

FACTORS ALTERING NUTRIENT NEEDS

The DRIs are affected by age, sex, rate of growth, pregnancy, lactation, physical activity, composition of diet, concomitant diseases, and drugs. When only slight differences exist between the requirements for nutrient sufficiency and excess, dietary planning becomes more difficult.

PHYSIOLOGIC FACTORS Growth, strenuous physical activity, pregnancy, and lactation increase needs for energy and several essential nutrients. Energy needs rise during pregnancy, due to the demands of fetal growth, and during lactation, because of the increased energy required for milk production. Energy needs decrease with loss of lean body mass, the major determinant of REE. Because both health and physical activity tend to decline with age, energy needs in older persons, especially those over 70, tend to be less than those of younger persons.

DIETARY COMPOSITION Dietary composition affects the biologic availability and utilization of nutrients. For example, the absorption of iron may be impaired by high amounts of calcium or lead; non-heme iron uptake may be impaired by the lack of ascorbic acid and amino acids in the meal. Protein utilization by the body may be decreased when essential amino acids are not present in sufficient amounts. Animal foods, such as milk, eggs, and meat, have high biologic values with most of the needed amino acids present in adequate amounts. Plant proteins in corn (maize), soy, and wheat have lower biologic values and must be combined with other plant or animal proteins to achieve optimal utilization by the body.

ROUTE OF ADMINISTRATION The RDAs apply only to oral intakes. When nutrients are administered parenterally, similar values can sometimes be used for amino acids, carbohydrates, fats, sodium, chloride, potassium, and most of the vitamins, since their intestinal absorption is nearly 100%. However, the oral bioavailability of most mineral elements may be only half that obtained by parenteral administration. For

some nutrients that are not readily stored in the body, or cannot be stored in large amounts, timing of administration may also be important. For example, amino acids cannot be used for protein synthesis if they are not supplied together; instead they will be used for energy production.

DISEASE Specific dietary deficiency diseases include protein-calorie malnutrition; iron, iodine, and vitamin A deficiency; megaloblastic anemia due to vitamin B_{12} or folic acid deficiency; vitamin D–deficiency rickets; and scurvy, beriberi, and pellagra (Chaps. 61 and 62). Each deficiency disease is characterized by imbalances at the cellular level between the supply of nutrients or energy and the body's nutritional needs for growth, maintenance, and other functions. Imbalances in nutrient intakes are recognized as risk factors for certain chronic degenerative diseases, such as saturated fat and cholesterol in coronary artery disease; sodium in hypertension; obesity in hormone-dependent endometrial and breast cancers; and ethanol in alcoholism. Since the etiology and pathogenesis of these disorders are multifactorial, diet is only one of many risk factors. Osteoporosis, for example, is associated with calcium deficiency, as well as risk factors related to environment (e.g., smoking, sedentary lifestyle), physiology (e.g., estrogen deficiency), genetic determinants (e.g., defects in collagen metabolism), and drug use (chronic steroids) (Chap. 333).

DIETARY ASSESSMENT

In clinical situations, nutritional assessment is an iterative process that involves: (1) screening for malnutrition, (2) assessing the diet and other data to establish either the absence or presence of malnutrition and its possible causes, and (3) planning for the most appropriate nutritional therapy. Some disease states affect the bioavailability, requirements, utilization, or excretion of specific nutrients. In these circumstances, specific measurements of various nutrients may be required to ensure adequate replacement (Chap. 62).

Most health care facilities have a nutrition screening process in place for identifying possible malnutrition after hospital admission. Nutritional screening is required by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), but there are no universally recognized or validated standards. The factors that are usually assessed include abnormal weight for height or body mass index (e.g., BMI <19 or >25); reported weight change (involuntary loss or gain of >5 kg in the past 6 months) (Chap. 36); diagnoses with known nutritional implications (metabolic disease, any disease affecting the gastrointestinal tract, alcoholism, and others); present therapeutic dietary prescription; chronic poor appetite; presence of chewing and swallowing problems or major food intolerances; need for assistance with preparing or shopping for food, eating, or other aspects of self care; and social isolation. Reassessment of nutrition status should occur periodically in hospitalized patients—at least once every week.

A more complete dietary assessment is indicated for patients who exhibit a high risk of malnutrition on nutrition screening. The type of assessment varies based on the clinical setting, severity of the patient's illness, and stability of his or her condition.

ACUTE CARE SETTINGS In acute care settings, anorexia, various diseases, test procedures, and medications can compromise dietary intake. Under such circumstances, the goal is to identify and avoid inadequate intake and assure appropriate alimentation. Dietary assessment focuses on what patients are currently eating, whether they are able and willing to eat, and whether they experience any problems with eating. Dietary intake assessment is based on information from observed intakes; medical record; history; clinical examination; and anthropometric, biochemical, and functional status. The objective is to gather enough information to establish the likelihood of malnutrition due to poor dietary intake or other causes to assess whether nutritional therapy is indicated.

Simple observations may suffice to suggest inadequate oral intake. These include dietitians' and nurses' notes, the amount of food eaten on trays, frequent tests and procedures that are likely to cause meals to be skipped, nutritionally inadequate diet orders such as clear liquids or full liquids for more than a few days, fever, gastrointestinal distress, vomiting, diarrhea, a comatose state, and diseases or treatments that involve any part of the alimentary tract. Acutely ill patients with diet-related diseases such as diabetes need assessment because an inappropriate diet may exacerbate these conditions and adversely affect other therapies. Abnormal biochemical values [serum albumin levels <35 g/L (<3.5 mg/dL); serum cholesterol levels <3.9 mmol/L (<150 mg/dL)] are nonspecific but may also indicate a need for further nutritional assessment.

Most therapeutic diets offered in hospitals are calculated to meet individual nutrient requirements and the RDA. Exceptions include clear liquids, some full liquid diets, and test diets, which are inadequate for several nutrients and should not be used, if possible, for more than 24 h. As much as half of the food served to hospitalized patients is not eaten, and so it cannot be assumed that the intakes of hospitalized patients are adequate. Dietary assessment should compare how much and what food the patient has consumed with the diet that has been provided. Major deviations in intakes of energy, protein, fluids, or other nutrients of special concern for the patient's illness should be noted and corrected.

Nutritional monitoring is especially important for patients who are very ill and who have extended lengths of stay. Patients who are fed by special enteral and parenteral routes also require special nutritional assessment and monitoring by physicians with training in nutrition support and/or dietitians with certification in nutrition support (Chap. 63).

AMBULATORY SETTINGS The aim of dietary assessment in the outpatient setting is to determine whether the patient's usual diet is a health risk in itself or if it contributes to existing chronic disease-related problems. Dietary assessment also provides the basis for planning a diet that fulfills therapeutic goals while ensuring patient adherence. The outpatient dietary assessment should review the adequacy of present and usual food intakes, including vitamin and mineral supplements, medications, and alcohol, as all of these may affect the patient's nutritional

status. The assessment should focus on the dietary constituents that are most likely to be involved or compromised by a specific diagnosis, as well as any comorbidities that are present. More than one day's intake should be reviewed to provide a better representation of the usual diet.

There are many ways to assess the adequacy of the patient's habitual diet. These include a food guide, a food exchange list, a diet history, or a food frequency questionnaire. A commonly used food guide for healthy persons is the USDA's food pyramid, which is useful as a basis for identifying inadequate intakes of essential nutrients, as well as likely excesses in fat, saturated fat, sodium, sugar, and alcohol (Table 60-3). The guide can be adjusted by varying the number of servings to provide for the needs of persons of different ages and life cycle stages. Those who follow ethnic or unusual dietary patterns may need extra instruction on how foods should be categorized, as well as the appropriate portion sizes that constitute a serving. The process of reviewing the guide with patients helps them transition to healthier dietary patterns and identifies food groups eaten in excess of recommendations or in insufficient quantities. For those on therapeutic diets, assessment against food exchange lists may be useful. These include, for example, the American Diabetes Association food exchange lists for diabetes, or the American Dietetic Association food exchange lists for renal disease.

NUTRITIONAL STATUS ASSESSMENT Full nutritional status assessment is reserved for seriously ill patients and those at very high nutritional risk when the cause of malnutrition is still uncertain after initial clinical evaluation and dietary assessment. It involves multiple dimensions, including documentation of dietary intake, anthropometric measurements, biochemical measurements of blood and urine, clinical examination, health history, and functional status. →***For further discussion of nutritional assessment, see Chap. 62.***

61 VITAMIN AND TRACE MINERAL DEFICIENCY AND EXCESS

Robert M. Russell

Vitamins and trace minerals are required constituents of the human diet since they are either inadequately synthesized or not synthesized in the human body. Only small amounts of these substances are needed for carrying out essential biochemical reactions (e.g., acting as coenzymes or prosthetic groups). Overt vitamin or trace mineral deficiencies are rare in western countries due to a plentiful, varied, and inexpensive food supply; however, multiple nutrient deficiencies may appear together in persons who are ill or alcoholic. Moreover, subclinical vitamin and trace mineral deficiencies, as diagnosed by laboratory testing, are quite common in the normal population—especially in the geriatric age group.

Body stores of vitamins and minerals vary tremendously. For example, vitamin B_{12} and vitamin A stores are large, and an adult may not become deficient for 1 or more years after being on a depleted diet. However, folate and thiamine may become depleted within weeks when eating a deficient diet. Therapeutic modalities can deplete essential nutrients from the body; for example, hemodialysis removes water-soluble vitamins, which must be replaced by supplementation.

There are several roles for vitamins and trace minerals in diseases: (1) deficiencies of vitamins and minerals may be caused by disease states such as malabsorption; (2) both deficiency and excess of vitamins and minerals can cause disease in and of themselves (e.g., vitamin A intoxication and liver disease); and (3) vitamins and minerals in high doses may be used as drugs (e.g., niacin for hypercholesterolemia). The hematologic-related vitamins and minerals (Chaps. 90, 92) are considered only briefly in this chapter, as are the bone-related vitamins and minerals (vitamin D, calcium, phosphorus; Chap. 331), since they are covered elsewhere (see Tables 61-1, 61-2, and Fig. 61-1).

VITAMINS

THIAMINE (VITAMIN B_1)

Thiamine was the first B vitamin to be identified and is therefore also referred to as vitamin B_1. Thiamine functions in the decarboxylation of α-ketoacids, such as pyruvate α-ketoglutarate, and branched-chain amino acids and thus is a source of energy generation. In addition, thiamine pyrophosphate acts as a coenzyme for a transketolase reaction that mediates the conversion of hexose and pentose phosphates. It has also been postulated that thiamine plays a role in peripheral nerve conduction, although the exact chemical reactions underlying this function are unknown.

FOOD SOURCES The median intake of thiamine in the United States from food alone is 2 mg/d. Primary food sources for thiamine include yeast, pork, legumes, beef, whole grains, and nuts. Milled and polished rice contain little thiamine, if any. Thiamine deficiency is therefore more common in cultures that rely heavily on a rice-based diet. Tea, coffee (caffeinated and decaffeinated), raw fish, and shellfish contain thiamineases, which can destroy the vitamin. Thus, drinking large amounts of tea or coffee can theoretically lower thiamine body stores.

DEFICIENCY Most dietary deficiency of thiamine worldwide is the result of poor dietary intake. In western countries, the primary causes of thiamine deficiency are alcoholism and chronic illness, such as cancer. Alcohol is known to interfere directly with the absorption of thiamine and with the synthesis of thiamine pyrophosphate. Thiamine should always be replenished when refeeding a patient with alcoholism, as carbohydrate repletion without adequate thiamine can precipitate acute thiamine deficiency.

Thiamine deficiency in its early stage induces anorexia and nonspecific symptoms (e.g., irritability). Prolonged thiamine deficiency causes beriberi, which is classically categorized as wet or dry, although there is considerable overlap. In either form of beriberi, patients may complain of pain and parathesia. *Wet beriberi* presents primarily with cardiovascular symptoms, due to impaired myocardial energy metabolism and dysautonomia, and can occur after 3 months of a thiamine-deficient diet. Patients present with an enlarged heart, tachycardia, high-output congestive heart failure, peripheral edema, and peripheral neuritis. Patients with *dry beriberi* present with a symmetric peripheral neuropathy of the motor and sensory systems with diminished reflexes. The neuropathy affects the legs most markedly, and patients have difficulty rising from a squatting position.

Alcoholic patients with chronic thiamine deficiency may also have central nervous system manifestations known as *Wernicke's enceph-*

TABLE 61-1 *Principal Clinical Findings of Vitamin Malnutrition*

Nutrient	Clinical Finding	Dietary Level per Day Associated with Overt Deficiency in Adults	Contributing Factors to Deficiency
Thiamine	Beriberi: neuropathy, muscle weakness and wasting, cardiomegaly, edema, ophthalmoplegia, confabulation	<0.3 mg/1000 kcal	Alcoholism
Riboflavin	Magenta tongue, angular stomatitis, seborrhea, cheilosis	<0.6 mg	—
Niacin	Pellagra: pigmented rash of sun-exposed areas, bright red tongue, diarrhea, apathy, memory loss, disorientation	<9.0 niacin equivalents	Alcoholism, vitamin B_6 deficiency, riboflavin deficiency
Vitamin B_6	Seborrhea, glossitis convulsions, neuropathy, depression, confusion, microcytic anemia	<0.2 mg	Alcoholism, isoniazid
Folate	Megaloblastic anemia, atrophic glossitis, depression, ↑ homocysteine,	<100 μg/d	Alcoholism, sulfasalazine, pyrimethamine, triamterene
Vitamin B_{12}	Megaloblastic anemia, loss of vibratory and position sense, abnormal gait, dementia, impotence, loss of bladder and bowel control, ↑ homocysteine, ↑ methylmalonic acid	<1.0 μg/d	Gastric atrophy (pernicious anemia), terminal ileal disease, strict vegetarianism
Vitamin C	Scurvy: petechiae, ecchymosis, coiled hairs, inflamed and bleeding gums, joint effusion, poor wound healing	<10 mg/d	Smoking, alcoholism
Vitamin A	Xerophthalmia, nightblindness, Bitôt spots, follicular hyperkeratosis, impaired embryonic development, immune dysfunction	<300 μg/d	Fat malabsorption, infection, measles, alcoholism, protein-energy malnutrition
Vitamin D	Rickets: skeletal deformation, rachitic rosary, bowed legs; osteomalacia	<2.0 μg/d	Aging, lack of sunlight exposure, fat malabsorption
Vitamin E	Peripheral neuropathy, spinocerebellar ataxia, skeletal muscle atrophy, retinopathy	Not described unless underlying contributing factor is present	Occurs only with fat malabsorption, or genetic abnormalities of vitamin E metabolism/transport
Vitamin K	Elevated prothrombin time, bleeding	<10 μg/d	Fat malabsorption, liver disease, antibiotic use

alopathy, consisting of horizontal nystagmus, ophthalmoplegia (due to weakness of one or more extraocular muscles), cerebellar ataxia, and mental impairment (Chap. 372). When there is an additional loss of memory and a confabulatory psychosis, the syndrome is known as *Wernicke-Korsakoff syndrome*.

The laboratory diagnosis of thiamine deficiency is usually made by a functional enzymatic assay of transketolase activity measured before and after the addition of thiamine pyrophosphate. A >25% stimulation by the addition of thiamine pyrophosphate (an activity coefficient of 1.25) is taken as abnormal. Thiamine or the phosphorylated esters of thiamine in serum or blood can also be measured by high-performance liquid chromatography (HPLC) to detect deficiency.

Rx TREATMENT

In acute thiamine deficiency with either cardiovascular or neurologic signs, 100 mg/d of thiamine should be given parenterally for 7 days, followed by 10 mg/d orally until there is complete recovery. Cardiovascular improvement occurs in ≤12 h, and ophthalmoplegic improvement occurs within 24 h. Other manifestations gradually clear, although psychosis in the Wernicke-Korsakoff syndrome may be permanent or persist for several months.

TOXICITY Although anaphylaxis has been reported after high doses of thiamine, no adverse effects have been recorded from either food or supplements at high doses. Thiamine supplements may be bought over the counter in doses of up to 50 mg/d.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is important for the metabolism of fat, carbohydrate, and protein, reflecting its role as a respiratory coenzyme and an electron donor. Enzymes that contain flavin adenine dinucleotide (FAD) or flavin-mononucleotide (FMN) as prosthetic groups are known as *flavoenzymes* (e.g., succinic acid dehydrogenase, monoamine oxidase, glutathione reductase).

Although much is known about the chemical and enzymatic reactions of riboflavin, the clinical manifestations of riboflavin deficiency are nonspecific and similar to those of other B vitamin deficiencies. Riboflavin deficiency is manifested principally by lesions of the mucocutaneous surfaces of the mouth and skin (Table 61-1). In addition to the mucocutaneous lesions, corneal vascularization, anemia, and personality changes have been described with riboflavin deficiency.

DEFICIENCY AND EXCESS Riboflavin deficiency is almost always due to dietary deficiency. Milk, other dairy products, and enriched breads and cereals are the most important dietary sources of riboflavin in the United States, although lean meat, fish, eggs, broccoli, and legumes are also good sources. Riboflavin is extremely sensitive to light, and milk should be stored in containers that protect against photodegradation. Laboratory diagnosis of riboflavin deficiency can be made by measurement of red blood cell or urinary riboflavin concentrations or by measurement of erythrocyte glutathione reductase activity, with and without added FAD. Because the capacity of the gastrointestinal tract to absorb riboflavin is limited (~20 mg if given in one oral dose), riboflavin toxicity has not been described.

NIACIN (VITAMIN B_3)

The term *niacin* refers to nicotinic acid and nicotinamide and their biologically active derivatives. Nicotinic acid and nicotinamide serve as precursors of two coenzymes, nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), which are important in numerous oxidation and reduction reactions in the body. In addition, NAD and NADP are active in adenine diphosphate–ribose transfer reactions involved in DNA repair and calcium mobilization.

METABOLISM AND REQUIREMENTS Nicotinic acid and nicotinamide are absorbed well from the stomach and small intestine. Niacin bioavailability is high from beans, milk, meat, and eggs; bioavailability from cereal grains is lower. Since flour is enriched with the "free" niacin (i.e., non-coenzyme form), bioavailability is excellent. Median intakes of niacin in the United States considerably exceed the recommended dietary allowance (RDA).

The amino acid tryptophan can be converted to niacin with an efficiency of 60:1 by weight. Thus, the RDA for niacin is expressed in niacin equivalents. A lower conversion of tryptophan to niacin occurs if a patient is vitamin B_6- or riboflavin-deficient or in the presence of

isoniazid. The urinary excretion products of niacin include 2-pyridone and 2-methyl nicotinamide, measurements of which are used in diagnosis of niacin deficiency.

DEFICIENCY Niacin deficiency causes *pellagra*, which is mostly found among people eating corn-based diets in parts of China, Africa, and India. Pellagra in North America is found mainly among alcoholics; in patients with congenital defects of intestinal and kidney absorption of tryptophan (Hartnup's disease; Chap. 343); and in patients with carcinoid syndrome (Chap. 329), where there is increased conversion of tryptophan to serotonin. The early symptoms of pellagra include loss of appetite, generalized weakness and irritability, abdominal pain, and vomiting. Bright-red glossitis then ensues, followed by a characteristic skin rash that is pigmented and scaling, particularly in skin areas exposed to sunlight. This rash is known as "Casal's necklace" because it forms a ring around the neck; it is seen in advanced cases. Vaginitis and esophagitis may also occur. Diarrhea (in part due to proctitis and in part due to malabsorption), depression, seizures, and dementia are also part of the pellagra syndrome—the four D's: *d*ermatitis, *d*iarrhea, and *d*ementia leading to *d*eath.

Treatment of pellagra consists of oral supplementation of 100 to 200 mg of nicotinamide or nicotinic acid three times daily for 5 days. High doses of nicotinic acid (≥3 g nicotinic acid per day) are used for the treatment of elevated cholesterol levels and in the treatment of types 2, 4, and 5 hyperlipidemias (Chap. 335).

TOXICITY Prostaglandin-mediated flushing has been observed at daily doses as low as 50 mg of niacin when taken as a supplement or as therapy for hypertriglyceridemia. There is no evidence of toxicity from niacin derived from food sources. Flushing may be accompanied by skin dryness, itching, and headache. Premedication with aspirin may alleviate these symptoms. Nausea, vomiting, and abdominal pain also occur at similar doses of niacin. Hepatic toxicity is the most serious toxic reaction due to niacin and may present as jaundice with elevated aspartate aminotransferase (AST) and alanine aminotranferase (ALT) levels. A few cases of fulminant hepatitis requiring liver transplantation have been reported at doses of 3 to 9 g/d. Other toxic reactions include glucose intolerance, macular edema, and macular cysts. The upper limit for daily niacin intake has been set at 35 mg. However, this upper limit does not pertain to the therapeutic use of niacin.

Vitamin	Active derivative or cofactor form	Principal function
Thiamine (B_1) 	Thiamine pyrophosphate	Coenzyme for cleavage of carbon-carbon bonds; amino acid and carbohydrate metabolism
Riboflavin (B_2) 	Flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD)	Cofactor for oxidation, reduction reactions, and covalently attached prosthetic groups for some enzymes
Niacin 	Nicotinamide adenine dinucleotide phosphate (NADP) and nicotinamide adenine dinucleotide (NAD)	Coenzymes for oxidation and reduction reactions
Vitamin B_6 	Pyridoxal phosphate	Cofactor for enzymes of amino acid metabolism
Folate 	Polyglutamate forms of (5, 6, 7, 8) tetrahydrofolate with carbon unit attachments	Coenzyme for one carbon transfer in nucleic acid and amino acid metabolism
Vitamin B_{12} 	Methylcobalamine Adenosylcobalamin	Coenzyme for methionine synthase and L-methylmalonyl-CoA mutase

FIGURE 61-1 The structures and principal functions of vitamins associated with human disorders.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 refers to a family of compounds including pyridoxine, pyridoxal, pyridoxamine, and their 5′-phosphate derivatives. 5′-Pyridoxal phosphate (PLP) is a cofactor for more than 100 enzymes involved in amino acid metabolism. Vitamin B_6 is also involved in heme and neurotransmitter synthesis and in the metabolism of glycogen, lipids, steroids, sphingoid bases, and several vitamins, including the conversion of tryptophan to niacin.

DIETARY SOURCES Plants contain vitamin B_6 in the form of pyridoxine, whereas animal tissues contain PLP and pyridoxamine phosphate. The

Vitamin	Active derivative or cofactor form	Principal function
Vitamin C 	Ascorbic acid and dehydrascorbic acid	Participation as a redox ion in many biological oxidation and hydrogen transfer reactions
Vitamin A 	Retinol, retinaldehyde, and retinoic acid	Formation of rhodopsin (vision) and glycoproteins (epithelial cell function); also regulates gene transcription
Vitamin D 	1, 25-Dihyroxy vitamin	Maintenance of blood calcium and phosphorous levels; antiproliferative hormone
Vitamin E 	Tocopherols and tocotrienols	Antioxidants
Vitamin K 	Vitamin K hydroquinone	Cofactor for posttranslation carboxylation of many proteins including essential clotting factors

FIGURE 61-1—*(continued)*

vitamin B_6 contained in plants is less bioavailable than that from animal tissues. Rich food sources of vitamin B_6 include legumes, nuts, wheat bran, and meat, although it is present in all food groups.

DEFICIENCY Symptoms of vitamin B_6 deficiency include epithelial changes, as seen frequently with other B vitamin deficiencies. In addition, severe vitamin B_6 deficiency can lead to peripheral neuropathy, abnormal electroencephalograms, and personality changes including depression and confusion. In infants, diarrhea, seizures, and anemia have been reported. Microcytic, hypochromic anemia is due to diminished hemoglobin synthesis, since the first enzyme involved in heme biosynthesis (amino-levulinate synthase) requires PLP as a cofactor (Chap. 90). In some case reports, platelet dysfunction has also been reported. Since vitamin B_6 is necessary for the conversion of homocysteine to cystathionine, it is possible that chronic low-grade vitamin B_6 deficiency may result in hyperhomocystinemia and increased risk of cardiovascular disease (Chaps. 225 and 343).

Certain medications such as isoniazid, L-dopa, penicillamine, and cycloserine interact with PLP due to a reaction with carbonyl groups. The increased ratio of AST (or SGOT) to ALT (or SGPT) seen in alcoholic liver disease reflects the relative vitamin B_6 dependence of ALT. Vitamin B_6 dependency syndromes that require pharmacologic doses of vitamin B_6 are rare, but include cystathionine β-synthase deficiency, pyridoxine-responsive (primarily sideroblastic) anemias, and gyrate atrophy with chorioretinal degeneration due to decreased activity of the mitochondrial enzyme ornithine aminotransferase. In these situations, 100 to 200 mg/d of oral vitamin B_6 are required for treatment.

High doses of vitamin B_6 have been used to treat carpal tunnel syndrome, premenstrual syndrome, schizophrenia, autism, and diabetic neuropathy but have not been found to be effective.

The laboratory diagnosis of vitamin B_6 deficiency is generally made on the basis of low plasma PLP values (<20 nmol/L). Treatment of vitamin B_6 deficiency is 50 mg/d; higher doses of 100 to 200 mg/d are given if vitamin B_6 deficiency is related to medication use. Vitamin B_6 should not be given with L-dopa, since the vitamin interferes with the action of this drug.

TOXICITY The safe upper limit for vitamin B_6 has been set at 100 mg/d, although no adverse effects have been associated with high intakes of vitamin B_6 from food sources only. When toxicity occurs, it causes a severe sensory neuropathy, leaving patients unable to walk. Some cases of photosensitivity and dermatitis have also been reported.

FOLATE, VITAMIN B_{12}

See Chap. 90.

VITAMIN C

Both ascorbic acid and its oxidized product dehydroascorbic acid are biologically active. Actions of vitamin C include antioxidant activity, promotion of nonheme iron absorption, carnitine biosynthesis, and the conversion of dopamine to norepinephrine. Vitamin C is also important for connective tissue metabolism and cross-linking, and it is a component of many drug-metabolizing enzyme systems, particularly the mixed-function oxidase systems.

ABSORPTION AND DIETARY SOURCES Almost complete absorption of vitamin C occurs if <100 mg is administered in a single dose; however, only 50% or less is absorbed at doses >1 g. Enhanced degradation and fecal and urinary excretion of vitamin C occur at higher intake levels.

Good dietary sources of vitamin C include citrus fruits, green vegetables (especially broccoli), tomatoes, and potatoes. Consumption of five servings of fruits and vegetables a day provides vitamin C in excess of the RDA, 60 mg/d for males and females. In addition, approximately 40% of the U.S. population takes vitamin C as a dietary supplement in which "natural forms" of vitamin C are no more bioavailable than synthetic forms. Smoking, hemodialysis, and stress (e.g., infection, trauma) appear to increase vitamin C requirements.

DEFICIENCY Vitamin C deficiency causes scurvy; in the United States, this is seen primarily among the poor and elderly and in alcoholics who consume <10 mg/d of vitamin C. Vitamin C deficiency has also been described among individuals consuming macrobiotic diets. Symptoms of scurvy primarily reflect impaired formation of mature connective tissue and include bleeding into skin (petechiae, ecchymoses, perifollicular hemorrhages); inflamed and bleeding gums; and manifestations of bleeding into joints, the peritoneal cavity, pericardium, and the adrenal glands. In children, vitamin C deficiency may cause impaired bone growth. Laboratory diagnosis of vitamin C deficiency is made on the basis of low plasma or leukocyte levels.

Administration of vitamin C (200 mg/d) improves the symptoms of scurvy within a matter of several days. High-dose vitamin C supplementation (e.g., 1 to 2 g/d) may slightly decrease the symptoms and duration of upper respiratory tract infections. Vitamin C supplementation has also been reported to be useful in Chédiak-Higashi syndrome (Chap. 55) and osteogenesis imperfecta (Chap. 342). Diets high in vitamin C have been claimed to lower the incidence of certain cancers, particularly esophageal and gastric cancers. If proven, this effect may be due to the fact that vitamin C can prevent the conversion of nitrites and secondary amines to carcinogenic nitrosomines. However, one intervention study from China did not show vitamin C to be protective.

TOXICITY Taking >2 g of vitamin C in a single dose may result in abdominal pain, diarrhea, and nausea; doses >3 g have been reported to elevate blood levels of ALT, lactic acid dehydrogenase, and uric acid. Since vitamin C may be metabolized to oxalate, it is feared that chronic, high-dose vitamin C supplementation could result in an increased prevalence of kidney stones. However, this has not been borne out in several trials, except in patients with preexisting renal disease. Thus, it is reasonable to advise patients with a past history of kidney stones to not take large doses of vitamin C. There is also an unproven, but possible, risk that chronic high doses of vitamin C could promote iron overload in patients taking supplemental iron. High doses of vitamin C can induce hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and doses >1 g/d can cause false-negative guaiac reactions as well as interfere with tests for urinary glucose.

BIOTIN

Biotin is a water-soluble vitamin that plays a role in gluconeogenesis and fatty acid synthesis and serves as a CO_2 carrier on the surface of both cytosolic and mitochondrial carboxylase enzymes. The vitamin also functions in the catabolism of specific amino acids (e.g., leucine). Excellent food sources of biotin include liver, soy, beans, yeast, and egg yolks; however, egg white contains the protein avidin, which strongly binds the vitamin and reduces its bioavailability.

Biotin deficiency has been induced by experimental feeding of egg white diets and in patients with short bowels who received biotin-free parenteral nutrition. In the adult, biotin deficiency results in mental changes (depression, hallucinations), paresthesia, anorexia, and nausea. A scaling, seborrheic, and erythematous rash may occur around the eyes, nose, and mouth as well as on the extremities. In infants, biotin deficiency presents as hypotonia, lethargy, and apathy. In addition, the infant may develop alopecia and a characteristic rash that includes the ears. The laboratory diagnosis of biotin deficiency can be established based on a decreased urinary concentration. Treatment requires pharmacologic doses of biotin, using up to 10 mg/d.

PANTOTHENIC ACID

Pantothenic acid is a component of coenzyme A and phosphopantetheine, which are involved in fatty acid metabolism and the synthesis of cholesterol, steroid hormones, and all compounds formed from isoprenoid units. In addition, pantothenic acid is involved in the acetylation of proteins. The vitamin is excreted in the urine, and the laboratory diagnosis of deficiency is made on the basis of low urinary vitamin levels.

The vitamin is ubiquitous in the food supply. Liver, yeast, egg yolks, and vegetables are particularly good sources. Human pantothenic acid deficiency has only been demonstrated in experimental feeding of diets low in pantothenic acid or by giving a specific pantothenic acid antagonist. The symptoms of pantothenic acid deficiency are nonspecific and include gastrointestinal disturbance, depression, muscle cramps, paresthesia, ataxia, and hypoglycemia. Pantothenic acid deficiency is believed to have caused the burning feet syndrome seen in prisoners of war during World War II. No toxicity of this vitamin has been reported.

CHOLINE

Choline is a precursor for acetylcholine, phospholipids, and betaine. Choline is necessary for the structural integrity of cell membranes, cholinergic neurotransmission, lipid and cholesterol metabolism, and transmembrane signaling. Recently, a recommended adequate intake was set at 550 mg/d for adult males and 425 mg/d for adult females. Choline is thought to be a "conditionally essential" nutrient, in that de novo synthesis occurs in the liver and is less than the vitamin's utilization only under certain stress conditions. Choline deficiency has occurred in patients receiving parenteral nutrition devoid of choline. Deficiency results in fatty liver and elevated transaminase levels. The diagnosis of choline deficiency is made on the basis of low plasma levels.

Toxicity from choline results in hypotension, cholinergic sweating, diarrhea, salivation, and a fishy body odor. The upper limit for choline has been set at 3.5 g/d. Therapeutically, choline has been suggested for patients with dementia and for patients at high risk of cardiovascular disease, due to its ability to lower cholesterol and homocysteine levels. However, such benefits have yet to be documented.

VITAMIN A

Vitamin A, in the strictest sense, refers to retinol. However, the oxidized metabolites, retinaldehyde and retinoic acid, are also biologically active compounds. The term *retinoids* includes synthetic molecules that are chemically related to retinol. Retinaldehyde (11-*cis*) is the essential form of vitamin A that is required for normal vision, whereas retinoic acid is necessary for normal morphogenesis, growth, and cell differentiation. Retinoic acid does not function in vision and, in contrast to retinol, is not involved in reproduction. Vitamin A also plays a role in iron utilization, humoral immunity, T cell–mediated immunity, natural killer cell activity, and phagocytosis. Vitamin A is commercially available in esterified forms (e.g., acetate, palmitate) since it is more stable as an ester.

There are over 600 carotenoids in nature, and approximately 50 of these can be metabolized to vitamin A. β-Carotene is the most prevalent carotenoid in the food supply that has provitamin A activity. It is estimated that 12 μg or greater of dietary β-carotene is equivalent to 1 μg of retinol, whereas 24 μg or greater of other dietary provitamin A carotenoids (e.g., cryptoxanthin, α-carotene) is equivalent to 1 μg of retinol.

METABOLISM The liver contains approximately 90% of the vitamin A reserves and secretes vitamin A in the form of retinol, which is bound to retinol-binding protein. Once this has occurred, the retinol-binding protein complex interacts with a second protein, transthryetin. This trimolecular complex functions to prevent vitamin A from being filtered by the kidney glomerulus, to protect the body against the toxicity of retinol and to allow retinol to be taken up by specific cell-surface receptors that recognize retinol-binding protein. A certain amount of vitamin A enters peripheral cells even if it is not bound to retinol-binding protein. After retinol is internalized by the cell, it becomes bound to a series of cellular retinol-binding proteins, which function as sequestering and transporting agents as well as coligands for enzymatic reactions. Certain cells also contain retinoic acid–binding proteins, which have the same sequestering functions as well as enabling retinoic acid metabolism.

Retinoic acid is a ligand for certain nuclear receptors that act as transcription factors. Two families of receptors (RAR and RXR receptors) are active in retinoid-mediated gene transcription. Retinoid receptors regulate transcription by binding as dimeric complexes to specific DNA sites, the retinoic acid response elements, in target genes (Chap. 317). The receptors can either stimulate or repress gene expression in response to their ligands. RAR binds all-*trans* retinoic acid and 9-*cis* retinoic acid, whereas RXR binds only 9-*cis* retinoic acid.

The retinoid receptors play an important role in controlling cell proliferation and differentiation. Retinoic acid is useful in the treat-

ment of promyeolcytic leukemia (Chap. 96) and is also used in the treatment of cystic acne because it inhibits keratinization, decreases sebum secretion, and possibly alters the inflammatory reaction (Chap. 47). RXRs dimerize with other nuclear receptors to function as co-regulators of genes responsive to retinoids, thyroid hormone, and calcitriol. RXR agonists induce insulin sensitivity experimentally, perhaps because RXR is a cofactor for the peroxisome-proliferator-activated receptors (PPARs), which are targets for the thiazolidinedione drugs such as rosiglitazone and troglitazone (Chap. 323).

DIETARY SOURCES The retinol activity equivalent (RAE) is used to express the vitamin A value of food. One RAE is defined as 1 μg of retinol (0.003491 mmol), 12 μg of β-carotene, and 24 μg of other provitamin A carotenoids. In older literature, vitamin A was often expressed in international units (IU), with 1 RAE being equal to 3.33 IU of retinol and 20 IU of β-carotene, but these units are no longer in current scientific use.

Liver and fish are excellent food sources for preformed vitamin A; vegetable sources of provitamin A carotenoids include dark-green and -colored fruits and vegetables. Children are particularly susceptible to vitamin A deficiency because neither breast nor cow's milk supplies enough vitamin A to prevent deficiency. Areas of the world where vitamin A deficiency is particularly prevalent include parts of Africa, South America, and Southeast Asia. Vitamin A deficiency occurs in more than 250,000 children each year, resulting in blindness and a 50% mortality rate within the year. In western countries, vitamin A deficiency is seen primarily among patients with diseases associated with fat malabsorption (e.g., celiac sprue, short-bowel syndrome). Concurrent zinc deficiency can interfere with the mobilization of vitamin A from liver stores. Alcohol interferes with the conversion of retinol to retinaldehyde in the eye by competing for alcohol (retinol) dehydrogenase. Drugs that interfere with the absorption of vitamin A include mineral oil, neomycin, and cholestyramine.

DEFICIENCY Symptoms of vitamin A deficiency include hyperkeratotic skin lesions, and xerophthalmia (e.g., Bitôt spots, which are white patches of keratinized epithelium appearing on the sclera). Aggressive xerophthalmia can result in corneal ulceration. If untreated, proteolytic destruction and rupture of the cornea ensues with permanent blindness, although vitamin A treatment of patients with corneal ulcers can also result in blindness due to permanent corneal scarring. Children with vitamin A deficiency have increased mortality, primarily from infectious diseases, measles, respiratory diseases, and diarrhea. Extremely low birth weight infants ($<$1000 g) should be treated parenterally with 1500 μg (or RAE) of vitamin A three times a week for 4 weeks.

There are no specific deficiency signs or symptoms that result from carotenoid deficiency. It was postulated that β-carotene would be an effective chemopreventive for cancer because numerous epidemiologic studies had shown that diets high in β-carotene were associated with lower incidences of cancers of the respiratory and digestive system. However, intervention studies using high doses of β-carotene actually resulted in more lung cancers than in placebo-treated groups. Non-provitamin A carotenoids, such as lutein and zeaxanthin, have been suggested to protect against macular degeneration. The non-provitamin A carotenoid lycopene has been proposed to protect against prostate cancer. However, the effectiveness of these agents has not been proven by intervention studies, and the mechanisms underlying these purported biologic actions are unknown.

The diagnosis of vitamin A deficiency is made by measurement of serum retinol (normal range, 30 to 65 μg/dL), tests of dark adaptation, impression cytology of the conjunctiva (decreased numbers of mucous-secreting cells), or measurement of body storage pools, either directly by liver biopsy or by isotopic dilution after administering a stable isotope of vitamin A.

Vitamin A deficiency with ocular changes should be treated by administering 30 mg of vitamin A intramuscularly, or 60 mg orally. In areas of endemic vitamin A deficiency, this is followed by 60 mg vitamin A capsules at 6-month intervals. Vitamin A deficiency in patients with malabsorptive diseases, who have abnormal dark adaptation or symptoms of night blindness without ocular changes, should be treated for 1 month with 15 mg/d orally of a water micelle preparation of vitamin A. This is followed by lower maintenance doses with the exact amount determined by monitoring serum retinol.

TOXICITY Acute toxicity of vitamin A was first noted in Arctic explorers who ate polar bear liver and has also been seen after administration of 150 mg in adults or 100 mg in children. Acute toxicity is manifested by increased intracranial pressure, vertigo, diplopia, bulging fontanels in children, seizures, and exfoliative dermatitis; it may result in death. Chronic vitamin A intoxication has been seen in normal adults who ingest 15 mg/d of vitamin A for a period of several months and in children who ingest 6 mg/d. Manifestations include dry skin, cheilosis, glossitis, vomiting, alopecia, bone pain, hypercalcemia, lymph node enlargement, hyperlipidemia, amenorrhea, and features of pseudotumor cerebri with increased intracranial pressure and papilledema. Liver fibrosis with portal hypertension and bone demineralization may also result from chronic vitamin A intoxication. When vitamin A is provided in excess to pregnant women, congenital malformations have included spontaneous abortions, craniofacial abnormalities, and valvular heart disease. In pregnancy, the daily dose of vitamin A should not exceed 3 mg. Commercially available retinoid derivatives are also toxic, including 13-*cis*-retinoic acid, which has been associated with birth defects. As a result, contraception should be continued for a least 1 year, and possibly longer, in women who have taken 13-*cis* retinoic acid.

High doses of carotenoids do not result in toxic symptoms. However, carotenemia, which is characterized by a yellowing of the skin (creases of the palms and soles) but not the sclerae, may be present after ingestion of $>$30 mg of β-carotene on a daily basis. Hypothyroid patients are particularly susceptible to the development of carotenemia due to impaired breakdown of carotene to vitamin A. Reduction of carotenes from the diet results in the disappearance of skin yellowing and carotenemia over a period of 30 to 60 days.

VITAMIN D

See Chap. 331, Fig. 61-1, and Table 61-1.

VITAMIN E

Vitamin E is a collective name for the 2R stereoisomers of α tocopherol. Vitamin E acts as a chain-breaking antioxidant and is an efficient pyroxyl radical scavenger, which protects low-density lipoproteins (LDLs) and polyunsaturated fats in membranes from oxidation. A network of other antioxidants (e.g., vitamin C, glutathione) and enzymes maintains vitamin E in a reduced state. Vitamin E also inhibits prostaglandin synthesis and the activities of protein kinase C and phospholipase A_2.

ABSORPTION AND METABOLISM After absorption, vitamin E is taken up from chylomicrons by the liver, and an hepatic α tocopherol transport protein mediates intracellular vitamin E transport and incorporation into very low density lipoprotein (VLDL). The transport protein has particular affinity for the RRR isomeric form of α tocopherol; thus this natural isomer has the most biologic activity.

REQUIREMENT Vitamin E is widely distributed in the food supply and is particularly high in sunflower oil, safflower oil, and wheat germ oil; γ tocotrionols are notably present in soybean and corn oils. Vitamin E is also found in meats, nuts, and cereal grains, and small amounts are present in fruits and vegetables. Vitamin E pills containing doses of 50 to 1000 mg are ingested by a large fraction of the U.S. population. Diets high in polyunsaturated fats may necessitate a slightly higher requirement for vitamin E.

Dietary deficiency of vitamin E does not exist. Vitamin E deficiency is seen in only severe and prolonged malabsorptive diseases, such as celiac disease, or after small-intestinal resection. Children with cystic fibrosis or prolonged cholestasis may develop vitamin E deficiency characterized by areflexia and hemolytic anemia. Children with

abetalipoproteinemia cannot absorb or transport vitamin E and become deficient quite rapidly. A familial form of isolated vitamin E deficiency also exists, which is due to a defect in the α tocopherol transport protein. Vitamin E deficiency causes axonal degeneration of the large myelinated axons and results in posterior column and spinocerebellar symptoms. Peripheral neuropathy is initially characterized by areflexia, with progression to an ataxic gait, and by decreased vibration and position sensations. Ophthalmoplegia, skeletal myopathy, and pigmented retinopathy may also be features of vitamin E deficiency. The laboratory diagnosis of vitamin E deficiency is made on the basis of low blood levels of α tocopherol (<5 μg/mL, or <0.8 mg of α tocopherol per gram of total lipids).

Rx TREATMENT

Symptomatic vitamin E deficiency should be treated with 800 to 1200 mg of α tocopherol per day. Patients with abetalipoproteinemia may need as much as 5000 to 7000 mg/d. Children with symptomatic vitamin E deficiency should be treated with 400 mg/d orally of water-miscible esters; alternatively, 2 mg/kg per day may be administered intramuscularly. Vitamin E in high doses may protect against oxygen-induced retrolental fibroplasia and bronchopulmonary dysplasia, as well as intraventricular hemorrhage of prematurity. Vitamin E has been suggested to increase sexual performance, to treat intermittent claudication, and to slow the aging process, but evidence for these properties is lacking. High doses (60 to 800 mg/d) of vitamin E have been shown in controlled trials to improve parameters of immune function, but intervention studies using vitamin E to prevent cardiovascular disease have not shown efficacy.

TOXICITY High doses of vitamin E (>800 mg/d) may reduce platelet aggregation and interfere with vitamin K metabolism and are therefore contraindicated in patients taking warfarin. Nausea, flatulence, and diarrhea have been reported at doses >1 g/d.

VITAMIN K

There are two natural forms of vitamin K: vitamin K I, also known as *phylloquinone*, from vegetable and animal sources, and vitamin K II, or *menaquinone*, which is synthesized by bacterial flora and found in hepatic tissue. *Menadione*, or vitamin K III, is a chemically synthesized pro-vitamin that can be converted to menaquinone by the liver.

Vitamin K is required for the posttranslational carboxylation of glutamic acid, which is necessary for calcium binding to γ-carboxylated proteins such as prothrombin (factor II); factors VII, IX, and X; protein C; protein S; and proteins found in bone (bone gla, matrix gla protein, and osteocalcin). However, the importance of vitamin K for bone mineralization is not known. Warfarin-type drugs inhibit γ carboxylation by preventing the conversion of vitamin K to its active hydroquinone form.

DIETARY SOURCES Vitamin K is found in green leafy vegetables such as kale and spinach, but appreciable amounts are also present in butter, margarine, liver, milk, ground beef, coffee, and pears. Vitamin K is present in vegetable oils and is particularly rich in olive oil and soybean oil. The average daily intake by Americans is estimated to be approximately 100 μg/d.

DEFICIENCY The symptoms of vitamin K deficiency are due to hemorrhage, and newborns are particularly susceptible because of low fat stores, low breast milk levels of vitamin K, sterility of the infantile intestinal tract, liver immaturity, and poor placental transport. Intracranial bleeding, as well as gastrointestinal and skin bleeding, can occur in vitamin K–deficient infants 1 to 7 days after birth. Thus, vitamin K (1 mg intramuscularly) is given prophylactically at the time of delivery.

Vitamin K deficiency in adults may be seen in patients with chronic small-intestinal disease (e.g., celiac disease, Crohn's disease), obstructed biliary tracts, or after small-bowel resection. Broad-spectrum antibiotic treatment can precipitate vitamin K deficiency by reducing gut bacteria, which synthesize menaquinones, and by inhibiting the metabolism of vitamin K. The diagnosis of vitamin K deficiency is usually made on the basis of an elevated prothrombin time or reduced clotting factors, although vitamin K may also be measured directly by HPLC. Vitamin K deficiency is treated using a parenteral dose of 10 mg. For patients with chronic malabsorption, 1 to 2 mg/d of vitamin K should be given orally, or 1 to 2 mg/week can be taken parenterally. Patients with liver disease may have an elevated prothrombin time because of liver cell destruction as well as vitamin K deficiency. If an elevated prothrombin time does not improve on vitamin K therapy, it can be deduced that it is not the result of vitamin K deficiency.

TOXICITY Parenteral doses of the water-soluble vitamin K derivative (menadione) have been reported to cause hemolytic anemia and hypobilirubinemia in infants. Toxicity from dietary phylloquinones and menaquinones has not been described. High doses of vitamin K can impair the actions of oral anticoagulants.

MINERALS See Table 61-2.

CALCIUM See Chap. 331.

ZINC

Zinc is an integral component of many metalloenzymes in the body; it is involved in the synthesis and stabilization of proteins, DNA, and RNA and plays a structural role in ribosomes and membranes. Zinc is necessary for the binding of steroid hormone receptors and several other transcription factors to DNA. Zinc is absolutely required for normal spermatogenesis, fetal growth, and embryonic development.

ABSORPTION The absorption of zinc from the diet is inhibited by dietary phytate, fiber, oxalate, iron, and copper, as well as by certain drugs including penicillamine, sodium valproate, and ethambutol. Meat, shellfish, nuts, and legumes are good sources of bioavailable zinc, whereas zinc in grains is less available for absorption.

DEFICIENCY Mild zinc deficiency has been described in many diseases including diabetes mellitus, AIDS, cirrhosis, alcoholism, inflammatory bowel disease, malabsorption syndromes, and sickle cell anemia. In these diseases, mild chronic zinc deficiency can cause stunted growth in children, decreased taste sensation (hypogusia), and impaired immune function. Severe chronic zinc deficiency has been described as a cause of hypogonadism and dwarfism in several Middle Eastern countries. In these children, hypopigmented hair is also part of the syndrome. Acrodermatitis enteropathica is a rare autosomal recessive disorder characterized by abnormalities in zinc absorption. Clinical manifestations include diarrhea, alopecia, muscle wasting, depression, irritability, and a rash involving the extremities, face, and perineum. The rash is characterized by vesicular and pustular crusting with scaling and erythema. Occasional patients with Wilson's disease have developed zinc deficiency as a consequence of penicillamine therapy (Chap. 339).

The diagnosis of zinc deficiency is usually made by a serum zinc level of <12 μmol/L (<70 μg/dL). Pregnancy and birth control pills may cause a slight depression in serum zinc levels, and hypoalbuminemia from any cause can result in hypozincemia. In acute stress situations, zinc may be redistributed from serum into tissues. Zinc deficiency may be treated with 60 mg elemental zinc, orally twice a day. Zinc gluconate lozenges (13 mg elemental Zn every 2 h while awake) have been reported to reduce the duration and symptoms of the common cold in adults, but studies are conflicting.

TOXICITY Acute zinc toxicity after oral ingestion causes nausea, vomiting, and fever. Zinc fumes from welding may also be toxic and cause fever, respiratory distress, excessive salivation, sweating, and headache. Chronic large doses of zinc may depress immune function and cause hypochromic anemia as a result of copper deficiency.

COPPER

Copper is an integral part of numerous enzyme systems including amine oxidases, ferrooxidase (ceruloplasmin), cytochrome-*c* oxidase,

TABLE 61-2 *Deficiencies and Toxicities of Metals*

Element	Deficiency	Toxicity	Tolerable Upper (Dietary) Intake Level
Boron	No biologic function determined	Developmental defects, male sterility, testicular atrophy	20 mg/d (extrapolated from animal data)
Calcium	Reduced bone mass, osteoporosis	Renal insufficiency (milk-alkalai syndrome), nephrolithiasis, impaired iron absorption	2500 mg/d (milk-alkalai)
Copper	Anemia, growth retardation, defective keratinization and pigmentation of hair, hypothermia, degenerative changes in aortic elastin, osteopenia, mental deterioration	Nausea, vomiting, diarrhea, hepatic failure, tremor, mental deterioration, hemolytic anemia, renal dysfunction	10 mg/d (liver toxicity)
Chromium	Impaired glucose tolerance	Occupational: renal failure, dermatitis, pulmonary cancer	ND
Fluoride	↑ Dental caries	Dental and skeletal fluorosis, osteoscleroisis	10 mg/d (fluorosis)
Iodine	Thyroid enlargement, ↓ T_4	Thyroid dysfunction, acne-like eruptions	1100 μg/d (thyroid dysfunction)
Iron	Muscle abnormalities, kilonychia, pica, anemia, ↓ work performance, impaired cognitive development, premature labor, ↑ perinatal maternal mortality	Gastrointestinal effects (nausea, vomiting, diarrhea, constipation), iron overload with organ damage, acute systemic toxicity	45 mg/d of elemental iron (GI side effects)
Manganese	Impaired growth and skeletal development, reproduction, lipid and carbohydrate metabolism; upper body rash	General: Neurotoxicity, Parkinson-like symptoms Occupational: Encephalitis-like syndrome, Parkinson-like syndrome, psychosis, pneumoconiosis	11 mg/d (neurotoxicity)
Molybdenum	Severe neurologic abnormalities	Reproductive and fetal abnormalities	2 mg/d extrapolated from animal data
Selenium	Cardiomyopathy, heart failure, striated muscle degeneration	General: Alopecia, nausea, vomiting, abnormal nails, emotional lability, peripheral neuropathy, lassitude, garlic odor to breath, dermatitis Occupational: Lung and nasal carcinomas, liver necrosis, pulmonary inflammation	400 μg/d (hair, nail changes)
Phosphorous	Rickets (osteomalacia), proximal muscle weakness, rhabdomyolysis, paresthesia, ataxia, seizure, confusion, heart failure, hemolysis, acidosis	Hyperphosphatemia	4000 mg/d
Zinc	Growth retardation, ↓ taste and smell, alopecia, dermatitis, diarrhea, immune dysfunction, failure to thrive, gonadal atrophy, congenital malformations	General: Reduced copper absorption, gastritis, sweating, fever, nausea, vomiting. Occupational: Respiratory distress, pulmonary fibrosis	40 mg/d (impaired copper metabolism)

Note: ND, not determined; GI, gastrointestinal.

superoxide dismutase, and dopamine hydroxylase. As such, copper plays a role in iron metabolism, melanin synthesis, and central nervous system function; the synthesis and cross-linking of elastin and collagen; and the scavenging of superoxide radicals. Dietary sources of copper include shellfish, liver, nuts, legumes, bran, and organ meats.

DEFICIENCY Dietary copper deficiency is relatively rare, although it has been described in premature infants who are fed milk diets and in infants with malabsorption (Table 61-2). Copper deficiency anemia has been reported in patients with malabsorptive diseases and nephrotic syndrome and in patients treated for Wilson's disease with chronic high doses of oral zinc, which can interfere with copper absorption. Menkes kinky hair syndrome is an X-linked metabolic disturbance of copper metabolism characterized by mental retardation, hypocupremia, and decreased circulating ceruloplasmin (Chap. 342). It is caused by mutations in a copper-transporting *ATP7A* gene. Children with this disease often die within 5 years because of dissecting aneurysms or cardiac rupture.

The diagnosis of copper deficiency is usually made on the basis of low serum levels of copper (<65 μg/dL) and low ceruloplasmin levels (<18 mg/dL). Serum levels of copper may be elevated in pregnancy or stress conditions since ceruloplasmin is an acute-phase reactant and 90% of circulating copper is bound to ceruloplasmin.

TOXICITY Copper toxicity is usually accidental (Table 61-2). In severe cases, kidney failure, liver failure, and coma may ensue. In Wilson's disease, mutations in the copper-transporting *ATP7B* gene lead to accumulation of copper in the liver and brain, with low blood levels due to decreased ceruloplasmin (Chap. 339).

SELENIUM

Selenium, in the form of selenocysteine, is a component of the enzyme glutathione peroxidase, which serves to protect proteins, cell membranes, lipids, and nucleic acids from oxidant molecules. Selenocysteine is also found in the deiodinase enzymes, which mediate the deiodination of thyroxine to triiodothyronine (Chap. 320). Rich dietary sources of selenium include seafood, muscle meat, and cereals, although the selenium content of cereal is determined by the soil concentration. Countries with low soil concentrations include parts of Scandinavia, China, and New Zealand. *Keshan disease* is an endemic cardiomyopathy found in children and young women residing in regions of China where dietary intake of selenium is low (<20 μg/d). Concomitant deficiencies of iodine and selenium may worsen the clinical manifestations of cretinism.

CHROMIUM

Chromium potentiates the action of insulin in patients with impaired glucose tolerance, presumably by increasing insulin receptor–mediated signaling. In addition, in some patients, improvement in blood lipid profiles has been reported. The usefulness of chromium supplements in muscle building are not substantiated. Rich food sources of chromium include yeast, meat, and grain products. Chromium in the trivalent state is found in supplements and is largely nontoxic; however, chromium-6 is a product of stainless steel welding and is a known pulmonary carcinogen, as well as causing liver, kidney, and central nervous system damage.

MAGNESIUM

See Chap. 331.

FLUORIDE, MANGANESE, AND ULTRATRACE ELEMENTS

An essential function for *fluoride* in humans has not been described, although it is useful for the maintenance of structure in teeth and bone. Adult fluorosis results in mottled and pitted defects in tooth enamel as well as brittle bone (skeletal fluorosis).

Manganese and molybdenum deficiencies have been reported in patients with rare genetic abnormalities and in a few patients receiving prolonged total parenteral nutrition. Several manganese-specific enzymes have been identified (e.g., manganese superoxide dismutase). Deficiencies of manganese have been reported to result in bone demineralization, poor growth, ataxia, and convulsions.

Ultratrace elements are defined as those needed in amounts <1 mg/d. Essentiality has not been established for most ultratrace elements, although *iodine* is clearly essential (Chap. 320). *Molybdenum* is necessary for the activity of sulfite and xanthine oxidase, and molybdenum deficiency may result in skeletal and brain lesions.

62 MALNUTRITION AND NUTRITIONAL ASSESSMENT

Charles H. Halsted

Malnutrition is a frequent component of acute and chronic illness and is found in ~50% of all hospitalized adults. It contributes to increased in-hospital morbidity and mortality in both medical and surgical patients, and leads to more frequent hospital admissions among the elderly. Malnutrition results from various combinations of starvation, abnormal assimilation of the diet, the stress response of illness, and abnormal nutrient metabolism. Nutritional assessment should be considered an integral part of the clinical evaluation and used as a basis for nutritional support in the overall therapeutic plan.

Two forms of severe malnutrition are recognized under conditions of inadequate food supply or distribution: *marasmus* refers to generalized starvation with loss of body fat and protein, whereas *kwashiorkor* refers to selective protein malnutrition with edema and fatty liver. These distinctions, however, seldom apply to malnourished patients in more developed societies where features of combined protein-calorie malnutrition (PCM) are seen in acute and chronic illnesses. The potential medical consequences of unrecognized malnutrition are depicted in Fig. 62-1.

Patients lose weight when the intake or gastrointestinal assimilation of dietary calories is insufficient to meet normal energy expenditure, the expenditure of body energy stores is greater than energy assimilated by the body, or the metabolism of energy is significantly impaired by the intrinsic disease process. The etiologies of malnutrition can be categorized according to decreased intake or assimilation of diet, increased loss of nutrients from the body, and mixed mechanisms that reflect abnormal nutrient metabolism, as summarized in Table 62-1.

ENERGY BALANCE AND BODY COMPOSITION IN HEALTH AND DISEASE

Energy balance and body weight are sustained in health by the consumption of dietary energy (calories) in an amount equal to the daily expenditure of energy. Simply put, undernutrition results from the intake or absorption of fewer calories than energy spent, and overnutrition represents less expenditure of energy than calories consumed. In healthy individuals, daily total energy expenditure (TEE) is composed of basal or resting energy expenditure (REE, about 60% of total), the thermic cost of digestion (about 10% of total), and modest physical activity (about 30% of total). The REE represents the cost of all intrinsic metabolic reactions and is directly related to the fat-free mass (FFM) of the body. As depicted in Fig. 62-2, the human body stores 15 to 25% of its energy as fat (greater in women than men), which is available for the release of stored fatty acids during starvation. The remaining FFM is composed of extracellular and intracellular water, the bony skeleton, glycogen, and skeletal and visceral protein. Aside from body fat, energy reserves are also provided by intracellular glycogen and protein, which, together with intracellular water, constitute the body cell mass (BCM). Thus, in addition to the enzymes that support the normal metabolic machinery of the body, the BCM provides reserve protein for energy production by gluconeogenesis during the stress response.

The energy stores in a healthy 70-kg man include about 15 kg as fat, 6 kg as protein, and 0.4 kg as glycogen. During a 24-h fast, energy needs are met by the consumption of liver glycogen stores and the conversion by gluconeogenesis of up to 75 g of body protein to glucose. During longer fasting, the REE decreases by as much as 25%

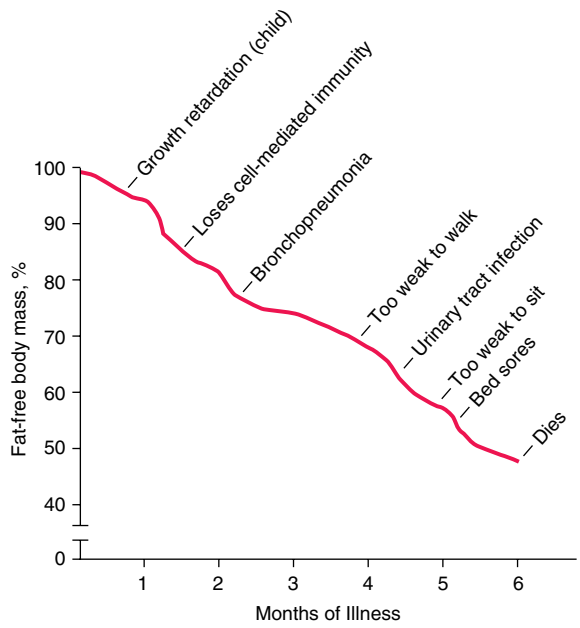

FIGURE 62-1 Hypothetical history of progressive protein-calorie malnutrition in a patient with wasting illness. *(Reproduced with permission from Heymsfield et al.)*

TABLE 62-1 Etiologies of Protein-Calorie Malnutrition

I. Starvation (hypometabolism with reliance on body fat stores)
  A. Decreased diet intake
    1. Social and economic: poverty, chronic alcoholism
    2. Psychiatric: anorexia nervosa, severe depression
    3. Neurodegenerative dementias of aging
    4. Anorexia associated with AIDS, disseminated cancer, renal failure
    5. Abdominal pain triggered by food intake: pancreatitis, intestinal ischemia
  B. Decreased assimilation of the diet
    1. Impaired transit of diet, e.g., benign or malignant esophageal, gastric, or intestinal obstruction
    2. Impaired digestion of diet, e.g., pancreatic insufficiency, short bowel syndrome
    3. Intestinal malabsorption of dietary constituents, e.g., celiac disease
II. Stress (hypermetabolism with reliance on protein stores for gluconeogenesis)
  A. Acute trauma, e.g., accident, burns, major surgery
  B. Acute sepsis
  C. Acute or chronic inflammation: pancreatitis, collagen diseases, chronic infectious disease, e.g., tuberculosis, AIDS opportunistic infections
III. Mixed mechanisms
  A. Futile metabolic cycles and anorexia, e.g., AIDS, disseminated cancer
  B. Increased energy demands, e.g., chronic obstructive pulmonary disease
  C. Abnormal metabolism and decreased biliary digestion, e.g., chronic liver disease
  D. Protein-losing enteropathy and chronic inflammation, e.g., Crohn's disease, ulcerative colitis

and the decreased energy needs are supplied by gluconeogenesis, derived from stores of body fat (about 150 g/d), which provides ketones, and muscle, which provides protein (about 20 g/d). While normal-weight individuals can sustain total fasting for about 2 months, obese individuals can fast for periods >12 months, depending on the size of their fat stores.

The metabolic responses to the stress of acute critical illness (e.g., following accidental or surgical trauma or sepsis) significantly modify energy balance. In contrast to the hypometabolism of starvation, the acute stress response is characterized by hypermetabolism, in which the demands of accelerated energy expenditure are met by skeletal and visceral proteolysis to provide amino acid substrate for gluconeogenesis. Muscle proteolysis and gluconeogenesis are promoted by high levels of circulating catecholamines, glucagon, cortisol, and cytokines, including tumor necrosis factor (TNF) α and interleukins 1 and 6, in the setting of insulin resistance. When untreated, body skeletal muscle and visceral protein catabolism is accelerated to as much as 150 g/d, an amount sufficient to deplete 50% of body protein stores within 3 weeks. In the malnourished patient with chronic illness in whom acute trauma or sepsis superimposes cytokine-mediated proteolysis, progressive PCM is associated with decreased cardiac and renal function, fluid retention, muscle and intestinal mucosal atrophy, loss of intracellular minerals (zinc, magnesium, and phosphorus), diminished cell-mediated immune functions, increased risk of infection, and eventual death (Fig. 62-1).

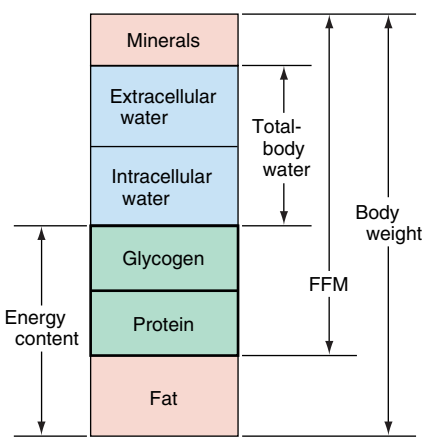

FIGURE 62-2 Schematic of body composition of a healthy subject. Body cell mass (BCM) is shown by shading as a composite of intracellular water, glycogen, and protein. FFM, fat-free mass. *(Adapted with permission from Heymsfield et al.)*

CLINICAL EVALUATION OF THE MALNOURISHED PATIENT

Both outpatients and inpatients are at risk for malnutrition if they meet one or more of the following criteria: (1) unintentional loss of ~10% of usual body weight in the preceding 3 months, (2) body weight <90% of ideal for height, or (3) body mass index [BMI; the weight (kg) divided by the height (m^2)] <18.5. With regard to varying levels of severity, body weight <90% of ideal for height represents risk of malnutrition, body weight <85% of ideal constitutes *malnutrition,* <70% of ideal represents *severe malnutrition,* and <60% of ideal is usually incompatible with survival. An overview of the evaluation of malnutrition in the sick adult is depicted in Fig. 62-3.

THE PATIENT HISTORY The clinical nutritional history is based on understanding the etiologies and pathophysiology of malnutrition and should focus on changes in diet and body weight, socioeconomic conditions, and symptoms unique to each clinical setting (Table 62-2). Social and economic conditions that may lead to poverty and malnutrition include inadequate income, homelessness, drug abuse, or chronic alcoholism. During binge drinking in chronic alcoholics, ethanol typically contributes more than half of daily food calories; ethanol catabolism consumes energy and promotes unbalanced metabolism of fat and carbohydrates. Depending on the severity of injury or illness, critically ill surgical and medical patients predictably develop stress-related PCM if increased nutritional needs are not met after 5 to 10 days. The malnourished patient with digestive disease etiology may complain of dysphagia or recurrent vomiting, chronic diarrhea, or recurrent abdominal pain that is exacerbated by eating. On the general medical service, PCM may be an integral part of the clinical presentation of chronic recurrent pancreatitis, renal failure, chronic liver disease, chronic obstructive pulmonary disease, disseminated cancer, or chronic infections such as AIDS or tuberculosis.

THE PHYSICAL EXAMINATION A careful physical examination can characterize the extent of malnutrition. Measurements of unclothed weight and height are essential for establishing the severity of malnutrition in all patients but may be confounded by the effects of fluid overload as a result of edema and ascites. Normal values of weight for height are shown in Table 62-3. Without recourse to a table, a simplified approach for estimating ideal body weight is to assume 106 lb for 5 ft plus 6 lb per additional inch for men, or 105 lb for 5 ft plus 5 lb per additional inch for women, assuming a range of ±10%.

Specific Physical Findings of Malnutrition During the conventional physical examination, the observant and experienced clinician can identify multiple and specific findings of PCM and its associated micronutrient deficiencies (Chap. 61). A variety of nutritional deficiencies can be identified by examination of the patient's general appearance, including skin, hair, nails, mucus membranes, and neurologic system (Table 62-4). Initially, a pinch of the posterior upper arm may reveal loss of subcutaneous fat in the malnourished patient. Hollowing of the temporal muscles, wasting of upper arms and thigh muscles, easily plucked hair, and peripheral edema are all consistent with protein deficiency. Examination of the skin may reveal the papular keratitis ("goose bump rash") of vitamin A deficiency, perifollicular hemorrhages of vitamin C deficiency, ecchymoses of vitamin K deficiency, the "flaky paint" lower extremity rash of zinc deficiency, hyperpigmentation of skin-exposed areas from niacin deficiency, seborrhea of essential fatty acid deficiency, spooning of nails in iron deficiency, and transverse nail pigmentation in protein deficiency. The eye examination yields conjunctival pallor of anemia, pericorneal and corneal opacities of severe vitamin A deficiency ("Bitot spots"), and nystagmus

and isolated ocular muscle paresis of thiamine deficiency. The oral examination may reveal angular stomatitis and cheilosis of either riboflavin or niacin deficiency; glossitis with smooth and red tongue of riboflavin, niacin, vitamin B_{12}, or pyridoxine deficiency; and hypertrophied bleeding gums of vitamin C deficiency. Examination of the neurologic system, particularly in the setting of chronic alcohol abuse, may detect memory loss with confabulation, a wide-based gait, and past pointing, which, together with ophthalmoplegia and peripheral neuropathy, constitute the Wernicke-Korsakoff syndrome of thiamine deficiency. Other neurologic causes of dementia include pellagra due to niacin and/or tryptophan deficiency. Additional causes of peripheral neuropathy include deficiencies of pyridoxine or vitamin E; loss of distal vibratory and position sense is characteristic of the subacute combined degeneration of vitamin B_{12} deficiency.

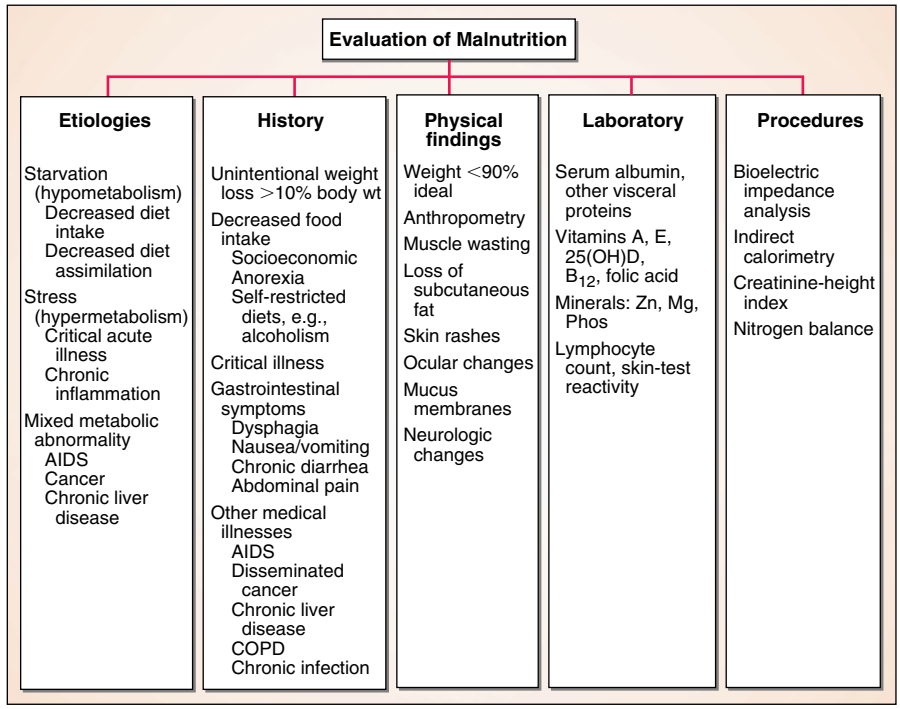

FIGURE 62-3 Conceptual framework for the nutritional assessment of sick patients. COPD, chronic obstructive pulmonary disease.

Anthropometry Measurements of subcutaneous fat and skeletal muscle are important to determine the severity of PCM. Using specialized calipers and a tape measure, anthropometry estimates body fat from the thickness of the skin fold of the posterior mid-upper arm. Anthropometric measurements in healthy and malnourished adults are shown in Table 62-5. Mid-arm muscle circumference is estimated by using the equation:

$$\text{Mid-arm muscle circumference} = \text{mid-upper circumference (cm)} - (\pi \times \text{triceps skin-fold thickness) (cm)}$$

LABORATORY ASSESSMENT Selected use of laboratory tests, most of which are widely available, is essential for characterizing and quantifying malnutrition. Laboratory findings that are often attributed to chronic disease may, in actuality, reflect the response to PCM or selected micronutrient deficiencies in the setting of chronic illness.

Serum Visceral Proteins Serum albumin, which has a 2- to 3-week half-life, is a sensitive but nonspecific measure of PCM. A normal serum albumin level in a well-hydrated patient is inconsistent with PCM. In contrast, a low serum albumin level could reflect PCM, but can also occur because of increased plasma volume in an overhydrated patient, or because of chronic liver, renal, or cardiopulmonary failure. The serum albumin level falls during the acute stress of surgery, sepsis, or other acute inflammatory illness because of a combination of increased circulating extracellular volume and TNF-α-mediated inhibition of albumin synthesis. Several shorter-lived visceral proteins can also be measured to estimate the severity of PCM. These include transferrin (1-week half-life), prealbumin or retinol-binding protein complex (2-day half-life), and fibronectin (1-day half-life).

Vitamins and Minerals Assays (see also Chap. 61) PCM is typically associated with low serum levels of vitamin A, zinc, and magnesium. Abnormal digestion and absorption of dietary fat are associated with deficiencies of fat-soluble vitamins A, D, and E, whereas intestinal mucosal malabsorption (as in celiac disease) is commonly associated with additional deficiencies of iron and folic acid. Chronic alcoholism is frequently associated with thiamine, folate, vitamin A, and zinc deficiencies. Normal ranges for vitamins are listed in the Appendix.

Assessment of Immune Function PCM is associated with atrophy of thymic-dependent lymphoid structures and reduced T cell–mediated immunity. Conversely, B cell–mediated production of immunoglobulins is usually unaffected. Total lymphocyte count (total white cell count $\times$ fraction as lymphocytes) is often $<1000/\mu L$ in PCM and may be accompanied by anergy to common skin test antigens.

SPECIALIZED PROCEDURES FOR NUTRITIONAL ASSESSMENT Several specialized procedures are used to assess energy and protein stores and energy expenditure in malnourished patients. These procedures may be employed during the initial nutritional assessment or may serve as an index of the efficacy of nutritional support during the treatment of malnourished patients.

Bioelectric Impedance Analysis Bioelectric impedance analysis (BIA) is a simplified and portable method for measurement of body fat, FFM,

TABLE 62-2 *The Patient History of Weight Loss and Malnutrition*

Finding	*Example/Interpretation*
Involuntary diet restriction	Poverty due to inadequate income
Anorexia	Anorexia nervosa, severe depression, dementia, AIDS, cancer, chronic renal disease
Inadequate diet selection	Chronic alcoholism, fad diets, strict vegetarianism
Critical illness	Untreated stress response to trauma, burn, major surgery, sepsis
Gastrointestinal symptoms	
Dysphagia	Esophageal obstruction impairs diet transit
Nausea, vomiting	Gastric or intestinal obstruction impairs diet transit
Chronic diarrhea	Pancreatic, biliary, or intestinal mucosal disease impairs digestion and absorption Protein-losing enteropathy in inflammatory bowel disease
Chronic abdominal pain	Self-limited food intake reduces pain: e.g., pancreatitis, intestinal ischemia, inflammatory bowel disease
Other chronic medical diseases	Combinations of anorexia, increased energy demands, and abnormal nutrient metabolism: e.g., recurrent pancreatitis, AIDS, disseminated cancer, chronic liver disease, chronic obstructive pulmonary disease, chronic infectious illness

TABLE 62-3 *Ideal Weight for Height*

Men				Women			
Height[a]	Weight[a]	Height	Weight	Height	Weight	Height	Weight
145	51.9	166	64.0	140	44.9	161	56.9
146	52.4	167	64.6	141	45.4	162	57.6
147	52.9	168	65.2	142	45.9	163	58.3
148	53.5	169	65.9	143	46.4	164	58.9
149	54.0	170	66.6	144	47.0	165	59.5
150	54.5	171	67.3	145	47.5	166	60.1
151	55.0	172	68.0	146	48.0	167	60.7
152	55.6	173	68.7	147	48.6	168	61.4
153	56.1	174	69.4	148	49.2	169	62.1
154	56.6	175	70.1	149	49.8		
155	57.2	176	70.8	150	50.4		
156	57.9	177	71.6	151	51.0		
157	58.6	178	72.4	152	51.5		
158	59.3	179	73.3	153	52.0		
159	59.9	180	74.2	154	52.5		
160	60.5	181	75.0	155	53.1		
161	61.1	182	75.8	156	53.7		
162	61.7	183	76.5	157	54.3		
163	62.3	184	77.3	158	54.9		
164	62.9	185	78.1	159	55.5		
165	63.5	186	78.9	160	56.2		

[a] Values are expressed in cm for height and kg for weight. To obtain height in inches, divide by 2.54. To obtain weight in pounds, multiply by 2.2.

Source: Adapted from GL Blackburn et al: J Parenter Enteral Nutr 1:11, 1977; with permission.

and total-body water. BIA is performed by measuring the electric conductivity of a weak current between electrodes placed on the dorsal surfaces of the hands and feet. The measurement reflects differences in the impedance to electric current, which is greatest through fat and least through water. Lean body mass can be calculated by subtracting fat mass from body weight or by dividing total-body water by 0.73.

Overall, BIA is most useful in assessing body fat and FFM in stable patients and in those who suffer from conditions leading to relative starvation. However, BIA can also be used to assess critically ill patients with decreased intracellular water space and BCM and expanded extracellular compartment size. Reduced BCM correlates inversely with increased metabolic rate. BIA may be confounded in AIDS patients receiving protease-inhibitor therapy, if they exhibit lipodystrophy with associated redistribution of interscapular, abdominal, and breast fat (Chap. 173).

Energy Expenditure The REE is directly proportional to both FFM and BCM and can be estimated in healthy individuals by the Harris and Benedict formula on the basis of weight in kg (W), height in cm (H), and age in years (A):

$$\text{REE (men)} = 66.473 + 13.751(W) + 5.0033\,(H) - 6.7550\,(A)\ \text{kcal/d}$$

$$\text{REE (women)} = 655.0955 + 9.4634(W) + 1.8496\,(H) - 4.6756\,(A)\ \text{kcal/d}$$

However, this equation tends to overestimate REE in obese individuals, and it is unreliable in estimating energy requirements in sick patients who may be hypo- or hypermetabolic. For estimating TEE, i.e., requirements, the REE in the nonexercising sick patient can be calculated by the Harrison and Benedict formula or estimated at 25% kcal/kg of ideal body weight for height, then modified by adding another 10% for digestion and metabolism of intravenous or enteral feeding and an additional 12.5% for each degree of fever over 37°C, as well as an additional multiplier commensurate with the severity of illness (e.g., 25% for general surgery, 50% for sepsis, and 100% for extensive third-degree burns). TEE can be measured at the bedside more precisely by the gas-exchange method of indirect calorimetry using a mobile metabolic cart. This procedure is applicable to ventilator-independent and -dependent patients whose fractional intake of oxygen is <0.45. Because the goal is to reach an accurate approximation of the 24-h energy requirement, measurements must be taken at intervals during the day and must account for several variables, including food intake and activity. To calculate the energy cost of metabolism by indirect calorimetry, the volumes (V) of oxygen consumed and carbon dioxide produced are measured over a given period of time, according to the modified Weir equation where

$$\text{REE} = 3.9\ V_{O_2} + 1.1\ V_{CO_2}$$

Indirect calorimetry also provides the respiratory quotient (RQ), which is the ratio of carbon dioxide produced to oxygen consumed during the process of gas collection. The RQ decreases when fat is the predominant substrate for metabolism (as in starvation) and increases when the contribution of carbohydrate increases (as during stress with gluconeogenesis). In healthy individuals, the RQ usually falls between 0.80 and 0.90. An RQ <0.7 is consistent with active ketogenesis from endogenous fatty acid metabolism with limited generation of carbon dioxide. An RQ >1.0 indicates net lipogenesis, or the conversion of substrate carbohydrate to fat—a situation that occurs with overfeed-

TABLE 62-4 *Physical Findings of Malnutrition*

Finding	Deficiency/Interpretation
General appearance	
Weight loss	Malnutrition <90% of ideal body weight Severe <70% of ideal body weight
Decreased temporal and proximal extremity muscle mass	Decreased skeletal protein
Decreased skin-fold thickness by "pinch test"	Decreased body fat stores
Skin, nails, and hair	
Easily plucked hair	Protein
Easy bruising, perifollicular hemorrhages	Vitamin C
"Flaky paint" rash of lower extremities	Zinc
Coarse skin, "goose bumps"	Vitamin A
Hyperpigmentation of sun-exposed areas	Niacin, tryptophan
Spooning of nails	Iron
Eyes	
Conjunctival pallor	Anemia (nonspecific)
Bitot spot	Vitamin A
Ophthalmoplegia	Thiamine
Mouth and mucus membranes	
Nasolabial seborrhea	Essential fatty acids
Glossitis (smooth, red tongue) and/or cheilosis	Riboflavin, niacin, vitamin B_{12}, pyridoxine, folate
Diminished taste	Zinc
Neurologic system	
Disorientation	Niacin, phosphorus
Confabulation	Thiamine
Cerebellar gait, past pointing	Thiamine
Peripheral neuropathy	Thiamine, pyridoxine, vitamin E
Lost vibratory, position sense	Vitamin B_{12}

TABLE 62-5 *Anthropometric Measurements in Adults*

% Standard	Men	Women	Interpretation
TRICEPS SKIN-FOLD, MM			
100	12.5	16.5	Adequate
50	6.0	8.0	Borderline
20	2.5	3.0	Severe depletion
MID-ARM MUSCLE CIRCUMFERENCE, CM			
100	25.5	23.0	Adequate
80	20.0	18.5	Borderline
60	15.0	14.0	Depletion
40	10.0	9.0	Severe depletion

ing. Values that fall outside the range of 0.65 to 1.25 suggest an error in measurement technique.

Creatinine Excretion in the 24-h Urine Creatinine, the metabolic product of skeletal muscle creatine, is produced at a constant rate and in an amount directly proportional to skeletal muscle mass. With steady-state day-to-day renal function, each gram of creatinine in the 24-h urine collection represents 18.5 g of fat-free skeletal muscle. Since skeletal muscle is the major component of FFM, measurement of creatinine in the 24-h urine collection can be used as a relative measure of this body compartment during the initial assessment or to assess the efficacy of nutritional support. The *creatinine coefficient* represents the amount of creatinine excreted per kilogram of body weight; it is equal to 23 mg/kg of ideal body weight in men and 18 mg/kg of ideal body weight in women. The *creatinine-height index* represents the ratio of the measured 24-h urine creatinine excretion to the value predicted by the creatinine coefficient for the patient's ideal body weight. These values can be calculated from estimation of the patient's ideal body weight according to height (Table 62-3). The constancy of creatinine excretion depends on steady-state renal function and the accuracy of the measurements depends on the reliability of the urine collection. Unpredictable creatinine excretion may occur through feces or skin in patients with serum creatinine levels >530 μmol/L (>6 mg/dL). The presence of ascites does not compromise the accuracy of the 24-h urine creatinine as a reflection of FFM or BCM in patients with chronic liver disease.

Urine Nitrogen Excretion and Nitrogen Balance Nitrogen balance provides an index of protein gain or loss: 1 g nitrogen is equivalent to 6.25 g protein. Nitrogen balance can be assessed by measuring the difference between nitrogen consumed through the mouth, enteral tube, or intravenous sources and nitrogen excreted in the urine, feces, and other intestinal sources. Accurate measurement of nitrogen balance requires complete measurement of nitrogen losses from all possible excretory routes. In most cases, total urine nitrogen can be calculated by dividing 24-h urinary urea nitrogen by 0.85 and assuming approximately 2 g/d for nitrogen losses in feces and sweat. On the other hand, when the clinical condition includes extensive diarrhea and/or protein losses from pancreatic or enterocutaneous fistulas, the accuracy of nitrogen balance requires measurement of total nitrogen by the modified Kjeldahl technique in both urine and enteric sources. Total nitrogen measurements are also advisable in patients with liver failure, where urinary ammonia becomes a major and alternative source of nitrogen.

INTEGRATED BEDSIDE NUTRITIONAL ASSESSMENT Several different approaches have been developed to simplify the process of nutritional assessment by using selective measurements that relate malnutrition to the specific medical condition and the severity of the underlying disease process.

Subjective Global Assessment This approach incorporates historic and physical findings as a basis for nutrition assessment by the trained physician. Major components in the history include evaluation of the extent of recent weight loss, changes in dietary intake, presence of significant gastrointestinal symptoms persisting more than 2 weeks, alterations in functional status, and the metabolic demand of the patient's underlying disease. During the physical examination, emphasis is placed on findings of depletion of subcutaneous body fat; skeletal muscle wasting; typical changes in skin, mucus membranes, and neurologic examination; as well as the presence of edema. Integration of the historic and physical data permits ranking of patients according to the following categories: adequate nutrition, moderate malnutrition, or severe malnutrition. Though the developers of the subjective global assessment have reported good sensitivity and specificity, the approach is still highly dependent on the training and experience of the clinician.

Prognostic Nutritional Assessment Several paradigms have been developed to link different parameters of nutritional assessment with clinical prognosis. Each approach links specific features of malnutrition with certain measurements of cell-mediated immunity, since abnormal immune function is a common pathway for increased risk in the malnourished patient. A surgical prognostic nutritional index predicts morbidity based on preoperative measurements of serum albumin, transferrin, triceps skin-fold thickness, and delayed hypersensitivity to skin-test antigens. Another PCM score links survival in alcoholic liver disease to both skin-fold and mid-arm muscle measurements; the creatinine-height index; values for serum albumin, transferrin, prealbumin, and retinol-binding protein; the total lymphocyte count; and the skin-test response to a series of antigens. The Maastricht index predicts survival in patients with serious gastrointestinal diseases on the basis of factors related to serum albumin, retinol-binding protein, lymphocyte count, and deviation from the patient's ideal body weight.

63 ENTERAL AND PARENTERAL NUTRITION THERAPY

Lyn Howard

Parenteral and enteral nutrition provide life-sustaining therapy for patients who cannot take adequate food by mouth and who consequently are at risk for malnutrition and its effects, including susceptibility to infection, weakness, and immobility; these features predispose the patient to aspiration pneumonia, pulmonary embolism, and pressure sores, all of which delay recovery from illness and increase mortality.

The term *enteral* refers to feeding via the gut and hence includes normal eating, but in the present context implies the infusion of formulas, via a tube, into the upper gastrointestinal tract. *Parenteral* refers to the infusion of nutrient solutions into the bloodstream. Although these are different approaches to nutritional support, their goals are the same.

Where feasible, enteral nutrition (EN) is the preferred route because it sustains the digestive, absorptive, and immunologic barrier functions of the gastrointestinal tract. Several developments have made tube feeding easier and more acceptable to patients. Small-bore pliable tubes have largely replaced large-bore rubber tubes, and double-lumen

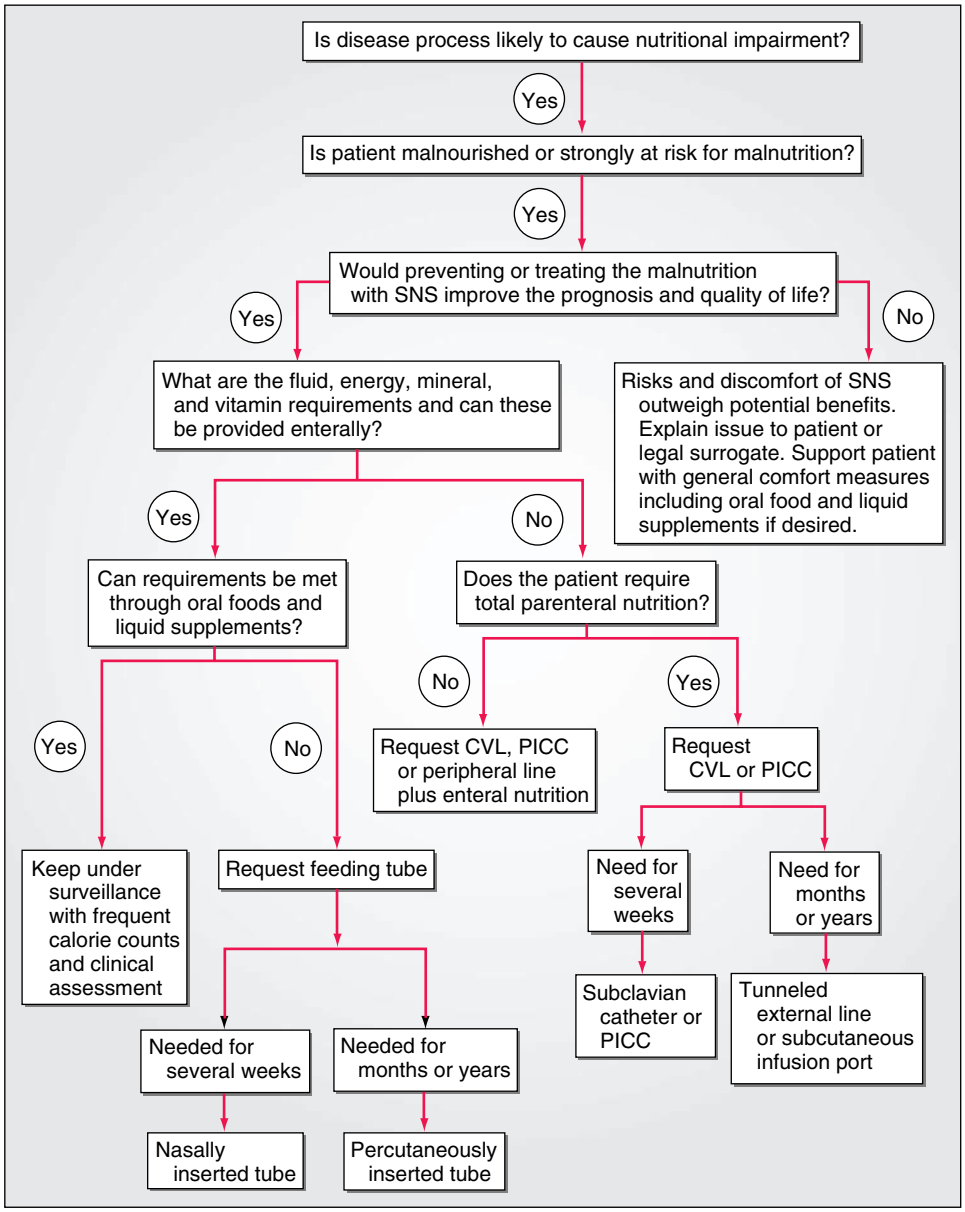

FIGURE 63-1 Should specialized nutrition support (SNS) be undertaken and, if so, how? An algorithm. PICC, peripherally inserted central catheter; CVL, central venous line.

tubes are now available for simultaneous gastric suction and jejunal feeding when there is concern about gastric retention and aspiration. Enteral tubes can be inserted into the stomach or jejunum through the nose or, for long-term use, directly through the abdominal wall, using endoscopic, radiologic, or surgical techniques. Once the enterocutaneous tract is established, a "button" entry port can replace the protruding tube.

Complete nutrition by vein with sufficient calories, amino acids, minerals, and vitamins to permit wound healing, restoration of normal body composition of a cachectic patient, and growth in children became feasible with the development of high-flow central vein catheters. Parental nutrition (PN) is now available in all large hospitals and for some patients at home.

THE DECISION PROCESS FOR USING PARENTERAL OR ENTERAL NUTRITION

The decision to use specialized nutrition support (SNS) should be based on the likelihood that averting or redressing malnutrition will improve the quality of life, or the ability to recover from a serious illness. Approximately 15 to 20% of hospitalized patients have evidence of malnutrition. Some malnourished patients benefit from SNS; for others, wasting is an inevitable component of a terminal disease. A flow diagram of the steps involved in deciding whether SNS should be undertaken and, if so, how, is depicted in Fig. 63-1.

The first step requires consideration of the nutritional implications of the disease process. Is the condition or its treatment likely to impair appetite or food ingestion and absorption for a prolonged period of time? The second step is to determine whether the patient is already sufficiently malnourished that lean body mass is decreased and critical functions such as healing and ventilation are impaired. The presence or absence of metabolic stress should be noted, since injury or infection evokes the secretion of hormonal and cytokine factors that reduce the efficiency of nutrition repletion.

Weight loss without physiologic impairment is probably of no consequence. Physiologic impairment usually develops when more than 20% of body protein is lost and is more likely if key organ systems, such as the gut or liver, are directly affected by disease. Once it is recognized that the patient is malnourished or at major risk, the next question is whether SNS will impact positively on the patient's response to the disease, improving quality of life. While the provision of food and water is part of basic medical care, nutrition delivered by tube, enteral or parenteral, is associated with risk and discomfort and should be recommended only when potential benefit exceeds risk, and undertaken with the consent of the patient. Like all life support measures, these therapies are difficult to withdraw, once started.

If preventing or treating malnutrition with SNS is appropriate, then nutritional requirements must be determined and the route of nutrient delivery should be selected. The route depends primarily on the degree of gut function but somewhat on the technical resources available.

RISKS AND BENEFITS OF SPECIALIZED NUTRITION SUPPORT

The risks are determined primarily by patient factors such as state of alertness and swallowing competence, the route of delivery, and the experience of the supervising clinical team. The safest and least costly approach is to avoid SNS, if possible, by close attention to oral food intake, by adding an oral liquid supplement, or by using medications to stimulate appetite. Nutrient intake is monitored with frequent calorie counts. This more physiologic approach is the most metabolically efficient since normal eating initiates the cephalic phase of digestion. Tube-fed infants grow better if the cephalic phase is stimulated by having the infant suck on a pacifier.

Anorexia, impairment of swallowing, or bowel disease can limit intake and absorption of oral nutrients, in which case tube EN is considered next. The bowel and its associated digestive organs derive 70% of their required nutrients directly from food in the lumen. Glutamine, short-chain fatty acids, and nucleotides may have particular importance in maintaining gut integrity. Enteral feeding also supports gut function by stimulating splanchnic blood flow, neuronal activity, IgA

antibody release, and secretion of gastrointestinal hormones such as epidermal growth factor that stimulate gut trophic activity. All these factors support the gut as an immunologic barrier against enteric pathogens. For these reasons, some luminal nutrition should always be provided, if possible, even when PN is required to provide most of the support. In the past, bowel rest through PN was thought to be the cornerstone of treatment for many severe gastrointestinal disorders, but the value of some EN is now widely accepted, and strict bowel rest is rarely appropriate. PN alone is necessary in severe hemorrhagic pancreatitis, necrotizing enterocolitis, prolonged ileus, and distal bowel obstruction.

SNS is expensive, accounting for >1% of all health care dollars. Consequently, in assessing effectiveness, hard clinical end points, such as mortality rate, incidence of major complications, and duration of hospital stay are required for risk-benefit studies. Better nitrogen balance, increased levels of serum albumin, and improved delayed hypersensitivity are softer end points. Table 63-1 summarizes the current evidence-based evaluation of SNS treatment in disease states. The data are strictly from randomized controlled trials, in many instances combined into meta-analyses. This analysis emphasized that SNS is beneficial primarily for conditions associated with severe protein-calorie malnutrition or when oral intake is interrupted for prolonged periods of time (e.g., >9 days).

A practical consideration is the availability of tube or line placement expertise, especially in critically ill patients. Placement of a central venous catheter is a widely available bedside technique and can be done by specially trained personnel using a peripherally inserted central catheter. While inserting a nasogastric tube is a bedside pro-

TABLE 63-1 *Evidence-Based Evaluation of SNS in Different Disease States*[a]

Disease State	Type of SNS	Comment
Perioperative		
Preoperative	PN	Only beneficial in severe PCM ↓ Postoperative complications 10%
	EN	↓ Postoperative complications ≥25%
Postoperative	PN	↓ Complications and MR if oral intake not resumed in 9 days
	Early EN vs PN	↓ Septic complications with EN if PN calories higher
	EN with CEN	↓ Postoperative complications and hospital stay (CEN: arginine, W_3FA, nucleotides)
Critical illness	PN	Only beneficial in severe PCM ↓ Complications if lipid not used
	Early EN vs PN	↓ Septic complications with EN if PN calories higher
	EN with CEN	Risk ≥ benefit if CEN arginine
Cancer		
Cachexia	PN	Risk ≥ benefit with CXT/RXT; beneficial in cancer surgery in severe PCM
	EN	No clear benefit
BMT	PN/EN	Better long-term survival
	PN with CEN	↓ Early MR, ↓ hospital stay (CEN: glutamine)
	Home PN vs IV hydration	Outcome same; PN associated with less weight loss but delayed oral intake
Liver failure	PN/EN with CEN	Beneficial if encephalopathy prevents adequate protein intake (CEN: ↑ BCAA, ↓ AAA)
Renal failure		
Acute	PN with AA vs PN without AA	PN with AA: ↓ septic complications; EAA or EAA and NEAA equally good
Chronic	Low-protein diet	Did not reduce rate of GFR deterioration
	IDPN	No benefit on MR shown
Pancreatitis	PN	Risk > benefit except in severe pancreatitis
Acute	Early PN vs late PN	Early PN, ↓ MR in severe pancreatitis
	EN vs PN	↓ Septic complications with EN if PN calories higher
Inflammatory bowel disease		
Crohn's	PN vs EN	No benefit from bowel rest
	EN polymeric vs elemental	No difference
	EN vs steroids	EN: slower improvement, shorter remissions
	Exclusion vs regular oral diet	Elimination of foods that induce GI distress prolongs remission
Ulcerative colitis	PN vs oral diet/steroids	No difference
Short bowel syndrome	PN with CEN	hGH and glutamine supplements did not ↑ bowel adaption
Pulmonary disease		
Acute, ventilated	PN/EN	↓ CHO, ↑ fat calories aided weaning process
	EN intermittent vs continuous	No difference in gastric colonization
Chronic	EN gastric vs jejunal	↓ Aspiration, better intake with jejunal
	EN gastric vs postpyloric	No difference in risk of aspiration
HIV disease	PN vs EN	Gain in body cell mass same but PN ↑ fat and water gain; EN led to better physical functioning
	PN vs dietary counseling	No difference in survival after 2 months, but PN led to better functioning

Note: SNS, specialized nutrition support; PN, parenteral nutrition; PCM, protein-calorie malnutrition; MR, mortality rate; Early EN, tube feeding started within 48 h of onset of acute condition; EN, tube feeding; CEN, conditionally essential nutrients; W_3FA, omega 3 fatty acids; CXT, chemotherapy; RXT, radiation therapy; BMT, bone marrow transplant; BCAA, branch chain amino acids; AAA, aromatic amino acids; EAA, essential amino acids; NEAA, nonessential amino acids; IDPN, intradialytic parenteral nutrition; GFR, glomerular filtration rate; hGH, human growth hormone; CHO, carbohydrate.

TABLE 63-2 *Summary of Outcomes for Patients on Home Parenteral and Enteral Nutrition (HPEN)*

Diagnosis	Number in Group	Age in Years	% Survival[a] on Therapy	Therapy Status, % at 1 year[b]			Rehabilitation[c] Status, % in 1st year			Complications[d] per Patient-Year

Cancer	1644	61	30	30	6	59	21	59	21	0.4	2.7

[a] Survival rates on therapy are values at 1 year, calculated by the life table method. This will differ from the percentage listed as died under Therapy Status, since all patients with known end points are considered in this latter measure. The ratio of observed versus expected deaths is equivalent to a Standard Mortality Ratio.
[b] Not shown are those patients who were back in hospital or who had changed therapy type by 12 months.
[c] Rehabilitation is designated complete (C), partial (P), or minimal (M), relative to the patient's ability to sustain normal age-related activity.
[d] Complications refer only to those complications that resulted in rehospitalization.
Source: Derived from North American HPEN Registry.

cedure, many sick patients have impaired gastric emptying, and intragastric feeding increases risk of aspiration pneumonia. Obtaining enteral access to the jejunum usually requires fluoroscopy in an endoscopic or radiologic unit. If a surgical laparotomy is required, a jejunal feeding tube can be placed simultaneously. Studies have shown that such tubes must be beyond the ligament of Treitz to avoid aspiration; an intraduodenal tube is no safer than an intragastric tube.

While most SNS is delivered in hospitals, some patients require SNS on a long-term basis. If they have a safe environment and a willingness to learn the self-care techniques, SNS can be administered at home. The clinical outcome of patients with severe intestinal disorders that use home PN or EN are summarized in Table 63-2. PN infused at home is usually cycled overnight to give greater daytime freedom. Cycling requires a 1-h taper up and down to avoid sudden changes in blood sugar. SNS is not usually appropriate in terminally ill patients but is an option if the patient and family request treatment and quality survival for several months is predicted.

TABLE 63-3 *Estimation of Daily Fluid Requirements*

NORMAL 70-KG MAN

Intake	Output
Normal requirement: 35 × 70 = ~2500 mL/d (derived from oral liquids of 1200 mL, or 5 glasses/cups per day and solid food providing 1300 mL, 1000 mL from water in food, 300 mL from water generated by metabolism of foods)	Urine: 1600 mL/d Insensible loss: 800 mL/d Stool: 100 mL/d [sweat loss can be up to 2 L/d; each degree of fever (C) = 200 mL/d]

TUBE ENTERAL PATIENT

58-kg woman recovering from total gastrectomy for gastric cancer and supported by jejunostomy feedings, taking nothing by mouth or intravenously but experiencing 600 mL of diarrheal losses/day:
Normal requirement 35 × 58 = ~2000 mL/d
Abnormal gastrointestinal loss 600 − 100 = 500 mL/d
Total per tube requirement = 2500 mL/d

PARENTERAL PATIENT

66-kg man with a high jejunostomy following massive bowel resection for Crohn's disease with oral intake of 2000 mL/day and jejunostomy loss of 4000 mL/day:
Normal requirement 35 × 66 = 2300 mL/d
Abnormal gastrointestinal loss (4000 − 100) minus oral intake (2000) = 1900 mL/d
Total parenteral requirement = 4200 mL/d

THE DESIGN OF INDIVIDUAL REGIMENS

FLUID REQUIREMENTS These can be determined by adding the normal daily requirement (120 mL/kg of body weight for infants, 35 mL/kg of body weight for adults) to any abnormal loss. If the patient is on PN or EN, any oral intake should be subtracted from the estimate (Table 63-3). Since abnormal loss of enteric fluid implies significant mineral losses, extra amounts of these nutrients, as well as fluid (Table 63-4), must be added to the SNS formula.

ENERGY REQUIREMENTS (See also Chap. 62) Ultimately, energy expenditure dictates energy requirements, but in the early phase of nutrition repletion, requirements may not reflect expenditure. For example, malnourished patients are hypometabolic and may expend only 85 kJ/kg (20 kcal/kg) per day, but more calories are needed both for tissue repletion and because the metabolic rate increases with refeeding. Conversely, a highly stressed patient (sepsis, trauma) may expend 165 kJ/kg (40 kcal/kg) per day with a significant proportion of the calories coming from protein breakdown and gluconeogenesis and

TABLE 63-4 *Enteric Fluid Volumes and Their Sodium, Potassium, Chloride, and Bicarbonate Content*[a]

	L/d[b]	Na, mmol/L	K,[c] mmol/L	Cl, mmol/L	HCO_3,[d] mmol/L
Oral intake	2–3				
Enteric secretions					
Saliva	1–2	10	30	10	30
Gastric juice	2	60	9	90	0
Bile	2–3	150	10	90	70
Small bowel	1	100	5	100	20
Colon	Variable	40	100	15	60

[a] Enteric secretions are also rich in divalent cations (Ca, Mg, Zn, Cu), and their loss is increased by steatorrhea, a high bowel fistula, or prolonged suction.
[b] Of the 9 L/d of oral and enteric fluid presented to the upper small bowel, normally 50% is absorbed in the jejunum, 40% in the ileum, and 10% in the colon. In short bowel patients, the colon may absorb greater amounts, up to 3 L/d.
[c] Potassium losses are small except in secretions distal to the ileocecal valve. The colon ion exchange is partly controlled by aldosterone, and therefore, Na^+ depletion increases K^+ loss in the stool.
[d] Bicarbonate losses must be replaced in parenteral solutions as acetane or lactate because of potential precipitation of bicarbonate with ingredients such as calcium.

from catecholamine-induced lipolysis. Oxidation of exogenous glucose plateaus at 100 kJ/kg (25 kcal/kg) per day, and administering a higher glucose load induces hepatic steatosis. Providing such patients with additional calories as exogenous fat does not suppress endogenous lipolysis. Furthermore, lipid solutions are made from vegetable oil and egg phospholipid and lack apoproteins, which they acquire from endogenous lipoproteins. Initially, the artificial chylomicron is taken up by the reticuloendothelial system, causing potential blockade. For all these reasons, modest hypocaloric glucose feeding with minimal parenteral fat is safer in the acutely stressed subject.

TABLE 63-6 *Central Venous Access for Parenteral Nutrition*

Type of Catheters	Advantages	Disadvantages
Peripherally inserted central catheter Single lumen Double lumen	Insertion cost low; can be done at bedside or by vascular radiology using Doppler guidance; especially advantageous for patients with neck wounds such as tracheostomies	High incidence of skin site irritation; tendency to break at hub; home patient requires assistance with weekly dressing change
Centrally inserted externalized catheter (subclavian, jugular, femoral) Single lumen Multilumen	Can be inserted at bedside; relatively low cost; can be changed over a guidewire if clinically indicated: best site subclavian > jugular > femoral vein	10% incidence of mechanical complication with insertion, higher if physician inexperienced; need dedicated nutrition line; multiple-lumen catheters have increased sepsis rate
Centrally inserted, tunneled catheter or subcutaneous port	More stable for long-term use; when needle out, patients with ports have less disturbance of body image and can shower and swim without risk	More expensive device requiring operating room insertion; ports require needle stick.

Parenteral lipid solutions are available as 10 or 20% isotonic solutions and are infused separately from amino acids and glucose or as a combined "three-in-one solution," obviating the need for an extra pump. Three-in-one PN solutions are less stable, and destabilized fat particles may coalesce into larger droplets, becoming fat emboli. For this reason, three-in-one solutions have a shorter storage life and must be mixed by a pharmacist who is knowledgeable about correct mixing sequence and safe levels of electrolytes and trace elements. Iron, for example, cannot be added to this solution.

Polyunsaturated vegetable oils are used in most enteral formulas because a diseased gastrointestinal tract absorbs them better than animal fat. Median-chain triglycerides (c8–12) may be added because of their simpler absorption. Though fat must supply the long-chain essential fatty acids (1 to 4% of energy from linoleic and linolenic acid) (Table 63-5), larger amounts (30% of energy) are safe in relatively stable patients and avoid the hazard of providing large amounts of carbohydrate calories (e.g., hyperglycemia and hepatic steatosis). Substituting omega-3 polyunsaturated fish oils for polyunsaturated vegetable fats may blunt the catabolic response to burn injury, trauma, and radiation by reducing the synthesis of prostaglandins that enhance the inflammatory response. Such fats are currently available in enteral formulas and are being tested in parenteral formulas.

Carbohydrate usually provides 60 to 70% of all calories and is provided as glucose [monohydrous dextrose, 14 kJ/g (3.4 kcal/g)] in parenteral solutions and as disaccharides (sucrose) and oligosaccharides (starch fragments) in enteral formulas to maximize absorption while limiting the intraluminal osmolar load. Fructooligosaccharides have been shown to promote normal gut flora.

PROTEIN OR AMINO ACID REQUIREMENTS The recommended dietary protein allowance of 0.8 g/kg per day is adequate for nonstressed patients, such as a starved patient with a high-grade esophageal stricture. Catabolic patients, in contrast, may require up to 1.5 g/kg per day of protein to induce positive nitrogen balance and reconstitute normal lean body mass. Early studies showed that recombinant human growth hormone increases lean body mass. However, subsequent trials have

TABLE 63-5 *Daily Enteral and Parenteral Requirements of Essential Fatty Acids, Minerals, and Vitamins*

	Daily Requirement, Adult Range	
Nutrient	Enteral	Parenteral
Essential fatty acids, % kcal	1–2	2–4
Calcium, g	0.8–1.2	0.2–0.4 (10–20 mmol)
Phosphorus, g	0.8–1.2	0.4–0.8
Potassium, g	2–5	3–4 (75–100 mmol)
Sodium, g	1–3	1–3 (50–150 mmol)
Chloride, g	2.5–5	3–4[a] (100–130 mmol)
Magnesium, g	0.3	0.3 (20 mmol)
Iron, mg	10	1–2
Zinc, mg	15	3–12
Copper, mg	2–3	0.3–0.5
Iodine, mg	0.15	0.15
Manganese, mg	2–5	2–5
Chromium, μg	50–200	15–30
Molybdenum, μg	150–300	20–120
Selenium, μg	50–200	50–100
Ascorbic acid, mg	60	100
Thiamine, mg	1.4	3.0
Riboflavin, mg	1.6	3.6
Niacin, mg	18	40
Biotin, μg	60	60
Pantothenic acid, mg	5	15
Pyridoxine, mg	2.0	4.0
Folic acid, μg	400	400
Cobalamin, μg	3.0	5
Vitamin A, μg	1000	1000
Vitamin D, μg	10	5–10
Vitamin E, mg	8–10	10–15
Vitamin K, μg	70–140	200

[a] In addition to chloride anions there is a parenteral requirement for bicarbonate equivalents to protect normal acid-base balance. These are provided as 100 mmol or more per day of acetate or lactate because of potential precipitation of bicarbonate with ingredients such as calcium.

TABLE 63-7 *Monitoring the Patient on Total Parenteral Nutrition*

CLINICAL DATA MONITORED DAILY	
Sense of well-being: symptoms suggesting fluid overload, high or low blood glucose, electrolyte imbalance, etc.	
Strength as judged by graded activity: getting out of bed, walking, stair climbing	
Vital signs: temperature, blood pressure, pulse rate, and respiratory rate	
Fluid balance: weight; fluid input (intravenous +/− enteral) vs fluid output (urine, stool, gastric suction, etc.)	
Delivery equipment for parenteral nutrition: tubing, pump, filter, catheter, dressing (skin checked for local infection at time of dressing change)	
Composition of nutrient solution	
LABORATORY DATA	
Finger stick glucose	Three times daily until patient stable
Blood glucose Na, K, Cl, HCO_3 Blood urea nitrogen	Daily until glucose infusion load and patient stable, then twice weekly
Liver function studies Serum creatinine, albumin PO_4, Ca, Mg Hb/Hct, WBC	Baseline, then twice weekly
INR	Baseline, then weekly
Micronutrient tests	As indicated

Note: Hb, hemoglobin; Hct, hematocrit; WBC, white blood cell (count); INR, international normalized ratio.

TABLE 63-8 *Complications of Total Parenteral Nutrition (TPN)*

First 48 h	First 2 Weeks	3 Months Onward
MECHANICAL		
Complications from catheter insertion: Cephalad displacement Pneumothorax Hemothorax Detachment of line at catheter hub with blood loss or air embolism	Catheter coming out of vein, more common if Silastic Detachment of line at catheter hub with blood loss or air embolism Thrombosis	Detachment of line at catheter hub with blood loss or air embolism Fractures or tears in catheter Catheter embedded in vein wall
METABOLIC		
Fluid overload Hyperglycemia Hypophosphatemia Hypokalemia	Cardiopulmonary failure Refeeding edema Hyperosmolar nonketotic hyperglycemic coma Acid-base imbalance Electrolyte imbalance	Essentially fatty acid deficiency Iron deficiency Vitamin deficiencies TPN metabolic bone disease TPN liver disease Zinc, copper, chromium, selenium, molybdenum, deficiency
INFECTIOUS		
	Catheter-induced sepsis Exit site infection	Catheter-induced sepsis Tunnel infections Exit site infection

TABLE 63-9 *Enteral Feeding Tubes*

Type/Insertion Technique	Clinical Uses	Potential Complications
NASOGASTRIC TUBE		
External measurement: nostril, ear, xiphisternum; tube stiffened by ice water or stylet; position verified by injecting air and auscultating, aspirating gastric acid, or by x-ray	Short-term clinical situation (weeks) or longer periods with intermittent insertion; bolus feeding simpler, but continuous drip with pump better tolerated	Aspiration; ulceration of nasal and esophageal tissues, leading to stricture
NASOJEJUNAL TUBE		
External measurement: nostril, ear, anterior superior iliac spine (medical malleolus in infants); tube stiffened by stylet and passed through pylorus under fluoroscopy or with endoscopic loop	Short-term clinical situations where gastric emptying impaired or proximal leak suspected; requires continuous drip with pump	Spontaneous pulling back into stomach (position verified by aspirating content, pH > 6); diarrhea common, fiber-containing formula may help
GASTROSTOMY TUBE		
Percutaneous placement endoscopically, radiologically, or surgically: after tract established, can be converted to a gastric "button"	Long-term clinical situations, swallowing disorders, or impaired small-bowel absorption requiring continuous drip	Aspiration; irritation around tube exit site; peritoneal leak; balloon migration and obstruction of pylorus
JEJUNOSTOMY TUBE		
Percutaneous placement endoscopically or radiologically via pylorus or endoscopically or surgically directly into the jejunum	Long-term clinical situations where gastric emptying impaired; requires continuous drip with pump; direct endoscopic placement (PEJ) is the most comfortable for the patient	Clogging or displacement of tube; jejunal fistula if large-bore tube used; diarrhea from dumping; irritation of surgical anchoring suture
COMBINED GASTROJEJUNOSTOMY TUBE		
Percutaneous placement endoscopically, radiologically, or surgically; intragastric arm for continuous or intermittent gastric suction; jejunal arm for enteral feeding	Used for patients with impaired gastric emptying and at high risk for aspiration or patients with acute pancreatitis or proximal leaks	Clogging: especially of small bore jejunal tube

Note: All small tubes are at risk for clogging, especially if used for crushed medications. In long-term enteral nutrition patients, gastrostomy and jejunostomy tubes can be exchanged for a low-profile "button" once the tract is established.

shown an association with increased mortality in critically ill patients.

In a stable patient the adequacy of protein support can be assessed acutely by analyzing protein balance:

$$\text{Protein balance} = \text{protein intake} - \text{protein loss}$$

where protein loss = [(24-h urine urea nitrogen (g) + 4) × 6.25]. Over a long period, protein balance is assessed by documenting wound healing, restoration of normal body composition, or resumption of longitudinal growth. In states of disturbed protein utilization (e.g., renal and hepatic failure), azotemia and abnormal plasma amino acid patterns develop. The benefit of special enteral and parenteral solutions that correct these aberrations is only established in hepatic encephalopathy (Table 63-1).

When amino acids are infused systemically, rather than via the more physiologic portal vein, methionine, the only sulfur-containing amino acid in most parenteral solutions, is transaminated in peripheral tissues rather than transulfurated in the liver. As a result, downstream sulfur products such as carnitine, taurine, and glutathione become relatively deficient. Preliminary studies suggest that the addition of an intermediate compound, *S*-adenosyl methionine, to parenteral solutions reduces cholestasis. In enteral formulas, protein is provided either as a complete protein with high biologic value and low immunogenicity, such as egg albumin or casein, or as partially hydrolysed short oligopeptides. Studies have shown that while amino acid transport mechanisms are defective with inflamed gastrointestinal mucosa, peptide absorption remains normal.

MINERAL AND VITAMIN REQUIREMENTS

Parenteral and enteral mineral and vitamin requirements are summarized in Table 63-5. Electrolyte modifications are necessary if the patient has significant gastrointestinal losses (Table 63-4) or renal failure. Requirements of some minerals and vitamins are higher when administered parenterally rather than enterally for several reasons: (1) many micronutrients delivered into the systemic rather than the portal circulation are not captured by the liver and instead pass directly into the urine; (2) patients with bowel disease often have increased enteric loss of sodium, potassium, chloride, and bicarbonate and malabsorption of divalent cations, fat-soluble vitamins, and vitamin B_{12}; and (3) nutrients may adhere to the tubing and delivery bags, and exposure to oxygen and light may destroy vitamins (particularly vitamin A).

PARENTERAL NUTRITION

INFUSION TECHNIQUE AND PATIENT MONITORING Partial and short-term PN can be provided via a peripheral vein if the majority of the energy is supplied by isotonic fat solutions; long-term PN using glucose as the chief energy source requires administration via a central vein catheter so the hypertonic solution is rapidly diluted in a high-flow system. The preferred site for central vein infusion is the superior vena cava. Access sites and catheter choices are summarized in Table 63-6. Peripherally inserted central catheters are the most economical option for short-term PN. Tunneled catheters and implanted subcutaneous ports require operating room insertion but are more stable for long-term use. Central catheters should be changed when clinically indicated; routine changes are costly and hazardous. Chlorhexidine solution is a more effective local antiseptic than iodophor or alcohol. Although transparent dressings are helpful in stabilizing catheters and allow easy observation of the skin site, the incidence of catheter-related sepsis is higher than with traditional dry gauze dressings; newer transparent dressings that trap less moisture are under investigation. Catheters made from Silastic material or polyurethane are associated with lower complications than polyvinylchloride catheters. Several types of needleless systems use hub valves, and while inadvertent needle sticks are prevented, contamination rates are higher with these devices used for long-term PN. Appropriate clinical and laboratory monitoring for patients on parenteral nutrition is summarized in Table 63-7.

TABLE 63-10 *Enteral Formulas*

Composition Characteristics	*Clinical Indications*
STANDARD ENTERAL FORMULA	
1. Complete dietary products (+)[a] a. Caloric density 1 kcal/mL b. Protein ~14% cals, caseinates, soy, lactalbumin c. Fat ~30% cals, corn, soy, safflower oils d. CHO ~60% cals, hydrolysed corn starch, maltodextrin, sucrose e. Recommended daily intake of all minerals and vitamins in >1500 kcal/d f. Osmolality (mosmol/kg): ~300	Suitable for most patients requiring tube feeding; flavors available for oral use
MODIFIED ENTERAL FORMULAS	
1. Caloric density 1.5–2 kcal/mL (+)	Fluid-restricted patients
2. a. High protein ~20% cals (+)	Protein malnutrition and ↓ wound healing
b. Hydrolysed protein to small peptides (++)	↓ Protein digestion/absorption or allergy
c. ↑ Glutamine, arginine, *S*-containing amino acids, nucleotides (+++)	Severely immunocompromised patients
d. ↑ Branch-chain amino acids, ↓ aromatic amino acids (+++)	Liver failure patients intolerant of 0.8 g/kg per day of regular protein
e. Low protein of high biologic value	Renal failure patients
3. a. Low fat, partial MCT substitution (+)	Fat malabsorption
b. ↑ Fat >40% cals (++)	Pulmonary failure with ↑ P_{CO_2} on standard formulas
c. ↑ Fat from MUFA (++)	Poorly controlled diabetes mellitus
d. Fat ↑ in w3 (fish oil) and ↓ w6 (+++)	Immunocompromised and autoimmune disorder
4. a. Fiber provided as soy polysaccharide (+)	Diarrhea/constipation
b. Fiber provided as blenderized fruits and vegetables (++)	↓ Binding of dilantin
5. ↑ Minerals (Zn) and vitamins (A and C) (++)	Decubitus ulcers

[a] Cost: + inexpensive; ++ moderately expensive; +++ very expensive.
Note: CHO, carbohydrate; MCT, medium-chain triglyceride; MUFA, monounsaturated fatty acids; w3 or w6, polyunsatuated fat with first double bond at carbon 3 (fish oils) or carbon 6 (vegetable oils).

COMPLICATIONS ■ Mechanical The insertion of a central venous catheter should be performed only by trained personnel, using an aseptic technique. The correct catheter position must be confirmed by x-ray before hypertonic nutrient solution is infused. Insertion complications are listed in Table 63-8. Catheter thrombosis may occur, especially if the catheter is used for withdrawing blood samples, and extension of the thrombosis to the central vein is frequently coincident with infection. Thrombosed catheters can sometimes be unblocked by thrombolytic agents. The addition of heparin (1000 U/L) to the PN solution to prevent thrombosis is controversial; no randomized, controlled studies demonstrate benefit, and heparin can contribute to loss of bone mineral, which is already a problem with long-term PN. Low-dose oral warfarin (1 mg/d), which does not alter prothrombin time, has been shown to reduce catheter thrombosis.

Metabolic Fluid overload can cause congestive heart failure, particularly in elderly and debilitated patients. Glucose overload can cause an osmotic diuresis or stimulate insulin secretion, which in turn promotes extracellular to intracellular shifts of potassium and phosphorous. Such shifts are most dangerous in cachectic patients with depletion of potassium and phosphorus stores and can cause arrhythmias, cardiopulmonary dysfunction, and neurologic symptoms. To avoid these problems, PN should be started slowly and monitored carefully. Glucose content is increased gradually as the patient demonstrates tolerance of the high glucose load. Late metabolic complications include cholestatic liver disease, with bile sludging and gallstone formation. The exact cause of the liver disease is not understood, but lack of enteral stimulation to bile flow and defective sulfur amino acid metabolism and cholesterol solubilization appear to play a role. Cholestasis is less likely to occur if some enteral feeding is maintained. PN induces hypercalciuria and can result in negative calcium balance and osteopenia. Once patients on long-term PN change to sustained anabolism, deficiencies of micronutrients such as essential fatty acids, trace minerals, and vitamins may develop unless they are supplied in adequate amounts (Table 63-5).

Infectious Infection of the access line rarely occurs in the first 72 h, and fever during this period is usually due to infection elsewhere or some other cause. Infection of the access line should be suspected if the fever defervesces when the infusion of the parenteral formula is tapered.

Positive central line and peripheral blood cultures suggest catheter sepsis, if no other infectious source is identified. *Staphylococcus epidermidis* infection can often be cleared (80 to 90% of the time) without catheter removal. To improve the chances of clearing the line, the biofilm from the internal surface is removed by thrombolytic treatment and antibiotics are given through the catheter and left as a "lock" in the catheter for several hours. *S. aureus* or fungal infections require catheter removal to prevent life-threatening metastatic spread. Catheter sepsis rates are similar in single-lumen central lines dedicated to PN whether inserted peripherally, via the subclavian vein, or tunneled; multiple-lumen catheters are associated with a greater incidence of sepsis. Although there is no evidence to support the use of prophylactic antibiotics, recurrent catheter sepsis may be avoided if small amounts of an antibiotic solution are left in the line, along with a heparin lock.

ENTERAL NUTRITION

TUBE PLACEMENT AND PATIENT MONITORING The types of enteral feeding tubes, methods of insertion, their clinical uses, and potential complications are outlined in Table 63-9. The different types of enteral formulas are listed in Table 63-10. Patients on enteral feeding are at risk for many of the same metabolic complications as those who receive PN and should be monitored in the same manner (Table 63-7). Since small-bore tubes are easily displaced, tube position should be checked

at intervals by aspirating and measuring the pH of the gut fluid (<4 in stomach, >6 in jejunum).

COMPLICATIONS ■ Aspiration The debilitated patient with poor gastric emptying and impairment of swallowing and cough mechanisms is at risk for aspiration; this is particularly so for those who are on respirators. Tracheal suctioning induces coughing and gastric regurgitation, and cuffs on endotracheal or tracheostomy tubes seldom protect against aspiration. Under these circumstances, it may be safer to institute jejunal feeding. A continuous gastric drip is better tolerated in sick patients than intermittent bolus feeding; a drip is essential for intrajejunal feeding.

Diarrhea Enteral feeding often causes diarrhea, especially if bowel function is compromised by disease or drugs, particularly broadspectrum antibiotics. Diarrhea may be controlled by the use of a continuous drip, with a fiber-containing formula or by adding an anticholinergic medication to the formula. Diarrhea associated with enteral feeding does not necessarily imply inadequate absorption of nutrients, other than water and electrolytes. Since luminal nutrients exert trophic effects on the gut mucosa and enhance the enteric immunologic barrier, it is often appropriate to persist with tube feeding, despite the diarrhea, even when this necessitates supplemental parenteral fluid support.

THE SCOPE AND COST OF NUTRITION SUPPORT

As many as 25% of patients entering tertiary care hospitals have central catheters placed, and 20 to 30% of these catheters are used for parenteral nutrition. The incidence of catheter-related infection reflects the severity of the underlying medical condition and varies from 2 to 30 per thousand catheter days, depending on the type of patients involved. In critically ill patients, catheter sepsis is associated with a 35% mortality rate and a high cost per survivor. Most catheter-related complications derive from faulty insertion and management of the catheter rather than defects in the device. In large tertiary care hospitals, the insertion and management of these lines by specially trained teams can reduce complications by 80%, impacting significantly on outcome and costs. The growing shift from parenteral to enteral nutrition may produce cost savings, but the true cost of complex enteral feeding is not known. Home PN costs approximately half as much as similar treatment in the hospital, and home EN costs significantly less.

64 OBESITY

Jeffrey S. Flier, Eleftheria Maratos-Flier

In a world where food supplies are intermittent, the ability to store energy in excess of what is required for immediate use is essential for survival. Fat cells, residing within widely distributed adipose tissue depots, are adapted to store excess energy efficiently as triglyceride and, when needed, to release stored energy as free fatty acids for use at other sites. This physiologic system, orchestrated through endocrine and neural pathways, permits humans to survive starvation for as long as several months. However, in the presence of nutritional abundance and a sedentary lifestyle, and influenced importantly by genetic endowment, this system increases adipose energy stores and produces adverse health consequences.

DEFINITION AND MEASUREMENT *Obesity* is a state of excess adipose tissue mass. Although often viewed as equivalent to increased body weight, this need not be the case—lean but very muscular individuals may be overweight by arbitrary standards without having increased adiposity. Body weights are distributed continuously in populations, so that a medically meaningful distinction between lean and obese is somewhat arbitrary. Obesity is therefore more effectively defined by assessing its linkage to morbidity or mortality.

Although not a direct measure of adiposity, the most widely used method to gauge obesity is the *body mass index* (BMI), which is equal to weight/height^2 (in kg/m^2) (Fig. 64-1). Other approaches to quantifying obesity include anthropometry (skin-fold thickness), densitometry (underwater weighing), computed tomography (CT) or magnetic resonance imaging (MRI), and electrical impedance. Using data from the Metropolitan Life Tables, BMIs for the midpoint of all heights and frames among both men and women range from 19 to 26 kg/m^2; at a similar BMI, women have more body fat than men. Based on unequivocal data of substantial morbidity, a BMI of 30 is most commonly used as a threshold for obesity in both men and women. Large-scale epidemiologic studies suggest that all-cause, metabolic, cancer, and cardiovascular morbidity begin to rise (albeit at a slow rate) when BMIs are ≥ 25, suggesting that the cut-off for obesity should be lowered. Some authorities use the term *overweight* (rather than obese) to describe individuals with BMIs between 25 and 30. A BMI between 25 and 30 should be viewed as medically significant and worthy of therapeutic intervention, especially in the presence of risk factors that are influenced by adiposity, such as hypertension and glucose intolerance.

The distribution of adipose tissue in different anatomic depots also has substantial implications for morbidity. Specifically, intraabdominal and abdominal subcutaneous fat have more significance than subcutaneous fat present in the buttocks and lower extremities. This distinction is most easily made by determining the waist-to-hip ratio, with a ratio >0.9 in women and >1.0 in men being abnormal. Many of the most important complications of obesity, such as insulin resistance, diabetes, hypertension, and hyperlipidemia, and hyperandrogenism in women, are linked more strongly to intraabdominal and/or upper body fat than to overall adiposity. The mechanism underlying this association is unknown but may relate to the fact that intraabdominal adipocytes are more lipolytically active than those from other depots. Release of free fatty acids into the portal circulation has adverse metabolic actions, especially on the liver.

PREVALENCE Data from the National Health and Nutrition Examination Surveys (NHANES) show that the percent of the American adult population with obesity (BMI > 30) has increased from 14.5% (between 1976 and 1980) to 30.5% (between 1999 and 2000). As many as 64% of U.S. adults ≥20 years of age were overweight (defined as BMI > 25) between the years of 1999 and 2000. Extreme obesity (BMI ≥ 40) has also increased and affects 4.7% of the population. The increasing prevalence of medically significant obesity raises great concern. Obesity is more common among women and in the poor; the prevalence in children is also rising at a worrisome rate.

PHYSIOLOGIC REGULATION OF ENERGY BALANCE Substantial evidence suggests that body weight is regulated by both endocrine and neural components that ultimately influence the effector arms of energy intake and expenditure. This complex regulatory system is necessary because even small imbalances between energy intake and expenditure will ultimately have large effects on body weight. For example, a 0.3%

positive imbalance over 30 years would result in a 9-kg (20-lb) weight gain. This exquisite regulation of energy balance cannot be monitored easily by calorie-counting in relation to physical activity. Rather, body weight regulation or dysregulation depends on a complex interplay of hormonal and neural signals. Alterations in stable weight by forced overfeeding or food deprivation induce physiologic changes that resist these perturbations: with weight loss, appetite increases and energy expenditure falls; with overfeeding, appetite falls and energy expenditure increases. This latter compensatory mechanism frequently fails, however, permitting obesity to develop when food is abundant and physical activity is limited. A major regulator of these adaptative responses is the adipocyte-derived hormone leptin, which acts through brain circuits (predominantly in the hypothalamus) to influence appetite, energy expenditure, and neuroendocrine function (see below).

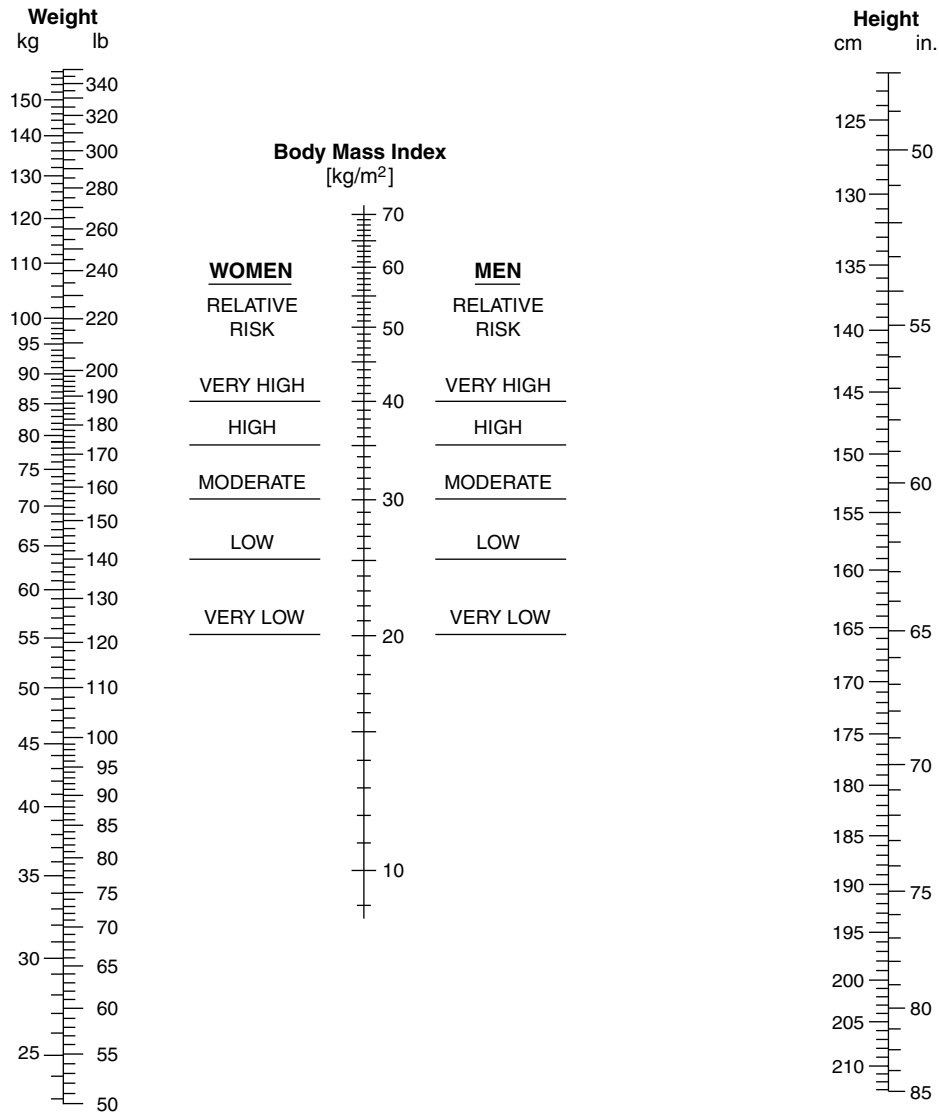

FIGURE 64-1 Nomogram for determining body mass index. To use this nomogram, place a ruler or other straight edge between the body weight (without clothes) in kilograms or pounds located on the left-hand line and the height (without shoes) in centimeters or inches located on the right-hand line. The body mass index is read from the middle of the scale and is in metric units. (*Copyright 1979, George A. Bray, M.D. Used with permission.*)

Appetite is influenced by many factors that are integrated by the brain, most importantly within the hypothalamus (Fig. 64-2). Signals that impinge on the hypothalamic center include neural afferents, hormones, and metabolites. Vagal inputs are particularly important, bringing information from viscera, such as gut distention. Hormonal signals include leptin, insulin, cortisol, and gut peptides such as ghrelin, peptide YY (PYY), and cholecystokinin, which signal to the brain through direct action on hypothalamic control centers and/or via the vagus nerve. Metabolites, including glucose, can influence appetite, as seen by the effect of hypoglycemia to induce hunger; however, glucose is not normally a major regulator of appetite. These diverse hormonal, metabolic, and neural signals act by influencing the expression and release of various hypothalamic peptides [e.g., neuropeptide Y (NPY), Agouti-related peptide (AgRP), α melanocyte-stimulating hormone (α-MSH), and melanin-concentrating hormone (MCH)] that are integrated with serotonergic, catecholaminergic, and opioid signaling pathways (see below). Psychological and cultural factors also appear to play a role in the final expression of appetite. Apart from rare syndromes involving leptin, its receptor, and the melanocortin system, specific defects in this complex appetite control network that influence common causes of obesity are not well understood.

Energy expenditure includes the following components: (1) resting or basal metabolic rate; (2) the energy cost of metabolizing and storing food; (3) the thermic effect of exercise; and (4) adaptive thermogenesis, which varies in response to chronic caloric intake (rising with increased intake). Basal metabolic rate accounts for about 70% of daily energy expenditure, whereas active physical activity contributes 5 to 10%. Thus, a significant component of daily energy consumption is fixed.

Genetic models in mice indicate that mutations in certain genes (e.g., targeted deletion of the insulin receptor in adipose tissue) protect against obesity, apparently by increasing energy expenditure. Adaptive thermogenesis occurs in *brown adipose tissue* (BAT), which plays an important role in energy metabolism in many mammals. In contrast to white adipose tissue, which is used to store energy in the form of lipids, BAT expends stored energy as heat. A mitochondrial *uncoupling protein* (UCP-1) in BAT dissipates the hydrogen ion gradient in the oxidative respiration chain and releases energy as heat. The metabolic activity of BAT is increased by a central action of leptin, acting through the sympathetic nervous system, which heavily innervates this tissue. In rodents, BAT deficiency causes obesity and diabetes; stimulation of BAT with a specific adrenergic agonist (β_3 agonist) protects against diabetes and obesity. Although BAT exists in humans (especially neonates), its physiologic role is not yet established. Homologues of UCP-1 may mediate uncoupled mitochondrial respiration in other tissues.

THE ADIPOCYTE AND ADIPOSE TISSUE Adipose tissue is composed of the lipid-storing adipose cell and a stromal/vascular compartment in which preadipocytes reside. Adipose mass increases by enlargement of adipose cells through lipid deposition, as well as by an increase in the number of adipocytes. The process by which adipose cells are derived from a mesenchymal preadipocyte involves an orchestrated series of differentiation steps mediated by a cascade of specific transcription factors. One of the key transcription factors is *peroxisome proliferator-activated receptor* γ (PPARγ), a nuclear receptor that binds the thiazoladinedione class of insulin-sensitizing drugs used in the treatment of type 2 diabetes (Chap. 323).

Although the adipocyte has generally been regarded as a storage

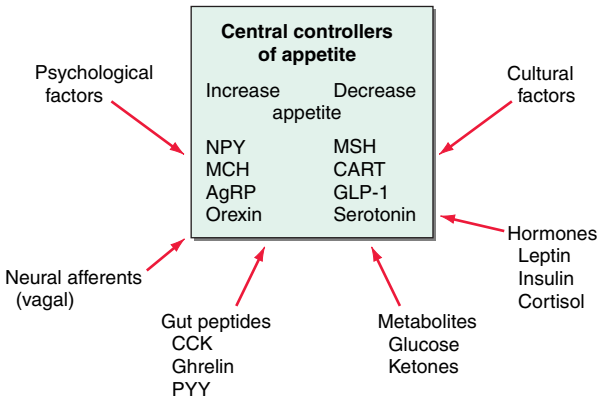

FIGURE 64-2 The factors that regulate appetite through effects on central neural circuits. Some factors that increase or decrease appetite are listed. NPY, neuropeptide Y; MCH, melanin-concentrating hormone; AgRP, Agouti-related peptide; MSH, melanocyte-stimulating hormone; CART, cocaine- and amphetamine-related transcript; GLP-1, glucagon-related peptide-1; CCK, cholecystokinin.

depot for fat, it is also an endocrine cell that releases numerous molecules in a regulated fashion (Fig. 64-3). These include the energy balance-regulating hormone leptin, cytokines such as tumor necrosis factor (TNF) α, complement factors such as factor D (also known as *adipsin*), prothrombotic agents such as plasminogen activator inhibitor I, and a component of the blood pressure regulating system, angiotensinogen. Adiponectin (or ACRP30) enhances insulin sensitivity and lipid oxidation, whereas resistin may induce insulin resistance. These factors, and others not yet identified, play a role in the physiology of lipid homeostasis, insulin sensitivity, blood pressure control, and coagulation and are likely to contribute to obesity-related pathologies.

ETIOLOGY OF OBESITY Though the molecular pathways regulating energy balance are beginning to be illuminated, the causes of obesity remain elusive. In part, this reflects the fact that obesity is a heterogeneous group of disorders. At one level, the pathophysiology of obesity seems simple: a chronic excess of nutrient intake relative to the level of energy expenditure. However, due to the complexity of the neuroendocrine and metabolic systems that regulate energy intake, storage, and expenditure, it has been difficult to quantitate all the relevant parameters (e.g., food intake and energy expenditure) over time in human subjects.

Role of Genes versus Environment Obesity is commonly seen in families, and the heredibility of body weight is similar to that for height. Inheritance is usually not Mendelian, however, and it is difficult to distinguish the role of genes and environmental factors. Adoptees usually resemble their biologic rather than adoptive parents with respect to obesity, providing strong support for genetic influences. Likewise, identical twins have very similar BMIs whether reared together or apart, and their BMIs are much more strongly correlated than those of dizygotic twins. These genetic effects appear to relate to both energy intake and expenditure.

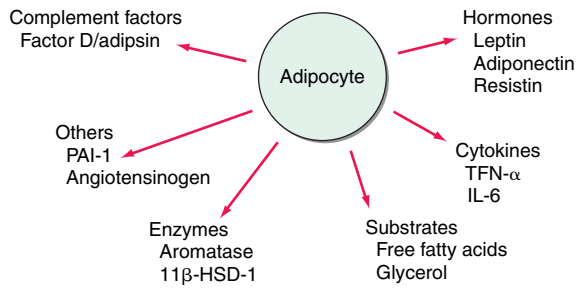

FIGURE 64-3 Factors released by the adipocyte that can affect peripheral tissues. PAI, plasminogen activator inhibitor; TNF, tumor necrosis factor.

Whatever the role of genes, it is clear that the environment plays a key role in obesity, as evidenced by the fact that famine prevents obesity in even the most obesity-prone individual. In addition, the recent increase in the prevalence of obesity in the United States is too rapid to be due to changes in the gene pool. Undoubtedly, genes influence the susceptibility to obesity when confronted with specific diets and availability of nutrition. Cultural factors are also important—these relate to both availability and composition of the diet and to changes in the level of physical activity. In industrial societies, obesity is more common among poor women, whereas in underdeveloped countries, wealthier women are more often obese. In children, obesity correlates to some degree with time spent watching television. High-fat diets may promote obesity, as may diets rich in simple (as opposed to complex) carbohydrates.

Specific Genetic Syndromes For many years obesity in rodents has been known to be caused by a number of distinct mutations distributed through the genome. Most of these single-gene mutations cause both hyperphagia and diminished energy expenditure, suggesting a link between these two parameters of energy homeostasis. Identification of the *ob* gene mutation in genetically obese (ob/ob) mice represented a major breakthrough in the field. The ob/ob mouse develops severe obesity, insulin resistance, and hyperphagia, as well as efficient metabolism (e.g., it gets fat even when given the same number of calories as lean littermates). The product of the *ob* gene is the peptide leptin, a name derived from the Greek root *leptos*, meaning thin. Leptin is secreted by adipose cells and acts primarily through the hypothalamus. Its level of production provides an index of adipose energy stores (Fig. 64-4). High leptin levels decrease food intake and increase energy expenditure. Another mouse mutant, db/db, which is resistant to leptin, has a mutation in the leptin receptor and develops a similar syndrome. The *OB* gene is present in humans and expressed in fat. Several families with morbid, early-onset obesity caused by inactivating mutations in either leptin or the leptin receptor have been described, thus demonstrating the biologic relevance of leptin in humans. The obesity in these individuals begins shortly after birth, is severe, and is accompanied by neuroendocrine abnormalities. The most prominent of these is hypogonadotropic hypogonadism, which is reversed by leptin replacement. Central hypothyroidism and growth retardation are seen in the mouse model, but their occurrence in leptin-deficient humans is less clear. To date, there is no evidence to suggest that mutations or polymorphisms in the leptin or leptin receptor genes play a prominent role in common forms of obesity.

Mutations in several other genes cause severe obesity in humans (Table 64-1); each of these syndromes is rare. Mutations in the gene encoding proopiomelanocortin (POMC) cause severe obesity through failure to synthesize α-MSH, a key neuropeptide that inhibits appetite in the hypothalamus. The absence of POMC also causes secondary

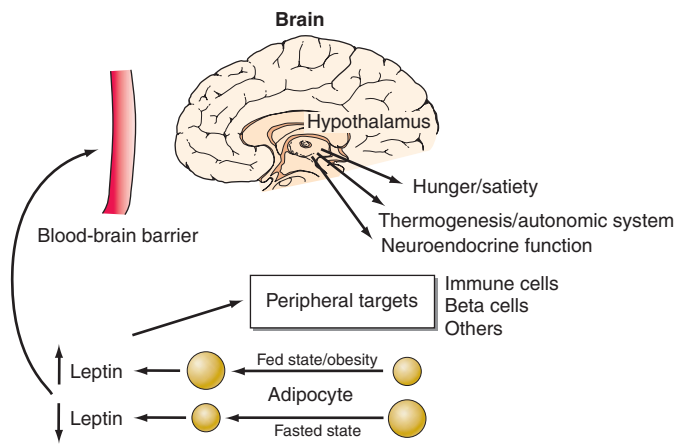

FIGURE 64-4 The physiologic system regulated by leptin. Rising or falling leptin levels act through the hypothalamus to influence appetite, energy expenditure, and neuroendocrine function and through peripheral sites to influence systems such as the immune system.

adrenal insufficiency due to absence of adrenocorticotropic hormone (ACTH), as well as pale skin and red hair due to absence of MSH. Proenzyme convertase 1 (PC-1) mutations are thought to cause obesity by preventing synthesis of α-MSH from its precursor peptide, POMC. α-MSH binds to the type 4 melanocortin receptor (MC4R), a key hypothalamic receptor that inhibits eating. Heterozygous mutations of this receptor appear to account for as much as 5% of severe obesity. These five genetic defects define a pathway through which leptin (by stimulating POMC and increasing MSH) restricts food intake and limits weight (Fig. 64-5).

In addition to these human obesity genes, studies in rodents reveal several other molecular candidates for hypothalamic mediators of human obesity or leanness. The *tub* gene encodes a hypothalamic peptide of unknown function; mutation of this gene causes late-onset obesity. The *fat* gene encodes carboxypeptidase E, a peptide-processing enzyme; mutation of this gene is thought to cause obesity by disrupting production of one or more neuropeptides. AgRP is coexpressed with NPY in arcuate nucleus neurons. AgRP antagonizes α-MSH action at MC4 receptors, and its overexpression induces obesity. In contrast, a mouse deficient in the peptide MCH, whose administration causes feeding, is lean.

TABLE 64-1 *Some Obesity Genes in Humans and Mice*

Gene	Gene Product	Mechanism of Obesity	In Human	In Rodent
Lep (*ob*)	Leptin, a fat-derived hormone	Mutation prevents leptin from delivering satiety signal; brain perceives starvation	Yes	Yes
LepR (*db*)	Leptin receptor	Same as above	Yes	Yes
POMC	Proopiomelanocortin, a precursor of several hormones and neuropeptides	Mutation prevents synthesis of melanocyte-stimulating hormone (MSH), a satiety signal	Yes	Yes
MC4R	Type 4 receptor for MSH	Mutation prevents reception of satiety signal from MSH	Yes	Yes
AgRP	Agouti-related peptide, a neuropeptide expressed in the hypothalamus	Overexpression inhibits signal through MC4R	No	Yes
PC-1	Prohormone convertase 1, a processing enzyme	Mutation prevents synthesis of neuropeptide, probably MSH	Yes	No
Fat	Carboxypeptidase E, a processing enzyme	Same as above	No	Yes
Tub	Tub, a hypothalamic protein of unknown function	Hypothalamic dysfunction	No	Yes

A number of complex human syndromes with defined inheritance are associated with obesity (Table 64-2). Although specific genes are undefined at present, their identification will likely enhance our understanding of more common forms of human obesity. In the Prader-Willi syndrome, obesity coexists with short stature, mental retardation, hypogonadotropic hypogonadism, hypotonia, small hands and feet, fish-shaped mouth, and hyperphagia. Most patients have a chromosome 15 deletion (Chap. 57). Laurence-Moon-Biedl syndrome is characterized by obesity, mental retardation, retinitis pigmentosa, polydactyly, and hypogonadotropic hypogonadism.

Other Specific Syndromes Associated with Obesity ■ *CUSHING'S SYNDROME* Although obese patients commonly have central obesity, hypertension, and glucose intolerance, they lack other specific stigmata of Cushing's syndrome (Chap. 321). Nonetheless, a potential diagnosis of Cushing's syndrome is often entertained. Cortisol production and urinary metabolites (17OH steroids) may be increased in simple obesity. Unlike in Cushing's syndrome, however, cortisol levels in blood and urine in the basal state and in response to corticotropin-releasing hormone (CRH) or ACTH are normal; the overnight 1-mg dexamethasone suppression test is normal in 90%, with the remainder being normal on a standard 2-day low-dose dexamethasone suppression test. Obesity may be associated with local reactivation of cortisol in fat by 11β hydroxysteroid dehydrogenase 1, an enzyme that converts cortisone to cortisol.

HYPOTHYROIDISM The possibility of hypothyroidism should be considered, but it is an uncommon cause of obesity; hypothyroidism is easily ruled out by measuring thyroid-stimulating hormone (TSH). Much of the weight gain that occurs in hypothyroidism is due to myxedema (Chap. 320).

INSULINOMA Patients with insulinoma often gain weight as a result of overeating to avoid hypoglycemia symptoms (Chap. 324). The increased substrate plus high insulin levels promote energy storage in fat. This can be marked in some individuals but is modest in most.

CRANIOPHARYNGIOMA AND OTHER DISORDERS INVOLVING THE HYPOTHALAMUS Whether through tumors, trauma, or inflammation, hypothalamic dysfunction of systems controlling satiety, hunger, and energy expenditure can cause varying degrees of obesity (Chap. 318). It is uncommon to identify a discrete anatomic basis for these disorders. Subtle hypothalamic dysfunction is probably a more common cause of obesity than can be documented using currently available imaging techniques. Growth hormone (GH), which exerts lipolytic activity, is diminished in obesity and is increased with weight loss. Despite low GH levels, insulin-like growth factor (IGF) I (somatomedin) production is normal, suggesting that GH suppression is a compensatory response to increased nutritional supply.

Pathogenesis of Common Obesity Obesity can result from increased energy intake, decreased energy expenditure, or a combination of the two. Thus, identifying the etiology of obesity should involve measurements of both parameters. However, it is nearly impossible to perform direct and accurate measurements of energy intake in free-living individuals. Obese people, in particular, often underreport intake. Measurements of chronic energy expenditure have only recently become available using doubly labeled water or metabolic chamber/rooms. In subjects at stable weight and body composition, energy intake equals expenditure. Consequently, these techniques allow determination of energy intake in free-living individuals. The level of energy expenditure differs in established obesity, during periods of weight gain or loss, and in the pre- or postobese state. Studies that fail to take note of this phenomenon are not easily interpreted.

There is increased interest in the concept of a body weight "set point." This idea is supported by physiologic mechanisms centered around a sensing system in adipose tissue that reflects fat stores and a receptor, or "adipostat," that is in the hypothalamic centers. When fat

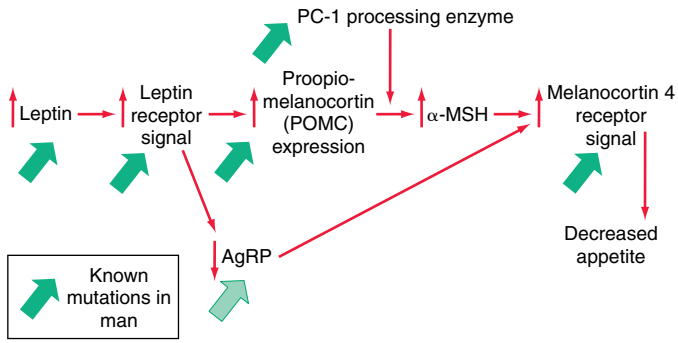

FIGURE 64-5 A central pathway through which leptin acts to regulate appetite and body weight. Leptin signals through proopiomelanocortin (POMC) neurons in the hypothalamus to induce increased production of α melanocyte-stimulating hormone (α-MSH), requiring the processing enzyme PC-1 (proenzyme convertase 1). α-MSH acts as an agonist on melanocortin-4 receptors to inhibit appetite, and the neuropeptide AgRp (Agouti-related peptide) acts as an antagonist of this receptor. Mutations that cause obesity in humans are indicated by the solid green arrows.

TABLE 64-2 *A Comparison of Syndromes of Obesity—Hypogonadism and Mental Retardation*

	Syndrome				
Feature	*Prader-Willi*	*Laurence-Moon-Biedl*	*Ahlstrom*	*Cohen*	*Carpenter*
Inheritance	Sporadic; two-thirds have defect	Autosomal recessive	Autosomal recessive	Probably autosomal recessive	Autosomal recessive
Stature	Short	Normal; infrequently short	Normal; infrequently short	Short or tall	Normal
Obesity	Generalized Moderate to severe Onset 1–3 yrs	Generalized Early onset, 1–2 yrs	Truncal Early onset, 2–5 yrs	Truncal Mid-childhood, age 5	Truncal, gluteal
Craniofacies	Narrow bifrontal diameter Almond-shaped eyes Strabismus V-shaped mouth High-arched palate	Not distinctive	Not distinctive	High nasal bridge Arched palate Open mouth Short philtrum	Acrocephaly Flat nasal bridge High-arched palate
Limbs	Small hands and feet Hypotonia	Polydactyly	No abnormalities	Hypotonia Narrow hands and feet	Polydactyly Syndactyly Genu valgum
Reproductive status	1° Hypogonadism	1° Hypogonadism	Hypogonadism in males but not in females	Normal gonadal function or hypogonadotrophic hypogonadism	2° Hypogonadism
Other features	Enamel hypoplasia Hyperphagia Temper tantrums Nasal speech			Dysplastic ears Delayed puberty	
Mental retardation	Mild to moderate		Normal intelligence	Mild	Slight

stores are depleted, the adipostat signal is low, and the hypothalamus responds by stimulating hunger and decreasing energy expenditure to conserve energy. Conversely, when fat stores are abundant, the signal is increased, and the hypothalamus responds by decreasing hunger and increasing energy expenditure. The recent discovery of the *ob* gene, and its product leptin, provides a molecular basis for this physiologic concept (see above).

What Is the Status of Food Intake in Obesity? (Do the Obese Eat More Than the Lean?) This question has stimulated much debate, due in part to the methodologic difficulties inherent in determining food intake. Many obese individuals believe that they eat small quantities of food, and this claim has often been supported by the results of food intake questionnaires. However, it is now established that average energy expenditure increases as people get more obese, due primarily to the fact that metabolically active lean tissue mass increases with obesity. Given the laws of thermodynamics, the obese person must therefore eat more than the average lean person to maintain their increased weight. It may be the case, however, that a subset of individuals who are predisposed to obesity have the capacity to become obese initially without an absolute increase in caloric consumption.

What Is the State of Energy Expenditure in Obesity? The average total daily energy expenditure is higher in obese than lean individuals when measured at stable weight. However, energy expenditure falls as weight is lost, due in part to loss of lean body mass and to decreased sympathetic nerve activity. When reduced to near-normal weight and maintained there for a while, (some) obese individuals have lower energy expenditure than (some) lean individuals. There is also a tendency for those who develop obesity as infants or children to have lower resting energy expenditure rates than those who remain lean.

The physiologic basis for variable rates of energy expenditure (at a given body weight and level of energy intake) is essentially unknown. A mutation in the human β_3 adrenergic receptor may be associated with increased risk of obesity and/or insulin resistance in certain (but not all) populations. Homologues of the BAT uncoupling protein, named UCP-2 and UCP-3, have been identified in both rodents and humans. UCP-2 is expressed widely, whereas UCP-3 is primarily expressed in skeletal muscle. These proteins may play a role in disordered energy balance.

One newly described component of thermogenesis, called *nonexercise activity thermogenesis* (NEAT), has been linked to obesity. It is the thermogenesis that accompanies physical activities other than volitional exercise, such as the activities of daily living, fidgeting, spontaneous muscle contraction, and maintaining posture. NEAT accounts for about two-thirds of the increased daily energy expenditure induced by overfeeding. The wide variation in fat storage seen in overfed individuals is predicted by the degree to which NEAT is induced. The molecular basis for NEAT and its regulation are unknown.

Leptin in Typical Obesity The vast majority of obese people have increased leptin levels but do not have mutations of either leptin or its receptor. They appear, therefore, to have a form of functional "leptin resistance." Data suggesting that some individuals produce less leptin per unit fat mass than others or have a form of relative leptin deficiency that predisposes to obesity are at present contradictory and unsettled. The mechanism for leptin resistance, and whether it can be overcome by raising leptin levels, is not yet established. Some data suggest that leptin may not effectively cross the blood-brain barrier as levels rise. It is also possible that leptin signaling inhibitors are involved in the leptin-resistant state.

PATHOLOGIC CONSEQUENCES OF OBESITY Obesity has major adverse effects on health. Morbidly obese individuals (>200% ideal body weight) have as much as a twelvefold increase in mortality. Mortality rates rise as obesity increases, particularly when obesity is associated with increased intraabdominal fat (see above). It is also apparent that the degree to which obesity affects particular organ systems is influenced by susceptibility genes that vary in the population.

Insulin Resistance and Type 2 Diabetes Mellitus Hyperinsulinemia and insulin resistance are pervasive features of obesity, increasing with weight gain and diminishing with weight loss. Insulin resistance is more strongly linked to intraabdominal fat than to fat in other depots. The molecular link between obesity and insulin resistance in tissues such as fat, muscle, and liver has been sought for many years. Major factors under investigation include: (1) insulin itself, by inducing receptor downregulation; (2) free fatty acids, known to be increased and capable of impairing insulin action; (3) intracellular lipid accumulation; and (4) various circulating peptides produced by adipocytes, including the cytokines TNF-α and interleukin (IL) 6 , and the "adipokines" adiponectin and resistin, which are produced by adipocytes, have altered expression in obese adipocytes, and are capable of mod-

ifying insulin action. Despite nearly universal insulin resistance, most obese individuals do not develop diabetes, suggesting that the onset of diabetes requires an interaction between obesity-induced insulin resistance and other factors that predispose to diabetes, such as impaired insulin secretion (Chap. 323). Obesity, however, is a major risk factor for diabetes, and as many as 80% of patients with type 2 diabetes mellitus are obese. Weight loss and exercise, even of modest degree, are associated with increased insulin sensitivity and often improve glucose control in diabetes.

Reproductive Disorders Disorders that affect the reproductive axis are associated with obesity in both men and women. Male hypogonadism is associated with increased adipose tissue, often distributed in a pattern more typical of females. In men >160% ideal body weight, plasma testosterone and sex hormone–binding globulin (SHBG) are often reduced, and estrogen levels (derived from conversion of adrenal androgens in adipose tissue) are increased (Chap. 325). Gynecomastia may be seen. However, masculinization, libido, potency, and spermatogenesis are preserved in most of these individuals. Free testosterone may be decreased in morbidly obese men whose weight exceeds 200% ideal body weight.

Obesity has long been associated with menstrual abnormalities in women, particularly in women with upper body obesity (Chap. 326). Common findings are increased androgen production, decreased SHBG, and increased peripheral conversion of androgen to estrogen. Most obese women with oligomenorrhea have the polycystic ovarian syndrome (PCOS), with its associated anovulation and ovarian hyperandrogenism; 40% of women with PCOS are obese. Most nonobese women with PCOS are also insulin-resistant, suggesting that insulin resistance, hyperinsulinemia, or the combination of the two are causative or contribute to the ovarian pathophysiology in PCOS in both obese and lean individuals. In obese women with PCOS, weight loss or treatment with insulin-sensitizing drugs often restores normal menses. The increased conversion of androstenedione to estrogen, which occurs to a greater degree in women with lower body obesity, may contribute to the increased incidence of uterine cancer in postmenopausal women with obesity.

Cardiovascular Disease The Framingham Study revealed that obesity was an independent risk factor for the 26-year incidence of cardiovascular disease in men and women [including coronary disease, stroke, and congestive heart failure (CHF)]. The waist/hip ratio may be the best predictor of these risks. When the additional effects of hypertension and glucose intolerance associated with obesity are included, the adverse impact of obesity is even more evident. The effect of obesity on cardiovascular mortality in women may be seen at BMIs as low as 25. Obesity, especially abdominal obesity, is associated with an atherogenic lipid profile, with increased low-density lipoprotein (LDL) cholesterol, very low density lipoprotein, and triglyceride, and decreased high-density lipoprotein cholesterol (Chap. 335). Obesity is also associated with hypertension. Measurement of blood pressure in the obese requires use of a larger cuff size to avoid artifactual increases. Obesity-induced hypertension is associated with increased peripheral resistance and cardiac output, increased sympathetic nervous system tone, increased salt sensitivity, and insulin-mediated salt retention; it is often responsive to modest weight loss.

Pulmonary Disease Obesity may be associated with a number of pulmonary abnormalities. These include reduced chest wall compliance, increased work of breathing, increased minute ventilation due to increased metabolic rate, and decreased total lung capacity and functional residual capacity (Chap. 234). Severe obesity may be associated with obstructive sleep apnea and the "obesity hypoventilation syndrome" (Chap. 246). Sleep apnea can be obstructive (most common), central, or mixed. Weight loss (10 to 20 kg) can bring substantial improvement, as can major weight loss following gastric bypass or restrictive surgery. Continuous positive airway pressure has been used with some success.

Gallstones Obesity is associated with enhanced biliary secretion of cholesterol, supersaturation of bile, and a higher incidence of gallstones, particularly cholesterol gallstones (Chap. 292). A person 50% above ideal body weight has about a sixfold increased incidence of symptomatic gallstones. Paradoxically, fasting increases supersaturation of bile by decreasing the phospholipid component. Fasting-induced cholecystitis is a complication of extreme diets.

Cancer Obesity in males is associated with higher mortality from cancer, including cancer of the esophagus, colon, rectum, pancreas, liver, and prostate; obesity in females is associated with higher mortality from cancer of the gallbladder, bile ducts, breasts, endometrium, cervix, and ovaries. Some of the latter may be due to increased rates of conversion of androstenedione to estrone in adipose tissue of obese individuals. It was recently estimated that obesity accounts for 14% of cancer deaths in men, and 20% in women in the United States.

Bone, Joint, and Cutaneous Disease Obesity is associated with an increased risk of osteoarthritis, no doubt partly due to the trauma of added weight bearing and joint malalignment. The prevalence of gout may also be increased (Chap. 313). Among the skin problems associated with obesity is acanthosis nigricans, manifested by darkening and thickening of the skin folds on the neck, elbows, and dorsal interphalangeal spaces. Acanthosis reflects the severity of underlying insulin resistance and diminishes with weight loss. Friability of skin may be increased, especially in skin folds, enhancing the risk of fungal and yeast infections. Finally, venous stasis is increased in the obese.

TREATMENT

Obesity is a chronic medical condition. Successful treatment, defined as the sustained attainment of normal body weight without producing unacceptable treatment-induced morbidity, is rarely achieved in clinical practice. Many approaches produce short-term weight loss, and this has clear benefits for associated morbidities such as hypertension and diabetes. Although enormous resources are expended in pursuit of obesity therapies, most patients are unsuccessful at achieving and sustaining weight loss over time.

Treatment goals should be guided by the health risks of obesity in any given individual (Fig. 64-6). The clinician should always consider

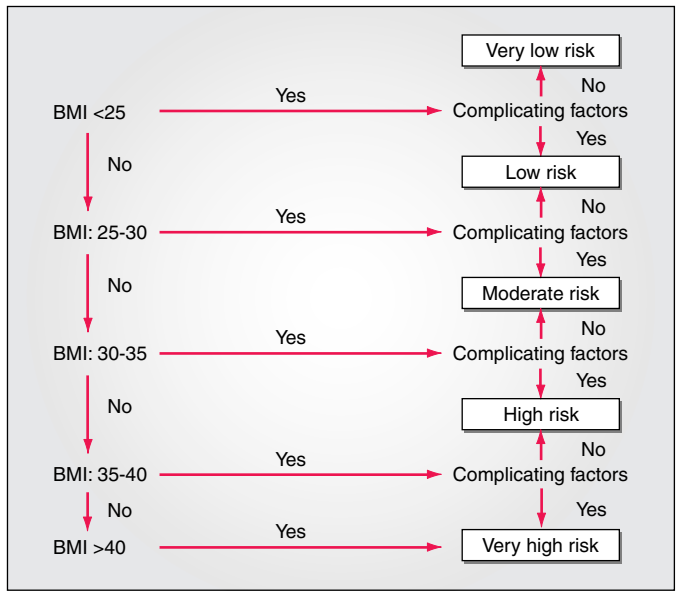

FIGURE 64-6 Risk classification algorithm. The patient is first placed into a category based on body mass index. The presence or absence of complicating factors determines the degree of health risk. Complicating factors include elevated abdominal-gluteal ratio (male: 1.0, female: 0.9), diabetes mellitus, hypertension, hyperlipidemia, male sex, and age <40. (*Copyright 1987, George A. Bray, MD. Used with permission.*)

the possibility that an individual has an identified cause of obesity, such as hypothyroidism, hypercortisolism, male hypogonadism, insulinoma, or central nervous system disease that affects hypothalamic function. Although they are infrequent causes of obesity, specific therapy may be available.

Behavior Modification The principles of behavior modification provide the underpinnings for many current programs of weight reduction. Typically, the patient is requested to monitor and record the circumstances related to eating, and rewards are designed to modify maladaptive behaviors. Patients may benefit from counseling offered in a stable group setting for extended periods of time, including after weight loss.

Diet Reduced caloric intake is the cornerstone of obesity treatment. The fundamental goal is the sustained reduction of energy intake below that of energy expenditure. The difficulty in achieving this goal has led to a wide array of suggested diets that vary in recommended calorie content (from total fasting to mild reductions), as well as specific food content and form (e.g., liquid vs. solid). There is no scientific evidence to validate the utility of specific "fad diets." The main diet regimens in use follow several general facts relevant to food intake and weight loss. First, a deficit of 7500 kcal will produce a weight loss of ~1 kg. Therefore, eating 100 kcal/d less for a year should cause a 5-kg weight loss, and a deficit of 1000 kcal/d should cause a loss of ~1 kg per week. The rate of weight loss on a given caloric intake is related to the rate of energy expenditure. Because obese individuals have a higher metabolic rate than lean individuals, and because men have a higher metabolic rate than women (due to their greater lean body mass), the rate of weight loss is greater among the more obese and among men (relative to women). With chronic caloric restriction, metabolic rate diminishes because of reduced lean body mass (along with much greater loss in fat mass) and possibly because of other adaptations. This fall in metabolic rate with food restriction slows the rate of weight loss on a constant diet. With total starvation or diets restricted to <600 kcal/d, initial weight loss over the first week results predominantly from natriuresis and the loss of fluids.

Very low energy diets (e.g., 400 to 600 kcal/d) may be appropriate for short-term treatment of obesity in selected patients. They are most commonly used for periods of 1 to 2 months to initiate more rapid weight loss, improve comorbidities, and provide patients with positive feedback. The liquid protein diets popularized in the 1970s were proved to be unsafe, causing >60 deaths. Life-threatening arrhythmias were documented in the clinical research setting, a consequence of both low-quality protein and deficiencies of vitamins, minerals, and trace elements. These types of diets have now been substantially modified. A very low energy diet consisting of 45 to 70 g high-quality protein, 30 to 50 g carbohydrate, and ~2 g fat per day, as well as supplements of vitamins, minerals, and trace elements, appears to be safe in selected patients under medical supervision. Patients should not be started on such diets unless they are >130% of their ideal body weight. Contraindications include pregnancy, cancer, recent myocardial infarction, cerebrovascular disease, hepatic disease, or untreated psychiatric disease. When used in patients with diabetes who are receiving insulin or oral agent therapy, close supervision is required and diabetic treatment will need to be adjusted. Whenever possible, exercise regimens and behavioral modification approaches should be used in conjunction with the diet.

Advantages of very low calorie diets are the greater rate of weight loss compared to less restrictive diets, as well as the possible beneficial effect of hunger suppression brought about by the production of ketones. In patients on such diets, blood pressure, blood glucose, cholesterol, and triglyceride levels fall, and pulmonary function and exercise tolerance improve. Sleep apnea may improve within a few weeks. Complications of these very low energy diets are usually minor and include fatigue, constipation or diarrhea, dry skin, hair loss, menstrual irregularities, orthostatic dizziness, and difficulty concentrating. Cholelithiasis and pancreatitis may occur when such diets are interrupted by binge eating; gallstones have been shown to develop in as many as 25% of patients while on the diet.

Low-calorie diets, >800 kcal/d, are applicable to most patients and have fewer restrictions than the very low calorie diets. Considerable controversy has attended the question of which diet composition is most appropriate for promoting weight loss. Though commonly recommended, benefits resulting from very low fat diets are modest at best. Nonetheless, the health effects of low-fat diets—apart from curbing obesity—may be important. A diet rich in fruits, vegetables, whole grains, and other low–glycemic index carbohydrates may promote weight loss and is preferable to low-fat diets in which large amounts of simple carbohydrates are substituted for fats. The latter may actually promote obesity. Some have advocated diets with protein replacement of simple carbohydrates in an effort to minimize insulin production. The efficacy of this strategy, aside from overall calorie reduction, is unknown. Recent data suggest that very low carbohydrate "Atkins" style diets are more effective for short-term weight loss when compared to standard caloric restriction. Weight loss on such diets is not associated with adverse effects on such indices as lipid profile, glycemic control, or blood pressure. However, these diets have not been shown to be more effective in maintaining weight loss, and the possible long-term consequences of maintaining a lower body weight at the expense of consuming more saturated fat are unknown.

An important aspect of diet therapy should include education aimed at preventing weight gain. Knowledge of the caloric and nutritional content of foods is generally poor. In the absence of studies demonstrating convincingly that one type of diet is more effective and safe than another, an emphasis on helping patients understand the caloric content of specific portions is a helpful aid to weight loss and weight maintenance in many individuals.

Exercise Exercise is an important component of the overall approach to treating obesity. Increased energy expenditure is the most obvious mechanism for an effect of exercise. The impact of an exercise regimen as a sole therapy of obesity has been difficult to document. On the other hand, exercise appears to be a valuable means to sustain diet therapy (Fig. 64-7). Even if exercise had no such salutary effect, it would be valuable in the obese individual for its effects on cardiovascular tone and blood pressure. Because many obese individuals have not engaged in exercise on a regular basis and may have cardiovascular risk factors, it should be introduced gradually and under medical supervision, especially in the most obese individuals.

Drugs Despite modest short-term benefits from several agents, medication-induced weight loss is not a cure and is often associated with rebound weight gain after the cessation of drug use. Substantial side effects from several anti-obesity medications, and the potential for drug abuse, have combined to create a wariness about this approach. On the other hand, there is a great medical need for safe and effective

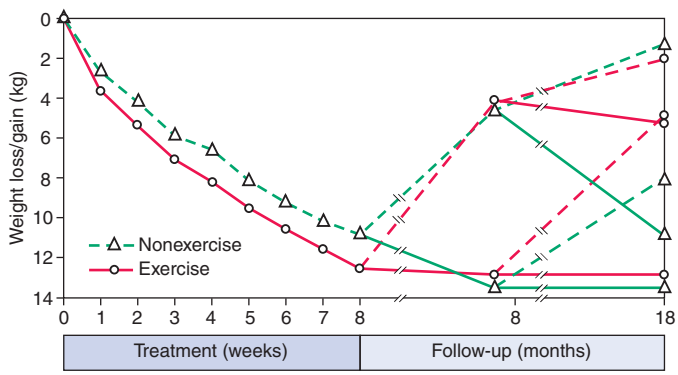

FIGURE 64-7 Weight loss and exercise. During the first 8 weeks, subjects were divided into two groups, one treated with diet and the other with diet plus exercise, with no difference in weight loss. Thereafter the subjects who exercised maintained better weight loss than those that did not. (*After KN Pavlou et al: Am J Clin Nutr 49: 1115, 1989.*)

therapies, so many possible compounds have been evaluated. On the basis of placebo-controlled trials, the U.S. Food and Drug Administration (FDA) approved several amphetamine-like agents for short-term use. Phentermine is an amphetamine-like drug with low addictive potential that showed modest efficacy (10 vs. 4.4 kg of weight loss over a 24-week period in a well-controlled study). This class of drugs is thought to act centrally by reducing appetite. The over-the-counter drug phenylpropanolamine HCl, had similar efficacy to prescription appetite suppressants in short-term studies but was withdrawn from the market in 2001 because of an association with cerebral hemorrhage. Drugs that promote serotonin release or inhibit serotonin reuptake, such as fenfluramine, have had modest efficacy as single agents. When fenfluramine was administered together with phentermine, as "fen-phen," the combination gained wide use for several years based on controlled trials that demonstrated modest but definite efficacy and reduction of comorbidities. However, the risk of primary pulmonary hypertension was increased up to 20-fold in association with this treatment. The FDA withdrew approval of the fen-phen combination in 1997 when reports demonstrated an association with right- and left-sided valvular heart disease. The histopathologic features of the valvular disease are similar to those seen in carcinoid syndrome and are thought to result from fenfluramine. The occurrence of this complication has been verified in multiple studies, and fenfluramine has been removed from the market.

Sibutramine is a central reuptake inhibitor of both norepinephrine and serotonin that was originally developed as an antidepressant. Using a once-daily dose over 24 weeks, it produced a 7% weight loss in a double-blind, placebo-controlled trial. It lowered cholesterol and triglyceride levels and exhibited similar clinical efficacy to fenfluramine. Sibutramine increases pulse by an average of 4 to 5 beats per minute and blood pressure by 1 to 3 mmHg, and this plus modest efficacy has limited its broad adoption. Orlistat is an inhibitor of intestinal lipase with no systemic availability that causes modest weight loss due to drug-induced fat malabsorption. A randomized, double-blind trial over 2 years revealed modest weight loss (8.7 kg for 120 mg orlistat versus 5.8 kg from diet alone) during the first year and better maintenance of weight loss in a second year compared to the placebo-treated group (3.2 kg regained vs. 5.6 kg regained for placebo). LDL cholesterol and insulin levels were also reduced. Gastrointestinal side effects include oily stools, flatulence, and fecal urgency and usually diminish as patients choose to limit fat intake to avoid the symptoms. Absorption of fat-soluble vitamins is decreased. In patients with obesity and type 2 diabetes mellitus, the antidiabetic medication metformin tends to decrease body weight. The mechanism appears to involve inhibition of appetite. Thyroid hormone has little place in the treatment of obesity, as the vast majority of obese individuals are euthyroid. It promotes loss of lean body mass and raises the risk of complications from the hyperthyroid state.

In the rare cases of leptin deficiency caused by mutations of the leptin gene, the administration of recombinant leptin is highly effective for regulating hunger and inducing loss of fat mass while preserving lean body mass. The response to leptin is limited or absent in common obesity, which is associated with hyperleptinemia and leptin resistance. New drugs are also being developed based on recent insights into central pathways that regulate body weight. These include antagonists for NPY receptors (subtypes Y1, Y5) and MCH receptors and agonists for melanocortin 4 receptors.

Surgery Morbid obesity, commonly defined as a BMI $>$ 40, is estimated to increase mortality by as much as twelvefold in men between 25 and 34 years of age and sixfold between 35 and 45 years of age. Deaths from cardiovascular disease, diabetes, and accidents have been documented. In response to typically ineffective treatment using diet, exercise, and available drugs, surgical approaches are increasingly being employed. The potential benefits of surgery include major weight loss and improvement in hypertension, diabetes, sleep apnea, CHF, angina, hyperlipidemia, and venous disease. Several different approaches have been used, sometimes without adequate long-term assessment of efficacy and complications. Jejunoileal bypass surgery has been abandoned because of complications, which included electrolyte disturbances, nephrolithiasis, gallstones, gastric ulcers, arthritis, and hepatic dysfunction, with cirrhosis occurring in as many as 7% of patients. Two procedures in common use today are the vertical-banded gastroplasty and the Roux-en-Y gastric bypass (Fig. 64-8). The former is a purely restrictive procedure, while the latter combines restriction with slight malabsorption and may also reduce appetite via suppression of the gastric hormone ghrelin, which stimulates appetite. Gastric bypass is most often performed by laparotomy but may be performed laparascopically in some patients. A third procedure, laparascopic adjustable gastric banding, is widely used in Europe and Australia and is being introduced in the United States. This procedure may be viewed as "less drastic" than gastric bypass but appears capable of producing substantial weight loss, albeit with shorter periods of follow-up.

Following the National Institutes of Health Consensus Conference on Gastrointestinal Surgery for Severe Obesity in 1991, it was recommended that suitable patients be selected using the following criteria: (1) a BMI $>$ 35 with an associated comorbidity or a BMI $>$ 40; (2) repeated failures of other therapeutic approaches; (3) at eligible weight for 3 to 5 years; (4) capability of tolerating surgery; (5) absence of alcoholism, other addictions, or major psychopathology; and (6) prior clearance by a psychiatrist. It is recommended that an appropriately experienced surgeon work together with nutritionists and other support personnel; evaluation and follow-up programs should be monitored closely.

65 EATING DISORDERS

B. Timothy Walsh

Anorexia nervosa and bulimia nervosa are characterized by severe disturbances of eating behavior. The salient feature of *anorexia nervosa* (AN) is a refusal to maintain a minimally normal body weight. *Bulimia nervosa* (BN) is characterized by recurrent episodes of binge eating followed by abnormal compensatory behaviors, such as self-induced vomiting. AN and BN are distinct clinical syndromes but share certain features in common. Both disorders occur primarily among previously healthy young women who become overly concerned with body shape and weight. Many patients with BN have past histories of anorexia nervosa, and many patients with anorexia nervosa engage in binge eating and purging behavior. In the current diagnostic system, the critical distinction between AN and BN depends on body weight: patients with AN are, by definition, significantly underweight, whereas patients with BN have body weights in the normal range or above.

Binge eating disorder (BED) is a more recently described syndrome characterized by repeated episodes of binge eating, similar to those of BN, in the absence of inappropriate compensatory behavior. Patients with BED are typically middle-aged men or women with significant obesity. They have an increased frequency of anxiety and depression compared to similarly obese patients without BED. It is not known whether patients with BED are at increased risk for medical complications or what treatment strategies are indicated.

ANOREXIA NERVOSA

EPIDEMIOLOGY Among women, the lifetime prevalence of the full syndrome of AN is approximately 0.5%. AN is much less common in males. AN is more prevalent in cultures where food is plentiful and in which being thin is associated with attractiveness. Individuals who pursue interests that place a premium on thinness, such as ballet and modeling, are at greater risk. The incidence of AN appears to have increased in recent decades.

ETIOLOGY The etiology of AN is unknown but appears to involve a combination of psychological, biologic, and cultural risk factors. Risk factors, such as sexual or physical abuse and a family history of mood disturbance, are best viewed as nonspecific risk factors that increase vulnerability to a range of psychiatric disorders, including AN.

Patients who develop AN are inclined to be more obsessional and perfectionist than their peers. The disorder often begins as a diet not distinguishable at the outset from those undertaken by many adolescents and young women. As weight loss progresses, the fear of gaining weight grows; dieting becomes stricter; and psychological, behavioral, and medical aberrations increase. Eating disorders, including AN, may develop among individuals with type 1 diabetes mellitus, and are associated with poorer glycemic control and an increased frequency of complications (Chap. 323).

Numerous physiologic disturbances, including abnormalities in a variety of neurotransmitter systems, have been described in AN (see below). It is difficult to distinguish neurochemical, metabolic, and hormonal changes that may have a role in the initiation or perpetuation of the syndrome from those that are secondary to the disorder. The resolution of most of these abnormalities with weight restoration argues against their having a critical etiologic role.

Genetic factors contribute to the risk of development of AN, as its incidence is greater in families with one affected member and the concordance in monozygotic twins is greater than in dizygotic twins. However, specific genes have not been identified.

CLINICAL FEATURES (Table 65-1) AN typically begins in mid to late adolescence, sometimes in association with a stressful life event such as leaving home for school. The disorder occasionally develops in early puberty, before menarche, but seldom begins after age 40. Despite being underweight, patients with AN are irrationally afraid of gaining weight, often out of a concern that weight gain will get "out of control." They also exhibit a distortion of body image, which may express itself in several ways. For example, despite being emaciated, patients with AN may believe that their body as a whole, or some part of their body, is too fat. Further weight loss is viewed by the patient as a fulfilling accomplishment, while weight gain is seen as a personal failure. Patients with AN rarely complain of hunger or fatigue and often exercise extensively. Despite the denial of hunger, one-quarter to one-half of patients with AN engage in eating binges. Patients tend to become socially withdrawn and increasingly committed to work or study, dieting, and exercise. As weight loss progresses, thoughts of food dominate mental life and idiosyncratic rules develop around eating. Patients with AN may obsessively collect cookbooks and recipes and be drawn to food-related occupations.

Physical Features Patients with AN typically have few physical complaints but may note cold intolerance. Gastrointestinal motility is diminished, leading to reduced gastric emptying and constipation. Some women who develop AN after menarche report that their menses ceased before significant weight loss occurred. Weight and height should be measured to allow calculation of body mass index (BMI; kg/m^2). Vital signs may reveal bradycardia, hypotension, and mild hypothermia. Soft, downy hair growth (lanugo) sometimes occurs, and alopecia may be seen. Salivary gland enlargement, which is associated with starvation as well as with binge eating and vomiting, may make the face appear surprisingly full in contrast to the marked general wasting. Acrocyanosis of the digits is common, and peripheral edema can be seen in the absence of hypoalbuminemia, particularly when the patient begins to regain weight. Some patients who consume large amounts of vegetables containing vitamin A develop a yellow tint to the skin (*hypercarotenemia*), which is especially notable on the palms.

Laboratory Abnormalities Mild normochromic, normocytic anemia is frequent, as is mild to moderate leukopenia, with a disproportionate reduction of polymorphonuclear leukocytes. Dehydration may result in slightly increased levels of blood urea nitrogen and creatinine. Serum transaminase levels may increase, especially during the early phases of refeeding. The level of serum proteins is usually normal. Blood sugar is often low and serum cholesterol may be moderately elevated. Hypokalemic alkalosis suggests self-induced vomiting or the use of diuretics. Hyponatremia is common and may result from excess fluid intake and disturbances in the secretion of antidiuretic hormone.

Endocrine Abnormalities The regulation of virtually every endocrine system is altered in AN, but the most striking changes occur in the reproductive system. Amenorrhea is hypothalamic in origin and reflects diminished production of gonadotropin-releasing hormone (GnRH). When exogenous GnRH is administered in a pulsatile manner, pituitary responses of luteinizing hormone (LH) and follicle stimulating hormone (FSH) are normalized, indicating the absence of a primary pituitary abnormality. The resulting gonadotropin deficiency causes low plasma estrogen in women and reduced testosterone in men. The hypothalamic GnRH pulse generator is exquisitely sensitive, particularly in women, to body weight, stress, and exercise, each of which may contribute to *hypothalamic amenorrhea* in AN (Chap. 326). Although the mechanisms underlying these effects are unknown, the decreased adipose tissue associated with weight loss leads to a marked reduction in leptin, a hormone that plays a permissive role in GnRH production (Chap. 64).

Serum cortisol and 24-h urine free cortisol levels are generally elevated but without characteristic clinical signs of cortisol excess. Thyroid function tests resemble the pattern seen in euthyroid sick syndrome (Chap. 320). Thyroxine (T_4) and free T_4 levels are usually in the low-normal range, triiodothyronine (T_3) levels are reduced, and reverse T_3 (rT_3) is elevated. The level of thyroid stimulating hormone (TSH) is normally or partially suppressed. Growth hormone is increased, but insulin-like growth factor 1 (IGF-1), which is produced mainly by the liver, is reduced, as in other conditions of starvation. Diminished bone density is routinely observed in AN and reflects the effects of multiple nutritional deficiencies, reduced gonadal steroids,

and increased cortisol. The degree of bone density reduction is proportional to the length of the illness, and patients are at risk for the development of symptomatic fractures. The occurrence of AN during adolescence may lead to the premature cessation of linear bone growth and a failure to achieve expected adult height.

Cardiac Abnormalities Cardiac output is reduced, and congestive heart failure occurs rarely during rapid refeeding. The electrocardiogram usually shows sinus bradycardia, reduced QRS voltage, and nonspecific ST-T-wave abnormalities. Some patients develop a prolonged QT_c interval, which may predispose to serious arrhythmias, particularly when electrolyte abnormalities are also present.

DIAGNOSIS The diagnosis of AN is based on the presence of characteristic behavioral, psychological, and physical attributes (Table 65-2). Widely accepted diagnostic criteria are provided by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). These criteria include weight <85% of that expected for age and height, which is roughly equivalent to a BMI of 18.5 kg/m^2 for adult women. This weight criterion is somewhat arbitrary, so that a patient who meets all other diagnostic criteria but weighs between 85 and 90% of expected would still merit the diagnosis of AN. The current diagnostic criteria require that women with AN not have spontaneous menses, but occasional patients with the characteristics and complications of AN describe regular menstruation. Two mutually exclusive subtypes of AN are specified in DSM-IV. Patients whose weight loss is maintained primarily by caloric restriction, perhaps augmented by excessive exercise, are considered to have the "restricting" subtype of AN. The "binge eating/purging" subtype is characterized by binge eating, self-induced vomiting and/or laxative abuse. Patients with the binge/purge subtype are more prone to develop electrolyte imbalances, are more emotionally labile, and are more likely to have other problems with impulse control, such as drug abuse.

The diagnosis of AN can usually be made confidently on the basis of history when significant weight loss is accomplished by restrictive dieting and excessive exercise and is accompanied by a marked reluctance to gain weight. Patients with AN often deny that they have a serious problem and may be brought to medical attention by concerned family or friends. In atypical presentations, other causes of significant weight loss in previously healthy young people should be considered, including inflammatory bowel disease, gastric outlet obstruction, diabetes mellitus, central nervous system (CNS) tumors, and neoplasm (Chap. 36).

PROGNOSIS The course and outcome of AN are highly variable. One-quarter to one-half of patients eventually recover fully, with few psychological or physical sequelae. However, many patients have persistent difficulties with weight maintenance, depression, and eating disturbances, including BN. The development of obesity following AN is rare. The long-term mortality of AN is among the highest associated with any psychiatric disorder. Approximately 5% of patients die per decade of follow-up, primarily due to the physical effects of chronic starvation or by suicide.

Virtually all of the physiologic abnormalities associated with AN are observed in other forms of starvation and markedly improve or disappear with weight gain. A worrisome exception is the reduction in bone mass, which may not recover fully, particularly when AN occurs during adolescence when peak bone mass is normally achieved.

TABLE 65-1 *Common Characteristics of Anorexia Nervosa and Bulimia Nervosa*

	Anorexia Nervosa[a]	*Bulimia Nervosa*
CLINICAL CHARACTERISTICS		
Onset	Mid-adolescence	Late adolescence/early adulthood
Female:male	10:1	10:1
Prevalence in women	0.5%	1–3%
Weight	Markedly decreased	Usually normal
Menstruation	Absent	Usually normal
Binge eating	25–50%	Required for diagnosis
Mortality	~5% Per decade	Low
PHYSICAL AND LABORATORY FINDINGS[A]		
Skin/extremities	Lanugo Acrocyanosis Edema	
Cardiovascular	Bradycardia Hypotension	
Gastrointestinal	Salivary gland enlargement Slow gastric emptying Constipation Elevated liver enzymes	Salivary gland enlargement Dental erosion
Hematopoietic	Normochromic, normocyctic anemia Leukopenia	
Fluid/Electrolyte	Increased BUN, creatinine Hyponatremia	Hypokalemia Hypochloremia Alkalosis
Endocrine	Hypoglycemia Low estrogen or testosterone Low LH and FSH Low-normal thyroxine Normal TSH Increased cortisol	
Bone	Osteopenia	

[a] Patients with the binge-eating/purging subtype of anorexia nervosa may also exhibit the physical and laboratory findings associated with bulimia nervosa.

Abbreviations: BUN, blood urea nitrogen; LH, luteinizing hormone; FSH, follicle stimulating hormone; TSH, thyroid stimulating hormone.

TREATMENT

Because of the profound physiologic and psychological effects of starvation, there is a broad consensus that weight restoration to 90% of predicted weight is the primary goal in the treatment of AN. Unfortunately, because most patients resist this goal, the management of AN is often accompanied by frustration for the patient, the family, and the physician. Patients typically exaggerate their food intake and minimize their symptoms. Some patients resort to subterfuge to make their weights appear higher, for example, by water-loading before they are weighed. In attempting to engage the patient in treatment, it may be useful for the physician to elicit the patient's physical concerns (e.g., about osteoporosis, weakness, or fertility) and, if possible, educate the patient regarding the importance of normalizing nutritional status in order to address those concerns. The physician should attempt to reassure the patient that weight gain will not be permitted to get "out of control" but simultaneously emphasize that weight restoration is medically and psychologically imperative.

TABLE 65-2 *Diagnostic Features of Anorexia Nervosa*

Refusal to maintain body weight at or above a minimally normal weight for age and height. (This includes a failure to achieve weight gain expected during a period of growth leading to an abnormally low body weight.)

Intense fear of weight gain or becoming fat.

Distortion of body image (e.g., feeling fat despite an objectively low weight or minimizing the seriousness of low weight).

Amenorrhea. (This criterion is met if menstrual periods occur only following hormone—e.g., estrogen—administration.)

The intensity of the initial treatment, including the need for hospitalization, is determined by the patient's current weight, the rapidity of recent weight loss, and the severity of medical and psychological complications (Fig. 65-1). Hospitalization should be strongly considered for patients weighing <75% of expected, even if the results of routine blood studies are within normal limits. Acute medical problems, such as severe electrolyte imbalances, should be identified and addressed. Nutritional restoration can almost always be successfully accomplished by oral feeding, and parenteral methods are rarely required. For severely underweight patients, sufficient calories (approximately 1500 to 1800 kcal/d) should be provided initially in divided meals as food or liquid supplements to maintain weight and to permit stabilization of fluid and electrolyte balance. Calories can then be gradually increased to achieve a weight gain of 1 to 2 kg (2 to 4 lb) per week, typically requiring an intake of 3000 to 4000 kcal/d. Meals must be supervised, ideally by personnel who are firm regarding the necessity of food consumption, empathic regarding the challenges entailed, and reassuring regarding the patient's eventual recovery. Patients have great psychological difficulty complying with the need for increased caloric consumption, and the assistance of psychiatrists or psychologists experienced in the treatment of AN is usually necessary.

Less severely affected patients may be treated in a partial hospitalization program where medical and psychiatric supervision is available and several meals can be monitored each day. Outpatient treatment may suffice for mildly ill patients. Weight must be monitored at frequent intervals, and explicit goals agreed on for weight gain, with the understanding that more intensive treatment will be required if the level of care initially employed is not successful. For younger patients, the active involvement of the family in treatment is crucial regardless of the treatment venue.

Psychiatric treatment focuses primarily on two issues. First, patients require much emotional support during the period of weight gain. Patients often intellectually agree with the need to gain weight, but strenuously resist increases in caloric intake, and often surreptitiously discard food that is provided. Second, patients must learn to base their self-esteem not on the achievement of an inappropriately low weight, but on the development of satisfying personal relationships and the attainment of reasonable academic and occupational goals. While this is often possible, some patients with AN develop other serious emotional and behavioral symptoms such as depression, self-mutilation, obsessive-compulsive behavior, and suicidal ideation. These symptoms may require additional therapeutic interventions, in the form of psychotherapy, medication, or hospitalization.

Medical complications occasionally occur during refeeding. As in other forms of malnutrition, fluid retention and peripheral edema may occur, but generally do not require specific treatment in the absence of cardiac, renal, or hepatic dysfunction. Acute gastric dilatation has been described when refeeding has been rapid. Transient modest elevations in serum levels of liver enzymes occasionally occur. Low levels of magnesium and phosphate should be repleted. Multivitamins should be given, and it is important to ensure adequate intake of vitamin D (400 IU/d) and calcium (1500 mg/d) to minimize bone loss.

No psychotropic medications are of established value in the treatment of AN; tricyclic antidepressants are contraindicated when there is prolongation of the QT_c interval. The alterations of cortisol and thyroid hormone metabolism do not require specific treatment and are corrected by weight gain. Estrogen treatment appears to have minimal impact on bone density in underweight patients but may be helpful to relieve symptoms of estrogen deficiency.

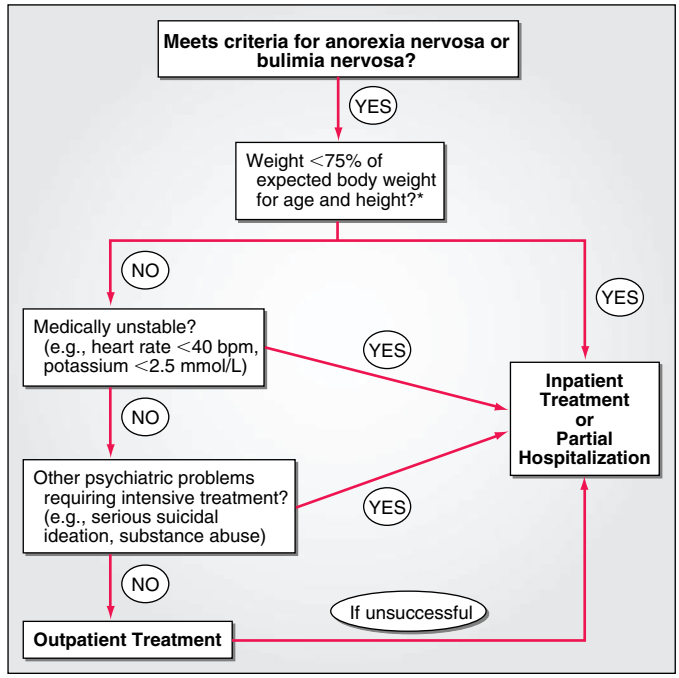

FIGURE 65-1 An algorithm for basic treatment decisions regarding patients with anorexia nervosa or bulimia nervosa. Based on the American Psychiatric Association's practice guidelines for the treatment of patients with eating disorders. *Although outpatient management may be considered for patients with anorexia nervosa weighing more than 75% of expected, there should be a low threshold for using more intensive interventions if the weight loss has been rapid or if current weight is <80% of expected.

BULIMIA NERVOSA

EPIDEMIOLOGY In women, the full syndrome of BN occurs with a lifetime prevalence of 1 to 3%. Variants of the disorder, such as occasional binge eating or purging, are much more common and occur in 5 to 10% of young women. The frequency of BN among men is less than one-tenth of that among women. The prevalence of BN increased dramatically in the early 1970s and 1980s but may have leveled off or declined somewhat in recent years.

ETIOLOGY As with AN, the etiology of BN is likely to be multifactorial. Patients who develop BN describe a higher-than-expected prevalence of childhood and parental obesity, suggesting that a predisposition towards obesity may increase vulnerability to this eating disorder. The marked increase in the number of cases of BN during the past 25 years and the rarity of BN in underdeveloped countries suggest that cultural factors are important. Several biologic abnormalities in patients with BN may perpetuate this disorder once it has begun. These include abnormalities of CNS serotonergic function, which is involved in the regulation of eating behavior, and disruption of peripheral satiety mechanisms, including the release of cholecystokinin (CCK) from the small intestine.

CLINICAL FEATURES (Table 65-3) The typical patient presenting for treatment of BN is a woman of normal weight in her mid-twenties who reports binge eating and purging 5 to 10 times a week for 5 to 10 years. The disorder usually begins in late adolescence or early adulthood during or following a diet, often in association with depressed mood. The self-imposed caloric restriction leads to increased hunger and to overeating. In an attempt to avoid weight gain, the patient induces vomiting, takes laxatives or diuretics, or engages in some other form of compensatory behavior. During binges, patients with this dis-

TABLE 65-3 Diagnostic Features of Bulimia Nervosa

Recurrent episodes of binge eating, which is characterized by the consumption of a large amount of food in a short period of time and a feeling that the eating is out of control.
Recurrent inappropriate behavior to compensate for the binge eating, such as self-induced vomiting.
The occurrence of both the binge eating and the inappropriate compensatory behavior at least twice weekly, on average, for 3 months.
Overconcern with body shape and weight.

Note: If the diagnostic criteria for anorexia nervosa are simultaneously met, only the diagnosis of anorexia nervosa is given.

order tend to consume large amounts of sweet foods with a high fat content, such as dessert items. The most frequent compensatory behaviors are self-induced vomiting and laxative abuse, but a wide variety of techniques have been described, including the omission of insulin injections by individuals with type 1 diabetes mellitus. Initially, patients may experience a sense of satisfaction that appealing food can be eaten without weight gain. However, as the disorder progresses, patients perceive diminished control over eating. Binges increase in size and frequency and are provoked by a variety of stimuli, such as transient depression, anxiety, or a sense that too much food has been consumed in a normal meal. Between binges, patients attempt to restrict caloric intake, which increases hunger and sets the stage for the next binge. Typically, patients with BN are ashamed of their behavior and endeavor to keep their disorder hidden from family and friends. Like patients with AN, those with BN place an unusual emphasis on weight and shape as a basis for their self-esteem. Many patients with BN have mild symptoms of depression. Some patients exhibit serious mood and behavioral disturbances, such as suicide attempts, sexual promiscuity, and drug and alcohol abuse. Although vomiting may be triggered initially by manual stimulation of the gag reflex, most patients with BN develop the ability to induce vomiting at will. Rarely, patients resort to the regular use of syrup of ipecac. Laxatives and diuretics are frequently taken in impressive quantities, such as 30 or 60 laxative pills on a single occasion. The resulting fluid loss produces dehydration and a feeling of emptiness but has little impact on caloric balance.

The physical abnormalities associated with BN primarily result from the purging behavior. Painless bilateral salivary gland hypertrophy (sialadenosis) may be noted. A scar or callus on the dorsum of the hand may develop due to repeated trauma from the teeth among patients who manually stimulate the gag reflex. Recurrent vomiting and the exposure of the lingual surfaces of the teeth to stomach acid lead to loss of dental enamel and eventually to chipping and erosion of the front teeth. Laboratory abnormalities are surprisingly infrequent, but hypokalemia, hypochloremia, and hyponatremia are observed occasionally. Repeated vomiting may lead to alkalosis, whereas repeated laxative abuse may produce a mild metabolic acidosis. Serum amylase may be mildly elevated due to an increase in the salivary isoenzyme.

Serious physical complications resulting from BN are rare. Oligomenorrhea and amenorrhea are more frequent than among women without eating disorders. Arrhythmias occasionally occur secondary to electrolyte disturbances. Tearing of the esophagus and rupture of the stomach have been reported, and constitute life-threatening events. Some patients who have chronically abused laxatives or diuretics develop transient peripheral edema when this behavior ceases, presumably due to high levels of aldosterone secondary to persistent fluid and electrolyte depletion.

DIAGNOSIS The critical diagnostic features of BN are repeated episodes of binge eating followed by inappropriate and abnormal behaviors aimed at avoiding weight gain (Table 65-3). The diagnosis of BN requires a candid history from the patient detailing frequent, large eating binges followed by the purposeful use of inappropriate mechanisms to avoid weight gain. Most patients with BN who present for treatment are distressed by their inability to control their eating behavior but are able to provide such details if queried in a supportive and nonjudgmental fashion.

As in AN, there are two mutually exclusive subtypes of BN. Patients with the "purging" subtype utilize compensatory behaviors that directly rid the body of calories or fluids (e.g., self-induced vomiting, laxative or diuretic abuse), whereas those with the "nonpurging" subtype attempt to compensate for binges by fasting or by excessive exercise. Patients with the nonpurging subtype tend to be heavier and are less prone to fluid and electrolyte disturbances.

PROGNOSIS The prognosis of BN is much more favorable than that of AN. Mortality is low, and full recovery occurs in approximately 50% of patients within 10 years. Approximately 25% of patients have persistent symptoms of BN over many years. Few patients progress from BN to AN.

℞ TREATMENT

BN can usually be treated on an outpatient basis (Figure 65-1). Cognitive behavioral therapy (CBT) is a short-term (4 to 6 months) psychological treatment that focuses on the intense concern with shape and weight, the persistent dieting, and the binge eating and purging that characterize this disorder. Patients are directed to monitor the circumstances, thoughts, and emotions associated with binge/purge episodes, to eat regularly, and to challenge their assumptions linking weight to self-esteem. CBT produces symptomatic remission in 25 to 50% of patients.

Numerous double-bind, placebo-controlled trials have documented that antidepressant medications are useful in the treatment of BN but are probably somewhat less effective than CBT. Although efficacy has been established for virtually all chemical classes of antidepressants, only the selective serotonin reuptake inhibitor fluoxetine (Prozac) has been approved for use in BN by the U.S. Food and Drug Administration. Antidepressant medications are helpful even for patients with BN who are not depressed, and the dose of fluoxetine recommended for BN (60 mg/d) is higher than that typically used to treat depression. These observations suggest that different mechanisms may underlie the utility of these medications in BN and in depression.

A subset of patients with BN does not respond adequately to CBT, antidepressant medication, or their combination. More intensive forms of treatment, including hospitalization, may be required for such patients.

66 APPROACH TO THE PATIENT WITH CANCER

Dan L. Longo

The application of current treatment techniques (surgery, radiation therapy, chemotherapy, and biological therapy) results in the cure of >50% of patients diagnosed with cancer. Nevertheless, patients experience the diagnosis of cancer as one of the most traumatic and revolutionary events that has ever happened to them. Independent of prognosis, the diagnosis brings with it a change in a person's self-image and in his or her role in the home and workplace. The prognosis of a person who has just been found to have pancreatic cancer is the same as the prognosis of the person with aortic stenosis who develops the first symptoms of congestive heart failure (median survival, about 8 months). However, the patient with heart disease may remain functional and maintain a self-image as a fully intact person with just a malfunctioning part, a diseased organ ("a bum ticker"). By contrast, the patient with pancreatic cancer has a completely altered self-image and is viewed differently by family and anyone who knows the diagnosis. He or she is being attacked and invaded by a disease that could be anywhere in the body. Every ache or pain takes on desperate significance. Cancer is an exception to the coordinated interaction among cells and organs. In general, the cells of a multicellular organism are programmed for collaboration. Many diseases occur because the specialized cells fail to perform their assigned task. Cancer takes this malfunction one step further. Not only is there a failure of the cancer cell to maintain its specialized function, but it also strikes out on its own; the cancer cell competes to survive using natural mutability and natural selection to seek advantage over normal cells in a recapitulation of evolution. One consequence of the traitorous behavior of cancer cells is that the patient feels betrayed by his or her body. The cancer patient feels that he or she, and not just a body part, is diseased.

THE MAGNITUDE OF THE PROBLEM

No nationwide cancer registry exists; therefore, the incidence of cancer is estimated on the basis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database, which tabulates cancer incidence and death figures from nine sites, accounting for about 10% of the U.S. population, and from population data from the Bureau of the Census. In 2004, 1.36 million new cases of invasive cancer (699,560 men, 668,470 women) were diagnosed and 563,700 persons (290,890 men, 272,810 women) died from cancer. The percent distribution of new cancer cases and cancer deaths by site for men and women are shown in Table 66-1. Cancer incidence has been declining by about 2% each year since 1992.

The most significant risk factor for cancer overall is age; two-thirds of all cases were in those over age 65. Cancer incidence increases as the third, fourth, or fifth power of age in different sites. For the interval between birth and age 39, 1 in 72 men and 1 in 51 women will develop cancer; for the interval between ages 40 and 59, 1 in 12 men and 1 in 11 women will develop cancer; and for the interval between ages 60 and 79, 1 in 3 men and 1 in 5 women will develop cancer.

Cancer is the second leading cause of death behind heart disease. Deaths from heart disease have declined 45% in the United States since 1950 and continue to decline. After a 70-year period of increases, cancer deaths began to decline in 1997 (Fig. 66-1). The five leading causes of cancer deaths are shown for various populations in Table 66-2. Along with the decrease in incidence has come an increase in survival for cancer patients. The 5-year survival for white patients was 39% in 1960–1963 and 64% in 1992–1998. Cancers are more often deadly in blacks; the 5-year survival was 53% for the 1992–1998 interval. Incidence and mortality vary among racial and ethnic groups (Table 66-3). The basis for these differences is unclear.

PATIENT MANAGEMENT

Important information is obtained from every portion of the routine history and physical examination. The duration of symptoms may reveal the chronicity of disease. The past medical history may alert the physician to the presence of underlying diseases that may affect the choice of therapy or the side effects of treatment. The social history may reveal occupational exposure to carcinogens or habits, such as smoking or alcohol consumption, that may influence the course of disease and its treatment. The family history may suggest an underlying familial cancer predisposition and point out the need to begin surveillance or other preventive therapy for unaffected siblings of the patient. The review of systems may suggest early symptoms of metastatic disease or a paraneoplastic syndrome.

DIAGNOSIS The diagnosis of cancer relies most heavily on invasive tissue biopsy and should never be made without obtaining tissue; no noninvasive diagnostic test is sufficient to define a disease process as cancer. Although in rare clinical settings (e.g., thyroid nodules) fine-needle aspiration is an acceptable diagnostic procedure, the diagnosis generally depends on obtaining adequate tissue to permit careful eval-

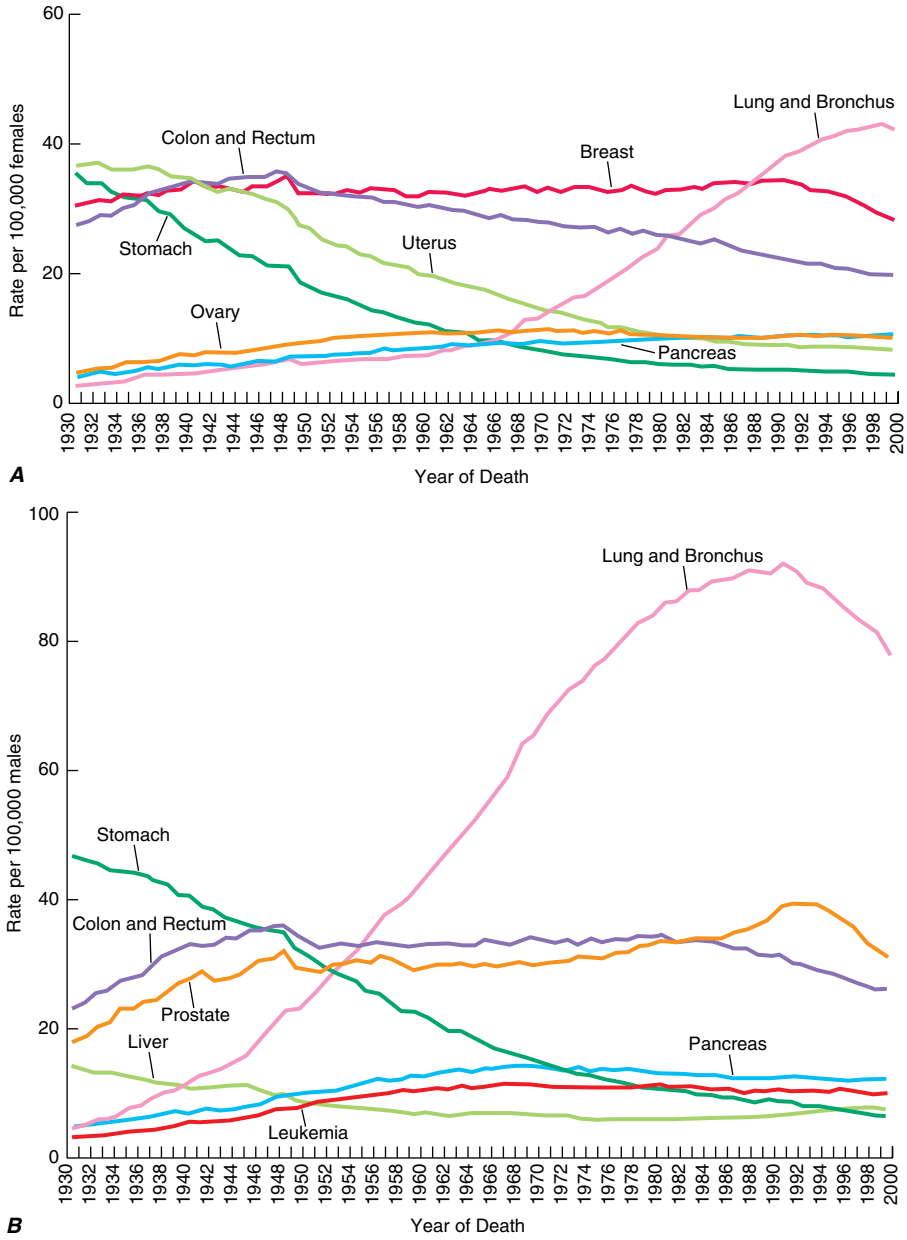

FIGURE 66-1 Sixty-year trend in cancer death rates for (*A*) women and (*B*) men, by site in the United States, 1930–1999. Rates are per 100,000 age-adjusted to the 2000 U.S. standard population. (*From Jemal et al.*)

uation of the histology of the tumor, its grade, and its invasiveness and to yield further molecular diagnostic information, such as the expression of cell-surface markers or intracellular proteins that typify a particular cancer, or the presence of a molecular marker, such as the t(8;14) translocation of Burkitt's lymphoma. Increasing evidence links the expression of certain genes with the prognosis and response to therapy (Chaps. 68, 69).

Occasionally a patient will present with a metastatic disease process that is defined as cancer on biopsy but has no apparent primary site of disease. Efforts should be made to define the primary site based on age, sex, sites of involvement, histology and tumor markers, and personal and family history. Particular attention should be focused on ruling out the most treatable causes (Chap. 85).

Once the diagnosis of cancer is made, the management of the patient is best undertaken as a multidisciplinary collaboration among the primary care physician, medical oncologists, surgical oncologists, radiation oncologists, oncology nurse specialists, pharmacists, social workers, rehabilitation medicine specialists, and a number of other consulting professionals working closely with each other and with the patient and family.

DEFINING THE EXTENT OF DISEASE AND THE PROGNOSIS The first priority in patient management after the diagnosis of cancer is established and shared with the patient is to determine the extent of disease. The curability of a tumor usually is inversely proportional to the tumor burden. Ideally, the tumor will be diagnosed before symptoms develop or as a consequence of screening efforts (Chap. 67). A very high proportion of such patients can be cured. However, most patients with cancer present with symptoms related to the cancer, caused either by mass effects of the tumor or by alterations associated with the production of cytokines or hormones by the tumor.

For most cancers, the extent of disease is evaluated by a variety of noninvasive and invasive diagnostic tests and procedures. This process is called *staging*. There are two types. *Clinical staging* is based on physical examination, radiographs, isotopic scans, computed tomography, and other imaging procedures; *pathologic staging* takes into account information obtained during a surgical procedure, which might include intraoperative palpation, resection of regional lymph nodes and/or tissue adjacent to the tumor, and inspection and biopsy of organs commonly involved in disease spread. Pathologic staging includes histologic examination of all tissues removed during the surgical procedure. Surgical procedures performed may include a simple lymph node biopsy or more extensive procedures such as thoracotomy, mediastinoscopy, or laparotomy. Surgical staging may occur in a separate procedure or may be done at the time of definitive surgical resection of the primary tumor.

Knowledge of the predilection of particular tumors for spread to adjacent or distant organs helps direct the staging evaluation.

Information obtained from staging is used to define the extent of disease either as localized, as exhibiting spread

outside of the organ of origin to regional but not distant sites, or as metastatic to distant sites. The most widely used system of staging is the TNM (tumor, node, metastasis) system codified by the International Union Against Cancer and the American Joint Committee on Cancer (AJCC).[1] The TNM classification is an anatomically based system that categorizes the tumor on the basis of the size of the primary tumor lesion (T1–4, where a higher number indicates a tumor of larger size), the presence of nodal involvement (usually N0 and N1 for the absence and presence, respectively, of involved nodes, although some tumors have more elaborate systems of nodal grading), and the presence of metastatic disease (M0 and M1 for the absence and presence, respectively, of metastases). The various permutations of T, N, and M scores (sometimes including tumor histologic grade G) are then broken into stages, usually designated by the roman numerals I through IV. Tumor burden increases and curability decreases with increasing stage. Other anatomic staging systems are used for some tumors, e.g., the Dukes classification for colorectal cancers, the International Federation of Gynecologists and Obstetricians (FIGO) classification for gynecologic cancers, and the Ann Arbor classification for Hodgkin's disease.

Note: M, male; F, female.

Certain tumors cannot be grouped on the basis of anatomic considerations. For example, hematopoietic tumors such as leukemia, myeloma, and lymphoma are often disseminated at presentation and do not spread like solid tumors. For these tumors, other prognostic factors have been identified (Chaps. 96, 97, 98).

In addition to tumor burden, a second major determinant of treatment outcome is the physiologic reserve of the patient. Patients who are bedridden before developing cancer are likely to fare worse, stage for stage, than fully active patients. Physiologic reserve is a determinant of how a patient is likely to cope with the physiologic stresses imposed by the cancer and its treatment. This factor is difficult to assess directly. Instead, surrogate markers for physiologic reserve are used, such as the patient's age or Karnofsky performance status (Table 66-4). Older patients and those with a Karnofsky performance status <70 have a poor prognosis unless the poor performance is a reversible consequence of the tumor.

Increasingly, biologic features of the tumor are being related to prognosis. The expression of particular oncogenes, drug-resistance genes, apoptosis-related genes, and genes involved in metastasis are being found to influence response to therapy and prognosis. The presence of selected cytogenetic abnormalities may influence survival. Tumors with higher growth fractions, as assessed by expression of proliferation-related markers such as proliferating cell nuclear antigen (PCNA), behave more aggressively than tumors with lower growth fractions. Information obtained from studying the tumor itself will increasingly be used to influence treatment decisions.

MAKING A TREATMENT PLAN From information on the extent of disease and the prognosis and in conjunction with the patient's wishes, it is determined whether the treatment approach should be curative or palliative in intent. Cooperation among the various professionals involved in cancer treatment is of the utmost importance in treatment planning. For some cancers, chemotherapy or chemotherapy plus radiation therapy delivered before the use of definitive surgical treatment (so-called neoadjuvant therapy) may improve the outcome, as seems to be the case for locally advanced breast cancer and head and neck cancers. In certain settings in which combined modality therapy is intended, coordination among the medical oncologist, radiation oncologist, and surgeon is crucial to achieving optimal results. Sometimes the chemotherapy and radiation therapy need to be delivered sequentially, and other times concurrently. Surgical procedures may precede or follow other treatment approaches. It is best for the treatment plan either to follow a standard protocol precisely or else to be part of an ongoing clinical research protocol evaluating new treatments. Ad hoc modifications of standard protocols are likely to compromise treatment results.

The choice of treatment approaches was formerly dominated by the local culture in both the university and the practice settings. However, it is now possible to gain access electronically to standard treatment protocols and to every approved clinical research study in North America through a personal computer interface with the Internet.[2]

The skilled physician also has much to offer the patient for whom curative therapy is no longer an option. Often a combination of guilt and frustration over the inability to cure the patient and the pressure of a busy schedule greatly limit the time a physician spends with a patient who is receiving only palliative care. Resist these forces. In addition to the medicines administered to alleviate symptoms (see below), it is important to remember the comfort that is provided by holding the patient's hand, continuing regular examinations, and taking time to talk.

MANAGEMENT OF DISEASE AND TREATMENT COMPLICATIONS Because cancer therapies are toxic (Chaps. 70, 71), patient management involves addressing complications of both the disease and its treatment as well as the complex psychosocial problems associated with cancer. In the short term during a course of curative therapy, the patient's functional status may decline. Treatment-induced toxicity is less acceptable if the goal of therapy is palliation. The most common side effects of treatment are nausea and vomiting (see below), febrile neutropenia (Chap. 72), and myelosuppression (Chap. 70). Therapeutic tools are now available to minimize the acute toxicity of cancer treatment.

New symptoms developing in the course of cancer treatment should

[1]The AJCC *Manual for Staging Cancer*, 5th edition, can be obtained from the AJCC at 55 East Erie Street, Chicago, IL, 60611.

[2]The National Cancer Institute maintains a database called PDQ (Physician Data Query) that is accessible on the Internet under the name CancerNet at *wwwicic.nci.nih.gov/health.htm*. Information can be obtained through a facsimile machine using CancerFax by dialing 301-402-5874. Patient information is also provided by the National Cancer Institute in at least three formats: on the Internet via CancerNet at *wwwicic.nci.nih.gov/patient.htm*, through the CancerFax number listed above, or by calling 1-800-4-CANCER. The quality control for the information provided through these services is rigorous.

TABLE 66-4 *Karnofsky Performance Index*

Performance Status	Functional Capability of the Patient
100	Normal; no complaints; no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or do active work
60	Requires occasional assistance but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated although death is not imminent
20	Very sick; hospitalization necessary; active supportive treatment is necessary
10	Moribund, fatal processes progressing rapidly
0	Dead

always be assumed to be reversible until proven otherwise. The fatalistic attribution of anorexia, weight loss, and jaundice to recurrent or progressive tumor could result in a patient dying from a reversible intercurrent cholecystitis. Intestinal obstruction may be due to reversible adhesions rather than progressive tumor. Systemic infections, sometimes with unusual pathogens, may be a consequence of the immunosuppression associated with cancer therapy. Some drugs used to treat cancer or its complications (e.g., nausea) may produce central nervous system symptoms that look like metastatic disease or may mimic paraneoplastic syndromes such as the syndrome of inappropriate antidiuretic hormone. A definitive diagnosis should be pursued and may even require a repeat biopsy.

A critical component of cancer management is assessing the response to treatment. In addition to a careful physical examination in which all sites of disease are physically measured and recorded in a flow chart by date, response assessment usually requires periodic repeating of imaging tests that were abnormal at the time of staging. If imaging tests have become normal, repeat biopsy of previously involved tissue is performed to document complete response by pathologic criteria. Biopsies are not usually required if there is macroscopic residual disease. A *complete response* is defined as disappearance of all evidence of disease, and a *partial response* as >50% reduction in the sum of the products of the perpendicular diameters of all measureable lesions. *Progressive disease* is defined as the appearance of any new lesion or an increase of >25% in the sum of the products of the perpendicular diameters of all measurable lesions. Tumor shrinkage or growth that does not meet any of these criteria is considered *stable disease*. Some sites of involvement (e.g., bone) or patterns of involvement (e.g., lymphangitic lung or diffuse pulmonary infiltrates) are considered unmeasurable. No response is complete without biopsy documentation of their resolution, but partial responses may exclude their assessment unless clear objective (though unmeasurable) progression has occurred.

Tumor markers may be useful in patient management in certain tumors. Response to therapy may be difficult to gauge with certainty. However, some tumors produce or elicit the production of markers that can be measured in the serum or urine and, in a particular patient, rising and falling levels of the marker are usually associated with increasing or decreasing tumor burden, respectively. Some clinically useful tumor markers are shown in Table 66-5. Tumor markers are not in themselves specific enough to permit a diagnosis of malignancy to be made, but once a malignancy has been diagnosed and shown to be associated with elevated levels of a tumor marker, the marker can be used to assess response to treatment.

The recognition and treatment of depression are important components of management. The incidence of depression in cancer patients is ~25% overall and may be greater in patients with greater debility. This diagnosis is likely in a patient with a depressed mood (dysphoria) and/or a loss of interest in pleasure (anhedonia) for at least 2 weeks. In addition, three or more of the following symptoms are usually present: appetite change, sleep problems, psychomotor retardation or agitation, fatigue, feelings of guilt or worthlessness, inability to concentrate, and suicidal ideation. Patients with these symptoms should receive therapy. Medical therapy with a serotonin reuptake inhibitor such as fluoxetine (10 to 20 mg/d), sertraline (50 to 150 mg/d), or paroxetine (10 to 20 mg/d) or a tricyclic antidepressant such as amitriptyline (50 to 100 mg/d) or desipramine (75 to 150 mg/d) should be tried, allowing 4 to 6 weeks for response. Effective therapy should be continued at least 6 months after resolution of symptoms. If therapy is unsuccessful, other classes of antidepressants may be used. In addition to medication, psychosocial interventions such as support groups, psychotherapy, and guided imagery may be of benefit.

Many patients opt for unproven or unsound approaches to treatment when it appears that conventional medicine is unlikely to be curative. Those seeking such alternatives are often well educated and may be early in the course of their disease. Unsound approaches are usually hawked on the basis of unsubstantiated anecdotes and not only cannot help the patient but may be harmful. Physicians should strive to keep communications open and nonjudgmental, so that patients are more likely to discuss with the physician what they are actually doing. The appearance of unexpected toxicity may be an indication that a supplemental therapy is being taken.[3]

LONG-TERM FOLLOW-UP/LATE COMPLICATIONS At the completion of treatment, sites originally involved with tumor are reassessed, usually by radiography or imaging techniques, and any persistent abnormality is biopsied. If disease persists, the multidisciplinary team discusses a new salvage treatment plan. If the patient has been rendered disease-free by the original treatment, the patient is followed regularly for disease recurrence. The optimal guidelines for follow-up care are not known. For many years, a routine practice has been to follow the patient monthly for 6 to 12 months, then every other month for a year, every 3 months for a year, every 4 months for a year, every 6 months for a year, and then annually. At each visit, a battery of laboratory and radiographic and imaging tests were obtained on the assumption that it is best to detect recurrent disease before it becomes symptomatic. However, where follow-up procedures have been examined, this assumption has been found to be untrue. Studies of breast cancer, melanoma, lung cancer, colon cancer, and lymphoma have all failed to support the notion that asymptomatic relapses are more readily cured by salvage therapy than symptomatic relapses. In view of the enormous cost of a full battery of diagnostic tests and their manifest lack of impact on survival, new guidelines are emerging for less frequent follow-up visits, during which the history and physical examination are the major investigations performed.

As time passes, the likelihood of recurrence of the primary cancer diminishes. For many types of cancer, survival for 5 years without recurrence is tantamount to cure. However, important medical problems can occur in patients treated for cancer and must be examined (Chap. 89). Some problems emerge as a consequence of the disease and some as a consequence of the treatment. An understanding of these disease- and treatment-related problems may help in their detection and management.

Despite these concerns, most patients who are cured of cancer return to normal lives.

SUPPORTIVE CARE In many ways, the success of cancer therapy depends on the success of the supportive care. Failure to control the symptoms

[3]Information about unsound methods may be obtained from the National Council Against Health Fraud, Box 1276, Loma Linda, CA 92354, or from the Center for Medical Consumers and Health Care Information, 237 Thompson Street, New York, NY 10012.

of cancer and its treatment may lead patients to abandon curative therapy. Of equal importance, supportive care is a major determinant of quality of life. Even when life cannot be prolonged, the physician must strive to preserve its quality. Quality-of-life measurements have become common end-points of clinical research studies. Furthermore, palliative care has been shown to be cost-effective when approached in an organized fashion. A credo for oncology could be to cure sometimes, to extend life often, and to comfort always.

TABLE 66-5 *Tumor Markers*

Tumor Markers	Cancer	Non-Neoplastic Conditions
HORMONES		
Human chorionic gonadotropin	Gestational trophoblastic disease, gonadal germ cell tumor	Pregnancy
Calcitonin	Medullary cancer of the thyroid	
Catecholamines	Pheochromocytoma	
ONCOFETAL ANTIGENS		
Alphafetoprotein	Hepatocellular carcinoma, gonadal germ cell tumor	Cirrhosis, hepatitis
Carcinoembryonic antigen	Adenocarcinomas of the colon, pancreas, lung, breast, ovary	Pancreatitis, hepatitis, inflammatory bowel disease, smoking
ENZYMES		
Prostatic acid phosphatase	Prostate cancer	Prostatitis, prostatic hypertrophy
Neuron-specific enolase	Small cell cancer of the lung, neuroblastoma	
Lactate dehydrogenase	Lymphoma, Ewing's sarcoma	Hepatitis, hemolytic anemia, many others
TUMOR-ASSOCIATED PROTEINS		
Prostate-specific antigen	Prostate cancer	Prostatitis, prostatic hypertrophy
Monoclonal immunoglobulin	Myeloma	Infection, MGUS[a]
CA-125	Ovarian cancer, some lymphomas	Menstruation, peritonitis, pregnancy
CA 19-9	Colon, pancreatic, breast cancer	Pancreatitis, ulcerative colitis
CD30	Hodgkin's disease, anaplastic large cell lymphoma	—
CD25	Hairy cell leukemia, adult T cell leukemia/lymphoma	—

[a] MGUS, monoclonal gammopathy of uncertain significance.

Pain Pain occurs with variable frequency in the cancer patient: 25 to 50% of patients present with pain at diagnosis, 33% have pain associated with treatment, and 75% have pain with progressive disease. The pain may have several causes. In about 70% of cases, pain is caused by the tumor itself—by invasion of bone, nerves, blood vessels, or mucous membranes or obstruction of a hollow viscus or duct. In about 20% of cases, pain is related to a surgical or invasive medical procedure, to radiation injury (mucositis, enteritis, or plexus or spinal cord injury), or to chemotherapy injury (mucositis, peripheral neuropathy, phlebitis, steroid-induced aseptic necrosis of the femoral head). In 10% of cases, pain is unrelated to cancer or its treatment.

Assessment of pain requires the methodical investigation of the history of the pain, its location, character, temporal features, provocative and palliative factors, and intensity (Chap. 11); a review of the oncologic history and past medical history as well as personal and social history; and a thorough physical examination. The patient should be given a 10-division visual analogue scale on which to indicate the severity of the pain. The clinical condition is often dynamic, making it necessary to reassess the patient frequently. Pain therapy should not be withheld while the cause of pain is being sought.

A variety of tools are available with which to address cancer pain. About 85% of patients will have pain relief from pharmacologic intervention. However, other modalities, including antitumor therapy (such as surgical relief of obstruction, radiation therapy, and strontium-89 or samarium-153 treatment for bone pain), neurostimulatory techniques, regional analgesia, or neuroablative procedures are effective in an additional 12% or so. Thus, very few patients will have inadequate pain relief if appropriate measures are taken. →***A specific approach to pain relief is detailed in Chap. 9.***

Nausea Emesis in the cancer patient is usually caused by chemotherapy (Chap. 70). Its severity can be predicted from the drugs used to treat the cancer. Three forms of emesis are recognized on the basis of their timing with regard to the noxious insult. *Acute emesis*, the most common variety, occurs within 24 h of treatment. *Delayed emesis* occurs 1 to 7 days after treatment; it is rare, but, when present, usually follows cisplatin administration. *Anticipatory emesis* occurs before administration of chemotherapy and represents a conditioned response to visual and olfactory stimuli previously associated with chemotherapy delivery.

Acute emesis is the best understood form. Stimuli that activate signals in the chemoreceptor trigger zone in the medulla, the cerebral cortex, and peripherally in the intestinal tract lead to stimulation of the vomiting center in the medulla, the motor center responsible for coordinating the secretory and muscle contraction activity that leads to emesis. Diverse receptor types participate in the process, including dopamine, serotonin, histamine, opioid, and acetylcholine receptors. The serotonin receptor antagonists ondansetron and granisetron are the most effective drugs against highly emetogenic agents, but they are expensive.

As with the analgesia ladder, emesis therapy should be tailored to the situation. For mildly and moderately emetogenic agents, prochlorperazine, 5 to 10 mg orally or 25 mg rectally, is effective. Its efficacy may be enhanced by administering the drug before the chemotherapy is delivered. Dexamethasone, 10 to 20 mg intravenously, is also effective and may enhance the efficacy of prochlorperazine. For highly emetogenic agents such as cisplatin, mechlorethamine, dacarbazine, and streptozocin, combinations of agents work best and administration should begin 6 to 24 h before treatment. Ondansetron, 8 mg orally every 6 h the day before therapy and intravenously on the day of therapy, plus dexamethasone, 20 mg intravenously before treatment, is an effective regimen. Addition of oral aprepitant (a substance P/neurokinin 1 receptor antagonist) to this regimen (125 mg on day 1, 80 mg on days 2 and 3) further decreases the risk of both acute and delayed vomiting. Like pain, emesis is easier to prevent than to alleviate.

Delayed emesis may be related to bowel inflammation from the therapy and can be controlled with oral dexamethasone and oral metoclopramide, a dopamine receptor antagonist that also blocks serotonin receptors at high dosages. The best strategy for preventing anticipatory emesis is to control emesis in the early cycles of therapy to prevent the conditioning from taking place. If this is unsuccessful, prophylactic antiemetics the day before treatment may help. Experimental studies are evaluating behavior modification.

Effusions Fluid may accumulate abnormally in the pleural cavity, pericardium, or peritoneum. Asymptomatic malignant effusions may not require treatment. Symptomatic effusions occurring in tumors responsive to systemic therapy usually do not require local treatment but respond to the treatment for the underlying tumor. Symptomatic effusions occurring in tumors unresponsive to systemic therapy may require local treatment in patients with a life expectancy of at least 6 months.

Pleural effusions due to tumors may or may not contain malignant cells. Lung cancer, breast cancer, and lymphomas account for about 75% of malignant pleural effusions. Their exudative nature is usually gauged by an effusion/serum protein ratio of ≥0.5 or an effusion/serum lactate dehydrogenase ratio of ≥0.6. When the condition is symptomatic, thoracentesis is usually performed first. In most cases, symptomatic improvement occurs for <1 month. Chest tube drainage is required if symptoms recur within 2 weeks. Fluid is aspirated until the flow rate is <100 mL in 24 h. Then either 60 units of bleomycin or 1 g of doxycycline is infused into the chest tube in 50 mL of 5% dextrose in water; the tube is clamped; the patient is rotated on four sides, spending 15 min in each position; and, after 1 to 2 h, the tube is again attached to suction for another 24 h. The tube is then disconnected from suction and allowed to drain by gravity. If <100 mL drains over the next 24 h, the chest tube is pulled, and a radiograph taken 24 h later. If the chest tube continues to drain fluid at an unacceptably high rate, sclerosis can be repeated. Bleomycin may be somewhat more effective than doxycycline but is very expensive. Doxycycline is usually the drug of first choice. If neither doxycycline nor bleomycin is effective, talc can be used.

Symptomatic pericardial effusions are usually treated by creating a pericardial window or by stripping the pericardium. If the patient's condition does not permit a surgical procedure, sclerosis can be attempted with doxycycline and/or bleomycin.

Malignant ascites is usually treated with repeated paracentesis of small volumes of fluid. If the underlying malignancy is unresponsive to systemic therapy, peritoneovenous shunts may be inserted. Despite the fear of disseminating tumor cells into the circulation, widespread metastases are an unusual complication. The major complications are occlusion, leakage, and fluid overload. Patients with severe liver disease may develop disseminated intravascular coagulation.

Nutrition Cancer and its treatment may lead to a decrease in nutrient intake of sufficient magnitude to cause weight loss and alteration of intermediary metabolism. The prevalence of this problem is difficult to estimate because of variations in the definition of cancer cachexia, but most patients with advanced cancer experience weight loss and decreased appetite. A variety of both tumor-derived factors (e.g., bombesin, adrenocorticotropic hormone) and host-derived factors (e.g., tumor necrosis factor, interleukins 1 and 6, growth hormone) contribute to the altered metabolism, and a vicious cycle is established in which protein catabolism, glucose intolerance, and lipolysis cannot be reversed by the provision of calories.

It remains controversial how to assess nutritional status and when and how to intervene. Efforts to make the assessment objective have included the use of a prognostic nutritional index based on albumin levels, triceps skin fold thickness, transferrin levels, and delayed-type hypersensitivity skin testing. However, a simpler approach has been to define the threshold for nutritional intervention as >10% unexplained body weight loss, serum transferrin level <1500 mg/L (150 mg/dL), and serum albumin <34 g/L (3.4 g/dL).

The decision is important, because it appears that cancer therapy is substantially more toxic and less effective in the face of malnutrition. Nevertheless, it remains unclear whether nutritional intervention can alter the natural history. Unless some pathology is affecting the absorptive function of the gastrointestinal tract, enteral nutrition provided orally or by tube feeding is preferred over parenteral supplementation. However, the risks associated with the tube may outweigh the benefits. Megestrol acetate, a progestational agent, has been advocated as a pharmacologic intervention to improve nutritional status. Research in this area may provide more tools in the future as cytokine-mediated mechanisms are further elucidated.

Psychosocial Support The psychosocial needs of patients vary with their situation. Patients undergoing treatment experience fear, anxiety, and depression. Self-image is often seriously compromised by deforming surgery and loss of hair. Women who receive cosmetic advice that enables them to look better also feel better. Loss of control over how one spends time can contribute to the sense of vulnerability. Juggling the demands of work and family with the demands of treatment may create enormous stresses. Sexual dysfunction is highly prevalent and needs to be discussed openly with the patient. An empathetic health care team is sensitive to the individual patient's needs and permits negotiation where such flexibility will not adversely affect the course of treatment.

Cancer survivors have other sets of difficulties. Patients may have fears associated with the termination of a treatment they associate with their continued survival. Adjustments are required to physical losses and handicaps, real and perceived. Patients may be preoccupied with minor physical problems. They perceive a decline in their job mobility and view themselves as less desirable workers. They may be victims of job and/or insurance discrimination. Patients may experience difficulty reentering their normal past life. They may feel guilty for having survived and may carry a sense of vulnerability to colds and other illnesses. Perhaps the most pervasive and threatening concern is the ever-present fear of relapse (the Damocles syndrome).

Patients in whom therapy has been unsuccessful have other problems related to the end of life.

Death and Dying The most common causes of death in patients with cancer are infection (leading to circulatory failure), respiratory failure, hepatic failure, and renal failure. Intestinal blockage may lead to inanition and starvation. Central nervous system disease may lead to seizures, coma, and central hypoventilation. About 70% of patients develop dyspnea preterminally. However, many months usually pass between the diagnosis of cancer and the occurrence of these complications, and during this period the patient is severely affected by the possibility of death. The path of unsuccessful cancer treatment usually occurs in three phases. First, there is optimism at the hope of cure; when the tumor recurs, there is the acknowledgment of an incurable disease, and the goal of palliative therapy is embraced in the hope of being able to live with disease; finally, at the disclosure of imminent death, another adjustment in outlook takes place. The patient imagines the worst in preparation for the end of life and may go through stages of adjustment to the diagnosis. These stages include denial, isolation, anger, bargaining, depression, acceptance, and hope. Of course, patients do not all progress through all the stages or proceed through them in the same order or at the same rate. Nevertheless, developing an understanding of how the patient has been affected by the diagnosis and is coping with it is an important goal of patient management.

It is best to speak frankly with the patient and the family regarding the likely course of disease. These discussions can be difficult for the physician as well as for the patient and family. The critical features of the interaction are to reassure the patient and family that everything that can be done to provide comfort will be done. They will not be abandoned. Many patients prefer to be cared for in their homes or in a hospice setting rather than a hospital. The American College of Physicians has published a book called *Home Care Guide for Cancer: How to Care for Family and Friends at Home* that teaches an approach to successful problem-solving in home care. With appropriate planning, it should be possible to provide the patient with the necessary medical care as well as the psychological and spiritual support that will prevent the isolation and depersonalization that can attend in-hospital death.

The care of dying patients may take a toll on the physician. A "burnout" syndrome has been described that is characterized by fatigue, disengagement from patients and colleagues, and a loss of self-fulfillment. Efforts at stress reduction, maintenance of a balanced life, and setting realistic goals may combat this disorder.

End-of-Life Decisions Unfortunately, a smooth transition in treatment goals from curative to palliative may not be possible in all cases because of the occurrence of serious treatment-related complications or rapid disease progression. Vigorous and invasive medical support for a reversible disease or treatment complication is assumed to be justified. However, if the reversibility of the condition is in doubt, the

patient's wishes determine the level of medical care. These wishes should be elicited before the terminal phase of illness and reviewed periodically. Information about advance directives can be obtained from the American Association of Retired Persons, 601 E Street, NW, Washington, DC 20049, 202-434-2277 or Choice in Dying, 250 West 57th Street, New York, NY 10107, 212-366-5540. →***A full discussion of end-of-life management is in Chap. 9.***

67 PREVENTION AND EARLY DETECTION OF CANCER

Otis W. Brawley, Barnett S. Kramer

Cancer prevention and control is a burgeoning field because of advances in understanding the biology of carcinogenesis. The field has expanded beyond the identification and avoidance of carcinogens to include studies of specific interventions to lower cancer risk, as well as screening for early detection of cancer.

Central to cancer prevention and control is the concept that carcinogenesis is not an event but a process, a series of discrete cellular changes that result in progressively more autonomous cellular processes. *Primary prevention* concerns the identification and manipulation of the genetic, biologic, and environmental factors in the causal pathway. Smoking cessation, diet modification, and chemoprevention are primary prevention activities. *Secondary prevention* concerns the identification of asymptomatic neoplastic lesions combined with effective therapy. Screening is a form of secondary prevention.

EDUCATION AND HEALTHFUL HABITS Public education on the avoidance of identified risk factors for cancer and encouraging healthy habits were among early efforts in cancer prevention and control. Many educational messages have come to the public through commercials in the print and electronic media and through school health courses. The physician is a potentially powerful messenger in this education campaign about the hazards of smoking, the benefits of a healthful diet and exercise, use of proven screening methods, and sun avoidance.

Smoking Cessation Tobacco use through cigarettes and other means is the most avoidable risk factor for cardiovascular disease and cancer. The degree of smoke exposure, meaning the number of cigarettes smoked per day as well as the level of inhalation of cigarette smoke, is correlated with risk of lung cancer mortality. Light and low-tar cigarettes are not safer because smokers tend to inhale them more frequently and deeply. Those who stop smoking have a lower lung cancer mortality rate than those who continue smoking, despite the fact that some carcinogen-induced genetic mutations persist for years. In addition to lung cancer, cigarette smoking is a causative agent in cancers of the larynx, oropharynx, esophagus, bladder, and pancreas.

Smoking cessation and avoidance have the potential to save and extend more lives than any other public health activity. A smoker has a one in three lifetime risk of dying prematurely of a smoking-related cancer or cardiovascular or pulmonary disease. Indeed, more human lives are lost due to cardiovascular disease caused by smoking than from smoking-related cancer. The risk of tobacco smoke is not necessarily limited to the smoker. Epidemiologic studies suggest that environmental tobacco smoke may cause lung cancer and other pulmonary diseases in nonsmokers.

Nonsmoking persons should be encouraged not to start smoking, and persons who smoke should be encouraged to stop. Tobacco prevention is a pediatric issue. Over 80% of American smokers begin smoking before the age of 18. Nearly 20% of Americans aged 12 to 18 have smoked a cigarette in the past month. Counseling of adolescents and young adults is critical to prevent smoking. A physician's simple advice to not start smoking or to quit smoking can be of benefit. Physicians should query patients on tobacco use on every office visit, record the answer with the vital signs, and ask smokers if they would like assistance in quitting.

Current approaches to smoking cessation recognize that smoking is an addiction (Chap. 375). The smoker who is quitting goes through a process with identifiable stages that include contemplation of quitting, an action phase in which the smoker quits, and a maintenance phase. Smokers who quit completely are more likely to be successful than those who gradually reduce the number of cigarettes smoked or change to lower tar or nicotine cigarettes. More than 90% of the Americans who have successfully quit smoking did so on their own without participation in an organized cessation program, but cessation programs are helpful for some smokers. The Community Intervention Trial for Smoking Cessation (COMMIT) was a community-based 4-year program. COMMIT demonstrated that light smokers (<25 cigarettes per day) can benefit from simple cessation messages and cessation programs. The quit rate (fraction of the subjects followed who achieved and maintained cessation at the end of the trial) was 30.6% in the intervention communities and 27.5% in the control communities. This finding is statistically significant, but modest. The control communities enjoyed a substantial decrease in smoking through study participation. The COMMIT interventions were not successful for heavy smokers (>25 cigarettes per day). Heavy smokers need an intensive, broad-based cessation program that includes counseling, behavioral strategies, and pharmacologic adjuncts such as nicotine replacement and bupropion.

Cigar smoking has increased in the past 10 years, especially in younger adults. The health risks of cigars are similar to those of cigarettes. Smoking two cigars per day doubles the risk for oral and esophageal cancer; three to four cigars per day increases the risk of oral cancer eight-fold and esophageal cancer four-fold. The risks of occasional cigar smoking are unknown.

Smokeless tobacco is the fastest growing part of the tobacco industry and represents a significant health risk. Chewing tobacco is a carcinogen linked to dental caries, gingivitis, oral leukoplakia, and oral cancer. The systemic effects of smokeless tobacco may increase risks for other cancers.

Diet Modification Dietary modification may have significant potential for lowering cancer risk in western culture. Studies of international dietary patterns and animal studies suggest that diets high in fat increase the risk for cancers of the breast, colon, prostate, and endometrium. These cancers have their highest incidence and mortalities in western countries, where fat comprises an average of 40 to 45% of the total calories consumed. In populations at low risk for these cancers, fat accounts for <20% of calories.

Despite correlations, dietary fat has not been proven to cause cancer. Case-control and cohort epidemiologic studies give conflicting

results. In addition, diet is a highly complex exposure to many nutrients and chemicals. Low-fat diets may render some protection through anticarcinogens found in vegetables, fruits, legumes, nuts, and grains. Protective substances found in these foods include phenols, sulfur-containing compounds, flavones, and fiber.

In observational studies, dietary fiber appears protective against colonic polyps and invasive cancer of the colon. The mechanisms involved are complex and speculative. They involve binding of oxidized bile acids and generation of soluble fiber products, such as butyrate, that may have differentiating properties. Transit time is not greatly affected. High-fiber diets may also protect against breast and prostate cancer by absorbing and inactivating dietary estrogenic and androgenic cancer promoters. Protective effects of fiber have not been proved in a prospective clinical trial.

The Polyp Prevention Trial randomly assigned 2000 elderly persons to a low-fat, high-fiber diet versus routine diet for 4 years. No differences were noted in polyp formation.

The U.S. National Institutes of Health Women's Health Initiative, launched in 1994, is a long-term clinical trial enrolling more than 100,000 women aged 45 to 69. It studies the potential cancer-preventing effects of a low-fat diet and vitamin supplementation. Results are not yet available. Scientific evidence does not currently establish the anticarcinogenic value of vitamin, mineral, or nutritional supplements in amounts greater than that provided by a good diet. However, consuming at least five servings of fruits and vegetables a day decreases dietary fat and increases fiber; such a diet may lower the risk of cardiovascular disease.

Sun Avoidance Nonmelanoma skin cancers (basal cell and squamous cell) are induced by cumulative exposure to ultraviolet radiation. Intermittent acute sun exposure and sun damage have been linked to melanoma. Sunburns, especially in childhood and adolescence, are associated with an increased risk of melanoma in adulthood. Reduction of sun exposure through use of protective clothing and changes in the pattern of outdoor activities can reduce skin cancer risk. Sunscreens decrease the risk of actinic keratoses, the precursor to squamous cell skin cancer, but melanoma risk may be increased. Sunscreens prevent burning and may encourage more prolonged exposure to the sun; yet they may not filter out wavelengths of energy that cause melanoma.

Educational interventions to help people assess their risk of developing skin cancer accurately have some impact. Self-examination for skin pigment characteristics associated with melanoma, such as freckling, may be useful in identifying people at high risk. People who recognize themselves as being at risk tend to be more compliant with sun-avoidance recommendations. Possible risk factors for melanoma include a propensity to sunburn, a large number of benign melanocytic nevi, and atypical nevi.

CANCER CHEMOPREVENTION Chemoprevention of cancer involves the use of specific natural or synthetic chemical agents to reverse, suppress, or prevent carcinogenesis before the development of invasive malignancy.

Cancer develops through an accumulation of genetic changes that are potential points of intervention to prevent cancer. The initial genetic changes are termed *initiation*. The alteration can be inherited or acquired through the action of physical, infectious, or chemical carcinogens. Like most human diseases, cancer arises through an interaction between genetics and environmental exposures (Table 67-1). Influences that cause the initiated cell to progress through the carcinogenic process and to change phenotypically are termed *promoters*. Promoters include hormones such as androgens, linked to prostate cancer, and estrogen, linked to breast and endometrial cancer. The distinction between an initiator and a promoter is sometimes arbitrary; some components of cigarette smoke are "complete carcinogens," acting as both initiators and promoters. Cancer can be prevented or controlled through interference with the factors that cause initiation, promotion, or progression. Compounds of interest in chemoprevention often have antimutagenic, antioxidant, antiproliferative, or pro-apoptotic activity.

TABLE 67-1 *Carcinogens and Associated Cancers or Neoplasms*

Carcinogens[a]	Associated Cancer or Neoplasm
Alkylating agents	Acute myelocytic leukemia, bladder cancer
Androgens	Prostate cancer
Aromatic amines (dyes)	Bladder cancer
Arsenic	Cancer of the lung, skin
Asbestos	Cancer of the lung, pleura, peritoneum
Benzene	Acute myelocytic leukemia
Chromium	Lung cancer
Diethylstilbestrol (prenatal)	Vaginal cancer (clear cell)
Epstein-Barr virus	Burkitt's lymphoma, nasal T cell lymphoma
Estrogens	Cancer of the endometrium, liver, breast
Ethyl alcohol	Cancer of the liver, esophagus, head and neck
Helicobacter pylori	Gastric cancer
Hepatitis B or C virus	Liver cancer
Human immunodeficiency virus	Non-Hodgkin's lymphoma, Kaposi's sarcoma, squamous cell carcinomas (especially of the urogenital tract)
	Human papilloma virus
Human T cell lymphotropic virus type I (HTLV-I)	Adult T cell leukemia/lymphoma
Immunosuppressive agents (azathioprine, cyclosporine, glucocorticoids)	Non-Hodgkin's lymphoma
Nitrogen mustard gas	Cancer of the lung, head and neck, nasal sinuses
Nickel dust	Cancer of the lung, nasal sinuses
Phenacetin	Cancer of the renal pelvis and bladder
Polycyclic hydrocarbons	Cancer of the lung, skin (especially squamous cell carcinoma of scrotal skin)
Schistosomiasis	Bladder cancer (squamous cell)
Sunlight (ultraviolet)	Skin cancer (squamous cell and melanoma)
Tobacco (including smokeless)	Cancer of the upper aerodigestive tract, bladder
Vinyl chloride	Liver cancer (angiosarcoma)

[a] Agents that are thought to act as cancer initiators and/or promoters.

A number of chemoprevention strategies are undergoing clinical trials. However, tamoxifen is the only chemoprevention currently approved by the U.S. Food and Drug Administration; it lowers risk of breast cancer in high-risk women.

Multiple Cancer Site Prevention Trials The Physicians' Health Trial involves 22,071 American male physicians. Participants were randomly assigned to receive β-carotene, aspirin, and/or placebo in a 2×2 factorial design. All major medical events were recorded. In 1988, the aspirin arm was unblinded after the trial demonstrated that aspirin therapy causes a significant reduction in cardiovascular mortality. β-Carotene was not associated with a decreased cancer risk compared to placebo.

The Women's Health Study, launched in 1992, is a 10-year trial involving 44,000 female nurses. Subjects are randomly assigned to β-carotene, α-tocopherol, aspirin, and/or placebo in a factorial design yielding eight different treatment groups. The end points are total epithelial cancers, breast cancer, lung cancer, colon cancer, and vascular disease.

The Women's Health Initiative uses a partial factorial design that places women in 22 intervention groups. Participants can receive calcium and vitamin D supplementation, hormone replacement therapy, and counseling to increase exercise and cease smoking. Prevention of a number of cancers, cardiovascular disease, osteoporosis, and other

diseases will be assessed. The portion of the trial comparing combined estrogen plus progestin replacement therapy to placebo in women with an intact uterus was halted in 2002 due to an excess of cardiovascular events and breast cancer in the hormone therapy arm. Colon cancer was decreased in the hormone therapy arm. Prior epidemiologic studies had consistently shown a decrease in cardiovascular disease in women taking hormone replacement therapy. The risk of developing Alzheimer's disease was doubled in the combined hormone therapy arm, and quality of life was not improved compared to placebo. Therefore the strength of evidence from prospective randomized, controlled trials is considered to outweigh the prior evidence of benefit. At present combined estrogen plus progestin therapy is not recommended for disease prevention because of the results of this study. The estrogen-only portion of the trial (in women with prior hysterectomy) is still in progress.

Chemoprevention of Cancers of the Upper Aerodigestive Tract Smoking causes diffuse epithelial injury in the head, neck, esophagus, and lung. Patients cured of squamous cell cancers of the lung, esophagus, head, and neck are at risk (as high as 5% per year) of developing a second cancer of the upper aerodigestive tract. Cessation of cigarette smoking does not markedly decrease the cured cancer patient's risk of second malignancy, even though it does lower the cancer risk in those who have never developed a malignancy. Smoking cessation may halt the early stages of the carcinogenic process (such as metaplasia), but it may have no effect on late stages of carcinogenesis. This "field carcinogenesis" hypothesis for cancer of the upper aerodigestive tract has made "cured" patients an important population for chemoprevention of second malignancies. A randomized, placebo-controlled clinical trial has demonstrated that adjuvant isoretinoin (13-*cis*-retinoic acid) can reduce the incidence of second primary tumors in patients treated with local therapy for head and neck cancer. However, overall survival was not improved due to mortality from recurrences of the primary tumor.

Oral leukoplakia, a premalignant lesion commonly found in smokers, has been used as an intermediate marker allowing the demonstration of chemopreventive activity in smaller, shorter-duration, randomized, placebo-controlled trials. Response was associated with upregulation of retinoic acid receptor β. Therapy with isoretinoin causes regression of oral leukoplakia. However, the lesions recur when the agent is withdrawn, suggesting the need for chronic administration of retinoids. Premalignant lesions in the oropharyngeal area have also responded to β-carotene, retinol, α-tocopherol (vitamin E), and selenium. Further study to improve the definition of the activity of these drugs is ongoing. Isoretinoin was shown not to prevent second malignancies in patients cured of early-stage non-small cell lung cancer, and those who were current smokers had higher lung cancer mortality rates than those not taking isoretinoin.

Several large-scale trials have assessed agents in the chemoprevention of lung cancer in patients at high risk. In the Alpha-Tocopherol/Beta-Carotene (ATBC) Lung Cancer Prevention Trial, participants were male smokers, aged 50 to 69 at entry. At entry, participants had smoked an average of one pack of cigarettes per day for 35.9 years. Participants received α-tocopherol, β-carotene, and/or placebo in a randomized, 2×2 factorial design. After a median follow-up of 6.1 years, lung cancer incidence and mortality were statistically significantly *increased* in those receiving β-carotene. α-Tocopherol had no effect on lung cancer mortality, and no evidence suggested interaction between the two drugs. Patients receiving α-tocopherol had a higher incidence of hemorrhagic stroke.

The Beta-Carotene and Retinol Efficacy Trial (CARET) involved 17,000 American smokers and workers with asbestos exposure. Entrants were randomly assigned to one of four arms and received β-carotene, retinol, and/or placebo in a 2×2 factorial design. This trial demonstrated harm from β-carotene: a lung cancer rate of 5 per 1000 subjects per year for those taking placebo and of 6 per 1000 subjects per year for those taking β-carotene. The difference was statistically significant.

These ATBC and CARET results demonstrate the importance of testing chemoprevention hypotheses before implementing them widely, because the results stand in contrast to a number of observational epidemiologic studies. In the ATBC trial, participants taking α-tocopherol had a one-third reduction in the incidence of prostate cancer, compared to those not taking α-tocopherol. The Physicians' Health Trial showed neither an increased nor a decreased risk of lung cancer in those using β-carotene; fewer of its participants were smokers than those in the ATBC and CARET studies.

Chemoprevention of Colon Cancer Many of the current colon cancer prevention trials are based on the premise that most colorectal cancers develop from adenomatous polyps. These trials use adenoma recurrence or disappearance as a surrogate end point to assess colon cancer prevention. Early clinical trial results suggest that nonsteroidal anti-inflammatory drugs (NSAIDs), such as piroxicam, sulindac, and aspirin, may prevent adenoma formation or cause regression of adenomatous polyps. The mechanism of action of NSAIDs is unknown, but they are presumed to work through the cyclooxygenase pathway. In the Physicians' Health Trial, aspirin had no effect on colon cancer incidence, although the 6-year assessment period may not have been long enough to evaluate this end point definitively. Studies evaluating NSAIDs as colon cancer chemopreventive agents have not yet been completed.

Cyclooxygenase 2 inhibitors may be even more effective at colon cancer prevention. High-dose celecoxib reduces the number of colorectal polyps in patients with familial adenomatous polyposis and is under study for prevention of sporadic colorectal cancer.

Epidemiologic studies suggest that diets high in calcium lower colon cancer risk. Calcium binds bile and fatty acids, which cause hyperproliferation of colonic epithelium. It is hypothesized that this effect reduces intraluminal exposure to these compounds. Early data from randomized studies suggest that calcium supplementation decreases the risk of adenomatous polyp recurrence by about 20%, even though it does not decrease the proliferative rate of the colonic epithelium. Epithelial proliferative rate may not be an adequate surrogate marker in colon cancer prevention trials. Trials of calcium with cancer incidence end points are underway.

The Women's Health Initiative demonstrated a significant reduction in colon cancer among women taking combined hormone replacement therapy. However, the increased risk of cardiovascular events and breast cancer probably outweighs the benefit.

Prevention of Hormonally Driven Cancers Hormonal manipulation is being tested in the primary prevention of breast and prostate cancer. Tamoxifen is an antiestrogen with partial estrogen agonistic activity in some tissues, such as endometrium and bone. One of its actions is to upregulate transforming growth factor β, which decreases breast cell proliferation. In randomized placebo-controlled trials to assess tamoxifen as an adjuvant in breast cancer treatment, this drug reduced the number of new breast cancers in the uninvolved breast by more than a third. In a randomized placebo-controlled trial involving >13,000 women at high risk, tamoxifen decreased the risk of developing cancer by 49% compared to placebo. Tamoxifen also reduced the risk of bone fractures; a small increase in risk of endometrial cancer, stroke, pulmonary emboli, and deep vein thrombosis was noted. A trial to compare tamoxifen with another selective estrogen receptor modulator, raloxifene, is ongoing. Raloxifene may have less risk of endometrial cancer.

Finasteride is a 5α-reductase inhibitor. It inhibits the conversion of testosterone to dihydrotestosterone, a more potent stimulator of prostate cell proliferation than testosterone. In an F344 rat model of carcinogen-induced prostate cancer, finasteride decreased the incidence of cancers. Finasteride produced a 20% decrease in overall prostate cancer, but a slight increase in high-grade (Gleason score 7–10) prostate cancer in men over age 55 years.

Selenium is being tested as a prostate cancer preventive agent based

on laboratory studies and a small clinical trial aimed at prevention of skin cancer. Men taking selenium to prevent skin cancer were found to have a significantly reduced incidence of prostate cancer (16 on placebo arm; 4 on selenium arm). The ATBC study cited above showed that risk of prostate cancer was reduced in those taking vitamin E (99 prostate cancers on vitamin E; 151 cases on placebo). The findings on selenium and vitamin E were serendipitous and based on secondary analysis. A prospective study is underway.

Vaccines and Cancer Prevention A number of infectious agents have been linked to the development of cancer, leading to interest in developing vaccines to protect against these agents. The hepatitis B vaccine is quite effective in preventing hepatitis and hepatomas due to chronic hepatitis B infection. Public health officials are encouraging widespread administration of this vaccine, especially in Asia, where the disease is epidemic. Human papilloma virus (HPV) vaccines are being developed to prevent cervical cancer, and *Helicobacter pylori* vaccines are aimed at gastric cancer. Antibiotic eradication of *H. pylori* may also be a cancer prevention strategy.

SURGICAL PREVENTION OF CANCER Some organs in some people are at such high risk of developing cancer that surgical removal of the organ at risk is recommended. Women with severe cervical dysplasia are treated with conization and occasionally even hysterectomy. Colectomy is used to prevent colon cancer in people with familial polyposis and those with ulcerative colitis. Based on a study in 139 women with *BRCA1* and *BRCA2* mutations, many women with a genetic predisposition to breast cancer opt to have bilateral mastectomy rather than close surveillance. Of the 139 women, 76 chose mastectomy and 63 chose surveillance; none of the 76 who underwent mastectomy developed breast cancer, but 8 of the 63 women under careful surveillance developed breast cancer. A randomized study is unlikely to be done, and assessment of the effects of prophylactic mastectomy on mortality is also unlikely to be done.

CANCER SCREENING Screening is a means of detecting disease early in asymptomatic individuals, with the goal of decreasing morbidity and mortality. While screening can potentially save lives and has clearly been shown to do so in the case of cervical, colon, and probably breast cancer, it is also subject to a number of biases, which can suggest a benefit when actually there is none. Bias can even mask net harm. Early detection does not in itself confer benefit. To be of value, screening must detect disease earlier, and treatment of earlier disease must yield a better outcome than treatment at the onset of symptoms. Cause-specific mortality, rather than survival after diagnosis, is the preferred end point (see below).

Because screening is done on asymptomatic, healthy persons, it should offer substantial likelihood of benefit that outweighs harm. Screening tests and their appropriate use should be carefully evaluated before their use is widely encouraged in screening programs as a matter of public policy.

Screening examinations, tests, or procedures are usually not diagnostic of cancer but instead indicate that a cancer may be present. The diagnosis is then made following a workup that includes a biopsy and pathologic confirmation.

A number of genes have been identified that predispose for a disease, and many more will be identified in the near future. Testing for these genes can define a high-risk population. The ability to predict the development of a particular cancer may some day present therapeutic options as well as ethical dilemmas. It may eventually allow for early intervention to prevent a cancer or limit its severity. People at high risk will be ideal candidates for chemoprevention and screening; however, efficacy of these interventions in the high-risk population should be investigated. Currently, persons at high risk for a particular cancer can engage in intensive screening. While this course is clinically prudent, it is not known if it saves lives in these populations.

TABLE 67-2 Definition of Terms

Term	Definition
Sensitivity	The proportion of persons with the condition who test positive: $a/(a + c)$
Specificity	The proportion of persons without the condition who test negative: $d/(b + d)$
Positive predictive value	The proportion of persons with a positive test who have the condition: $a/(a + b)$
Negative predictive value	The proportion of persons with a negative test who do not have the condition: $d/(c + d)$

a = true positive
b = false positive
c = false negative
d = true negative

	Condition present	Condition absent
Positive test	a	b
Negative test	c	d

The Accuracy of Screening A screening test's accuracy or ability to discriminate disease is described by four indices: sensitivity, specificity, positive predictive value, and negative predictive value (Table 67-2). *Sensitivity* is the proportion of persons with the disease who test positive in the screen (i.e., the ability of the test to detect disease when it is present). *Specificity* is the proportion of persons who do not have the disease and test negative in the screening test (i.e., the ability of a test to tell that the disease is not present). The *positive predictive value* is the proportion of persons who test positive who actually have the disease. Similarly, *negative predictive value* is the proportion of who test negative and do not have the disease. The sensitivity and specificity of a test are relatively independent of the underlying prevalence (or risk) of the disease in the population screened, but the predictive values depend strongly on the prevalence of the disease (Table 67-3).

Screening is most beneficial, efficient, and economical when the target disease is common in the population being screened. To be valuable, the screening test should have a high specificity; sensitivity need not be very high, as demonstrated in Table 67-3.

Potential Biases of Screening Tests The common biases of screening are lead time, length, and selection. These biases can make a screening test seem beneficial when actually it is not (or even causes net harm). Whether beneficial or not, screening can create the false impression of an epidemic by increasing the number of cancers diagnosed. It can also produce a shift in proportion of patients diagnosed at an early stage that improves survival statistics without reducing mortality (i.e., the number of deaths from a given cancer relative to the number of people at risk for the cancer). In such a case, the *apparent* duration of

TABLE 67-3 Predictive Value Relationships[a]

Positive predictive value (PPV) is a function of sensitivity, specificity, and prevalence:

$$\text{PPV} = \frac{\text{prevalence} \times \text{sensitivity}}{(\text{prevalence} \times \text{sensitivity}) + (1 - \text{prevalence})(1 - \text{specificity})}$$

PPV for a prevalence of 5 per 1000:

	PPV for a Sensitivity of, %	
Specificity	0.8	0.95
0.95	7	9
0.999	80	83

PPV for a prevalence of 1 per 10,000:

	PPV for a Sensitivity of, %	
Specificity	0.8	0.95
0.95	0.2	0.2
0.999	7	9

[a] The positive predictive value is expressed as a percentage. It is influenced by the sensitivity and specificity of the screening test and the prevalence of the disease being screened for. As shown here, for relatively uncommon diseases, such as cancer, the positive predictive value is influenced particularly strongly by the specificity of the screening test at a given prevalence.

survival increases without lives being saved or life expectancy changed.

Lead-time bias occurs when a test does not influence the natural history of the disease; the patient is merely diagnosed at an earlier date. When lead-time bias occurs, survival *appears* increased, but life is not really prolonged. The screening test only prolongs the time the subject is aware of the disease and spends as a patient.

Length bias occurs when slow-growing, less aggressive cancers are detected during screening. Cancers diagnosed due to the onset of symptoms between scheduled screenings are on average more aggressive, and treatment outcomes are not as favorable. An extreme form of length bias is termed *overdiagnosis*, the detection of "pseudodisease." The reservoir of some undetected slow-growing tumors is large. Many of these tumors fulfill the histologic criteria of cancer but will never become clinically significant or cause death. This problem is compounded by the fact that the most common cancers appear most frequently at ages when competing causes of death are more frequent.

Selection bias must be considered in assessing the results of any screening effort. The population most likely to seek screening may differ from the general population to which the screening test might be applied. The individuals screened may have volunteered because of a particular risk factor not found in the general population, such as a strong family history. In general, volunteers for studies may be more health conscious and likely to have a better prognosis or lower mortality rate, irrespective of the screening result. This is termed the *healthy volunteer effect*.

TABLE 67-4 *Screening Recommendations for Asymptomatic Normal-Risk Subjects*[a]

Test or Procedure	USPSTF	ACS	CTFPHC
Sigmoidoscopy	>50, periodically <50, not recommended	≥50, every 3–5 years	Insufficient evidence
Fecal occult blood testing	≥50, every year	≥50, every year	Insufficient evidence
Digital rectal examination	No recommendation	≥40, every year	Poor evidence to include or exclude
Prostate-specific antigen	Insufficient evidence to recommend	M: ≥50, every year	Recommendation against
Pap test	F: 18–65, every 1–3 years	F with uterine cervix, beginning 3 years after first intercourse or by age 21. Yearly for standard Pap; every 2 years with liquid test.	Fair evidence to include in examination of sexually active women
Pelvic examination	Do not recommend, advise adnexal palpation during exam for other reasons	F: 18–40, every 1–3 years with Pap test; >40, every year	Not considered
Endometrial tissue sampling	Not considered	At menopause if obese or a history of unopposed estrogen use	Not considered
Breast self-examination	No recommendation	≥20, monthly	Insufficient evidence to make a recommendation
Breast clinical examination	F: >50, every year	F: 20–40, every 3 years; >40, yearly	F: >50, every year
Mammography	F: 40–75, every 1–2 years	F: ≥40, every year	F: 50–69, every year
Complete skin examination	Not recommended	20–39, every 3 years	Poor evidence to include or exclude

[a] Summary of the screening procedures recommended for the general population by U.S. Preventive Services Task Force (USPSTF), the American Cancer Society (ACS), and the Canadian Task Force on Prevention Health Care (CTFPHC). These recommendations refer to asymptomatic persons who have no risk factors, other than age or gender, for the targeted condition.
Note: F, female; M, male.

Potential Drawbacks of Screening Risks associated with screening include harm caused by the screening intervention itself, harm due to the further investigation of persons with positive test results (both true and false positives), and harm from the treatment of persons with a true-positive result, even if life is extended by treatment. The diagnosis and treatment of cancers that would never have caused medical problems can lead to the harm of unnecessary treatment and give patients the anxiety of a cancer diagnosis. The psychosocial impact of cancer screening, whether the result is positive or negative, can also be substantial when applied to the entire population.

Assessment of Screening Tests Good clinical trial design can offset some biases of screening and demonstrate the relative risks and benefits of a screening test. A randomized, controlled screening trial with cause-specific mortality as the end point provides the strongest support for a screening intervention. In a randomized trial, two like populations are randomly established. One is given the medical standard of care (which may be no screening at all), and the other receives the screening intervention being assessed. The two populations are compared over time. Efficacy for the population studied is established when the group receiving the screening test has a better cause-specific mortality rate than the control group. Studies showing a reduction in the incidence of advanced-stage disease, an improved survival, or a stage shift are weaker (and possibly misleading) evidence of benefit. These latter criteria are necessary but not sufficient to establish the value of a screening test.

Although a randomized, controlled screening trial provides the strongest evidence to support the usefulness of a screening test, it is not perfect. Unless the trial is population-based, it does not remove the issue of generalizability to the target population. Screening trials generally involve thousands of persons and last for years. Less definitive study designs are therefore often used to estimate the effectiveness of screening practices. After a randomized controlled clinical trial, in descending order of strength, evidence may be derived from:

The findings of internally controlled trials using intervention allocation methods other than randomization (e.g., allocation determined by birth date, date of clinic visit);

The findings of cohort or case-control analytic observational studies;

The results of multiple time series studies with or without the intervention;

The opinions of respected authorities based on clinical experience, descriptive studies, or consensus reports of experts (the weakest evidence because even experts can be misled by the biases described above).

Screening for Specific Cancers Widespread screening for cervical, colon, and probably breast cancer is beneficial for certain age groups. Special surveillance of those at high risk for a specific cancer because of a family history or a genetic risk factor may be prudent, but few studies have been carried out to assess the impact of this practice on mortality in specific high-risk populations. A number of organizations have considered whether or not to endorse routine use of certain screening tests. Because these groups have not used the same criteria to judge whether a screening test should be endorsed, they have arrived at different recommendations. The screening guidelines of the U.S. Preventive Services Task Force, the Canadian Task Force on Preventive Health Care, and the American Cancer Society are often quoted and show a range of recommendations (Table 67-4).

BREAST CANCER Breast self-examination, clinical breast examination by a care giver, and mammography have been advocated as useful screening tools. Only breast self-examination, screening mammography alone, and screening mammography with clinical examination have been evaluated in randomized controlled trials. Magnetic resonance

imaging is being assessed and may be more accurate than mammography in women at high risk.

A number of trials have suggested that annual or biennial screening with mammography or mammography plus clinical breast examination in women over the age of 50 saves lives. Each trial has been criticized for design flaws. In most trials, the breast cancer mortality rate is decreased by 20 to 30%. Experts disagree on whether average-risk women aged 40 to 49 should receive regular screening (Table 67-4). The significance of the screening effect in women aged 40 to 49 depends on the statistical test used. An analysis of eight large randomized trials showed no benefit from mammographic screening for women aged 40 to 49 when assessed 5 to 7 years after trial entry. However, a small benefit emerged 10 to 12 years after study entry. What proportion of this benefit is due to screening after these women turned 50 is not known. In randomized screening studies of women aged 50 to 69, the decline in mortality begins about 5 years after initiation of screening. Nearly half of women aged 40 to 49 years screened annually will have false-positive mammograms necessitating further evaluation, often including biopsy. The risk of false-positive testing should be discussed with the patient.

While no study has shown breast self-examination to decrease mortality, it is recommended as prudent by many organizations. A substantial fraction of breast cancers are first detected by patients. Self-examination leads to increased biopsy rate without reducing breast cancer mortality.

Genetic screening for *BRCA1* and *BRCA2* mutations and other markers of breast cancer risk has identified a group of women at high risk for breast cancer. Unfortunately, when to begin and the optimal frequency of screening have not been defined. Mammography is less sensitive at detecting breast cancers in women carrying *BRCA* mutations, possibly because such cancers occur in younger women, in whom mammography is known to be less sensitive.

CERVICAL CANCER Screening with Papanicolaou smears decreases cervical cancer mortality. The cervical cancer mortality rate has fallen substantially since the widespread use of the Pap smear, although this trend actually began earlier. Most screening guidelines recommend regular Pap testing for all women who are or have been sexually active for 3 years or have reached the age of 21. With the onset of sexual activity comes the risk of sexual transmission of HPV, the most common etiologic factor for cervical cancer. The recommended interval for Pap screening varies from 1 to 3 years. At age 30, women who have had three normal test results in a row may get screened every 2 to 3 years. An upper age limit at which screening ceases to be effective is not known, but women age $\geq$70 years who have had no abnormal results in the previous 10 years may choose to stop screening.

COLORECTAL CANCER Fecal occult blood testing, digital rectal examination, rigid and flexible sigmoidoscopy, radiographic barium contrast studies, and colonoscopy have been considered for colorectal cancer screening. Annual fecal occult blood testing using hydrated specimens could reduce colorectal cancer mortality by a third. The sensitivity for fecal occult blood is increased if specimens are rehydrated before testing, but at the cost of lower specificity. The false-positive rate for rehydrated fecal occult blood testing is high; 1 to 5% of persons tested have a positive result. About 2 to 10% of those with occult blood in the stool have cancer, and 20 to 30% have adenomas. The high false-positive rate of fecal occult blood testing dramatically increases the number of colonoscopies performed.

Two case-control studies suggest that regular screening of people over 50 with sigmoidoscopy decreases mortality. These types of studies are prone to selection biases. A quarter to a third of polyps can be discovered with the rigid sigmoidoscope; half are found with a 35-cm flexible scope, and two-thirds to three-quarters are found with a 60-cm scope. Diagnosis of polyposis by sigmoidoscopy should lead to evaluation of the entire colon with colonoscopy and/or barium enema. The most efficient interval for screening sigmoidoscopy is unknown. Case-control studies suggest that testing at intervals of up to 15 years may confer benefit.

One-time colonoscopy detects about 25% more advanced lesions (polyps $>$ 10 mm, villous adenomas, polyps with high-grade dysplasia, invasive cancer) than does one-time fecal occult blood testing with sigmoidoscopy. Colonoscopy is well suited to screening subjects at high risk, such as those with ulcerative colitis or family predisposition. Perforation rates are 3/1000 for colonoscopy and 1/1000 for sigmoidoscopy. Debate continues on whether full colonoscopy is too expensive and invasive for widespread use as a screening tool in standard-risk populations. Data are not available on digital rectal examination or barium enema as colon cancer screening tools, but both are insensitive.

LUNG CANCER Chest radiographs and sputum cytology have been evaluated as methods for lung cancer screening. No reduction in lung cancer mortality has been found in these studies, although all the controlled trials performed have had low statistical power. Even screening of high-risk subjects (smokers) has not been proved to be beneficial. Spiral computed tomography (CT) can diagnose lung cancers at early stages; however, false-positive rates are high. Spiral CT screening increases the number of lesions detected and increases the number of diagnostic and therapeutic procedures. However, its capacity to save lives is being tested.

OVARIAN CANCER Adnexal palpation, transvaginal ultrasound, and serum CA-125 determination have been considered for ovarian cancer screening. Adnexal palpation is too insensitive to detect ovarian cancer at an early enough stage to affect mortality substantially. Neither transvaginal ultrasound nor CA-125 screening has been tested in a completed randomized prospective trial. Ovarian cancer screening can lead to an invasive diagnostic workup, which may include laparotomy. In a clinical study, 0.6% of 900 adult women had a serum CA-125 level $>$35 U/mL. Thus, if 100,000 adult women were screened, 600 would be identified as having a high CA-125 level. The prevalence of ovarian cancer in the female adult population is $\sim$20 per 100,000. Thus, the screening test would identify 600 women who would undergo further evaluation to identify 20 cases of ovarian cancer. Some of these 600 would only be inconvenienced by an ultrasound examination. Others would undergo an exploratory laparotomy. A large proportion of the 20 women identified as having ovarian cancer would have advanced, incurable disease and thus not benefit from screening. A National Institutes of Health consensus conference in 1994 concluded that routine screening for ovarian cancer was not indicated for standard-risk women or those with a single affected family member, but that it might be worthwhile in families with genetic ovarian cancer syndromes.

PROSTATE CANCER The most common prostate cancer screening modalities are digital rectal examination and assays for serum prostate-specific antigen (PSA). Newer serum tests, such as measurement of the ratio of bound to free serum PSA, have yet to be fully evaluated. An emphasis on PSA screening has caused prostate cancer to become the most common non-skin cancer diagnosed in American males. Screening for this disease is very prone to lead-time bias, length bias, and overdiagnosis, and substantial debate rages among experts on whether it is effective. Some experts are concerned that prostate cancer screening, more than screening for other cancers, may cause net harm. Prostate cancer screening clearly detects many asymptomatic cancers, but the ability to distinguish tumors that are lethal but still curable from those that pose little or no threat to health is limited. Men over age 50 have a very high prevalence of indolent, clinically insignificant prostate cancers. No well-designed trial has demonstrated the benefit of prostate cancer screening and treatment.

The placebo arm of the Prostate Cancer Prevention Trial showed that rigorous screening of low-risk men for 7 years leads to the diagnosis of prostate cancer in $>$12% of patients. However, $>$12% of patients with normal annual DREs and PSAs biopsied after 7 years were found to have cancer. Thus, prostate cancer screening had moderate success in early detection, but screening missed half the prostate cancers.

The effectiveness of radical prostatectomy, radiation therapy, and other treatments for low-stage prostate cancer is also under study in randomized trials. Definitive treatment of cancers detected by screening may cause morbidity for some men, such as impotence and urinary incontinence, and carries a low but finite risk of death. Comparison of radical prostatectomy to "watchful waiting" in clinically diagnosed (not screening PSA-detected) prostate cancers showed a decreased rate of death from prostate cancer for those undergoing surgery, but overall mortality was not different in the two arms. Patients undergoing surgery had a higher rate of impotence and urinary incontinence.

Ongoing randomized trials are comparing usual care to prostate screening and comparing definitive therapy to "watchful waiting." The American Cancer Society and the American Urologic Association recommend that men be offered screening after being informed of the potential risks and benefits. A man should have a life expectancy of at least 10 years to be eligible for screening. The U.S. Preventive Services Task Force finds insufficient evidence to recommend prostate cancer screening (Table 67-4).

ENDOMETRIAL CANCER Transvaginal ultrasound and endometrial sampling have been advocated as screening tests for endometrial cancer. Benefit from routine screening has not been shown. Transvaginal ultrasound and endometrial sampling are indicated for workup of vaginal bleeding in postmenopausal women but are not considered as screening tests in symptomatic women.

SKIN CANCER Visual examination of all skin surfaces by the patient or by a health care provider is used in screening for basal and squamous cell cancers and melanoma. No prospective randomized study has been performed to look for a mortality decrease. Observational epidemiologic evidence from Scotland and Australia suggests that screening programs have caused a stage shift in melanomas diagnosed. Screening may reinforce sun avoidance and other skin cancer prevention behaviors.

68 CANCER GENETICS

Pat J. Morin, Jeffrey M. Trent, Francis S. Collins, Bert Vogelstein

CANCER IS A GENETIC DISEASE Cancer arises through a series of somatic alterations in DNA that results in unrestrained cellular proliferation. Most of these alterations involve actual sequence changes in DNA (i.e., mutations). They may arise as a consequence of random replication errors, exposure to carcinogens (e.g., radiation), or faulty DNA repair processes. While most cancers arise sporadically, familial clustering of cancers occurs in certain families who carry a germline mutation in a cancer gene.

HISTORIC PERSPECTIVE The concept of cancer genetics is relatively new. The idea that cancer progression is driven by sequential somatic mutations in specific genes has only gained general acceptance in the last 25 years. Before the advent of the microscope, cancer was believed to be composed of aggregates of mucus or other noncellular matter. By the middle of the nineteenth century, it became clear that tumors were masses of cells and that these cells arose from the normal cells of the tissue in which the cancer originated. However, the molecular basis for the uncontrolled proliferation of cancer cells was to remain a mystery for another century. During that time, a number of theories for the origin of cancer were postulated. The great biochemist Otto Warburg proposed the combustion theory of cancer, which stipulated that cancer was due to abnormal oxygen metabolism: while normal cells required oxygen, cancer cells could survive in its absence. In addition, some believed that all cancers were caused by viruses, and that cancer was in fact a contagious disease.

In the end, observations of cancer occurring in chimney sweeps, studies of x-rays, and the overwhelming data demonstrating cigarette smoke as a causative agent in lung cancer, together with Ames's work on chemical mutagenesis, were sufficient to convince many that cancer originated through changes in DNA. Although the viral theory of cancer did not prove to be generally accurate, the study of retroviruses led to the discovery of the first human *oncogenes* in the mid to late 1970s. Soon after, the study of families with genetic predisposition to cancer was instrumental in the discovery of *tumor suppressor genes*. The field that studies the type of mutations, as well as the consequence of these mutations in tumor cells, is now known as cancer genetics.

THE CLONAL ORIGIN AND MULTISTEP NATURE OF CANCER Nearly all cancers originate from a single cell; this clonal origin is a critical discriminating feature between neoplasia and hyperplasia. Multiple cumulative mutational events are invariably required for the progression from normal to fully malignant phenotype. The process can be seen as Darwinian microevolution in which, at each successive step, the mutated cells gain a growth advantage resulting in an increased representation relative to their neighbors (Fig. 68-1). It is believed that five to ten accumulated mutations are necessary for a cell to progress from the normal to the fully malignant phenotype.

We are beginning to understand the precise nature of the genetic alterations responsible for some malignancies and to get a sense of the order in which they occur. The best studied example is colon cancer, in which analyses of DNA from tissues extending from normal colon epithelium through adenoma to carcinoma have identified some of the genes mutated in the process (Fig. 68-2). Similar progression models are being elucidated for other malignancies.

GENERAL CLASSES OF CANCER GENES There are two major classes of cancer genes. The first class comprises genes that directly affect cell growth either positively (*oncogenes*) or negatively (*tumor suppressor*

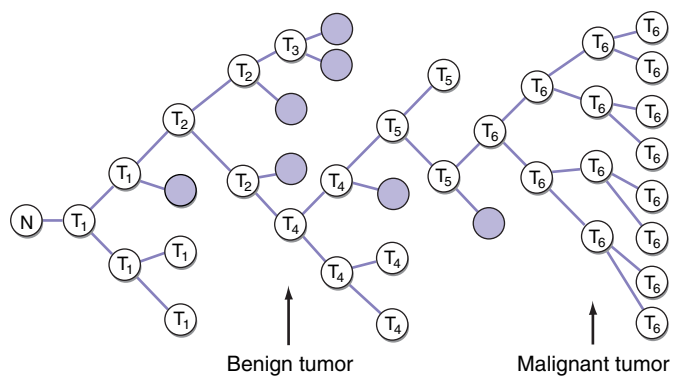

FIGURE 68-1 Multistep clonal development of malignancy. In this diagram a series of five cumulative mutations (T1, T2, T4, T5, T6), each with a modest growth advantage acting alone, eventually results in a malignant tumor. Note that not all such alterations result in progression; for example, the T3 clone is a dead end. The actual number of cumulative mutations necessary to transform from the normal to the malignant state is unknown in most tumors. (*After P Nowell, Science 194:23, 1976, with permission.*)

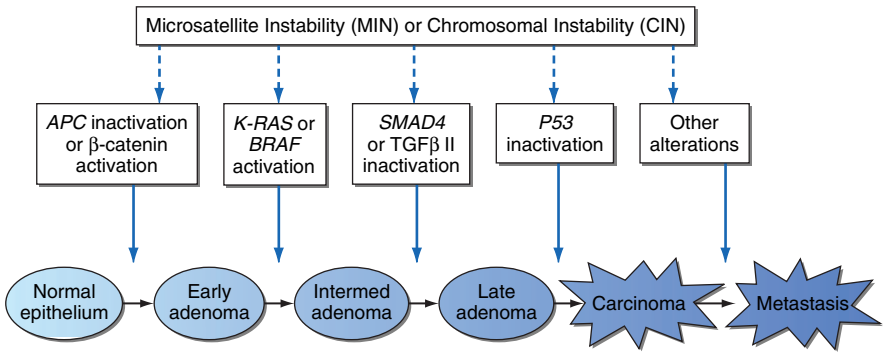

FIGURE 68-2 Progressive somatic mutational steps in the development of colon carcinoma. The accumulation of alterations in a number of different genes results in the progression from normal epithelium through adenoma to full-blown carcinoma. Genetic instability (microsatellite or chromosomal) accelerates the progression by increasing the likelihood of mutation at each step. Patients with familial polyposis are already one step into this pathway, since they inherit a germline alteration of the *APC* gene. TGF, transforming growth factor.

genes). These genes exert their effects on tumor growth through their ability to control cell division (cell birth) or cell death (apoptosis). Oncogenes are tightly regulated in normal cells. In cancer cells, oncogenes acquire mutations that relieve this control and lead to increased activity of the gene product. This mutational event typically occurs in a single allele of the oncogene and acts in a dominant fashion. In contrast, the normal function of tumor suppressor genes is to restrain cell growth and this function is lost in cancer. Because of the diploid nature of mammalian cells, both alleles must be inactivated to completely lose the function of a tumor suppressor gene, leading to a recessive mechanism at the cellular level. From these ideas and studies on the inherited form of retinoblastoma, Knudson and others formulated the *two-hit hypothesis*, which in its modern version states that both copies of a tumor suppressor gene must be inactivated in cancer.

The second class of cancer genes, the *caretakers*, do not directly affect cell growth but rather affect the ability of the cell to maintain the integrity of its genome. Cells with deficiency in these genes have an increased rate of mutations in all the genes, including oncogenes and tumor suppressor genes. This "mutator" phenotype was first hypothesized by Loeb to explain how the multiple mutational events required for tumorigenesis can occur in the lifetime of an individual. A mutation phenotype has now been observed in cancer at both the nucleotide sequence and chromosomal levels.

MECHANISMS OF TUMOR SUPPRESSOR INACTIVATION The two major types of somatic lesions observed in tumor suppressor genes during tumor development are *point mutations* and *large deletions*. Point mutations in the coding region of tumor suppressor genes will frequently lead to truncated protein products or otherwise nonfunctional proteins. Similarly, deletions lead to the loss of a functional product and sometimes encompass the entire gene or even the entire chromosome arm, leading to loss of heterozygosity (LOH) in the tumor DNA compared to the corresponding normal tissue DNA (Fig. 68-3). LOH in tumor DNA is considered a hallmark for the presence of a tumor suppressor gene at a particular locus and LOH studies have been useful in the positional cloning of many tumor suppressor genes. Gene silencing, which occurs in conjunction with hypermethylation of the promoter, is another mechanism of tumor suppressor gene inactivation.

FAMILIAL CANCER SYNDROMES A small fraction of the cancers occur in patients with a genetic predisposition. In these families, the affected individuals have a predisposing loss-of-function mutation in one allele of a tumor suppressor gene or caretaker gene. The tumors in these patients show a loss of the remaining normal allele as a result of somatic events (point mutations or deletions), in agreement with the Knudson hypothesis (Fig. 68-3). Thus, most cells of an individual with an inherited loss-of-function mutation in a tumor suppressor gene are functionally normal and only the rare cells that develop a mutation in the remaining normal allele will exhibit uncontrolled growth. The normal function of tumor suppressors is to restrain growth, to promote differentiation (gatekeeper genes), or to preserve genome integrity (caretaker genes).

Roughly 100 syndromes of familial cancer have been reported, although many are rare. The majority are inherited as autosomal dominant traits although some of those associated with DNA repair abnormalities (xeroderma pigmentosum, Fanconi's anemia, ataxia telangiectasia) are autosomal recessive. Table 68-1 shows a number of cancer predisposition syndromes and the responsible genes. The current paradigm states that the genes mutated in familial syndromes can also be targets for somatic mutations in sporadic (noninherited) tumors. The study of cancer syndromes has thus provided invaluable insights into the mechanisms of progression for many tumor types. This section examines the case of inherited colon cancer in detail, but the same general lessons can be applied to all the cancer syndromes listed in Table 68-1.

Familial adenomatous polyposis (FAP) is a dominantly inherited colon cancer syndrome due to germline mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene on chromosome 5. Patients with this syndrome develop hundreds to thousands of adenomas in the colon. Each of these adenomas has lost the normal remaining allele of *APC* but has not yet accumulated the required additional mutations to generate fully malignant cells (Fig. 68-2). However, out of these thousands of benign adenomas, several will invariably acquire further abnormalities and a subset will even develop into fully malignant cancers. *APC* is thus considered to be a gatekeeper for colon tumorigenesis; Fig. 68-4 shows germline and somatic mutations found in the *APC* gene. The function of the APC protein is still not completely understood but likely provides differentiation and apoptotic cues to colonic cells as they migrate up the crypts. Defects in this process may lead to abnormal accumulation of cells that should normally undergo apoptosis and slough off.

In contrast to FAP, patients with hereditary nonpolyposis colon cancer (HNPCC or Lynch syndrome) do not develop multiple polyposis but instead develop only one or a small number of adenomas that rapidly progress to cancer. HNPCC is commonly defined by family

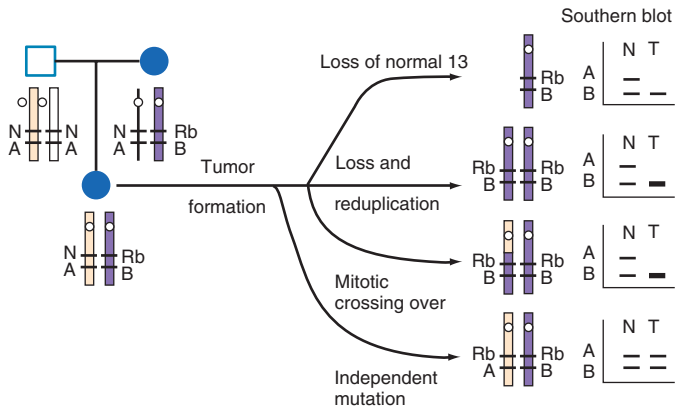

FIGURE 68-3 Diagram of possible mechanisms for tumor formation in an individual with hereditary (familial) retinoblastoma. On the left is shown the pedigree of an affected individual who has inherited the abnormal (Rb) allele from her affected mother. The four chromosomes of her two parents are drawn to indicate their origin. Just below the retinoblastoma locus a polymorphic marker is also analyzed in this family. The patient is AB at this locus, like her mother, whereas her father is AA. Thus the B allele must be on the chromosome carrying the retinoblastoma disease gene. Tumor formation results when the normal allele (N), which this patient inherited from her father, is inactivated. On the right are shown four possible ways in which this could occur. In each case, the resulting chromosome 13 arrangement is shown, as well as the results of a Southern blot comparing normal tissue with tumor tissue. Note that in the first three situations the normal allele (A) has been lost in the tumor tissue, which is referred to as loss of heterozygosity (LOH). (*From TD Gelehrter and FS Collins, in Principles of Medical Genetics, Baltimore, Williams and Wilkins, 1990, with permission.*)

history, with at least three individuals over at least two generations developing colon or endometrial cancer, and with at least one individual diagnosed before the age of 50. Most HNPCC is due to mutations in one of four DNA mismatch repair genes (Table 68-1), which are components of a repair system that is normally responsible for correcting errors in freshly replicated DNA. Germline mutations in *MSH2* and *MLH1* account for more than 60% of HNPCC cases, while mutations in *MSH6* and *PMS2* are much less frequent. When a somatic mutation inactivates the remaining wild-type allele of a mismatch repair gene, the cell develops a hypermutable phenotype characterized by profound genomic instability, especially for the short repeated sequences called *microsatellites*. This microsatellite instability (MIN) favors the development of cancer by increasing the rate of mutations in many genes, including oncogenes and tumor suppressor genes (Fig. 68-2). These genes can thus be considered caretakers. Figure 68-5 shows an example of the instability in allele sizes for dinucleotide repeats in the cancers of HNPCC patients.

While most autosomal dominant inherited cancer syndromes are due to mutations in tumor suppressor genes (Table 68-1), there are a few interesting exceptions. Multiple endocrine neoplasia type II, a dominant disorder characterized by pituitary adenomas, medullary carcinoma of the thyroid, and (in some pedigrees) pheochromocytoma, is due to gain-of-function mutations in the protooncogene *RET* on chromosome 10. Similarly, gain-of-function mutations in the tyrosine kinase domain of the *MET* oncogene lead to hereditary papillary renal carcinoma. Interestingly, loss-of-function mutations in the *RET* gene cause a completely different disease, Hirschsprung's disease [aganglionic megacolon (Chaps. 279 and 330)].

Although the Mendelian forms of cancer described above have taught us much about the mechanisms of growth control, most forms of cancer do not follow simple patterns of inheritance. In many instances (e.g., lung cancer), a strong environmental contribution is at work. Even in such circumstances, however, some individuals may be more genetically susceptible to developing cancer, given the appropriate exposure, due to the presence of modifier alleles.

TABLE 68-1 *Cancer Syndromes and Associated Genes*

Syndrome	Gene	Chromosome	Inheritance	Tumors
Ataxia telangiectasia	*ATM*	11q22-q23	AR	Breast cancer
Bloom syndrome	*BLM*	15q26.1	AR	Cancer of all types
Familial adenomatous polyposis	*APC*	5q21	AD	Intestinal adenoma, colorectal cancer
Familial melanoma	*p16INK4*	9p21	AD	Melanoma, pancreatic cancer
Familial Wilms' tumor	*WT1*	11p13	AD	Pediatric kidney cancer
Hereditary breast/ ovarian cancer	*BRCA1* *BRCA2*	17q21 13q12.3	AD	Breast, ovarian, colon, prostate
Hereditary multiple exostoses	*EXT1* *EXT2*	8q24 11p11-12	AD	Exostoses, chondrosarcoma
Hereditary prostate cancer	*HPC1*	1q24-25	AD	Prostate carcinoma
Hereditary retinobastoma	*RB1*	13q14.2	AD	Retinoblastoma, osteosarcoma
Hereditary nonpolyposis colon cancer (HNPCC)	*MSH2* *MLH1* *MSH6* *PMS2*	2p16 3p21.3 2p16 7p22	AD	Colon, endometrial, ovarian, stomach, small bowel, ureter carcinoma
Hereditary papillary renal carcinoma	*MET*	7q31	AD	Papillary renal tumor
Li-Fraumeni	*TP53*	17p13.1	AD	Sarcoma, breast cancer
Multiple endocrine neoplasia type 1	*MEN1*	11q13	AD	Parathyroid, endocrine, pancreas, pituitary
Multiple endocrine neoplasia type 2a	*RET*	10q11.2	AD	Medullary thyroid carcinoma, pheochromocytoma
Neurofibromatosis type 1	*NF1*	17q11.2	AD	Neurofibroma, neurofibrosarcoma, brain tumor
Neurofibromatosis type 2	*NF2*	22q12.2	AD	Vestibular schwannoma, meningioma, spine
Nevoid basal cell carcinoma syndrome (Gorlin syndrome)	*PTCH*	9q22.3	AD	Basal cell carcinoma, medulloblastoma, jaw cysts
Tuberous sclerosis	*TSC1* *TSC2*	9q34 16p13.3	AD	Angiofibroma, renal angiomyolipoma
Von Hippel–Lindau	*VHL*	3p25-26	AD	Kidney, cerebellum, pheochromocytoma

Note: AD, autosomal dominant; AR, autosomal recessive.

GENETIC TESTING FOR FAMILIAL CANCER The discovery of cancer susceptibility genes raises the possibility of DNA testing to predict the risk of cancer in individuals of affected families. An algorithm for cancer risk assessment and decision-making in high-risk families using genetic testing is shown in Fig. 68-6. Once a mutation is discovered in a family, subsequent testing of asymptomatic family members can be crucial in patient management. A negative gene test in these individuals can prevent years of anxiety in the knowledge that their cancer risk is no higher than that of the general population. On the other hand, a positive test may lead to alteration of clinical management, such as increased frequency of cancer screening and, when feasible and appropriate, prophylactic surgery. Potential negative consequences of a positive test result include psychological distress (anxiety, depression) and discrimination (insurance, employment). Testing should therefore not be conducted without counseling before and after disclosure of the test result. In addition, the decision to test should depend on whether effective interventions exist for the particular type of cancer to be tested. Despite these caveats, genetic cancer testing for some cancer syndromes already appears to have greater benefits than risks and many companies now offer testing for various genes associated with the predisposition to breast cancer (*BRCA1* and *BRCA2*), melanoma (*p16INK4*), and colon cancer (*APC* and the HNPCC genes).

Because of the inherent problems of genetic testing such as cost, specificity, and sensitivity, it is not yet appropriate to offer these tests to the general population. However, testing may be appropriate in some subpopulations with a known increased risk, even without a defined family history. For example, two mutations in the breast cancer susceptibility gene *BRCA1*, 185delAG and 5382insC, exhibit a sufficiently high frequency in the Ashkenazi Jewish population that genetic testing of an individual of this ethnic group may be warranted.

It is important that genetic test results be communicated to families by trained genetic counselors. To ensure that the families clearly understand its advantages and disadvantages and the impact it may have on their management and psyche, genetic testing should never be done before counseling. Significant expertise is needed to communicate the results of genetic testing to families. For example, one common mistake is to misinterpret the result of negative genetic tests. For many cancer predisposition genes, the sensitivity of genetic testing is only 70% or less (i.e., of 100 kindreds tested, disease-causing mutations can be identified in only 70). Therefore, such testing should in general begin with an affected member of the kindred (the youngest family member still alive who has had the cancer of interest). If a mutation is not identified in this individual, then the test should be reported as noninformative (Fig. 68-6) rather than negative (because it is possible that the mutation in this individual is not detectable by standard genetic assays for purely technical reasons). On the other hand, if a mutation can be identified in this individual, then testing of other family mem-

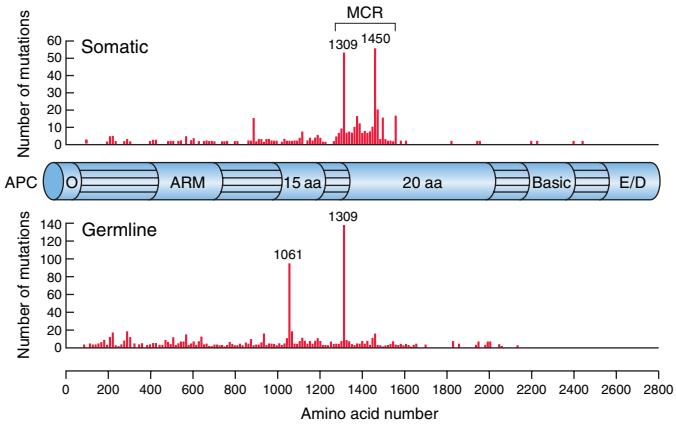

FIGURE 68-4 Germline and somatic mutations in the tumor suppressor gene *APC*. *APC* encodes a 2843-amino-acid protein with 6 major domains: an oligomerization region (O), armadillo repeats (ARM), 15-amino-acid repeats (15 AA), 20-amino-acid repeats (20 AA), a basic region, and a domain involved in binding EB1 and the *Drosophila* discs large homologue (E/D). Shown are the positions within the *APC* gene of a total of 650 somatic and 826 germline mutations (from the APC database at http://p53.curie.fr/). The vast majority of these mutations result in the truncation of the APC protein. Germline mutations are found to be relatively evenly distributed up to codon 1600 except for 2 mutation hotspots at amino acids 1061 and 1309, which together account for one-third of the mutations found in familial adenomatous polyposis (FAP) families. Somatic *APC* mutations in colon tumors cluster in an area of the gene known as the *mutation cluster region* (MCR). The location of the MCR suggests that the 20-amino-acid domain plays a crucial role in tumor suppression. Note that loss of the second functional *APC* allele in tumors from FAP families often occurs through loss of heterozygosity.

bers can be performed, and the sensitivity of such subsequent tests will be 100% (because the mutation in the family is in this case known to be detectable by the assay methods used).

ONCOGENES IN HUMAN CANCER Oncogenes of the kind found in human cancers were initially discovered through their presence in the genome of retroviruses capable of causing cancers in chickens, mice, and rats. The cellular homologues of these viral genes are often targets of mutation or aberrant regulation in human cancer. Whereas many oncogenes were discovered because of their presence in retroviruses, other oncogenes, particularly those involved in translocations characteristic of particular leukemias and lymphomas, were isolated through genomic approaches. Investigators cloned the sequences surrounding the chromosomal translocations observed cytogenetically and then deduced the nature of the genes that were the targets of these translocations (see below). Some of these were oncogenes known from retroviruses [like *ABL*, involved in chronic myelogenous leukemia (CML)], while others were new (like *BCL2*, involved in B cell lymphoma). In the normal cellular environment, protooncogenes have crucial roles in cell proliferation and differentiation. Table 68-2 is a partial list of oncogenes known to be involved in human cancer.

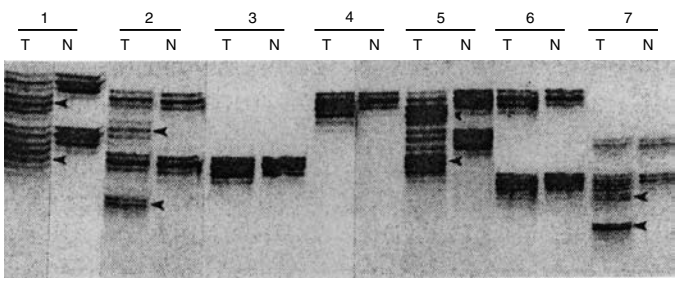

FIGURE 68-5 Demonstration of microsatellite instability in normal and tumor tissue from hereditary nonpolyposis colon cancer (HNPCC) patients. In each case the lane marked T contains DNA from a tumor, and the lane marked N contains DNA from normal tissue of the same patient. The marker (*D2S123*, located on chromosome 2) is a microsatellite composed of a tandem repeat of the dinucleotide CA, which varies in length from chromosome to chromosome. Normally, however, the length of the repeat is stable in somatic tissues. In this example, a polymerase chain reaction analysis has been applied to genomic DNA, and new alleles for the marker are apparent in tumors 1, 2, 5, and 7. Because the tumor tissue is defective in DNA mismatch repair, clonal abnormalities in copying of the CA repeat have arisen. Errors are also occurring in functional genes, eventually resulting in the malignant phenotype. (*From LA Aaltonen et al, Clues to the pathogenesis of familial colorectal cancer. FIGURE 68-6 Algorithm for genetic testing in a family with cancer predisposition. The key step is the identification of a mutation in a cancer patient, which allows testing of asymptomatic family members. Asymptomatic family members who test positive may require increased screening or surgery, whereas others are at no greater risk for cancer than the general population.

The normal growth and differentiation of cells is controlled by growth factors, which bind to receptors on the surface of the cell. The signals generated by the membrane receptors are transmitted inside the cells through signaling cascades involving kinases, G proteins, and other regulatory proteins. Ultimately, these signals affect the activity of transcription factors in the nucleus, which regulate the expression of genes crucial in cell proliferation, cell differentiation, and cell death. Oncogene products have been found to function at critical steps in these pathways (Chap. 69), and inappropriate activation of these pathways can lead to tumorigenesis.

MECHANISMS OF ONCOGENE ACTIVATION Mechanisms that upregulate (or activate) cellular oncogenes fall into three broad categories: point mutation, DNA amplification, and chromosomal rearrangement.

Point Mutation Point mutation is a common mechanism of oncogene activation. For example, mutations in one of the *RAS* genes (*HRAS*, *KRAS*, or *NRAS*) are present in up to 85% of pancreatic cancers and 50% of colon cancers but are relatively uncommon in other cancer types. Remarkably—and in contrast to the diversity of mutations found in tumor suppressor genes (Fig. 68-4)—most of the activated *RAS* genes contain point mutations in codons 12, 13, or 61 (which convey resistance to GAP, a protein that interacts with RAS and inactivates it through substitution of the GTP cofactor with GDP). The restricted pattern of mutation compared to tumor suppressor genes

reflects the fact that gain-of-function mutations of oncogenes are more difficult to attain than simple inactivation. Indeed, inactivation of a gene can be attained through the introduction of a stop codon anywhere in the coding sequence, whereas activations require precise substitutions at residues that normally downregulate the activity of the encoded protein. The specificity of oncogene mutations provides specific diagnostic opportunities, as it is much simpler to find mutations at specified positions than it is when mutations can be scattered throughout the gene (as in tumor suppressor genes).

DNA Amplification The second mechanism for activation of oncogenes is DNA sequence amplification, leading to overexpression of the gene product. This increase in DNA copy number may cause cytologically recognizable chromosome alterations referred to as *homogeneous staining regions* (HSRs), if integrated within chromosomes or *double minutes* (dmins), if extrachromosomal in nature. The recognition of DNA amplification is accomplished through various cytogenetic techniques such as comparative genomic hybridization (CGH) and fluorescence in situ hybridization (FISH), which allow the visualization of chromosomal aberrations using fluorescent dyes. With these techniques, the entire genome can be surveyed for gains and losses of DNA sequences, thus pinpointing chromosomal regions likely to contain genes important in the development or progression of cancer. Noncytogenetic, molecular techniques for identifying amplifications have more recently become available.

Numerous genes have been reported to be amplified in cancer. Several genes, including *NMYC* and *LMYC*, were identified through their presence within the amplified DNA sequences of a tumor and had homology to known oncogenes. Because the region amplified often extends to hundreds of thousands of base pairs, more than one oncogene may be amplified in some cancers (particularly sarcomas). Genes simultaneously amplified in many cases include *MDM2*, *GLI*, *CDK4*, and *SAS*. Demonstration of amplification of a cellular gene is often a predictor of poor prognosis. For example, *ERBB2*/*HER2* and *NMYC* are often amplified in aggressive breast cancers and neuroblastoma, respectively.

Chromosomal Rearrangement Chromosomal alterations provide important clues to the genetic changes in cancer. The chromosomal alterations in human solid tumors such as carcinomas are heterogeneous and complex and likely reflect selection for the loss of tumor suppressor genes on the involved chromosome. In contrast, the chromosome alterations in liquid tumors (leukemias and lymphomas) are often simple translocations, i.e., reciprocal transfers of chromosome arms from one chromosome to another. Consequently, many detailed and informative chromosome analyses have been performed on hematopoietic cancers. The breakpoints of recurring chromosome abnormalities usually occur at the site of cellular oncogenes. Table 68-3 lists representative examples of recurring chromosome alterations in malignancy and the associated gene(s) rearranged or deregulated by the chromosomal rearrangement. Translocations are particularly common in lymphoid tumors, probably because these cell types normally rearrange their DNA to generate antigen receptors. Indeed, antigen receptor genes are commonly involved in the translocations, implying that an imperfect regulation of receptor gene rearrangement may be involved in the pathogenesis. An example is Burkitt's lymphoma, a B cell tumor characterized by a reciprocal translocation between chromosomes 8 and 14. Molecular analysis of Burkitt's lymphomas demonstrated that the breakpoints occurred within or near the *MYC* locus on chromosome 8 and within the immunoglobulin heavy chain locus on chromosome 14, resulting in the transcriptional activation of *MYC*. Enhancer activation by translocation, although not universal, appears to play an important role in malignant progression. In addition to transcription factors and signal transduction molecules, translocation may result in the overexpression of cell cycle regulatory proteins such as cyclins and of proteins that regulate cell death such as bcl-2.

The first reproducible chromosome abnormality detected in human malignancy was the Philadelphia chromosome detected in CML. This cytogenetic abnormality is generated by reciprocal translocation involving the *ABL* oncogene, a tyrosine kinase on chromosome 9, being placed in proximity to the *BCR* (breakpoint cluster region) on chromosome 22. Figure 68-7 illustrates the generation of the translocation and its protein product. The consequence of expression of the *BCR-ABL* gene product is the activation of signal transduction pathways leading to cell growth independent of normal external signals. Interestingly, a compound (gleevec) that specifically blocks the activity of *BCR-ABL* was synthesized and shown to exhibit remarkable efficacy with little toxicity in patients with CML. Knowledge of genetic alterations in cancer can lead to mechanism-based design and development of a new generation of cancer drugs.

TABLE 68-2 *Common Oncogenes Altered in Human Cancers*

Oncogene	Function	Alteration in Cancer	Neoplasm
AKT1	Serine/threonine kinase	Amplification	Gastric carcinoma
AKT2	Serine/threonine kinase	Amplification	Ovarian, breast, pancreas
CTNNB1	Signal transduction	Point mutation	Colon, prostate, melanoma, skin, others
FOS	Transcription factor	Overexpression	Osteosarcomas
ERBB2	Receptor tyrosine kinase	Point mutation, amplification	Breast, ovary, stomach, neuroblastoma
JUN	Transcription factor	Overexpression	Lung
MET	Receptor tyrosine kinase	Point mutation, rearrangement	Osteocarcinoma, kidney, glioma
MYB	Transcription factor	Amplification	AML, CML, colon, melanoma
MYC	Transcription factor	Amplification	Breast, colon, gastric, lung
LMYC	Transcription factor	Amplification	Lung carcinoma, bladder
NMYC	Transcription factor	Amplification	Neuroblastoma, lung cancer
HRAS	GTPase	Point mutation	Colon, lung, pancreas
KRAS	GTPase	Point mutation	Melanoma, colorectal cancer, AML
NRAS	GTPase	Point mutation	Various carcinomas, melanoma
REL	Transcription factor	Rearrangement, amplification	Lymphomas
WNT1	Growth factor	Amplification	Retinoblastoma

Note: AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia.

TABLE 68-3 *Representative Oncogenes at Chromosomal Translocations*

Gene (Chromosome)	Translocation	Malignancy
ABL (9q34.1)–BCR (22q11)	(9;22)(q34;q11)	Chronic myelogenous leukemia
ATF1 (12q13)–EWS (22q12)	(12;22)(q13;q12)	Malignant melanoma of soft parts (MMSP)
BCL1 (11q13.3)–IgH (14q32)	(11;14)(q13;q32)	Mantle cell lymphoma
BCL2 (18q21.3)–IgH (14q32)	(14;18)(q32;q21)	Follicular lymphoma
FLI1 (11q24)–EWS (22q12)	(11;22)(q24;q12)	Ewing's sarcoma
LCK (1p34)–TCRB (7q35)	(1;7)(p34;q35)	T cell acute lymphocytic leukemia (ALL)
MYC (8q24)–IgH (14q32)	(8;14)(q24;q32)	Burkitt's lymphoma, B cell ALL
WT1 (11p13)–EWS (22q12)	(11;22)(p13;q12)	Desmoplastic small round cell tumor (DSRCT)
PAX3 (2q35)–FKHR/ALV(13q14)	(2;13)(q35;q14)	Alveolar rhabdomyosarcoma
PAX7 (1p36)–KHR/ALV(13q14)	(1;13)(p36;q14)	Alveolar rhabdomyosarcoma
RET (10q11.2)	(10;17)(q11.2;q23)	Papillary thyroid carcinomas

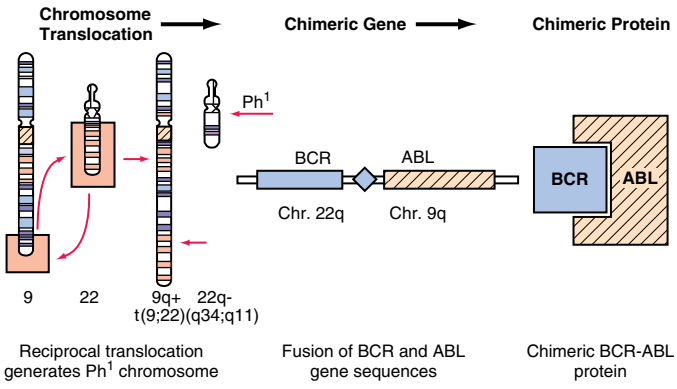

FIGURE 68-7 Specific translocation seen in chronic myelogenous leukemia (CML). The Philadelphia chromosome (Ph) is derived from a reciprocal translocation between chromosomes 9 and 22 with the breakpoint joining the sequences of the *ABL* oncogene with the *BCR* gene. The fusion of these DNA sequences allows the generation of an entirely novel fusion protein with modified function. (*Courtesy of ER Fearon and KR Cho.*)

CHROMOSOMAL INSTABILITY IN SOLID TUMORS Solid tumors are generally highly aneuploid, containing an abnormal number of chromosomes; these chromosomes also exhibit structural alterations such as translocations, deletions, and amplifications. Again, colon cancer has proven to be a particularly useful model for the study of chromosomal instability (CIN). As described above, some familial cases are characterized by the presence of MIN. Interestingly, MIN and CIN appear to be mutually exclusive in colon cancer, suggesting that they represent alternative mechanisms for the generation of a mutator phenotype in this cancer (Fig. 68-2). Other cancer types rarely exhibit MIN but almost always exhibit CIN. Normal cells possess several cell cycle checkpoints, often defined as quality control requirements that have to be met before subsequent events are allowed to take place. The spindle checkpoint, which ensures proper chromosome attachment to the mitotic spindle before allowing the sister chromatid to separate, has been shown to be deficient in certain cancers. The genes that, when mutated, may cause CIN have in general not yet been identified, although a few candidates mutated in a small number of tumors have been discovered. The identification of the cause of CIN in tumors will likely be a formidable task, considering that several hundred genes are thought to control the mitotic checkpoint and other cellular processes assuring proper chromosome segregation. Regardless of the mechanisms underlying CIN, the measurement of the number of chromosomal alterations present in tumors is now possible with both cytogenetic and molecular techniques, and several studies have shown that this information can be useful for prognostic purposes.

VIRUSES IN HUMAN CANCER Certain human malignancies are associated with viruses. Examples include Burkitt's lymphoma (Epstein-Barr virus), hepatocellular carcinoma (hepatitis virus), cervical cancer [human papillomavirus (HPV)], and T cell leukemia (retroviruses). The mechanisms of action of these viruses are varied but always involve activation of growth-promoting pathways or inhibition of tumor suppressor products in the infected cells. For example, HPV proteins E6 and E7 bind and inactivate cellular tumor suppressors p53 and pRB, respectively. Viruses are not sufficient for cancer development but constitute one alteration in the multistep process of cancer.

EPIGENETIC REGULATION OF GENE EXPRESSION IN CANCER An *epigenetic modification* refers to a change in the genome, heritable by cell progeny, that does not involve a change in the DNA sequence. The inactivation of the second X chromosome in female cells is an example of an epigenetic mechanism that prevents gene expression from the inactivated chromosome. During embryologic development, regions of chromosomes from one parent are silenced and gene expression proceeds from the chromosome of the other parent. For most genes, expression occurs from both alleles or randomly from one allele or the other. The preferential expression of a particular gene exclusively from the allele contributed by one parent is called *parental imprinting* and is thought to be regulated by covalent modifications of chromatin protein and DNA (particularly methylation) of the silenced llele.

The role of epigenetic control mechanisms in the development of human cancer is unclear. However, a general decrease in the level of DNA methylation has been noted as a common change in cancer. In addition, numerous genes, including some tumor suppressor genes, appear to become hypermethylated and silenced during tumorigenesis. *VHL* and *p16INK4* are well-studied examples of tumor suppressor genes that are silenced through methylation in human cancers. Overall, epigenetic mechanisms may be responsible for reprogramming the expression of a large number of genes in cancer and, together with the mutation of specific genes, are likely to be crucial in the development of human malignancies.

GENE EXPRESSION PROFILING IN CANCER The tumorigenesis process, driven by alterations in tumor suppressors, oncogenes, and epigenetic regulation, is accompanied by changes in gene expression. The advent of powerful new techniques such as microarrays and serial analysis of gene expression (SAGE) has allowed the study of gene expression in neoplastic cells on a scale never before accomplished. Indeed, it is now possible to identify expression levels of thousands of genes expressed in normal and cancer tissues. Figure 68-8 shows a typical cDNA array experiment examining gene expression in cancer. This global knowledge of gene expression allows the identification of differentially expressed genes and, in principle, the understanding of the complex molecular circuitry regulating normal and neoplastic behaviors. Such studies have led to molecular profiling of tumors, which has suggested general methods for distinguishing tumors of various biologic behaviors (molecular classification), elucidating pathways relevant to the development of tumors and identifying molecular targets for the detection and therapy of cancer. The first practical applications of this technology have suggested that global gene expression profiling can provide prognostic information not evident from other clinical or

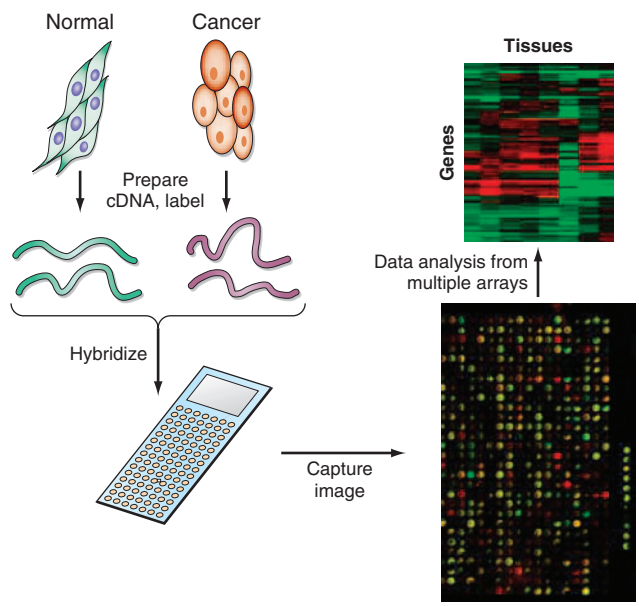

FIGURE 68-8 A cDNA array experiment. RNA is prepared from cells, reverse transcribed to cDNA, and labeled with fluorescent dyes (typically green for normal cells and red for cancer cells). The fluorescent probes are mixed and hybridized to the cDNA array. Each spot on the array is a cDNA fragment that represents a different gene. The image is then captured with a fluorescence camera; red spots indicate higher expression in tumor compared with reference while green spots represent the opposite. Yellow signals indicate equal expression levels in normal and tumor specimens. After clustering analysis of multiple arrays, the results are typically represented graphically using Treeview software, which shows, for each sample, a color-coded representation of gene expression for every gene on the array.

laboratory tests. The National Cancer Institute, in conjunction with the National Center for Biotechnology Information, has undertaken the Cancer Genome Anatomy Project (CGAP) (*www.ncbi.nlm.nih.gov/ncicgap/*) to collect data on gene expression in normal and malignant tissues and make it available on the Internet.

THE FUTURE It is clear that there has been a revolution in cancer genetics in the past 20 years. Identification of cancer genes has led to a better understanding of the tumorigenesis process and has had important repercussions on all fields of biology. In spite of these spectacular advances, however, there has been little overall improvement in cancer death rates. It is hoped that, as the molecular mechanisms of cancer initiation and development continue to be elucidated, novel therapies based on pathophysiology rather than empiricism will emerge. Time will tell whether these strategies will rely on novel combinations or dosing schedules of conventional drugs or will be based on new approaches such as those involving gene therapy or immunotherapy. In addition, a better understanding of the molecular pathways and genetic alterations in cancer cells may lead to the development of sensitive strategies for early detection of cancer.

69 CANCER CELL BIOLOGY AND ANGIOGENESIS

Robert G. Fenton, Dan L. Longo

Two characteristic features define a cancer: unregulated cell growth and tissue invasion/metastasis. Unregulated cell growth without invasion is a feature of *benign neoplasms*, or new growths. Cancer is a synonym for *malignant neoplasm*. Cancers of epithelial tissues are called *carcinomas*; cancers of nonepithelial (mesenchymal) tissues are called *sarcomas*.

Cancer is a genetic disease. The malignant phenotype often requires mutations in several different genes. Cancer cells generally retain the capacity to proliferate by acquiring mutations in cell cycle regulatory genes (particularly those regulating the G_1 checkpoint). Often mutations activate cell pathways leading to proliferation and block pathways of differentiation. The normal cell has protective mechanisms that lead to the repair of cell damage; these repair pathways are often abnormal in cancer cells. When a normal cell has sustained too much damage to repair, the cell activates a suicide pathway to prevent damage to the organ. These cell death pathways are also commonly altered in cancer cells, leading to the survival of damaged cells that would normally die.

The accumulation of genetic lesions may lead through an identifiable progression of altered phenotypes as is noted in colon cancer: hyperplasia → adenoma → dysplasia → carcinoma in situ → invasive carcinoma. However, in many tissues, premalignant changes cannot be readily identified. Genetic changes lead to both loss and acquisition of properties: a loss of the differentiated function of the cell but the acquisition of novel characteristics that facilitate metastasis, such as the ability to break through basement membranes, migrate through the extracellular matrix and into the vascular tree, and generate new blood vessels to support colonization in remote sites.

CANCER CELL BIOLOGY

The treatment of most human cancers with conventional cytoreductive agents has been unsuccessful due to the Gompertzian-like growth kinetics of solid tumors and the genetic instability that predisposes to the development of intrinsic and acquired drug resistance. Rationally designed, target-based therapeutic agents directed against the specific molecular derangements that distinguish malignant from nonmalignant cells have become possible with advances in the understanding of oncogene and tumor-suppressor pathways. New agents can be classified by their specific molecular targets, such as tyrosine kinase inhibitors or farnesyltransferase inhibitors, or by their general mechanism of action, such as inhibition of cell cycle progression or angiogenesis. Novel therapeutics include small molecules, peptides, oligonucleotides, and monoclonal antibodies. This chapter describes the convergence of scientific, pharmacologic, and medical knowledge that has led to the targeted therapy of cancer.

THERAPEUTIC APPROACHES TO CELL CYCLE ABNORMALITIES IN CANCER The mechanism of cell division is substantially the same in all dividing cells and has been conserved throughout evolution. The process assures that the cell accurately duplicates its contents, especially its chromosomes. The cell cycle is divided into four phases. During M-phase, the replicated chromosomes are separated and packaged into two new nuclei by mitosis and the cytoplasm is divided between the two daughter cells by cytokinesis. The other three phases of the cell cycle are called *interphase*: G_1 (gap 1), during which the cell determines its readiness to commit to DNA synthesis; S (DNA synthesis), during which the genetic material is replicated and no re-replication is permitted; and G_2 (gap 2), during which the fidelity of DNA replication is assessed and errors are corrected.

Deregulation of the molecular mechanisms controlling cell cycle progression is a hallmark of cancer. Progression from one phase of the cell cycle to the next is controlled by the orderly activation of cyclin-dependent kinases (CDKs) that are regulated by signaling events that couple a cell's physiologic response to its extracellular milieu. The transition through G_1 into S-phase is a critical regulator of cell proliferation, and the phosphorylation state of the retinoblastoma tumor-suppressor protein (pRB) at the restriction point determines whether a cell will enter S-phase (where DNA synthesis occurs). The complex of CDK4 or CDK6 with D type cyclins forms a G_1-specific kinase whose activity is regulated by growth factors, nutrients, and cell-cell and cell-matrix interactions. Subsequent formation of an active CDK2/cyclin E complex results in full phosphorylation of pRB, relieving its inhibitory effects on the S-phase-regulating transcription factor E2F/DP1, and permitting the activation of genes required for S-phase (such as dihydrofolate reductase, thymidine kinase, and DNA polymerase). The activity of CDK/cyclin complexes can be blocked by CDK-inhibitors including $p21^{Cip1/Waf1}$, $p16^{Ink4a}$, and $p27^{Kip1}$, which block S-phase progression by preventing the phosphorylation of pRB.

Genetic lesions that render the retinoblastoma pathway nonfunctional are thought to occur in almost all human cancers. The result of these lesions is loss of the function of pRB as guardian of the G_1 restriction point, enabling cancer cells to enter a mitotic cycle without

the normal input from external signals. Current therapeutic efforts to reverse the derangements of the retinoblastoma pathway have taken two main approaches. All kinases require the binding of ATP (and substrate) to the enzyme active site, followed by transfer of the γ-phosphate to serine, threonine, or tyrosine residues of the substrate. One of the first kinase inhibitors to reach clinical trial was UCN-01, a staurosporine analogue, which had broad activity against many serine/threonine kinases and hence lacked specificity. Flavopiridol was the first relatively selective CDK inhibitor identified, with Ki or IC_{50}s in the 40- to 400-n*M* range. Although flavopiridol was initially thought to inhibit tumor cell proliferation by inhibition of cell cycle CDKs, it is now clear that non-cell cycle functions of the CDK7/cyclin H and CDK9/cyclin T1 complexes may be critical for flavopiridol's antitumor activity due to inhibition of transcription of cellular mRNA. Phase II clinical trials of flavopiridol are in progress. Laboratory efforts are focused on the development of novel classes of CDK inhibitors capable of specifically targeting individual CDK/cyclin complexes. This may prove difficult given the great structural similarity of the active sites of these kinases. A second therapeutic endeavor to regain control of pRB function involves reversing the epigenetic silencing of $p16^{Ink4a}$ gene and is discussed below.

p53, the "guardian of the genome," is a sequence-specific transcription factor whose activity is regulated through tight control of p53 protein levels. Normally, levels of p53 are kept low by its association with the mdm2 oncogene product, which binds p53 and shuttles it out of the nucleus for proteolytic degradation. In response to noxious stimuli that induce DNA damage, such as gamma irradiation or chemotherapy, p53 is phosphorylated by several kinases that regulate the DNA damage checkpoint. This causes dissociation of p53 from mdm2, leading to increased p53 protein levels. This activates transcription of genes leading to cell cycle arrest ($p21^{Cip1/Waf1}$) or apoptosis (pro-apoptotic Bcl-2 family members, genes regulating metabolism of reactive oxygen species, and death receptors such as DR5). Inducers of p53 include hypoxia, DNA damage (caused by ultraviolet radiation, gamma irradiation, or chemotherapy), ribonucleotide depletion, and telomere shortening. Further, deregulated activity of oncogenes such as *Myc*, which promote aberrant G_1/S transition, results in p53-induced apoptosis. This is mediated by a second product of the Ink4a locus, $p14^{ARF}$, which is encoded by an *a*lternative *r*eading *f*rame from $p16^{Ink4a}$. Levels of ARF are upregulated by *Myc* and E2F, and ARF binds to mdm2 and rescues p53 from its inhibitory effect. This oncogene checkpoint leads to the death of renegade cells that attempt to transverse the restriction point without appropriate physiologic signals.

Acquired mutation in p53 is the most common genetic alteration found in human cancer (>50%); germline mutation in p53 is the causative genetic lesion of the Li-Fraumeni familial cancer syndrome. In many tumors, one p53 allele on chromosome 17p is deleted and the other is mutated. The mutations often abrogate the DNA binding function of p53 that is required for its transcription factor activity and tumor-suppressor functions. Inactivation of the p53 pathway compromises cell cycle arrest, attenuates apoptosis induced by DNA damage or other stimuli, and predisposes cells to chromosome instability. This genomic instability greatly increases the probability that p53 null cells will acquire additional mutations and become malignant. Almost all human cancers have genetic alterations that bypass the Rb and p53 tumor-suppressor pathways.

Therapies directed at p53 are based on the observations that tumors expressing mutant p53 are often more resistant to chemotherapy than tumors with wild-type p53, and that mutant p53 proteins accumulate to high levels in tumor cells. If the transcriptional functions of the mutant p53 could be reestablished in tumor cells, massive apoptosis might ensue, whereas normal cells would be protected because they express very low levels of wild-type 53. Investigators have screened chemical libraries for compounds that inhibit tumor cell growth in a mutant p53-dependent manner. One compound entered cells and induced mutant p53 to adopt an active conformation such that p53-dependent transcriptional activation was restored and apoptosis was selectively induced. This compound also had anti-tumor activity in murine xenograft models. These experiments constitute a proof of principle for targeting mutant p53 in human cancer through the novel mechanism of restoring an active conformation to a mutant tumor-suppressor protein. Clinical development is planned.

Compounds have been identified that act through a p53-dependent mechanism to protect normal cells from genotoxic damage. Selenium has been known as a cancer preventative for many years, but its mechanism of action is unknown. Selenomethionine, the main form of selenium in our diets, participates in a redox reaction resulting in the reduction of two cysteine residues within p53, leading to an induction of p53 DNA-binding activity. However, this form of p53 activates DNA repair pathways without affecting cell growth; the repair of genetic lesions may explain the cancer-preventative activity of selenomethionine. Other investigators have identified a low-molecular-weight, cell-permeable compound that inhibits the apoptotic functions of wild-type p53. This compound protected mice from the toxic effects of radiation therapy and chemotherapy, including bone marrow suppression, gastrointestinal dysfunction, and hair loss.

Knowledge of the molecular events governing cell cycle regulation has led to the development of viruses that replicate selectively in tumor cells with defined genetic lesions. Such "oncolytic" viruses include adenoviruses designed to replicate in tumor cells that lack functional p53 or have defects in the pRB pathway, in which replication of the mutant virus is dependent on deregulated E2F transcription factor activity. The former group includes an adenovirus mutant lacking the viral p55 protein (which binds and inhibits p53 in normal cells). This virus has demonstrated efficacy in phase II clinical trials of head and neck tumors, especially when combined with 5-fluorouracil and cisplatin (50% partial or complete response). The complexities of virus-host interactions (i.e., the immune response against replicating virus) will require further refinements of this novel technology before the clinical utility of this approach can be fully realized.

TELOMERASE DNA polymerase is unable to replicate the end of chromosomes, resulting in the loss of DNA at the specialized ends of chromosomes (called *telomeres*) with each replication cycle. At birth, human telomeres are 15- to 20-kilobase pairs long and are composed of tandem repeats of a six-nucleotide sequence (TTAGGG) that associate with specialized telomere-binding proteins to form a T-loop structure that protects the ends of chromosomes from being recognized as broken or damaged DNA. The loss of telomeric repeats with each cell division cycle causes gradual telomere shortening, leading to growth arrest (called *replicative senescence*) when one or more critically short telomeres triggers a p53-regulated DNA-damage checkpoint response. Cells can bypass this growth arrest if pRB and p53 are nonfunctional, but cell death ensues when the unprotected ends of chromosomes precipitate chromosome fusions or other catastrophic DNA rearrangements (termed *crisis*). The ability to bypass telomere-based growth limitations is thought to be a critical step in the evolution of most malignancies. This occurs by the reactivation of telomerase expression in cancer cells. Telomerase is an enzyme that adds TTAGGG repeats onto the 3′ ends of chromosomes. It contains a catalytic subunit with reverse transcriptase activity (hTERT) and an RNA component that provides the template for telomere extension. Most normal somatic cells do not express sufficient telomerase to prevent telomere attrition with each cell division. Exceptions include stem cells (including those found in hematopoietic tissues, gut and skin epithelium, and germ cells) that require extensive cell division to maintain tissue homeostasis. More than 90% of human cancers express high levels of telomerase that prevent telomere exhaustion and allow indefinite cell proliferation. In vitro experiments indicate that inhibition of telomerase enzymatic activity leads to tumor cell apoptosis. Major efforts are underway to develop methods to inhibit telomerase activity in cancer cells. The reverse transcriptase activity of telomerase is a prime target for small-molecule pharmaceuticals that will enter clinical trials. The protein component of telomerase (hTERT) can act as a tumor-associated an-

tigen that could be recognized by antigen-specific cytotoxic T lymphocytes (CTL) that lyse human melanoma, prostate, lung, breast, and colon cancer cells in vitro. Phase I clinical studies of telomerase vaccines are underway.

SIGNAL TRANSDUCTION PATHWAYS AS THERAPEUTIC TARGETS IN CANCER CELLS Since the discovery that the v-*src* oncogene has protein tyrosine kinase activity, the central role of tyrosine phosphorylation in the regulation of cell proliferation in response to growth factors has become apparent. Many tyrosine kinases act at the apex of signaling pathways and are transmembrane proteins (receptor tyrosine kinases, RTK) or are associated with structures at the plasma membrane (*Src*-, Janus-, and *Fak*-family kinases). Tyrosine kinases are normally activated by specific ligands, and their activity is short-lived and reversed by protein tyrosine phosphatases (PTP). Phosphotyrosine and adjacent amino acid residues serve as docking sites for signal transduction proteins including those with protein-kinase, lipid-kinase, nucleotide exchange, lipase, and other enzymatic activities (Fig. 69-1). The unregulated activity of specific tyrosine kinases characterizes a number of human cancers, and their important roles in cancer cell proliferation and survival has validated these enzymes as targets for drug development efforts. Tyrosine kinases become constitutively activated and lead to the development of neoplastic diseases in three ways: chromosomal translocation, overexpression, and point mutation (Table 69-1). More than 30 different tyrosine kinases have been implicated in human cancer.

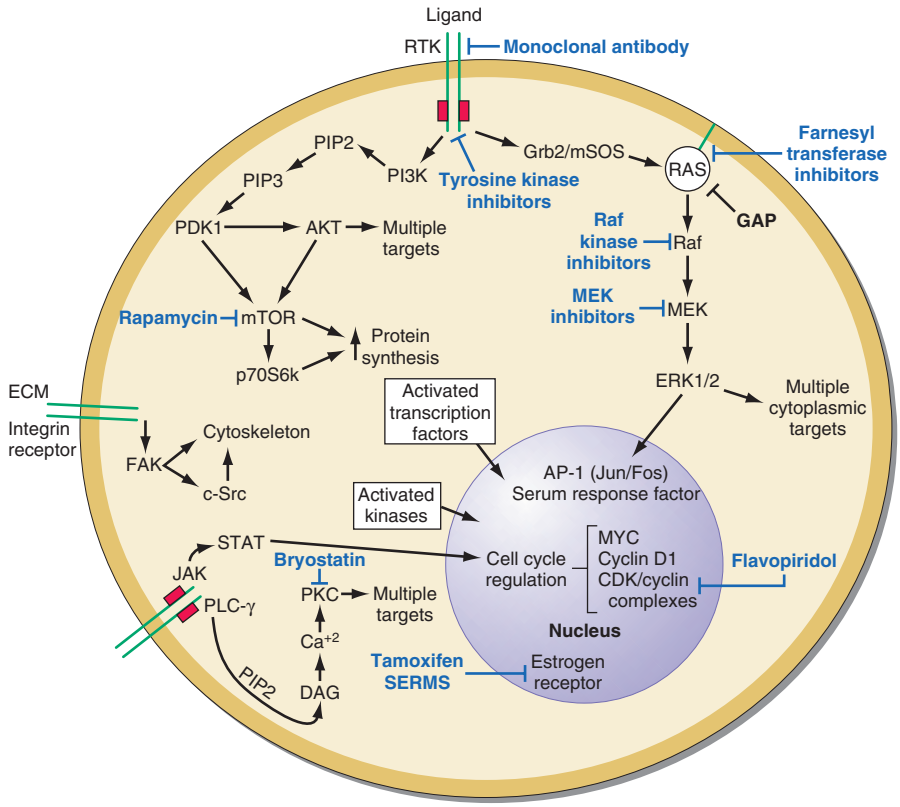

FIGURE 69-1 Therapeutic targeting of signal transduction pathways in cancer cells. Three major signal transduction pathways are activated by receptor tyrosine kinases (RTK). 1. The protooncogene Ras is activated by the Grb2/mSOS guanine nucleotide exchange factor, which induces an association with Raf and activation of downstream kinases (MEK and ERK1/2). 2. Activated PI3K phosphorylates the membrane lipid PIP2 to generate PIP3, which acts as a membrane-docking site for a number of cellular proteins including the serine/threonine kinases PDK1 and Akt. PDK1 has numerous cellular targets including Akt and mTOR. Akt phosphorylates target proteins that promote resistance to apoptosis and cell cycle progression, while mTOR and its target p70S6K upregulate protein synthesis to potentiate cell growth. 3. Activation of PLC-γ leads the formation of diacylglycerol (DAG) and increased intracellular calcium, with activation of multiple isoforms of PKC and other enzymes regulated by the calcium/calmodulin system. Other important signaling pathways involve non-RTKs that are activated by cytokine or integrin receptors. Janus kinases (JAK) phosphorylate STAT (signal transducer and activator of transcription) transcription factors, which translocate to the nucleus and activate target genes. Integrin receptors mediate cellular interactions with the extracellular matrix (ECM), inducing activation of FAK (focal adhesion kinase) and c-Src, which activate multiple downstream pathways, including modulation of the cell cytoskeleton. Many activated kinases and transcription factors migrate into the nucleus where they regulate gene transcription, thus completing the path from extracellular signals, such as growth factors, to a change in cell phenotype, such as induction of differentiation or cell proliferation. The nuclear targets of these processes include transcription factors (e.g., Myc, AP-1, and serum response factor) and the cell cycle machinery (CDKs and cyclins). Inhibitors of many of these pathways have been developed for the treatment of human cancers. Examples of inhibitors that are currently being evaluated in clinical trials are shown in blue.

TARGETING Bcr-Abl WITH IMATINIB: PROOF OF PRINCIPLE The protein product of the Philadelphia chromosome occurs in all patients with chronic myeloid leukemia (CML) and in about 30% of patients with adult acute lymphoid leukemia (ALL) and encodes the fusion protein Bcr-Abl. Although the c-*Abl* protooncogene is a nuclear protein whose kinase activity is tightly regulated as a part of the DNA damage response pathway (and actually induces growth arrest), the Bcr-Abl fusion protein is largely cytoplasmic with a constitutively activated tyrosine kinase domain. The deregulated tyrosine kinase activity of Bcr-Abl is required for its transforming activity. The Abl tyrosine kinase inhibitor, imatinib mesylate (Gleevec), has validated the concept of a molecularly targeted approach to cancer treatment.

Imatinib is a low-molecular-weight competitive inhibitor of the ATP binding site of Bcr-Abl, c-Abl, platelet-derived growth factor receptor (PDGFR), and c-Kit; hence it is not absolutely specific for the *Bcr-Abl* oncogene product. Clinical studies have demonstrated remarkable activity of this agent in CML. In Phase II studies of 532 chronic phase CML patients in whom interferon treatment had failed, 95% obtained a hematologic complete response, with only 9% relapse after a median follow-up of 18 months. Imatinib was also active in CML blast crisis with a 52% response rate, although the responses were short lived (78% relapse within 1 year). Relapse during treatment with imatinib was associated with reactivation of the tyrosine kinase either by amplification of the *Bcr-Abl* locus leading to increased levels of Bcr-Abl protein or, more commonly, by point mutations within the Bcr-Abl kinase domain that decreased imatinib binding without loss of Bcr-Abl kinase activity. These data constitute genetic proof that the target of imatinib is the Bcr-Abl tyrosine kinase, and that Bcr-Abl kinase activity is still required by imatinib-resistant cells. Computer modeling of the x-ray crystal structure of Bcr-Abl and its mutant forms is being used to guide the synthesis of the next generation of kinase inhibitors that may be able to overcome this acquired drug resistance.

Imatinib has also demonstrated targeted activity against gastrointestinal stromal tumors (GIST), rare mesenchymal tumors of the gastrointestinal tract (stomach and small intestine). The pathogenic molecular event in this disease is mutation of the proto-oncogene c-*Kit*, leading to the constitutive activation of this receptor tyrosine kinase. This prevents the normal differentiation of gut stem cells into interstitial cells of Cajal and induces proliferation and survival of tumor cells. Imatinib, which inhibits the c-Kit kinase domain, has demonstrated significant activity (>50% partial responses, many of long duration) in this chemotherapy-refractory tumor. Patients with chronic myelomonocytic leukemia (CMML, a myeloproliferative disorder) often harbor a Tel-PDGFR translocation that results in constitutive activation of the PDGFR kinase domain exclusively in the leukemic cells. Imatinib inhibits this kinase and has demonstrated significant activity in this disease. It may have activity in glioblastomas, which often express a PDGFR/PDGF autocrine growth loop.

TABLE 69-1 *Tyrosine Kinases Are Activated by Multiple Genetic Events in Human Cancers*[a]

Mechanisms	Tyrosine Kinases	Cancers
1. Translocations generate fusion proteins with BCR, TEL, or NPM. Oligomerization leads to activation of the kinase by cross-phosphorylation.	ABL, ALK, FGFR, JAK2, PDGFR, TRKC	Acute and chronic leukemias, fibrosarcoma
2. Overexpression causing receptor dimerization in absence of ligand.	EGFR family, IGFR PDGFR, FGFR family, c-MET	Breast, ovarian, lung, gastric, prostate, glioblastoma, others
3. Gain-of-function point mutation leading to receptor dimerization and kinase activation	c-KIT	Gastrointestinal stromal tumors
	c-RET	Medullary thyroid CA
4. Autocrine growth pathway	MET/HGF	Rhabdomyosarcomas
	PDGF/PDGFR	Glioblastoma
5. Overexpression of ligands such as VEGF or angiopoietins by stroma or tumor cells	VEGFR	Many tumors
	TIE2	

[a] Deregulation of protein tyrosine kinases is a common genetic event leading to the development of human neoplasia. Tumor cells are highly mutagenic and have defects in DNA-damage checkpoints. This permits the outgrowth of tumor clones with multiple genetic anomalies, some of which promote tumor progression by increasing proliferation, enhancing resistance to apoptosis, and promoting angiogenesis.

Abbreviations: BCR, breakpoint cluster region; TEL, Ets-family transcription factor; NPM, nucleophosmin; ABL, Abelson tyrosine kinase; ALK, anaplastic lymphoma kinase; FGFR, fibroblast growth factor receptor; JAK2, Janus kinase 2; PDGFR, platelet-derived growth factor receptor; TRKC, neurotropin tyrosine receptor kinase C; EGFR, epidermal growth factor receptor; IGFR, insulin-like growth factor receptor; c-MET, receptor for hepatocyte growth factor (HGF); c-KIT, receptor for stem cell factor; c-RET, receptor for glial-derived neurotrophic factors; VEGFR, vascular endothelial growth factor receptor; TIE2, angiopoietin receptor.

These examples extend the proof of principle that selective targeting of signaling pathways in cancer cells can be highly efficacious with minimal toxicity. Imatinib has become the paradigm of targeted drug development in other diseases. For instance, 30% of acute myeloid leukemias (AML) encode mutations in the Fms-like tyrosine kinase FLT-3. Internal tandem duplications of the juxtamembrane domain of this RTK, or point mutations in the activation loop of the kinase domain, lead to constitutive activation of the kinase and confer a poor prognosis. Four chemically distinct inhibitors of FLT-3 are currently in clinical trials. These differ in potency of inhibition of the FLT-3 kinase and in the spectrum of cross-reactivity against other tyrosine kinases. Differences in toxicity are expected, as is the development of drug resistance. However, if multiple clinically active inhibitors can be developed, drug resistance may be avoided by combination therapy.

RECEPTOR TYROSINE KINASES RTKs are transmembrane glycoproteins that undergo dimerization upon ligand binding, with activation of their cytoplasmic tyrosine kinase domains by proximity-induced transphosphorylation of the activation loop. Tyrosine residues of the receptor or adaptor proteins (such as IRS-1 or Shc) are phosphorylated and act as docking sites for proteins containing SH2 (Src-homology 2) or PTB (phosphotyrosine binding) domains, thus initiating multiple signal transduction pathways (Fig. 69-1). These pathways regulate the proliferation, survival, migration, and angiogenesis of many solid tumors and are therefore viewed as attractive potential targets for cancer therapy. HER2/*neu* is a target in human breast cancer.

The gene encoding HER2/*neu* [a member of the epidermal growth factor receptor (EGFR) family] is amplified in ~30% of breast cancers. Tumors that overexpress HER2/*neu* are less responsive to chemotherapy, and patients with these tumors have a reduced survival compared with patients with normal levels of HER2/*neu*. Trastuzumab (Herceptin) is a humanized monoclonal antibody that binds HER2/*neu* on the surface of tumor cells and induces internalization of the receptor, thereby reducing the level of surface expression. This leads to inhibition of cell cycle progression and renders cancer cells more susceptible to the induction of apoptosis. In clinical trials, trastuzumab as a single agent induced 15% responses in previously treated metastatic breast cancer patients. In phase III studies, a statistically significant increased survival occurred when trastuzumab was combined with chemotherapy in breast cancers in which HER-2/*neu* was overexpressed.

The EGFR (ERBB1) is another member of the RTK family that includes ERBB2 (HER2/*neu*), ERBB3, and ERB4. The EGFR is broadly expressed in normal cells and is overexpressed in many human cancers including head and neck, lung, esophageal, gastric, pancreatic, colon, renal cell, breast, ovarian, cervical, and prostate cancers, and gliomas. Overexpression correlates with poor clinical outcome. Targeted approaches include the use of antibodies directed against the EGFR extracellular domain and small-molecule inhibitors of the kinase domain. Single-agent clinical trials of anti-EGFR monoclonal antibodies or tyrosine kinase inhibitors in patients with previously treated lung and colon cancer demonstrated some antitumor activity, and studies combining these agents with chemotherapy are in progress. Overall, however, the therapeutic efficacy of EGFR-targeted agents has been disappointing. Of interest is that some breast cancers overexpress both the EGFR and HER2/*neu*, and clinical trials to simultaneously target both RTKs are under consideration.

The PDGFR and its ligand platelet-derived growth factor (PDGF), are overexpressed in many glioblastomas and in subsets of melanoma, ovarian, pancreatic, gastric, lung, and prostate cancers. Overexpression of the hepatocyte growth factor receptor MET has been observed in many human cancers and correlates with a poor prognosis, perhaps due to its role in invasion and metastasis. Small-molecular inhibitors of these RTKs are being developed for clinical use. As described below, the vascular endothelial growth factor receptor (VEGFR), TIE, and EPH RTK families have been identified as important therapeutic targets for inhibition of angiogenesis.

Signaling Pathways Downstream of RTKs: Ras and PI3K Several oncogene and tumor-suppressor gene products are components of signal transduction pathways that emanate from RTK activation (Fig. 69-1). The most extensively studied are the Ras/mitogen-activated protein (MAP) kinase pathway and the phosphatidylinositol-3-kinase (PI3K) pathway, both of which regulate multiple processes in cancer cells, including cell cycle progression, resistance to apoptotic signals, and cell motility. The development of inhibitors of these pathways constitutes an important avenue of anticancer drug development.

Mutations of the *Ras* protooncogene occur in 20% of human cancers and result in loss of the response of oncogenic Ras to GTPase-activating proteins (GAPs). The constitutively activated, GTP-bound Ras activates downstream effectors including the Ras/MAP kinase and PI3K/Akt pathways. Cancers of the pancreas, colon, and lung and AML harbor frequent *Ras* mutations, with the K-*Ras* allele affected more commonly (85%) than N-*Ras* (15%); H-*Ras* mutations are uncommon in human cancers. In addition, *Ras* activity in tumor cells can be aberrantly increased by other mechanisms, including upregulation of RTK activity and mutation of GAP proteins (e.g., *NF1* mutations in type I neurofibromatosis). Ras proteins localize to the inner plasma membrane and require posttranslational modifications, including addition of a farnesyl lipid moiety to the cysteine residue of the carboxy-terminal CAAX-box motif. Inhibition of RAS farnesylation by rationally designed farnesyltransferase inhibitors (FTIs) demonstrated encouraging efficacy in preclinical models, most of which utilized oncogenic forms of H-Ras. Despite this, clinical trials of FTIs in patients whose tumors harbor *Ras* mutations have been disappointing. Lack of efficacy has been shown in pancreatic, colon, and bladder carcinomas, while some activity has been seen in AML and CML. Upon further study, it appears that in the presence of FTIs, lipid modification of the K- and N-Ras proteins occurs by addition of a distinct lipid (geran-

ylgeranyl) by the action of geranylgeranyl transferase (GGT), which results in restoration of Ras function. Thus, while FTIs are likely to have antitumor activity in select human cancers, their mechanism of action appears to occur by inhibition of farnesylation of proteins other than Ras, perhaps RhoB.

Effector pathways downstream of Ras are also targets of anticancer drug efforts. Activation of the Raf serine/threonine kinase is induced by binding to Ras and leads to activation of the MAP kinase pathway (Fig. 69-1). Two-thirds of melanomas and 10% of colon cancers harbor activating mutations in the *BRAF* gene, leading to constitutive activation of the downstream MAP/ERK kinase (MEK) and extracellular signal-regulated kinases (ERK1/2). This results in the phosphorylation of ERK's cytoplasmic and nuclear targets and alters the pattern of normal cellular gene expression. Inhibitors of Raf kinases have entered phase I clinical trials; their activity against tumors expressing mutant *BRAF* will be of special interest. MEK inhibitors are also demonstrating activity in phase I clinical trials.

PI3K is a heterodimeric lipid kinase that catalyses the conversion of phosphatidylinositol bisphosphate (PIP_2) to phosphatidylinositol trisphosphate (PIP_3), which acts as a plasma membrane docking site for proteins that contain a pleckstrin homology (PH) domain. These include the serine/threonine kinases Akt and PDK1 that are key downstream effectors of PI3K action (Fig. 69-1). The PI3K pathway is activated in 30 to 40% of human cancers and is thought to play a critical role in tumor cell survival, as well as promoting proliferation and migration. Amplification of the gene encoding the catalytic subunit of PI3K (p110) is observed in ovarian cancer, and amplification of the *Akt2* gene occurs in breast, ovarian, and pancreatic cancers. The tumor suppressor PTEN (phosphatase with tensin homology), a lipid phosphatase that acts as an off signal for PI3K by dephosphorylating PIP_3, is mutated in many human cancers, leading to unchecked activity of the PI3K pathway. Akt promotes cell survival by inhibiting apoptosis-promoting proteins and through activation of the transcription factor nuclear factor of κB (NFκB); it also enhances cell cycle progression by inhibition of glycogen synthetase kinase 3 (GSK3), which prevents cyclin D1 degradation. Furthermore, the growth of cancer cells requires the activation of two downstream kinases, mammalian target of rapamycin (mTOR) and p70S6K, whose activities promote the translation of cellular mRNAs. Targeted interruption of the PI3K pathway is being attempted at multiple levels. Inhibitors of mTOR, including rapamycin and its more soluble ester derivative CCI-779, selectively kill human tumor cell lines with PTEN mutations and upregulated PI3K pathway activity. Clinical trials of CCI-779 are under way. Because of the great sequence homology between kinase domains, it is unclear if isoform-specific drugs can be developed and whether these will enable tumor targeting without undue toxicity.

RTKs activate other signaling pathways. Activation of phospholipase C-γ(PLC) results in the hydrolysis of PIP_2 into diacylglycerol (DAG) and IP_3. DAG together with calcium ion (Ca^{2+}) activates protein kinase C (PKC), a family of serine/threonine-specific protein kinases with different activation requirements, subcellular locations, and substrates in different cell types. PKC is the target of tumor-promoting phorbol esters, and its activation can modulate cell proliferation, differentiation, and tumorigenesis. The PKC inhibitor bryostatin 1 has reached phase II clinical trials and thus far has demonstrated only minimal antitumor activity. However, an antisense oligonucleotide directed against PKC and a number of small molecule inhibitors that demonstrate greater selectivity for PKC isoforms are undergoing clinical evaluation.

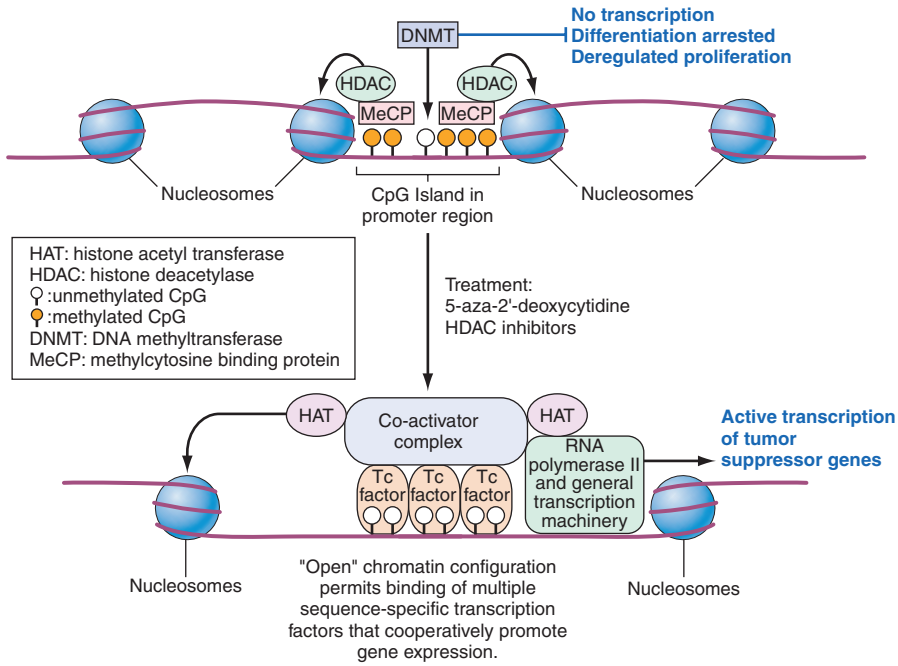

FIGURE 69-2 Epigenetic regulation of gene expression in cancer cells. Tumor-suppressor genes are often epigenetically silenced in cancer cells. In the upper panel, a CpG island within the promoter and enhancer regions of the gene has been methylated, resulting in the recruitment of methyl-cytosine binding proteins and complexes with histone deacetylase (HDAC) activity. Chromatin is in a condensed, nonpermissive conformation that inhibits transcription. Clinical trials are under way utilizing the combination of demethylating agents such as 5-aza-2′-deoxycytidine plus HDAC inhibitors, which together confer an open, permissive chromatin structure (*lower panel*). Transcription factors bind to specific DNA sequences in promoter regions and, through protein-protein interactions, recruit coactivator complexes containing histone acetyl transferase (HAT) activity. This enhances transcription initiation by RNA polymerase II and associated general transcription factors. The expression of the tumor-suppressor gene commences, with phenotypic changes that may include growth arrest, differentiation, or apoptosis.

ALTERATIONS IN GENE TRANSCRIPTION IN CANCER CELLS: ROLE OF EPIGENETIC CHANGES

Chromatin structure regulates the hierarchical order of sequential gene transcription that governs differentiation and tissue homeostasis. Disruption of chromatin remodeling leads to aberrant gene expression and can induce proliferation of undifferentiated cells, leading to cancer. *Epigenetics* is defined as changes that alter the pattern of gene expression that persist across at least one cell division, but are not caused by changes in the DNA code. Epigenetic changes include alterations of chromatin structure mediated by methylation of cytosine residues in CpG dinucleotides, modification of histones by acetylation or methylation, or changes in higher-order chromosome structure (Fig. 69-2). The transcriptional regulatory regions of active genes often contain a high frequency of CpG dinucleotides (referred to as *CpG islands*), which under normal circumstances remain unmethylated. Expression of these genes is regulated by transient association with repressor or activator proteins. However, hypermethylation of promoter regions is a common mechanism by which tumor-suppressor loci are epigenetically silenced in cancer cells. Thus one allele may be inactivated by mutation or deletion (as occurs in loss of heterozygosity), while expression of the other allele is epigenetically silenced. The mechanisms that target suppressor oncogenes for this form of gene silencing are unknown.

Acetylation of the amino terminus of the core histones H3 and H4 induces an open chromatin conformation that promotes transcription initiation. Histone acetylases are components of coactivator complexes recruited to promoter/enhancer regions by sequence-specific transcription factors during the activation of genes (Fig. 69-2). Histone deacetylases (HDACs; at least 17 encoded in the human genome) are recruited to genes by transcriptional repressors and prevent the initiation of gene transcription. Methylated cytosine residues in promoter

regions become associated with methyl-cytosine–binding proteins that recruit protein complexes with HDAC activity. The balance between permissive and inhibitory chromatin structure is therefore largely determined by the activity of transcription factors in modulating the "histone code" and the methylation status of the genetic regulatory elements of genes.

The pattern of gene transcription is aberrant in all human cancers, and in many cases, epigenetic events are responsible. Unlike genetic events that alter DNA primary structure (e.g., deletions), epigenetic changes are potentially reversible and appear amenable to therapeutic intervention. In many human cancers, including pancreatic cancer and multiple myeloma, the $p16^{Ink4a}$ promoter is inactivated by methylation, thus permitting the unchecked activity of CDK4/cyclin D and rendering pRB nonfunctional. In sporadic forms of renal, breast, and colon cancer, the von Hippel–Lindau (*VHL*), breast cancer 1 (*BRCA1*), and serine/threonine kinase 11 (*STK11*) genes, respectively, are epigenetically silenced. Other targeted genes include the $p15^{Ink4b}$ CDK inhibitor, glutathione-S-transferase (which detoxifies reactive oxygen species), and the E-cadherin molecule (important for junction formation between epithelial cells). Epigenetic silencing can occur in premalignant lesions and can affect genes involved in DNA repair, thus predisposing to further genetic damage. Examples include MLH1 (mut L homologue) in hereditary nonpolyposis colon cancer (HNPCC), which is critical for repair of mismatched bases that occur during DNA synthesis, and 0^6-methylguanine-DNA methyltransferase, which removes alkylated guanine adducts from DNA and is often silenced in colon, lung, and lymphoid tumors.

Many human leukemias have chromosomal translocations that code for novel fusion proteins with enzymatic activities that alter chromatin structure. The PML-RARα fusion protein, generated by the t(15;17) observed in most cases of acute promyelocytic leukemia (APL), binds to promoters containing retinoic acid response elements and recruits HDAC to these promoters, effectively inhibiting gene expression. This arrests differentiation at the promyelocyte stage and promotes tumor cell proliferation and survival. Treatment with pharmacologic doses of all-*trans* retinoic acid (ATRA), the ligand for RARα, results in the release of HDAC activity and the recruitment of coactivators, which overcomes the differentiation block. This induced differentiation of APL cells has greatly improved treatment of these patients and has provided a treatment paradigm for the reversal of epigenetic changes in cancer. However, for other leukemia-associated fusion proteins, such as AML-ETO and the MLL fusion proteins seen in AML and ALL, no ligand is known. Therefore, efforts are ongoing to determine the structural basis for interactions between translocation fusion proteins and chromatin remodeling proteins, and to use this information to rationally design small molecules that will disrupt specific protein-protein associations. Drugs that block the enzymatic activity of HDAC are being developed. A number of different chemical classes of HDAC inhibitors have demonstrated antitumor activity in phase I studies. The next generation of such agents may have specific activity against a subset of HDAC proteins, permitting selective activation of genes in different types of cancers.

Major therapeutic efforts are also under way to reverse the hypermethylation of CpG islands that characterizes many solid tumors. Drugs that induce DNA demethylation, such as 5-aza-2′-deoxycytidine, can lead to reexpression of silenced genes in cancer cells with restoration of function. However, 5-aza-2′-deoxycytidine has limited aqueous solubility and is myelosuppressive. Other inhibitors of DNA methyltransferases are in development. In ongoing clinical trials, inhibitors of DNA methylation are being combined with HDAC inhibitors. The hope is that by reversing coexisting epigenetic changes, the deregulated patterns of gene transcription in cancer cells will be at least partially reversed.

Aberrant signal transduction pathways activate a number of transcription factors that promote tumor cell proliferation and survival. These include signal transducer and activator of transcription (STAT)-3 and STAT5, NFκB, β-catenin (a component of the APC tumor-suppressor pathway), the heterodimer of c-Jun and Fos known as AP1, and c-Myc. The ability to target these transcription factors therapeutically does not currently exist. However, structural and molecular approaches may make it possible to identify small molecules that would inhibit protein-protein interactions needed for transcription factor dimerization or interaction with coactivator proteins. A small-molecule inhibitor has been developed that blocks the association of Myc with its partner Max, thereby inhibiting Myc-induced transformation. Many transcription factors are activated by phosphorylation, which can be prevented by tyrosine- or serine/threonine kinase inhibitors. The transcription factor NFκB is a heterodimer composed of p65 and p50 subunits that associate with an inhibitor, IκB, in the cell cytoplasm. In response to growth factor or cytokine signaling, a multi-subunit kinase called IKK (IκB-kinase) phosphorylates IκB and directs its degradation by the ubiquitin/proteasome system. NFκB, free of its inhibitor, translocates to the nucleus and activates target genes, many of which promote the survival of tumor cells. Novel drugs called *proteasome inhibitors* block the proteolysis of IκB, thereby preventing NFκB activation. For unexplained reasons, this is selectively toxic to tumor cells. Further studies have indicated that the antitumor effects of proteasome inhibitors are more complicated and involve the inhibition of the degradation of multiple cellular proteins. Proteasome inhibitors [bortezomib (Velcade)] have shown very significant activity in patients with multiple myeloma, including partial and complete remissions. Inhibitors of IKK are also in development, with the hope of more selectively blocking the degradation of IκB, thus "locking" NFκB in an inhibitory complex and rendering the cancer cell more susceptible to apoptosis-inducing agents.

Estrogen receptors (ERs) and androgen receptors, members of the steroid hormone family of nuclear receptors, are targets of inhibition by drugs used to treat breast and prostate cancers, respectively. Tamoxifen, a partial agonist and antagonist of ER function, can mediate tumor regression in metastatic breast cancer and can prevent disease recurrence in the adjuvant setting, saving thousands of lives each year. Tamoxifen binds to the ER and modulates its transcriptional activity, inhibiting activity in the breast but promoting activity in bone and uterine epithelium. Selective estrogen receptor modulators (SERMs) have been developed with the hope of a more beneficial modulation of ER activity, i.e., antiestrogenic activity in the breast, uterus, and ovary, but estrogenic for bone, brain, and cardiovascular tissues. Aromatase inhibitors, which block the conversion of androgens to estrogens in breast and subcutaneous fat tissues, have significant antitumor activity in postmenopausal breast cancer patients. However, deleterious effects may occur in other tissues due to estrogen deprivation, such as loss of bone density. The development of agents that modulate the activity of transcription factors in defined ways will yield important new agents for the treatment of cancer and other diseases.

APOPTOSIS

The homeostasis of adult organisms requires a balance between the death of aged, terminally differentiated cells and their renewal by proliferation of committed stem cell progenitors. Genetic damage to growth-regulating genes of stem cells could lead to catastrophic results for the host as a whole. However, genetic events such as activation of Myc expression or loss of the Rb checkpoint, which would be predicted to lead to unregulated cell proliferation, instead lead to the death of that cell. Metazoans have evolved a genetic program that induces the programmed death of cells that lose normal growth regulation; this process is referred to as *apoptosis*. Much as a panoply of intra- and extracellular signals impinge upon the core cell cycle machinery to regulate cell division, so too these signals regulate a core enzymatic machinery that regulates cell death and survival.

Programmed cell death is induced by two main pathways (Fig. 69-3). The extrinsic pathway of apoptosis is activated by cross-linking members of the tumor necrosis factor (TNF) receptor superfamily, such as CD95 (Fas) by its ligand (CD95L), or the binding to death receptors DR4 and DR5 by their ligand TRAIL (TNF-related apop-

tosis-inducing ligand). This induces the association of FADD (Fas-associated death domain) and procaspase-8 to death domain motifs of the receptors. Caspase-8 is activated by proximity-induced proteolysis and then cleaves and activates effector caspases-3 and -7, which then target cellular constituents (including DNA, cytoskeletal proteins, and a variety of regulatory proteins), inducing the morphologic appearance characteristic of apoptosis. The intrinsic pathway of apoptosis is initiated by the release of cytochrome c and SMAC (second mitochondrial activator of caspases) from the mitochondrial intermembrane space in response to a variety of noxious stimuli, including DNA damage, loss of adherence to the extracellular matrix (ECM), oncogene-induced proliferation, and growth factor deprivation. Upon release into the cytoplasm, cytochrome c associates with dATP, procaspase-9, and the adaptor protein APAF-1, leading to the sequential activation of caspase-9 and effector caspases. SMAC binds to and blocks the function of inhibitor of apoptosis proteins (IAPs), negative regulators of caspase activation. The release of apoptosis-inducing proteins from the mitochondria is regulated by pro- and antiapoptotic members of the Bcl-2 family. Antiapoptotic members (e.g., Bcl-2, Bcl-XL, and Mcl-1) associate with the mitochondrial outer membrane via their carboxy termini, exposing to the cytoplasm a hydrophobic binding pocket composed of Bcl-2 homology (BH) domains 1, 2, and 3 that is crucial for their activity. Perturbations of normal physiologic processes in specific cellular compartments lead to the activation of BH3-only proapoptotic family members (such as Bad, Bik, Bid, Puma, and others) that can induce pore formation in the mitochondrial outer membrane by altering the conformation of the outer-membrane proteins Bax and Bak. If BH3-only proteins are sequestered by Bcl-2, Bcl-XL, or Mcl-1, pores do not form and apoptosis-inducing proteins are not released from the mitochondrion. The relative levels of expression of antiapoptotic Bcl-2 family members compared to the levels of proapoptotic BH3-only proteins at the mitochondrial membrane determines the activation state of the intrinsic pathway. The mitochondrion must therefore be recognized not only as an organelle with vital roles in intermediary metabolism and oxidative phosphorylation but also as a central regulatory structure of the apoptotic process.

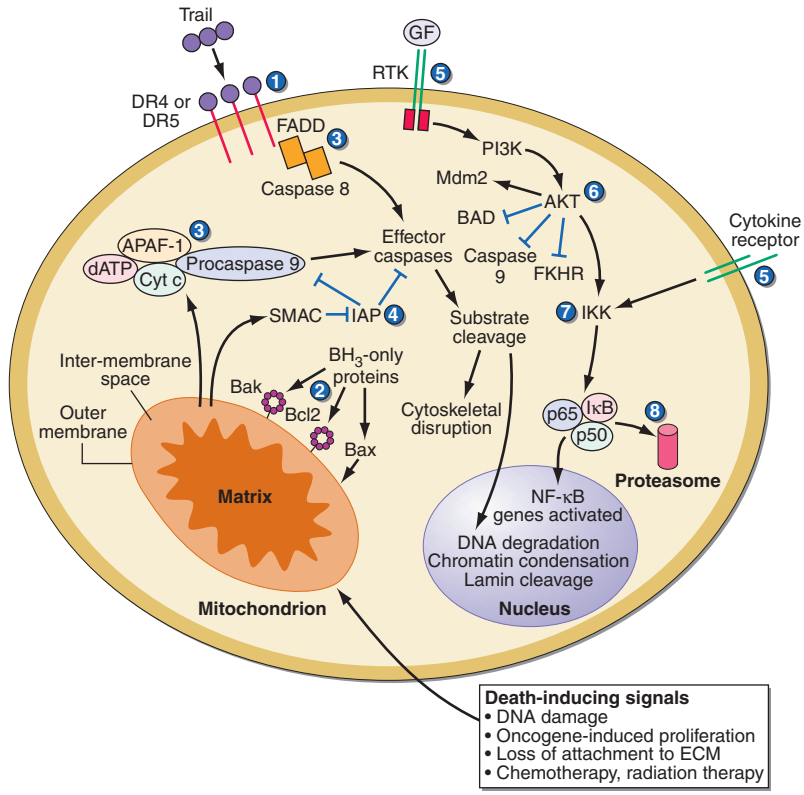

FIGURE 69-3 Therapeutic strategies to overcome aberrant survival pathways in cancer cells. 1. The extrinsic pathway of apoptosis can be selectively induced in cancer cells by TRAIL (the ligand for death receptors 4 and 5) or by agonistic monoclonal antibodies. 2. Inhibition of antiapoptotic Bcl-2 family members with antisense oligonucleotides or inhibitors of the BH3-binding pocket will promote formation of Bak- or Bax-induced pores in the mitochondrial outer membrane. 3. Epigenetic silencing of APAF-1, caspase-8, and other proteins can be overcome using demethylating agents and inhibitors of histone deacetylases. 4. Inhibitor of apoptosis proteins (IAP) block activation of caspases; small-molecule inhibitors of IAP function (mimicking SMAC action) should lower the threshold for apoptosis. 5. Signal transduction pathways originating with activation of receptor tyrosine kinase receptors (RTKs) or cytokine receptors promote survival of cancer cells by a number of mechanisms. Inhibiting receptor function with monoclonal antibodies, such as trastuzumab, or inhibition of receptor-associated tyrosine kinase activity can inhibit the pathway. 6. The Akt kinase phosphorylates many regulators of apoptosis to promote cell survival; inhibitors of Akt may render tumor cells more sensitive to apoptosis-inducing signals; however, the possibility of toxicity to normal cells may limit the therapeutic value of these agents. 7 and 8. Activation of the transcription factor NFκB (composed of p65 and p50 subunits) occurs when its inhibitor, IκB, is phosphorylated by IκB-kinase (IKK), with subsequent degradation of IκB by the proteasome. Inhibition of IKK activity should selectively block the activation of NFκB target genes, many of which promote cell survival. Inhibitors of proteasome function have entered clinical trials and may work in part by preventing destruction of IκB, thus blocking NFκB nuclear localization. NFκB is unlikely to be the only target for proteasome inhibitors.

The evolution of tumor cells to a more malignant phenotype requires the acquisition of a broad range of genetic changes that subvert apoptosis pathways and permit the cancer cells to survive. Resistance to apoptosis predisposes not only to the development of cancer but also to resistance to anticancer therapies, including radiation and chemotherapy. However, because of their deranged physiology, cancer cells may be more vulnerable than normal cells to therapeutic interventions that target apoptosis pathways. For instance, overexpression of Bcl-2 occurs in non-Hodgkin lymphoma; prostate, breast, and lung cancers; and melanoma. Genasense is phosphorothioate antisense oligonucleotide directed at the first six codons of the Bcl-2 open reading frame, which mediates the destruction of Bcl-2 mRNA and subsequent downmodulation of Bcl-2 protein levels. Genasense has demonstrated activity in phase I and phase II clinical trials. Targeting of antiapoptotic Bcl-2 family members has also been accomplished by the identification of several low-molecular-weight compounds that bind to the hydrophobic pockets of either Bcl-2 or Bcl-XL and block their ability to associate with death-inducing BH3-only proteins. These first-generation compounds inhibit the antiapoptotic activities of Bcl-2 and Bcl-XL at micromolar concentrations, and higher-affinity derivatives with better pharmacokinetic properties should soon enter clinical testing. Of note is that the chemotherapeutic drug, paclitaxel, binds to and stabilizes microtubules. This induces the phosphorylation and inactivation of Bcl-2, thus enhancing its activity against resistant tumor cells.

The IAP family member, survivin, is highly expressed in many human cancers but is undetectable in most adult tissues, suggesting that tumor-specific modalities can be found to inhibit its antiapoptotic functions. Small-molecule inhibitors are in development that will block the caspase-inhibitory functions of survivin and other IAP family members. Preclinical studies targeting death receptors DR4 and DR5 have demonstrated that recombinant, soluble, human TRAIL or humanized monoclonal antibodies with agonist activity against DR4 or DR5 can induce apoptosis of tumor cells while sparing normal cells. The mechanisms for this selectivity may include expression of decoy receptors or elevated levels of intracellular inhibitors (such as FLIP, which competes with caspase-8 for FADD) by normal cells but not tumor cells. Synergy has been shown between TRAIL-induced apoptosis and chemotherapeutic agents. For instance, some colon cancers encode mutated Bax protein as the result of mismatch repair (MMR) defects and are resistant to TRAIL. However, upregulation of Bak by chemotherapy restores the ability of TRAIL to activate the mitochondrial pathway of apoptosis (by death receptor–mediated cleavage of the BH3-only protein Bid, which activates Bak). Other protein-based

therapeutics, including the use of monoclonal antibodies trastuzumab (see previous sections) and rituximab (directed against CD20 on B cell malignancies), may owe efficacy in part to the inhibition of survival pathways leading to apoptosis.

Many of the signal transduction pathways perturbed in cancer promote tumor cell survival. These include activation of the PI3K/Akt pathway, increased levels of the NFκB transcription factor in many cancers, and epigenetic silencing of genes such as APAF-1 and caspase-8. Each of these pathways is a target for therapeutic agents that, in addition to affecting cancer cell proliferation or gene expression, can be expected to render cancer cells more susceptible to apoptosis, thus promoting synergy when combined with other chemotherapeutic agents.

Some tumor cells resist drug-induced apoptosis by expression of one or more members of the ABC family of ATP-dependent efflux pumps that mediate the multidrug resistance (MDR) phenotype. The prototype, P-glycoprotein (PGP), spans the plasma membrane 12 times and has two ATP-binding sites. Hydrophobic drugs (e.g., anthracyclines and vinca alkaloids) are recognized by PGP as they enter the cell and are pumped out. Numerous clinical studies have failed to demonstrate that drug resistance can be overcome using inhibitors of PGP. However, ABC transporters have different substrate specificities, and inhibition of a single family member may not be sufficient to overcome the MDR phenotype. A new generation of inhibitors is under development with higher affinities for transporters and better pharmacokinetic profiles.

OTHER THERAPEUTIC TARGETS

The geldanamycin derivative 17-AAG (17-allylaminogeldanamycin) has entered clinical trials as a selective inhibitor of heat-shock protein (Hsp)90. Hsp90 functions as a chaperone by binding to and promoting the proper folding of many cellular proteins including steroid hormone receptors, HER2/*neu*, Raf, Cdk4 and -6, Bcr-Abl, and mutant forms of p53. Inhibition of Hsp90 function results in the unfolding and subsequent degradation of its target proteins, leading to an inhibition of cell proliferation. Hsp90 inhibitors have activity against CML cells that are resistant to imatinib, perhaps by destabilizing mutant Bcr-Abl proteins. The growth of a wide range of human cancer cells was inhibited by 17AAG, often with rapid decrease in the levels of Raf and loss of MAP kinase signaling activity. Promising synergy was noted with a number of chemotherapeutic agents, including paclitaxel and doxorubicin. Inhibition of Hsp90 also blocks signaling via the androgen and estrogen receptors, thus making it an attractive therapeutic target in prostate and breast cancers. The fact that tumor cells express high levels of Hsp90 supports an important role in tumor cell survival. Phase I clinical trials of 17AAG did not demonstrate dramatic single-agent activity, but studies of 17AAG in combination with other chemotherapeutic agents are planned.

Cyclooxygenase 2 (COX-2) catalyzes the rate-limiting step in prostaglandin biosynthesis. Prostaglandins bind to G protein–coupled receptors and have pleiotropic biologic effects, promoting proliferation, enhanced survival, migration, and angiogenesis. Prostaglandins are pro-inflammatory and some can directly damage DNA. Tumor cell expression of COX-2 and the synthesis of prostaglandins such as PGE_2 are upregulated by cytokines and growth factors and by tumor-associated inflammatory cells. Chronic inflammation is etiologic in some cases of stomach cancers (*Helicobacter pylori*), colon cancer (ulcerative colitis), hepatic cancer (chronic hepatitis), and bladder cancer (schistosomiasis). COX-2 levels are upregulated in many premalignant lesions including oral leukoplakia, actinic keratosis, and carcinoma in situ of the bladder, breast, and prostate. Its overexpression in many cancers correlates with invasiveness and decreased survival. COX-2 upregulation in HER2/*neu*-expressing breast cancer is associated with induction of aromatase expression, leading to increased production of estrogen and enhanced tumor growth. In a number of animal models, COX-2 inhibitors prevented the development of tumors, including the Min mouse model of adenomatous polyposis. Clinical data indicate that patients taking cyclooxygenase inhibitors have decreased risk of cancer, especially colon cancers. Studies are in progress to define the cyclooxygenase products and their downstream targets that promote tumorigenesis in efforts to further enhance chemoprevention of human cancers.

METASTASIS: DETERMINING RISK AND DEVELOPING THERAPEUTIC STRATEGIES

The three major features of tissue invasion are cell adhesion to the basement membrane, local proteolysis of the membrane, and movement of the cell through the rent in the membrane and the ECM. Malignant cells that gain access to the circulation must then repeat those steps at a remote site and generate blood vessels to support local growth. There are currently few drugs that directly target the process of metastasis. Metalloproteinase inhibitors (see "Tumor Angiogenesis," below) represent an initial attempt to inhibit the migration of tumor cells into blood and lymphatic vessels. The rate-limiting step for metastasis is the ability for tumor cells to survive and expand in the novel microenvironment of the metastatic site, and multiple host-tumor interactions determine the ultimate outcome.

Analysis of gene expression patterns of primary tumors by microarray technology may predict the likelihood of metastasis. It remains unclear if the metastatic phenotype is a characteristic of most cells constituting the primary tumor, or if clonal variants with this capacity evolve during tumor progression. About eight metastasis-suppressor genes have been identified that normally suppress the growth of micrometastases in their new environment. The loss of function of these genes enhances metastasis, although the molecular mechanisms remain to be determined. It may soon be possible to predict which primary tumors are at greatest risk to metastasize and to block tumor spread using specific inhibitors of the metastatic process.

Bone metastases are extremely painful, cause fractures of weight-bearing bones, can lead to hypercalcemia, and are a major cause of morbidity for cancer patients. Osteoclasts and their bone marrow–derived precursors express the surface receptor RANK (receptor activator of NFκB), which is required for terminal differentiation and activation of osteoclasts. Osteoblasts and other stromal cells express RANK ligand, as both a membrane-bound and soluble ligand. Osteoprotegerin (OPG), a soluble receptor for RANK ligand produced by stromal cells, acts as a decoy receptor to inhibit RANK activation. The relative balance of RANK ligand and OPG determines the activation state of RANK on osteoclasts. Many tumors increase osteoclast activity by secretion of substances such as parathyroid hormone (PTH), PTH-related peptide, interleukin (IL) 1, or Mip1, that perturb the homeostatic balance of bone remodeling by increasing RANK signaling. One example is multiple myeloma, where tumor cell–stromal cell interactions activate osteoclasts and inhibit osteoblasts, leading to the development of multiple lytic lesions. Inhibition of RANK ligand by intravenous administration of recombinant OPG or the extracellular domain of RANK linked to an immunoglobulin Fc-receptor (RANK-Fc) can prevent further bone destruction. Bisphosphonates are also effective inhibitors of osteoclast function. Better understanding of signaling pathways downstream of RANK and the mechanisms that regulate the formation of blastic bone lesions should lead to novel therapies to prevent bone destruction, induce bone healing, and may even alter the bone microenvironment in ways that induce the death of metastatic tumor cells.

TUMOR ANGIOGENESIS

The growth of primary and metastatic tumors to larger than a few millimeters requires the recruitment of neighboring blood vessels and vascular endothelial cells to support their metabolic requirements. This is because the diffusion limit for oxygen in tissues is $\sim$100 μM. This is true of solid tumors and hematologic malignancies such as lymphomas, acute leukemia, and multiple myeloma, where increased numbers of blood vessels are observed in the pathologic bone marrow. A critical element in the growth of primary tumors and formation of metastatic

sites is the *angiogenic switch*: the ability of the tumor to promote the formation of new capillaries from preexisting host vessels. The angiogenic switch is a phase in tumor development when the dynamic balance of pro- and antiangiogenic factors is tipped in favor of vessel formation by the effects of the tumor on its immediate environment. Stimuli for tumor angiogenesis include hypoxia, inflammation, and genetic lesions in oncogenes or tumor suppressors that alter tumor cell gene expression. Angiogenesis consists of several steps, including the stimulation of endothelial cells (ECs) by growth factors, the degradation of the ECM by proteases, proliferation of ECs and migration into the tumor, and the eventual formation of new capillary tubes.

Tumor blood vessels are not normal; they have chaotic architecture and blood flow. Due to an imbalance of angiogenic regulators such as vascular endothelial growth factor (VEGF) and angiopoietins (see below), tumor vessels are tortuous and dilated with an uneven diameter, excessive branching, and shunting. Tumor blood flow is variable, with areas of hypoxia and acidosis leading to the selection of variants that are resistant to hypoxia-induced apoptosis (often due to the loss of p53 expression). Tumor vessel walls have numerous openings, widened interendothelial junctions, and discontinuous or absent basement membrane; this contributes to the high vascular permeability of these vessels and, together with lack of functional intratumoral lymphatics, causes interstitial hypertension within the tumor (which also interferes with the delivery of therapeutics to the tumor). Tumor blood vessels lack perivascular cells such as pericytes and smooth muscle cells that normally regulate vasoactive control in response to tissue metabolic needs.

Unlike normal blood vessels, the vascular lining of tumor vessels is not a homogenous layer of ECs but often consists of a mosaic of ECs and tumor cells; the concept of cancer cell–derived vascular channels, which may be lined by ECM secreted by the tumor cells, is referred to as *vascular mimickry*. It is unclear whether tumor cells actually form structural elements of vascular channels or represent tumor cells in transit into or out of the vessel. However, the former is supported by evidence that in some human colon cancers, tumor cells can comprise up to 15% of vessel walls. The ECs of angiogenic blood vessels are unlike quiescent ECs found in adult vessels, where only 0.01% of ECs are dividing. During tumor angiogenesis, ECs are highly proliferative and express a number of plasma membrane proteins that are characteristic of activated endothelium, including growth factor receptors and adhesion molecules such as integrins.

MECHANISMS OF TUMOR VESSEL FORMATION Tumors utilize a number of mechanisms to promote their vascularization, and in each case they subvert normal angiogenic processes to suit this purpose (Fig. 69-4). Primary or metastatic tumor cells sometimes arise in proximity to host blood vessels and grow around these vessels, parasitizing nutrients by coopting the local blood supply. However, most tumor blood vessels arise by the process of *sprouting*, in which tumors secrete trophic angiogenic molecules, the most potent being VEGF, that induce the proliferation and migration of host ECs into the tumor. Sprouting in normal and pathogenic angiogenesis is regulated by three families of transmembrane RTKs expressed on ECs and their ligands (VEGFs, angiopoietins, ephrins), which are produced by tumor cells, inflammatory cells, or stromal cells in the tumor microenvironment.

When tumor cells arise in or metastasize to an avascular area, they grow to a size limited by hypoxia and nutrient deprivation. Hypoxia, a key regulator of tumor angiogenesis, causes the transcriptional induction of the gene encoding VEGF by a process that involves stabilization of the transcription factor hypoxia-inducible factor (HIF)1. Under normoxic conditions, EC HIF-1 levels are maintained at a low level by proteasome-mediated destruction regulated by a ubiquitin E3-ligase encoded by the VHL tumor-suppressor locus. However, under hypoxic conditions, the HIF-1 protein is not hydroxylated and association with VHL does not occur; therefore HIF-1 levels increase, and target genes including VEGF, nitric oxide synthetase (NOS), and Ang2 are induced. Loss of the *VHL* genes, as occurs in familial and sporadic renal cell carcinomas, also results in HIF-1 stabilization and induction

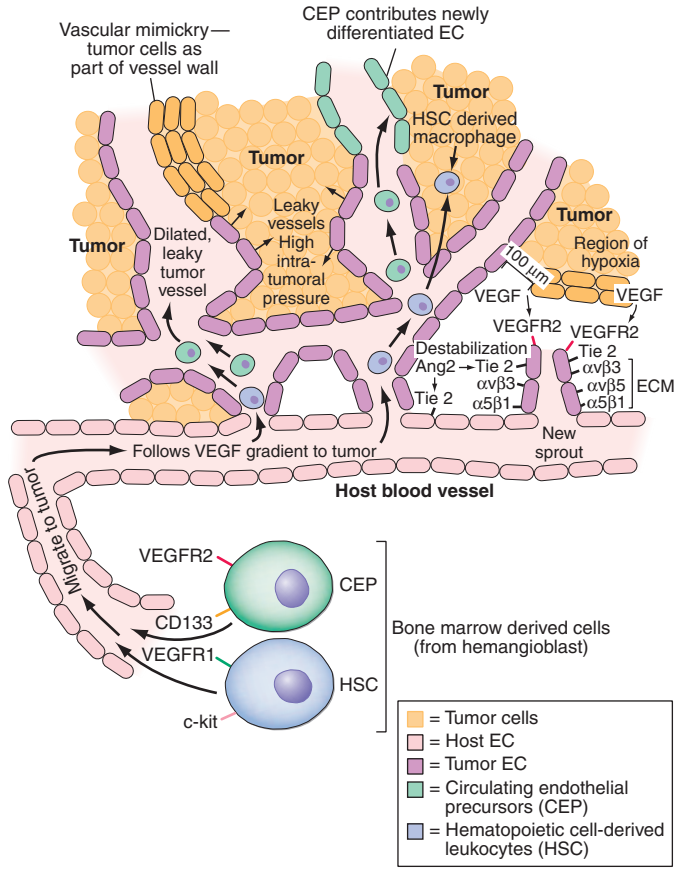

FIGURE 69-4 Tumor angiogenesis is a complex process involving many different cell types that must proliferate, migrate, invade, and differentiate in response to signals from the tumor microenvironment. Endothelial cells (ECs) sprout from host vessels in response to VEGF, bFGF, Ang2, and other proangiogenic stimuli. Sprouting is stimulated by VEGF/VEGFR2, Ang2/Tie-2, and integrin/extracellular matrix (ECM) interactions. Bone marrow–derived circulating endothelial precursors (CEPs) migrate to the tumor in response to VEGF and differentiate into ECs, while hematopoietic stem cells differentiate into leukocytes, including tumor-associated macrophages that secrete angiogenic growth factors and produce MMPs that remodel the ECM and release bound growth factors. Tumor cells themselves may directly form parts of vascular channels within tumors. The pattern of vessel formation is haphazard: vessels are tortuous, dilated, leaky, and branch in random ways. This leads to uneven blood flow within the tumor, with areas of acidosis and hypoxia (which stimulate release of angiogenic factors) and high intratumoral pressures that inhibit delivery of therapeutic agents.

of VEGF. Most tumors have hypoxic regions due to poor blood flow, and tumor cells in these areas stain positive for HIF-1 expression; in renal cancers with *VHL* deletion, all of the tumor cells express high levels of HIF-1, and VEGF-induced angiogenesis leads to high microvascular density (hence the term *hypernephroma*).

VEGF and its receptors are required for *vasculogenesis* (the de novo formation of blood vessels from differentiating endothelial cells, as occurs during embryonic development) and angiogenesis under normal (wound healing, corpus luteum formation) and pathologic processes (tumor angiogenesis, inflammatory conditions such as rheumatoid arthritis). VEGF-A is a heparin-binding glycoprotein with at least four isoforms (splice variants) that regulates blood vessel formation by binding to the RTKs VEGFR1 and VEGFR2, which are expressed on all ECs in addition to a subset of hematopoietic cells (Fig. 69-5). VEGFR2 regulates EC proliferation, migration, and survival, while VEGFR1 may act as an antagonist of R1 in ECs but is probably also important for angioblast differentiation during embryogenesis. Tumor vessels appear to be more dependent on VEGFR signaling for growth and survival than normal ECs. While VEGF signaling is a critical initiator of angiogenesis, this is a complex process regulated by additional signaling pathways. The angiopoietin, Ang1,

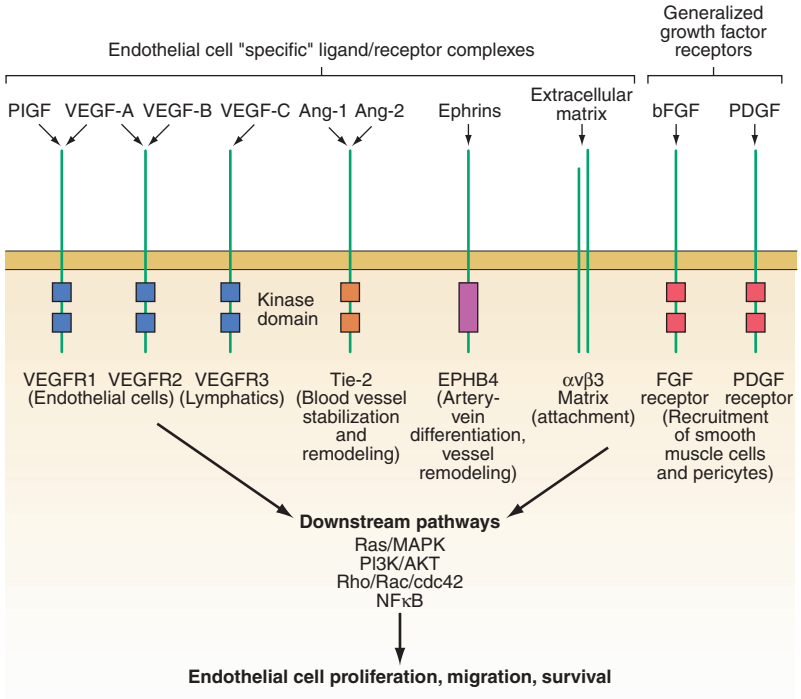

FIGURE 69-5 Critical molecular determinants of endothelial cell biology. Angiogenic endothelium expresses a number of receptors not found on resting endothelium. These include receptor tyrosine kinases (RTK) and integrins that bind to the extracellular matrix and mediate endothelial cells adhesion, migration, and invasion. Endothelial cells (ECs) also express RTK (i.e., the FGF and PDGF receptors) that are found on many other cell types. Critical functions mediated by activated RTK include proliferation, migration, and enhanced survival of endothelial cells, as well as regulation of the recruitment of perivascular cells and bloodborne circulating endothelial precursors and hematopoietic stem cells to the tumor. Intracellular signaling via EC-specific RTK utilizes molecular pathways that may be targets for future antiangiogenic therapies.

produced by stromal cells, binds to the EC RTK Tie-2 and promotes the interaction of ECs with the ECM and perivascular cells, such as pericytes and smooth muscle cells, to form tight, non-leaky vessels. PDGF and basic fibroblast growth factor (bFGF) help to recruit these perivascular cells. Ang1 is required for maintaining the quiescence and stability of mature blood vessels and prevents the vascular permeability normally induced by VEGF and inflammatory cytokines.

For tumor cell–derived VEGF to initiate sprouting from host vessels, the stability conferred by the Ang1/Tie2 pathway must be perturbed; this occurs by the secretion of Ang2 by ECs that are undergoing active remodeling. Ang2 binds to Tie2 and is a competitive inhibitor of Ang1 action: under the influence of Ang2, preexisting blood vessels become more responsive to remodeling signals, with less adherence of ECs to stroma and associated perivascular cells and more responsiveness to VEGF. Therefore, Ang2 is required at early stages of tumor angiogenesis for destabilizing the vasculature by making host ECs more sensitive to angiogenic signals. Since tumor ECs are blocked by Ang2, there is no stabilization by the Ang1/Tie2 interaction, and tumor blood vessels are leaky, hemorrhagic, and have poor association of ECs with underlying stroma. Sprouting tumor ECs express high levels of the transmembrane protein Ephrin-B2 and its receptor, the RTK EPH whose signaling appears to work with the angiopoietins during vessel remodeling. During embryogenesis, EPH receptors are expressed on the endothelium of primordial venous vessels while the transmembrane ligand ephrin-B2 is expressed by cells of primordial arteries; the reciprocal expression may regulate differentiation and patterning of the vasculature.

A number of ubiquitously expressed host molecules play critical roles in normal and pathologic angiogenesis. Proangiogenic cytokines, chemokines, and growth factors secreted by stromal cells or inflammatory cells make important contributions to neovascularization, including bFGF, transforming growth factor-α (TGF-α), TNF-α, and IL-8. In contrast to normal endothelium, angiogenic endothelium overexpresses specific members of the integrin family of ECM-binding proteins that mediate EC adhesion, migration, and survival. Specifically, expression of integrins $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$ mediate spreading and migration of ECs and are required for angiogenesis induced by VEGF and bFGF, which in turn can upregulate EC integrin expression. The $\alpha_v\beta_3$ integrin physically associates with VEGFR2 in the plasma membrane and promotes signal transduction from each receptor to promote EC proliferation (via focal adhesion kinase, src, PI3K, and other pathways) and survival (by inhibition of p53 and increasing the Bc12/Bax expression ratio). In addition, $\alpha_v\beta_3$ forms cell surface complexes with matrix metalloproteinases (MMPs), zinc-requiring proteases that cleave ECM proteins, leading to enhanced EC migration and the release of heparin-binding growth factors including VEGF and bFGF. EC adhesion molecules can be upregulated (i.e., by VEGF, TNF-α) or downregulated (by TGF-β); this, together with chaotic blood flow explains poor leukocyte-endothelial interactions in tumor blood vessels and may help tumor cells avoid immune surveillance.

In addition to sprouting, the architecture of the tumor vasculature is influenced by two other mechanisms. One process, called *intussuception*, occurs when tumor cells grow into a vessel, functionally dividing it into two branches. More recently, it was discovered that cells derived from hematopoietic progenitors in the host bone marrow contribute to tumor angiogenesis in a process linked to the secretion of VEGF, and PlGF (placenta-derived growth factor) by tumor cells and their surrounding stroma. VEGF promotes the mobilization and recruitment of circulating endothelial cell precursors (CEPs) and hematopoietic stem cells (HSCs) to tumors where they colocalize and appear to cooperate in neovessel formation. CEPs express VEGFR2, while HSCs express VEGFR1, a receptor, or VEGF and PlGF. Both CEPs and HSCs are derived from a common precursor, the hemangioblast. CEPs are thought to differentiate into ECs, whereas the role of HSC-derived cells (such as tumor-associated macrophages) may be to secrete angiogenic factors required for sprouting and stabilization of ECs (VEGF, bFGF, angiopoietins) and to activate MMPs, resulting in ECM remodeling and growth factor release. In mouse tumor models and in human cancers, increased numbers of CEPs and subsets of VEGFR1$^+$ or VEGFR-expressing HSCs can be detected in the circulation, which may correlate with increased levels of serum VEGF. It is not yet known whether levels of these cells have prognostic value or if changes during treatment correlate with inhibition of tumor angiogenesis. Whether CEPs and VEGFR1-expressing HSCs are required to maintain the long-term integrity of established tumor vessels is also unknown.

Lymphatic vessels also exist within tumors. Development of tumor lymphatics is associated with expression of VEGFR3 and its ligands VEGF-C and VEGF-D. The role of these vessels in tumor cell metastasis to regional lymph nodes remains to be determined, since, as discussed above, interstitial pressures within tumors are high and most lymphatic vessels may exit in a collapsed and nonfunctional state. However, VEGF-C levels in primary human tumors, including lung, prostate, and colorectal cancers, correlate significantly with metastasis to regional lymph nodes.

ANTIANGIOGENIC THERAPY Understanding the molecular mechanisms that regulate tumor angiogenesis may provide unique opportunities for cancer treatment. Acquired drug resistance of tumor cells due to their high intrinsic mutation rate is a major cause of treatment failure in human cancers. ECs comprising the tumor vasculature are genetically stable and do not share genetic changes with tumor cells; the EC apoptosis pathways are therefore intact. Each EC of a tumor vessel helps provide nourishment to many tumor cells, and although tumor angiogenesis can be driven by a number of exogenous proangiogenic stim-

uli, experimental data indicate that blockade of a single growth factor (e.g., VEGF) may inhibit tumor-induced vascular growth. Because tumor blood vessels are distinct from normal ones, they may be selectively destroyed without affecting normal vessels. Angiogenesis inhibitors function by targeting the critical molecular pathways involved in EC proliferation, migration, and/or survival, many of which are unique to the activated endothelium in tumors. Inhibition of growth factor and adhesion-dependent signaling pathways can induce EC apoptosis with concomitant inhibition of tumor growth. Different types of tumors use distinct molecular mechanisms to activate the angiogenic switch. Therefore, it is doubtful that a single antiangiogenic strategy will suffice for all human cancers; rather, a number of therapeutics will need to be developed, each responding to distinct programs of angiogenesis that have been developed by specific human cancers.

A number of strategies have been developed to selectively target tumor vasculature (Table 69-2, Fig. 69-6), and many novel antiangiogenic agents are currently in clinical trials. Inhibition of VEGF function blunts angiogenesis and tumor growth in a variety of tumor models by selectively inducing the apoptosis of immature ECs that are not associated with pericytes or smooth muscle cells, but spares normal host vessels. Humanized anti-VEGF monoclonal antibodies are active in colon cancer. A number of small, cell-permeable chemicals that inhibit the tyrosine kinase activity of VEGFR2 or VEGFR1 are being tested. The latter drugs may synergize in their antiangiogenic effects, since VEGFR2 inhibitors should block EC proliferation, migration, and survival, while VEGFR1 inhibitors are predicted to inhibit VEGF and PlGF-mediated recruitment of CEPs, HSCs, and inflammatory cells to the tumor bed. The relative efficacy of these agents may vary since some tumors may be dependent on VEGFR2-induced sprouting while others are more dependent on the bone marrow–derived EC precursors. Angiogenesis induced by bFGF can be blocked by inhibitors of the VEGF pathway, demonstrating a linkage between these pathways. Inhibitors of the Ang/Tie2 and Ephrin/EPH pathways are in development.

Blocking antibodies or antagonistic peptides to $\alpha_v\beta_3$ integrin, which interrupt the $\alpha_v\beta_3$- mediated adhesion to matrix proteins, leads to the inhibition of tumor and growth factor–induced angiogenesis in vivo by selectively inducing apoptosis of ECs in newly formed vessels. This indicates that ligation of the $\alpha_v\beta_3$ receptor is required for the survival of ECs of the angiogenic phenotype. Integrins are also required for EC migration and are important regulators of MMP activity, which modulates movement through and the release of growth factors from the ECM. Humanized monoclonal antibodies directed against $\alpha_v\beta_3$ are currently in clinical trial, as are small-molecule inhibitors of $\alpha_v\beta_3$, such as circular peptides containing the arg-gly-asp (RGD) integrin binding site. A number of clinical trials are testing the ability of MMP inhibitors to block tumor metastasis as well as angiogenesis. The discovery that ECs from various normal tissues encode unique surface markers suggests that tumors arising in different tissues may also express unique "vascular addressins," which could be targeted.

A number of endogenous, physiologic inhibitors of angiogenesis have been discovered. *Angiostatin* is a 38-kDa kringle domain–containing polypeptide fragment of plasminogen generated in the tumor microenvironment by proteases derived from tumor and stromal cells (including MMPs secreted by tumor-associated macrophages). Angiostatin inhibits in vivo tumor angiogenesis and induces tumor dormancy in murine models, and its antiangiogenic effects are mediated in part by induction of EC apoptosis. *Endostatin* is a C-terminal cleavage product of collagen XVIII generated by cathepsin or elastase-like proteolytic activities. It inhibits EC migration and promotes apoptosis by binding to $\alpha_v\beta_3$ and -β_5 integrins and downregulating expression of survival factors such as Bcl-2 and Bcl-XL. Antiangiogenic peptide domains of other normal host proteins have also been defined. Purified angiostatin and endostatin are highly specific inhibitors of activated ECs in vitro and in murine models and have entered clinical trials. Although tumor responses have been disappointingly rare, pharmacokinetic data indicate bolus administration of recombinant endostatin does not maintain sufficient serum concentrations of the inhibitor for antiangiogenic activity to occur.

A number of more general signaling pathways are also important for EC function and can be targeted. Trastuzumab, a monoclonal antibody that inhibits signaling from the ERB-B2 tyrosine kinase receptor expressed by some breast and ovarian cancers, decreases expression of VEGF and upregulates expression of thrombospondin-1 (an angiogenic inhibitor), by tumor cells. Inhibition of fibroblast growth

TABLE 69-2 *Antiangiogenic Treatments Currently in Clinical Trials: Molecular Pathways as Targets*

I. Receptor tyrosine kinase pathways	
A. Endothelial cell (EC) specific	
1. VEGFR1 kinase inhibitors	Decreased recruitment of CEPs, HSCs to tumor vessels
2. VEGFR2 kinase inhibitors	Inhibition of EC proliferation, migration, survival
3. Anti-VEGF monoclonal antibody	Inhibition of VEGF signaling to EC, CEPs, HSCs
B. Non-EC specific	
1. FGFR, PDGF kinase inhibitors	Inhibition of EC functions; decreased recruitment of perivascular cells
2. Anti-ERB-B2 monoclonal antibody	Inhibition of tumor VEGF production; increased thrombospondin-1
II. Integrin receptors/ extracellular matrix	
A. Integrin inhibitors	
1. RGD circular pentapeptides	Inhibition of integrin-mediated attachment to ECM with induction of EC apoptosis
2. Anti-$\alpha_v\beta_3$ monoclonal antibodies	Detachment of EC from matrix with induction of apoptosis
B. Matrix metalloproteinase inhibitors	Inhibition of EC and tumor invasion; decreased release of GF from matrix binding sites
III. Endogenous angiogenesis inhibitors	
A. Peptides derived from host proteins	
1. Angiostatin (plasminogen fragment)	Mechanisms of action unclear; may inhibit EC cell surface ATP synthase activity; binds to $\alpha_v\beta_3$ and other integrins
2. Endostatin (collagen XVIII fragment)	Mechanisms unclear; binds to EC integrins; may block GF binding to heparin sulfate; inhibits EC migration and induces apoptosis
B. Hormones	Inhibits EC microtubules
1. 2-methoxy-estradiol (2-ME)	
IV. Other agents	
A. Chemokines/cytokines	
1. IL-12	Induction of IFN-γ, IP-10, and MiG
2. IFN-α	Inhibition of bFGF production by tumor
B. Synthetic compounds	
1. TNP-490 (fumagillan analogue)	Inhibition of EC methionine aminopeptidase (required for EC proliferation)
2. Thalidomide	In vitro evidence for antiangiogenic activity; proven therapeutic activity in human multiple myeloma

Abbreviations: VEGFR, vascular endothelial growth factor receptor; CEP, circulating endothelial cell precursors; HSC, hematopoietic stem cells; FGFR, fibroblast growth factor receptor; PDGF, platelet-derived growth factor; RGD, arg-gly-asp; ECM, extracellular matrix; GF, growth factor; IL, interleukin; IFN, interferon; IP-10, interferon-inducible protein-10; MiG, monokine induced by IFN-γ; bFGF, basic fibroblast growth factor.

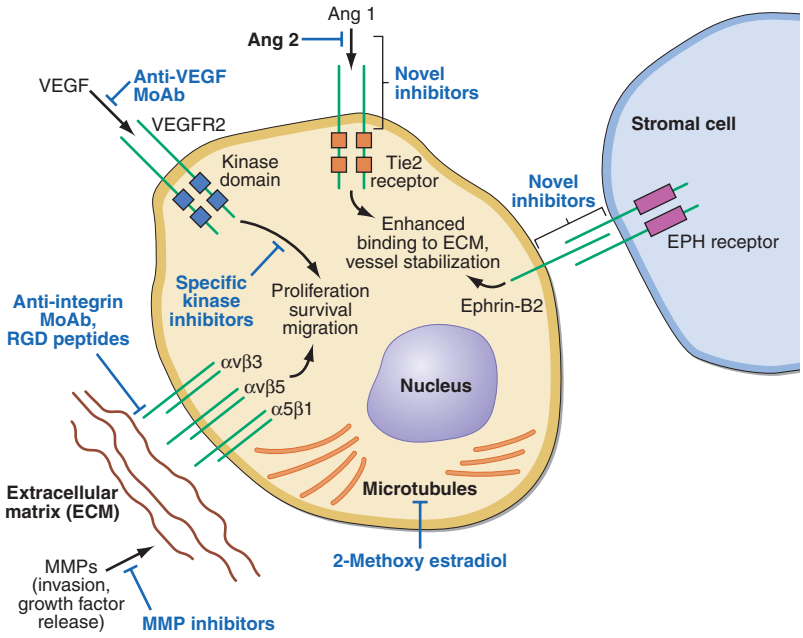

FIGURE 69-6 Knowledge of the molecular events governing tumor angiogenesis has led to a number of therapeutic strategies to block tumor blood vessel formation. Multiple inhibitors of the VEGF/VEGFR pathway are in clinical trial, and other endothelial cell–specific receptor tyrosine kinase pathways (e.g., angiopoietin/Tie2 and ephrin/EPH) are likely targets for the future. Inhibition of integrin binding to the ECM, and ECM breakdown by matrix-metalloproteinase inhibitors (MMPs), should lead to EC apoptosis and inhibition of EC migration and invasion. Other targets include intracellular signaling pathways, inhibition of cytoskeletal elements (i.e., by 2-methoxy estradiol, 2-ME), and compounds whose mechanisms of antiangiogenic activity are unknown, such as thalidomide and the endogenous inhibitors (endostatin, angiostatin).

factor (FGF) and PDGF receptor signaling by kinase inhibitors may block EC proliferation and recruitment of supporting stromal cells into the tumor milieu. Signal transduction pathways downstream of RTK and integrin signaling, such as the Ras/MAP kinase, PI3K/Akt, and Src family kinase pathways, are important antitumor therapeutic targets that are also important for angiogenesis. FTIs have been shown to block VEGF expression by tumor cells. EC survival requires the activity of the serine/threonine kinase Akt, and inhibitors of this kinase may have potent antiangiogenic activity. Src kinases integrate VEGF/integrin signaling associated with focal adhesion kinase (FAK) activation and dynamic remodeling of the cell cytoskeleton; Src inhibitors should block EC motility as well as survival. Arachidonic acid metabolism may be important for $\alpha_v\beta_3$-induced proliferation and migration of EC; COX-2 inhibitors may inhibit $\alpha_v\beta_3$-mediated EC activities. Giant cell tumors of bone and angioblastomas that occur in young children, and can be severely debilitating or life-threatening, appear to depend uniquely on bFGF as their main angiogenic factor. Low daily doses of interferon block tumor cell production of bFGF and after 1 to 2 years of treatment can mediate the complete eradication of these tumors.

The conceptual design of antiangiogenic clinical trials may require a paradigm shift from conventional chemotherapy. In tumor models, the combination of low daily doses of standard chemotherapy agents combined with antiangiogenic agents can synergize to induce apoptosis of the tumor vasculature, even when the tumor cells are resistant to high doses of the same agents. The initial response to successful antiangiogenic treatment is a decrease in vascular permeability and lower intratumoral pressure; this results in an initial increase in tumor blood flow that can transiently increase tumor growth (but could also provide increased delivery of chemotherapeutic drugs to the tumor). Clinicians will need to be prepared to weather this initial "tumor flare" without stopping antiangiogenic treatment. Inhibition of new vessel formation in human cancers may induce stable disease rather than tumor regression, and progression-free survival may be a more appropriate endpoint than a reduction of tumor volume. This implies a need for chronic, daily administration to prevent regrowth of blood vessels between doses, and will require orally administered drugs that can be tolerated for prolonged times. Surrogate markers will therefore be needed to evaluate the clinical effectiveness of antiangiogenic therapies. Circulating factors may not be useful, since tumors and their stroma produce a number of positive and negative regulators of angiogenesis. The circulating levels of CEPs might be a marker of response, but this remains speculative. The promise of the antiangiogenic approach to cancer treatment depends on tumor selectivity, which may not always be predictable. Phase I clinical trial testing of a VEGFR2 kinase inhibitor demonstrated no serious toxicity. Yet when it was combined with cisplatin and gemcitibine for the treatment of solid tumors, 8 of 19 patients experienced serious thrombotic events, including pulmonary embolism and stroke. Antiangiogenic agents may sensitize normal ECs to apoptosis induction by chemotherapeutic agents, with exposure of tissue factor in subendothelial vessel wall. This underscores the potential toxicity of targeting ECs in vivo.

70 PRINCIPLES OF CANCER TREATMENT: SURGERY, CHEMOTHERAPY, AND BIOLOGIC THERAPY

Edward A. Sausville, Dan L. Longo

The goal of cancer treatment is first to eradicate the cancer. If this primary goal cannot be accomplished, the goal of cancer treatment shifts to palliation, the amelioration of symptoms, and preservation of quality of life while striving to extend life. The dictum *primum non nocere* is not necessarily the guiding principle of cancer therapy. When cure of cancer is possible, cancer treatments may be undertaken despite the certainty of severe and perhaps life-threatening toxicities. Every cancer treatment has the potential to cause harm, and treatment may be given that produces toxicity with no benefit. The therapeutic index of many interventions is quite narrow, and most treatments are given to the point of toxicity. Conversely, when the clinical goal is palliation, careful attention to minimizing the toxicity of potentially toxic treat-

ments becomes a significant goal. Irrespective of the clinical scenario, the guiding principle of cancer treatment should be *primum succerrere*, "first hasten to help." Radical surgical procedures, large-field hyperfractionated radiation therapy, high-dose chemotherapy, and maximum tolerable doses of cytokines such as interleukin (IL) 2 are all used in certain settings where 100% of the patients will experience toxicity and side effects from the intervention, and only a fraction of the patients will experience benefit. One of the challenges of cancer treatment is to use the various treatment modalities alone and together in a fashion that maximizes the chances for patient benefit.

Cancer treatments are divided into four main types: surgery, radiation therapy (including photodynamic therapy), chemotherapy (including hormonal therapy and molecularly targeted therapy), and biologic therapy (including immunotherapy and gene therapy). The modalities are often used in combination, and agents in one category can act by several mechanisms. For example, cancer chemotherapy agents can induce differentiation, and antibodies (a form of immunotherapy) can be used to deliver radiation therapy. Surgery and radiation therapy are considered local treatments, though their effects can influence the behavior of tumor at remote sites. Chemotherapy and biologic therapy are usually systemic treatments. *Oncology*, the study of tumors including treatment approaches, is a multidisciplinary effort with surgical-, radiotherapy-, and internal medicine–related areas of expertise. Treatments for patients with hematologic malignancies are often shared by hematologists and medical oncologists. →***Principles of radiation therapy are discussed in Chap. 71.***

Cancer behaves in many ways as an organ that attempts to regulate its own growth. However, cancers have not set an appropriate limit on how much growth should be permitted. Normal organs and cancers share the property of having a population of cells in cycle and actively renewing and a population of cells not in cycle. In cancers, cells that are not dividing are heterogeneous; some have sustained too much genetic damage to replicate but have defects in their death pathways that permit their survival; some are starving for nutrients and oxygen; and some are reversibly out of cycle poised to be recruited back into cycle and expand if needed. Severely damaged and starving cells are unlikely to kill the patient. The problem is that the cells that are reversibly not in cycle are capable of replenishing tumor cells physically removed or damaged by radiation and chemotherapy.

Tumors follow a Gompertzian growth curve (Fig. 70-1); the growth fraction of a neoplasm starts at 100% with the first transformed cell and declines exponentially over time until by the time of diagnosis at a tumor burden of 1 to 5 × 10^9 tumor cells, the growth fraction is usually 1 to 4%. Thus, peak growth rate may actually occur before the tumor is detectable. A key aspect of a successful tumor is the ability to stimulate the development of a new supporting stroma through angiogenesis and production of proteases to allow invasion through basement membranes and normal tissue barriers (Chap. 69). Specific cellular mechanisms promote entry or withdrawal of tumor cells from the cell cycle. For example, when a tumor recurs after surgery or chemotherapy, frequently its growth is accelerated and the growth fraction of the tumor is increased. This pattern is similar to that seen in regenerating organs. Partial resection of the liver results in the recruitment of cells into the cell cycle, and the resected liver volume is replaced. Similarly, chemotherapy-damaged bone marrow increases its growth to replace cells killed by chemotherapy. However, cancers do not recognize a limit on their expansion. Monoclonal gammopathy of uncertain significance may be an example of a clonal neoplasm with intrinsic features that stop its growth before a lethal tumor burden is reached. A fraction of patients with this disorder go on to develop fatal multiple myeloma, but probably this occurs because of the accumulation of additional genetic lesions. Elucidation of the mechanisms that regulate this "organ-like" behavior of tumors may provide additional clues to cancer control and treatment.

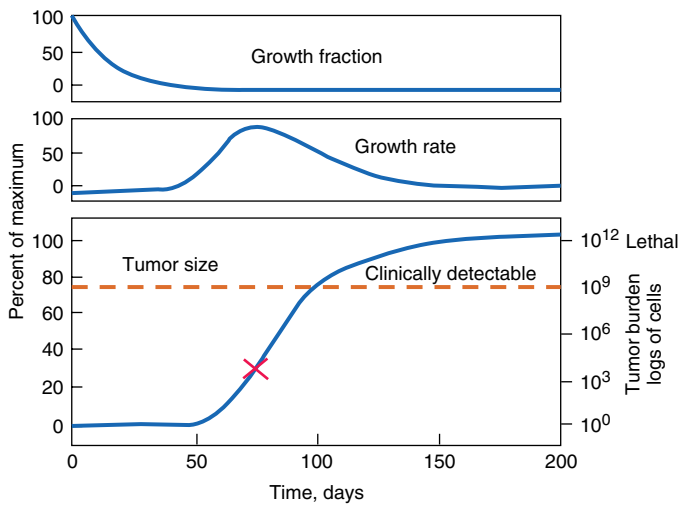

FIGURE 70-1 Gompertzian tumor growth. The growth fraction of a tumor declines exponentially over time (*top*). The growth rate of a tumor peaks before it is clinically detectable (*middle*). Tumor size increases slowly, goes through an exponential phase, and slows again as the tumor reaches the size at which limitation of nutrients or auto- or host regulatory influences can occur. The maximum growth rate occurs at 1/e, the point at which the tumor is about 37% of its maximum size (marked with an X). Tumor becomes detectable at a burden of about 10^9 (1 cm^3) and kills the patient at a tumor burden of about 10^{12} (1 kg). Efforts to treat the tumor and reduce its size can result in an increase in the growth fraction and an increase in growth rate.

PRINCIPLES OF CANCER SURGERY

Surgery is used in cancer prevention, diagnosis, staging, treatment (for both localized and metastatic disease), palliation, and rehabilitation.

PREVENTION Cancer can be prevented by surgery in people who have premalignant lesions resected (e.g., premalignant lesions of skin, colon, cervix) and in those who are at increased risk of cancer from either an underlying disease (colectomy in those with pancolonic involvement with ulcerative colitis), the presence of genetic lesions (colectomy for familial polyposis; thyroidectomy for multiple endocrine neoplasia type 2; bilateral mastectomy or oophorectomy for familial breast or ovarian cancer syndromes), or a developmental anomaly (orchiectomy in those with an undescended testis). In some cases, prophylactic surgery is more radical than the surgical procedures used to treat the cancer after it develops. The assessment of risk involves many factors and should be undertaken with care before advising a patient to undergo such a major procedure. For breast cancer prevention, many experts use a 20% risk of developing breast cancer over the next 5 years as a threshold. However, patient fears play a major role in defining candidates for cancer prevention surgery. Counseling and education may not be enough to allay the fears of someone who has lost close family members to a malignancy.

DIAGNOSIS The ideal diagnostic procedure varies with the type of cancer, its anatomical location, and the medical condition of the patient. However, the underlying principle is to obtain as much tissue as safely possible. Tumors may be heterogeneous in appearance. Pathologists are better able to make the diagnosis when they have more tissue to examine. In addition to light-microscopic inspection of a tumor for pattern of growth, degree of cellular atypia, invasiveness, and morphologic features that aid in the differential diagnosis, sufficient tissue is of value in searching for genetic abnormalities and protein expression patterns that may aid in differential diagnosis or to provide information about prognosis or likely response to treatment. Histologically similar tumors may have very different gene expression patterns when assessed by such techniques as microarray analysis using gene chips, with important differences in response to treatment. Such testing requires that the tissue be handled properly (e.g., immunologic detection of proteins is more effective in fresh-frozen tissue rather than in formalin-fixed tissue); thus, coordination among the surgeon, pathologist, and primary care physician is essential to ensure that the amount of information learned from the biopsy material is maximized.

These goals are best met by an *excisional biopsy* in which the entire tumor mass is removed with a small margin of normal tissue surrounding it. If an excisional biopsy cannot be performed, *incisional biopsy* is the procedure of second choice. A wedge of tissue is removed, and an effort is made to include the majority of the cross-sectional diameter of the tumor in the biopsy to minimize sampling error. When the diagnosis is being made through an endoscope or via fluoroscopy, it may be necessary to obtain a *core-needle biopsy* of the mass; considerably less tissue is obtained and the diagnosis may be less certain. However, this procedure often provides enough information to plan a definitive surgical procedure. Least reliable in diagnosis of primary cancer is *fine-needle aspiration*. This technique generally obtains only a suspension of cells from within a mass. This approach (with stereotactic guidance of the needle) is the procedure of choice in the diagnosis of brain tumors and may be useful in diagnosing thyroid nodules and in confirming persistent or recurrent disease in a patient with known cancer, but the procedure is overutilized in primary diagnosis. It would be preferable to perform a larger open operation to obtain more tissue in most sites. The biopsy techniques that involve cutting into tumor carry with them a risk of facilitating the spread of the tumor.

STAGING As noted in Chap. 66, an important component of patient management is defining the extent of disease. Radiographic and other imaging tests can be helpful in defining the clinical stage; however, pathologic staging requires defining the extent of involvement by documenting the histologic presence of tumor in tissue biopsies obtained through a surgical procedure. Axillary lymph node sampling in breast cancer and lymph node sampling at laparotomy for lymphomas and testicular, colon, and other intraabdominal cancers provide crucial information for treatment planning and may determine the extent and nature of primary cancer treatment.

TREATMENT Surgery is the most effective means of treating cancer. About 40% of cancer patients are cured today by surgery. Unfortunately, a large fraction of patients with solid tumors (perhaps 60%) have metastatic disease that is not accessible for removal. However, even when the disease is not curable by surgery alone, the removal of tumor can obtain important benefits, including local control of tumor, preservation of organ function, debulking that permits subsequent therapy to work better, and staging information on extent of involvement. Cancer surgery aiming for cure is usually planned to excise the tumor completely with an adequate margin of normal tissue (the margin varies with the tumor and the anatomy), touching the tumor as little as possible to prevent vascular and lymphatic spread, and minimizing operative risk. Extending the procedure to resect draining lymph nodes obtains prognostic information, but such resections alone generally do not improve survival.

Increasingly, laparoscopic approaches are being used to address primary abdominal and pelvic tumors. Lymph node spread may be assessed using the sentinel node approach, in which the first draining lymph node a spreading tumor would encounter is defined by injecting a dye at operation and then resecting the first node to turn blue. The sentinel node assessment is continuing to undergo clinical evaluation but appears to provide reliable information without the risks (lymphedema, lymphangiosarcoma) associated with resection of all the regional nodes. Advances in adjuvant chemotherapy and radiation therapy following surgery have permitted a substantial decrease in the extent of primary surgery necessary to obtain the best outcomes. Thus, lumpectomy with radiation therapy is as effective as modified radical mastectomy for breast cancer, and limb-sparing surgery followed by adjuvant radiation therapy and chemotherapy has replaced radical primary surgical procedures involving amputation and disarticulation for childhood rhabdomyosarcomas. More limited surgery is also being employed to spare organ function, as in larynx and bladder cancer. The magnitude of operations necessary to optimally control and cure cancer has also been diminished by technical advances; for example, the circular anastomotic stapler has allowed narrower (<2 cm) margins in colon cancer without compromise of local control rates, and many patients who would have had colostomies are able to maintain normal anatomy.

In some settings, e.g., bulky testicular cancer or stage III breast cancer, surgery is not the first treatment modality employed. After an initial diagnostic biopsy, chemotherapy and/or radiation therapy are delivered to reduce the size of the tumor and control clinically undetected metastatic disease, and such therapy is followed by a surgical procedure to remove residual masses. This is called *neoadjuvant therapy*. Because the sequence of treatment is critical to success and is different from the standard surgery-first approach, coordination among the surgical oncologist, radiation oncologist, and medical oncologist is crucial.

Surgery may be curative in a subset of patients with metastatic disease. Patients with lung metastases from osteosarcoma may be cured by resection of the lung lesions. In patients with colon cancer who have fewer than five liver metastases restricted to one lobe and no extrahepatic metastases, hepatic lobectomy may produce long-term disease-free survival in 25% of selected patients. Surgery can also be associated with systemic antitumor effects. In the setting of hormonally responsive tumors, oophorectomy and/or adrenalectomy may control estrogen production and orchiectomy may reduce androgen production, both with effects on metastatic tumor growth. If resection of the primary lesion takes place in the presence of metastases, the noted change in tumor behavior is most often acceleration of growth, perhaps based on the removal of a source of angiogenesis inhibitors and mass-related growth regulators in the tumor. However, on rare occasions (certain renal cancers), primary tumor resection is accompanied by regression of metastatic lesions. Similarly, splenectomy in some cases of lymphoma may be associated with regression of disease at remote sites. This phenomenon, called the *abscopal effect*, is attributed to the removal of a source of growth or angiogenic factors upon which the remote sites depend for growth.

PALLIATION Surgery is employed in a number of ways for supportive care: insertion of central venous catheters, diagnostic evaluation of pulmonary infiltrates, control of pleural and pericardial effusions and ascites, caval interruption for recurrent pulmonary emboli, stabilization of cancer-weakened weight-bearing bones, and control of hemorrhage, among others. Surgical bypass of gastrointestinal, urinary tract, or biliary tree obstruction can alleviate symptoms and prolong survival. Surgical procedures may provide relief of otherwise intractable pain or reverse neurologic dysfunction (cord decompression). Splenectomy may relieve symptoms and reverse hypersplenism. Intrathecal or intrahepatic therapy relies on surgical placement of appropriate infusion portals. Surgery may correct other treatment-related toxicities such as adhesions or strictures.

REHABILITATION Surgical procedures are also valuable in restoring a cancer patient to full health. Orthopedic procedures may be necessary to assure proper ambulation. Breast reconstruction can make an enormous impact on the patient's perception of successful therapy. Plastic and reconstructive surgery can correct the effects of disfiguring primary treatment.

PRINCIPLES OF CHEMOTHERAPY

Medical oncology is the subspecialty of internal medicine that cares for and designs treatment approaches to patients with cancer, in conjunction with surgical and radiation oncologists. The core skills of the medical oncologist include the use of drugs that may have a beneficial effect on the natural history of the patient's illness or favorably influence the patient's quality of life.

HISTORIC BACKGROUND The treatment of patients with cancer using chemicals, in the hope of causing regressions of established tumors or to slow the rate of tumor growth, arose by analogy to the proposition of Ehrlich that bacteria might be killed selectively by compounds with intrinsic affinity for bacteria, in effect acting as "magic bullets." Candidate compounds that might have selectivity for cancer cells were

suggested by the marrow-toxic effects of sulfur and nitrogen mustards, first noted in their use in chemical warfare. These observations led in the 1940s to the first clinical experiments where notable regressions of hematopoietic tumors followed use of these compounds by Gilman and colleagues. As these compounds caused covalent modification of DNA, the structure of DNA was thereby identified as a potential target for drug design efforts to produce antineoplastic agents. Biochemical studies demonstrating the requirement of growing tumor cells for precursors of nucleic acids led to nearly contemporaneous studies by Farber of folate analogues. The cure of patients with advanced choriocarcinoma by methotrexate in the 1950s provided further impetus to define the value of chemotherapeutic agents in many different tumor types. This resulted in efforts to understand unique metabolic requirements for biosynthesis of nucleic acids and led to the design, rational for the time, of compounds that might selectively inhibit DNA synthesis in proliferating cancer cells. The capacity of hormonal manipulations including oophorectomy and orchiectomy to cause regressions of breast and prostate cancers, respectively, provided a rationale for efforts to interdict various aspects of hormone function in hormone-dependent tumors. The serendipitous finding that certain poisons derived from bacteria or plants could affect normal DNA or mitotic spindle function allowed completion of the classic armamentarium of drugs with proven efficacy and a relative margin of safety in the treatment of certain cancers.

END POINTS OF DRUG ACTION Chemotherapy agents may be used for the treatment of active, clinically apparent cancer. Table 70-1,**A** lists those tumors considered curable by conventionally available chemotherapeutic agents when used to address disseminated or metastatic cancers. If a tumor is localized to a single site, serious consideration of surgery or primary radiation therapy should be given, as these treatment modalities may be curative as local treatments. Chemotherapy may be employed after the failure of these modalities to eradicate a local tumor or as part of multimodality approaches to offer primary treatment to a clinically localized tumor. In this event, it can allow organ preservation when given with radiation, as in larynx or other upper airway sites; or sensitize tumors to radiation when given, for example, to patients concurrently receiving radiation for lung or cervix cancer (Table 70-1,**B**). Chemotherapy can be administered as an adjuvant, i.e., in addition to surgery (Table 70-1,**C**) or radiation, after all clinically apparent disease has been removed. This use of chemotherapy may have curative potential in breast and colorectal neoplasms, as it attempts to eliminate clinically unapparent tumor that may have already disseminated. As noted above, small tumors frequently have high growth fractions and therefore may be intrinsically more susceptible to the action of antiproliferative agents. Chemotherapy is routinely used in "conventional" dose regimens. In general, these doses produce reversible acute side effects primarily consisting of transient myelosuppression with or without gastrointestinal toxicity (usually nausea), which are readily managed. High-dose chemotherapy regimens are predicated on the observation that the concentration-effect curve for many anticancer agents is rather steep, and increased dose can produce markedly increased therapeutic effect, although at the cost of potentially life-threatening complications that require intensive support, usually in the form of hematopoietic stem cell support from the patient (*autologous*) or from donors matched for histocompatibility loci (*allogeneic*). High-dose regimens nonetheless have definite curative potential in defined clinical settings (Table 70-1,**D**).

Karnofsky was among the first to champion the evaluation of a chemotherapeutic agent's benefit by carefully quantitating its effect on tumor size and using these measurements to decide objectively the basis for further treatment of a particular patient or further clinical evaluation of a drug's potential. A partial response (PR) is defined conventionally as a decrease by at least 50% in a tumor's bi-dimensional area; a complete response (CR) connotes disappearance of all tumor; progression of disease signifies an increase in size of existing lesions by >25% from baseline or best response or development of new lesions; and "stable" disease fits into none of the above categories. More recently proposed evaluation systems utilize unidimensional measurement, but the intent is similar in rigorously defining evidence for the activity of the agent in assessing its value to the patient.

If cure is not possible, chemotherapy may be undertaken with the goal of palliating some aspect of the tumor's effect on the host. Common tumors that may be meaningfully addressed with palliative intent are listed in Table 70-1,**E**. Usually tumor-related symptoms may manifest as pain, weight loss, or some local symptom related to the tumor's effect on normal structures. Patients treated with palliative intent should be aware of their diagnosis and the limitations of the proposed treatments, have access to supportive care, and have suitable "performance status," according to assessment algorithms such as the one developed by Karnofsky or by the Eastern Cooperative Oncology Group (ECOG). ECOG performance status 0 (PS0) patients are without symptoms; PS1 patients have mild symptoms not requiring treatment; PS2, symptoms requiring some treatment; PS3, disabling symptoms, but allowing ambulation for >50% of the day; PS4, ambulation <50% of the day. Only PS0 to PS2 patients are generally considered suitable for palliative (noncurative) treatment. If there is curative potential, even poor performance status patients may be treated, but their prognosis is usually inferior to that of good performance patients treated with similar regimens.

PATH FOR NEW CANCER DRUG DISCOVERY AND DEVELOPMENT The usefulness of any drug is governed by the extent to which a given dose causes a

TABLE 70-1 *Curability of Cancers with Chemotherapy*

A. Advanced cancers with possible cure
- Acute lymphoid and acute myeloid leukemia (pediatric/adult)
- Hodgkin's disease (pediatric/adult)
- Lymphomas—certain types (pediatric/adult)
- Germ cell neoplasms
  - Embryonal carcinoma
  - Teratocarcinoma
  - Seminoma or dysgerminoma
  - Choriocarcinoma
- Gestational trophoblastic neoplasia
- Pediatric neoplasms
  - Wilm's tumor
  - Embryonal rhabdomyosarcoma
  - Ewing's sarcoma
  - Peripheral neuroepithelioma
  - Neuroblastoma
- Small-cell lung carcinoma
- Ovarian carcinoma

B. Advanced cancers possibly cured by chemotherapy and radiation
- Squamous carcinoma (head and neck)
- Squamous carcinoma (anus)
- Breast carcinoma
- Carcinoma of the uterine cervix
- Non-small cell lung carcinoma (stage III)
- Small-cell lung carcinoma

C. Cancers possibly cured with chemotherapy as adjuvant to surgery
- Breast carcinoma
- Colorectal carcinoma[a]
- Osteogenic sarcoma
- Soft tissue sarcoma

D. Cancers possibly cured with "high-dose" chemotherapy with stem cell support
- Relapsed leukemias, lymphoid and myeloid
- Relapsed lymphomas, Hodgkin's and non-Hodgkin's
- Chronic myeloid leukemia
- Multiple myeloma

E. Cancers responsive with useful palliation, but not cure, by chemotherapy
- Bladder carcinoma
- Chronic myeloid leukemia
- Hairy cell leukemia
- Chronic lymphocytic leukemia
- Lymphoma—certain types
- Multiple myeloma
- Gastric carcinoma
- Cervix carcinoma
- Endometrial carcinoma
- Soft tissue sarcoma
- Head and neck cancer
- Adrenocortical carcinoma
- Islet-cell neoplasms
- Breast carcinoma
- Colorectal carcinoma

F. Tumor poorly responsive in advanced stages to chemotherapy
- Pancreatic carcinoma
- Biliary-tract neoplasms
- Renal carcinoma
- Thyroid carcinoma
- Carcinoma of the vulva
- Non-small cell lung carcinoma
- Prostate carcinoma
- Melanoma
- Hepatocellular carcinoma

[a] Rectum also receives radiation therapy.

useful result (therapeutic effect; in the case of anticancer agents, toxicity to tumor cells) as opposed to a toxic effect, reflecting injury to the host. The *therapeutic index* is the degree of separation between toxic and therapeutic doses. Really useful drugs have large therapeutic indices, and this usually occurs when the drug target is expressed in the disease-causing compartment as opposed to the normal compartment. Classically, selective toxicity of an agent for an organ is governed by the expression of an agent's target; or differential accumulation into or elimination from compartments where toxicity is experienced or ameliorated, respectively. Current "conventional cytotoxic" antineoplastic agents have the unfortunate property that their targets are present in both normal and tumor tissues. In the main they therefore have relatively narrow therapeutic indices.

Agents with promise for the treatment of cancer have in the past been detected empirically through screening for antiproliferative effects in animal or human tumors, usually in rodent hosts or through inhibition of tumor cells growing in tissue culture. An optimal schedule for demonstrating antitumor activity in animals is defined in further preclinical studies, as is the optimal drug formulation for a given route and schedule. Safety testing in two species on an analogous schedule of administration defines the starting dose for a phase I trial in humans. This is established as a fraction, usually one-sixth to one-tenth, of the dose just causing easily reversible toxicity in the more sensitive animal species. Escalating doses of the drug are then given during the human phase I trial until reversible toxicity is observed. Dose-limiting toxicity (DLT) defines a dose that conveys greater toxicity than would be acceptable in routine practice, allowing definition of a lower maximal tolerated dose (MTD). The occurrence of toxicity is correlated if possible with plasma drug concentrations. The MTD or a dose just lower than the MTD is usually the dose suitable for phase II trials, where a fixed dose is administered to a relatively homogeneous set of patients in an effort to define whether the drug causes regression of tumors. An "active" agent conventionally has PR rates of at least 20 to 25% with reversible non-life-threatening side effects, and it may then be suitable for study in phase III trials to assess efficacy in comparison to standard or no therapy. Response is but the most immediate indicator of drug effect. To be clinically valuable, responses must translate into clinical benefit. This is conventionally established by a beneficial effect on overall survival, or at least an increased time to further progression of disease. Active efforts are being made to quantitate effects of anticancer agents on quality of life. Cancer drug clinical trials conventionally use a toxicity grading scale where grade I toxicities do not require treatment; grade II often require symptomatic treatment but are not life-threatening; grade III toxicities are potentially life-threatening if untreated; grade IV toxicities are actually life-threatening; and grade V toxicities are those that result in the patient's death.

The process of cancer drug development is likely to evolve in significant ways in the near future as (1) the molecular analysis of human tumors defines more precisely the molecular targets that can be the focus of drug discovery efforts, and (2) clinical trials are undertaken only after means of assessing the behavior of the drug in relation to its target have been developed. The basis for optimism and anticipated change in clinical trials methodology extends from emerging understanding of the basis for cancer incidence and progression. Cancer arises from genetic lesions that cause an excess of cell growth or division, with inadequate cell death (Chap. 68). In addition, failure of cellular differentiation results in altered cellular position and capacity to proliferate while cut off from normal cell regulatory signals. An overall schema for understanding cancer progression can be seen in Fig. 70-2. Normally, cells in a differentiated state are stimulated to enter the cell cycle from a quiescent state, or G_0, or continue after completion of a prior cell division cycle in response to environmental cues including growth factor and hormonal signals. Cells progress through G_1 and enter S-phase after passing through "checkpoints," which are biochemically regulated transition points, to assure that the genome is "ready" for replication. The cyclin-dependent kinases

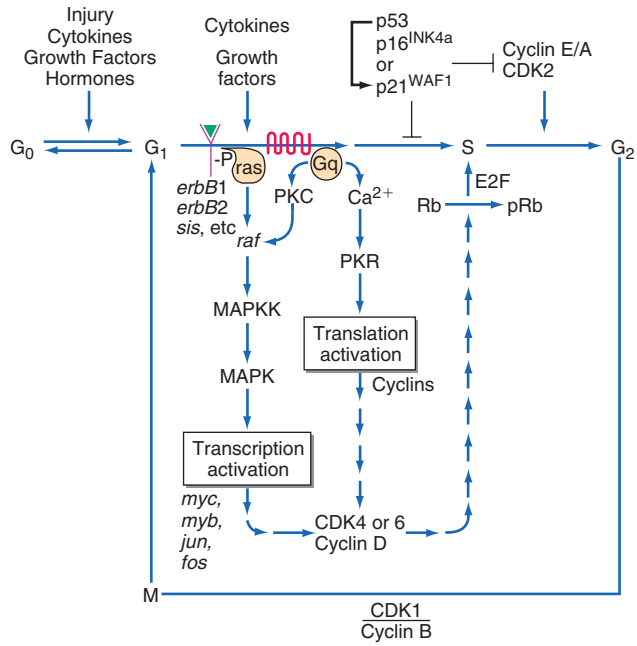

FIGURE 70-2 Basis for neoplastic growth and progression. Normally cells are stimulated to enter a proliferating state through the action of growth factors, positional signals, or cytokines. Cells enter G_1 under the influence of normal signaling pathways including tyrosine kinase receptors coupled to ras protooncogenes or seven-transmembrane receptors coupled through heterotrimeric guanine nucleotide binding (0) proteins, especially Gq linked to calcium- and lipid-mediated signaling pathways through protein kinase C (PKC). Cells activate transcription and translation of key regulatory molecules such as the cyclins, which activate cyclin-dependent kinases (CDKs) 4 or 6. Phosphorylation of the retinoblastoma susceptibility protein (pRb) causes release of E2F transcription factors to an active state, promoting the transcription of multiple genes allowing progression through S-phase, where DNA is replicated. Tumor cells possess activated oncogenes such as *erbB*1, *erbB*2, and *sis* or mutated *ras* gene products that are tonically activated, thus driving proliferation autonomously. *Raf* and the mitogen-activated kinases, MAPKK and MAPK, amplify the growth signal in a kinase cascade. "Brakes" to cell cycle progression include the p53-mediated G_1 to S-phase checkpoint, mediated by the CDK inhibitors $p16^{INK4a}$ and $p21^{WAF1}$. Progression through S-phase is also promoted by CDK2 acting in concert with cyclins E and A, and initiation of cell division is governed by the action of CDK1 acting in concert with cyclin B.

(CDKs) are enzymes that critically regulate cell cycle progression from one phase to the next. One important checkpoint is mediated by the p53 tumor-suppressor gene product, acting through its upregulation of the $p21^{WAF1}$ inhibitor of CDK function, acting on CDKs 4 or 6. These kinase molecules can also be inhibited by the $p16^{INK4A}$ and $p27^{KIP1}$ CDK inhibitors, but in turn are activated by cyclins of the D family (which appear during G_1) and the proper sequence of regulatory phosphorylations. Activated CDKs 4 or 6 phosphorylate, and thus inactivate, the product of the retinoblastoma susceptibility gene, *pRb*, which in its nonphosphorylated state complexes with transcription factors of the E2F family. Phosphorylated *pRb* releases E2Fs, which activate genes important in completing DNA replication during S-phase, progression through which is promoted by CDK2 acting in concert with cylins A and E. During G_2, another checkpoint occurs, in which the cell assures the completion of correct DNA synthesis. Cells then progress into M-phase under the influence of CDK1 and cyclin B. Cells may then go on to a subsequent division cycle or enter into a quiescent, differentiated state.

Also shown in Fig. 70-2 are the sites of action of protooncogenes, regulators of cellular proliferation that, in an active state, promote cell growth, and whose deregulation produces oncogenes, originally discovered as the genes encoded by tumor-forming viruses in animals. Oncogenes can be divided into two families: (1) those that act in the cytoplasm to disrupt normal growth factor–related signaling, including *ras*, *raf*, and the tyrosine kinases of the *src* and *erb*B or *sis* families; and (2) nuclear oncogenes, including *jun*, *fos*, *myc*, and *myb*, that act to alter transcriptional control of cassettes of genes. In contrast, tumor-suppressor genes, including *p53* and *pRb*, act as cellular "brakes"

whose normal function is to inhibit or prevent unregulated cellular growth. The capacity to divide indefinitely is provided by activation of telomerase, which allows continued replication of chromosomes by addressing the unique need of chromosome ends to be continually renewed to a proper length to allow normal mitosis. The capacity to invade and metastasize is conveyed by elaboration of matrix metalloproteases and plasminogen activators and the capacity to recruit host stromal cells at the site of invasion through tumor-induced angiogenesis.

Currently used drugs for the treatment of cancer focus principally on the proximate biochemistry of nucleic acid and mitotic spindle structure or function. Drugs of the future may seek to replace lost function of tumor-suppressor genes; counter the action of activated oncogenes; influence the capacity of cells to die; prevent normal chromosomal end replication; actually infect cells with viruses designed to replicate in the milieu of the cancer but not the normal cell; cause differentiation of cells with exit from the cell cycle by activating the appropriate genes; and use immunologic strategies, including antibodies and engineered cells to be directed at targets expressed on the surface of cancer cells.

BIOLOGIC BASIS FOR CANCER CHEMOTHERAPY The classic view of how cancer chemotherapeutic agents cause regressions of tumors focused on animal models such as the L1210 murine leukemia system, where cancer cells grow exponentially after inoculation into the peritoneal cavity of an isogenic mouse. The interaction of drug with its biochemical target in the cancer cell was proposed to result in "unbalanced growth" that was not sustainable and therefore resulted in cell death, directly as a result of interacting with the drug's proximal target. Agents could be categorized (Fig. 70-3) as cell cycle–active, phase-specific (e.g., antimetabolites, purines, and pyrimidines in S-phase; vinca alkaloids in M), and phase-nonspecific agents [e.g., alkylators, and antitumor antibiotics including the anthracyclines, dactinomycin (formerly actinomycin D), and mitomycin], which can injure DNA at any phase of the cell cycle but appear to then block in S-phase or G_2 at a checkpoint in the cell cycle before cell division. Cells arrested at a checkpoint may repair DNA lesions. Checkpoints have been defined at the G_1 to S transition, mediated by the tumor-suppressor gene *p53* (giving rise to the characterization of *p53* as a "guardian of the genome"); at the G_2 to M transition, mediated by the *chk1* kinase and additional p53-related pathways influencing the function of CDK1; and during M-phase, to ensure the integrity of the mitotic spindle. The importance of the concept of checkpoints extends from the hypothesis that repair of chemotherapy-mediated damage can occur while cells

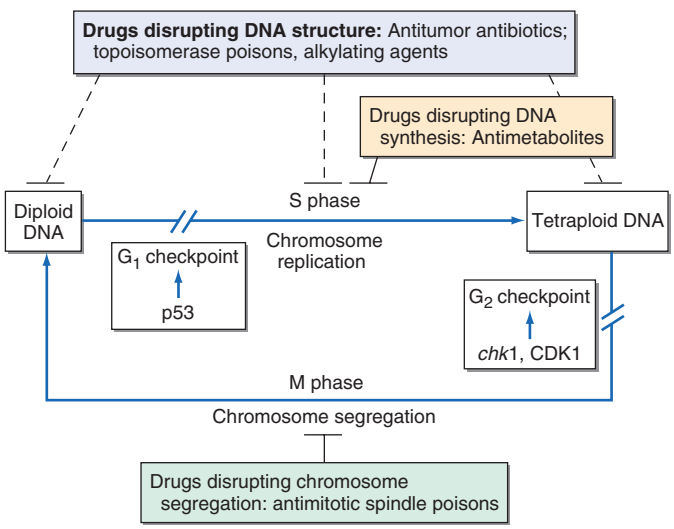

FIGURE 70-3 Location of drug action in the cell cycle. Cancer chemotherapy agents can be broadly described as phase-specific agents acting in S-(antimetabolites) and M-(spindle poisons) phase, respectively, and phase-nonspecific agents that injure their targets throughout the cycle but cause arrest of cell cycle progression at checkpoints. The G_1 checkpoint is mediated through p53 acting on CDKs 4,6, and 2, and the G_2 checkpoint is mediated in part by the *chk1* kinase acting on CDK1.

are stopped at a checkpoint; therefore, manipulation of checkpoint function emerges as an important basis of affecting resistance to chemotherapeutic agents.

Resistance to drugs was postulated to arise either from cells not being in the appropriate phase of the cell cycle or from decreased uptake, increased efflux, metabolism of the drug, or alteration of the target, e.g., by mutation or overexpression. Indeed, p170PGP (p170 P-glycoprotein; *mdr* gene product) was recognized from experiments with cells growing in tissue culture as mediating the efflux of chemotherapeutic agents in resistant cells. Certain neoplasms, particularly hematopoietic tumors, have an adverse prognosis if they express high levels of p170PGP, and modulation of this protein's function has been attempted by a variety of strategies.

Combinations of agents were proposed to afford the opportunity to affect many different targets or portions of the cell cycle at once, particularly if the toxic effects for the host of the different components of the combination were distinct. Combinations of agents were actually more effective in animal model systems than single agents, particularly if the tumor cell inoculum was high. This thinking led to the design of "combination chemotherapy" regimens, where drugs acting by different mechanisms (e.g., an alkylating agent plus an antimetabolite plus a mitotic spindle blocker) were combined. Particular combinations were chosen to emphasize drugs whose individual toxicities to the host were, if possible, distinct.

This view of cancer drug action is grossly oversimplified. Most tumors do not grow in an exponential pattern but rather follow Gompertzian kinetics, where the rate of tumor growth decreases as tumor mass increases (Fig. 70-1). Thus, a tumor has quiescent, differentiated compartments; proliferating compartments; and both well-vascularized and necrotic regions. Also, cell death is itself a closely regulated process. *Necrosis* refers to cell death induced, for example, by physical damage with the hallmarks of cell swelling and membrane disruption. *Apoptosis*, or programmed cell death, refers to a highly ordered process whereby cells respond to defined stimuli by dying, and it recapitulates the necessary cell death observed during the ontogeny of the organism. *Anoikis* refers to death of epithelial cells after removal from the normal milieu of substrate, particularly from cell-to-cell contact. Cancer chemotherapeutic agents can cause both necrosis and apoptosis. Apoptosis is characterized by chromatin condensation (giving rise to "apoptotic bodies"); cell shrinkage; and, in living animals, phagocytosis by surrounding stromal cells without evidence of inflammation. This process is regulated either by signal transduction systems that promote a cell's demise after a certain level of insult is achieved, or in response to specific cell-surface receptors that mediate cell death signals. Modulation of apoptosis by manipulation of signal transduction pathways has emerged as a basis for understanding the actions of currently used drugs and designing new strategies to improve their use.

The current view envisions that the interaction of a chemotherapeutic drug with its target, e.g., of an alkylating agent with DNA, causes or is itself a signal that initiates a "cascade" of further signaling steps to trigger an "execution phase" where proteases, nucleases, and endogenous regulators of the cell death pathway are activated. Effective cancer chemotherapeutic agents are efficient activators of apoptosis through signal transduction pathways (Fig. 70-4). For example, in the cytokine-mediated pathway, exogenous ligands such as the Fas ligand (FasL) bind to cell-surface receptors (CD95; Fas), or tumor necrosis factor (TNF) or its homologue Apo2L binds to its cognate receptors and directly recruits accessory molecules to activate a protease cascade (utilizing members of the caspase family of *c*ysteine *asp*artyl prote*ases*), resulting in apoptosis. In a second pathway, growth factor deprivation elicits poorly defined signals that result in protease activation. Chemotherapeutic agents create molecular lesions (in DNA or cellular membranes) as a consequence of combining with their respective molecular targets. These lesions are sensed by a cellular "damage sensor," whose molecular nature is unclear, which leads to mitochondrial damage. Release of mitochondrial factors (e.g.,

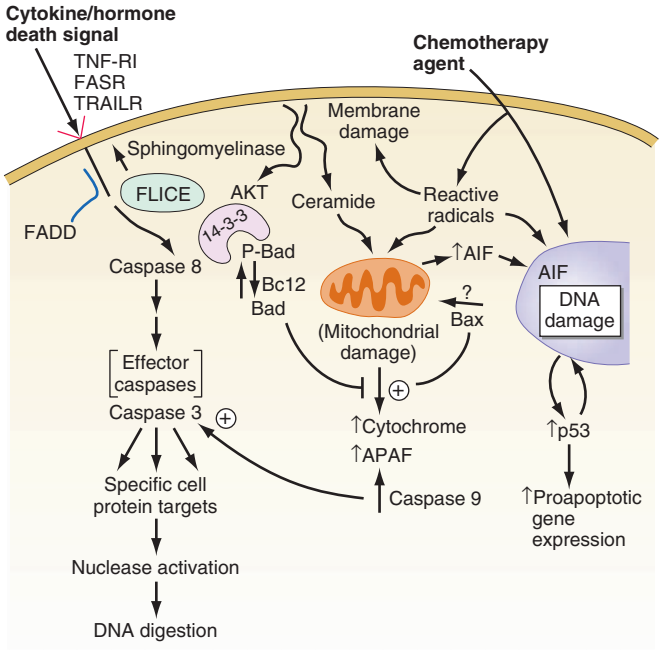

FIGURE 70-4 Integration of cell death responses. Cell death through an apoptotic mechanism requires active participation of the cell. In response to hormonal or cytokine death signals, receptors activate "upstream" cysteine aspartyl proteases (caspases), which then directly digest cytoplasmic and nuclear proteins, resulting in activation of "downstream" caspases; these cause activation of nucleases resulting in the characteristic DNA fragmentation that is a hallmark of apoptosis. Chemotherapy agents that create lesions in DNA seem to activate aspects of this process through a pathway that appears to result in damage to mitochondria, perhaps by activating the transcription of genes whose products can produce or modulate the toxicity of free radicals. In addition, membrane damage with activation of sphingomyelinases results in the production of ceramides that can have a direct action at mitochondria. The antiapoptotic protein bcl2 attenuates mitochondrial toxicity, while proapoptotic gene products such as bax antagonize the action of bcl2. Damaged mitochondria release cytochrome C and "apoptosis activating factor," which can directly activate caspase 9, resulting in propagation of a direct signal to other downstream caspases through protease activation. Apoptosis-inducing factor (AIF) is also released from the mitochondrion and then can translocate to the nucleus, bind to DNA, and generate free radicals to further damage DNA. An additional proapoptotic stimulus is the bad protein, which can heterodimerize with *bcl2* gene family members to antagonize apoptosis. Importantly, though, bad protein function can be retarded by its sequestration as phospho-bad through the 14-3-3 adapter proteins. The phosphorylation of bad is mediated by the action of the AKT kinase in a way that defines how growth factors that activate this kinase can retard apoptosis and promote cell survival.

APAF1, cytochrome c) promotes the activation of another set of caspases. Apoptosis-inducing factor (AIF) is another mitochondrial factor that upon release can translocate to the nucleus and promote DNA damage in its own right, without necessarily activating caspases. Damage to the plasma membrane, e.g., from free radicals generated by certain chemotherapeutic agents, leads to activation of acid sphingomyelinase to release lipid components including ceramides, which then promote apoptosis through a variety of pathways including direct mitochondrial damage.

While apoptotic mechanisms are important in regulating cellular proliferation and the behavior of tumor cells in vitro, in vivo it is unclear whether all of the actions of chemotherapeutic agents to cause cell death can be attributed to apoptotic mechanisms. Loss of clonogenic survival (conventionally detecting the capacity of a few cells to survive) may predict clinical value more reliably than detection of apoptotic changes in the majority of tumor cells. However, changes in molecules that regulate apoptosis are clearly correlated with clinical outcomes (e.g., bcl_2 overexpression in certain lymphomas conveys poor prognosis; proapoptotic bax expression is associated with a better outcome in ovarian carcinoma). A better understanding of the relationship of cell death and cell survival mechanisms is needed.

CHEMOTHERAPEUTIC AGENTS USED FOR CANCER TREATMENT Table 70-2 lists commonly used cancer chemotherapy agents and pertinent clinical aspects of their use. The drugs and schedules listed are examples of regimens that have proved tolerable and useful; the specific doses that may be used in a particular patient may vary somewhat with the particular treatment protocol, or plan, of treatment. Significant variation from these dose ranges should be carefully verified to avoid or anticipate toxicity. Not included in Table 70-2 are hormone receptor–directed agents, as the side effects are generally those expected from the interruption or augmentation of hormonal effect, and doses used in most cases are those that adequately saturate the intended hormone receptor. The drugs listed may be usefully grouped into three general categories: those affecting DNA, those affecting microtubules, and molecularly targeted agents.

Direct DNA-Interactive Agents ■ *FORMATION OF COVALENT DNA ADDUCTS* Alkylating agents as a class break down, either spontaneously or after normal organ or tumor cell metabolism, to reactive intermediates that covalently modify bases in DNA. This leads to cross-linkage of DNA strands or the appearance of breaks in DNA as a result of repair efforts. "Broken" or cross-linked DNA is intrinsically unable to complete normal replication or cell division; in addition, it is a potent activator of cell cycle checkpoints and signaling pathways that can activate apoptosis. As a class, alkylating agents share similar toxicities: myelosuppression, alopecia, gonadal dysfunction, mucositis, and pulmonary fibrosis. They differ greatly in a spectrum of normal organ toxicities. As a class they share the capacity to cause "second" neoplasms, particularly leukemia, many years after use, particularly when used in low doses for protracted periods.

Nitrogen mustard (mechlorethamine) is the prototypic agent of this class, decomposing rapidly in aqueous solution to yield potentially a bifunctional carbonium ion. It must be administered shortly after preparation into a rapidly flowing intravenous line. It is a powerful vesicant, and infiltration may be symptomatically ameliorated by infiltration of the affected site with 1/6 *M* thiosulfate. Even without infiltration, aseptic thrombophlebitis is frequent. It can be used topically as a dilute solution in cutaneous lymphomas, with a notable incidence of hypersensitivity reactions. It causes moderate nausea after intravenous administration.

Cyclophosphamide is inactive unless metabolized by the liver to 4-hydroxy-cyclophosphamide, which decomposes into alkylating species, as well as to chloroacetaldehyde and acrolein. The latter causes chemical cystitis; therefore excellent hydration must be maintained while using cyclophosphamide. If severe, the cystitis may be effectively treated by mesna (2-mercaptoethanesulfonate). Liver disease impairs drug activation. Sporadic interstitial pneumonitis leading to pulmonary fibrosis can accompany the use of cyclophosphamide, and high doses used in conditioning regimens for bone marrow transplant can cause cardiac dysfunction. Ifosfamide is a cyclophosphamide analogue also activated in the liver, but more slowly, and it requires coadministration of mesna to prevent bladder injury. Central nervous system (CNS) effects, including somnolence, confusion, and psychosis, can follow ifosfamide use; the incidence appears related to low body surface area or the presence of nephrectomy.

Several alkylating agents are less commonly used. Chlorambucil causes predictable myelosuppression, azoospermia, nausea, and pulmonary side effects. Busulfan can cause profound myelosuppression, alopecia, and pulmonary toxicity but is relatively "lymphocyte sparing." Its routine use in treatment of chronic myeloid leukemia (CML) has been curtailed in favor of imatinib (Gleevec), hydroxyurea, and interferon (IFN), but it still is employed in transplant preparation regimens. Melphalan shows variable oral bioavailability and undergoes extensive binding to albumin and α_1-acidic glycoprotein. Mucositis appears more prominently.

Nitrosoureas break down to carbamoylating species that not only cause a distinct pattern of DNA base pair–directed toxicity but also can covalently modify proteins. They share the feature of causing relatively delayed bone marrow toxicity, which can be cumulative and

TABLE 70-2 *Commonly Used Cancer Chemotherapy Agents*

Drug	Examples of Usual Doses	Toxicity	Interactions, Issues
DIRECT DNA-INTERACTING AGENTS			
Alkylators			
Cyclophosphamide	400–2000 mg/m^2 IV 100 mg/m^2 PO qd	Marrow (relative platelet sparing) Cystitis Common alkylator[a] Cardiac (high dose)	Liver metabolism required to activate to phosphoramide mustard + acrolein Mesna protects against "high-dose" bladder damage
Mechlorethamine	6 mg/m^2 IV day 1 and day 8	Marrow Vesicant Nausea	Topical use in cutaneous lymphoma
Chlorambucil	1–3 mg/m^2 qd PO	Marrow Common alkylator[a]	
Melphalan	8 mg/m^2 qd × 5, PO	Marrow (delayed nadir) GI (high dose)	Decreased renal function delays clearance
Carmustine (BCNU)	200 mg/m^2 IV 150 mg/m^2 PO	Marrow (delayed nadir) GI, liver (high dose) Renal	
Lomustine (CCNU)	100–300 mg/m^2 PO	Marrow (delayed nadir)	
Ifosfamide	1.2 g/m^2 per day qd × 5 + mesna	Myelosuppressive Bladder Neurologic Metabolic acidosis Neuropathy	Isomeric analogue of cyclophosphamide More lipid soluble Greater activity vs testicular neoplasms and sarcomas Must use mesna
Procarbazine	100 mg/m^2 per day qd ×14	Marrow Nausea Neurologic Common alkylator[a]	Liver and tissue metabolism required Disulfiran-like effect with ethanol Acts as MAOI HBP after tyrosinase-rich foods
Dacarbazine (DTIC)	375 mg/m^2 IV day 1 & day 15	Marrow Nausea Flulike	Metabolic activation
Temozolomide	150–200 mg/m^2 qd × 5 q28d *or* 75 mg/m^2 qd × 6–7 weeks	Nausea/vomiting Headache/fatigue Constipation	Infrequent myelosuppression
Altretamine (formerly hexamethylmelamine)	260 mg/m^2 per day qd ×14–21 as 4 divided oral doses	Nausea Neurologic (mood swing) Neuropathy Marrow (less)	Liver activation Barbiturates enchance/cimetidine diminishes
Cisplatin	20 mg/m^2 qd ×5 IV 1 q3–4 weeks *or* 100–200 mg/m^2 per dose IV q3–4 weeks	Nausea Neuropathy Auditory Marrow platelets > WBCs Renal Mg^{2+}, Ca^{2+}	Maintain high urine flow; osmotic diuresis, monitor intake/output K^+, Mg^{2+} Emetogenic—prophylaxis needed Full dose if CrCl > 60 mL/min and tolerate fluid push
Carboplatin	365 mg/m^2 IV q3–4 weeks as adjusted for CrCl	Marrow platelets > WBCs Nausea Renal (high dose)	Reduce dose according to CrCl: to AUC of 5–7 mg/mL per min [AUC = dose/(CrCl + 25)]
Oxaliplatin	130 mg/m^2 q3 weeks over 2 h *or* 85 mg/m^2 q2 weeks	Nausea Anemia	Acute reversible neurotoxicity; chronic sensory neurotox cumulative with dose; reversible laryngopharyngeal spasm
Antitumor antibiotics			
Bleomycin	15–25 mg/d qd ×5 IV bolus or continuous IV	Pulmonary Skin effects Raynaud's Hypersensitivity	Inactivate by bleomycin hydrolase (decreased in lung/skin) O_2 enhances pulmonary toxicity Cisplatin-induced decrease in CrCl may increase skin/lung toxicity Reduce dose if CrCl < 60 mL/min
Actinomycin D	10–15 μg/kg per day qd ×5 IV bolus	Marrow Nausea Mucositis Vesicant Alopecia	Radiation recall

(continued)

TABLE 70-2 *Commonly Used Cancer Chemotherapy Agents—(Continued)*

Drug	Examples of Usual Doses	Toxicity	Interactions, Issues
Mithramycin	15–20 μg/kg qd ×4–7 (hypercalcemia) *or* 50 μg/kg qod ×3–8 (antineoplastic)	Marrow Liver Renal Mucositis Hypocalcemia Nausea Vesicant	Acute hemorrhagic syndrome
Mitomycin C	6–10 mg/m² q6 weeks	Marrow Vesicant Hemolytic-uremic syndrome Lung CV—heart failure	Treat superficial bladder cancers by intravesical infusion Delayed marrow toxicity Cumulative marrow toxicity
Etoposide (VP16-213)	100–150 mg/m² IV qd ×3–5d *or* 50 mg/m² PO qd ×21d *or* up to 1500 mg/m² per dose (high dose with stem cell support)	Marrow (WBCs > platelet) Alopecia Hypotension Hypersensitivity (rapid IV) Nausea Mucositis (high dose)	Hepatic metabolism—renal 30% Reduce doses with renal failure Schedule-dependant (5 day better than 1 day) Late leukemogenic Accentuate antimetabolite action
Teniposide (VM-26)	150–200 mg/m² twice per week for 4 weeks	Marrow Alopecia	
Amsacrine	100–150 mg/m² IV qd ×5	Marrow Mucositis Nausea CV—arrhythmia (avoid hypokalemia)	Decrease dose by 30% if liver or renal failure
Topotecan	20 mg/m² IV q3–4 weeks over 30 min *or* 1.5–3 mg/m² q3–4 weeks over 24 h *or* 0.5 mg/m² per day over 21 days	Marrow Mucositis Nausea Mild alopecia	Reduce dose with renal failure No liver toxicity
Irinotecan (CPT II)	100–150 mg/m² IV over 90 min q3–4 weeks *or* 30 mg/m² per day over 120 h	Diarrhea: "early onset" with cramping, flushing, vomiting; "late onset" after several doses Marrow Alopecia Nausea Vomiting Pulmonary	Prodrug requires enzymatic clearance to active drug "SN 38" Early diarrhea likely due to biliary excretion Late diarrhea, use "high-dose" loperamide (2 mg q2–4 h)
Doxorubicin and daunorubicin	45–60 mg/m² dose q3–4 weeks *or* 10–30 mg/m² dose q week *or* continuous-infusion regimen	Marrow Mucositis Alopecia Cardiovascular acute/chronic Vesicant	Heparin aggregate; coadministration increases clearance Acetaminophen, BCNU increase liver toxicity Radiation recall
Idarubicin	10–15 mg/m² IV q 3 weeks *or* 10 mg/m² IV qd ×3	Marrow Cardiac (less than doxorubicin)	None established
Epirubicin	150 mg/m² IV q3 weeks	Marrow Cardiac	None established
Mitoxantrone	12 mg/m² qd ×3 *or* 12–14 mg/m² q3 weeks	Marrow Cardiac (less than doxorubicin) Vesicant (mild) Blue urine, sclerae, nails	Interacts with heparin Less alopecia, nausea than doxorubicin Radiation recall
INDIRECT DNA-INTERACTING AGENTS			
Antimetabolites			
Deoxycoformycin	4 mg/m² IV every other week	Nausea Immunosuppression Neurologic Renal	Excretes in urine Reduce dose for renal failure Inhibits adenosine deaminase
6-Mercaptopurine	75 mg/m² PO *or* up 500 mg/m² PO (high dose)	Marrow Liver Nausea	Variable bioavailability Metabolize by xanthine oxidase Decrease dose with allopurinol Increased toxicity with thiopurine methyltransferase deficiency

(continued)

TABLE 70-2—(Continued)

Drug	Examples of Usual Doses	Toxicity	Interactions, Issues
6-Thioguanine	2–3 mg/kg per day for up to 3–4 weeks	Marrow Liver Nausea	Variable bioavailability Increased toxicity with thiopurine methyltransferase deficiency
Azathioprine	1–5 mg/kg per day	Marrow Nausea Liver	Metabolizes to 6MP, therefore reduce dose with allopurinol Increased toxicity with thiopurine methyltransferase deficiency
2-Chlorodeoxyadenosine	0.09 mg/kg per day qd ×7 as continuous infusion	Marrow Renal Fever	Notable use in hairy cell leukemia
Hydroxyurea	20–50 mg/kg (lean body weight) PO qd *or* 1–3 g/d	Marrow Nausea Mucositis Skin changes Rare renal, liver, lung, CNS	Decrease dose with renal failure Augments antimetabolite effect
Methotrexate	15–30 mg PO or IM qd ×3–5 *or* 30 mg IV days 1 and 8 *or* 1.5–12 g/m^2 per day (with leucovorin)	Marrow Liver/lung Renal tubular Mucositis	Rescue with leucovorin Excreted in urine Decrease dose in renal failure NSAIDs increase renal toxicity
5-Fluorouracil	375 mg/m^2 IV qd ×5 *or* 600 mg/m^2 IV days 1 and 8	Marrow Mucositis Neurologic Skin changes	Toxicity enhanced by leucovorin Dihydropyrimidine dehydrogenase deficiency increases toxicity Metabolizes in tissues
Capecitabine	665 mg/m^2 bid continuous; 1250 mg/m^2 bid 2 weeks on/ 1 off; 829 mg/m^2 bid 2 weeks on/ 1 off + 60 mg/d leucovorin	Diarrhea Hand-foot syndrome	Prodrug of 5FU due to intratumoral metabolism
Cytosine arabinoside	100 mg/m^2 per day qd ×7 by continuous infusion *or* 1–3 g/m^2 dose IV bolus	Marrow Mucositis Neurologic (high dose) Conjunctivitis (high dose) Noncardiogenic pulmonary edema	Enhances activity of alkylating agents Metabolizes in tissues by deamination
Azacytidine	750 mg/m^2 per week *or* 150–200 mg/m^2 per day ×5–10 (bolus) or (continuous IV)	Marrow Nausea Liver Neurologic Myalgia	Use limited to leukemia Altered methylation of DNA alters gene expression
Gemcitabine	1000 mg/m^2 IV weekly ×7	Marrow Nausea Hepatic Fever/"flu syndrome"	
Fludarabine phosphate	25 mg/m^2 IV qd ×5	Marrow Neurologic Lung	Dose reduction with renal failure Metabolized to F-ara converted to F-ara ATP in cells by deoxycytidine kinase
Asparaginase	25,000 IU/m^2 q3–4 weeks *or* 6000 IU/m^2 per day qod for 3–4 weeks *or* 1000–2000 IU/m^2 for 10–20 days	Protein synthesis Clotting factors Glucose Albumin Hypersensitivity CNS Pancreatitis Hepatic	Blocks methotrexate action
Antimitotic agents			
Vincristine	1–1.4 mg/m^2 per week	Vesicant Marrow Neurologic GI: ileus/constipation; bladder hypotoxicity; SIADH Cardiovascular	Hepatic clearance Dose reduction for bilirubin >1.5 mg/dL Prophylactic bowel regimen

(continued)

TABLE 70-2 *Commonly Used Cancer Chemotherapy Agents—(Continued)*

Drug	Examples of Usual Doses	Toxicity	Interactions, Issues
Vinblastine	6–8 mg/m^2 per week	Vesicant Marrow Neurologic (less common but similar spectrum to other vincas) Hypertension Raynaud's	Hepatic clearance Dose reduction as with vincristine
Vinorelbine	15–30 mg/m^2 per week	Vesicant Marrow Allergic/bronchospasm (immediate) Dyspnea/cough (subacute) Neurologic (less prominent but similar spectrum to other vincas)	Hepatic clearance
Paclitaxel	135–175 mg/m^2 per 24-h infusion *or* 175 mg/m^2 per 3-h infusion *or* 140 mg/m^2 per 96-h infusion *or* 250 mg/m^2 per 24-h infusion plus G-CSF	Hypersensitivity Marrow Mucositis Alopecia Sensory neuropathy CV conduction disturbance Nausea—infrequent	Premedicate with steroids, H_1 and H_2 blockers Hepatic clearance Dose reduction as with vincas
Docetaxel	100 mg/m^2 per 1-h infusion q3 weeks	Hypersensitivity Fluid retention syndrome Marrow Dermatologic Sensory neuropathy Nausea infrequent Some stomatitis	Premedicate with steroids, H_1 and H_2 blockers
Estramustine phosphate	14 mg/kg per day in 3–4 divided doses with water >2 h after meals Avoid Ca^{2+}-rich foods	Nausea Vomiting Diarrhea CHF Thrombosis Gynecomastia	
MOLECULARLY TARGETED AGENTS			
Imatinib	400 mg/d, continuous	Nausea Periorbital edema	Myelosuppression not frequent in solid tumor indications
Tretinoin	45 mg/m^2 per day until complete response + anthrocycline-based regimen in APL	Teratogenic Cutaneous	APL differentiation syndrome: pulmonary dysfunction/infiltrate, pleural/pericardial effusion, fever
Bexarotene	300–400 mg/m^2 per day, continuous	Hypercholesterolemia Hypertriglyceridemia Cutaneous Teratogenic	Central hypothyroidism
Gemtuzumab ogomicin	9 mg/m^2 over 2 h q2 weeks, usually followed by chemotherapy or marrow transplant	Neutropenia Thrombosytopenia Hepatic	Postinfusion syndrome: fever, chills, hypotension Rare hepatic venoocclusive disease Mucositis uncommon
Denileukin deftitox	9–18 μg/kg per day × 5 d q 3 wk	Nausea/vomiting Chills/fever Asthenia Hepatic	Acute hypersensitivity: hypotension, vasodilation, rash, chest tightness Vascular leak: hypotension, edema, hypoalbuminemia, thrombotic events (MI, DVT, CVA)
MISCELLANEOUS			
Arsenic trioxide	0.16 mg/kg per day up to 50 days in APL	↑QT_c Peripheral neuropathy Musculoskeletal pain Hyperglycemia	APL differentiation syndrome (see under tretinoin)

[a] Common alkylator: alopecia, pulmonary, infertility, plus teratogenesis.

Note: APL, acute promyelocytic leukemia; AUC, area under the curve; CHF, congestive heart failure; CNS, central nervous system; CrCl, creatinine clearance; CV, cardiovascular; CVA, cerebrovascular accident; DVT, deep venous thrombosis; G-CSF, granulocyte colony-stimulating factor; GI, gastrointestinal; HBP, high blood pressure; MAOI, monoamine oxidase inhibitors; MI, myocardial infarction; 6MP, 6-mercaptopurine; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone; WBCs, white blood cells.

long-lasting. Streptozotocin is unique in that its glucose-like structure conveys specific toxicity to the islet cells of the pancreas (for whose derivative tumor types it is prominently indicated) as well as causing renal toxicity in the form of Fanconi's syndrome, including amino aciduria, glycosuria, and renal tubular acidosis. Methyl CCNU (lomustine) causes direct glomerular as well as tubular damage, cumulatively related to dose and time of exposure.

Procarbazine is metabolized in the liver and possibly in tumor cells to yield a variety of free radical and alkylating species. In addition to myelosuppression, it causes hypnotic and other CNS effects, including vivid nightmares. It can cause a disulfiram-like syndrome on ingestion of ethanol. Altretamine (formerly hexamethylmelamine) and thiotepa can chemically give rise to alkylating species, although the nature of the DNA damage has not been well characterized in either case. Thiotepa can be used for intrathecal treatment of neoplastic meningitis. Dacarbazine (DTIC) is activated in the liver to yield the highly reactive methyl diazonium cation. It causes only modest myelosuppression 21 to 25 days after a dose but causes prominent nausea on day 1. Temozolomide is structurally related to dacarbazine but was designed to be activated by nonenzymatic hydrolysis in tumors, and is orally bioavailable.

Cisplatin was discovered fortuitously by observing that bacteria present in electrolysis solutions could not divide. Only the *cis* diamine configuration is active as an antitumor agent. It is hypothesized that in the intracellular environment, a chloride is lost from each position, being replaced by a water molecule. The resulting positively charged species is an efficient bifunctional interactor with DNA, forming Pt-based cross-links. Cisplatin requires administration with adequate hydration, including forced diuresis with mannitol to prevent kidney damage; even with the use of hydration, gradual decrease in kidney function is common, along with noteworthy anemia. Hypomagnesemia frequently attends cisplatin use and can lead to hypocalcemia and tetany. Other common toxicities include neurotoxocity with stocking and glove sensorimotor neuropathy. Hearing loss occurs in 50% of patients treated with conventional doses. Cisplatin is intensely emetogenic, requiring prophylactic antiemetics. Myelosuppression is less evident than with other alkylating agents. Chronic vascular toxicity (Raynaud's syndrome, coronary artery disease) is a more unusual toxicity. Carboplatin displays less nephro-, oto-, and neurotoxicity. However, myelosuppression is more frequent, and as the drug is exclusively cleared through the kidney, adjustment of dose for creatinine clearance must be accomplished through use of various dosing nomograms. Oxaliplatin is used in colon cancers refractory to other treatments. Its place in the primary and adjuvant treatment of colon tumors is being defined, along with tests of activity in other tumors. It is prominently neurotoxic.

ANTITUMOR ANTIBIOTICS AND TOPOISOMERASE POISONS Antitumor antibiotics are substances produced by bacteria that in nature appear to provide chemical defense against other hostile microorganisms. As a class they bind to DNA directly and can frequently undergo electron transfer reactions to generate free radicals in close proximity to DNA, leading to DNA damage in the form of single strand breaks or cross-links. Topoisomerase poisons include natural products or semi-synthetic species derived ultimately from plants, and they modify enzymes that regulate the capacity of DNA to unwind to allow normal replication or transcription. DNA damage from these agents can occur in any cell cycle phase, but cells tend to arrest in S-phase or G_2 of the cell cycle in cells with p53 and Rb pathway lesions as the result of defective checkpoint mechanisms in cancer cells.

Doxorubicin is the most widely active and frequently used antineoplastic agent. It can intercalate into DNA, thereby altering DNA structure, replication, and topoisomerase function. It can also undergo redox cycling by accepting electrons into its quinone ring system. It causes predictable myelosuppression, alopecia, nausea, and mucositis. In addition, it causes acute cardiotoxicity in the form of atrial and ventricular dysrhythmias, but these are rarely of clinical significance. In contrast, cumulative doses >550 mg/m^2 are associated with a 10% incidence of chronic cardiomyopathy. The incidence of cardiomyopathy appears to be related to schedule (peak serum concentration), with low dose, frequent treatment, or continuous infusions better tolerated than intermittent higher dose exposures. Its cardiotoxicity is increased when given together with trastuzumab (Herceptin), the anti-HER2/*neu* antibody. Radiation recall or interaction with concomitantly administered radiation to cause local site complications is frequent. The drug is a powerful vesicant, with necrosis of tissue apparent 4 to 7 days after an extravasation; therefore it should be administered into a rapidly flowing intravenous line. The drug is metabolized by the liver, so doses must be reduced by 50 to 75% in the presence of liver dysfunction. Daunorubicin is closely related to doxorubicin and was actually introduced first into leukemia treament, where it remains part of curative regimens and has been shown preferable to doxorubicin owing to less mucositis and colonic damage. Idarubicin is an orally acting doxorubicin analogue whose ultimate place in therapy is uncertain. Encapsulation of daunorubicin into a liposome has been accomplished, with attenuation of cardiac toxicity and noteworthy activity in Kaposi's sarcoma. Liposome-encapsulated doxorubicin may have activity in prostate cancer.

Bleomycin refers to a mixture of glycopeptides that have the unique feature of forming complexes with Fe^{2+} while also bound to DNA. Oxidation of Fe^{2+} gives rise to superoxide and hydroxyl radicals. The drug causes little, if any, myelosuppression. The drug is cleared rapidly, but augmented skin and pulmonary toxicity in the presence of renal failure has led to the recommendation that doses be reduced by 50 to 75% in the face of a creatinine clearance <25 mL/min. Bleomycin is not a vesicant and can be administered intravenously, intramuscularly, or subcutaneously. Common side effects include fever and chills, facial flush, and Raynaud's syndrome. Hypertension can follow rapid intravenous administration, and the incidence of anaphylaxis with early preparations of the drug has led to the practice of administering a test dose of 0.5 to 1 unit before the rest of the dose. The most feared complication of bleomycin treatment is pulmonary fibrosis, which increases in incidence at >300 cumulative units administered and is minimally responsive to treatment (e.g., glucocorticoids). The earliest indicator of an adverse effect is a decline in the DL_{CO}, although cessation of drug immediately upon documentation of a decrease in DL_{CO} may not prevent further decline in pulmonary function. Bleomycin is inactivated by a bleomycin hydrolase, whose concentration is diminished in skin and lung. Because bleomycin-dependent electron transport is dependent on O_2, bleomycin toxicity may become apparent after exposure to transient very high PI_{O_2}. Thus, during surgical procedures, patients with prior exposure to bleomycin should be maintained on the lowest PI_{O_2} consistent with maintaining adequate tissue oxygenation.

Dactinomycin intercalates into DNA and appears to have less, but not absent, capacity to undergo electron transfer reactions. It causes severe myelosuppression, nausea, alopecia, and mucositis. It is a notable vesicant. Mithramycin historically was used against testicular and other neoplasms; however, in addition to causing nausea, myelosuppression, and vesicant properties, it causes an acute hemorrhagic syndrome consisting of platelet function defects in association with indicators of disseminated intravascular coagulation. It is used in current practice to control hypercalcemia. In addition, renal and hepatic dysfunction may complicate its use.

Mitomycin C undergoes reduction of its quinone function to generate a bifunctional DNA alkylating agent. It is a broadly active antineoplastic agent with a number of unpredictable toxicities, including delayed bronchospasm 12 to 14 h after dosing and a chronic pulmonary fibrosis syndrome more frequent at doses of 50 to 60 mg/m^2. Cardiomyopathy has been described, particularly in a setting of prior radiation therapy. A hemolytic/uremic syndrome carries an ultimate mortality rate of 25 to 50% and is poorly treated by conventional component support and exchange transfusion. Mitomycin is a notable vesicant and causes substantial nausea and vomiting. It can be used

for intravesical instillation for curative treatment of superficial transitional bladder carcinomas and, with radiation therapy, for curative treatment of anal carcinoma.

Mitoxantrone is a synthetic compound that was designed to recapitulate features of doxorubicin but with less cardiotoxicity. It is quantitatively less cardiotoxic (comparing the ratio of cardiotoxic to therapeutically effective doses), but its status in therapy is unclear as doses of 150 mg/m^2 have produced evidence of 10% incidence of cardiotoxicity; it also causes alopecia.

Etoposide was synthetically derived from the plant product podophyllotoxin; it binds directly to topoisomerase II and DNA in a reversible ternary complex. It stabilizes the covalent intermediate in the enzyme's action where the enzyme is covalently linked to DNA. This "alkali-labile" DNA bond was historically a first hint that an enzyme such as a topoisomerase might exist. The drug therefore causes a prominent G_2 arrest, reflecting the action of a DNA damage checkpoint. Prominent clinical effects include myelosuppression, nausea, and transient hypotension related to the speed of administration of the agent. Etoposide is a mild vesicant but is relatively free from other large-organ toxicities. Teniposide is a structural relative with unique activity in childhood acute lymphoid leukemia. When given at high doses or very frequently, topoisomerase inhibitors may cause acute leukemia associated with chromosome 11q23 abnormalities in up to 1% of exposed patients.

Camptothecin was isolated from extracts of a Chinese tree and had notable antileukemia activity. Early clinical studies with the sodium salt of the hydrolyzed camptothecin lactone showed evidence of toxicity with little antitumor activity. Identification of topoisomerase I as the target of camptothecins and the need to preserve lactone structure allowed additional efforts to identify active members of this series. Topoisomerase I is responsible for unwinding the DNA strand by introducing single strand breaks and allowing rotation of one strand about the other. In S-phase, topoisomerase I–induced breaks that are not promptly resealed lead to progress of the replication fork off the end of a DNA strand. The DNA damage is a potent signal for induction of apoptosis. Camptothecins promote the stabilization of the DNA linked to the enzyme in a so-called cleavable complex, analogous to the action of etoposide with topoisomerase II. Topotecan is a camptothecin derivative approved for use in ovarian tumors. Toxicity is limited to myelosuppression and mucositis. CPT-11, or irinotecan, is a camptothecin with evidence of activity in colon carcinoma. In addition to myelosuppression, it causes a secretory diarrhea, which can be treated effectively with loperamide or octreotide.

Indirect Effectors of DNA Function: Antimetabolites A broad definition of antimetabolites would include compounds with structural similarity to precursors of purines or pyrimidines or that interfere with purine or pyrimidine synthesis. Antimetabolites can cause DNA damage indirectly, through misincorporation into DNA, abnormal timing or progression through DNA synthesis, or altered function of pyrimidine and purine biosynthetic enzymes. They tend to convey greatest toxicity to cells in S-phase, and the degree of toxicity increases with duration of exposure. Common toxic manifestations include stomatitis, diarrhea, and myelosuppression. Second malignancies are not associated with their use.

Methotrexate inhibits dihydrofolate reductase, which regenerates reduced folates from the oxidized folates produced when thymidine monophosphate is formed from deoxyuridine monophosphate. Without reduced folates, cells die a "thymineless" death. N-5 tetrahydrofolate or N-5 formyltetrahydrofolate (leucovorin) can bypass this block and rescue cells from methotrexate, which is maintained in cells by polyglutamylation. The drug and other reduced folates are transported into cells by the folate carrier, and high concentrations of drug can bypass this carrier and allow diffusion of drug directly into cells. These properties have suggested the design of "high-dose" methotrexate regimens with leucovorin rescue of normal marrow and mucosa as part of curative approaches to osteosarcoma in the adjuvant setting and hematopoietic neoplasms of children and adults. Methotrexate is cleared by the kidney by both glomerular filtration and tubular secretion, and toxicity is augmented by renal dysfunction and drugs such as salicylates, probenecid, and nonsteroidal anti-inflammatory agents that undergo tubular secretion. With normal renal function, 15 mg/m^2 leucovorin will rescue 10^{-8} to 10^{-6} M methotrexate in three to four doses. However, with decreased creatinine clearance, doses of 50 to 100 mg/m^2 are continued until methotrexate levels are $<5 \times 10^{-8}$ M. In addition to bone marrow suppression and mucosal irritation, methotrexate can cause renal failure itself at high doses owing to crystallization in renal tubules; therefore high-dose regimens require alkalinization of urine with increased flow by hydration. Methotrexate can be sequestered in third space collections and leech back into the general circulation, causing prolonged myelosuppression. Less frequent adverse effects include reversible increases in transaminases and hypersensitivity-like pulmonary syndrome. Chronic low-dose methotrexate can cause hepatic fibrosis. When administered to the intrathecal space, methotrexate can cause chemical arachnoiditis and CNS dysfunction. Trimetrexate is a methotrexate derivative that is not polyglutamylated and does not use the reduced folate carrier.

5-Fluorouracil (5FU) represents an early example of "rational" drug design in that it originated from the observation that tumor cells incorporate radiolabeled uracil more efficiently into DNA than normal cells, especially gut. 5FU is metabolized in cells to 5′FdUMP, which inhibits thymidylate synthetase (TS). In addition, misincorporation can lead to single strand breaks, and RNA can aberrantly incorporate FUMP. 5FU is metabolized by dihydropyrimidine dehydrogenase, and deficiency of this enzyme can lead to excessive toxicity from 5FU. Oral bioavailability varies unreliably, but orally administered analogues of 5FU such as capecitabine have been developed that allow at least equivalent activity to many parenteral 5FU-based approaches to refractory cancers. Intravenous administration of 5FU leads to bone marrow suppression after short infusions but to stomatitis after prolonged infusions. Leucovorin augments the activity of 5FU by promoting formation of the ternary covalent complex of 5FU, the reduced folate, and TS. Less frequent toxicities include CNS dysfunction, with prominent cerebellar signs, and endothelial toxicity manifested by thrombosis, including pulmonary embolus and myocardial infarction.

Cytosine arabinoside (ara-C) is incorporated into DNA after formation of ara-CTP, resulting in S-phase-related toxicity. Continuous infusion schedules allow maximal efficiency, with uptake maximal at 5 to 7 μM. Ara-C can be administered intrathecally. Adverse effects include nausea, diarrhea, stomatitis, chemical conjunctivitis, and cerebellar ataxia. Gemcitabine is a cytosine derivative that is similar to ara-C in that it is incorporated into DNA after anabolism to the triphosphate, rendering DNA susceptible to breakage and repair synthesis, which differs from that in ara-C in that gemcitabine-induced lesions are very inefficiently removed. In contrast to ara-C, gemcitabine appears to have useful activity in a variety of solid tumors, with limited nonmyelosuppressive toxicities. 6-Thioguanine and 6-mercaptopurine (6MP) are used in the treatment of acute lymphoid leukemia. Although administered orally, they display variable bioavailability. 6MP is metabolized by xanthine oxidase and therefore requires dose reduction when used with allopurinol.

Fludarabine phosphate is a prodrug of F-adenine arabinoside (F-ara-A), which in turn was designed to diminish the susceptibility of ara-A to adenosine deaminase. F-ara-A is incorporated into DNA and can cause delayed cytotoxicity even in cells with low growth fraction, including chronic lymphocytic leukemia and follicular B cell lymphoma. CNS dysfunction and T cell depletion leading to opportunistic infections can occur in addition to myelosuppression. 2-Chlorodeoxyadenosine is a similar compound with activity in hairy cell leukemia. 2-Deoxycoformycin inhibits adenosine deaminase, with resulting increase in dATP levels. This causes inhibition of ribonucleotide reductase as well as augmented susceptibility to apoptosis, particularly in T cells. Renal failure and CNS dysfunction are notable toxicities in addition to immunosuppression.

Hydroxyurea inhibits ribonucleotide reductase, resulting in S-phase block. It is orally bioavailable and the drug of choice for the acute management of myeloproliferative states. Asparaginase is not classically considered an antimetabolite as it causes breakdown of extracellular asparagine required for protein synthesis in certain leukemic cells. However, it effectively stops DNA synthesis by preventing the requisite concurrent protein synthesis, and therefore it has a similar functional outcome as the classic antimetabolites. As asparaginase is a foreign protein, hypersensitivity reactions are common, as are effects on organs such as pancreas and liver that require continuing protein synthesis. This results in decreased insulin secretion with hyperglycemia, with or without hyperamylasemia and clotting function abnormalities. The latter may be associated with CNS and dural vein thrombosis.

Mitotic Spindle Inhibitors Microtubules are cellular structures that form the mitotic spindle and in interphase cells are responsible for the cellular "scaffolding" along which various motile and secretory processes occur. Microtubules are composed of repeating noncovalent multimers of a heterodimer of α and β subunits of the protein tubulin. Vincristine binds to the tubulin dimer with the result that microtubules are disaggregated. This results in the block of growing cells in M-phase; however, toxic effects in G_1 and S-phase are also evident. The drug is bound to blood-formed elements, leading to its occasional use as vinca-loaded platelets to treat autoimmune thrombocytopenia. The drug is metabolized by the liver, and dose adjustment in the presence of hepatic dysfunction is required. It is a powerful vesicant, and infiltration can be treated by local heat and infiltration of hyaluronidase. At clinically used intravenous doses, neurotoxicity in the form of glove-and-stocking neuropathy is frequent. Children tolerate 2 mg/m^2, but adult doses may be capped at 2 mg total to lower the incidence of disabling chronic neuropathy; whether this compromises needed dose intensity in curative regimens is uncertain. Acute neuropathic effects include jaw pain, paralytic ileus, urinary retention, and the syndrome of inappropriate antidiuretic hormone secretion. Myelosuppression is not seen. Vinblastine is similar to vincristine, except that it tends to be more myelotoxic, with more frequent thrombocytopenia and also mucositis and stomatitis. Vinorelbine is a vinca alkaloid that appears to have differences in resistance patterns in comparison to vincristine and vinblastine; it may be administered orally.

The taxanes include paclitaxel and docetaxel. These agents differ from the vinca alkaloids in that the taxanes stabilize microtubules against depolymerization. The "stabilized" microtubules function abnormally and are not able to undergo the normal dynamic changes of microtubule function necessary for cell cycle completion. Taxanes are among the most broadly active antineoplastic agents for use in solid tumors, with evidence of activity in ovarian cancer, breast cancer, Kaposi's sarcoma, and lung tumors. They are administered intravenously, and paclitaxel requires use of a cremophore-containing vehicle that can cause hypersensitivity reactions. Premedication with regimens including dexamethasone (20 mg orally or intravenously 12 and 6 h before treatment) and diphenhydramine (50 mg) and cimetidine (300 mg), both 30 min before treatment, decreases but does not eliminate the risk of hypersensitivity reactions to the paclitaxel vehicle. Docetaxel uses a polysorbate 80 formulation, which can cause fluid retention in addition to hypersensitivity reactions, and dexamethasone premedication with or without antihistamines is frequently used. Paclitaxel causes hypersensitivity reactions, myelosuppression, neurotoxicity in the form of glove-and-stocking numbness, and paresthesia. Cardiac rhythm disturbances were observed in phase I and II trials, most commonly asymptomatic bradycardia but also, much more rarely, varying degrees of heart block. These have not emerged as clinically significant in the majority of patients. Infrequently occurring evidence of myocardial ischemia during paclitaxel administration cannot yet be clearly related to the drug. Docetaxel causes comparable degrees of myelosuppression and neuropathy. Hypersensitivity reactions, including bronchospasm, dyspnea, and hypotension, are less frequent but occur to some degree in up to 25% of patients. Fluid retention appears to result from a vascular leak syndrome that can aggravate preexisting effusions. Rash can complicate docetaxel administration, appearing prominently as a pruritic maculopapular rash affecting the forearms, but it has also been associated with fingernail ridging, breakdown, and skin discoloration. Stomatitis appears to be somewhat more frequent than with paclitaxel.

Estramustine was originally synthesized as a mustard derivative that might be useful in neoplasms that possessed estrogen receptor sites. However, no evidence of interaction with DNA was observed. Surprisingly, the drug caused metaphase arrest, and subsequent study revealed that it binds to microtubule-associated proteins, resulting in abnormal microtubule function. Estramustine binds to estramustine-binding proteins (EMBP), which are notably present in prostate tumor tissue. The drug is used as an oral formulation in patients with prostate cancer. Gastrointestinal and cardiovascular adverse effects related to the estrogen moiety occur in up to 10% of patients, including worsened heart failure and thromboembolic phenomena. Gynecomastia and nipple tenderness can also occur.

Hormonal Agents The family of steroid hormone receptor–related molecules have emerged as prominent targets for small molecules useful in cancer treatment. When bound to their cognate ligands, these receptors can alter gene transcription and, in certain tissues, induce apoptosis. The pharmacologic effect is a mirror or parody of the normal effects of the agent acting in nontransformed tissue, although the effects on tumors are mediated by indirect effects in some cases.

Glucocorticoids are generally given in "pulsed" high-dose exposure in leukemias and lymphomas, where they induce apoptosis in tumor cells. Cushing's syndrome or inadvertent adrenal suppression on withdrawal from high-dose glucocorticoids can be significant complications, along with infections common in immunosuppressed patients, in particular *Pneumocystis* pneumonia, which classically appears a few days after completing a course of high-dose steroids. Tamoxifen is a partial estrogen receptor antagonist; it has a tenfold greater degree of antitumor activity in breast cancer patients whose tumors express estrogen receptors than in those who have low or no levels of expression. Side effects include a somewhat increased risk of estrogen-related cardiovascular complications, such as thromboembolic phenomena, and a small increased incidence of endometrial carcinoma, which appears after chronic use. Progestational agents including medroxyprogesterone acetate, androgens including fluoxymesterone (Halotestin), and, paradoxically, estrogens have approximately the same degeree of activity in primary hormonal treatment of breast cancers that have elevated expression of estrogen receptor protein. Estrogen is not used often owing to prominent cardiovascular and uterotropic activity.

Prostate cancer is classically treated by diethylstilbesterol (DES) acting as an estrogen at the level of the hypothalamus to downregulate hypothalamic luteinizing hormone (LH) production, resulting in decreased elaboration of testosterone by the testicle. For this reason, orchiectomy is equally as effective as moderate-dose DES, inducing responses in 80% of previously untreated patients with prostate cancer but without the prominent cardiovascular side effects of DES, including thrombosis and exacerbation of coronary artery disease. In the event that orchiectomy is not accepted by the patient, testicular androgen suppression can also be effected by luteinizing hormone–releasing hormone (LHRH) agonists such as leuprolide and goserelin. These agents cause tonic stimulation of the LHRH receptor, with the loss of its normal pulsatile activation resulting in its desensitization and decreased output of LH by the anterior pituitary. Therefore, as primary hormonal manipulation in prostate cancer one can choose orchiectomy or leuprolide, not both. The addition of actual antagonists of androgens acting at the androgen receptor, including flutamide or bicalutamide, is of uncertain additional benefit in extending overall response duration, but it clearly prevents the activation of androgen receptors by adrenal androgens, and the combined use of orchiectomy or leuprolide plus flutamide is referred to as "total androgen blockade."

Tumors that respond to a primary hormonal manipulation may frequently respond to second and third hormonal manipulations. Thus, breast tumors that had previously responded to tamoxifen have, on relapse, notable response rates to withdrawal of tamoxifen itself or to subsequent addition of a progestin. Likewise, initial treatment of prostate cancers with leuprolide plus flutamide may be followed after disease progression by response to withrawal of flutamide. These responses may result from the removal of antagonists from mutant steroid hormone receptors that have come to depend on the presence of the antagonist as a growth-promoting influence.

Additional strategies to treat refractory breast and prostate cancers that possess steroid hormone receptors may also address adrenal capacity to produce androgens and estrogens, even after orchiectomy or oophorectomy, respectively. Thus, aminoglutethimide or ketoconazole can be used to block adrenal synthesis by interfering with the enzymes of steroid hormone metabolism. Administration of these agents requires concomitant hydrocortisone replacement and additional glucocorticoid doses administered in the event of physiologic stress. Steroid hormone–inducing "aromatase" activity may be present in tumor tissue, and second- or third-line approaches to inhibition of aromatase activity may also be affected by such agents as anastrazole and letrozole. The toxicity profile and activity of the aromatase inhibitors make them candidates for first-line therapy for breast cancer.

Humoral mechanisms can also result in complications of an underlying malignancy. Adrenocortical carcinomas can cause Cushing's syndrome as well as syndromes of androgen or estrogen excess. Mitotane can counteract these by decreasing synthesis of steroid hormones. Islet cell neoplasms can cause debilitating diarrhea, treated with the somatostatin analogue octreotide. Prolactin-secreting tumors can be effectively managed by the dopaminergic agononist bromocriptine.

MOLECULARLY TARGETED THERAPIES A better understanding of cancer cell biology has suggested many new targets for cancer drug discovery and development. These include the products of oncogenes and tumor-suppressor genes; regulators of cell death pathways; mediators of cellular immortality such as telomerase; and molecules responsible for microenvironmental molding such as proteases or angiogenic factors. The essential difference in the development of agents that would target these processes is that the basis for discovery of the candidate drug is the a priori importance of the target in the biology of the tumor, rather than the initial detection of drug candidates based on the phenomenon of tumor cell regression in tissue culture or in animals.

The most successful example of this class is imatinib mesylate (Gleevec). This protein kinase antagonist was selected as an inhibitor of the platelet-derived growth factor receptor (PDGFR) tyrosine kinase and was subsequently found to inhibit the bcr-abl kinase present in CML cells and reflecting the pathogenic t(9;22) chromosomal translocation in that tumor. It is also a potent inhibitor of the kit kinase originally defined as the stem cell factor receptor, a hematopoetic growth factor. Outstanding activity of imatinib has been noted in IFN-refractory CML with minimal toxicity, and it is also active in neoplasms driven by kit, such as gastrointestinal stromal sarcomas (GISTs), and by PDGFR, such as dermatofibrosarcoma protuberans. In each of these cases a clear link of the biology of the successfully treated neoplasm to the activity of the drug-susceptible target was a key factor in identifying patients who derived benefit from the drug.

Many classes of molecularly targeted small-molecule cancer therapeutics are under development or are in active clinical trials, including various protein kinase antagonists, farnesyltransferase antagonists originally designed to counter *ras* oncogene function, and protease inhibitors (Chap. 69). Many of these agents have not had evidence of frequent antitumor activity as single drugs in phase II trials. Their future use will likely depend on the evolution of more refined strategies to diagnose with accuracy the dependence of the tumor's biology on the presence of the drugs' targets. Alternatively, combinations of molecularly targeted agents with chemotherapeutic agents or with each other may evolve to address the multiplicity of genetic lesions present in solid tumors. These combinations will differ strategically from the approach used to evolve combinations of cytotoxic agents, which frequently combined agents with the same target, but which possessed differing toxicity. In contrast, combinations of molecularly targeted agents may address different pathways governing tumor biology in a manner more conceptually analogous to highly active antiretroviral therapy, where optimal disease suppression results from addressing two different gene products upon which successful viral replication depends.

An additional example related conceptually to molecularly targeted strategies is the use of retinoids, including tretinoin, the all-*trans*-isomer of retinoic acid, or isotretinoin, the 13-*cis* isomer of retinoic acid, to cause "differentiation" by acting on the retinoid receptor, a member of the steroid hormone receptor family. Leukemias and certain squamous neoplasms, including those of the skin and cervix, appear to be uniquely responsive in certain cases to retinoids. In particular, tretinoin is part of curative regimens for acute promyelocytic leukemia (APL) and appears to act by causing accelerated degradation of the fusion protein created by the t(15; 17) translocation that fuses the retinoic acid receptor α and the promyelocytic leukemia (PML) transcription factor. Acute side effects related to differentiation of promyelocytes to mature granulocytes may result in pulmonary symptoms related to granulocyte sequestration in the pulmonary vasculature; these are treated by respiratory support and glucocorticoids. This example also illustrates the important role of defining the molecular basis of empirical observations to refine a treatment strategy. Long before the definition of the t(15; 17)-derived fusion protein transcription factor now known to be the target of tretinoin, the growth and differentiation of certain leukemia cells including APL cells were known to be greatly influenced by retinoids. Empirical clinical trials of retinoids in China confirmed evidence of clinical activity of the agent before trials in the west. In this case, understanding the action of a drug led to the definition of the target. Another retinoid with activity in empirically driven clinical trials is the synthetic retinoid X receptor ligand bexarotene, which has noteworthy activity in cutaneous T cell lymphoma.

Whether derived by design a priori or through the explication of antiproliferative activity on the part of novel agents, the future will evolve additional classes of molecules whose targets are known to be causally related to neoplastic behavior. How to evaluate these agents efficiently and thoroughly is a current challenge. Empirical strategies treat a series of diseases with the novel agents without reference to the expression or activity of the target. Clinical utility dictates which agents move forward in development. While potentially inefficient, this approach has nonetheless yielded curative regimens in leukemias, lymphomas, germ cell neoplasms, and breast and colon tumors; e.g., when the latter two diseases are treated with chemotherapy after primary treatment of the local tumor with surgery and/or radiation therapy. Rigorously applied molecularly targeted development strategies, exemplified by imatinib's initial studies, would restrict drug use only to tumors with known activity or presence of the target. The former strategy risks inefficiency but is open to clinical observations that importantly influence development strategies. In all likelihood, a mix of empirical and targeted strategies will be of value in defining new, useful treatments for cancer. Examples of encouraging results of the empirical type include preliminary evidence of activity of bortezomib (Velcade), a proteosome inhibitor, in refractory multiple myeloma, and the epidermal growth factor receptor (EGFR) antagonist gefitinib (Iressa) in refractory lung cancer. Bortezomib was rationally designed to inhibit the proteosome, the multicomponent subcellular complex that degrades cell proteins as part of their normal turnover processes. The observation of activity in myeloma was an empirical outcome of a clinical trial. Likewise, simple expression of EGFR does not appear to uniquely correlate with gefitinib activity in patients with lung cancer. These examples highlight a difficulty in the more general use of molecularly targeted agents; specifically, how to select patients likely to respond to such agents. In many cases it is not obvious, as the

relation of their target's action to the biologic success of the tumors in which they might be used is not clear. This is in contrast to conventional chemotherapeutic agents, where successful tumor growth obviously depends on DNA synthesis and microtubule function. These issues are very much a matter for current clinical and basic research.

An alternative way of thinking about molecularly targeted cancer therapeutics might recognize that there are actually many classes of cancer molecular targets. *Pathogenic targets* address the important events in the incidence and spread of a tumor; *differentiation-related targets* might reflect the tissue of origin; *pharmacological targets* would capitalize on intratumoral capacity to metabolize potentially active agents; *microenvironmental targets* would define processes important in molding stroma to allow successful blood supply and invasive properties. Drugs addressing all of these types of targets are in development. Certain "targeted toxins" exemplify some of these approaches. Targeted toxins utilize molecules with high affinity for defined tumor cell surface molecules, such as a leukemia differentiation antigen, to which a therapeutic antibody can deliver a covalently linked potent cytotoxin (e.g., gemtuzumab ozogamicin, a drug linked to anti-CD33), or a growth factor such as IL-2 to deliver a toxin (in the form of diphtheria toxin in denileukin diftitox) to cells bearing the IL-2 receptor. The value of such targeted approaches is that in addition to maximizing the therapeutic index by differential expression of the target in tumor (as opposed to nonrenewable normal cells), selection of patients for clinical trial and (perhaps eventually for routine clinical use) can capitalize on assessing the target in the tumor. The tools to accomplish this goal will include newer strategies to categorize tumors based on their biology rather than simply tissue of origin or histologic features.

ACUTE COMPLICATIONS OF CANCER CHEMOTHERAPY ■ Myelosuppression The common cytotoxic chemotherapeutic agents almost invariably affect bone marrow function. Titration of this effect determines in many cases the MTD of the agent on a given schedule. The normal kinetics of blood cell turnover influence the sequence and sensitivity of each of the formed elements. Polymorphonuclear leukocytes (PMNs; $t_{1/2}$ = 6 to 8 h), platelets ($t_{1/2}$ = 5 to 7 days), and red blood cells (RBCs; $t_{1/2}$ = 120 days) have respectively most, less, and least susceptibility to usually administered cytotoxic agents. The nadir count of each cell type in response to classes of agents is characteristic. Maximal neutropenia occurs 6 to 14 days after conventional doses of anthracyclines, antifolates, and antimetabolites. Alkylating agents differ from each other in the timing of cytopenias. Nitrosoureas, DTIC, and procarbazine can display delayed marrow toxicity, first appearing 6 weeks after dosing.

Complications of myelosuppression result from the predictable sequelae of the missing cells' function. *Febrile neutropenia* refers to the clinical presentation of fever (one temperature ≥38.5°C or three readings ≥38°C but ≤38.5°C per 24 h) in a neutropenic patient with an uncontrolled neoplasm involving the bone marrow or, more usually, in a patient undergoing treatment with cytotoxic agents. Mortality from uncontrolled infection varies inversely with the neutrophil count. If the nadir neutrophil count is >1000/μL, there is little risk; if <500/μL, risk of death is markedly increased. Management of febrile neutropenia has conventionally included empirical coverage with antibiotics for the duration of neutropenia (Chap. 72). Selection of antibiotics is governed by the expected association of infections with certain underlying neoplasms; careful physical examination (with scrutiny of catheter sites, dentition, mucosal surfaces, and perirectal and genital orifices by gentle palpation); chest x-ray; and Gram stain and culture of blood, urine, and sputum (if any) to define a putative site of infection. In the absence of any originating site, a broadly acting β-lactam with anti-*Pseudomonas* activity, such as ceftazidime, is begun empirically. The addition of vancomycin to cover potential cutaneous sites of origin (until these are ruled out or shown to originate from methicillin-sensitive organisms) or metronidazole or imipenem for abdominal or other sites favoring anaerobes reflects modifications tailored to individual patient presentations. The coexistence of pulmonary compromise raises a distinct set of potential pathogens, including *Legionella*, *Pneumocystis*, and fungal agents that may require further diagnostic evaluations such as bronchoscopy with bronchoalveolar lavage. Febrile neutropenic patients can be stratified broadly into two prognostic groups. The first, with expected short duration of neutropenia and no evidence of hypotension or abdominal or other localizing symptoms, may be expected to do well even with less complex, oral regimens, e.g., ciprofloxacin or amoxicillin and clavulinic acid. Detailed evaluation of such simple oral programs and intravenous regimens is ongoing. A less favorable prognostic group are patients with expected prolonged neutropenia, evidence of sepsis, and end-organ compromise, particularly pneumonia. These patients clearly require tailoring of their antibiotic regimen to their underlying presentation, with frequent empirical addition of antifungal agents if fever persists for 7 days without identification of an adequately treated organism or site.

Transfusion of granulocytes has no role in the management of febrile neutropenia, owing to their exceedingly short half-life, mechanical fragility, and clinical syndromes of pulmonary compromise with leukostasis after their use. Instead, colony-stimulating factors (CSFs) are used to augment bone marrow production of PMNs. These include early-acting factors such as IL-1, IL-3, and stem cell factor, which act on multiple lineages, and late-acting lineage-specific factors such as G-CSF (granulocyte colony-stimulating factor) or GM-CSF (granulocyte-macrophage colony-stimulating factor), erythropoietin, thrombopoietin, IL-6, and IL-11. CSFs are overused in oncology practice. The settings in which their use has been proved effective are limited. G-CSF, GM-CSF, erythropoietin, and IL-11 are currently approved for use. The American Society of Clinical Oncology has developed practice guidelines for the use of G-CSF and GM-CSF (Table 70-3). Primary administration (i.e., shortly after completing chemotherapy to reduce the nadir) of G-CSF to patients receiving cytotoxic regimens associated with a 40% incidence of febrile neutropenia has reduced the incidence of febrile neutropenia in several studies by about 50%. Most patients, however, receive regimens that do not have such a high risk of expected febrile neutropenia, and therefore most patients initially should not receive G-CSF or GM-CSF. Special circumstances such as a documented history of febrile neutropenia with the regimen in a particular patient; extensive compromise of marrow by prior radiation or chemotherapy; or active, open wounds or deep-seated infection may support primary treatment with G-CSF or GM-CSF. Administration of G-CSF or GM-CSF to afebrile neutropenic patients or to patients with low-risk febrile neutropenia as defined above is not recommended, although administration to high-risk patients with febrile neutropenia and evidence of organ compromise is reasonable. G-CSF or GM-CSF is conventionally started 24 to 72 h after completion of chemotherapy and continued until a PMN count of 10,000/μL is achieved. Also, patients with myeloid leukemias undergoing induction therapy may have a slight reduction in the duration of neutropenia if G-CSF (not GM-CSF) is commenced after completion of therapy and may be of particular value in elderly patients, but the influence on long-term outcome has not been defined. GM-CSF probably has a more restricted utility than G-CSF, with its use currently limited to patients after autologous bone marrow transplants, although proper head-to-head comparisons with G-CSF have not been conducted in most instances. GM-CSF may be associated with more systemic side effects.

Dangerous degrees of thrombocytopenia do not frequently complicate the management of patients with solid tumors receiving cytotoxic chemotherapy (with the possible exception of certain carboplatin-containing regimens), but they are frequent in patients with certain hematologic neoplasms where marrow is infiltrated with tumor. Severe bleeding related to thrombocytopenia occurs with increased frequency at platelet counts <20,000/μL and is very prevalent at counts <5000/μL. Prophylactic transfusions to keep platelets >20,000/μL are warranted in patients with leukemia (the threshold for transfusion is

TABLE 70-3 Indications for the Clinical Use of G-CSF or GM-CSF

Preventive Uses
With the first cycle of chemotherapy (so-called primary CSF administration)
Not needed on a routine basis
Use if the probability of febrile neutropenia is ≥40%
Use if patient has preexisting neutropenia or active infection
With subsequent cycles if febrile neutropenia has previously occurred (so-called secondary CSF administration)
Not needed after short duration neutropenia without fever
Use if patient had febrile neutropenia in previous cycle
Use if prolonged neutropenia (even without fever) delays therapy
Therapeutic Uses
Afebrile neutropenic patients
No evidence of benefit
Febrile neutropenic patients
No evidence of benefit
May feel compelled to use in the face of clinical deterioration from sepsis, pneumonia, or fungal infection, but benefit unclear
To augment dose-intensity of chemotherapy in patients with curable malignancies
No evidence of benefit
In bone marrow or peripheral blood stem cell transplantation
Use to mobilize stem cells from marrow
Use to hasten myeloid recovery
In acute myeloid leukemia
G-CSF of minor or no benefit
GM-CSF of no benefit and may be harmful
In myelodysplastic syndromes
Not routinely beneficial
Use intermittently in subset with neutropenia and recurrent infection
What Dose and Schedule Should Be Used?
G-CSF: 5 μg/kg per day subcutaneously
GM-CSF: 250 μg/m^2 per day subcutaneously
When Should Therapy Begin and End?
When indicated, start 24–72 h after chemotherapy
Continue until absolute neutrophil count is 10,000/μL
Do not use concurrently with chemotherapy or radiation therapy

Note: G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

10,000/μL in patients with solid tumors and no other bleeding diathesis or physiologic stressors such as fever or hypotension). Careful review of medication lists to prevent exposure to nonsteroidal anti-inflammatory agents and maintenance of clotting factor levels adequate to support near-normal prothrombin and partial thromboplastin time tests are of import in minimizing the risk of bleeding in the thrombocytopenic patient. Certain cytokines in clinical investigation have shown ability to increase platelets (e.g., IL-6, IL-1, thrombopoietin), but clinical benefit and safety are not yet proven. IL-11 (oprelvekin) is approved for use in the setting of expected thrombocytopenia, but its effects on platelet counts are small and it is associated with side effects such as headache, fever, malaise, syncope, cardiac arrhythmias, and fluid retention.

Anemia associated with chemotherapy can be managed by transfusion of packed RBCs. Transfusion is not undertaken until the hemoglobin falls to <80 g/L (8 g/dL) or if compromise of end-organ function occurs or an underlying condition (e.g., coronary artery disease) calls for maintenance of hemoglobin >90 g/L (9 g/dL). Patients who are to receive therapy for >2 months on a "stable" regimen and who are likely to require continuing transfusions are also candidates for erythropoietin to maintain hemoglobin of 90 to 100 g/L (9 to 10 g/dL). In the setting of adequate iron stores and serum erythropoietin levels <100 ng/mL, erythropoietin, 150 U three times a week, can produce a slow increase in hemoglobin over about 2 months of administration. Depot formulations can be administered less frequently. It is unclear whether higher hemoglobin levels, up to 110 to 120 g/L (11 to 12 g/dL) are associated with improved quality of life to a degree that justifies the more intensive erythropoietin use. In addition, certain treatment regimens, e.g., chemoradiation of cervix and head and neck neoplasms, may have enhanced likelihood of response in association with improved delivery of O_2. Evidence is emerging that erythropoietin may have undesirable effects in that it can rescue hypoxic cells from death. This may be a disadvantage in cancer but a great advantage in the setting of heart attacks and strokes.

Nausea and Vomiting The most common side effect of chemotherapy administration is nausea, with or without vomiting. Antineoplastic agents vary in their capacity to cause nausea and vomiting. Mechlorethamine, nitrosoureas, streptozotocin, DTIC, cisplatin, and actinomycin are highly emetogenic and produce vomiting in virtually all patients. Doxorubicin, daunorubicin, and conventional-dose cyclophosphamide are moderately emetogenic. Antimetabolites are dose- and schedule-dependent, with single doses of methotrexate and fluorouracil producing at worst anorexia; while 5-day regimens of 5FU and high-dose methotrexate produce nausea in ~50% of patients. Other agents such as chlorambucil, melphalan, and busulfan in conventional doses produce little tendency to emesis.

Emesis is a reflex caused by stimulation of the vomiting center in the medulla. Input to the vomiting center comes from the chemoreceptor trigger zone (CTZ) and afferents from the peripheral gastrointestinal tract, cerebral cortex, and heart. In addition, a conditioned reflex may contribute to anticipatory nausea arising after repeated cycles of chemotherapy. Accordingly, antiemesis agents differ in their locus of action. Combining agents from different classes or the sequential use of different classes of agent is the cornerstone of successful management of chemotherapy-induced nausea and vomiting. Of great importance are the prophylactic administration of agents and such psychological techniques as the maintenance of a supportive milieu, counseling, and relaxation to augment the action of antiemetic agents.

Antidopaminergic phenothiazines act directly at the CTZ and include prochlorperazine (Compazine), 10 mg intramuscularly or intravenously, 10 to 25 mg orally, or 25 mg per rectum every 4 to 6 h for up to four doses; and thiethylperazine (Torecan), 10 mg by potentially all the above routes every 6 h. Haloperidol (Haldol) is a butyrophenone dopamine antagonist given at 0.5 to 1.0 mg intramuscularly or orally every 8 h. Antihistamines such as diphenhydramine (Benadryl) have little intrinsic antiemetic capacity but are frequently given to prevent or treat dystonic reactions that can complicate use of the antidopaminergic agents. Lorazepam (Ativan) is a short-acting benzodiazepine that provides an anxiolytic effect to augment the effectiveness of a variety of agents when used at 1 to 2 mg intramuscularly, intravenously, or orally every 4 to 6 h. Dexamethasone (Decadron) likewise augments the action of a variety of agents when used at 4 to 40 mg intravenously or orally, given before treatment and repeated up to 10 mg orally every 6 h four times. Metoclopramide (Reglan) acts on peripheral dopamine receptors to augment gastric emptying and is used in high doses for highly emetogenic regimens (1 to 2 mg/kg intravenously 30 min before chemotherapy and every 2 h for up to three additional doses as needed); intravenous doses of 10 to 20 mg every 4 to 6 h as needed or 50 mg orally 4 h before and 8 and 12 h after chemotherapy are used for moderately emetogenic regimens. Serotonin antagonists are useful in moderately to severely emetogenic regimens; ondansetron (Zofran) is given as 0.15 mg/kg intravenously for three doses just before and at 4 and 8 h after chemotherapy, and granisetron (Kytril) is given as a single dose of 0.01 mg/kg just before chemotherapy. 5-9-Tetrahydrocannabinol (Marinol) is a rather weak antiemetic compared to other available agents, but it may be useful for persisting nausea and is used orally at 10 mg every 3 to 4 h as needed. Aprepitant is the first of a novel class of drugs, neurokinin receptor blockers; its addition to serotonin antagonists improves control of emesis against strongly emetogenic agents such as cisplatin. The usual dose is 125 mg orally on day 1, 80 mg orally on days 2 and 3.

Alopecia Chemotherapeutic agents vary widely in causing alopecia, with anthracyclines, alkylating agents, and topoisomerase inhibitors

reliably causing near total alopecia when given at therapeutic doses. Antimetabolites are more variably associated with alopecia. Psychological support and the use of cosmetic resources are to be encouraged, and "chemo caps" that reduce scalp temperature to decrease the degree of alopecia should be discouraged, particularly during the treatment with curative intent of neoplasms such as leukemia, lymphoma, or in adjuvant breast cancer therapy. The richly vascularized scalp can certainly harbor micrometastatic or disseminated disease.

Gonadal Dysfunction and Pregnancy Cessation of ovulation and azoospermia reliably result from alkylating agent– and topoisomerase poison–containing regimens. The duration of these effects varies with age and sex. Males treated for Hodgkin's disease with mechlorethamine- and procarbazine-containing regimens are effectively sterile, whereas fertility usually returns after regimens including cisplatin, vinblastine, or etoposide and after bleomycin for testicular cancer. Sperm banking before treatment may be considered to support patients likely to be sterilized by treatment. Females experience amenorrhea with anovulation after alkylating agent therapy but are likely to recover normal menses if treatment is completed before age 30 and unlikely to recover menses after age 35. Even those who regain menses usually experience premature menopause. As the magnitude and extent of decreased fertility can be difficult to predict, patients should be counseled to maintain effective contraception, preferably by barrier means, during and after therapy. Resumption of efforts to conceive should be considered in the context of the likely prognosis of the patient. Hormone-replacement therapy should be undertaken in women who do not have a hormonally responsive tumor. For those patients who have had a hormone-sensitive tumor primarily treated by a local modality, conventional practice would counsel against hormone replacement, but this issue is very much a matter for current clinical investigations.

Chemotherapy agents have variable effects on the success of pregnancy (Chap. 6). All agents tend to have increased risk of adverse outcomes when administered during the first trimester, and strategies to delay chemotherapy, if possible, until after this milestone should be considered if the pregnancy is to continue to term. Patients in their second or third trimester can be treated with most regimens for the common neoplasms afflicting women in their child-bearing years with the exception of antimetabolites, particularly antifolates, which have notable teratogenic or fetotoxic effects throughout pregnancy. The need for anticancer chemotherapy per se is infrequently a clear basis to recommend termination of a concurrent pregnancy, although each treatment strategy in this circumstance must be tailored to the individual needs of the patient. →***Chronic effects of cancer treatment are reviewed in Chap. 89.***

BIOLOGIC THERAPY

No postulates resembling principles have emerged from efforts to develop biologic approaches to cancer treatment. The goal of biologic therapy is to manipulate the host-tumor interaction in favor of the host. Theoretically, biologic approaches should reflect a bell-shaped dose-response curve where the maximum biologic effect is less than the MTD. Empirical trial and error has led to the discovery that a number of biologic treatment approaches may produce antitumor effects, but nearly all of them are most active at their MTD. As a class, biologic therapies may be distinguished from molecularly targeted agents in that biologic therapies require an active response (e.g., reexpression of silenced genes) on the part of the tumor cell or on the part of the host (e.g., immunologic effects) to allow therapeutic effect. This may be contrasted with the antiproliferative or apoptotic response that is the ultimate goal of molecularly targeted agents discussed above. However, there is much commonality in the strategies to evaluate and use molecularly targeted and biologic therapies.

IMMUNE MEDIATORS OF ANTITUMOR EFFECTS The very existence of a cancer in a person is testimony to the failure of the immune system to deal effectively with the cancer. Tumors have a variety of means of avoiding the immune system: (1) they are often only subtly different from their normal counterparts; (2) they are capable of downregulating their major histocompatibility complex antigens, effectively masking them from recognition by T cells; (3) they are inefficient at presenting antigens to the immune system; (4) they can cloak themselves in a protective shell of fibrin to minimize contact with surveillance mechanisms; and (5) they can produce a range of soluble molecules, including potential immune targets, that can distract the immune system from recognizing the tumor cell. Some of the cell products initially polarize the immune response away from cellular immunity (shifting from T_H1 to T_H2 responses; Chap. 295) and ultimately lead to defects in T cells that prevent their activation and cytotoxic activity. Cancer treatment further suppresses host immunity. A variety of strategies are being tested to overcome these barriers.

Cell-Mediated Immunity The strongest evidence that the immune system can exert clinically meaningful antitumor effects comes from allogeneic bone marrow transplantation. Adoptively transferred T cells from the donor expand in the tumor-bearing host, recognize the tumor as being foreign, and can mediate impressive antitumor effects (graft-versus-tumor effects). Three types of experimental interventions are being developed to take advantage of the ability of T cells to kill tumor cells.

1. Allogeneic T cells are being transferred to cancer-bearing hosts in three major settings: in the form of allogeneic bone marrow transplantation, as pure lymphocyte transfusions following bone marrow recovery after allogeneic bone marrow transplantation, and as pure lymphocyte transfusions following immunosuppressive (but not myeloablative) therapy (so-called minitransplants). In each of these settings, the effector cells are donor T cells that recognize the tumor as being foreign, probably through minor histocompatibility differences. The main risk of such therapy is the development of graft-versus-host disease because of the minimal difference between the cancer and the normal host cells. This approach has been highly effective in certain hematologic cancers.
2. Autologous T cells are being removed from the tumor-bearing host, manipulated in several ways in vitro, and given back to the patient. The two major classes of autologous T cell manipulation are (1) to develop tumor antigen–specific T cells and expand them to large numbers over many weeks ex vivo before administration, and (2) to activate the cells with polyclonal stimulators such as anti-CD3 and anti-CD28 after a short period ex vivo and try to expand them in the host after adoptive transfer with stimulation by IL-2, for example. Short periods removed from the patient permit the cells to overcome the tumor-induced T cell defects, and such cells traffic and home to sites of disease better than cells that have been in culture for many weeks. Individual centers have successful experiences with one or the other approach but not both, and whether one is superior to the other is not known.
3. Tumor vaccines are aimed at boosting T cell immunity. The finding that mutant oncogenes that are expressed only intracellularly can be recognized as targets of T cell killing greatly expanded the possibilities for tumor vaccine development. No longer is it difficult to find something different about tumor cells. However, major difficulties remain in getting the tumor-specific peptides presented in a fashion to prime the T cells. Tumors themselves are very poor at presenting their own antigens to T cells at the first antigen exposure (*priming*). Priming is best accomplished by professional antigen-presenting cells (dendritic cells). Thus, a number of experimental strategies are aimed at priming host T cells against tumor-associated peptides. Vaccine adjuvants such as GM-CSF appear capable of attracting antigen-presenting cells to a skin site containing a tumor antigen. Such an approach has been documented to eradicate microscopic residual disease in follicular lymphoma and give rise to tumor-specific T cells. Purified antigen-presenting cells can be pulsed with tumor, its membranes, or particular tumor antigens and delivered as a vaccine. Tumor cells can be transfected with genes that attract antigen-presenting cells. Other ideas are also being tested. In a variation on the theme of adop-

tive transfer, the tumor vaccine may be given to the normal bone marrow and lymphoid cell donor of an allogeneic transplant so that the donor immune system has more cells capable of recognizing the tumor specifically. Vaccines against viral cancers (papilloma virus in cervical cancer), lymphomas, and melanomas have had modest clinical success.

Antibodies In general, antibodies are not very effective at killing cancer cells. Because the tumor seems to influence the host toward making antibodies rather than generating cellular immunity, it is inferred that antibodies are easier for the tumor to fend off. Many patients can be shown to have serum antibodies directed at their tumors, but these do not appear to influence disease progression. However, the ability to grow very large quantities of high-affinity antibody directed at a tumor by the hybridoma technique has led to the application of antibodies to the treatment of cancer. The first study of a monoclonal antibody in cancer was published in 1980 and demonstrated many hurdles that needed to be overcome to make the approach successful. It seemed best to attack a determinant that was not shed or modulated by the tumor. A target that was involved in an important function for the tumor cells might be superior to a physiologically irrelevant target. Murine antibodies were not very effective because they did not mediate human effector mechanisms well and the host nearly always made antibodies against the therapeutic antibody that prevented it from finding the target.

The lessons were learned; humanized antibodies against the CD20 molecule expressed on B cell lymphomas (rituximab) and against the HER-2/*neu* receptor overexpressed on epithelial cancers, especially breast cancer (trastuzumab), have become reliable tools in the oncologists armamentarium. Each used alone can cause tumor regression (rituximab > trastuzumab), and both appear to potentiate the effects of combination chemotherapy given just after antibody administration. Antibodies to CD52 and vascular endothelial growth factor are active in chronic lymphoid leukemia and colon cancer, respectively. Conjugation of antibodies to drugs and toxins was discussed above, and conjugates of antibodies with isotopes, photodynamic agents, and other killing moieties may also be effective. Radioconjugates targeting CD20 on lymphomas have been approved for use [ibritumomab tiuxetan (Zevalin), using yttrium-90)]. Other conjugates are associated with problems that have not yet been solved (e.g., antigenicity, instability, poor tumor penetration).

Cytokines There are >70 separate proteins and glycoproteins with biologic effects in humans: IFN-α, -β, -γ; IL-1 through -29 (so far); the TFN family [including lymphotoxin, TFN-related apoptosis-inducing ligand (TRAIL), CD40 ligand, and others]; and the chemokine family. Only a fraction of these has been tested against cancer; only IFN-α and IL-2 are in routine clinical use.

About 20 different genes encode IFN-α, and their biologic effects are indistinguishable. Interferon induces the expression of many genes, inhibits protein synthesis, and exerts a number of different effects on diverse cellular processes. Its antitumor effects appear to be antagonized in vitro by thymidine, suggesting that de novo thymidylate synthesis is also affected. The two recombinant forms that are commercially available are IFN-α2a and -α2b. In general, interferon antitumor effects are dose-related, and IFN is most effective at its MTD. Interferon is not curative for any tumor but can induce partial responses in follicular lymphoma, hairy cell leukemia, CML, melanoma, and Kaposi's sarcoma. It has been used in the adjuvant setting in stage II melanoma, multiple myeloma, and follicular lymphoma, with uncertain effects on survival. It produces fever, fatigue, a flulike syndrome, malaise, myelosuppression, and depression and can induce clinically significant autoimmune disease.

IL-2 must exert its antitumor effects indirectly through augmentation of immune function. Its biologic activity is to promote the growth and activity of T cells and natural killer (NK) cells. High doses of IL-2 can produce tumor regressions in certain patients with metastatic melanoma and renal cell cancer. About 2 to 5% of patients may experience complete remissions that are durable, unlike any other treatment for these tumors. IL-2 is associated with myriad clinical side effects: intravascular volume depletion, capillary leak syndrome, adult respiratory distress syndrome, hypotension, fever, chills, skin rash, and impaired renal and liver function. Patients may require blood pressure support and intensive care to manage the toxicity. However, once the agent is stopped, most of the toxicities reverse completely within 3 to 6 days.

GENE THERAPIES

No gene therapy has been approved for routine clinical use. Several strategies are under evaluation, including the use of viruses that cannot replicate to express genes that can allow the action of drugs or directly inhibit cancer cell growth; viruses that can actually replicate but only in the context of the tumor cell; or viruses that can express antigens in the context of the tumor and therefore provoke a host-mediated immune response. Key issues in the success of these approaches will be in defining safe viral vector systems that escape host immune function and effectively target the tumor or tumor cell milieu. Other gene therapy strategies would utilize therapeutic oligonucleoides to target the expression of genes important in the maintenance of tumor cell viability.

71 PRINCIPLES OF RADIATION THERAPY

Stephen M. Hahn, Eli Glatstein

All human beings are constantly exposed to ionizing radiation. Environmental sources include the cosmic radiation from space and radiation from the ground and from inhaled and ingested materials. Airline travel and mining both increase exposure to the background radiation. For example, air travel at 30,000 ft exposes individuals to a dose equivalent of 0.5 mrem/h. Radiation originating in the body comes mainly from radioactive potassium, which emits beta and gamma rays. Lungs are exposed to radiation from inhaled air, which contains small amounts of radioactive radon. Cosmic exposure contributes ~28 mrem per year. The ground and internal sources contribute ~26 and 27 mrem per year, respectively. The most prominent man-made sources of radiation include x-ray equipment, nuclear weapons, and radioactive medications.

TERMINOLOGY AND DEFINITIONS

The first major unit of radiation exposure was the roentgen (R), defined as an amount of x-rays or gamma rays that produces a specific amount of ionization in a unit of air under standard temperature and pressure (Table 71-1); this quantity can be measured directly in an ionization chamber. The rad (*r*adiation *a*bsorbed *d*ose) is defined as 100 ergs/g of tissue. Thus, the rad represents a net deposition of energy in a three-dimensional volume, because x-rays attenuate as they traverse tissue. The rad has been replaced by the Système Internationale (SI) unit of the gray (Gy), which represents 100 rad. Roentgens and rads can be

TABLE 71-1 *Units and Definitions*

Unit	Quantity Measured	Definition
Roentgen (R)	Exposure	Amount of x-rays or gamma rays that produces a specific amount of ionization in a given volume of air
Rad	Dose	100 ergs deposited per gram of tissue
Gray (Gy)	Dose	SI unit of dose; equals 100 rad
Rem	Dose equivalence	Unit that reflects the biologic response. It is used to compare various types of radiation
Sievert (Sv)	Dose equivalence	SI unit of dose equivalence; equals 100 rem

converted by means of various tables; the relation between them depends on photon energy.

The above definitions reflect physical variables. The unit that reflects the biologic response and that can be used to compare the effects of various types of radiation is the unit of dose equivalence, the rem (*r*oentgen *e*quivalent in *m*an). The rem has been replaced by the SI unit, the sievert (Sv), which equals 100 rem. These units reflect the exposure or absorption dose multiplied by a biologic factor that represents the biologic effectiveness of the specific type of radiation (see below).

TYPES OF IONIZING RADIATION

The absorption of energy from radiation in tissue often leads to excitation or ionization. Excitation involves elevation of an electron in an atom or molecule to a higher energy state without actual ejection of the electron. Ionization involves actual ejection of one or more electrons from the atom. Ionizing radiation is subclassified as electromagnetic (photon) or particulate radiation (Table 71-2). X-rays and gamma rays are examples of electromagnetic photon radiation; they differ only in their source. X-rays are produced mechanically, by making electrons strike a target, which causes the electrons to give up their kinetic energy as x-rays, while gamma rays are produced by nuclear disintegration of radioactive isotopes.

X-rays can be thought of as packets of energy, or photons. X-rays have no mass or charge, travel in straight lines, and attenuate continuously as they traverse tissue. Gamma rays have similar properties. Each photon contains an amount of energy equal to $h\nu$, where h is Planck's constant and ν is the radiation frequency. The critical difference between nonionizing and ionizing radiation is the energy of individual photons, not the energy of the total dose.

Types of *particulate radiation* include electrons, protons, alpha particles, neutrons, negative pi-mesons, and heavy charged ions; these have discrete mass and charge (except for neutrons, which lack charge; Table 71-2). *Electrons*, or *beta particles*, are small and negatively charged and can be accelerated to close to the speed of light. They decelerate fairly rapidly in tissue and penetrate it to only a limited depth. Thus, electron beams are often used to treat superficial problems. *Protons* are positively charged and have a mass about 2000 times that of an electron. Protons stop abruptly, depending on their energy; in the process of sudden deceleration, most of their energy is given up, which tends to cause ionization just before the proton stops. This region of enhanced ionization, sometimes called the Bragg peak, means that proton beams exert their effects in a relatively compact region. Therefore, protons may have advantages over other types of particulate radiation with respect to conforming the dose to the treatment volume. *Alpha particles* are helium nuclei, consisting of two protons and two neutrons. The mass and charge are great enough that these particles do not penetrate far through matter unless they have tremendous energy; even a piece of paper is enough to protect against most alpha particles. Because these particles are charged, they can be accelerated in electrical fields.

TABLE 71-2 *Common Types of Ionizing Radiation*

Type	Mass	Charge	Comment
Electromagnetic			
X-ray	0	0	X-rays and gamma rays do not differ except in the source. Gamma rays are produced intranuclearly, and x-rays are produced extranuclearly (i.e., mechanically).
Gamma ray	0	0	
Particulate			
Electron (e)	9.1×10^{-31} kg	−1	—
Proton (p)	$2000 \times$ e	+1	Exhibits a Bragg peak
Neutron (n)	$2000 \times$ e	0	Cannot be accelerated by an electrical field
Alpha particle	2p + 2n ~8000 × e	+2	Helium nucleus

Neutrons are similar in mass to protons (having an atomic mass of 1), but they are not charged and therefore cannot be accelerated in an electrical field. Neutron beams are produced by colliding charged particles into a suitable target or are emitted as a fission product of heavy radioactive atoms. *Heavy charged ions* are nuclei of heavier elements that have a positive charge owing to the stripping away of some or all of the orbiting electrons.

Equal doses of different types of radiation do not necessarily produce equal biologic effects; thus 1 Gy of neutrons produces a greater biologic effect than 1 Gy of x-rays. The biologic effects produced by a given dose of radiation can be quantified by the relative biologic effectiveness (RBE) value, which relates them to the effects produced by 250-keV photon radiation as a standard. In general, the greater the RBE value for a given type of radiation, the greater the biologic effect. The RBE value will be greater for more densely ionizing radiation, such as neutrons. The RBE value depends on the linear energy transfer (see below), the dose, the dose rate, and the nature of the biologic system.

The linear energy transfer (LET) is the amount of ionization occurring per unit length of the radiation track. It is usually expressed as kilovolts per micron and increases with the square of the charge of the incident particle. High-LET radiation is biologically different from low-LET (i.e., conventional) radiation: Hypoxic and oxygenated cells respond similarly to high-LET irradiation, whereas it takes about three times as much low-LET radiation to produce a given killing effect in hypoxic cells as in oxygenated cells. It is thought that low-LET radiation must produce multiple hits on DNA to destroy a cell, whereas high-LET radiation need produce only a single hit on DNA to kill a cell. Representative values of LET and RBE are given in Table 71-3.

Radiation, especially x-rays, is absorbed and causes ionization in three major ways: the *photoelectric effect*, the *Compton effect*, and *pair production*. At low energies (30 to 100 keV), as in diagnostic radiology, the photoelectric effect is important. In this process, the incident photon interacts with an electron in one of the outer shells of an atom (typically K, L, or M). If the energy of the photon is greater than the

TABLE 71-3 *Linear Energy Transfer and Relative Biologic Effectiveness Values*

Type of Radiation	LET Values, keV/μm
Cobalt-60 gamma rays	0.2
250-keV x-rays	2.0
10 MeV protons	4.7
Type of Radiation	**RBE Values (Quality Factors)**
X-rays, gamma rays, and electrons	1
Neutrons	3–20
Heavy particles	1–20

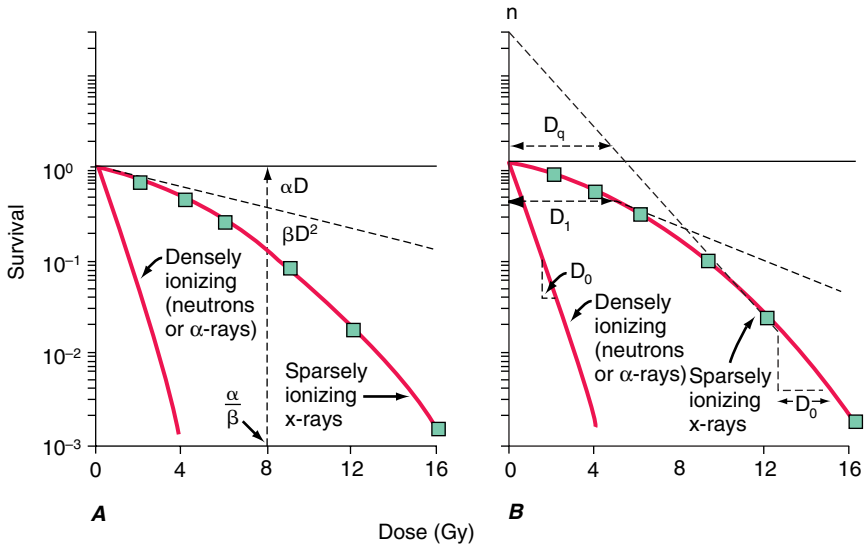

FIGURE 71-1 Shape of survival curve for mammalian cells exposed to radiation. The fraction of cells surviving is plotted on a logarithmic scale against dose on a linear scale. For alpha particles or low-energy neutrons (said to be densely ionizing), the dose-response curve is a straight line from the origin (i.e., survival is an exponential function of dose). The survival curve can be described by just one parameter, the slope. For x-rays or gamma rays (said to be sparsely ionizing), the dose-response curve has an initial linear slope, followed by a shoulder; at higher doses the curve tends to become straight again. *A*. The experimental data are fitted to a linear-quadratic function. There are two components of cell killing: one is proportional to dose (αD), while the other is proportional to the square of the dose (βD^2). The dose at which the linear and quadratic components are equal is the ratio α/β. The linear-quadratic curve bends continuously but is a good fit to experimental data for the first few decades of survival. *B*. The curve is described by the initial slope (D_1), the final slope (D_0), and a parameter that represents the width of the shoulder, either *n* or D_q. *(From Hall, with permission.)*

binding energy of the electron, then the electron is expelled from the orbit with a kinetic energy that is equal to the energy of the incident photon minus the binding energy of the electron. The photoelectric effect varies as a function of the cube of the atomic number of the material exposed (Z^3); this fact explains why bone is visualized much better than soft tissue on radiographs.

At higher energies, as used in therapeutic radiology, the Compton effect dominates. In this process, the incident photon interacts with an electron in an orbital shell. Part of the incident photon energy appears as kinetic energy of electrons, and the residual energy continues as a less energetic deflected photon.

At energy levels >1.02 MeV, the photons may be absorbed through pair production. In this process, both a positron and an electron are produced in the absorbing material. A positron has the same mass as an electron but has a positive instead of a negative charge. The positron travels a very short distance in the absorbing medium before it interacts with another electron. When that happens, the entire mass of both particles is converted to energy, with the emission of two photons in exactly opposite directions.

BIOLOGIC EFFECTS OF RADIATION

Radiation must produce double-strand breaks in DNA to kill a cell, owing partly to the high capacity of mammalian cells for repairing single-strand damage. Radiation can also produce effects indirectly by interacting with water (which makes up ~80% of a cell's volume) to generate free radicals, which can damage the cell. Free radicals are highly reactive chemical entities that lack a stable number of outer-shell electrons. A free radical is not stable and has a life span of a fraction of a second. It is estimated that most x-ray-induced cell damage is due to the formation of hydroxyl radicals, as follows:

$$\text{Ionizing radiation} + H_2O \rightarrow H_2O^+ + e^-$$
$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH\bullet$$
$$OH\bullet \rightarrow \text{Cell damage}$$

The usual end result of radiation damage is cell death. The biologic effects on epithelial cell reproduction are typically expressed only when the damaged cells attempt to divide. Another biologic effect is the induction of cancerous growth by mutation many years after radiation exposure. Patients who receive radiation have a significant risk of neoplasm for at least two to three decades after their exposure; this risk is significantly higher than that of the population as a whole.

RADIATION-INDUCED CHROMOSOME ABERRATIONS

Chromosome breaks can occur when cells are irradiated. The broken ends of chromosomes can combine with broken ends of different chromosomes. These abnormal combinations are most readily seen during mitosis. Chromosome abnormalities typically occur in cells irradiated in the G_1 phase of the cell cycle, before the doubling of genetic material. If cells are irradiated in the G_2 phase, chromatid aberrations may result. The frequency of chromosomal aberrations in peripheral circulating lymphocytes can be used to correlate with the total body dose received. The dose can be estimated by comparing the chromosomal changes to in vitro cultures exposed to controlled doses of irradiation. The minimum dose that can be detected by peripheral lymphocyte analysis is about 0.1 to 0.2 Sv (10 to 20 rem). Lymphocyte analysis may provide evidence of recent total-body exposure.

CELL SURVIVAL CURVE

The dose-response curve for all mammalian cells appears to have a linear-quadratic relationship. In simple terms, the mathematical model that explains the relationship between the dose and the fraction of surviving cells has both linear and exponential components. The linear component results from double-stranded chromosomal breaks produced by single hits. The exponential component represents breaks produced by multiple hits. Figure 71-1 shows the shape of a typical survival curve for mammalian cells exposed to radiation. The fraction of cells surviving is plotted on a semilogarithmic scale. For x-rays or gamma rays, the dose-response curve has a shoulder that is followed by a straight line curve as the dose is increased. The shoulder appears to represent the cell's ability to repair sublethal injury. For alpha particles or lower energy neutrons, the dose-response curve is a straight line from the origin. Thus, the survival rate is an exponential function of the dose.

In all mammalian cell lines studied, increases in the radiation dose decrease the survival rate of cells. However, a number of factors may contribute to a reduced sensitivity to radiation in human tumors in vivo, including extrinsic factors such as hypoxia and intrinsic factors such as expression of particular oncogenes, including *ras*. The biologic basis for this altered sensitivity to radiation has not been fully defined.

Four important processes that occur after radiation exposure can be summarized as the "four R's" of radiobiology. The first is *repair*. Repair is temperature dependent and is thought to represent the enzymatic mechanisms for healing intracellular injury. The second R is *reoxygenation*, a process whereby oxygen (and other nutrients) are actually better distributed to viable cells following radiation injury and cell killing. The third R is *repopulation*, the ability of the cell population to continue to divide and to replace dying and dead cells. The fourth R is *redistribution*, which reflects the variability of a cell's radiosensitivity over the cell cycle. Radiosensitivity can vary through the cell cycle by as much as a factor of 3. The G_1 phase has the most variable length of all the phases of the cell cycle. For most cell lines, cells that have a short G_1 period are most sensitive at the G_2/mitosis interface, less sensitive in G_1, and most resistant toward the end of the synthesis (S) period.

Radiation therapy is effective in cancer treatment when it exerts greater cytotoxic effects on tumor cells than on normal tissues (i.e., improving the therapeutic index). A major determinant of the therapeutic index is exploiting differences in the four R's between tumor cells and normal tissues. Fractionated radiation exploits differences in the four R's between tumor and normal tissues, thereby improving the therapeutic index.

NORMAL TISSUE EFFECTS OF RADIATION Therapeutic radiation leads to acute effects that typically manifest during treatment and resolve a few weeks after the completion of therapy. Late effects are also produced by radiotherapy and typically do not occur until several months or years after treatment is delivered. The clinical response to radiation may be related to the interactions of various growth factors and cytokines. For example, radiation can induce growth factors and cytokines such as tumor necrosis factor (TNF) and interleukin (IL) 1. TNF can induce proliferation of fibroblasts and enhance the inflammatory response. TNF and IL-1 have been shown to radioprotect hematopoietic cells in vitro by increasing the D_0 of the cell survival curve (Fig. 71-1). TNF also enhances killing of a human tumor cell line by irradiation. TNF may produce radioprotection or radiosensitization, depending on the cell type. Efforts to modulate radiation effects with TNF remain experimental. Other factors implicated in the radiation response are basic fibroblast growth factor and platelet-derived growth factor β, which may be associated with late effects of radiation on vessels.

The degree and the duration of functional recovery of normal tissues are related to the number of stem cells surviving after irradiation. If the stem cells are destroyed in the irradiated volume and replacement from adjacent tissues is inadequate, radiation injury will persist, causing late toxic effects. True late effects develop independent of early reactions; they may also occur despite recovery from acute radiation injury.

Table 71-4 shows the frequency of radiation tolerance seen with fractionated radiotherapy at 5 years of follow-up. These numbers are rough estimates at best. The clinical manifestations of irradiation will depend on the volume of the organ irradiated, the total dose, the dose per fraction, and the length of time taken to deliver the dose, and probably genetic/biologic factors. Dose per fraction is the most important factor determining normal tissue effects. This is why daily fractionation doses of 180 cGy to 200 cGy are used in most curative treatment situations. In addition, the cellular consequences of treatment can be progressive over time. Thus, length of follow-up is also crucial in judging late clinical sequelae from radiation.

THERAPEUTIC RADIATION Radiation therapy is a physical form of treatment that damages any tissue in its path. In the target tissue, radiation damages DNA (usually single-strand breaks) and generates free radicals from cell water that are capable of damaging cell membranes, proteins, and organelles. Radiation damage is dependent on oxygen; hypoxic cells are more resistant. Augmentation of oxygen is the basis for radiation sensitization. Sulfhydryl compounds interfere with free radical generation and may act as radiation protectors. The challenge for radiation treatment planning is to deliver the radiation to the tumor volume with as little normal tissue in the field as possible.

Therapeutic radiation is delivered in three ways: *teletherapy*, with beams of radiation generated at a distance and aimed at the tumor within the patient; *brachytherapy*, with encapsulated sources of radiation implanted directly into or adjacent to tumor tissues; and *systemic therapy*, with radionuclides targeted in some fashion to a site of tumor. Teletherapy is the most commonly used form of radiation therapy.

Radiation from any source decreases in intensity as a function of the square of the distance from the source (inverse square law). Thus, if the radiation source is 5 cm above the skin surface and the tumor is 5 cm below the skin surface, the intensity of radiation in the tumor will be $5^2/10^2$, or 25% of the intensity at the skin. By contrast, if the radiation source is moved to 100 cm from the patient, the intensity of radiation in the tumor will be $100^2/105^2$, or 91% of the intensity at the skin. Teletherapy maintains intensity over a larger volume of target tissue by increasing the source-to-surface distance. In brachytherapy, the source-to-surface distance is small; thus, the effective treatment volume is small.

X-rays and gamma rays are the forms of radiation most commonly used to treat cancer. They are both electromagnetic, nonparticulate waves that cause the ejection of an orbital electron when absorbed. This orbital electron ejection is called *ionization*. X-rays are generated by linear accelerators; gamma rays are generated from decay of atomic nuclei in radioisotopes such as cobalt and radium. These waves behave biologically as packets of energy, called *photons*. Particulate forms of radiation are also used in certain circumstances. Electron beams have a very low tissue penetrance and are used to treat skin conditions such as mycosis fungoides. Neutron beams may be somewhat more effective than x-rays in treating salivary gland tumors. However, aside from these specialized uses, particulate forms of radiation such as neutrons, protons, and negative mesons, which should do more tissue damage because of their higher LET and be less dependent on oxygen, have not yet found wide applicability to cancer treatment.

A number of parameters influence the damage done to tissue by radiation. Hypoxic cells are relatively resistant. Nondividing cells are more resistant than dividing cells. In addition to these biologic parameters, physical parameters of the radiation are also crucial. The energy of the radiation determines its ability to penetrate tissue. Low-energy orthovoltage beams (150 to 400 kV) scatter when they strike the body, much like light diffuses when it strikes particles in the air. Such beams result in more damage to adjacent normal tissues and less radiation delivered to the tumor. Megavoltage radiation (>1 MeV) has very low lateral scatter; this produces a skin-sparing effect, more homogeneous distribution of the radiation energy, and greater deposit of the energy in the tumor, or *target volume*. The tissues that the beam passes through to get to the tumor are called the *transit volume*. The maximum dose in the target volume is often the cause of complications to tissues in the transit volume, and the minimum dose in the target volume influences the likelihood of tumor recurrence. Dose homogeneity in the target volume is the goal.

Radiation is quantitated on the basis of the amount of radiation absorbed in the patient, not based upon the amount of radiation generated by the machine. Radiation dose is measured by placing detectors at the body surface or calculating the dose based on radiating phantoms that resemble human form and substance. Radiation dose has three determinants: total absorbed dose, number of fractions, and time. A frequent error is to omit the number of fractions and the duration of treatment. This is analogous to saying that a runner completed a race in 20 s; without knowing how far he or she ran, the result is difficult to interpret. The time could be very good for a 200-m race or very

TABLE 71-4 *Class 1 Organs: Fatal or Severe Morbidity Following Cumulative Doses of Radiation Delivered with Standard Fractionation*

Organ	Injury	$TD_{5/5}$[a]	$TD_{50/5}$[b]	Whole or Partial Organ (Field Size or Length)
Bone marrow	Aplasia, pancytopenia	250	450	Whole
		3000	4000	Segmental
Liver	Acute and chronic hepatitis	2500	4000	Whole
		1500	2000	Whole (strip)
Stomach	Perforation, ulcer, hemorrhage	4500	5500	100 cm
Intestine	Ulcer, perforation, hemorrhage	4500	5500	400 cm
		5000	6500	100 cm
Brain	Infarction, necrosis	5000	6000	Whole
Spinal cord	Infarction, necrosis	4500	5500	10 cm
Heart	Pericarditis, pancarditis	4500	5500	60%

poor for a 100-m race. Thus, a typical course of radiation therapy should be described as 4500 cGy delivered to a particular target (e.g., mediastinum) over 5 weeks in 180-cGy fractions. Most curative radiation treatment programs are delivered once a day, 5 days a week in 150- to 200-cGy fractions.

Although radiation can interfere with many cellular processes, many experts feel that a cell must undergo a double-strand DNA break from radiation in order to be killed. The factors that influence tumor cell killing include the D_0 of the tumor (the dose required to deliver an average of one lethal hit to all the cells in a population), the D_q of the tumor (the threshold dose—a measure of the cell's ability to repair sublethal damage), hypoxia, tumor mass, growth fraction, and cell cycle time and phase (cells in late G_1 and S are more resistant). Rate of clinical response is not predictive; some cells do not die after radiation exposure until they attempt to replicate.

Compounds that incorporate into DNA and alter its stereochemistry (e.g., halogenated pyrimidines, cisplatin) augment radiation effects. Hydroxyurea, another DNA synthesis inhibitor, also potentiates radiation effects. Compounds that deplete thiols (e.g., buthionine sulfoximine) can also augment radiation effects. Hypoxia is a major factor that interferes with radiation effects.

APPLICATION TO PATIENTS ■ Teletherapy Radiation therapy can be used alone or together with chemotherapy to produce cure of localized tumors and control of the primary site of disease in tumors that have disseminated. Therapy is planned based on the use of a simulator with the treatment field or fields designed to accommodate an individual patient's anatomic features. Individualized treatment planning employs lead shielding tailored to shape the field and limit the radiation exposure of normal tissue. Often the radiation is delivered from two or three different positions. Conformal three-dimensional treatment planning permits the delivery of higher doses of radiation to the target volume without increasing complications in the transit volume.

Radiation therapy is a component of curative therapy for a number of diseases including breast cancer, Hodgkin's disease, head and neck cancer, prostate cancer, and gynecologic cancers. Radiation therapy can also palliate disease symptoms in a variety of settings: relief of bone pain from metastatic disease, control of brain metastases, reversal of spinal cord compression and superior vena caval obstruction, shrinkage of painful masses, and opening threatened airways. In high-risk settings, radiation therapy can prevent the development of leptomeningeal disease and brain metastases in acute leukemia and lung cancer.

Brachytherapy Brachytherapy involves placing a sealed source of radiation into or adjacent to the tumor and withdrawing the radiation source after a period of time precisely calculated to deliver a chosen dose of radiation to the tumor. This approach is often used to treat brain tumors and cervical cancer. The difficulty with brachytherapy is the short range of radiation effects (the inverse square law) and the inability to shape the radiation to fit the target volume. Normal tissue may receive substantial exposure to the radiation, with attendant radiation enteritis or cystitis in cervix cancer or brain injury in brain tumors.

Radionuclides and Radioimmunotherapy Nuclear medicine physicians or radiation oncologists may administer radionuclides with therapeutic effects. Iodine 131 is used to treat thyroid cancer as iodine is naturally taken up preferentially by the thyroid. It emits gamma rays that destroy the normal thyroid as well as the tumor. Strontium 89 and samarium 153 are two radionuclides that are preferentially taken up in bone, particularly sites of new bone formation. Both are capable of controlling bone metastases and the pain associated with them, but the dose-limiting toxicity is myelosuppression.

Monoclonal antibodies and other ligands can be attached to radioisotopes by conjugation (for nonmetal isotopes) or by chelation (for metal isotopes), and the targeting moiety can result in the accumulation of the radionuclide preferentially in tumor. Iodine 131–labeled anti-CD20 and yttrium 90–labeled anti-CD20 are active in B cell lymphoma, and other labeled antibodies are being evaluated. Thyroid uptake of labeled iodine is blocked by cold iodine. Dose-limiting toxicity is myelosuppression.

Photodynamic Therapy Some chemical structures (porphyrins, phthalocyanines) are selectively taken up by cancer cells by mechanisms not fully defined. When light, usually delivered by a laser, is shone on cells containing these compounds, free radicals are generated and the cells die. Hematoporphyrins and light are being used with increasing frequency to treat skin cancer; ovarian cancer; and cancers of the lung, colon, rectum, and esophagus. Palliation of recurrent locally advanced disease can sometimes be dramatic and last many months.

TOXICITY Though radiation therapy is most often administered to a local region, systemic effects, including fatigue, anorexia, nausea, and vomiting, may develop related in part to the volume of tissue irradiated, dose fractionation, radiation fields, and individual susceptibility. Bone is among the most radioresistant organs, radiation effects being manifested mainly in children through premature fusion of the epiphyseal growth plate. By contrast, the male testis, female ovary, and bone marrow are the most sensitive organs. Any bone marrow in a radiation field will be eradicated by therapeutic irradiation. Organs with less need for cell renewal, such as heart, skeletal muscle, and nerves, are more resistant to radiation effects. In radiation-resistant organs, the vascular endothelium is the most sensitive component. Organs with more self-renewal as a part of normal homeostasis, such as the hematopoietic system and mucosal lining of the intestinal tract, are more sensitive. Acute toxicities include mucositis, skin erythema (ulceration in severe cases), and bone marrow toxicity. Often these can be alleviated by interruption of treatment.

Chronic toxicities are more serious. Radiation of the head and neck region often produces thyroid failure. Cataracts and retinal damage can lead to blindness. Salivary glands stop making saliva, which leads to dental caries and poor dentition. Taste and smell can be affected. Mediastinal irradiation leads to a threefold increased risk of fatal myocardial infarction. Other late vascular effects include chronic constrictive pericarditis, lung fibrosis, viscus stricture, spinal cord transection, and radiation enteritis. A serious late toxicity is the development of second solid tumors in or adjacent to the radiation fields. Such tumors can develop in any organ or tissue and occur at a rate of about 1% per year beginning in the second decade after treatment. Some organs vary in susceptibility to radiation carcinogenesis. Women under age 30 experience a $\geq$100-fold increase in the incidence of breast cancer after chest or mantle-field radiation; women treated after age 30 have little or no increased risk of breast cancer. No data suggest that a threshold dose of therapeutic radiation exists below which the incidence of second cancers is decreased. High rates of second tumors have been documented in people who receive as little as 1000 cGy.

Central Nervous System Traditionally, the central nervous system (CNS) has been described as relatively resistant to radiation-induced changes. When the human brain is treated with standard fractionation (180 to 200 cGy/d), acute reactions are seldom observed.

Subacute CNS reactions to radiation treatment are more common. The clinical manifestations may include *Lhermitte's sign*, which is a self-limited paresthesia occurring with flexion of the neck. It is believed to be due to transient demyelination of the spinal cord following significant radiation exposure. It can be seen 1 to 3 months after completion of radiation treatment to the spinal cord. The frequency of Lhermitte's sign varies according to the type of radiation therapy and has been reported to be as high as 15% after mantle-field radiation. Mild encephalopathy and focal neurologic changes can also occur after irradiation limited to the cranium. If radiation treatments to the brain are given at the same time that chemotherapeutic agents are administered, the effects can be more severe, presumably reflecting altered permeability to the drugs. The effect of cranial irradiation is believed to be secondary to radiation effects on the replicating oligodendrocytes

and possibly on the microvasculature. Both clinical and radiologic changes may simulate tumor progression and can often pose diagnostic and treatment dilemmas. A typical example of this kind of conundrum would be attempting to distinguish clinically between radionecrosis and recurrent tumor in patients with gliomas after radiotherapy.

Postirradiation pathology and associated clinical symptoms typically begin 6 to 36 months after radiation therapy and are related to the total dose and volume treated. Fraction size appears to be the most important variable affecting the rate of postirradiation brain necrosis. Neurocognitive changes can also be seen in children after cranial irradiation. The important pretreatment factors that predict the degree of late CNS effects include the age of the patient when cranial irradiation was given and neurocognitive functional level at the time of treatment.

A unique late effect of cranial irradiation combined with chemotherapy, known as *leukoencephalopathy*, has been described in some patients. Leukoencephalopathy is a necrotizing reaction usually noted 4 to 12 months after combined treatment with methotrexate and cranial irradiation. Dementia and dysarthria are often observed and may progress to seizures, ataxia, or death.

Transverse myelitis after radiation treatment is a spinal cord reaction similar to cerebral necrosis. This syndrome consists of progressive and irreversible leg weakness and loss of bladder function and sensation referrable to a single spinal cord level. Flaccid paralysis eventually occurs. Symptoms can occur as early as 6 months after radiation treatment, but the usual time to onset is 12 to 24 months. Lhermitte's sign does not correlate with transverse myelitis.

Skin Skin reaction can be seen within 2 weeks of fractionated radiotherapy, a delay that correlates with the time required for cells to move from the basal to the keratinized layer of skin. The severity of the reaction depends on the skin dose per fraction and the total dose delivered to an area of skin. Erythema is observed, soon followed by dry desquamation. The skin at this time can be erythematous, warm, and sometimes edematous. The vessels in the upper dermis are dilated, and inflammatory infiltration with granulocytes, macrophages, eosinophils, plasma cells, and lymphocytes is noted.

When a severe skin reaction occurs, it is usually located where the beam strikes the skin tangentially. *Moist desquamation* consists of eruption of the epidermal layer. Healing is through reepithelialization from cells of less affected basal layers. When skin reactions are severe, treatment interruptions are needed to permit healing.

Dry desquamation is treated conservatively. Symptoms of dryness can be alleviated by advising the patient to wear only cotton fabric next to the affected skin and to refrain from the use of irritants of any kind. If treatment becomes necessary, hydrophilic agents that do not contain heavy metals are recommended. Moist desquamation is best managed by leaving the affected area dry and open to air.

A chronic reaction to radiation can be seen starting 6 to 12 months after irradiation. The epidermis may become atrophic and may be more easily injured than normal skin. Interstitial fibrosis and telangiectasia may also be increased. Hyperpigmentation of irradiated skin outlining the treatment field can be seen within a couple of months after completion of irradiation. This will fade gradually. The skin becomes thin, and hair loss may be permanent. Radiation therapy can induce second malignancies, which tend to be more aggressive than cancers arising in patients without significant radiation exposure.

Heart and Blood Vessels When cardiac disease appears after radiation treatment, it is often difficult to tell to what extent the radiation treatment was causative. The pathogenesis of atherosclerotic heart disease is multifactorial. Exposure of a large heart volume to high-dose radiation therapy accelerates the development of coronary artery disease. Acute "pericarditis" may result from cardiac irradiation. The symptoms may include chest pain and fever, with or without pericardial effusion. This syndrome is usually self-limited and typically manifests itself a few months after treatment. Asymptomatic pericardial effusion may be the most common manifestation of radiation-induced heart disease. It is usually detected by chest x-ray and confirmed by an echocardiogram.

Most patients with symptomatic radiation-induced constrictive pericarditis will have received >40 Gy to a large portion of the heart. The risk increases significantly with cardiac doses >50 Gy.

Chronic cardiac changes may have their onset from 6 months to several years after irradiation. The clinical symptoms may indicate chronic constrictive disease due to pericardial, myocardial, and endocardial fibrosis—a pancarditis. The clinical signs may include dyspnea, chest pain, venous distention, pleural effusion, and paradoxical pulse.

Lung The clinical symptoms of radiation pneumonitis can be separated into early and late phases. During the early phase, clinical manifestations may include dyspnea, cough, and fever. Shortness of breath is relatively infrequent. It is more common to observe only the radiologic changes on a chest x-ray, without clinical symptoms. The clinical signs and symptoms of radiation pneumonitis may appear in 3 to 6 weeks if a large region of lung is irradiated to a dose >25 Gy. An infiltrate outlining the treatment field may become evident on the chest x-ray. Radiation changes rarely occur outside the treated field. Computed tomography can often help in distinguishing radiation pneumonitis from other causes of the infiltrate. The frequency of radiation pneumonitis can be reduced with careful treatment planning designed to lower the total dose given to the treated lung volume. Permanent scarring that results in respiratory compromise may develop if the dose and the volume of lung irradiated are excessive. Dyspnea and cough may be severe and debilitating.

Patients with symptoms of radiation pneumonitis may respond rapidly to glucocorticoids, but the medication has little effect on fibrotic changes. Glucocorticoids must be tapered very slowly to avoid rebound exacerbation of symptoms, which can prove lethal for some patients. Prophylactic administration of glucocorticoids is of no proven merit. Supportive care includes bronchodilators and oxygen at the lowest possible $F_{I_{O_2}}$.

Digestive Tract Pathologic changes of the epithelial layer occur early during radiation treatments. The underlying submucosa may become edematous, with dilation of capillaries. Recovery from radiation damage can be expected within a few weeks after completion of radiation therapy, provided that sufficient numbers of stem cells are left. The radioresponsiveness of the aerodigestive tract, like that of other structures, is not uniform but varies according to the location.

Patients often have symptoms from radiation exposure that are similar to other forms of acute gastritis. The clinical signs include epigastric pain, loss of appetite, nausea, and vomiting. Decreased gastric acidity is observed after 15 to 20 Gy of fractionated radiation therapy. The tolerance of the stomach to radiation is also aggravated by addition of systemic chemotherapy, such as 5-fluorouracil.

The germinal centers of the bowel mucosa are in the crypts of Lieberkühn. Newly formed cells move upward along the walls of the crypts as transitional cells, undergoing maturation. The epithelial lining of the small bowel is the most rapidly renewed system in the human body and is completely renewed in 3 to 6 days. Within 12 to 24 h after the first dose of radiation therapy, pathologic evidence of dead cells are seen in the mucosal lining. Complete denudation of the mucosal surface rarely occurs during a regular course of radiation treatment because of the high capacity of the mucosa for regeneration. However, a focal area of erosion may be seen. The histologic appearance may be nearly normal within 2 to 3 weeks after radiation therapy.

Clinical manifestations of acute radiation enteropathy are nausea and vomiting, diarrhea, and cramping pain. Relevant factors contributing to the pathogenesis of diarrhea include malabsorption and alterations in the intestinal bacterial flora. The severity of symptoms, as in other anatomic areas, is proportional to the irradiated volume and the total dose.

Symptoms of chronic radiation enteropathy include diarrhea, abdominal cramping, nausea, malabsorption, vomiting, and obstruction. Progressive fibrosis, perforation, fistula formation, and stenosis of the irradiated portion of the bowel can occur during the chronic phase of radiation enteropathy. Most clinical manifestations of chronic changes occur between 6 months and 5 years after radiation therapy.

Conservative noninvasive treatment can frequently control gastrointestinal symptoms. A low-residue or elemental diet may be beneficial. When nonsurgical treatment fails to relieve severe symptoms, surgical intervention is often indicated.

Bladder Radiation injury to the bladder generally becomes symptomatic 3 to 6 weeks after the start of treatment, and symptoms usually subside 3 to 4 weeks after completion of radiation therapy. Patients often complain of increased frequency and dysuria. Cystoscopy often shows diffuse mucosal changes similar to those of acute cystitis. Sometimes desquamation and ulceration can be seen. Without infection, urinary symptoms are managed symptomatically. Concurrent chemotherapy with cytotoxic agents such as cyclophosphamide increases the severity of the acute bladder reaction.

The late effects of high radiation doses to the bladder may include contracture in size, interstitial fibrosis, telangiectasia, and ulceration. The blood vessels may be dilated and prone to rupture, resulting in painless hematuria. These changes are often difficult to distinguish from tumor recurrence and progression. A contracted bladder may result from doses >60 Gy.

Testes and Ovaries In general, type B spermatogonia are exquisitely sensitive to the effects of radiation. The type A spermatogonia are thought to be more resistant because their longer cell cycle time allows considerable variation in radiosensitivity among different phases of the cell cycle. Sertoli cells and Leydig cells are less radiosensitive than the spermatogonia. Elevated levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) have been observed after as little as 75 cGy. Doses as low as 10 cGy to the testicles may result in injury to the type B spermatogonia. The single dose required for permanent sterilization on normal human males is believed to be between 6 and 10 Gy. In normal human males, sperm count recovery requires 9 to 18 months after a fractionated dose of 8 to 100 cGy.

The radiation dose necessary to induce ovarian failure is age-dependent. A single dose of 3 to 4 Gy can induce amenorrhea in almost all women over 40 years of age. In young women, oogenesis is much less sensitive to radiation than is spermatogenesis in men.

ACUTE TOTAL-BODY IRRADIATION The data regarding the acute effects of total-body irradiation on humans come primarily from Japanese survivors of the atomic bomb, Marshallese exposed to radioactive fallout in 1954, and persons exposed to radiation from the Chernobyl nuclear accident. Early symptoms of acute total-body irradiation, known as the *prodromal radiation syndrome*, may last for a limited time. Clinical manifestations depend on the total-body dose. At doses >100 Gy, death usually occurs 24 to 48 h later from neurologic and cardiovascular failure. This is known as the *cerebrovascular syndrome*. Because cerebrovascular damage causes death very quickly, the failures of other systems do not have time to develop.

At doses between 5 and 12 Gy, death may occur in a matter of days as a result of the *gastrointestinal syndrome*. The symptoms during this period may include nausea, vomiting, and prolonged diarrhea for several days leading to dehydration, sepsis, and death. A total-body dose >10 Gy is uniformly fatal unless supportive therapy (fluid, electrolytes, blood products, and antibiotics) is given. The process of intestinal denudation depends on the dose and may take between 3 and 120 days. Death from intestinal denudation usually occurs before the full effects of radiation on the blood-forming elements are seen.

At total-body doses between 2 and 8 Gy, death may occur 2 to 4 weeks after exposure from bone marrow failure, the *hematopoietic syndrome*. The full effect of radiation is not apparent until the mature hematopoietic cells are depleted. Clinical symptoms during this period may include chills, fatigue, and petechial hemorrhage. Peripheral blood lymphopenia develops during the first 12 to 48 h after any significant exposure. Beyond 5 to 6 Gy, the rate and magnitude of the drop are not well correlated to radiation exposure. Some stem cells may survive acute exposure to ≥10 Gy. Death is from infection or bleeding and usually occurs before anemia can develop (red blood cell half-life is 100 to 120 days).

The $LD_{50/60}$ (the dose at which 50% of the population is dead by 60 days) is around 3.25 Gy if support is not given. There is considerable variability in the total-body dose tolerated. The very young and the old are more radiosensitive than middle-aged and young adults. Females in general appear to be more tolerant of radiation than males. Persons exposed to <2 Gy will require little or no therapy but should probably be observed closely with daily blood counts for a few days.

The role of bone marrow transplantation for patients exposed to acute total-body irradiation is debated. At doses <8 Gy, the patient is likely to survive with supportive care. Most people exposed to doses >10 Gy will die from the gastrointestinal syndrome. Therefore, 8 to 10 Gy may be the dose range in which bone marrow transplantation could have a role, although the Chernobyl experience did not confirm this prediction. Estimating the dose received by a given patient after radiation exposure is difficult. However, exposure estimation must be done quickly because bone marrow transplantation is most effective if it is performed within the first 3 to 5 days after exposure.

RADIATION AND CANCER INDUCTION Some nonlethal changes in DNA sequences caused by irradiation may cause malignant transformations. Thus, it is not surprising that second neoplasms can be caused by exposure to ionizing radiation. However, paradoxically, this risk decreases with doses above a certain level. Whether there is a "safe" dose that will not induce any cancer is not likely. Estimates of the risk of developing cancer after low-level exposure to ionizing radiation are often derived by extrapolation from the risks for higher doses and acute exposures. Predicted risks of cancer are, therefore, prone to modification depending on the assumptions made about the data available for analysis.

Throughout the history of human exposure to ionizing radiation, increased rates of cancer have been noted after exposure to radiation. The populations studied include survivors of the atomic bomb during World War II; radium watch-dial painters who shaped their brush tips with their tongues; patients who underwent multiple fluoroscopic examinations for tuberculosis, received spinal irradiation for ankylosing spondylitis, and received breast irradiation for postpartum mastitis; and others. Exposure to ionizing radiation at an earlier age appears to increase the chance of developing radiation-induced carcinomas. However, the radiation-induced cancers have an age of onset similar to that of the native cancers, and the available data argue against radiation as the only cause of the increased incidence of cancers seen after exposure to radiation. Table 71-5 shows examples of cancer observed in specific situations.

Because a safe dose of radiation is unknown at present, it is prudent to avoid routine exposures to ionizing irradiation.

TABLE 71-5 *Examples of Radiation-Induced Cancers*

Types of Exposure	*Types of Cancer Observed*
Neck irradiation during infancy for benign conditions	Thyroid carcinoma
Radiation therapy for other malignant tumors	Thyroid carcinoma Breast cancer Gastric cancer Melanoma Lung cancer Sarcomas in the field
Cranial irradiation	Central nervous system tumors
Breast irradiation for postpartum mastitis	Breast cancer
Brush-licking by radium dial painters	Bone sarcomas
Uranium mining	Lung cancer
In utero exposure	Leukemia

72 INFECTIONS IN PATIENTS WITH CANCER

Robert Finberg

Infections are a common cause of death and an even more common cause of morbidity in patients with a wide variety of neoplasms. Autopsy studies show that most deaths from acute leukemia and half of deaths from lymphoma are caused directly by infection. With more intensive chemotherapy, patients with solid tumors have also become more likely to die of infection.

A physical predisposition to infection (Table 72-1) can be a result of the neoplasm's production of a break in the skin; for example, a squamous cell carcinoma may cause local invasion of the epidermis, which allows bacteria to gain access to the subcutaneous tissue and permits the development of cellulitis. The artificial closing of a normally patent orifice can also predispose to infection: Obstruction of a ureter by a tumor can cause urinary tract infection, and obstruction of the bile duct can cause cholangitis. Part of the host's normal defense against infection depends on the continuous emptying of a viscus; without emptying, a few bacteria present as a result of bacteremia or local transit can multiply and cause disease.

A similar problem can affect patients whose lymph node integrity has been disrupted by radical surgery, particularly patients who have had radical node dissections. A common clinical problem following radical mastectomy is the development of cellulitis (usually caused by streptococci or staphylococci) because of lymphedema and/or inadequate lymph drainage. In most cases, this problem can be addressed by local measures designed to prevent fluid accumulation and breaks in the skin, but antibiotic prophylaxis has been necessary in refractory cases.

A life-threatening problem common to many cancer patients is the loss of the reticuloendothelial capacity to clear microorganisms after splenectomy. Splenectomy may be performed as part of the management of hairy cell leukemia, chronic lymphocytic leukemia (CLL), and chronic myelocytic leukemia (CML) and in Hodgkin's disease. Even after curative therapy for the underlying disease, the lack of a spleen predisposes such patients to rapidly fatal infections. The loss of the spleen through trauma similarly predisposes the normal host to overwhelming infection for as long as 25 years after splenectomy. The splenectomized patient should be counseled about the risks of infection with certain organisms, such as the protozoan *Babesia* (Chap. 195) and *Capnocytophaga canimorsus* (formerly dysgonic fermenter 2, or DF-2), a bacterium carried in the mouths of animals (Chap. 131). Since encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) are the organisms most commonly associated with postsplenectomy sepsis, splenectomized persons should be vaccinated (and revaccinated; Table 72-2) against the capsular polysaccharides of these organisms. Many clinicians recommend giving splenectomized patients a small supply of antibiotics effective against *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* to avert rapid, overwhelming sepsis in the event that they cannot present for medical attention immediately after the onset of fever or other symptoms of bacterial infection.

The level of suspicion of infections with certain organisms should depend on the type of cancer diagnosed (Table 72-3). Diagnosis of multiple myeloma or CLL should alert the clinician to the possibility of hypogammaglobulinemia. While immunoglobulin replacement therapy can be effective, in most cases prophylactic antibiotics are a cheaper, more convenient method of eliminating bacterial infections in CLL patients with hypogammaglobulinemia. Patients with acute lymphocytic leukemia (ALL), patients with non-Hodgkin's lymphoma, and all cancer patients treated with high-dose glucocorticoids (or glucocorticoid-containing chemotherapy regimens) should receive antibiotic prophylaxis for *Pneumocystis* infection (Table 72-3) for the duration of their chemotherapy. In addition to exhibiting susceptibility to certain infectious organisms, patients with cancer are likely to manifest their infections in characteristic ways.

TABLE 72-1 *Normal Barriers to Infections*

Type of Defense	*Specific Lesion*	*Cells Involved*	*Organism*	*Cancer Association*	*Disease*
Physical barrier	Breaks in skin	Skin epithelial cells	Staphylococci, streptococci	Head and neck, squamous cell carcinoma	Cellulitis, extensive skin infection
Emptying of fluid collections	Occlusion of orifices: ureters, bile duct, colon	Luminal epithelial cells	Gram-negative bacilli	Renal, ovarian, biliary tree, metastatic diseases of many cancers	Rapid, overwhelming bacteremia, urinary tract infection
Lymphatic disease	Node dissection	Lymph nodes	Staphylococci, streptococci	Breast cancer surgery	Cellulitis
Splenic clearance of microorganisms	Splenectomy	Splenic reticuloendothelial cells	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Babesia*, *Capnocytophaga canimorsus*	Hodgkin's disease, leukemia, idiopathic thrombocytopenic purpura	Rapid, overwhelming sepsis
Phagocytosis	Lack of granulocytes	Granulocytes (neutrophils)	Staphylococci, streptococci, enteric organisms, fungi	Hairy cell, acute myelocytic, and acute lymphocytic leukemias	Bacteremia
Humoral immunity	Lack of antibody	B cells	*S. pneumoniae*, *H. influenzae*, *N. meningitidis*	Chronic lymphocytic leukemia, multiple myeloma	Infections with encapsulated organisms, sinusitis, pneumonia
Cellular immunity	Lack of T cells	T cells and macrophages	*Mycobacterium tuberculosis*, *Listeria*, herpesviruses, fungi, other intracellular parasites	Hodgkin's disease, leukemia, T cell lymphoma	Infections with intracellular bacteria, fungi, parasites

TABLE 72-2 *Vaccination of Cancer Patients Receiving Chemotherapy*

Vaccine	Use in Indicated Patients		
	Intensive Chemotherapy	Hodgkin's Disease	Bone Marrow Transplantation
Diphtheria-tetanus (diphtheria, pertussis, tetanus; DPT) for children <7 years old	Primary series and boosters as necessary	No special recommendation	12, 14, and 24 months after transplantation
Poliomyelitis[a]	Complete primary series and boosters	No special recommendation	12, 14, and 24 months after transplantation
Haemophilus influenzae type b conjugate	Primary series and booster for children	Immunization before treatment and booster 3 months afterward	12, 14, and 24 months after transplantation
Hepatitis A	Not routinely recommended	Not routinely recommended	Not routinely recommended
Hepatitis B	Complete series	No special recommendation	12, 14, and 24 months after transplantation
23-Valent pneumococcal	Every 5 years	Immunization before treatment and booster 3 months afterward	12 and 24 months after transplantation
4-Valent meningococcal	Should be administered to splenectomized patients and patients living in endemic areas, including college students in dormitories	Should be administered to splenectomized patients and patients living in endemic areas, including college students in dormitories	Should be administered to splenectomized patients and patients living in endemic areas, including college students in dormitories
Influenza	Seasonal immunization	Seasonal immunization	Seasonal immunization
Measles/mumps/rubella	Contraindicated	Contraindicated	After 24 months in patients without graft-versus-host disease
Varicella-zoster virus	Contraindicated[b]	Contraindicated	Contraindicated

[a] Live-virus vaccine is contraindicated; inactivated vaccine should be used.
[b] Contact the manufacturer for more information on use in children with acute lymphocytic leukemia.

SYSTEM-SPECIFIC SYNDROMES

SKIN-SPECIFIC SYNDROMES Skin lesions are common in cancer patients, and their appearance may permit the diagnosis of systemic bacterial or fungal infection. While cellulitis caused by skin organisms such as *Streptococcus* or *Staphylococcus* is common, neutropenic patients [those with fewer than 500 functional polymorphonuclear leukocytes (PMNs) per microliter] and patients with impaired blood or lymphatic drainage may develop infections with unusual organisms. Innocent-looking macules or papules may be the first sign of bacterial or fungal sepsis in immunocompromised patients (Fig. 72-1). In the neutropenic host, a macule progresses rapidly to ecthyma gangrenosum, a usually painless, round, necrotic lesion consisting of a central black or gray-black eschar with surrounding erythema. Ecthyma gangrenosum is located in nonpressure areas (as distinguished from necrotic lesions associated with lack of circulation) and is often associated with *Pseudomonas aeruginosa* bacteremia (Chap. 136) but may be caused by other bacteria.

Candidemia (Chap. 187) is also associated with a variety of skin conditions and commonly presents as a maculopapular rash. Punch biopsy of the skin may be the best method for diagnosis.

Cellulitis, an acute spreading inflammation of the skin, is most often caused by infection with group A *Streptococcus* or *Staphylococcus aureus*, virulent organisms normally found on the skin (Chap. 110). Although cellulitis tends to be circumscribed in normal hosts, it may spread rapidly in neutropenic patients. A tiny break in the skin may lead to spreading cellulitis, which is characterized by pain and erythema; in such patients, signs of infection (e.g., purulence) are often lacking. What might be a furuncle in a normal host may require amputation because of uncontrolled infection in a patient presenting with leukemia. A dramatic response to an infection that might be trivial in a normal host can mark the first sign of leukemia. Fortunately, granulocytopenic patients are likely to be infected with certain types of organisms (Table 72-4); thus the selection of an antibiotic regimen is somewhat easier than it might otherwise be. (See discussion below on the selection of antibiotics for use in neutropenic patients.) It is essential to recognize cellulitis early and to treat it aggressively. Patients who are neutropenic or have previously received antibiotics for other reasons may develop cellulitis with unusual organisms (e.g., *Escherichia coli*, *Pseudomonas*, or fungi). Early treatment, even of innocent-looking lesions, is essential to prevent necrosis and loss of tissue. Debridement to prevent spread may sometimes be necessary early in the course of disease, but it can often be performed after chemotherapy, when the PMN count increases.

Sweet's syndrome, or *febrile neutrophilic dermatosis*, was originally described in women with elevated white blood cell counts. The disease is characterized by the presence of leukocytes in the lower dermis, with edema of the papillary body. Ironically, this disease now is usually seen in neutropenic patients with cancer, most often in association with acute leukemia but also in association with a variety of other malignancies. Sweet's syndrome usually presents as red or bluish-red papules or nodules that may coalesce and form sharply bordered plaques. The edema may suggest vesicles, but on palpation the lesions are solid, and vesicles probably never arise in this disease. The lesions are most common on the face, neck, and arms. On the legs, they may

TABLE 72-3 *Infections and Cancer*

Cancer	Underlying Immune Abnormality	Organisms Causing Infection
Multiple myeloma	Hypogammaglobulinemia	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*
Chronic lymphocytic leukemia	Hypogammaglobulinemia	*S. pneumoniae*, *H. influenzae*, *N. meningitidis*
Acute myelocytic or lymphocytic leukemia	Granulocytopenia, skin and mucous-membrane lesions	Extracellular gram-positive and gram-negative bacteria, fungi
Hodgkin's disease	Abnormal T cell function	Intracellular pathogens (*Mycobacterium tuberculosis*, *Listeria*, *Salmonella*, *Cryptococcus*, *Mycobacterium avium*)
Non-Hodgkin's lymphoma and acute lymphocytic leukemia	Glucocorticoid chemotherapy, T and B cell dysfunction	*Pneumocystis*
Colon and rectal tumors	Local abnormalities[a]	*Streptococcus bovis* (bacteremia)
Hairy cell leukemia	Abnormal T cell function	Intracellular pathogens (*M. tuberculosis*, *Listeria*, *Cryptococcus*, *M. avium*)

[a] The reason for this association is not well defined.

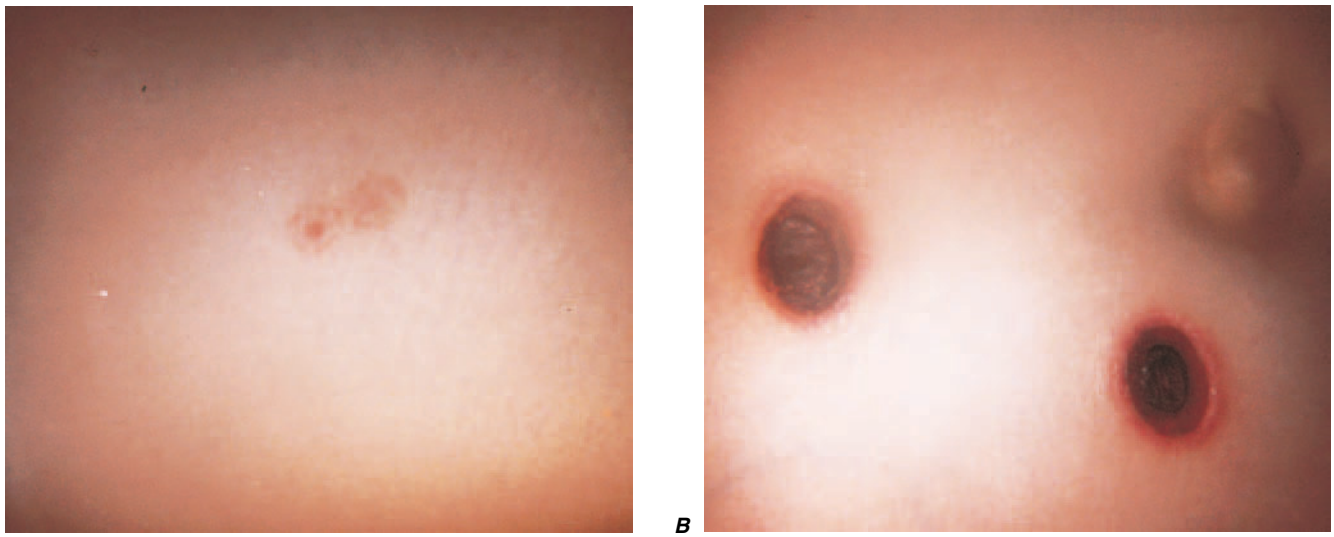

FIGURE 72-1 *A*. Papules related to *Escherichia coli* bacteremia in a neutropenic patient with acute lymphocytic leukemia. *B*. The same lesion the following day.

be confused with erythema nodosum. The development of lesions is often accompanied by high fevers and an elevated erythrocyte sedimentation rate. Both the lesions and the temperature elevation respond dramatically to glucocorticoids. Treatment begins with high doses of glucocorticoids (60 mg/d of prednisone) followed by tapered doses over the next 2 to 3 weeks.

Data indicate that *erythema multiforme* with mucous membrane involvement is often associated with herpes simplex virus (HSV) infection and is distinct from Stevens-Johnson syndrome, which is associated with drugs and tends to have a more widespread distribution. Since cancer patients are both immunosuppressed (and therefore susceptible to herpes infections) and heavily treated with drugs (and therefore subject to Stevens-Johnson syndrome), both of these conditions are common in this population.

Cytokines, which are used as adjuvants or primary treatments for cancer, can themselves cause characteristic rashes, further complicating the differential diagnosis. This phenomenon is a particular problem in bone marrow transplant recipients (Chap. 117), who, in addition to having the usual chemotherapy-, antibiotic-, and cytokine-induced rashes, are plagued by graft-versus-host disease.

CATHETER-RELATED INFECTIONS Because intravenous catheters are commonly used in cancer chemotherapy and are prone to infection (Chap. 116), they pose a major problem in the care of patients with cancer. Some catheter-associated infections can be treated with antibiotics, while in others the catheter must be removed. If the patient has a "tunneled" catheter (which consists of an entrance site, a subcutaneous tunnel, and an exit site), a red streak over the subcutaneous part of the line (the tunnel) is grounds for immediate removal of the catheter. Failure to remove catheters under these circumstances may result in extensive cellulitis and tissue necrosis.

More common than tunnel infections are exit-site infections, often with erythema around the area where the line penetrates the skin. Most authorities (Chap. 120) recommend treatment (usually with vancomycin) for an exit-site infection caused by a coagulase-negative *Staphylococcus*. Treatment of coagulase-positive staphylococcal infection is associated with a poorer outcome, and it is advisable to remove the catheter if possible. Similarly, many clinicians remove catheters associated with infections due to *P. aeruginosa* and *Candida* species, since such infections are difficult to treat and bloodstream infections with these organisms are likely to be deadly. Catheter infections caused by *Burkholderia cepacia*, *Stenotrophomonas* spp., *Agrobacterium* spp., and *Acinetobacter baumannii* as well as *Pseudomonas* spp. other than *aeruginosa* are likely to be very difficult to eradicate with antibiotics alone. Similarly, isolation of *Bacillus*, *Corynebacterium*, and *Mycobacterium* spp. should prompt removal of the catheter.

TABLE 72-4 Organisms Likely to Cause Infections in Granulocytopenic Patients

Gram-positive cocci	*Enterobacter* spp.
Staphylococcus epidermidis	*Serratia* spp.
Staphylococcus aureus	*Acinetobacter* spp.[a]
Viridans *Streptococcus*	*Citrobacter* spp.
Enterococcus faecalis	Gram-positive bacilli
Streptococcus pneumoniae	Diphtheroids
Gram-negative bacilli	JK bacillus[a]
Escherichia coli	Fungi
Klebsiella spp.	*Candida* spp.
Pseudomonas aeruginosa	*Aspergillus* spp.
Non-*aeruginosa Pseudomonas* spp.[a]	

[a] Often associated with intravenous catheters.

GASTROINTESTINAL TRACT–SPECIFIC SYNDROMES ■ Upper Gastrointestinal Tract Disease ■ *INFECTIONS OF THE MOUTH* The oral cavity is rich in aerobic and anaerobic bacteria (Chap. 148) that normally live in a commensal relationship with the host. The antimetabolic effects of chemotherapy cause a breakdown of host defenses, leading to ulceration of the mouth and the potential for invasion by resident bacteria. Mouth ulcerations afflict most patients receiving chemotherapy and have been associated with viridans streptococcal bacteremia. A variety of topical rinses and elixirs have been proposed to treat these ulcerations. Although some may have a local anesthetic effect, the efficacy of any of these therapies in the prevention of disease is unproven. Similarly, the efficacy of mouthwashes in the prevention of esophagitis or invasive candidiasis is doubtful. Fluconazole, on the other hand, is clearly effective in the treatment of both local infections (thrush) and systemic infections (esophagitis) due to *Candida albicans*. Newer azoles (such as voriconazole) are similarly effective.

Noma (*cancrum oris*), commonly seen in malnourished children, is a penetrating disease of the soft and hard tissues of the mouth and adjacent sites, with resulting necrosis and gangrene. It has a counterpart in immunocompromised patients and is thought to be due to invasion of the tissues by *Bacteroides*, *Fusobacterium*, and other normal inhabitants of the mouth. Noma is associated with debility, poor oral hygiene, and immunosuppression.

Viruses, particularly HSV, are a prominent cause of morbidity in immunocompromised patients, in whom they are associated with severe mucositis. The use of acyclovir, either prophylactically or therapeutically, is of value.

ESOPHAGEAL INFECTIONS The differential diagnosis of esophagitis (usually presenting as substernal chest pain upon swallowing) includes herpes simplex and candidiasis, both of which are readily treatable.

Lower Gastrointestinal Tract Disease Hepatic candidiasis (Chap. 187) results from seeding of the liver (usually from a gastrointestinal source)

in neutropenic patients. It is most common in patients being treated for acute leukemia and usually presents symptomatically around the time the neutropenia resolves. The characteristic picture is that of persistent fever unresponsive to antibiotics; abdominal pain and tenderness or nausea; and elevated serum levels of alkaline phosphatase in a patient with hematologic malignancy who has recently recovered from neutropenia. The diagnosis of this disease (which may present in an indolent manner and persist for several months) is based on the finding of yeasts or pseudohyphae in granulomatous lesions. Hepatic ultrasound or computed tomography (CT) may reveal bull's-eye lesions. In some cases, magnetic resonance imaging (MRI) reveals small lesions not visible by other imaging modalities. The pathology (a granulomatous response) and the timing (with resolution of neutropenia and an elevation in granulocyte count) suggest that the host response to *Candida* is an important component of the manifestations of disease. In many cases, although organisms are visible, cultures of biopsied material may be negative. The designation *hepatosplenic candidiasis* or *hepatic candidiasis* is a misnomer because the disease often involves the kidneys and other tissues; the term *chronic disseminated candidiasis* may be more appropriate. Because of the risk of bleeding with liver biopsy, diagnosis is often based on imaging studies (MRI, CT). Amphotericin B is traditionally used for therapy (often for several months, until all manifestations of disease have disappeared), but fluconazole may be useful for outpatient therapy. The use of other antifungal agents and combination therapy is less well studied.

Typhlitis *Typhlitis*, sometimes referred to as necrotizing colitis, neutropenic colitis, necrotizing enteropathy, ileocecal syndrome, or cecitis, is a clinical syndrome of fever and right-lower-quadrant tenderness in an immunosuppressed host. This syndrome is classically seen in neutropenic patients after chemotherapy with cytotoxic drugs. It may be more common among children than among adults and appears to be much more common among patients with acute myelocytic leukemia (AML) or ALL than among those with other types of cancer. Physical examination reveals right-lower-quadrant tenderness, with or without rebound tenderness. Associated diarrhea (often bloody) is common, and the diagnosis can be confirmed by the finding of a thickened cecal wall on CT or ultrasonography. Plain films may reveal a right-lower-quadrant mass, but CT with contrast or MRI is a much more sensitive means of making the diagnosis. Although surgery is sometimes attempted to avoid perforation from ischemia, most cases resolve with medical therapy alone. The disease is sometimes associated with positive blood cultures (usually for aerobic gram-negative bacilli), and therapy is recommended for a broad spectrum of bacteria (particularly gram-negative bacilli, likely bowel flora).

***Clostridium difficile*–Induced Diarrhea** Cancer patients are predisposed to the development of *C. difficile* diarrhea (Chap. 114) as a consequence of chemotherapy alone. Thus, they may have positive toxin tests before receiving antibiotics. Obviously, such patients are also subject to *C. difficile*–induced diarrhea as a result of antibiotic pressure. *C. difficile* should always be considered as a possible cause of diarrhea in cancer patients who have received antibiotics.

CENTRAL NERVOUS SYSTEM–SPECIFIC SYNDROMES ■ Meningitis The presentation of meningitis in patients with lymphoma or CLL, patients receiving chemotherapy (particularly with glucocorticoids) for solid tumors, and patients who have received bone marrow transplants suggests a diagnosis of cryptococcal or listerial infection. As noted previously, splenectomized patients are susceptible to rapid, overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Similarly, patients who are antibody-deficient (such as patients with CLL, those who have received intensive chemotherapy, or those who have undergone bone marrow transplantation) are likely to have infections caused by these bacteria. Other cancer patients, however, because of their defective cellular immunity, are likely to be infected with other pathogens (Table 72-3).

TABLE 72-5 *Differential Diagnosis of Central Nervous System Infections in Patients with Cancer*

Findings on CT or MRI	Underlying Predisposition	
	Prolonged Neutropenia	Defects in Cellular Immunity[a]
Mass lesions	*Aspergillus* brain abscess *Nocardia* brain abscess *Cryptococcus* brain abscess	Toxoplasmosis EBV-LPD
Diffuse encephalitis	PML (J-C virus)	Infection with VZV, CMV, HSV, HHV-6, J-C virus (PML), *Listeria*

[a] High-dose glucocorticoid therapy, cytotoxic chemotherapy.
Abbreviations: CMV, cytomegalovirus; CT, computed tomography; EBV-LPD, Epstein-Barr virus lymphoproliferative disease; HHV-6, human herpesvirus type 6; HSV, herpes simplex virus; PML, progressive multifocal leukoencephalopathy.

Encephalitis The spectrum of disease resulting from viral encephalitis is expanded in immunocompromised patients. Cancer patients receiving high-dose cytotoxic chemotherapy or any chemotherapy that affects T cell function (e.g., fludarabine) or antibodies that eliminate T cells (e.g., anti-CD3) or cytokine activity are predisposed to infections with intracellular organisms similar to those encountered in patients with AIDS (Chap. 173). Infection with varicella-zoster virus (VZV) has been associated with encephalitis that may be caused by VZV-related vasculitis. Chronic viral infections may also be associated with dementia and encephalitic presentations, and a diagnosis of progressive multifocal leukoencephalopathy should be considered when a patient who has received chemotherapy presents with dementia (Table 72-5). Other abnormalities of the central nervous system (CNS) that may be confused with infection include normal-pressure hydrocephalus and vasculitis resulting from CNS irradiation. It may be possible to differentiate these conditions by MRI.

Brain Masses Mass lesions of the brain most often present as headache with or without fever or neurologic abnormalities. Infections associated with mass lesions may be caused by bacteria (particularly *Nocardia*), fungi (particularly *Cryptococcus* or *Aspergillus*), or parasites (*Toxoplasma*). Epstein-Barr virus (EBV)–associated lymphoproliferative disease may also present as single or multiple mass lesions of the brain. A biopsy may be required for a definitive diagnosis.

PULMONARY INFECTIONS Pneumonia (Chap. 239) in immunocompromised patients may be difficult to diagnose because conventional methods of diagnosis depend on the presence of neutrophils. Bacterial pneumonia in neutropenic patients may present without purulent sputum—or, in fact, without any sputum at all—and may not produce physical findings suggestive of chest consolidation (rales or egophony).

In granulocytopenic patients with persistent or recurrent fever, the chest x-ray pattern may help to localize an infection and thus to determine which investigative tests and procedures should be undertaken and which therapeutic options should be considered (Table 72-6). The difficulties encountered in the management of pulmonary infiltrates relate in part to the difficulties of performing diagnostic procedures on

TABLE 72-6 *Differential Diagnosis of Chest Infiltrates in Immunocompromised Patients*

Infiltrate	Cause of Pneumonia	
	Infectious	Noninfectious
Localized	Bacteria, *Legionella*, mycobacteria	Local hemorrhage or embolism, tumor
Nodular	Fungi (e.g., *Aspergillus* or *Mucor*), *Nocardia*	Recurrent tumor
Diffuse	Viruses (especially CMV), *Chlamydia*, *Pneumocystis*, *Toxoplasma gondii*, mycobacteria	Congestive heart failure, radiation pneumonitis, drug-induced lung injury, diffuse alveolar hemorrhage (described after BMT)

Abbreviations: BMT, bone marrow transplantation; CMV, cytomegalovirus.

the patients involved. When platelet counts can be increased to adequate levels by transfusion, microscopic and microbiologic evaluation of the fluid obtained by endoscopic bronchial lavage is often diagnostic. Lavage fluid should be cultured for *Mycoplasma*, *Chlamydia*, *Legionella*, *Nocardia*, fungi, and more common bacterial pathogens. In addition, the possibility of *Pneumocystis* pneumonia should be considered, especially in patients with ALL or lymphoma who have not received prophylactic trimethoprim-sulfamethoxazole (TMP-SMX). The characteristics of the infiltrate may be helpful in decisions about further diagnostic and therapeutic maneuvers. Nodular infiltrates suggest fungal pneumonia (e.g., that caused by *Aspergillus* or *Mucor*). Such lesions may best be approached by visualized biopsy procedures.

Aspergillus spp. (Chap. 188) can colonize the skin and respiratory tract or cause fatal systemic illness. Although *Aspergillus* may cause aspergillomas in a previously existing cavity or may produce allergic bronchopulmonary aspergillosis, the major problem posed by this genus in neutropenic patients is invasive disease due to *A. fumigatus* or *A. flavus*. The organisms enter the host following colonization of the respiratory tract, with subsequent invasion of the blood vessels. The disease is likely to present as a thrombotic or embolic event because of the ability of the organisms to invade blood vessels. The risk of infection with *Aspergillus* correlates directly with the duration of neutropenia. In prolonged neutropenia, positive surveillance cultures for colonization of the nasopharynx with *Aspergillus* may predict the development of disease.

Patients with *Aspergillus* infection often present with pleuritic chest pain and fever, which are sometimes accompanied by cough. Hemoptysis may be an ominous sign. Chest x-rays may reveal new focal infiltrates or nodules. Chest CT may reveal a characteristic halo consisting of a mass-like infiltrate surrounded by an area of low attenuation. The presence of a "crescent sign" on a chest x-ray or a chest CT scan, in which the mass progresses to central cavitation, is characteristic of invasive *Aspergillus* infection but may develop as the lesions are resolving.

In addition to causing pulmonary disease, *Aspergillus* may invade through the nose or palate, with deep sinus penetration. The appearance of a discolored area in the nasal passages or on the hard palate should prompt a search for invasive *Aspergillus*. This situation is likely to require surgical debridement. Treatment (Chap. 188) with high doses of amphotericin B has been successful in curing granulocytopenic patients of invasive *Aspergillus* infection after the return of granulocytes. Catheter infections with *Aspergillus* usually require both removal of the catheter and antifungal therapy.

Diffuse interstitial infiltrates suggest viral, parasitic, or *Pneumocystis* pneumonia. If the patient has a diffuse interstitial pattern on chest x-ray, it may be reasonable to institute empirical treatment with TMP-SMX (for *Pneumocystis*) and a quinolone (for *Chlamydia*, *Mycoplasma*, and *Legionella*) or an erythromycin derivative (e.g., azithromycin) while considering invasive diagnostic procedures. Noninvasive procedures, such as staining of sputum smears for *Pneumocystis*, serum cryptococcal antigen tests, and urine testing for *Legionella* only, may be helpful. In transplant recipients who are seropositive for cytomegalovirus (CMV), a determination of CMV load in the serum should be considered. The availability of viral load studies (which allow physicians to quantitate viruses) has superseded simple measurement of serum IgG, which merely documents prior exposure to virus. Infections with viruses that cause only upper respiratory symptoms in immunocompetent hosts, such as respiratory syncytial virus, influenza viruses, and parainfluenza viruses, may be associated with fatal pneumonitis in immunocompromised hosts. An attempt at early diagnosis by nasopharyngeal aspiration should be considered so that appropriate treatment can be instituted.

While bleomycin is the most common cause of chemotherapy-induced lung disease, other causes include alkylating agents (such as cyclophosphamide, chlorambucil, and melphalan), nitrosoureas [carmustine (BCNU), lomustine (CCNU), and methyl-CCNU], busulfan, procarbazine, methotrexate, and hydroxyurea. Both infectious and noninfectious (drug- and/or radiation-induced) pneumonitis can cause fever and abnormalities on chest x-ray; thus, the differential diagnosis of an infiltrate in a patient receiving chemotherapy encompasses a broad range of conditions (Table 72-6). Since the treatment of radiation pneumonitis (which may respond dramatically to glucocorticoids) or drug-induced pneumonitis is different from that of infectious pneumonia, a biopsy may be important in the diagnosis. Unfortunately, no definitive diagnosis can be made in ~30% of cases, even after bronchoscopy.

Open-lung biopsy is the "gold standard" of diagnostic techniques. Biopsy via a visualized thoracostomy can replace an open procedure in many cases. When a biopsy cannot be performed, empirical treatment can be undertaken with a quinolone or erythromycin (or an erythromycin derivative such as azithromycin) and TMP-SMX (in the case of diffuse infiltrates) or with amphotericin B or other antifungal agents (in the case of nodular infiltrates). The risks should be weighed carefully in these cases. If inappropriate drugs are administered, empirical treatment may prove toxic or ineffective; either of these outcomes may be riskier than biopsy.

CARDIOVASCULAR INFECTIONS Patients with Hodgkin's disease are prone to persistent infections by *Salmonella*, sometimes (and particularly often in elderly patients) affecting a vascular site. The use of intravenous catheters deliberately lodged in the right atrium is associated with a high incidence of bacterial endocarditis (presumably related to valve damage followed by bacteremia). Nonbacterial thrombotic endocarditis has been described in association with a variety of malignancies (most often solid tumors) and may follow bone marrow transplantation as well. The presentation of an embolic event with a new cardiac murmur suggests this diagnosis. Blood cultures are negative in this disease of unknown pathogenesis.

ENDOCRINE SYNDROMES In addition to infections of the skin, gastrointestinal tract, and pulmonary and cardiovascular systems, infections of the endocrine system have been described in immunocompromised patients. *Candida* infection of the thyroid during neutropenia can be defined by indium-labeled white cell scans or gallium scans after neutrophil counts increase. CMV infection can cause adrenalitis with or without resulting adrenal insufficiency. The presentation of a sudden endocrine anomaly in an immunocompromised patient may be a sign of infection in the involved end organ.

MUSCULOSKELETAL INFECTIONS Infection that is a consequence of vascular compromise (resulting in gangrene) can occur when a tumor restricts the blood supply to muscles, bones, or joints. The process of diagnosis and treatment of such infection is similar to that in normal hosts, with the following caveats: (1) In terms of diagnosis, a lack of physical findings resulting from a lack of granulocytes in the granulocytopenic patient should make the clinician more aggressive in obtaining tissue rather than relying on physical signs. (2) In terms of therapy, aggressive debridement of infected tissues may be required, but it is usually difficult to operate on patients who have recently received chemotherapy, both because of a lack of platelets (which results in bleeding complications) and because of a lack of white blood cells (which may lead to secondary infection). A blood culture positive for *Clostridium perfringens* (an organism commonly associated with gas gangrene) can have a number of meanings (Chap. 126). Bloodstream infections with intestinal organisms like *Streptococcus bovis* and *C. perfringens* may arise spontaneously from lower gastrointestinal lesions (tumor or polyps); alternatively, these lesions may be harbingers of invasive disease. The clinical setting must be considered in order to define the appropriate treatment for each case.

RENAL AND URETERAL INFECTIONS Infections of the urinary tract are common among patients whose ureteral excretion is compromised (Table 72-1). *Candida*, which has a predilection for the kidney, can invade either from the bloodstream or in a retrograde manner (via the ureters or bladder) in immunocompromised patients. The presence of "fungus balls" or persistent candiduria suggests invasive disease. Persistent

funguria (with *Aspergillus* as well as *Candida*) should prompt a search for a nidus of infection in the kidney.

Certain viruses are typically seen only in immunosuppressed patients. BK virus (polyomavirus hominis 1) has been documented in the urine of bone marrow transplant recipients and, like adenovirus, may be associated with hemorrhagic cystitis. BK-induced cystitis usually remits with decreasing immunosuppression. Anecdotal reports have described the treatment of infections due to adenovirus and BK virus with cidofovir (see below).

ABNORMALITIES THAT PREDISPOSE TO INFECTION

THE LYMPHOID SYSTEM It is beyond the scope of this chapter to detail how all the immunologic abnormalities that result from cancer or from chemotherapy for cancer lead to infections. Disorders of the immune system are discussed in other sections of this book. As has been noted, patients with antibody deficiency are predisposed to overwhelming infection with encapsulated bacteria (including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*). Infections that result from the lack of a functional cellular immune system are described in Chap. 173. It is worth mentioning, however, that patients undergoing intensive chemotherapy for any form of cancer will have not only defects due to granulocytopenia but also lymphocyte dysfunction, which may be profound. Thus, these patients—especially those receiving glucocorticoid-containing regimens or drugs that inhibit T cell activation or cytokine induction—should be given prophylaxis for *Pneumocystis* pneumonia.

THE HEMATOPOIETIC SYSTEM Initial studies in the 1960s revealed a dramatic increase in the incidence of infections (fatal and nonfatal) among cancer patients with a granulocyte count of $<500/\mu L$. Recent studies have cited a figure of 48.3 infections per 100 neutropenic patients (<1000 granulocytes per microliter) with hematologic malignancies and solid tumors, or 46.3 infections per 1000 days at risk.

Neutropenic patients are unusually susceptible to infection with a wide variety of bacteria; thus, antibiotic therapy should be initiated promptly to cover likely pathogens if infection is suspected. Indeed, early initiation of antibacterial agents is mandatory to prevent deaths. These patients are susceptible to gram-positive and gram-negative organisms found commonly on the skin and in the bowel (Table 72-4). Because treatment with narrow-spectrum agents leads to infection with organisms not covered by the antibiotics used, the initial regimen should target pathogens likely to be initial causes of bacterial infection in neutropenic hosts (Fig. 72-2).

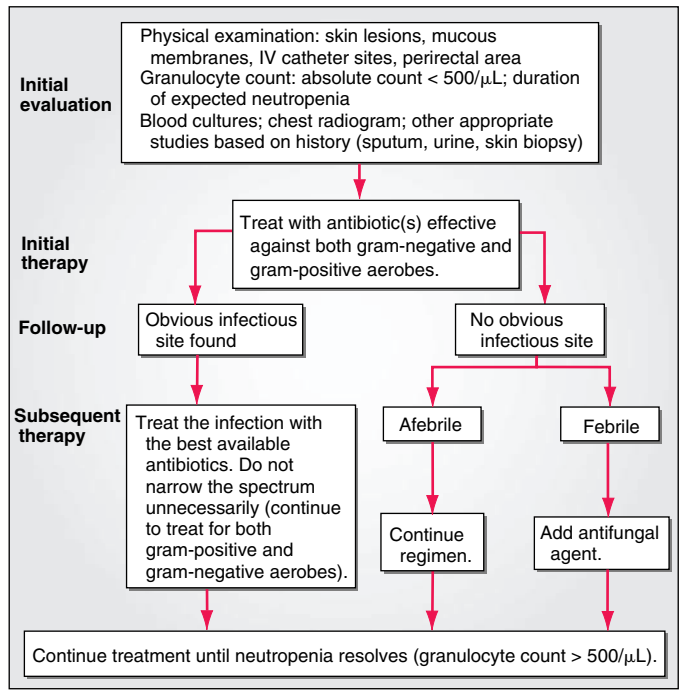

FIGURE 72-2 Algorithm for the diagnosis and treatment of febrile neutropenic patients.

TREATMENT

Antibacterial Therapy Hundreds of antibacterial regimens have been tested for use in patients with cancer. The major risk of infection is related to the degree of neutropenia seen as a consequence of either the disease or therapy. Many of the relevant studies involved small populations in which the outcomes were generally good, and most lacked the statistical power to detect differences among the regimens studied. Each febrile neutropenic patient should be approached as a unique problem, with particular attention given to previous infections and recent exposures to antibiotics. Several general guidelines are useful in the initial treatment of neutropenic patients with fever (Fig. 72-2):

1. It is necessary to use antibiotics active against both gram-negative and gram-positive bacteria (Table 72-4) in the initial regimen.
2. An aminoglycoside or an antibiotic without good activity against gram-positive organisms (e.g., ciprofloxacin or aztreonam) alone is not adequate in this setting.
3. The agents used should reflect both the epidemiology and the antibiotic resistance pattern of the hospital. For example, in hospitals where there is gentamicin resistance, amikacin-containing regimens should be considered; in hospitals with frequent *P. aeruginosa* infections, a regimen with the highest level of activity against this pathogen (such as tobramycin plus a semisynthetic penicillin) would be reasonable for initial therapy.
4. A single third-generation cephalosporin constitutes an appropriate initial regimen in many hospitals (if the pattern of resistance justifies its use).
5. Most standard regimens are designed for patients who have not previously received prophylactic antibiotics. The development of fever in a patient receiving antibiotics affects the choice of subsequent therapy (which should target resistant organisms and organisms known to cause infections in patients being treated with the antibiotics already administered).
6. Randomized trials have indicated that it is safe to use oral antibiotic regimens to treat "low-risk" patients with fever and neutropenia. Outpatients who are expected to remain neutropenic for <10 days and who have no concurrent medical problems (such as hypotension, pulmonary compromise, or abdominal pain) can be classified as low risk and treated with a broad-spectrum oral regimen. On the basis of large studies, it can be concluded that this therapy is safe and effective, at least when delivered in the inpatient setting. Outpatient treatment has been assessed in small studies, but data from large randomized trials demonstrating the safety of outpatient treatment of fever and neutropenia are not yet available.

The initial antibacterial regimen should be refined on the basis of culture results (Fig. 72-2). Blood cultures are the most relevant on which to base therapy; surface cultures of skin and mucous membranes may be misleading. In the case of gram-positive bacteremia or another gram-positive infection, it is important that the antibiotic be optimal for the organism isolated. If the infection is caused by certain gram-negative pathogens (such as *P. aeruginosa*), a synergistic combination of antibiotics (usually a semisynthetic penicillin, such as piperacillin, plus an aminoglycoside) may be appropriate. Although it is not desirable to leave the patient unprotected, the addition of more and more antibacterial agents to the regimen is not appropriate unless there is a clinical or microbiologic reason to do so. Planned progressive therapy (the serial, empirical addition of one drug after another without culture data) is not efficacious in most settings and may have unfortunate consequences. Simply adding another antibiotic for fear that a gram-negative infection is present is a dubious practice. The synergy exhib-

ited by β-lactams and aminoglycosides against certain gram-negative organisms (especially *P. aeruginosa*) provides the rationale for using two antibiotics in this setting. Mere addition of a quinolone or another antibiotic not likely to exhibit synergy for "double coverage" has not been shown to be of benefit and may cause additional toxicities and side effects. Cephalosporins can cause bone marrow suppression, and vancomycin is associated with neutropenia in some healthy people (Chap. 118). Furthermore, the addition of multiple cephalosporins may induce β-lactamase production by some organisms; cephalosporins and double β-lactam combinations should probably be avoided altogether in *Enterobacter* infections.

TABLE 72-7 *Antiviral Agents Active against Herpesviruses*

Agent	Description	Spectrum	Toxicity	Other Issues
Acyclovir	Inhibits HSV polymerase	HSV, VZV (± CMV, EBV)	Rarely has side effects; crystalluria can occur at high doses	Long history of safety; original antiviral agent
Famciclovir	Prodrug of penciclovir (a guanosine analogue)	HSV, VZV (± CMV)	Associated with cancer in rats	Longer effective half-life than acyclovir
Valacyclovir	Prodrug of acyclovir; better absorption	HSV, VZV (± CMV)	Associated with thrombotic microangiopathy in one study of immunocompromised patients	Better oral absorption and longer effective half-life than acyclovir; can be given as a single daily dose for prophylaxis
Ganciclovir	More potent polymerase inhibitor; more toxic than acyclovir	HSV, VZV, CMV, HHV-6	Bone marrow suppression	Neutropenia may respond to G-CSF or GM-CSF
Valganciclovir	Prodrug of ganciclovir; better absorption	HSV, VZV, CMV, HHV-6	Bone marrow suppression	—
Cidofovir	Nucleotide analogue of cytosine	HSV, VZV, CMV; has good in vitro activity against adenovirus and others	Nephrotoxic marrow suppression	Given IV once a week
Foscarnet	Phosphonoformic acid; inhibits viral DNA polymerase	HSV, VZV, CMV, HHV-6	Nephrotoxic; electrolyte abnormalities common	IV only

Abbreviations: ±, agent has some activity but not enough for the treatment of infections; CMV, cytomegalovirus; EBV, Epstein-Barr virus; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HHV, human herpesvirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

Antifungal Therapy Fungal infections in cancer patients are most often associated with neutropenia. Neutropenic patients are predisposed to the development of invasive fungal infections, most commonly those due to *Candida* and *Aspergillus* species and occasionally those caused by *Fusarium*, *Trichosporon*, and *Bipolaris*. Cryptococcal infection, which is common among patients taking immunosuppressive agents, is uncommon among neutropenic patients receiving chemotherapy for AML. Invasive candidal disease is usually caused by *C. albicans* or *C. tropicalis* but can be caused by *C. krusei*, *C. parapsilosis*, and *C. glabrata*.

For decades it has been common clinical practice to add amphotericin B to antibacterial regimens if a neutropenic patient remains febrile despite 4 to 7 days of treatment with antibacterial agents. The rationale for the empirical addition of amphotericin B is that it is difficult to culture fungi before they cause disseminated disease and that mortality from disseminated fungal infections in granulocytopenic patients is high. Prior to the introduction of newer azoles into clinical practice, amphotericin B was the mainstay of antifungal therapy. The insolubility of amphotericin B has resulted in the marketing of several amphotericin B–lipid formulations. Lipid preparations have been shown to be less toxic than the amphotericin B deoxycholate complex. However, because of the high cost of the lipid preparations, at many centers their use is reserved for patients who fail to respond to standard amphotericin B. Since the side effects of the formulations differ, unnecessary switching from one to another is not recommended.

Although fluconazole has been demonstrated to be efficacious in the treatment of infections due to many *Candida* spp., its use against serious fungal infections in immunocompromised patients has been limited by its narrow spectrum: it has no activity against *Aspergillus* or against several non-*albicans Candida* spp. The release of newer broad-spectrum azoles (such as voriconazole) has provided another option for the treatment of *Aspergillus* infection (including CNS infection, in which amphotericin B has usually failed). In fact, experience indicates that these drugs may well supplant amphotericin B as the mainstay of treatment because of their lesser toxicity and better penetration into cerebrospinal fluid and other sites. Clinicians should be aware that the spectrum of each azole is somewhat different and that no drug can be assumed to be efficacious against all fungi. For example, while voriconazole is active against *Pseudallescheria boydii*, amphotericin B is not; however, voriconazole has no activity against *Mucor*. →***For a full discussion of antifungal therapy, see Chap. 182.***

The introduction of new antifungal agents with different mechanisms of activity (e.g., the echinocandins) has opened the door to combination antifungal therapy. Studies in progress are assessing the use of these agents in cancer patients.

Antiviral Therapy The availability of a variety of agents with activity against herpes group viruses (and of some new agents with a broader spectrum of activity) has resulted in a greater focus on the treatment of viral infections, which pose a major problem in cancer patients. Among the viral diseases that affect cancer patients, those caused by the herpes group viruses are prominent. Serious (and sometimes fatal) infections due to HSV and CMV are well documented, and VZV infections may be fatal to patients receiving chemotherapy. The roles of human herpesvirus (HHV) 6, HHV-7, and HHV-8 (also known as Kaposi's sarcoma herpesvirus) in cancer patients are currently being defined (Chap. 166). While most clinical experience is with acyclovir, which can be used therapeutically or prophylactically, a number of derivative drugs offer advantages over this agent (Table 72-7).

In addition to the herpes group viruses, several respiratory viruses (especially respiratory syncytial virus) may cause serious disease in cancer patients. While vaccination with influenza vaccine is recommended (see below), it may be ineffective in this patient population. The availability of antiviral drugs with activity against influenza viruses gives the clinician additional options for the treatment of these patients (Table 72-8).

Other Therapeutic Modalities Another way to address the problems of the febrile neutropenic patient is to replenish the neutrophil population. Although granulocyte transfusions are efficacious in the treatment of refractory gram-negative bacteremia, they do not have a documented role in prophylaxis. Because of the expense, the risk of leukoagglutinin reactions (which has probably been decreased by improved cell-separation procedures), and the risk of transmission of CMV from unscreened donors (which has been reduced by the use of filters),

TABLE 72-8 *Other Antiviral Agents Useful in the Treatment of Infections in Cancer Patients*

Agent	Description	Spectrum	Toxicity	Other Issues
Amantadine Rimantadine	Interferes with uncoating	Influenza A only	5–10% fewer CNS effects with rimantadine	May be given prophylactically
Zanamivir	Neuraminidase inhibitor	Influenza A and B	Usually well tolerated	Inhalation only
Oseltamivir	Neuraminidase inhibitor	Influenza A and B	Usually well tolerated	PO dosing
Pleconaril	Blocks enterovirus binding and uncoating	90% of enteroviruses, 80% of rhinoviruses	Generally well tolerated	Decreases duration of meningitis; available for compassionate use only
Interferons	Cytokines with broad spectrum of activity	Used locally for warts, systemically for hepatitis	Fever, myalgias, bone marrow suppression	Not shown to be helpful in CMV infection; use limited by toxicity
Ribavirin	Purine analogue (precise mechanism of action unknown)	Broad theoretical spectrum; documented use against RSV, Lassa fever virus, and hepatitis viruses (with interferon)	IV form causes anemia	Given by aerosol for RSV infection (efficacy in doubt); approved for use in children with heart/lung disease

Abbreviations: CMV, cytomegalovirus; CNS, central nervous system; RSV, respiratory syncytial virus.

granulocyte transfusion is reserved for patients unresponsive to antibiotics. This modality is efficacious for documented gram-negative bacteremia refractory to antibiotics, particularly in situations where granulocyte numbers will be depressed for only a short period. The demonstrated usefulness of granulocyte colony-stimulating factor (G-CSF) in mobilizing neutrophils and advances in preservation techniques may make this option more useful than in the past.

A variety of cytokines, including G-CSF and granulocyte-macrophage colony-stimulating factor, enhance granulocyte recovery after chemotherapy and consequently shorten the period of maximal vulnerability to fatal infections. The role of these cytokines in routine practice is still a matter of some debate. Most authorities recommend their use only when neutropenia is both severe and prolonged. The cytokines themselves may have adverse effects, including fever, hypoxemia, and pleural effusions or serositis in other areas (Chap. 295). Since there is little evidence that their routine administration lessens the risk of death and since they are still expensive, the use of these cytokines has not become the standard of care in all centers. The role of other cytokines (such as macrophage colony-stimulating factor for monocytes or interferon-γ) in preventing or treating infections in granulocytopenic patients is under investigation.

Once neutropenia has resolved, patients are not at increased risk of infection. However, depending on what drugs they receive, patients who continue on chemotherapeutic protocols remain at high risk for certain diseases. Any patient receiving more than a maintenance dose of glucocorticoids (including many treatment regimens for diffuse lymphoma) should also receive prophylactic TMP-SMX because of the risk of *Pneumocystis* infection; those with ALL should receive such prophylaxis for the duration of chemotherapy.

PREVENTION OF INFECTION IN CANCER PATIENTS

EFFECT OF THE ENVIRONMENT Outbreaks of fatal *Aspergillus* infection have been associated with construction projects and materials in several hospitals. The association between spore counts and risk of infection suggests the need for a high-efficiency air-handling system in hospitals that care for large numbers of neutropenic patients. The use of laminar-flow rooms and prophylactic antibiotics has decreased the number of infectious episodes in severely neutropenic patients. However, because of the expense of such a program and the failure to show that it dramatically affects mortality, most centers do not routinely use laminar flow to care for neutropenic patients. Some centers use "reverse isolation," in which health care providers and visitors to a patient who is neutropenic wear gowns and gloves. Since most of the infections these patients develop are due to organisms that colonize the patients' own skin and bowel, the validity of such schemes is dubious, and limited clinical data do not support their use. Hand washing by all staff caring for neutropenic patients should be required to prevent the spread of resistant organisms.

The presence of large numbers of bacteria (particularly *P. aeruginosa*) in certain foods, especially fresh vegetables, has led some authorities to recommend a special "low-bacteria" diet. A diet consisting of cooked and canned food is satisfactory to most neutropenic patients and does not involve elaborate disinfection or sterilization protocols. However, there are no studies to support even this type of dietary restriction. Counseling of patients to avoid leftovers, deli foods, and unpasteurized dairy products is recommended.

PHYSICAL MEASURES Although few studies address this issue, patients with cancer are predisposed to infections resulting from anatomic compromise (e.g., lymphedema resulting from node dissections after radical mastectomy). Surgeons who specialize in cancer surgery can provide specific guidelines for the care of such patients, and patients benefit from common-sense advice about how to prevent infections in vulnerable areas.

IMMUNOGLOBULIN REPLACEMENT Many patients with multiple myeloma or CLL have immunoglobulin deficiencies as a result of their disease, and all allogeneic bone marrow transplant recipients are hypogammaglobinemic for a period after transplantation. However, current recommendations reserve intravenous immunoglobulin (IVIg) replacement therapy for those patients with severe (<400 mg/dL), prolonged hypogammaglobulinemia. Antibiotic prophylaxis has been shown to be cheaper and efficacious in preventing infections in most CLL patients with hypogammaglobulinemia. Routine use of IVIg replacement is not recommended.

SEX The use of condoms is recommended for severely immunocompromised patients. Any sexual practice that results in oral exposure to feces is not recommended. Neutropenic patients should be advised to avoid any practice that results in trauma, as even microscopic cuts may result in bacterial invasion and fatal sepsis.

ANTIBIOTIC PROPHYLAXIS There is no consensus on the use of prophylactic antibiotics in neutropenic patients. The incidence of infection is lower among patients who receive broad-spectrum antibiotic prophylaxis than among those who do not. Because of the prolongation of neutropenia associated with the use of TMP-SMX, some clinicians use broad-spectrum agents such as quinolones (e.g., levofloxacin). Either regimen can be given orally, and both have the advantage of inactivity against anaerobic organisms; thus, neither is likely to disrupt the bowel flora and permit colonization with new aerobes or *Candida*. However, all antibiotic regimens have adverse effects and can lead to the selection of resistant organisms in a hospital. For these reasons, many clinicians reserve their use for patients with the longest periods of neutropenia (e.g., bone marrow transplant recipients). The same issues apply to the use of antifungal agents. While agents such as fluconazole may prevent infections with susceptible organisms (e.g., *C. albicans*), they can cause a concomitant increase in infections due to resistant fungi (e.g., *C. krusei*). Thus, the decision to use antifungal prophylaxis may vary with the fungi endemic in a given hospital. Prophylaxis for

Pneumocystis is mandatory for patients with ALL and for all cancer patients receiving glucocorticoid-containing chemotherapy regimens.

VACCINATION OF CANCER PATIENTS In general, patients undergoing chemotherapy respond less well to vaccines than normal hosts. Their greater need for vaccines thus leads to a dilemma in their management. Purified proteins and inactivated vaccines are almost never contraindicated and should be given to patients even during chemotherapy. For example, all adults should receive diphtheria-tetanus toxoid boosters at the indicated times as well as seasonal influenza vaccine. However, if possible, vaccination should not be undertaken concurrent with cytotoxic chemotherapy. If patients are expected to be receiving chemotherapy for several months and vaccination is indicated (for example, influenza vaccination in the fall), the vaccine should be given midcycle—as far apart in time as possible from the antimetabolic agents that will prevent an immune response. The meningococcal and pneumococcal polysaccharide vaccines should be given to patients before splenectomy, if possible. The *H. influenzae* type b conjugate vaccine should be administered to all splenectomized patients.

In general, live virus (or live bacterial) vaccines should not be given to patients during intensive chemotherapy because of the risk of disseminated infection. Recommendations on vaccination are summarized in Table 72-2.

73 CANCER OF THE SKIN

Katarina G. Chiller, Carl Washington, Arthur J. Sober, Howard K. Koh

NONMELANOMA SKIN CANCER

Nonmelanoma skin cancer (NMSC) is the most common cancer in the United States, with an estimated annual incidence of >1.3 million cases. Basal cell carcinomas (BCCs) account for 70 to 80% of NMSCs. Squamous cell carcinomas (SCCs), while representing only ~20% of NMSC, are more significant because of their ability to metastasize; they account for most of the 2300 deaths annually. Incidence rates have risen dramatically over the past decade.

ETIOLOGY The cause of BCC and SCC is multifactorial. Cumulative exposure to sunlight, principally the ultraviolet B (UV-B) spectrum, is the most significant factor. Other factors associated with a higher incidence of skin cancer are male sex, older age, Celtic descent, a fair complexion, a tendency to sunburn easily, and an outdoor occupation. The incidence of these tumors increases with decreasing latitude. Most tumors develop on sun-exposed areas of the head and neck. Tumors are more common on the left side of the body in the United States but on the right side in England, presumably owing to asymmetric exposure during driving. As the earth's protective ozone shield continues to thin, further increases in the incidence of skin cancer can be anticipated. In certain geographic areas, exposure to arsenic in well water or from industrial sources may significantly increase the risk of BCC and SCC. Skin cancer in affected individuals may be seen with or without other cutaneous markers of chronic arsenism (e.g., arsenical keratoses). Less common is exposure to the cyclic aromatic hydrocarbons in tar, soot, or shale. The risk of lip or oral SCC is increased with cigarette smoking. Human papillomaviruses and UV radiation may act as cocarcinogens.

Host factors associated with a high risk of skin cancer include immunosuppression induced by disease or drugs. Transplant recipients receiving chronic immunosuppressive therapy are particularly prone to SCC. The frequency of skin cancer is proportional to the duration of immunosuppression and the extent of sun exposure. Skin cancer is not uncommon in patients infected with HIV, and it may be more aggressive in this setting. Other factors include ionizing radiation, thermal burn scars, and chronic ulcerations. Several heritable conditions are associated with skin cancer (e.g., albinism, xeroderma pigmentosum, and basal cell nevus syndrome). Mutations in the tumor suppressor *patch* gene have been implicated in the development of BCC.

CLINICAL PRESENTATION NMSCs are often asymptomatic, but nonhealing ulceration, bleeding, or pain can occur in advanced lesions.

Basal Cell Carcinoma BCC is a malignancy arising from epidermal basal cells. The least invasive of BCC subtypes, *superficial BCC*, classically consists of truncal erythematous, scaling plaques that slowly enlarge. This BCC subtype may be confused with benign inflammatory dermatoses, especially nummular eczema and psoriasis. BCC can also present as a small, slow growing pearly nodule, often with small telangiectatic vessels on its surface (*nodular BCC*). The occasional presence of melanin in this variant of nodular BCC (*pigmented BCC*) may lead to the erroneous diagnosis of malignant melanoma. *Morpheaform (fibrosing) BCC*, the most invasive subtype, manifests itself as a solitary, flat or slightly depressed, indurated, whitish or yellowish plaque. Borders are typically indistinct, a feature associated with a greater potential for extensive subclinical spread.

Squamous Cell Carcinoma Primary *cutaneous SCC* is a malignant neoplasm of keratinizing epidermal cells. SCC can grow rapidly and metastasize. The clinical features of SCC vary widely. Commonly, SCC appears as an ulcerated erythematous nodule or superficial erosion on the skin or lower lip, but it may present as a verrucous papule or plaque. Overlying telangiectasias are uncommon. The margins of this tumor may be ill defined, and fixation to underlying structures may occur. Cutaneous SCC may develop anywhere on the body but usually arises on sun-damaged skin. A related neoplasm, keratoacanthoma, typically appears as a dome-shaped papule with a central keratotic crater, expands rapidly, and commonly regresses without therapy. This lesion can be difficult to differentiate from SCC.

Actinic keratoses and *cheilitis*, both premalignant forms of SCC, present as hyperkeratotic papules on sun-exposed areas. The potential for malignant degeneration in untreated lesions ranges from 0.25 to 20%. *Bowen's disease*, the in situ form of SCC, presents as a scaling, erythematous plaque. Treatment of premalignant and in situ lesions reduces the subsequent risk of invasive disease.

NATURAL HISTORY ■ Basal Cell Carcinoma The natural history of BCC is that of a slowly enlarging, locally invasive neoplasm. The degree of local destruction and risk of recurrence vary with the size, duration, location, and histologic subtype of the tumor; presence of recurrent disease; and various patient characteristics. Location on the central face, ears, or the scalp may portend a higher risk. Small nodular, pigmented, cystic, or superficial BCCs respond well to most treatments. Large lesions or morpheaform subtype may be more aggressive. The metastatic potential of BCC has been estimated to be 0.0028 to 0.1%. Persons with either BCC or SCC have an increased risk of developing subsequent skin cancers, estimated to be up to 40% in 5 years.

Squamous Cell Carcinoma The natural history of SCC depends on both tumor and host characteristics. Tumors arising on actinically damaged skin have a lower metastatic potential than those on protected surfaces. The metastatic frequency of cutaneous SCC, reported at 0.3 to 5.2%, occurs most frequently in regional draining lymph nodes. Tumors occurring on the lower lip and ear have metastatic potentials approaching 13 and 11%, respectively. The metastatic potential of SCC arising in scars, chronic ulcerations, and genital or mucosal surfaces is higher. The overall metastatic rate for recurrent tumors may approach 30%. Large, poorly differentiated, deep tumors, with perineural or lymphatic invasion, often behave aggressively. Multiple tumors with rapid growth and aggressive behavior can be a therapeutic challenge in immunosuppressed patients.

TREATMENT

Basal Cell Carcinoma The most frequently used treatment modalities for BCC include electrodesiccation and curettage (ED&C), excision, cryosurgery, radiation therapy, laser therapy, Mohs micrographic surgery (MMS), topical 5-fluorouracil, and topical immunomodulators. The mode of therapy chosen depends on tumor characteristics, patient age, medical status, preferences of the patient, and other factors. ED&C remains the method most commonly employed by dermatologists. This method is selected for low-risk tumors (e.g., a small primary tumor of a less aggressive subtype in a favorable location). Excision, which offers the advantage of histologic control, is usually selected for more aggressive tumors or those in high-risk locations or, in many instances, for aesthetic reasons. Cryosurgery using liquid nitrogen may be used in certain low-risk tumors, but it requires specialized equipment (cryoprobes) to be effective for advanced neoplasms. Radiation therapy, while not employed as often as surgical modalities, offers an excellent chance for cure in many cases of BCC. It is useful in patients not considered surgical candidates and as a surgical adjunct in high-risk tumors. Younger patients may not be good candidates for radiation therapy because of the risks of long-term carcinogenesis and radiodermatitis. Despite rapidly advancing technology in laser development, their long-term efficacy in treating infiltrative or recurrent lesions is still unknown. On the other hand, MMS, a specialized type of surgical excision that permits the best histologic control and preservation of uninvolved tissue, is associated with cure rates >98%. It is the preferred modality for lesions that are recurrent, in a high-risk location, or large and ill-defined and where maximal tissue conservation is critical (e.g., the eyelids). Topical 5-fluorouracil therapy should be limited to superficial BCC. New lines of topicals, the immunomodulators, show promise in their efficacy at treating superficial and even nodular BCCs. Imiquimod, a relatively well-tolerated cream, has successfully undergone phase III clinical trials. Intralesional chemotherapy (5-fluorouracil and interferon) and photodynamic therapy (which employs selective activation of a photoactive drug by visible light) have been used successfully in patients with numerous tumors.

Squamous Cell Carcinoma The therapy of cutaneous SCC should be based on an analysis of risk factors influencing the biologic behavior of the tumor. These include the size, location, and degree of histologic differentiation of the tumor as well as the age and physical condition of the patient. Surgical excision, MMS, and radiation therapy are standard methods of treatment. Cryosurgery and ED&C have been used successfully for premalignant lesions and small primary tumors. Metastases are treated with lymph node dissection, irradiation, or both. 13-*cis*-retinoic acid (1 mg orally every day) plus interferon α (3 million units subcutaneously or intramuscularly every day) may produce a partial response in most patients. Systemic chemotherapy combinations that include cisplatin may also be palliative in some patients.

PREVENTION As the vast majority of skin cancers are related to chronic UV radiation exposure, patient and physician education could dramatically reduce their incidence. Emphasis should be placed on preventive measures beginning early in life. Patients must understand that damage from UV-B begins early, despite the fact that cancers develop years later. Regular use of sunscreens and protective clothing should be encouraged. Avoidance of tanning salons and midday (10 A.M. to 2 P.M.) sun exposure is recommended. Precancerous and in situ lesions should be treated early. Early detection of small tumors affords simpler treatment modalities with higher cure rates and lower morbidity. In patients with a history of skin cancer, long-term follow-up for the detection of recurrence, metastasis, and new skin cancers should be emphasized. Chemoprophylaxis using synthetic retinoids is useful in controlling new lesions in some patients with multiple tumors.

OTHER NONMELANOMA CUTANEOUS MALIGNANCIES Neoplasms of cutaneous adnexa and sarcomas of fibrous, mesenchymal, fatty, and vascular tissues make up 1 to 2% of NMSC (Table 73-1). Some can portend a poor prognosis such as *Merkel cell carcinoma*, which is a neural crest–derived, highly aggressive malignancy that exhibits a metastatic rate of 75%, and a 5-year survival rate of 30 to 40%. Others, such as the human herpes virus 8–induced, HIV-related *Kaposi's sarcoma*, exhibit a more indolent course. The recent marked decrease in incidence of this tumor parallels the institution of the highly active antiretroviral therapy.

MELANOMA

Pigmented skin lesions are among the most common findings on physical examination. The challenge is to distinguish cutaneous melanomas, which may be lethal, from the remainder, which with rare exceptions are benign. Cutaneous neoplasms are depicted in Fig. 73-1; benign and malignant pigmented lesions are shown in Fig. 73-2.

EPIDEMIOLOGY Melanomas originate from neural crest–derived melanocytes, pigment cells present normally in the epidermis and sometimes in the dermis. This tumor will affect approximately 54,200 individuals per year in the United States, resulting in >8,200 deaths. The tumor can affect adults of all ages, even young individuals (starting in the mid-teens); it has distinct clinical features that make it detectable at a time when cure by surgical excision is possible; and it is located on the skin surface, where it is visible. The incidence has increased dramatically (a 300% increase in the past 40 years). If the incidence continues to increase at the present rate, within a decade, lifetime risk of melanoma will be ≳1%. The reason for this increase is uncertain but may involve increased recreational sun exposure, especially early in life. Individuals of similar ethnic background who immigrate after childhood to areas of high sun exposure (e.g., Israel and Australia) have lower melanoma rates than individuals of similar age who were either born in those countries or immigrated before age 10. The individuals most susceptible to development of melanoma are those with fair complexions, red or blond hair, blue eyes, and freckles and who tan poorly and sunburn easily. In one literature survey, 9 of 11 studies linked increased melanoma risk to history of sunburn. Other factors associated with increased risk include a family history of melanoma (~1 in 10 melanoma patients have a family member with mel-

TABLE 73-1 *Other Nonmelanoma Cutaneous Malignancies*

Tumor Type	Most Common Location	Recurrence Rate,[a] %	Metastatic Rate, %
Atypical fibroxanthoma	Head and neck	21	4
Merkel cell carcinoma	Head and neck	40	75
Dermatofibrosarcoma protuberans	Trunk	50	1
Sebaceous carcinoma	Eyelid	12	30
Microcystic adnexal carcinoma	Face	50	1 case
Porocarcinoma	Extremity	20	10
Eccrine carcinoma	Head and neck	36	11
Angiosarcoma	Head and neck	75	75

[a] Recurrence rates are the highest reported and were established prior to widespread use of Mohs micrographic surgery.

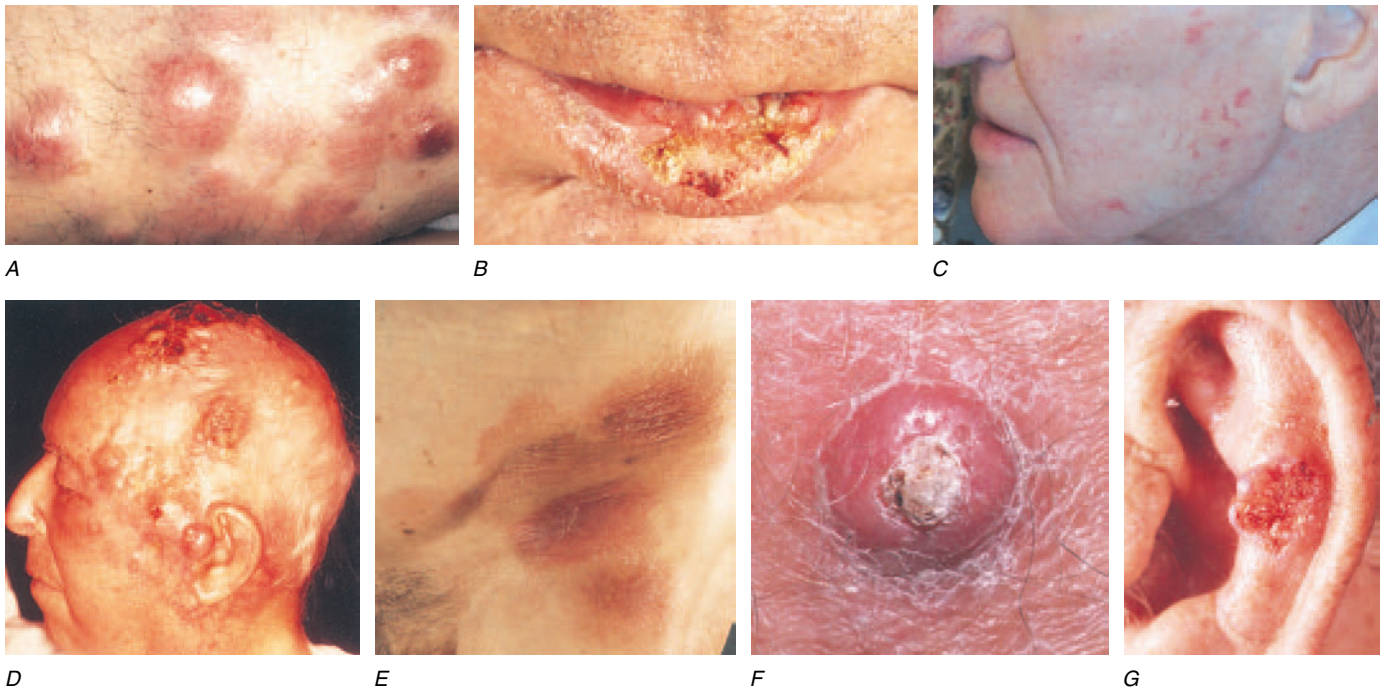

FIGURE 73-1 *A.* Non-Hodgkin's lymphoma involves the skin with typical violaceous, "plum-colored" nodules. *B.* Squamous cell carcinoma is seen here as a hyperkeratotic crusted and somewhat eroded plaque on the lower lip. Sun-exposed skin such as the head, neck, hands, and arms are other typical sites of involvement. *C.* Actinic keratoses consists of hyperkeratotic erythematous papules and patches on sun-exposed skin. They arise in middle-aged to older adults and have some potential for malignant transformation. *D.* Metastatic carcinoma to the skin is characterized by inflammatory, often ulcerated dermal nodules. *E.* Mycosis fungoides is a cutaneous T cell lymphoma, and plaque stage lesions are seen in this patient. *F.* Keratoacanthoma is a low-grade squamous cell carcinoma that presents as an exophytic nodule with central keratinous debris. *G.* This basal cell carcinoma shows central ulceration and a pearly, rolled, telangiectatic tumor border.

anoma); the presence of a clinically atypical mole (dysplastic nevus), a giant congenital melanocytic nevus, or a small to medium-sized congenital melanocytic nevus (see below); the presence of a higher than average number of ordinary melanocytic nevi; and immunosuppression (Table 73-2). A 64-fold increased risk for individuals with 50 or more moles ≥2 mm in size has been reported. About 30% of melanomas arise in a nevus. Melanoma is relatively rare in heavily pigmented peoples. Dark-skinned populations (such as those of India and Puerto Rico), blacks, and East Asians have rates 10 to 20 times lower than lighter-skinned whites. In keeping with the role of sun exposure, the incidence is inversely correlated with the latitude of residence; at any latitude, darker-skinned persons have the lowest incidence.

CLINICAL CHARACTERISTICS There are four types of cutaneous melanoma (Table 73-3). In three of these—*superficial spreading melanoma*, *lentigo maligna melanoma*, and *acral lentiginous melanoma*—the lesion has a period of superficial (so-called radial) growth during which it increases in size but does not penetrate deeply. It is during this period that the melanoma is most capable of being cured by surgical excision. The fourth type—*nodular melanoma*—does not have a recognizable radial growth phase and usually presents as a deeply invasive lesion, capable of early metastasis. When tumors begin to penetrate deeply into the skin, they are in the so-called vertical growth phase. Melanomas with a radial growth phase are characterized by irregular and sometimes notched borders, variation in pigment pattern, and variation

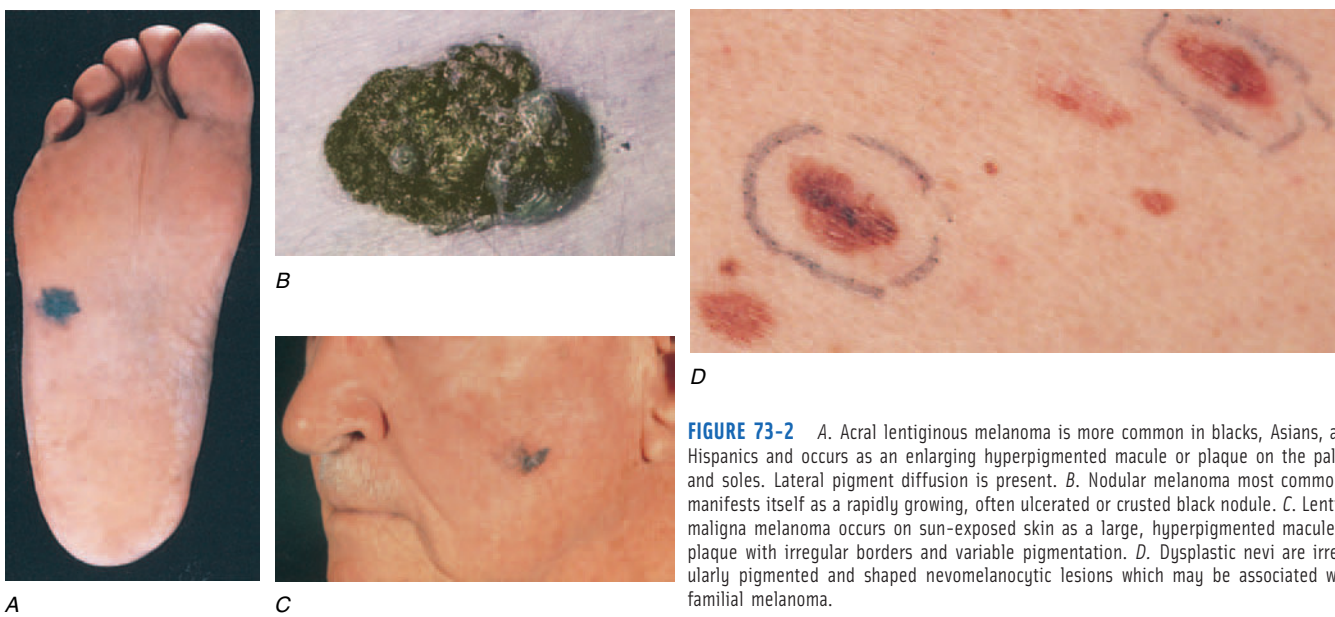

FIGURE 73-2 *A.* Acral lentiginous melanoma is more common in blacks, Asians, and Hispanics and occurs as an enlarging hyperpigmented macule or plaque on the palms and soles. Lateral pigment diffusion is present. *B.* Nodular melanoma most commonly manifests itself as a rapidly growing, often ulcerated or crusted black nodule. *C.* Lentigo maligna melanoma occurs on sun-exposed skin as a large, hyperpigmented macule or plaque with irregular borders and variable pigmentation. *D.* Dysplastic nevi are irregularly pigmented and shaped nevomelanocytic lesions which may be associated with familial melanoma.

TABLE 73-2 Risk Factors for Cutaneous Melanoma

High risk (>50-fold increase in risk)
Persistently changing mole
Clinically atypical moles in patient with two family members with melanoma
Adulthood (vs. childhood)
>50 nevi ≥2 mm in diameter
Intermediate risk (~10-fold increase in risk)
Family history of melanoma
Sporadic clinically atypical moles
Congenital nevi (?)
White ethnicity (vs. black or East Asian ethnicity)
Personal history of prior melanoma
Low risk (2- to 4-fold increase in risk)
Immunosuppression
Sun sensitivity or excess exposure to sun

in color. An increase in size or change in color is noted by the patient in 70% of early lesions. Bleeding, ulceration, and pain are late signs and are of little help in early recognition. Nodular melanomas are dark brown-black to blue-black nodules. Melanomas occasionally are amelanotic, in which case the diagnosis is established histologically after biopsy of a new or changing skin nodule. Lentigo maligna melanoma is usually confined to chronically sun-damaged, sun-exposed sites (face, neck, back of hands) in older individuals. Acral lentiginous melanoma occurs on the palms, soles, nail beds, and mucous membranes. While this type occurs in whites, it is most frequent (along with nodular melanoma) in blacks and East Asians. Superficial spreading melanoma is most frequent in whites. Melanomas arising in dysplastic nevi (see below) are usually of this type. The back is the most common site for melanoma in men. In women, the back and the lower leg (from knee to ankle) are frequent sites.

PROGNOSTIC FACTORS The most important prognostic factor is the stage at the time of presentation. Fortunately, most melanomas are diagnosed in clinical stages I and II. The revised staging system for melanoma is based on microscopic primary tumor depth (Breslow's thickness), presence of ulceration, evidence of nodal involvement, presence of microscopic satellites, and presence of metastatic disease (Table 73-4). Certain anatomic sites may affect the prognosis. The favorable sites appear to be the forearm and leg (excluding feet), while unfavorable sites include scalp, hands, feet, and mucous membranes. In general, women with stage I or II disease have a better survival than men, perhaps in part because of earlier diagnosis; women frequently have melanomas on the lower leg, where self-recognition is more likely and prognosis is better. Older individuals, in general, have poorer prognoses. This finding has been explained in part by a tendency toward later diagnosis (and thus thicker tumors) in men and by a higher proportion in men of acral melanomas (palmar-plantar), which have a poorer prognosis. Melanoma may recur after many years. About 10 to 15% of first-time recurrences develop >5 years after treatment of the original lesion. The time to recurrence varies inversely with tumor thickness. An alternative prognostic scheme for clinical stages I and II melanoma, proposed by Clark, is based on the anatomic level of invasion in the skin. Level I is intraepidermal (in situ); level II penetrates the papillary dermis; level III spans the papillary dermis; level IV penetrates the reticular dermis; and level V penetrates into the subcutaneous fat. The 5-year survival for these stages averages 100, 95, 82, 71, and 49%, respectively.

NATURAL HISTORY Melanomas may spread by the lymphatic channels or the bloodstream. The earliest metastases are often to regional lymph nodes. Surgical lymphadenectomy may control early regional disease. Liver, lung, bone, and brain are common sites of hematogenous spread, but unusual sites, such as the anterior chamber of the eye, may also be involved. Once widespread metastatic disease is established, the likelihood of cure is low.

MANAGEMENT The entire cutaneous surface, including the scalp and mucous membranes, should be examined in each patient. Bright room illumination is important, and a 7× to 10× hand lens is helpful for evaluating variation in pigment pattern. A history of relevant risk factors should be elicited. Any suspicious lesions should be biopsied, evaluated by a specialist, or recorded by chart and/or photography for follow-up. Examination of the lymph nodes and palpation of the abdominal viscera are part of the staging examination for suspected melanoma. The patient should be advised to have other family members screened if either melanoma or clinically atypical moles (dysplastic nevi) are present. The detection of early melanoma in relatives on screening has been reported. Melanoma prevention is based on protection from the sun. Routine use of a sunblock with sun protection factor ≥15, use of protective clothing, and avoiding intense midday ultraviolet exposure should be recommended. The patient should be educated in the clinical features of melanoma and advised to report any growth or other change in a pigmented lesion. Patient education brochures are available from the American Cancer Society, the American Academy of Dermatology, the National Cancer Institute, and the Skin Cancer Foundation. Self-examination at 6- to 8-week intervals may enhance the likelihood of detecting change. The importance of routine follow-up visits for melanoma patients and patients with clinically atypical moles (dysplastic nevi) should be emphasized, as these visits may facilitate early detection of new tumors.

Precursor Lesions Clinically atypical moles, also termed *dysplastic nevi*, occur in certain families affected by melanoma. In some families, melanomas occur nearly exclusively in the individuals with dysplastic nevi. These nevi appear to be transmitted as an autosomal dominant trait that involves chromosome 9p16. In other families, the nevi may

TABLE 73-3 Clinical Features of Malignant Melanoma

Type	Site	Average Age at Diagnosis, Years	Duration of Known Existence, Years	Color
Lentigo maligna melanoma	Sun-exposed surfaces, particularly malar region of cheek and temple	70	5–20[a] or longer	In flat portions, shades of brown and tan predominant, but whitish gray occasionally present; in nodules, shades of reddish brown, bluish gray, bluish black
Superficial spreading melanoma	Any site (more common on upper back and, in women, on lower legs)	40–50	1–7	Shades of brown mixed with bluish red (violaceous), bluish black, reddish brown, and often whitish pink, and the border of lesion is at least in part visibly and/or palpably elevated
Nodular melanoma	Any site	40–50	Months to less than 5 years	Reddish blue (purple) or bluish black; either uniform in color or mixed with brown or black
Acral lentiginous melanoma	Palm, sole, nail bed, mucous membrane	60	1–10	In flat portions, dark brown predominantly; in raised lesions (plaques) brown-black or blue-black predominantly

[a] During much of this time, the precursor stage, lentigo maligna, is confined to the epidermis.

Source: Adapted from AJ Sober, in *Pathophysiology of Dermatologic Diseases*, NA Soter, HP Baden (eds). New York, McGraw-Hill, 1984.

not be present in all individuals with an increased risk of melanoma. The melanomas may arise in clinically atypical moles or in normal skin (in the latter situation the mole acts as a marker of increased risk). Individuals with clinically atypical moles and two family members with melanoma have been reported to have a >50% lifetime risk for developing melanoma. Table 73-5 lists the features that are characteristic of clinically atypical moles and that differentiate them from benign acquired nevi. The number of clinically atypical moles may vary from one to several hundred. Clinically atypical moles usually differ from each other in appearance. The borders are often hazy and indistinct, and the pigment pattern is more highly varied than that in benign acquired nevi. Of the 90% of melanoma patients whose disease is regarded as sporadic (i.e., who lack a family history of melanoma), ~40% have clinically atypical moles, as compared with an estimated 5 to 10% of the population at large. Further studies to determine the background frequency of clinically atypical moles are required, once greater unanimity exists regarding their clinical and histopathologic features. The observation that at least 20% of sporadic melanomas arise in association with a clinically atypical mole makes this the most important precursor for melanoma. Less frequent precursors include the giant congenital melanocytic nevus and the small congenital melanocytic nevus (although the latter relationship is disputed by some). Congenital melanocytic nevi are present at birth or appear in the neonatal period (tardive form). The *giant melanocytic nevus*, also called the bathing trunk, cape, or garment nevus, is a rare malformation that affects perhaps 1 in 30,000 to 1 in 100,000 individuals. These nevi are usually >20 cm in diameter and may cover more than half the body surface. Giant nevi often occur in association with multiple small congenital nevi. The borders are sharp, and hair may be present. The lesions are usually dark brown and may have darker and lighter areas. Pigment is haphazardly displayed. The surface is smooth to rugose or cerebriform and may vary from one portion of the lesion to another. A lifetime risk of melanoma development of 6% has been estimated. The risk is greatest before age 5 and next greatest between ages 5 and 10. Early detection of melanoma is difficult in these lesions because of the deep dermal or subcutaneous origin of primary melanoma and because of the large and varied surface of the nevus. Prophylactic excision early in life can be accomplished by staged removal with coverage by split-thickness skin grafts. The use of cultured keratinocytes for coverage appears promising. At present, there are no uniform management guidelines for giant congenital nevi. The *small- to medium-sized congenital melanocytic nevus*, which affects approximately 1% of persons, presents usually as a raised dark- to medium-brown lesion with a smooth or papillomatous surface. The border is sharp, and lesions may be oriented along lines of skin cleavage. Follicular hyper- and hypopigmentation may coexist in a salt-and-pepper configuration. The lesion may have an excess of thick, coarse hairs. The risk of melanoma developing in these lesions is not known; however, melanomas can arise in these lesions. Considerations of body surface area suggest that the incidence of melanomas arising in small congenital melanocytic nevi is probably higher than would be expected by chance. The remnants of a nevus with histopathologic features of a congenital nevus have been observed in 2 to 6% of melanomas. The management of small- to medium-sized congenital melanocytic nevi remains controversial; prophylactic removal under local anesthesia in the early teen years is appropriate. Melanomas in small congenital melanocytic nevi appear to occur after this period of life.

Differential Diagnosis The aim of differential diagnosis is to distinguish benign pigmented lesions from melanoma and its precursor. If melanoma is a consideration, then biopsy is appropriate. Some benign lookalikes may be removed in the process of trying to detect authentic melanoma. Table 73-6 summarizes the distinguishing features of benign lesions that may be confused with melanoma. Early detection of melanoma may be facilitated by applying the "ABCD rules": A—asymmetry, benign lesions are usually symmetric; B—border irregularity, most nevi have clear-cut borders; C—color variegation, benign lesions usually have uniform light or dark pigment; D—diameter >6 mm (the size of a pencil eraser). Consideration may be given for ev-

TABLE 73-5 *Clinical Features Distinguishing Atypical Moles from Benign Acquired Nevi*

Clinical Feature	Clinically Atypical Moles	Benign Acquired Nevi
Color	Variable mixtures of tan, brown, black, or red/pink within a single nevus; nevi may look very different from each other	Uniformly tan or brown
Shape	Irregular borders; pigment may fade off into surrounding skin; macular portion at the edge of the nevus	Round; sharp, clear-cut borders between the nevus and the surrounding skin; may be flat or elevated
Size	Usually >6 mm in diameter; may be >10 mm; occasionally <6 mm	Usually <6 mm in diameter
Number	Often very many (>100), but occasionally may be only one	In a typical adult, 10 to 40 are scattered over the body; perhaps 15% of patients have no nevi
Location	Sun-exposed areas; the back is the most common site, but dysplastic nevi may also be seen on the scalp, breasts, and buttocks	Generally on the sun-exposed surfaces of the skin above the waist; the scalp, breasts, and buttocks are rarely involved

TABLE 73-6 Pigmented Lesions that Must Be Distinguished from Cutaneous Melanoma and Its Precursors

Blue nevus	Gunmetal or cerulean blue, blue-gray. Stable over time. One-half occur on dorsa of hands and feet. Lesions are usually single, small, 3 mm to <1 cm. Must be distinguished from nodular melanoma.
Compound nevus	Round or oval shape, well-demarcated, smooth-bordered. May be dome-shaped or papillomatous; colors range from flesh colored to very dark brown, with individual nevi being relatively homogeneous in color.
Hemangioma	Dome-shaped reddish, purple, blue nodule. Compression with a glass microscope slide may result in blanching. Must be distinguished from nodular melanoma.
Junctional nevus	Flat to barely raised brown lesion. Sharp border. Fine pigmentary stippling visible, especially upon magnification.
Lentigo Juvenile Solar	Flat, uniformly medium or dark brown lesion with sharp border. Solar lentigines are acquired lesions on sites of chronic solar exposure (face and backs of hands). Lesions are 2 mm to ≥1 cm. Solar lentigines have reticulate pigmentation upon magnification.
Pigmented basal cell carcinoma	Papular border. May have central ulceration. Usually on a sun-exposed surface in an older patient. Patient usually has dark brown eyes and dark brown or black hair.
Pigmented dermatofibroma	Lesion is not well demarcated visually, is firm, and dimples downward when compressed laterally. Usually on extremities. Usually <6 mm.
Seborrheic keratosis	Rough, sharp-bordered lesions that feel waxy and "stuck on"; range in color from flesh to tan, to dark brown. Presence of keratin plugs in surface is helpful for discriminating especially dark lesions from melanoma.
Subungual hematoma	Maroon (red-brown) coloration. As lesion grows out from nail fold, a curving clear area is seen.
Tattoo (medical or traumatic)	In medical tattoo, lesions are small pigmentary dots, often blue or green, which make a regular pattern (rectangle). Traumatic tattoos are irregular, and pigmentation may appear black.

olution ("E"), as any of the other features become more significant as the lesion is changing.

Biopsy Any pigmented cutaneous lesion that has changed in size or shape or has other features suggestive of malignant melanoma is a candidate for biopsy. The recommended technique is a full-thickness excisional biopsy, as that facilitates pathologic assessment of the lesion, permits accurate measurement of thickness if the lesion is melanoma, and constitutes treatment if the lesion is benign. Shave biopsy or curettage of a suspected melanoma is contraindicated. For large lesions or lesions on anatomic sites where excisional biopsy may not be feasible (such as the face, hands, or feet), an incisional biopsy through the most nodular or darkest area of the lesion is acceptable; this should include the vertical growth phase of the primary tumor, if present. Data from prospective studies do not indicate that an incisional biopsy facilitates the spread of melanoma.

Staging Once the diagnosis of malignant melanoma has been confirmed, the tumor must be staged to determine prognosis and treatment. The history should probe for evidence of metastatic disease, such as malaise, weight loss, headaches, visual difficulty, or bone pain. The physical examination should be directed especially to the skin, regional draining lymph nodes, central nervous system, liver, and spleen. In the absence of signs or symptoms of metastasis, few laboratory or radiologic tests are indicated for staging purposes. Aside from a chest radiograph and, possibly, liver function tests, no other tests or scans are routinely indicated unless the history or physical examination suggests metastasis to a specific organ. Specifically, liver-spleen scans and computed tomography have a low yield and are not cost-effective. However, once signs of metastasis exist, favored sites of spread, such as the liver, lungs, bone, and brain, should be scanned. Appropriate evaluations place patients into four clinical stages (Table 73-4).

TREATMENT

Surgical Management For a newly diagnosed cutaneous melanoma, wide surgical excision of the lesion with a margin of normal skin is necessary to remove all malignant cells and minimize local recurrence. The appropriate width of the margin is a source of controversy. A World Health Organization trial prospectively randomized between 1- and 3-cm margins in 612 patients with thin malignant melanomas (≤2 mm thick) reported that the narrower margin resulted in higher rates of local recurrence but no difference in rates of nodal or distant metastases, disease-free survival, or overall survival after 7.5 years of follow-up. Another large randomized trial comparing 2- or 4-cm surgical margins for intermediate-thickness lesions (1 to 4 mm thick) also found no significant differences in overall survival. The following margins can be recommended for primary melanoma: in situ: 0.5 cm; invasive up to 1 mm thick: 1.0 cm; 1 to 4 mm thick: 2.0 cm; >4 mm thick: 2.5 to 3.0 cm. For lesions on the face, hands, and feet, strict adherence to these margins must give way to individual considerations about the constraints of surgery and minimization of morbidity. In all instances, however, inclusion of subcutaneous fat in the surgical specimen facilitates adequate thickness measurement and assessment of surgical margins by the pathologist.

ELECTIVE REGIONAL NODE DISSECTION Elective regional node dissection in the American Joint Commission for Cancer (AJCC) stage II disease (without palpable adenopathy) has been advocated, based on the hypothesis that melanoma metastasizes in an orderly fashion from the skin to regional lymph nodes and finally to distant sites. If that is the case, surgical excision of nodal micrometastasis could theoretically provide definitive treatment at a time of relatively low tumor burden and perhaps improve survival. The efficacy of this procedure remains controversial; while some retrospective series suggest a survival benefit, two randomized studies examining this question in patients with limb melanomas and clinical stage I disease showed no survival advantage for wide local excision followed by immediate elective regional node dissection compared with wide local excision followed by delayed dissection (only if nodes became palpable). Furthermore, the procedure has associated morbidity, and some lesions, especially those on the trunk, have ambiguous nodal draining sites, making it difficult to decide which area to dissect. Sentinel lymph node examination has been shown to be a valuable staging tool and, in instances of a negative sentinel lymph node, may obviate the need for elective regional nodal dissection. Patients with lesions <0.75 mm thick have an excellent prognosis and need no node dissection; at the other extreme, patients with lesions 3.5 mm thick have such a high risk for distant metastases that elective node dissection may not alter the ultimate clinical outcome. A subset of patients with AJCC stage II lesions of intermediate thickness may benefit from elective regional node dissection, but there is no consensus about which patients should undergo this procedure. An ongoing randomized surgical trial may resolve this issue.

Adjuvant Therapy For patients who are free of disease but at high risk for metastases, adjuvant therapy that complements surgery is needed to destroy occult micrometastases, prolong disease-free survival, and improve the cure rate. Many strategies have been tried unsuccessfully. However, adjuvant interferon α (either 2a or 2b) may be capable of improving disease-free and overall survival in some, particularly in patients with nodal metastases (stage III disease). The U.S. Food and Drug Administration has approved a high-dose interferon adjuvant protocol consisting of 20 million units per square meter intravenously 5 days a week for 4 weeks followed by 10 million units per square meter subcutaneously three times a week for 11 months. Ongoing studies are attempting to define the minimal effective dose, because, in

nearly half of patients, these doses of interferon are associated with severe toxicity, including flulike illness and decline in performance status. The toxicity reverses promptly with lower doses and when therapy is stopped.

Treatment of Metastatic Disease Melanoma can metastasize to any organ, the brain being a particularly common site. Metastatic melanoma is generally incurable, with survival in patients with visceral metastases generally <1 year. Thus, the goal of treatment is usually palliation. Patients with soft tissue and node metastases fare better than those with liver and brain metastases. Metastases limited to regional nodes (AJCC stage III disease) warrant a therapeutic lymph node dissection. Surgical excision of a single metastasis to the lung or to a surgically accessible brain site can prolong survival. Trials of stereotactic radiosurgery will determine its future role in the treatment of brain metastases. More often, however, patients have multiple brain metastases that require radiation therapy and glucocorticoids. Radiation therapy can provide local palliation for recurrent tumors or metastases. Patients who have advanced regional disease limited to a limb may benefit from hyperthermic limb perfusion with melphalan and tumor necrosis factor. Complete response rates >90% have been reported; responses are associated with significant palliation of symptoms.

A number of drugs and biologicals have minimal antitumor activity (15 to 20% partial response rates) in metastatic melanoma, including dacarbazine (DTIC); the nitrosoureas carmustine (BCNU), lomustine (CCNU), and semustine (methyl-CCNU); platinum analogues such as cisplatin and carboplatin; vinca alkyloids such as vincristine, vinblastine, and vindesine; the taxanes paclitaxel and docetaxel; interferon α; and interleukin 2 (IL-2). Single-agent dacarbazine is considered the standard treatment. This agent has been given at a number of different doses and schedules; 250 mg/m^2 intravenously every day for 5 days every 3 weeks is a standard schedule. Dacarbazine-based combination regimens are probably more effective. Ongoing trials are attempting to define superior combinations. Interferon and IL-2 produce response rates similar to those seen with cytotoxic agents; however, at active doses, they usually cause greater toxicity than chemotherapy.

Melanoma can express cell surface antigens that may be recognized by host immune cells. Melanoma antigens (MAGEs)-1, -2, and -3 (endogenous proteins controlled by genes on the X chromosome; there may be up to 12 of these genes) and tyrosinase, an enzyme involved in melanin synthesis, are antigens that are processed into peptides and presented to T cells via HLA-A antigens on the tumor, particularly the HLA-A1 and A2 alleles, which are expressed in about 85% of patients with melanoma. In addition, a melanoma antigen called MART is recognized in the context of class II MHC antigens. These melanoma-associated antigens alone or in combination may make it possible to develop vaccination strategies against melanoma. Such strategies include the use of purified proteins as immunogens and the use of genetically altered tumor cells to elicit a T cell response. Alternative experimental approaches include efforts to expand tumor-specific T cells (obtained either from the tumor as tumor-infiltrating lymphocytes or harvested from the peripheral blood after vaccination) in vitro and transfer them into patients in large numbers. In addition, monoclonal antibodies to tumor antigens are being tested, with some early indication of efficacy in ~15% of patients. All of these experimental approaches will need considerable further development before being applicable on a wide scale. Advances in treating metastatic disease may be applicable in the adjuvant setting.

The absence of curative therapy for patients with metastatic melanoma underscores the importance of early detection and prevention as strategies to decrease melanoma mortality.

74 HEAD AND NECK CANCER

Everett E. Vokes

Epithelial carcinomas of the head and neck arise from the mucosal surfaces in the head and neck area and typically are squamous cell in origin. This category includes tumors of the paranasal sinuses, the oral cavity, and the nasopharynx, oropharynx, hypopharynx, and larynx. Tumors of the salivary glands differ from the more common carcinomas of the head and neck in etiology, histopathology, clinical presentation, and therapy. Thyroid malignancies are described in Chap. 320.

INCIDENCE AND EPIDEMIOLOGY The number of new cases of head and neck cancers in the United States was 38,530 in 2004, accounting for about 3% of adult malignancies. The worldwide incidence exceeds half a million cases annually. In North America and Europe, the tumors usually arise from the oral cavity, oropharynx, or larynx, whereas nasopharyngeal cancer is more common in the Mediterranean countries and in the Far East.

ETIOLOGY AND GENETICS Alcohol and tobacco use are the most common risk factors for head and neck cancer in the United States. Smokeless tobacco is an etiologic agent for oral cancers. Other potential carcinogens include marijuana and occupational exposures such as nickel refining, exposure to textile fibers, and woodworking.

Dietary factors may contribute. The incidence of head and neck cancer is highest in people with the lowest consumption of fruits and vegetables. Certain vitamins, including dietary carotenoids, may be protective; retinoids are being tested for prevention.

Some head and neck cancers may have a viral etiology. The DNA of human papillomavirus has been detected in the tissue of oral and tonsil cancers, and may predispose to oral cancer in the absence of tobacco and alcohol use. Epstein-Barr virus (EBV) infection is associated with nasopharyngeal cancer. Nasopharyngeal cancer occurs endemically in some countries of the Mediterranean and Far East, where EBV antibody titers can be measured to screen high-risk populations. Nasopharyngeal cancer has also been associated with consumption of salted fish.

No specific risk factors or environmental carcinogens have been identified for salivary gland tumors.

HISTOPATHOLOGY, CARCINOGENESIS, AND MOLECULAR BIOLOGY Squamous cell head and neck cancers can be divided into well-differentiated, moderately well-differentiated, and poorly differentiated categories. Patients with poorly differentiated tumors have a worse prognosis than those with well-differentiated tumors. For nasopharyngeal cancers, the less common differentiated squamous cell carcinoma is distinguished from nonkeratinizing and undifferentiated carcinoma (lymphoepithelioma) that contains infiltrating (bystander) lymphocytes.

Salivary gland tumors can arise from the major (parotid, submandibular, sublingual) or minor salivary glands (located in the submucosa

of the upper aerodigestive tract). Most parotid tumors are benign, but half of submandibular and sublingual gland tumors and most minor salivary gland tumors are malignant. Malignant tumors include mucoepidermoid and adenoidcystic carcinomas and adenocarcinomas.

The mucosal surface of the entire pharynx is exposed to alcohol- and tobacco-related carcinogens and is at risk for the development of a premalignant or malignant lesion, such as erythroplakia or leukoplakia (hyperplasia, dysplasia), that can progress to invasive carcinoma. Alternatively, multiple synchronous or metachronous cancers can develop. In fact, patients with early-stage head and neck cancer are at greater risk of dying of a second malignancy than of dying from a recurrence of the primary disease.

Second head and neck malignancies are not therapy-induced; they reflect the exposure of the upper aerodigestive mucosa to the same carcinogens that caused the first cancer. These second primaries develop in the head and neck area, the lung, or the esophagus.

Chromosomal deletions and other alterations, most frequently involving chromosomes 3p, 9p, 17p, and 13q, have been identified in both premalignant and malignant head and neck lesions, as have mutations in tumor suppressor genes, commonly the p53 gene. Amplification of oncogenes is less common, but overexpression of PRAD-1/bcl-1 (cyclin D1), bc1-2, transforming growth factor β, and the epidermal growth factor receptor have been described. The latter finding correlates positively with tumor size and poor outcome and is a target for experimental treatments.

Resected tumor specimens with histopathologically negative margins ("complete resection") can have undetectable residual tumor cells with persistent p53 mutations at the margins. Thus, a tumor-specific p53 mutation can be detected in some phenotypically "normal" surgical margins, indicating residual disease. Patients with such submicroscopic marginal involvement may have a worse prognosis than patients with negative margins.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS Most head and neck cancers occur after age 50, although these cancers can appear in younger patients, including those without known risk factors. The manifestations vary according to the stage and primary site of the tumor. Patients with nonspecific signs and symptoms in the head and neck area should be evaluated with a thorough otolaryngologic exam, particularly if symptoms persist longer than 2 to 4 weeks.

Cancer of the nasopharynx typically does not cause early symptoms. However, on occasion it may cause unilateral serous otitis media due to obstruction of the eustachian tube, unilateral or bilateral nasal obstruction, or epistaxis. Advanced nasopharyngeal carcinoma causes neuropathies of the cranial nerves.

Carcinomas of the oral cavity present as nonhealing ulcers, changes in the fit of dentures, or painful lesions. Tumors of the tongue base or oropharynx can cause decreased tongue mobility and alterations in speech. Cancers of the oropharynx or hypopharynx rarely cause early symptoms, but they may cause sore throat and/or otalgia.

Hoarseness may be an early symptom of laryngeal cancer, and persistent hoarseness requires referral to a specialist for indirect laryngoscopy and/or radiographic studies. If a head and neck lesion treated initially with antibiotics does not resolve in a short period, further workup is indicated; to simply continue the antibiotic treatment may be to lose the chance of early diagnosis of a malignancy.

Advanced head and neck cancers in any location can cause severe pain, otalgia, airway obstruction, cranial neuropathies, trismus, odynophagia, dysphagia, decreased tongue mobility, fistulas, skin involvement, and massive cervical lymphadenopathy, which may be unilateral or bilateral. Some patients have enlarged lymph nodes even though no primary lesion can be detected by endoscopy or biopsy; these patients are considered to have carcinoma of unknown primary (Fig. 74-1). If the enlarged nodes are located in the upper neck and the tumor cells are of squamous cell histology, the malignancy probably arose from a mucosal surface in the head or neck. Tumor cells in supraclavicular lymph nodes may also arise from a primary site in the chest or abdomen.

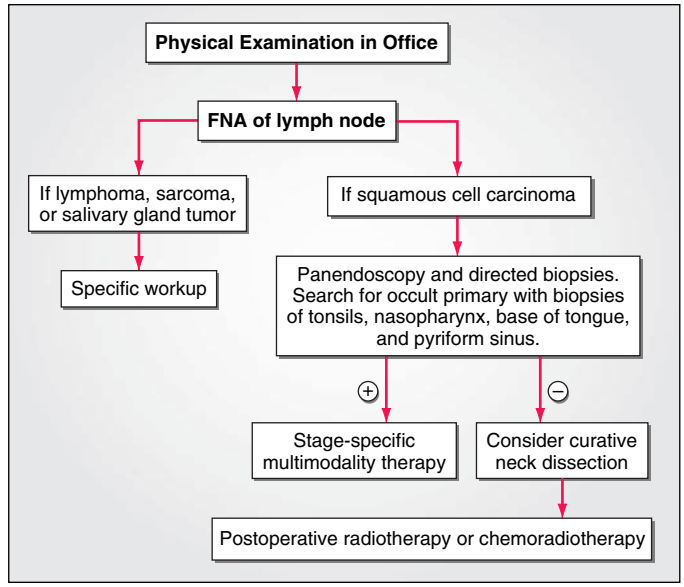

FIGURE 74-1 Evaluation of a patient with cervical adenopathy without a primary mucosal lesion; a diagnostic workup. FNA, fine-needle aspiration.

The physical examination should include inspection of all visible mucosal surfaces and palpation of the floor of mouth and tongue and of the neck. In addition to tumors themselves, leukoplakia, a white mucosal patch, or erythroplakia, a red mucosal patch, may be observed; these "premalignant" lesions can represent hyperplasia, dysplasia, or carcinoma in situ. All visible or palpable lesions should be biopsied. Further examination should be performed by a specialist. Additional staging procedures include computed tomography of the head and neck to identify the extent of the disease. Patients with lymph node involvement should have chest radiography and a bone scan to screen for distant metastases. The definitive staging procedure is an endoscopic examination under anesthesia, which may include laryngoscopy, esophagoscopy, and bronchoscopy; during this procedure, multiple biopsy samples are obtained to establish a primary diagnosis, define the extent of primary disease, and identify any additional premalignant lesions or second primaries.

Head and neck tumors are classified according to the TNM system of the American Joint Committee on Cancer. This classification varies according to the specific anatomic subsite (Tables 74-1 and 74-2). Distant metastases are found in $<10\%$ of patients at initial diagnosis, but in autopsy series, microscopic involvement of the lungs, bones, or liver is more common, particularly in patients with advanced neck lymph node disease.

In patients with lymph node involvement and no visible primary, the diagnosis should be made by lymph node excision. If the results indicate squamous cell carcinoma, a panendoscopy should be performed, with biopsy of all suspicious-appearing areas and directed biopsies of common primary sites, such as the nasopharynx, tonsil, tongue base, and pyriform sinus.

TREATMENT

Patients with head and neck cancer can be categorized into three clinical groups: those with localized disease, those with locally or regionally advanced disease, and those with recurrent and/or metastatic disease. Comorbidities associated with tobacco and alcohol abuse can affect treatment outcome.

Localized Disease Nearly one-third of patients have localized disease; that is, T1 or T2 (stage I or stage II) lesions without detectable lymph node involvement or distant metastases. These lesions are treated with curative intent by surgery or radiation therapy. The choice of modality differs according to institutional expertise. Radiation therapy is often

preferred for laryngeal cancer to preserve voice function, and surgery is preferred for small lesions in the oral cavity to avoid the long-term complications of radiation, such as xerostomia and dental decay. Overall 5-year survival is 60 to 90%.

Locally or Regionally Advanced Disease Locally or regionally advanced disease—disease with a large primary tumor and/or lymph node metastases—can also be treated with curative intent, but not with surgery or radiation therapy alone. Combined modality therapy including surgery, radiation therapy, and chemotherapy is most successful. Concomitant chemotherapy and radiation therapy appears to be most effective.

INDUCTION CHEMOTHERAPY In this strategy, patients receive chemotherapy [usually cisplatin and fluorouracil (5FU)] before surgery and radiation therapy. Most patients who receive three cycles show tumor reduction, and the response is clinically "complete" in up to half. This "sequential" multimodality therapy does not cure more patients than surgery plus radiation therapy alone. However, induction chemotherapy allows for organ preservation in patients with laryngeal and hypopharyngeal cancer.

CONCOMITANT CHEMORADIOTHERAPY With the concomitant strategy, chemotherapy and radiation therapy are given simultaneously rather than sequentially. Because most patients with head and neck cancer develop recurrent disease in the head and neck area, this approach is aimed at killing radiation-resistant cancer cells with chemotherapy. In addition, chemotherapy can enhance cell killing by radiation therapy. Toxicity (mucositis) is increased with concomitant chemoradiotherapy; however, meta-analysis of randomized trials documents an improvement in 5-year survival of 8% with concomitant 5FU and radiation therapy. Results seem even better with 5FU and cisplatin plus radiation therapy. Five-year survival is 34 to 50%. In addition, concomitant chemoradiotherapy produces better laryngectomy-free survival (organ preservation) than induction chemotherapy in patients with advanced larynx cancer. The use of radiation therapy together with cisplatin has produced markedly improved survival in patients with advanced nasopharyngeal cancer. The success of concomitant chemoradiotherapy in patients with unresectable disease has led to the testing of a similar approach in patients with resected disease as a postoperative therapy, but results to date have not convincingly shown improvement over postoperative radiation therapy alone.

Recurrent and/or Metastatic Disease Patients with recurrent and/or

TABLE 74-1 *TNM Classification for Head and Neck Cancer (Except Nasopharyngeal)*

PRIMARY TUMOR SITE

T Grade	Oropharynx	Hypopharynx
T1	0–2 cm	0–2 cm
T2	2.1–4 cm	>1 site, 2–4 cm
T3	>4 cm	>4 cm
T4a	Larynx, muscle of tongue, medial pterygoid, hard palate, mandible invasion	Thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue invasion
T4b	Lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery invasion	Invasion of prevertebral fascia, encases carotid artery, or involves mediastinal structures

REGIONAL LYMPH NODES (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Unilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the supraclavicular fossa
N2	Bilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the supraclavicular fossa
N3	Metastasis in a lymph node(s) >6 cm and/or to supraclavicular fossa N3a > 6 cm N3b Extension to the supraclavicular fossa
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

metastatic disease are, with few exceptions, treated with palliative intent. Some patients may require local or regional radiation therapy for pain control, but most are given chemotherapy. Response rates to chemotherapy average only 30 to 50%; the duration of response averages only 3 months, and the median survival time is 6 to 8 months. Therefore, chemotherapy provides transient symptomatic benefit. Drugs with single-agent activity in this setting include methotrexate, 5FU, cisplatin, paclitaxel, and docetaxel. Combinations of cisplatin and 5FU, carboplatin and 5FU, and cisplatin or carboplatin and paclitaxel or docetaxel are frequently used.

CHEMOPREVENTION β-Carotene and *cis*-retinoic acid can lead to the regression of leukoplakia. However, *cis*-retinoic acid does not reduce the incidence of second primaries.

TREATMENT COMPLICATIONS Complications from treatment of head and neck cancer are usually related to the extent of surgery. Several attempts have been made to limit the extent of surgery or to replace it with chemotherapy and radiation therapy. Acute complications of radiation include mucositis and dysphagia. Long-term complications include xerostomia, loss of taste, decreased tongue mobility, second malignancies, dysphagia, and neck fibrosis. The complications of chemotherapy vary with the regimen used but usually include myelosuppression, mucositis, nausea and vomiting, and nephrotoxicity (with cisplatin).

SALIVARY GLAND TUMORS Most benign salivary gland tumors are treated with surgical excision, and patients with invasive salivary gland tumors are treated with surgery and radiation therapy. Neutron radiation may be particularly effective. These tumors may recur regionally; adenoidcystic carcinoma has a tendency to recur along the nerve tracks. Distant metastases may occur as late as 10 to 20 years after the initial diagnosis. For metastatic disease, therapy is given with palliative intent, usually chemotherapy with doxorubicin and/or cisplatin.

75 NEOPLASMS OF THE LUNG

John D. Minna

Each year, primary carcinoma of the lung affects 93,000 males and 80,000 females in the United States, 86% of whom die within 5 years of diagnosis, making it the leading cause of cancer death in both men and women. The incidence of lung cancer peaks between ages 55 and 65 years. Lung cancer accounts for 28% of all cancer deaths (32% in men, 25% in women). The smoking cessation efforts begun 30 years ago have lowered the age-adjusted lung cancer death rate in males (~70 per 100,000 male population); but, unfortunately, the rate in females is still increasing (~35 per 100,000 female population). The 5-year overall lung cancer survival rate (14%) has nearly doubled in the past 30 years. The improvement is due to advances in combined-modality treatment with surgery, radiotherapy, and chemotherapy. Thus, primary carcinoma of the lung is a major health problem with a generally grim prognosis.

PATHOLOGY

The term *lung cancer* is used for tumors arising from the respiratory epithelium (bronchi, bronchioles, and alveoli). Mesotheliomas, lymphomas, and stromal tumors (sarcomas) are distinct from epithelial lung cancer. Four major cell types make up 88% of all primary lung neoplasms according to the World Health Organization classification (Table 75-1). These are *squamous* or *epidermoid carcinoma*, *small cell* (also called *oat cell*) *carcinoma*, *adenocarcinoma* (including bronchoalveolar), and *large cell* (also called *large cell anaplastic*) *carcinoma*. The remainder include undifferentiated carcinomas, carcinoids, bronchial gland tumors (including adenoid cystic carcinomas and mucoepidermoid tumors), and rarer tumor types. The various cell types have different natural histories and responses to therapy, and thus a correct histologic diagnosis by an experienced pathologist is the first step to correct treatment. In the past 25 years, for unknown reasons, adenocarcinoma has replaced squamous cell carcinoma as the most frequent histologic subtype (Table 75-1).

Major treatment decisions are made on the basis of whether a tumor is classified as a small cell carcinoma or as one of the non-small cell varieties (squamous, adenocarcinoma, large cell carcinoma, bronchoalveolar carcinoma, and mixed versions of these). Some of the distinctions are summarized in Tables 75-1 and 75-2. At presentation, small cell carcinomas usually have already spread such that surgery is unlikely to be curative, and they are managed primarily by chemotherapy with or without radiotherapy. In contrast, non-small cell cancers that are localized at the time of presentation may be cured with either surgery or radiotherapy. Non-small cell cancers do not respond as well to chemotherapy as small cell cancers.

Ninety percent of patients with lung cancer of all histologic types are current or former cigarette smokers. Of the an-

TABLE 75-1 *Frequency, Age-Adjusted Incidence, and Survival Rates for Different Histologic Types of Lung Cancer*[a]

Histologic Type of Thoracic Malignancy	Frequency, %	Age-Adjusted Rate	5-Year Survival Rate (All Stages)
Adenocarcinoma (and all subtypes)	32	17	17
Bronchioloalveolar carcinoma	3	1.4	42
Squamous cell (epidermoid) carcinoma	29	15	15
Small cell carcinoma	18	9	5
Large cell carcinoma	9	5	11
Carcinoid	1.0	0.5	83
Mucoepidermoid carcinoma	0.1	<0.1	39
Adenoid cystic carcinoma	<0.1	<0.1	48
Sarcoma and other soft tissue tumors	0.1	0.1	30
All others and unspecified carcinomas	11.0	6	NA
Total	100	52	14

[a] Data on histology frequency and age-adjusted incidence rates per 100,000 U.S. population are from 60,514 cases of invasive lung cancer involving all races and both sexes obtained from the data for 1983–1987 of the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute; 5-year relative survival rates for all stages, all races, and both sexes are from the SEER data on 87,128 carcinomas, 1978–1986. NA, not available.

Source: Summarized from Travis et al: Cancer 75:191, 1995.

nual 171,900 new cases of lung cancer, ~50% develop in former smokers. With increased success in smoking cessation efforts, the number of former smokers will grow, and these individuals will be important candidates for early detection and chemoprevention efforts. By far the most common form of lung cancer arising in lifetime nonsmokers, in women, and in young patients (<45 years) is adenocarcinoma. However, in nonsmokers with adenocarcinoma involving the lung, the possibility of other primary sites should be considered. Squamous and small cell cancers usually present as central masses with endobronchial growth, while adenocarcinomas and large cell cancers tend to present as peripheral nodules or masses, frequently with pleural involvement. Squamous and large cell cancers cavitate in ~10 to 20% of cases. Bronchoalveolar carcinoma, a form of adenocarcinoma arising from peripheral airways, can present radiographically as a single mass; as a diffuse, multinodular lesion; or as a fluffy infiltrate.

ETIOLOGY

Most lung cancers are caused by carcinogens and tumor promoters ingested via cigarette smoking. The prevalence of smoking in the United States is 28% for males and 25% for females, age 18 years or older; 38% of high school seniors smoke. The relative risk of developing lung cancer is increased about 13-fold by active smoking and about 1.5-fold by long-term passive exposure to cigarette smoke. Chronic obstructive pulmonary disease, which is also smoking-related, further increases the risk of developing lung cancer. The lung cancer death rate is related to the total amount (often expressed in "cigarette pack-years") of cigarettes smoked, such that the risk is increased 60- to 70-fold for a man smoking two packs a day for 20 years as compared with a nonsmoker. Conversely, the chance of developing lung cancer decreases with cessation of smoking but may never return to the nonsmoker level. The increase in lung cancer rate in women is also associated with a rise in cigarette smoking. Women have a higher relative risk per given exposure than men (~1.5 fold higher), and women with lung cancer are more likely than men to have never smoked. This sex difference is likely due to a higher susceptibility to tobacco carcinogens in women.

Efforts to get people to stop smoking are mandatory. However, smoking cessation is extremely difficult, because the smoking habit represents a powerful addiction to nicotine (Chap. 375). Smoking addiction is both biologic and psychosocial. Different methods are available to help motivated smokers give up the habit including counseling, behavioral therapy, nicotine replacement (gum, patch, sublingual spray, inhaler), and antidepressants (buproprion). However, these methods are successful in only 20 to 25% of individuals at 1 year. Preventing people from starting to smoke may be more effective, an effort that needs to be targeted to children.

Molecular genetic studies have shown the acquisition by lung cancer cells of a number of genetic lesions, including activation of dominant oncogenes and inactivation of tumor suppressor or recessive oncogenes (Chaps. 68 and 69). In fact, lung cancer cells may have to accumulate a large number (perhaps ≥20) of such lesions. For the

TABLE 75-2 *Comparison of Small Cell and Non-Small Cell Lung Cancers*

Feature	Small Cell	Non-Small Cell
Histology	Scant cytoplasm; small, hyperchromatic nuclei with fine chromatin pattern; nucleoli indistinct; diffuse sheets of cells	Abundant cytoplasm; pleomorphic nuclei with coarse chromatin pattern; nucleoli often prominent; glandular or squamous architecture
GENERAL NEUROENDOCRINE PROPERTIES		
Dense-core granules	Present	Absent
Chromogranin	Present	Absent
Synaptophysin	Present	Absent
CD56 and CD57 antigens	Present	Absent
PEPTIDE HORMONE PRODUCTION		
Gastrin-releasing peptide gene products	Present	Absent
Other neuropeptides	ACTH, AVP, calcitonin, ANF	PTH
Autocrine loops	GRP/GRP receptor SCF/KIT	HGF/MET NDF/ERBB2
OTHER MARKERS		
HLA, β_2-microglobulin	Absent/low	Present
Intermediate filament pattern	"SCLC"	"Non-SCLC"
Neurofilaments	Present	Absent
Opioid receptors	Present	Present
Nicotine receptors	Present	Present
EGF receptors	Low or absent	Present
Mucin	Absent	Present in adenocarcinomas
Surfactant-associated proteins	Absent	Often present
Carcinoembryonic antigen	Present	Present
RECESSIVE ONCOGENE (TUMOR SUPPRESSOR GENE) AND ALLELOTYPE ABNORMALITIES		
3p allele loss	100%	>90%
RASSF1A methylation	90%	40%
rb mutations	~90%	~20%
p16/CDKN2 mutations/absent expression	~10%	~50%
p53 mutations/abnormal expression	>90%	>50%
Promoter hypermethylation overall (*p16*, DAP Kinase, GSTP1, MGMT, *FHIT*, *RARβ*, *APC*, *ECAD*, *HCAD*, *RASSF1A*)	>80%	>80%
4p, 4q, 5q, 8p, 11p and other allele losses	Present	Present
Microsatellite alterations	Present	Present
DOMINANT ONCOGENE ABNORMALITIES		
ras mutations	<1%	~30%
myc family overexpression	>50%	10–35%
bcl-2 overexpression	>75%	>50%
Her-2/neu overexpression	<10%	~30%
Telomerase overexpression	>90%	>90%
RESPONSE		
Radiotherapy	Objective shrinkage in 80–90%; often complete response	Objective shrinkage in 30–50%; response uncommonly complete
Combination chemotherapy		
Overall regression rate	90%	40–60%
Rate of complete regression	30%	5%

dominant oncogenes, these include point mutations in the coding regions of the *ras* family of oncogenes (particularly in the K-*ras* gene in adenocarcinoma of the lung); amplification, rearrangement, and/or loss of transcriptional control of *myc* family oncogenes (c-, N-, and L-*myc*; changes in c-*myc* are found in non-small cell cancers, while changes in all *myc* family members are found in small cell lung cancer); and overexpression of *bcl-2*, *Her-2/neu*, and the telomerase gene (Table 75-2). Tumor mutations in *ras* genes are associated with a poor prognosis in non-small cell lung cancer, while tumor amplification of c-*myc* is associated with a poor prognosis in small cell lung cancer.

For the recessive oncogenes (*tumor suppressor genes*), allele loss occurs at chromosome regions 1p, 1q, 3p12-13, 3p14 (*FHIT* gene), 3p21 (*RASSF1A* gene), 3p24-25 (*RARβ* gene), 4p, 4q, 5q, 8p, 9p (*p16/CDKN2*, *p15,p14ARF* gene cluster), 11p13, 11p15, 13q14 (retinoblastoma, *rb*, gene), 16q, and 17p13 (*p53* gene), as well as other sites. Several candidate recessive oncogenes on chromosome 3p appear to be involved in nearly all lung cancers and may be affected early in preneoplastic lesions. The *p53* and *rb* genes are both mutated in >90% of small cell lung cancers, while *p53* is mutated in >50% and *rb* in 20% of non-small cell lung cancers. *p16/CDKN2* is abnormal in 10% of small cell and >50% of non-small cell lung cancers. The *rb* and *p16/CDKN2* genes are part of the same G_1-to-S cell cycle regulatory pathway. Either one or the other of these elements appears to be mutated or to have its expression turned off (e.g., by hypermethylation of the promoter) in the large majority of lung cancers. Tumor acquired promoter methylation may be the most frequent method of inactivating tumor-suppressor genes in lung cancer (>10 such genes commonly affected). These methylation changes inhibit gene expression and can be detected in tumor cells, preneoplastic lesions, and DNA in the sputum; their detection may improve early diagnosis and follow-up of the disease. Preneoplastic lesions found in the respiratory epithelium of lung cancer patients and smokers include hyperplasia, dysplasia (progressively severe), and carcinoma in situ. 3p allele loss (hyperplasia) followed by 9p (*p16/CDKN2*) allele loss (hyperplasia) are the earliest events; 17p (*p53*) abnormalities and then *ras* mutations are usually found only in carcinoma in situ and invasive cancer. Thus, molecular changes can be found in the earliest preneoplastic lesions and potentially even before any histologic changes are noted. Clinical trials of early diagnosis are needed to prove the usefulness of these molecular markers in the identification of very early lung cancer and in the monitoring of treatment and chemoprevention.

The large number of genetic and epigenetic lesions shows that lung cancer, like other common epithelial malignancies, is a multistep process that is likely to involve both carcinogens and tumor promoters. Prevention can be directed at both processes. Lung cancer cells produce many peptide hormones and express receptors for these hormones, which can act to stimulate tumor cell growth in an "autocrine" fashion. Highly carcinogenic derivatives of nicotine are formed in cigarette smoke. Lung cancer cells of all histologic types (and the cells from which they are derived) express nicotinic acetylcholine receptors. Nicotine activates signaling pathways in tumor and normal cells that block apoptosis. Thus, nicotine itself could be directly involved in lung cancer pathogenesis.

While lung cancer does not have a clear pattern of Mendelian inheritance, several features suggest a potential for familial association. Inherited mutations in *rb* (patients with retinoblastomas living to adulthood) and *p53* (Li-Fraumeni syndrome) genes may develop lung cancer. First-degree relatives of lung cancer probands have a two- to threefold excess risk of lung cancer or other cancers, many of which are not smoking-related. Certain alleles of the P450 enzyme system (which metabolizes carcinogens) or chromosome fragility (*mutagen sensitivity*) genotypes are associated with the development of lung cancer. The use of these polymorphisms to identify persons at very high risk of developing lung cancer would be useful in early detection and prevention efforts.

CLINICAL MANIFESTATIONS

Lung cancer gives rise to signs and symptoms caused by local tumor growth, invasion or obstruction of adjacent structures, growth in regional nodes through lymphatic spread, growth in distant metastatic sites after hematogenous dissemination, and remote effects of tumor products (paraneoplastic syndromes) (Chaps. 86 and 87).

Although 5 to 15% of patients with lung cancer are identified while they are asymptomatic, usually as a result of a routine chest radiograph, most patients present with some sign or symptom. Central or endobronchial growth of the primary tumor may cause cough, hemoptysis, wheeze and stridor, dyspnea, and postobstructive pneumonitis (fever and productive cough). Peripheral growth of the primary tumor may cause pain from pleural or chest wall involvement, cough, dyspnea on a restrictive basis, and symptoms of lung abscess resulting from tumor cavitation. Regional spread of tumor in the thorax (by contiguous growth or by metastasis to regional lymph nodes) may cause tracheal obstruction, esophageal compression with dysphagia, recurrent laryngeal nerve paralysis with hoarseness, phrenic nerve paralysis with elevation of the hemidiaphragm and dyspnea, and sympathetic nerve paralysis with Horner's syndrome (enophthalmos, ptosis, miosis, and ipsilateral loss of sweating). Malignant pleural effusion often leads to dyspnea. *Pancoast's* (or *superior sulcus tumor*) *syndrome* results from local extension of a tumor growing in the apex of the lung with involvement of the eighth cervical and first and second thoracic nerves, with shoulder pain that characteristically radiates in the ulnar distribution of the arm, often with radiologic destruction of the first and second ribs. Often Horner's syndrome and Pancoast's syndrome coexist. Other problems of regional spread include *superior vena cava syndrome* from vascular obstruction; pericardial and cardiac extension with resultant tamponade, arrhythmia, or cardiac failure; lymphatic obstruction with resultant pleural effusion; and lymphangitic spread through the lungs with hypoxemia and dyspnea. In addition, bronchoalveolar carcinoma can spread transbronchially, producing tumor growing along multiple alveolar surfaces with impairment of gas exchange, respiratory insufficiency, dyspnea, hypoxemia, and sputum production.

Extrathoracic metastatic disease is found at autopsy in >50% of patients with squamous carcinoma, 80% of patients with adenocarcinoma and large cell carcinoma, and >95% of patients with small cell cancer. Lung cancer metastases may occur in virtually every organ system. Common clinical problems related to metastatic lung cancer include brain metastases with neurologic deficits; bone metastases with pain and pathologic fractures; bone marrow invasion with cytopenias or leukoerythroblastosis; liver metastases causing liver dysfunction, biliary obstruction, and pain; lymph node metastases in the supraclavicular region and occasionally in the axilla and groin; and spinal cord compression syndromes from epidural or bone metastases. Adrenal metastases are common but rarely cause adrenal insufficiency.

Paraneoplastic syndromes are common in patients with lung cancer and may be the presenting finding or first sign of recurrence. In addition, paraneoplastic syndromes may mimic metastatic disease and, unless detected, lead to inappropriate palliative rather than curative treatment. Often the paraneoplastic syndrome may be relieved with successful treatment of the tumor. In some cases, the pathophysiology of the paraneoplastic syndrome is known, particularly when a hormone with biologic activity is secreted by a tumor (Chap. 86). However, in many cases the pathophysiology is unknown. Systemic symptoms of anorexia, cachexia, weight loss (seen in 30% of patients), fever, and suppressed immunity are paraneoplastic syndromes of unknown etiology. *Endocrine syndromes* are seen in 12% of patients: hypercalcemia and hypophosphatemia resulting from the ectopic production by squamous tumors of parathyroid hormone (PTH) or, more commonly, PTH-related peptide; hyponatremia with the syndrome of inappropriate secretion of antidiuretic hormone or possibly atrial natriuretic factor by small cell cancer; and ectopic secretion by small cell cancer of adrenocorticotropic hormone (ACTH). ACTH secretion usually results in additional electrolyte disturbances, especially hypokalemia, rather

than the changes in body habitus that occur in Cushing's syndrome from a pituitary adenoma.

Skeletal–connective tissue syndromes include clubbing in 30% of cases (usually non-small cell carcinomas) and hypertrophic pulmonary osteoarthropathy in 1 to 10% of cases (usually adenocarcinomas) with periostitis and clubbing causing pain, tenderness, and swelling over the affected bones and a positive bone scan. *Neurologic-myopathic syndromes* are seen in only 1% of patients but are dramatic and include the myasthenic *Eaton-Lambert syndrome* and retinal blindness with small cell cancer, while peripheral neuropathies, subacute cerebellar degeneration, cortical degeneration, and polymyositis are seen with all lung cancer types. Many of these are caused by autoimmune responses such as the development of anti-voltage-gated calcium channel antibodies in the Eaton-Lambert syndrome (Chap. 87). Coagulation, thrombotic, or other hematologic manifestations occur in 1 to 8% of patients and include migratory venous thrombophlebitis (*Trousseau's syndrome*), nonbacterial thrombotic (marantic) endocarditis with arterial emboli, disseminated intravascular coagulation with hemorrhage, and anemia, granulocytosis, and leukoerythroblastosis. Thrombotic disease complicating cancer is usually a poor prognostic sign. Cutaneous manifestations such as dermatomyositis and acanthosis nigricans are uncommon (≤1%), as are the renal manifestations of nephrotic syndrome or glomerulonephritis (≤1%).

DIAGNOSIS AND STAGING

EARLY DIAGNOSIS The screening of asymptomatic persons at high risk (men >45 years who smoke ≥40 cigarettes per day) by means of sputum cytology and chest radiographs has not improved the survival rate. Although 90% of patients whose lung cancer was detected by screening were asymptomatic, no difference was found in the survival rates of the screened and nonscreened groups. Women have not been studied. The use of low-dose spiral computed tomography (CT) lung scanning may be more sensitive, particularly for peripheral lesions. However, false-positive rates are high (25% have abnormal tests, only 10% of which are cancers), and survival benefit for screening has not yet been shown (Chap. 67).

ESTABLISHING A TISSUE DIAGNOSIS OF LUNG CANCER Once signs, symptoms, or screening studies suggest lung cancer, a tissue diagnosis must be established. Tumor tissue can be obtained by a bronchial or transbronchial biopsy during fiberoptic bronchoscopy; by node biopsy during mediastinoscopy; from the operative specimen at the time of definitive surgical resection; by percutaneous biopsy of an enlarged lymph node, soft tissue mass, lytic bone lesion, bone marrow, or pleural lesion; by fine-needle aspiration of thoracic or extrathoracic tumor masses using CT guidance; or from an adequate cell block obtained from a malignant pleural effusion. In most cases, the pathologist should be able to make a definite diagnosis of epithelial malignancy and distinguish small cell from non-small cell lung cancer.

STAGING PATIENTS WITH LUNG CANCER Lung cancer staging consists of two parts: first, a determination of the location of tumor (anatomic staging) and, second, an assessment of a patient's ability to withstand various antitumor treatments (physiologic staging). In a patient with non-small cell lung cancer, *resectability* (whether the tumor can be entirely removed by a standard surgical procedure such as a lobectomy or pneumonectomy), which depends on the anatomic stage of the tumor, and *operability* (whether the patient can tolerate such a surgical procedure), which depends on the cardiopulmonary function of the patient, are determined.

Non-Small Cell Lung Cancer The TNM International Staging System should be used for cases of non-small cell lung cancer, particularly in preparing patients for curative attempts with surgery or radiotherapy (Table 75-3). The various T (tumor size), N (regional node involvement), and M (presence or absence of distant metastasis) factors are combined to form different stage groups. At presentation, approximately one-third of patients have disease localized enough for a curative attempt with surgery or radiotherapy (patients with stage I or II disease and some with stage IIIA disease), one-third have distant metastatic disease (stage IV disease), and one-third have local or regional disease that may or may not be amenable to a curative attempt (some patients with stage IIIA disease and others with stage IIIB disease) (see below). This staging system provides useful prognostic information.

TABLE 75-3 *Tumor, Node, Metastasis International Staging System for Lung Cancer*

Stage	TNM Descriptors	5-Year Survival Rate, %	
		Clinical Stage	Surgical-Pathologic Stage
IA	T1 N0 M0	61	67
IB	T2 N0 M0	38	57
IIA	T1 N1 M0	34	55
IIB	T2 N1 M0	24	39
IIB	T3 N0 M0	22	38
IIIA	T3 N1 M0	9	25
	T1–2–3 N2 M0	13	23
IIIB	T4 N0–1–2 M0	7	<5
	T1–2–3–4 N3 M0	3	<3
IV	Any T any N M1	1	<1

TUMOR (T) STATUS DESCRIPTOR

T0	No evidence of a primary tumor
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
TIS	Carcinoma in situ
T1	Tumor <3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than lobar bronchus (i.e., not in main bronchus)
T2	Tumor with any of following: >3 cm in greatest dimension; involves main bronchus, ≥2 cm distal to the carcina; invades visceral pleura; associated with atelectasis or obstructive pneumonitis extending to hilum but does not involve entire lung
T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in main bronchus <2 cm distal to carina but without involvement of carina; or associated atelectasis or obstructive pneumonitis of entire lung
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural or pericardial effusion[a], or with satellite tumor nodule(s) within the ipsilateral primary-tumor lobe of the lung.

LYMPH NODE (N) INVOLVEMENT DESCRIPTOR

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and intrapulmonary nodes involved by direct extension of the primary tumor
N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph nodes(s)
N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

DISTANT METASTASIS (M) DESCRIPTOR

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present[b]

[a] Most pleural effusions associated with lung cancer are due to tumor. However, in a few patients with multiple negative cytopathologic exams of a non-bloody, non-exudative pleural or pericardial effusion that clinical judgment dictates is not related to the tumor, the effusion should be excluded as a staging element and the patient's disease staged as T1, T2, or T3.

[b] Separate metastatic pulmonary tumor nodule(s) in the ipsilateral nonprimary tumor lobe(s) of the lung are classified as M1.

Source: Adapted from CF Mountain. Revisions in the International System for Staging of Lung Cancer. Chest 111:1710, 1997; with permission.

Small Cell Lung Cancer A simple two-stage system is used. In this system, limited-stage disease (seen in about 30% of all patients with small cell lung cancer) is defined as disease confined to one hemithorax and regional lymph nodes (including mediastinal, contralateral hilar, and usually ipsilateral supraclavicular nodes), while extensive-stage disease (seen in about 70% of patients) is defined as disease exceeding those boundaries. Clinical studies such as physical examination, x-rays, CT and bone scans, and bone marrow examination are used in staging. In part, the definition of limited-stage disease relates to whether the known tumor can be encompassed within a tolerable radiation therapy port. Thus, contralateral supraclavicular nodes, recurrent laryngeal nerve involvement, and superior vena caval obstruction can all be part of limited-stage disease. However, cardiac tamponade, malignant pleural effusion, and bilateral pulmonary parenchymal involvement generally qualify disease as extensive-stage because the organs within a curative radiation therapy port cannot safely tolerate curative radiation doses.

GENERAL STAGING PROCEDURES (Table 75-4) All patients with lung cancer should have a complete history and physical examination, with evaluation of all other medical problems, determination of performance status and history of weight loss, and a CT scan of the chest and abdomen with contrast. Positron emission tomography (PET) scans are sensitive in detecting both intrathoracic and metastatic disease. PET is useful in assessing the mediastinum and solitary pulmonary nodules. A Standardized Uptake Value (SUV) of >2.5 is highly suspicious for malignancy. False negatives can be seen in diabetes, slow-growing tumors such as bronchoalveolar carcinoma, concurrent infection such as tuberculosis, and in lesions <1 cm. Fiberoptic bronchoscopy obtains material for pathologic examination and information on tumor size, location, degree of bronchial obstruction (i.e., assesses resectability), and recurrence.

Chest radiographs and CT scans are needed to evaluate tumor size and nodal involvement; old radiographs are useful for comparison. CT scans of the thorax and upper abdomen are of use in the preoperative staging of non-small cell lung cancer to detect mediastinal nodes and pleural extension and occult abdominal disease (e.g., liver, adrenal), and in planning curative radiation therapy. However, mediastinal nodal involvement should be documented histologically if the findings will influence therapeutic decisions. Thus, sampling of lymph nodes via mediastinoscopy or thoracotomy to establish the presence or absence of N2 or N3 nodal involvement is crucial in considering a curative surgical approach for patients with non-small cell lung cancer with clinical stage I, II, or III disease. A standard nomenclature for referring to the location of lymph nodes involved with cancer has evolved (Fig. 75-1). Likewise, unless the CT-detected abnormalities are unequivocal, histology of suspicious abdominal lesions should be confirmed by procedures such as fine-needle aspiration if the patient would otherwise be considered for curative treatment. In small cell lung cancer, CT scans are used in the planning of chest radiation treatment and in the assessment of the response to chemotherapy and radiation therapy. Surgery or radiotherapy can make interpretation of conventional chest x-rays difficult; after treatment, CT scans can provide good evidence of tumor recurrence.

If signs or symptoms suggest involvement by tumor, brain CT or bone scans are performed, as well as radiography of any suspicious bony lesions. Any accessible lesions suspicious for cancer should be biopsied if involvement would influence treatment.

In patients presenting with a mass lesion on chest x-ray or CT scan and no obvious contraindications to a curative approach after the initial evaluation, the mediastinum must be investigated. Approaches vary among centers and include performing chest CT scan and mediastinoscopy (for right-sided tumors) or mediastinotomy (for left-sided lesions) on all patients and proceeding directly to thoracotomy for staging of the mediastinum. In patients presenting with disease that is confined to the chest but not resectable, and who thus are candidates for neoadjuvant chemotherapy plus surgery or for curative radiotherapy with or without chemotherapy, other tests are done as indicated to evaluate specific symptoms. In patients presenting with non-small cell cancer that is not curable, all the general staging procedures are done, plus fiberoptic bronchoscopy as indicated to evaluate hemoptysis, obstruction, or pneumonitis, as well as thoracentesis with cytologic examination (and chest tube drainage as indicated) if fluid is present. As a rule, a radiographic finding of an isolated lesion (such as an enlarged adrenal gland) should be confirmed as cancer by fine-needle aspiration before a curative attempt is rejected.

TABLE 75-4 Pretreatment Staging Procedures for Patients with Lung Cancer

ALL PATIENTS
Complete history and physical examination Determination of performance status and weight loss
Complete blood count with platelet determination
Measurement of serum electrolytes, glucose, calcium, and phosphorus; renal and liver function tests
Electrocardiogram
Skin test for tuberculosis
Chest x-ray
CT scan of chest and abdomen
CT scan of brain and radionuclide scan of bone if any finding suggests the presence of tumor metastasis in these organs
Fiberoptic bronchoscopy with washings, brushings, and biopsy of suspicious lesions unless medically contraindicated or if it would not alter therapy (e.g., very late stage patient)
X-rays of suspicious bony lesions detected by scan or symptom
Barium-swallow radiographic examination if esophageal symptoms exist
Pulmonary function studies and arterial blood gas measurements if signs or symptoms of respiratory insufficiency are present
Biopsy of accessible lesions suspicious for cancer if a histologic diagnosis is not yet made or if treatment or staging decisions would be based on whether or not a lesion contained cancer
PATIENTS WITH NON-SMALL CELL LUNG CANCER WHO HAVE NO CONTRAINDICATION[a] TO CURATIVE SURGERY OR RADIOTHERAPY WITH OR WITHOUT CHEMOTHERAPY
All the above procedures, plus the following:
PET scan to evaluate mediastinum and detect metastatic disease
Pulmonary function tests and arterial blood gas measurements
Coagulation tests
CT scan of brain if symptoms suggestive
Cardiopulmonary excercise testing if performance status or pulmonary function tests are borderline
If surgical resection is planned: surgical evaluation of the mediastinum at mediastinoscopy or at thoracotomy
If the patient is a poor surgical risk or a candidate for curative radiotherapy: transthoracic fine-needle aspiration biopsy or transbronchial forceps biopsy of peripheral lesions if material from routine fiberoptic bronchoscopy is negative
PATIENTS PRESENTING WITH SMALL CELL OR ADVANCED NON-SMALL CELL LUNG CANCER
For proven small cell lung cancer, all the procedures under "All Patients," plus the following:
CT scan of brain
Bone marrow aspiration and biopsy (if peripheral blood counts abnormal)
For non-small cell lung cancer or cancer of unknown histology, all the procedures under "All Patients," plus the following:
Fiberoptic bronchoscopy if indicated by hemoptysis, obstruction, pneumonitis, or no histologic diagnosis of cancer
Biopsy of accessible lesions suspicious for tumor to obtain a histologic diagnosis or if therapy would be altered by finding of tumor
Transthoracic fine-needle aspiration biopsy or transbronchial forceps biopsy of peripheral lesions if fiberoptic bronchoscopy is negative and no other material exists for a histologic diagnosis
Diagnostic and therapeutic thoracentesis if a pleural effusion is present

[a] Patients with non-small cell lung cancer and extrathoracic metastatic disease, malignant pleural effusion, or intrathoracic disease beyond the bounds of a tolerable radiotherapy port.

Note: CT, computed tomography; PET, positron emission tomography.

STAGING OF SMALL CELL LUNG CANCER Pretreatment staging for patients with small cell lung cancer includes the initial general lung cancer

evaluation with chest and abdominal CT scans (because of the high frequency of hepatic and adrenal involvement) as well as fiberoptic bronchoscopy with washings and biopsies to determine the tumor extent before therapy; brain CT scan (10% of patients have metastases); bone marrow biopsy and aspiration (20 to 30% of patients have tumor in the bone marrow); and radionuclide scans (bone) if symptoms or other findings suggest disease involvement in these areas. Chest and abdominal CT scans are very useful to evaluate and follow tumor response to therapy, and chest CT scans are helpful in planning chest radiotherapy ports.

If signs or symptoms of spinal cord compression or leptomeningitis develop at any time in lung cancer patients with disease of any histologic type, a spinal CT scan or magnetic resonance imaging (MRI) scan and examination of the cerebrospinal fluid cytology are performed. If malignant cells are detected, radiotherapy to the site of compression and intrathecal chemotherapy (usually with methotrexate) are given. In addition, a brain CT or MRI scan is performed to search for brain metastases, which often are associated with spinal cord or leptomeningeal metastases.

DETERMINATION OF RESECTABILITY AND OPERABILITY

In patients with non-small cell lung cancer, the following are major contraindications to curative surgery or radiotherapy alone: extrathoracic metastases; superior vena cava syndrome; vocal cord and, in most cases, phrenic nerve paralysis; malignant pleural effusion; cardiac tamponade; tumor within 2 cm of the carina (not curable by surgery but potentially curable by radiotherapy); metastasis to the contralateral lung; bilateral endobronchial tumor (potentially curable by radiotherapy); metastasis to the supraclavicular lymph nodes; contralateral mediastinal node metastases (potentially curable by radiotherapy); and involvement of the main pulmonary artery. Most patients with small cell lung cancer have unresectable disease; however, if clinical findings suggest the potential for resection (most common with peripheral lesions), that option should be considered.

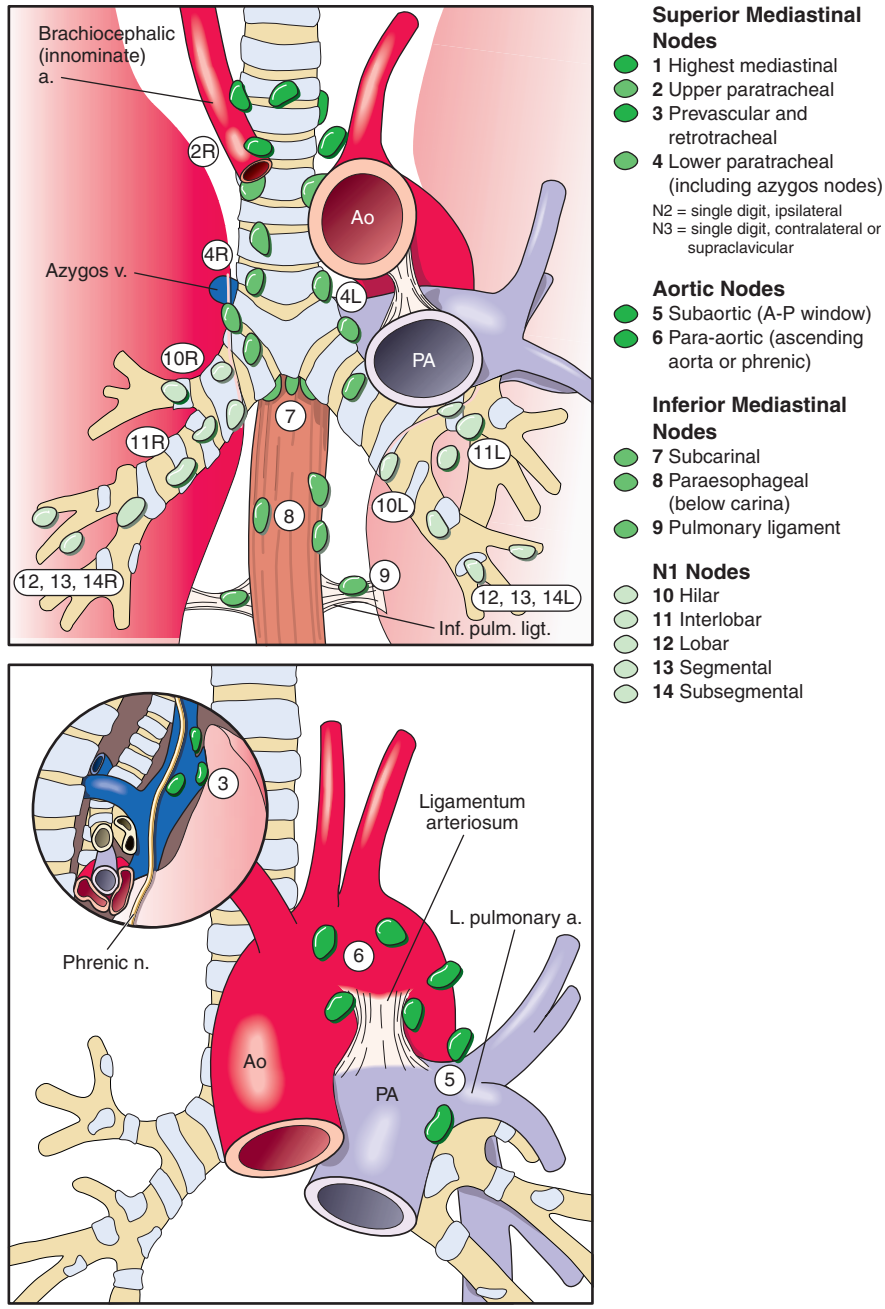

FIGURE 75-1 Regional lymph node stations for lung cancer staging. (*Used by permission from CF Mountain, C Dresler: Chest 111:1718, 1997.*)

PHYSIOLOGIC STAGING Patients with lung cancer often have cardiopulmonary and other problems related to chronic obstructive pulmonary disease as well as other medical problems. To improve their preoperative condition, correctable problems (e.g., anemia, electrolyte and fluid disorders, infections, and arrhythmias) should be addressed, smoking stopped, and appropriate chest therapy instituted. Since it is not always possible to predict whether a lobectomy or pneumonectomy will be required until the time of operation, a conservative approach is to restrict resectional surgery to patients who could potentially tolerate a pneumonectomy. In addition to nonambulatory performance status, a myocardial infarction within the past 3 months is a contraindication to thoracic surgery because 20% of patients will die of reinfarction, while an infarction in the past 6 months is a relative contraindication. Other major contraindications include uncontrolled major arrhythmias, an FEV_1 (forced expiratory volume in 1 s) <1 L, CO_2 retention (resting $PCO_2 > 45$ mmHg), DLCO < 40%, and severe pulmonary hypertension. Recommending surgery when the FEV_1 is 1.1 to 2.0 L or <80% predicted requires careful judgment, while an $FEV_1 > 2.5$ L or >80% predicted usually permits a pneumonectomy. In patients with borderline lung function but a resectable tumor, cardiopulmonary exercise testing could be performed as part of the physiologic evaluation. This test allows an estimate of the maximal oxygen consumption ($\dot{V}max_{O_2}$). A $\dot{V}max_{O_2} < 15$ mL/kg per min predicts for high risk of postoperative complications.

TREATMENT

The overall treatment approach to patients with lung cancer is shown in Table 75-5. Patients should be encouraged to stop smoking. Those who do fare better than those who continue to smoke.

Non-Small Cell Lung Cancer: Localized Disease ■ *SURGERY* In patients with non-small cell lung cancer of stages IA, IB, IIA and IIB (Table 75-3) who can tolerate operation, the treatment of choice is pulmonary resection. In stage IIIA cases where the patient's age, cardiopulmonary function, and anatomy are favorable, a team approach (involving pulmonary medicine, thoracic surgery, medical and radiation oncology) is useful. Neoadjuvant chemotherapy with or without radiotherapy

TABLE 75-5 Summary of Treatment Approach to Patients with Lung Cancer

NON-SMALL CELL LUNG CANCER
Stages IA, IB, IIA, IIB, and some IIIA:
Surgical resection for stages IA, IB, IIA, and IIB
Surgical resection with complete-mediastinal lymph node dissection and consideration of neoadjuvant CRx for stage IIIA disease with "minimal N2 involvement" (discovered at thoracotomy or mediastinoscopy)
Postoperative RT for patients found to have N2 disease if no neoadjuvant CRx given
Discussion of risks/benefits of adjuvant CRx with individual patients
Curative potential RT for "nonoperable" patients
Stage IIIA with selected types of stage T3 tumors:
Tumors with chest wall invasion (T3): en bloc resection of tumor with involved chest wall and consideration of postoperative RT
Superior sulcus (Pancoast's) (T3) tumors: preoperative RT (30–45 Gy) followed by en bloc resection of involved lung and chest wall with consideration of postoperative RT or intraoperative brachytherapy
Proximal airway involvement (<2 cm from carina) without mediastinal nodes: sleeve resection if possible preserving distal normal lung or pneumonectomy
Stages IIIA "advanced, bulky, clinically evident N2 disease" (discovered preoperatively) and IIIB disease that can be included in a tolerable RT port:
Curative potential RT + CRx if performance status and general medical condition are reasonable; otherwise, RT alone
Consider neoadjuvant CRx and surgical resection for IIIA disease with advanced N2 involvement
Stage IIIB disease with carinal invasion (T4) but without N2 involvement:
Consider pneumonectomy with tracheal sleeve resection with direct reanastomosis to contralateral mainstem bronchus
Stage IV and more advanced IIIB disease:
RT to symptomatic local sites; CRx for ambulatory patients
Chest tube drainage of large malignant pleural effusions
Consider resection of primary tumor and metastasis for isolated brain or adrenal metastases
SMALL CELL LUNG CANCER
Limited stage (good performance status): combination CRx + chest RT
Extensive stage (good performance status): combination CRx
Complete tumor responders (all stages): consider prophylactic cranial RT
Poor-performance-status patients (all stages):
Modified-dose combination CRx; palliative RT
BRONCHOALVEOLAR CARCINOMA (EGF receptor mutations)
Gefitinib, inhibitor of EGF receptor kinase activity
ALL PATIENTS
RT for brain metastases, spinal cord compression, weight-bearing lytic bony lesions, symptomatic local lesions (nerve paralyses, obstructed airway, hemoptysis, intrathoracic large venous obstruction, in non-small cell lung cancer and in small cell cancer not responding to CRx)
Appropriate diagnosis and treatment of other medical problems and supportive care during CRx
Encouragement to stop smoking
Entrance into clinical trial, if eligible

Abbreviations: CRx, chemotherapy; RT, radiotherapy.

may shrink the local tumor, treat micrometastases, and make surgical resection safer and more effective in selected patients. If a complete resection is possible, the 5-year survival rate for N1 disease is about 50%, while it is about 20% for N2 disease. However, only 20% of cases of N2 disease are technically resectable, and most of these are discovered to be N2 only at thoracotomy. Surgery for N2 disease is the most controversial area in the surgical management of lung cancer. Patients with N2 disease can be divided into "minimal" disease (involvement of only one node with microscopic foci, usually discovered at thoracotomy or mediastinoscopy) and the more common "advanced," bulky disease, clinically obvious on CT scans and discovered preoperatively. Patients with contralateral or bilateral positive mediastinal (N3) nodes, extracapsular nodal involvement, or fixed nodes are not considered candidates for resection. Approaches that may make resection possible include chest wall resection for direct extension of tumor, tracheal sleeve pneumonectomy, and sleeve lobectomy for lesions near the carina. Neoadjuvant (preoperative) chemotherapy has response rates of 50 to 60% and causes unresectable disease to become resectable in many patients who respond (see below). Video-assisted thoracic surgery (VATS) via thoracoscopy is not usually used for curative lung cancer resection but may be useful for peripheral lesions in patients with poor lung function. VATS has been advocated to reduce postoperative impairment of lung function, pain, length of hospital stay, and recovery time. However, randomized controlled trials have not confirmed the advantages. Open thoracotomy remains the preferred surgical approach to curative resection of lung cancer. VATS can be used for diagnostic purposes to examine the pleural surface and cavity and biopsy peripheral lung nodules or accessible mediastinal nodes; its major therapeutic use is resection of peripheral lung nodules.

The extent of resection is a matter of surgical judgment based on findings at exploration. Conservative resection that encompasses all known tumor gives survival equal to that obtained with more extensive procedures. However, lobectomy is superior to wedge resection in reducing the rate of local recurrence. Thus, lobectomy is preferred to pneumonectomy and wedge resection. Wedge resection and segmentectomy (potentially by VATS) are reserved for patients with poor pulmonary reserve and small peripheral lesions. About 40% of all patients with lung cancer undergo thoracotomy. Of these, 75% have a definitive resection, 12% are explored only for disease extent, and 12% have a palliative procedure with known disease left behind. About 30% of patients treated with resection for cure survive for 5 years, and 15% survive for 10 years (Table 75-3). The 30-day hospital mortality rate after pulmonary resection is 3% for lobectomy and 6% for pneumonectomy. Thus, most patients thought to have a "curative" resection ultimately die of metastatic disease (usually within 5 years of surgery).

MANAGEMENT OF OCCULT AND STAGE 0 CARCINOMAS In the uncommon situation where malignant cells are identified in a sputum or bronchial washing specimen but the chest radiograph appears normal (TX tumor stage), the lesion must be localized. More than 90% can be localized by meticulous examination of the bronchial tree with a fiberoptic bronchoscope under general anesthesia and collection of a series of differential brushings and biopsies. Often, carcinoma in situ or multicentric lesions are found in these patients. Current recommendations are for the most conservative surgical resection, allowing removal of the cancer and conservation of lung parenchyma, even if the bronchial margins are positive for carcinoma in situ. The 5-year overall survival rate for these occult cancers is ~60%. Close follow-up of these patients is indicated because of the high incidence of second primary lung cancers (5% per patient per year). One approach to in situ or multicentric lesions uses systemically administered hematoporphyrin (which localizes to tumors and sensitizes them to light) followed by bronchoscopic phototherapy.

SOLITARY PULMONARY NODULE When a patient presents with an asymptomatic, solitary pulmonary nodule (defined as an x-ray density completely surrounded by normal aerated lung, with circumscribed margins, of any shape, usually 1 to 6 cm in greatest diameter), a decision to resect or follow the nodule must be made. Approximately 35% of all such lesions in adults are malignant, most being primary lung cancer, while <1% are malignant in nonsmokers under 35 years of age. A complete history, including a smoking history, physical examination, routine laboratory tests, chest CT scan, fiberoptic bronchoscopy, and old chest x-rays are obtained. PET scans are useful in detecting lung cancers >1 cm in diameter. If no diagnosis is immediately apparent, the following risk factors would all argue strongly in favor of proceeding with resection to establish a histologic diagnosis: a history of cigarette smoking; age ≥ 35 years; a relatively large lesion; lack of calcification; chest symptoms; associated atelectasis, pneumonitis, or adenopathy; growth of the lesion revealed by comparison with old x-rays; or positive PET scan. At present, only two radiographic criteria are reliable predictors of the benign nature of a solitary pulmonary nodule: lack of growth over a period >2 years and certain

characteristic patterns of calcification. Calcification alone does not exclude malignancy. However, a dense central nidus, multiple punctate foci, and "bull's eye" (granuloma) and "popcorn ball" (hamartoma) calcifications are all highly suggestive of a benign lesion. An algorithm for evaluating a solitary pulmonary nodule is shown in Fig. 75-2.

When old x-rays are not available and the characteristic calcification patterns are absent, the following approach is reasonable: Nonsmoking patients <35 years can be followed with serial CT every 3 months for 1 year and then yearly. If any significant growth is found, a histologic diagnosis is needed. For patients >35 years and all patients with a smoking history, a histologic diagnosis must be made. The sample for histologic diagnosis can be obtained either at the time of nodule resection or, if the patient is a poor operative risk, via VATS or transthoracic fine-needle biopsy. Some institutions use preoperative fine-needle aspiration on all such lesions; however, all positive lesions have to be resected, and negative cytologic findings in most cases have to be confirmed by histology on a resected specimen. While much has been made of sparing patients an operation, the high probability of finding a malignancy (particularly in smokers >35 years) and the excellent chance for surgical cure when the tumor is small both suggest an aggressive approach to these lesions.

The application of low-dose spiral CT scanning to high-risk populations is under investigation. The test identifies a large number of asymptomatic pulmonary nodules that require evaluation. Approximately 23% of screened high-risk patients have an abnormality, and ~12% of the detected abnormalities are lung cancer. The American College of Radiology has developed scoring of CT-detected lesions as "benign," "indeterminate," or "abnormal." Lesions > 1 cm are usually resected; those ≤1 cm are followed for change at 3 to 6-month intervals. Although a number of early lung cancers are detected in this way, it is not yet clear that survival is improved.

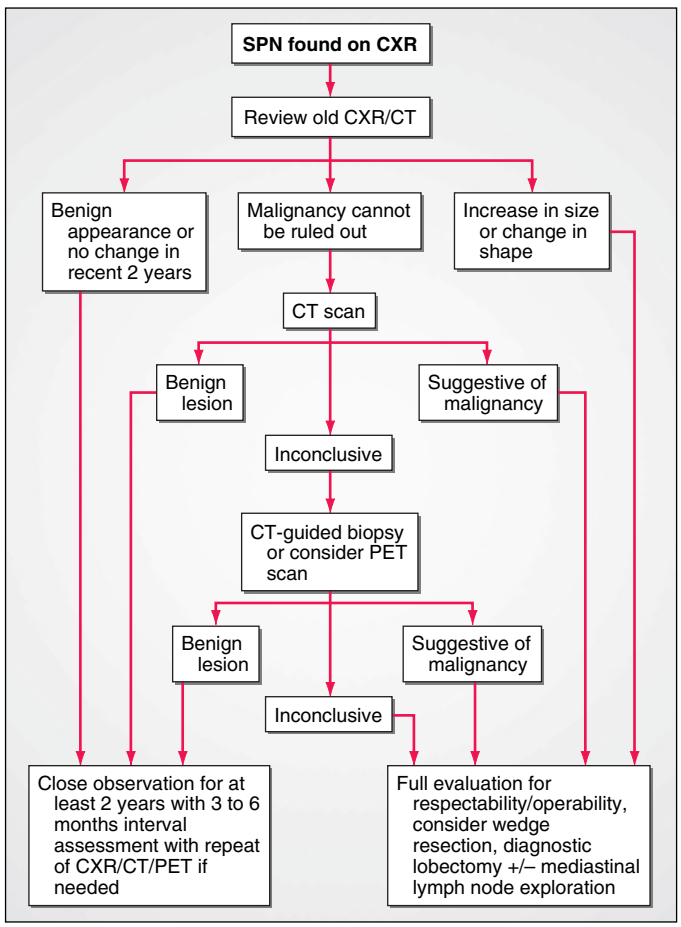

FIGURE 75-2 Algorithm for evaluation of a solitary pulmonary nodule (SPN). (CXR, chest x-ray; CT, computed tomography scan; PET, positron emission tomography.)

RADIOTHERAPY WITH CURATIVE INTENT Patients with stage III disease, as well as patients with stage I or II disease who refuse surgery or are not candidates for pulmonary resection, should be considered for radiation therapy with curative intent. The decision to administer high-dose radiotherapy is based on the extent of disease and the volume of the chest that requires irradiation. Patients with distant metastases, malignant pleural effusion, or cardiac involvement are generally not considered for curative radiation treatment. The median survival period for patients with unresectable non-small cell lung cancer localized to the chest who undergo primary radiotherapy with curative intent is <1 year. However, 6% of these patients are alive at 5 years and are cured by radiotherapy alone. In addition to being potentially curative, radiotherapy, by controlling the primary tumor, may increase the quality and length of life of noncured patients. Treatment usually involves midplane doses of 55 to 60 Gy, and the major concern is the amount of lung parenchyma and other organs in the thorax included in the treatment plan, including the spinal cord, heart, and esophagus. In patients with a major degree of underlying pulmonary disease, the treatment plan may have to be compromised because of the deleterious effect of radiation on pulmonary function. The risk of radiation pneumonitis is proportional to the radiation dose and the volume of lung in the field. The full clinical syndrome (dyspnea, fever, and radiographic infiltrate corresponding to the treatment port) occurs in 5% of cases. Acute radiation esophagitis occurs during treatment but is usually self-limited, while spinal cord injury should be avoided by careful treatment planning. Continuous hyperfractionated accelerated radiation therapy (CHART) involves delivery of 36 treatments of 1.5 Gy given 3 times a day for 12 consecutive days to a total dose of 54 Gy. The 2-year survival rate increased from 20 to 29% with CHART, although more esophagitis occurred. Brachytherapy (local radiotherapy delivered by placing radioactive "seeds" in a catheter in the tumor bed) provides a way to give a high local dose while sparing surrounding normal tissue.

COMBINED-MODALITY THERAPY WITH CURATIVE INTENT After apparently complete resection, adjuvant radiation therapy does not improve survival and may be detrimental in N0 and N1 disease.

Carcinomas of the superior pulmonary sulcus producing *Pancoast's syndrome* are usually treated with combined radiotherapy and surgery. Patients with these carcinomas should have the usual preoperative staging procedures, including mediastinoscopy and CT and PET scans, to determine tumor extent and a neurologic examination (and sometimes nerve conduction studies) to document neurologic findings. Sometimes a histologic diagnosis is not made, but the combination of tumor location and pain distribution permit a diagnostic accuracy for cancer of >90%. If mediastinoscopy is negative, curative approaches may be used in treating a Pancoast's syndrome tumor. Preoperative irradiation [30 Gy in 10 treatments] is given to the area, followed by an en bloc resection of the tumor and involved chest wall 3 to 6 weeks later. The 3-year survival rate is 40% for squamous and 20% for adeno- and large cell carcinomas. Another approach involves radiotherapy alone in curative doses and standard fractionation, which leads to survival rates similar to those from combined-modality therapy. Chemotherapy with etoposide and cisplatin plus radiotherapy to the area produces high rates of tumor resectability and >50% survival at 4 years.

A meta-analysis of chemotherapy in non-small cell lung cancer used updated data on 9387 individual patients from 52 randomized trials, both published and unpublished, with the main outcome measure being survival. Regimens containing cisplatin were significantly more effective than no treatment. Trials in early-stage disease comparing surgery with surgery plus chemotherapy gave a hazard ratio of 0.87 (13% reduction in risk of death at 5 years) in favor of chemotherapy. Confidence intervals of these data are wide. Ongoing randomized trials of adjuvant chemotherapy for stage I and II disease appear to show benefit.

The most impressive benefits were obtained when chemotherapy was added to radiotherapy for locally advanced disease (stage IIIB and some stage IIIA disease) and when chemotherapy was given preoperatively in a neoadjuvant fashion in stage IIIA disease. Preoperative neoadjuvant chemotherapy is widely used for stage IIIA disease. Preoperative combined modality therapy followed by surgical resection has given promising early results. Whether the surgery adds benefit after chemoradiotherapy has not been defined. Provided the risk/benefit ratio of using chemotherapy is discussed appropriately with patients, such therapy can be given in a noninvestigational setting. For stage IIIA disease, resection followed by postoperative radiation plus chemotherapy for N2 disease, neoadjuvant chemotherapy followed by surgical resection, or neoadjuvant chemoradiotherapy followed by resection are options. For stage IIIB and bulky IIIA disease, neoadjuvant chemotherapy (two or three cycles of a cisplatin-based combination) followed by chest radiation therapy (60 Gy) has improved median survival time from 10 to 14 months and the 5-year survival rate from 7 to 17% compared to results with radiation therapy alone. Administration of radiation and chemotherapy concurrently is being tested; myelotoxicity and esophagitis are increased, but survival improvement is not yet proven. Randomized clinical trials are also needed to evaluate the usefulness of the new agents with activity against non-small cell lung cancer, including the taxanes (paclitaxel and docetaxel), vinorelbine, gemcitabine, and the camptothecins (topotecan and irinotecan) in both adjuvant and neoadjuvant settings.

Disseminated Non-Small Cell Lung Cancer The 70% of patients who have unresectable non-small cell cancer have a poor prognosis. Patients with performance status scores of 0 (asymptomatic), 1 (symptomatic, fully ambulatory), 2 (in bed <50% of the time), 3 (in bed >50% of the time), and 4 (bedridden) have median survival times of 34, 25, 17, 8, and 4 weeks, respectively. Standard medical management, the judicious use of pain medications, the appropriate use of radiotherapy, and outpatient chemotherapy form the cornerstone of management. Patients whose primary tumor is causing symptoms such as bronchial obstruction with pneumonitis, hemoptysis, or upper airway or superior vena cava obstruction should have radiotherapy to the primary tumor. The case for prophylactic treatment of the asymptomatic patient is to prevent major symptoms from occurring in the thorax. Usually a course of 30 to 40 Gy over 2 to 4 weeks is given to the tumor. Radiation therapy provides relief of intrathoracic symptoms with the following frequencies: hemoptysis, 84%; superior vena cava syndrome, 80%; dyspnea, 60%; cough, 60%; atelectasis, 23%; and vocal cord paralysis, 6%. Cardiac tamponade (treated with pericardiocentesis and radiation therapy to the heart), painful bony metastases (with relief in 66%), brain or spinal cord compression, and brachial plexus involvement may also be palliated with radiotherapy. Usually, with brain metastases and cord compression, dexamethasone (25 to 100 mg/d in four divided doses) is also given and then rapidly tapered to the lowest dosage that relieves symptoms.

Brain metastases are often isolated instances of relapse in patients with adenocarcinoma of the lung otherwise controlled by surgery or radiotherapy. However, there is no proven value for prophylactic cranial irradiation or for CT scans of the head in asymptomatic patients.

Pleural effusions are common and are usually treated with thoracentesis. If they recur and are symptomatic, chest tube drainage with a sclerosing agent such as intrapleural talc is used. First, the chest cavity is completely drained. Xylocaine 1% is instilled (15 mL), followed by 50 mL normal saline. Then, 10 g sterile talc is dissolved in 100 mL normal saline, and this solution is injected through the chest tube. The chest tube is clamped for 4 h if tolerated, and the patient is rotated onto different sides to distribute the sclerosing agent. The chest tube is removed 24 to 48 h later, after drainage has become slight (usually <100 mL/24 h). VATS has been used to drain and treat large malignant effusions. An indwelling pleurex catheter is equivalent to chest tube drainage and better tolerated by the patient. Symptomatic endobronchial lesions that recur after surgery or radiotherapy or that develop in patients with severely compromised pulmonary function are difficult to treat with conventional therapy. Neodynium-YAG (yttrium-aluminum-garnet) laser therapy administered through a flexible fiberoptic bronchoscope (usually under general anesthesia) can provide palliation in 80 to 90% of patients even when the tumor has relapsed after radiotherapy. Local radiotherapy delivered by brachytherapy, photodynamic therapy using a photosensitizing agent, and endobronchial stents are other measures that can relieve airway obstruction from tumor.

CHEMOTHERAPY The use of chemotherapy for non-small cell lung cancer requires careful judgment to balance potential benefits and toxicity. Modest survival benefits (of 1 to 2 months), symptom palliation, and improved quality of life may accrue from combination chemotherapy. Randomized trials in advanced disease comparing supportive care with supportive care plus chemotherapy gave a hazard ratio of 0.73 (27% reduction in risk of death at 1 year) in favor of including chemotherapy. Economic analysis has found chemotherapy to be cost-effective palliation. Combination chemotherapy produces an objective tumor response in ~20 to 30% of patients; the response is complete in <5%. Median survival for chemotherapy-treated patients is 9 to 10 months, and the 1-year survival rate is 40%. Thus, in patients with non-small cell lung cancer who desire chemotherapy, it is reasonable to give chemotherapy if the patient is ambulatory and is able to understand and accept the risk/benefit ratio from such therapy. The chemotherapy should be one of the published standard regimens, such as paclitaxel plus carboplatin, paclitaxel plus cisplatin, or vinorelbine plus cisplatin. Improved antiemetics have made treatment tolerable on an outpatient basis. New drugs with proven activity in non-small cell lung cancer include docetaxel, irinotecan, and gemcitabine. Docetaxel may provide a survival benefit after relapse from initial chemotherapy. Furthermore, novel agents aimed at growth factor and angiogenesis receptors and signaling pathways are being tested. Gefitinib (Iressa) inhibits the EGF receptor and has antitumor activity. Optimal combinations of agents are being sought in clinical trials.

Small Cell Lung Cancer Untreated patients with small cell lung cancer have a median survival period of 6 to 17 weeks, while patients treated with combination chemotherapy have a median survival period of 40 to 70 weeks. Thus, chemotherapy with or without radiotherapy or surgery can prolong survival in patients with small cell lung cancer. The goal of treatment is to achieve a complete clinical regression of tumor documented by repeating the initial positive staging procedures. The initial response, determined 6 to 12 weeks after the start of therapy, predicts both the median and long-term survivals, the likelihood of response to second line therapy, and the potential for cure. Patients who achieve a complete clinical regression survive longer than patients with only partial regression, who in turn survive longer than patients with no response. Complete response is required for long-term (>3-year) survival.

After initial staging, patients are classified as having limited or extensive disease and as being physiologically able or not able to tolerate combination chemotherapy or chemoradiotherapy. The overall mortality rate from initial combination chemotherapy even in these selected patients is 1 to 5%, comparable with the operative mortality rate for pulmonary resection. Such therapy should be reserved for ambulatory patients with no prior chemotherapy or radiotherapy; no other major medical problems; and adequate heart, liver, renal, and bone marrow function. The arterial P_{O_2} on room air should be >6.6 kPa (50 mmHg), and there should be no CO_2 retention. For patients with limitations in any of these areas, the initial combined-modality therapy or chemotherapy must be modified to prevent undue toxicity. In all patients, these treatments must be coupled with supportive care for infectious, hemorrhagic, and other medical complications.

CHEMOTHERAPY The combination most widely used is etoposide plus cisplatin or carboplatin, given every 3 weeks on an outpatient basis for 4 to 6 cycles. Other active regimens are etopside, cisplatin, and paclitaxel or the combination of irinotecan and etoposide, which con-

veys a longer median survival but is more toxic than etoposide plus cisplatin. Increased dose intensity of chemotherapy adds toxicity without clear survival benefit. Appropriate supportive care (antiemetic therapy, administration of fluid and saline boluses with cisplatin, monitoring of blood counts and blood chemistries, monitoring for signs of bleeding or infection, and, as required, administration of erythropoietin and granulocyte colony-stimulating factor) and adjustment of chemotherapy doses on the basis of nadir granulocyte counts are essential. The initial combination chemotherapy may result in moderate to severe granulocytopenia (e.g., granulocyte counts $<$500 to 1500/μL) and thrombocytopenia (platelet counts $<$50,000 to 100,000/μL). After the initial 4 to 6 cycles of therapy, patients should be restaged to determine if they have entered a complete clinical remission, indicated by complete disappearance of all clinically evident lesions and paraneoplastic syndromes; a partial remission; or have no response or tumor progression (seen in 10 to 20% of patients). Chemotherapy is then stopped in responding patients. More prolonged chemotherapy has not been shown to be of value. Patients whose tumors are progressing or not responding should be switched to a new, experimental chemotherapy regimen. Topotecan alone or combined with paclitaxel is active in such second-line therapy. Oral etoposide, as a single agent, has been shown to be of clinical benefit in the initial treatment of patients who are elderly or have a very poor performance status.

RADIOTHERAPY High-dose (40-Gy) radiotherapy to the whole brain should be given to patients with documented brain metastases. Prophylactic cranial irradiation (PCI) may be given to patients with complete responses, since it significantly decreases the development of brain metastases (which occur in 60 to 80% of patients living $\geq$2 years who do not receive PCI), but survival benefit is small (5%). Because some studies indicate possible deficits in cognitive ability that could be related to PCI, the long-term quality of life after PCI needs to be further studied. The patient needs to be informed of the risks and benefits of PCI. In the case of symptomatic, progressive lesions in the chest or at other critical sites, if radiotherapy has not yet been given to these areas, it may be administered in full doses (e.g., 40 Gy to the chest tumor mass).

COMBINED-MODALITY THERAPY Most patients with limited-stage small cell lung cancer should receive combined-modality therapy with etoposide plus cisplatin (or other platinum-containing regimen) and concurrent chest radiotherapy encompassing sites of known disease in the chest. Acute and chronic toxicities are expected with chemoradiotherapy, particularly when the chemotherapy and radiotherapy are given concurrently. However, the addition of chest radiation therapy to chemotherapy reduces the local failure rate and improves survival. Patients should be selected (limited-stage disease, a performance status of 0 to 1, and initial good pulmonary function) such that radiotherapy can be given in full doses and in a manner that does not sacrifice too much lung function. Some studies show twice-daily radiation fractions produce less toxicity and improve survival compared to once-daily treatments.

For extensive-stage disease, initial chest radiotherapy is usually not advocated. However, for favorable patients (e.g., those with a performance status of 0 to 1, good pulmonary function, and only one site of extensive disease), the addition of chest radiotherapy to chemotherapy can be considered. In patients who are in a chemotherapy-induced complete remission, radiotherapy appears to increase survival. For all patients, if chemotherapy is inadequate to relieve local tumor symptoms, a course of radiotherapy can be added.

About 20 to 30% of patients with limited-stage disease and 1 to 5% of patients with extensive-stage disease are cured. About 50% of patients with limited-stage and 30% of patients with extensive-stage disease enter complete remission, and 90 to 95% of all patients have complete or partial responses. These responses increase the median survival period to 10 to 12 months for patients with extensive-stage disease and to 14 to 18 months for patients with limited-stage disease, as compared with 2 to 4 months for untreated patients. In addition, most patients have relief of their tumor-related symptoms and improvement of performance status. However, the maintenance of good performance status in a patient receiving outpatient chemotherapy requires judgment and skill to avoid undue therapeutic toxicity. New treatments, such as new drug combinations, very intensive initial or "reinduction" therapy with autologous bone marrow infusion, and novel ways of combining chemotherapy, radiotherapy, and surgery should be given only in the context of an approved clinical protocol.

Although surgical resection is not routinely recommended for small cell lung cancer, occasional patients meet the usual requirements for resectability (stage I or II disease with negative mediastinal nodes). Moreover, this histologic diagnosis is made in some patients only on review of the resected surgical specimen. Such patients have been reported to have high cure rates ($>$25%) if adjuvant chemotherapy is used.

LUNG CANCER PREVENTION

Deterring children from taking up smoking and helping young adults stop smoking is likely to be the most effective lung cancer prevention. Smoking cessation programs are successful in 5 to 20% of volunteers; the poor efficacy is because of the nature of nicotine addiction.

Chemoprevention is an experimental approach to reduce lung cancer risk; at present, no benefit has been proven for chemoprevention intervention, and at least two putative chemoprevention agents, vitamin E and β-carotene, actually increase the risk of lung cancer in heavy smokers.

BENIGN LUNG NEOPLASMS

The benign neoplasms of the lung, representing $<$5% of all primary tumors, include bronchial adenomas and hamartomas (90% of such lesions) and a group of very uncommon benign neoplasms (epithelial tumors such as bronchial papillomas, fibroepithelial polyps; mesenchymal tumors such as chondromas, fibromas, lipomas, hemangiomas, leiomyomas, pseudolymphomas; tumors of mixed origin such as teratomas; and other diseases such as endometriosis). The diagnostic and primary-treatment approach (surgery) is basically the same for all these neoplasms. They can present as central masses causing airway obstruction, cough, hemoptysis, and pneumonitis. The masses may or may not be visible on radiographs but are usually accessible to fiberoptic bronchoscopy. Alternatively, they can present without symptoms as solitary pulmonary nodules and thus will be evaluated as part of a solitary pulmonary nodule workup. In all cases, the extent of surgery must be determined at operation, and a conservative procedure with appropriate reconstructions is usually performed.

BRONCHIAL ADENOMAS Bronchial adenomas (80% are central) are slow-growing, endobronchial lesions; they represent 50% of all benign pulmonary neoplasms. About 80 to 90% are carcinoids, 10 to 15% are adenocystic tumors (or cylindromas), and 2 to 3% are mucoepidermoid tumors. Adenomas present in patients 15 to 60 years old (average age, 45) as endobronchial lesions and are often symptomatic for several years. Patients may have a chronic cough, recurrent hemoptysis, or obstruction with atelectasis, lobar collapse, or pneumonitis and abscess formation. Bronchial carcinoids, which usually follow a benign course, and small cell lung cancers, which are highly malignant, both express a neuroendocrine phenotype. Carcinoids, like small cell lung cancers, may secrete other hormones, such as ACTH or arginine vasopressin, and can cause paraneoplastic syndromes that resolve on resection. Uncommonly, bronchial carcinoid metastases (usually to the liver) may produce the carcinoid syndrome, with cutaneous flush, bronchoconstriction, diarrhea, and cardiac valvular lesions (Chap. 329), which small cell lung cancer does not. Occasionally, pathologists may have difficulty distinguishing carcinoids from small cell lung cancers. Carcinoid tumors that have an unusually aggressive histologic appearance (referred to as *atypical carcinoids*) metastasize in 70% of cases to regional nodes, liver, or bone, compared with only a 5% rate of metastasis for carcinoids with typical histology.

Bronchial adenomas of all types, because of their endobronchial and often central location, are usually visible by fiberoptic bronchoscopy, and tissue for histologic diagnosis is obtained in this manner. Because they are hypervascular, they can bleed profusely after bronchoscopic biopsy, and this problem should be anticipated. Bronchial adenomas must be dealt with as potentially malignant and thus require removal not only for symptom relief but also because they can be locally invasive or recurrent, potentially can metastasize, and may produce paraneoplastic syndromes. Surgical excision is the primary treatment for all types of bronchial adenomas. The extent of surgery is determined at operation and should be as conservative as possible. Often bronchotomy with local excision, sleeve resection, segmental resection, or lobectomy is sufficient. Five-year survival rates after surgical resection are 95%, decreasing to 70% if regional nodes are involved. The treatment of metastatic pulmonary carcinoids is unclear because they can either be indolent or behave more like small cell lung carcinoma. Assessment of the tempo and histology of the disease in the individual patient is necessary to determine if and when chemotherapy or radiotherapy is indicated.

HAMARTOMAS Pulmonary hamartomas have a peak incidence at age 60 and are more frequent in men than in women. Histologically, they contain normal pulmonary tissue components (smooth muscle and collagen) in a disorganized fashion. They are usually peripheral, clinically silent, and benign in their behavior. Unless the radiographic findings are pathognomonic for hamartoma, with "popcorn" calcification, the lesions usually have to be resected for diagnosis, particularly if the patient is a smoker. VATS may minimize the surgical complications.

METASTATIC PULMONARY TUMORS

The lung is a frequent site of metastases from primary cancers outside the lung. Usually such metastatic disease is considered incurable. However, two special situations should be borne in mind. The first is the development of a solitary pulmonary shadow on a chest x-ray in a patient known to have an extrathoracic neoplasm. This shadow may represent a metastasis or a new primary lung cancer. Because the natural history of lung cancer is often worse than that of other primary tumors, a single pulmonary nodule in a patient with a known extrathoracic tumor is approached as though the nodule is a primary lung cancer, particularly if the patient is older than 35 years and a smoker. If a vigorous search for other sites of active cancer proves negative, the nodule is surgically resected. Second, in some cases, multiple pulmonary nodules can be resected with curative intent. This tactic is usually recommended if, after careful staging, it is found that (1) the patient can tolerate the contemplated pulmonary resection, (2) the primary tumor has been definitively and successfully treated (disease-free for >1 year), and (3) all known metastatic disease can be encompassed by the projected pulmonary resection. The key is selection and screening of patients to exclude those with uncontrolled primary tumors and other extrapulmonary metastases. Primary tumors whose pulmonary metastases have been successfully resected for cure include osteogenic and soft tissue sarcomas; colon, rectal, uterine, cervix, and corpus tumors; head and neck, breast, testis, and salivary gland cancer; melanoma; and bladder and kidney tumors. Five-year survival rates of 20 to 30% have been found in carefully selected patients, and dramatic results have been achieved in patients with osteogenic sarcomas, where resection of pulmonary metastases (sometimes requiring several thoracotomies) is becoming a standard curative treatment approach.

76 BREAST CANCER

Marc E. Lippman

Breast cancer is a malignant proliferation of epithelial cells lining the ducts or lobules of the breast. In the year 2004, about 216,000 cases of invasive breast cancer and 40,000 deaths occurred in the United States. Epithelial malignancies of the breast are the most common cause of cancer in women (excluding skin cancer), accounting for about one-third of all cancer in women. As a result of improved treatment and earlier detection, mortality from breast cancer has begun to decrease substantially in the United States. This chapter will not consider rare malignancies of the breast, such as sarcomas and lymphomas, but will focus on the epithelial cancers. Human breast cancer is a clonal disease; a single transformed cell—the product of a series of somatic (acquired) or germline mutations—is eventually able to express full malignant potential. Thus, breast cancer may exist for a long period as either a noninvasive disease or an invasive but nonmetastatic disease. These facts have very significant clinical ramifications.

GENETIC CONSIDERATIONS Not more than 10% of human breast cancers can be linked directly to germline mutations. Several genes have been implicated in familial cases. The Li-Fraumeni syndrome is characterized by inherited mutations in the p53 tumor-suppressor gene, which lead to an increased incidence of breast cancer, osteogenic sarcomas, and other malignancies. Inherited mutations in *PTEN* have also been reported.

Another tumor-suppressor gene, *BRCA-1*, has been identified at the chromosomal locus 17q21; this gene encodes a zinc finger protein, and the product therefore may function as a transcriptional factor. The gene appears to be involved in gene repair. Women who inherit a mutated allele of this gene from either parent have at least a 60 to 80% lifetime chance of developing breast cancer and about a 33% chance of developing ovarian cancer. The risk is higher among women born after 1940, presumably due to promotional effects of hormonal factors. Men who carry a mutant allele of the gene have an increased incidence of prostate cancer and breast cancer. A fourth gene, termed *BRCA-2*, which has been localized to chromosome 13q12, is also associated with an increased incidence of breast cancer in men and women.

BRCA-1 and *BRCA-2* can now be sequenced readily and germline mutations detected; patients with these mutations can be counseled appropriately. All women with strong family histories for breast cancer should be referred to genetic screening programs whenever possible, particularly women of Ashkenazi Jewish descent who have a high likelihood of a specific *BRCA-1* mutation (deletion of adenine and guanine at position 185).

Even more important than the role these genes play in inherited forms of breast cancer may be their role in sporadic breast cancer. The p53 mutation is present in approximately 40% of human breast cancers as an acquired defect. Acquired mutations in *PTEN* occur in about 10% of the cases. *BRCA-1* mutation in primary breast cancer has not been reported. However, decreased expression of *BRCA-1* mRNA (possibly via gene methylation) and abnormal cellular location of the *BRCA-1* protein have been found in some breast cancers. Loss of heterozygosity of *BRCA-1* and *BRCA-2* suggests that tumor-suppressor activity may be inactivated in sporadic cases of human breast cancer.

Finally, increased expression of a dominant oncogene plays a role in about a quarter of human breast cancer cases. The product of this gene, a member of the epidermal growth factor receptor superfamily, is called *erbB2* (HER-2, neu) and is overexpressed in these breast cancers due to gene amplification; this overexpression can contribute to transformation of human breast epithelium.

EPIDEMIOLOGY Breast cancer is a hormone-dependent disease. Women without functioning ovaries who never receive estrogen-replacement therapy do not develop breast cancer. The female to male ratio is about 150:1. For most epithelial malignancies, a log-log plot of incidence versus age shows a single-component straight-line increase with every year of life. A similar plot for breast cancer shows two components: a straight-line increase with age but with a decrease in slope beginning at the age of menopause. The three dates in a woman's life that have a major impact on breast cancer incidence are age at menarche, age at first full-term pregnancy, and age at menopause. Women who experience menarche at age 16 have only 50 to 60% of the breast cancer risk of a woman having menarche at age 12; the lower risk persists throughout life. Similarly, menopause occurring 10 years before the median age of menopause (52 years), whether natural or surgically induced, reduces lifetime breast cancer risk by about 35%. Women who have a first full-term pregnancy by age 18 have a 30 to 40% lower risk of breast cancer compared with nulliparous women. Thus, length of menstrual life—particularly the fraction occurring before first full-term pregnancy—is a substantial component of the total risk of breast cancer. These three factors (menarche, age of first full-term pregnancy, and menopause) can account for 70 to 80% of the variation in breast cancer frequency in different countries. A meta-analysis has shown that duration of maternal nursing correlates with substantial risk reduction independent of either parity or age at first full-term pregnancy.

International variation in incidence has provided some of the most important clues on hormonal carcinogenesis. A woman living to age 80 in North America has one chance in nine of developing invasive breast cancer. Asian women have one-fifth to one-tenth the risk of breast cancer of women in North America or Western Europe. Asian women have substantially lower concentrations of estrogens and progesterone. These differences cannot be explained on a genetic basis because Asian women living in a western environment have sex steroid hormone concentrations and risks identical to those of their western counterparts. These migrant women and more notably their daughters also differ markedly in height and weight from Asian women in Asia; height and weight are critical regulators of age of menarche and have substantial effects on plasma concentrations of estrogens.

The role of diet in breast cancer etiology is controversial. While there are associative links between total caloric and fat intake and breast cancer risk, the exact role of fat in the diet is unproven. Increased caloric intake contributes to breast cancer risk in multiple ways: earlier menarche, later age at menopause, and increased postmenopausal estrogen concentrations reflecting enhanced aromatase activities in fatty tissues. Moderate alcohol intake also increases the risk by an unknown mechanism. Recommendations favoring abstinence from alcohol must be weighed against other social pressures and the possible cardioprotective effect of moderate alcohol intake.

Understanding the potential role of exogenous hormones in breast cancer is of extraordinary importance because millions of American women regularly use oral contraceptives and postmenopausal hormone replacement therapy (HT). The most credible meta-analyses of oral contraceptive use suggest that these agents cause little if any increased risk of breast cancer. By contrast, oral contraceptives offer a substantial protective effect against ovarian epithelial tumors and endometrial cancers. Far more controversial are the data surrounding HT in postmenopausal women. Data from the Women's Health Initiative (WHI) trial showed in a prospectively randomized design that conjugated equine estrogens plus progestins increased the risk of breast cancer and adverse cardiovascular events but with decreases in bone fractures and colorectal cancer. On balance there were more negative events with HT. A parallel WHI trial with >12,000 women enrolled testing conjugated estrogens alone (in women who have had hysterectomies) continues. A meta-analysis of nonrandomized HT studies suggests that most of the previously attributed benefit of HT can be accounted for by higher socioeconomic status among users, which is presumably associated with better access to health care and healthier behaviors. Certain potential benefits of HT, such as a putative protective effect on cognition with age, were not assessed in WHI. HT is an area of rapid reevaluation, but it would appear (at least from breast cancer and cardiovascular disease vantage points) that there are serious grounds for concern about long-term HT use.

In addition to the other factors, radiation may be a risk factor in younger women. Women who have been exposed before age 30 to radiation in the form of multiple fluoroscopies (200 to 300 cGy) or treatment for Hodgkin's disease (>3600 cGy) have a substantial increase in risk of breast cancer, whereas radiation exposure after age 30 appears to have a minimal carcinogenic effect on the breast.

EVALUATION OF BREAST MASSES IN MEN AND WOMEN Because the breasts are a common site of potentially fatal malignancy in women and because they frequently provide clues to underlying systemic diseases in both men and women, examination of the breast is an essential part of the physical examination. Unfortunately, internists frequently do not examine breasts in men, and, in women, they are apt to defer this evaluation to gynecologists. Because of the plausible association between early detection and improved outcome, it is the duty of every physician to distinguish breast abnormalities at the earliest possible stage and to institute a definite diagnostic workup. It is for this reason that all women should be trained in breast self-examination (BSE). Although breast cancer in men is unusual, unilateral lesions should be evaluated in the same manner as in women, with the recognition that gynecomastia in men can sometimes begin unilaterally and is often asymmetric.

Virtually all breast cancer is diagnosed by biopsy of a nodule detected either on a mammogram or by palpation. Algorithms have been developed to enhance the likelihood of diagnosing breast cancer and reduce the frequency of unnecessary biopsy (Fig. 76-1).

The Palpable Breast Mass Women should be strongly encouraged to examine their breasts monthly. A flawed study from China has sug-

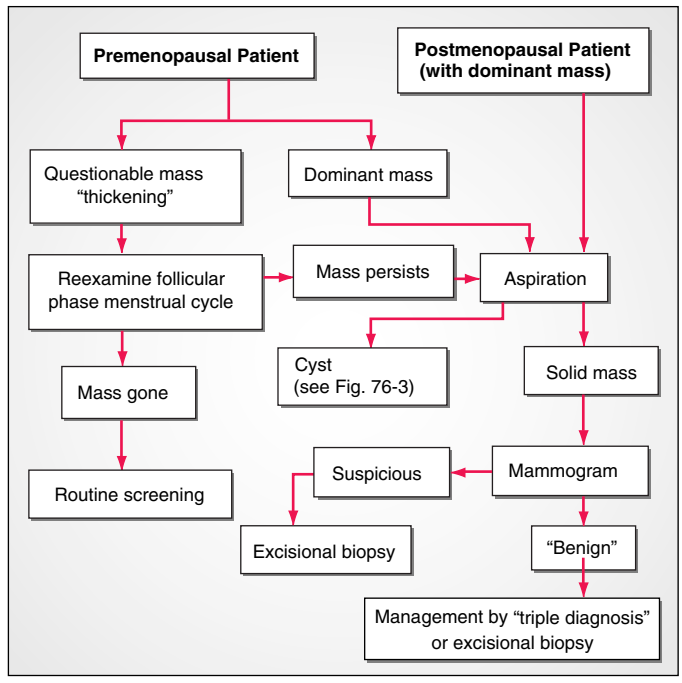

FIGURE 76-1 Approach to a palpable breast mass.

gested that BSE does not alter survival, but given its safety, the procedure should still be encouraged. The minimum benefit of this practice is the greater likelihood of detecting a mass at a smaller size when it can be treated with more limited surgery. Breast examination by the physician should be performed in good light so as to see retractions and other skin changes. The nipple and areolae should be inspected, and an attempt should be made to elicit nipple discharge. All regional lymph node groups should be examined, and any lesions should be measured. While lesions with certain features are more likely to be cancerous (hard, irregular, tethered or fixed, or painless lesions), physical examination alone cannot exclude malignancy. Furthermore, a negative mammogram in the presence of a persistent lump in the breast does not exclude malignancy.

In premenopausal women, lesions that are either equivocal or nonsuspicious on physical examination should be reexamined in 2 to 4 weeks, during the follicular phase of the menstrual cycle. Days 5 to 7 of the cycle are the best time for breast examination. A dominant mass in a postmenopausal woman or a dominant mass that persists through a menstrual cycle in a premenopausal woman should be aspirated by fine-needle biopsy or referred to a surgeon. If nonbloody fluid is aspirated and the lesion is thereby cured, the diagnosis (cyst) and therapy have been accomplished together. Solid lesions that are persistent, recurrent, complex, or bloody cysts require mammography and biopsy, although in selected patients the so-called triple diagnostic techniques (palpation, mammography, aspiration) can be used to avoid biopsy (Figs. 76-1 to 76-3). Ultrasound can be used in place of fine-needle aspiration to distinguish cysts from solid lesions. Not all solid masses are detected by ultrasound; thus, a palpable mass that is not visualized on ultrasound must be presumed to be solid.

Several points are essential in pursuing these management decision trees. First, risk factor analysis is not part of the decision structure. No constellation of risk factors, by their presence or absence, can be used to exclude biopsy. Second, fine-needle aspiration should be used only in centers that have proven skill in obtaining such specimens and analyzing them. Although the likelihood of cancer is low in the setting of a "triple negative" (benign-feeling lump, negative mammogram, and negative fine-needle aspiration), it is not zero, and the patient and physician must be aware of an 1% risk of false negativity. Third, additional technologies such as magnetic resonance imaging, ultrasound, and sestamibi imaging cannot be used to exclude the need for biopsy, although in unusual circumstances they may provoke a biopsy.

The Abnormal Mammogram Diagnostic mammography should not be confused with screening mammography, which is performed after a palpable abnormality has been detected. Diagnostic mammography is aimed at evaluating the rest of the breast before biopsy is performed or occasionally is part of the triple-test strategy to exclude immediate biopsy.

Subtle abnormalities that are first detected by screening mammography should be evaluated carefully by compression or magnified views. These abnormalities include clustered microcalcifications, densities (especially if spiculated), and new or enlarging architectural distortion. For some nonpalpable lesions ultrasound may be helpful either to identify cysts or to guide biopsy. If there is no palpable lesion and detailed mammographic studies are unequivocally benign, the patient should have routine follow-up appropriate to the patient's age.

If a nonpalpable mammographic lesion has a low index of suspicion, mammographic follow-up in 3 to 6 months is reasonable. Workup of indeterminate and suspicious lesions has been rendered more complex by the advent of stereotactic biopsies. Morrow and colleagues have suggested that these procedures are indicated for lesions that require biopsy but are likely to be benign—that is, for cases in which the procedure probably will eliminate additional surgery. When a lesion is more probably malignant, open excisional biopsy should be performed with a needle localization technique. Others have proposed more widespread use of stereotactic core biopsies for nonpalpable lesions, on economic grounds and because diagnosis leads to earlier treatment planning. However, stereotactic diagnosis of a malignant lesion does not eliminate the need for definitive surgical procedures, particularly if breast conservation is attempted. For example after a breast biopsy with needle localization (i.e., local excision) of a stereotactically diagnosed malignancy, reexcision may still be necessary to achieve negative margins. To some extent, these issues are decided on the basis of referral pattern and the availability of the resources for stereotactic core biopsies. A reasonable approach is shown in Fig. 76-4.

Breast Masses in the Pregnant or Lactating Woman During pregnancy, the breast grows under the influence of estrogen, progesterone, prolactin, and human placental lactogen. Lactation is suppressed by progester-

one, which blocks the effects of prolactin. After delivery, lactation is promoted by the fall in progesterone levels, which leaves the effects of prolactin unopposed. The development of a dominant mass during pregnancy or lactation should never be attributed to hormonal changes, and biopsy should never be performed under local anesthesia. Breast cancer develops in 1 in every 3000 to 4000 pregnancies. Stage for stage, breast cancer in pregnant patients is no different from premenopausal breast cancer in nonpregnant patients. However, pregnant women often have more advanced disease because the significance of a breast mass was not fully considered. Persistent lumps in the breast of pregnant or lactating women *can not* be attributed to benign changes based on physical findings; such patients should be promptly referred for diagnostic evaluation.

Benign Breast Masses Only about 1 in every 5 to 10 breast biopsies leads to a diagnosis of cancer, although the rate of positive biopsies varies in different countries. (These differences may be related to interpretation, medicolegal considerations, and availability of mammograms.) The vast majority of benign breast masses are due to "fibrocystic" disease, a descriptive term for small fluid-filled cysts and modest epithelial cell and fibrous tissue hyperplasia. However, fibrocystic disease is a histologic, not a clinical, diagnosis, and women who have had a biopsy with benign findings are at greater risk of developing breast cancer than those who have not had a biopsy. The subset of women with ductal or lobular cell proliferation (about 30% of patients), particularly the small fraction (3%) with atypical hyperplasia, have a fourfold greater risk of developing breast cancer than unbiopsied women, and the increase in the risk is about ninefold for women in this category who also have an affected first-degree relative. Thus, careful follow-up of these patients is required. By contrast, patients with a benign biopsy without atypical hyperplasia are at little risk and may be followed routinely.

SCREENING Breast cancer is virtually unique among the epithelial tumors in adults in that screening (in the form of annual mammography) has been proven to improve survival. Meta-analysis examining outcomes from every randomized trial of mammography conclusively shows a 25 to 30% reduction in the chance of dying from breast cancer with annual screening after age 50; the data for women between ages 40 and 50 are almost as positive. While controversy continues to surround the assessment of screening mammography, the preponderance of data as well as this author's evaluation of the literature continue to strongly support the positive benefits of screening mammography. New analyses of older randomized studies have suggested that screening may not work. While the defects in some studies cannot be corrected, most experts, including panels of the American Society of Clinical Oncology and the American Cancer Society, continue to believe that screening conveys substantial benefit. Furthermore, the profound drop in breast cancer mortality seen over the past decade is unlikely to be solely attributable to improvements in therapy. It seems prudent to recommend annual mammography for women past the age of 40. Although no randomized study of BSE has ever shown any improvement in survival, its major benefit appears to be identification of tumors appropriate for conservative local therapy. Better mammographic technology, including digitized mammography, routine use of magnified views, and greater skill in mammographic interpretation, combined with newer diagnostic techniques (magnetic resonance imaging, magnetic resonance spectroscopy, positron emission tomography, etc.) may make it possible to identify breast cancers even more reliably and earlier.

STAGING Correct staging of breast cancer patients is of extraordinary importance. Not only does it permit an accurate prognosis, but in many cases therapeutic decision-making is based largely on the TNM classification (Table 76-1). Comparison with historic series should be undertaken with caution, as the staging has changed several times in the past 20 years.

TREATMENT

PRIMARY BREAST CANCER A series of randomized clinical trials both in the United States and abroad have shown that breast-conserving treatments, consisting of the removal of the primary tumor by some form of lumpectomy with or without irradiating the breast, results in a survival that is as good as that after extensive procedures, such as mastectomy or modified radical mastectomy, with or without further irradiation. Postlumpectomy breast irradiation greatly reduces the risk of recurrence in the breast. While breast conservation is associated with a possibility of recurrence in the breast, 10-year survival is at least as good as that after more radical surgery. Postoperative radiation to regional nodes following mastectomy is also associated with an improvement in survival. Since radiation therapy can also reduce the rate of local or regional recurrence, it should be strongly considered following mastectomy for women with high-risk primary tumors (i.e., T2 in size, positive margins, positive nodes). At present, approximately one-third of women in the United States are managed by lumpectomy. Breast-conserving surgery is not suitable for all patients: it is not generally suitable for tumors >5 cm (or for smaller tumors if the breast is small), for tumors involving the nipple areola complex, for tumors with extensive intraductal disease involving multiple quadrants of the breast, for women with a history of collagen-vascular disease, and for women who either do not have the motivation for breast conservation or do not have convenient access to radiation therapy. However, these groups probably do not account for more than one-third of patients who are treated with mastectomy. Thus, a great many women still undergo mastectomy who could safely avoid this procedure and probably would if appropriately counseled.

An extensive intraductal component is a predictor of recurrence in the breast, and so are several clinical variables. Both axillary lymph node involvement and involvement of vascular or lymphatic channels

by metastatic tumor in the breast are associated with a higher risk of relapse in the breast but are not contraindications to breast-conserving treatment. When these patients are excluded, and when lumpectomy with negative tumor margins is achieved, breast conservation is associated with a recurrence rate in the breast of substantially <10%. The survival of patients who have recurrence in the breast is somewhat worse than that of women who do not. Thus, recurrence in the breast is a negative prognostic variable for long-term survival. However, recurrence in the breast is not the *cause* of distant metastasis. If recurrence in the breast caused metastatic disease, then women treated with lumpectomy, who have a higher rate of recurrence in the breast, should have poorer survival than women treated with mastectomy and they do not. Most patients should consult with a radiation oncologist before making a final decision concerning local therapy. However, a multimodality clinic in which the surgeon, radiation oncologist, medical oncologist, and other caregivers cooperate to evaluate the patient and develop a treatment is usually considered a major advantage by patients.

Adjuvant Therapy The use of systemic therapy after local management of breast cancer improves survival. More than one-third of the women who would otherwise die of metastatic breast cancer remain disease-free when treated with the appropriate systemic regimen.

PROGNOSTIC VARIABLES The most important prognostic variables are provided by *tumor staging*. The size of the tumor and the status of the axillary lymph nodes provide reasonably accurate information on the likelihood of tumor relapse. The relation of pathologic stage to 5-year survival is shown in Table 76-2. For most women, the need for adjuvant therapy can be readily defined on this basis alone. In the absence of lymph node involvement, involvement of microvessels (either capillaries or lymphatic channels) in tumors is nearly equivalent to lymph node involvement. The greatest controversy concerns women with intermediate prognoses. *There is rarely justification for adjuvant chemotherapy in most women with tumors <1 cm in size whose axillary lymph nodes are negative*. The most exciting development in this area is the use of gene expression arrays to analyze patterns of tumor gene expression.

Other prognostic variables have been sought, and some appear to influence disease-free and overall survival. What is less clear is whether they add to the information from pathologic staging.

Estrogen and progesterone receptor status are of prognostic significance. Tumors that lack either or both of these receptors are more likely to recur than tumors that have them.

Several *measures of tumor growth rate* correlate with early relapse. S-phase analysis using flow cytometry is the most accurate measure. Indirect S-phase assessments using antigens associated with the cell cycle, such as PCNA (Ki67), are also valuable. Several studies suggest that tumors with a high proportion (more than the median) of cells in the S phase pose a greater risk of relapse and that chemotherapy offers the greatest survival benefit for these tumors. For this reason, some clinicians use S-phase assessment as a deciding factor for instituting adjuvant therapy when other pathologic features are unclear. Assessment of DNA content in the form of ploidy is of modest value, with nondiploid tumors having a somewhat worse prognosis.

Histologic classification of the tumor has also been used as a prognostic factor. Tumors with a poor nuclear grade have a higher risk of recurrence than tumors with a good nuclear grade. Semiquantitative measures such as the Elston score improve the reproducibility of this measurement.

Molecular changes in the tumor are also useful. Tumors that overexpress *erbB2* (HER-2/neu) or have a mutated p53 gene have a worse prognosis. Particular interest has centered on *erbB2* overexpression as measured by histochemistry or by fluorescence in situ hybridization. In experienced hands either methodology is acceptable. Tumors that overexpress *erbB2* are more likely to respond to higher doses of doxorubicin-containing regimens. For this reason, *erbB2* expression is usually worth measuring as a means of deciding on therapy. Results of ongoing adjuvant therapy trials evaluating the role of monoclonal HER-2/neu antibodies (trastuzumab) are awaited with great interest.

To grow, a tumor must generate a neovasculature (Chap. 69). The presence of more microvessels, particularly when localized in so-called "hot spots," in a tumor is associated with a worse prognosis.

Other variables that have also been used to evaluate prognosis include proteins associated with invasiveness, such as type IV collagenase, cathepsin D, plasminogen activator, plasminogen activator receptor, and the metastasis-suppressor gene, *nm23*. None of these has been widely accepted as a prognostic variable for therapeutic decision-making. One problem in interpreting these prognostic variables is that most of them have not been examined in a study using a large cohort of patients.

ADJUVANT REGIMENS Adjuvant therapy is the use of systemic therapies in patients whose known disease has received local therapy but who are at risk of relapse. Selection of appropriate adjuvant chemotherapy or hormone therapy is highly controversial in some situations. Meta-analyses have helped to define broad limits for therapy but do not help in choosing optimal regimens or in choosing a regimen for certain subgroups of patients. A summary of recommendations is shown in Table 76-3. In general, premenopausal women for whom any form of adjuvant systemic therapy is indicated should receive multidrug chemotherapy. The antiestrogen (tamoxifen) improves survival in premenopausal patients with positive estrogen receptor values and should be added following completion of chemotherapy. Prophylactic castration may also be associated with a substantial survival benefit (primarily in estrogen receptor–positive patients) but is not widely used in this country.

Data on postmenopausal women are also controversial. The impact of adjuvant chemotherapy is quantitatively less clear-cut than in premenopausal patients, although some survival advantage has been shown. The first decision is whether chemotherapy or tamoxifen should be used. While adjuvant tamoxifen improves survival regardless of axillary lymph node status, the improvement in survival is modest for patients in whom multiple lymph nodes are involved. For this reason, it has been usual to give chemotherapy to postmenopausal patients who have no medical contraindications and who have more than one positive lymph node; tamoxifen is commonly given simultaneously or subsequently. For postmenopausal women for whom systemic therapy is warranted but who have a more favorable prognosis, tamoxifen may be used as a single agent. Data from the ATAC trial in which >9000 women were randomly assigned to tamoxifen, anastrazole (an aromatase inhibitor), or the combination showed that anastrazole was superior to tamoxifen or the combination in preventing recurrence at 32 months of follow-up. Whether these observations will persist with longer follow-up and/or other effects on cardiovascular disease will become issues awaits further follow-up.

Most comparisons of adjuvant chemotherapy regimens show little difference among them, although slight advantages for doxorubicin-containing regimens are usually seen.

One approach—so-called neoadjuvant chemotherapy—involves the administration of adjuvant therapy before definitive surgery and radiation therapy. Because the objective response rates of patients with breast cancer to systemic therapy in this setting exceed 75%, many

patients will be "downstaged" and may become candidates for breast-conserving therapy. At least one large randomized study has failed to show any difference in survival using this approach.

Other adjuvant treatments under investigation include the use of new drugs, such as paclitaxel and docetaxel, and therapy based on alternative kinetic and biologic models. In such approaches, high doses of single agents are used separately in relatively dose-intensive cycling regimens. One large randomized trial for node-positive patients suggests that patients treated with doxorubicin-cyclophosphamide for four cycles followed by four cycles of paclitaxel have a substantial additional gain in survival as compared with women receiving doxorubicin-cyclophosphamide alone, an outcome not validated in another large trial. Taxane use remains controversial. Very high dose therapy with stem cell transplantation in the adjuvant setting has not proved superior to standard dose therapy and should not be routinely used.

TABLE 76-3 *Suggested Approaches to Adjuvant Therapy*

Age Group	Lymph Node Status[a]	Endocrine Receptor (ER) Status	Tumor	Recommendation
Premenopausal	Positive	Any	Any	Multidrug chemotherapy + tamoxifen if ER-positive
Premenopausal	Negative	Any	>2 cm, or 1–2 cm with other poor prognostic variables	Multidrug chemotherapy + tamoxifen if ER-positive
Postmenopausal	Positive	Negative	Any	Multidrug chemotherapy
Postmenopausal	Positive	Positive	Any	Tamoxifen with or without chemotherapy
Postmenopausal	Negative	Positive	>2 cm, or 1–2 cm with other poor prognostic variables	Tamoxifen
Postmenopausal	Negative	Negative	>2 cm, or 1–2 cm with other poor prognostic variables	Consider multidrug chemotherapy

[a] As determined by pathologic examination.

Systemic Therapy of Metastatic Disease Nearly half of patients treated for apparently localized breast cancer develop metastatic disease. Although a very small number of these patients can enjoy long remissions when treated with combinations of systemic and local therapy, most eventually succumb. Soft tissue, bony, and visceral (lung and liver) metastases each account for approximately one-third of sites of initial relapses. However, by the time of death, most patients will have bony involvement. Recurrences can appear at any time after primary therapy. Half of all initial cancer recurrences occur >5 years after initial therapy.

Because the diagnosis of metastatic disease alters the outlook for the patient so drastically, it should not be made without biopsy. Every oncologist has seen patients with tuberculosis, gallstones, primary hyperparathyroidism, or other nonmalignant diseases misdiagnosed and treated as though they had metastatic breast cancer. This is a catastrophic mistake and justifies biopsy for virtually every patient at the time of initial suspicion of metastatic disease.

The choice of therapy requires consideration of local therapy needs, the overall medical condition of the patient, and the hormone receptor status of the tumor, as well as the exercise of clinical judgment. Because therapy of systemic disease is palliative, the potential toxicities of therapies should be balanced against the response rates. Several variables influence the response to systemic therapy. For example, the presence of estrogen and progesterone receptors is a strong indication for endocrine therapy, since the response rates for tumors that express both receptors may approach 70%. On the other hand, patients with short disease-free intervals, rapidly progressive visceral disease, lymphangitic pulmonary disease, or intracranial disease are unlikely to respond to endocrine therapy.

In many cases, systemic therapy can be withheld while the patient is managed with appropriate local therapy. Radiation therapy and occasionally surgery are effective at relieving the symptoms of metastatic disease, particularly when bony sites are involved. Many patients with bone-only or bone-dominant disease have a relatively indolent course. Under such circumstances, systemic chemotherapy has a modest effect, whereas radiation therapy may be effective for long periods. Other systemic treatments, such as strontium 89 and/or bisphosphonates, may provide a palliative benefit without inducing objective responses. Most patients with metastatic disease and certainly all who have bone involvement should receive concurrent bisphosphonates. Since the goal of therapy is to maintain well-being for as long as possible, emphasis should be placed on avoiding the most hazardous complications of metastatic disease, including pathologic fracture of the axial skeleton and spinal cord compression. New back pain in patients with cancer should be explored aggressively on an emergent basis; to wait for neurologic symptoms is a potentially catastrophic error. Metastatic involvement of endocrine organs can cause profound dysfunction, including adrenal insufficiency and hypopituitarism. Similarly, obstruction of the biliary tree or other impaired organ function may be better managed with a local therapy than with a systemic approach.

Endocrine Therapy Normal breast tissue is estrogen-dependent. Both primary and metastatic breast cancer may retain this phenotype. The best means of ascertaining whether a breast cancer is hormone-dependent is through analysis of estrogen and progesterone receptor levels on the tumor. Tumors that are positive for the estrogen receptor and negative for the progesterone receptor have a response rate of ~30%. Tumors that have both receptors have a response rate approaching 70%. If neither receptor is present, the objective response rates are <10%. Receptor analyses provide information as to the correct ordering of endocrine therapies as opposed to chemotherapy. Because of their lack of toxicity and because some patients whose receptor analyses are reported as negative respond to endocrine therapy, an endocrine treatment should be attempted in virtually every patient with metastatic breast cancer. Potential endocrine therapies are summarized in Table 76-4. The choice of endocrine therapy is usually determined

TABLE 76-4 *Endocrine Therapies for Breast Cancer*

Therapy	Comments
Castration	For premenopausal women
Surgical	
LHRH agonists	
Antiestrogens	
Tamoxifen	Useful in pre- and postmenopausal women
"Pure" antiestrogens	Promising early clinical data; responses in tamoxifen-resistant patients
Surgical adrenalectomy	Rarely employed second-line choice
Aromatase inhibitors	Low toxicity and superiority to additive hormone therapy; now first choice for metastatic disease
High-dose progestogens	Common third-line choice
Hypophysectomy	Rarely used
Additive androgens or estrogens	Plausible third-line therapies; potentially toxic

Note: LHRH, luteinizing hormone–releasing hormone.

by toxicity profile and availability. In most patients, the initial endocrine therapy should now be an aromatase inhibitor rather than tamoxifen. Newer "pure" antiestrogens that are free of agonistic effects are also in clinical trial. Cases in which tumors shrink in response to tamoxifen withdrawal (as well as withdrawal of pharmacologic doses of estrogens) have been reported. Endogenous estrogen formation may be blocked by analogues of luteinizing hormone–releasing hormone in premenopausal women. Additive endocrine therapies, including treatment with progestogens, estrogens, and androgens, may also be tried in patients who respond to initial endocrine therapy; the mechanism of action of these latter therapies is unknown. Patients who respond to one endocrine therapy have at least a 50% chance of responding to a second endocrine therapy. It is not uncommon for patients to respond to two or three sequential endocrine therapies; however, combination endocrine therapies do not appear to be superior to individual agents, and combinations of chemotherapy with endocrine therapy are not useful. The median survival of patients with metastatic disease is approximately 2 years, and many patients, particularly older persons and those with hormone-dependent disease, may respond to endocrine therapy for 3 to 5 years or longer.

Chemotherapy Unlike many other epithelial malignancies, breast cancer responds to several chemotherapeutic agents, including anthracyclines, alkylating agents, taxanes, and antimetabolites. Multiple combinations of these agents have been found to improve response rates somewhat, but they have had little effect on duration of response or survival. The choice among multidrug combinations frequently depends on whether adjuvant chemotherapy was administered and, if so, what type. While patients treated with adjuvant regimens such as cyclophosphamide, methotrexate, and fluorouracil (CMF regimens) may subsequently respond to the same combination in the metastatic disease setting, most oncologists use drugs to which the patients have not been previously exposed. Once patients have progressed after combination drug therapy, it is most common to treat them with single agents. Given the significant toxicity of most drugs, the use of a single effective agent will minimize toxicity by sparing the patient exposure to drugs that would be of little value. Unfortunately, no form of in vitro drug sensitivity testing to select the drugs most efficacious for a given patient has been demonstrated to be useful.

Most oncologists use either an anthracycline or paclitaxel following failure with the initial regimen. However, the choice has to be balanced with individual needs.

The use of a humanized antibody to *erbB2* [trastuzumab (Herceptin)] combined with paclitaxel can improve response rate and survival for women whose metastatic tumors overexpress *erbB2*. The magnitude of the survival extension is modest in patients with metastatic disease. Application to adjuvant therapy may prove even more beneficial. In the past few years a series of newer agents has emerged as useful in inducing objective responses in previously treated patients, including gemcitabine, capecitabine, navelbine, and oral etoposide.

HIGH-DOSE CHEMOTHERAPY INCLUDING AUTOLOGOUS BONE MARROW TRANSPLANTATION Autologous bone marrow transplantation combined with high doses of single agents can produce improvement even in heavily pretreated patients. However, such responses are rarely, if ever, durable and are unlikely to substantially alter the clinical course for most patients with advanced metastatic disease. Randomized trials have not been encouraging, and these approaches cannot be recommended as part of clinical care outside of research settings.

STAGE III BREAST CANCER Between 10 and 25% of patients present with so-called locally advanced, or stage III, breast cancer at diagnosis. Many of these cancers are technically operable, whereas others, particularly cancers with chest wall involvement, inflammatory breast cancers, or cancers with large matted axillary lymph nodes, cannot be managed with surgery initially. Although no randomized trials have proved the efficacy of induction chemotherapy, this approach has gained widespread use. More than 90% of patients with locally advanced breast cancer show a partial or better response to multidrug chemotherapy regimens that include an anthracycline. Early administration of this treatment reduces the bulk of the disease and frequently makes the patient a suitable candidate for salvage surgery and/or radiation therapy. These patients should be managed in multimodality clinics to coordinate surgery, radiation therapy, and systemic chemotherapy. Such approaches produce long-term disease-free survival in about 30 to 50% of patients.

BREAST CANCER PREVENTION Women who have one breast cancer are at risk of developing a contralateral breast cancer at a rate of approximately 0.5% per year. When adjuvant tamoxifen is administered to these patients, the rate of development of contralateral breast cancers is reduced. In other tissues of the body, tamoxifen has estrogen-like effects that are beneficial: preservation of bone mineral density and long-term lowering of cholesterol. However, tamoxifen has estrogen-like effects on the uterus, leading to an increased risk of uterine cancer (0.75% incidence after 5 years on tamoxifen). Tamoxifen also increases the risk of cataract formation. The Breast Cancer Prevention Trial (BCPT) revealed a >49% reduction in breast cancer among women with a risk of at least 1.66% taking the drug for 5 years. Raloxifene has shown similar breast cancer prevention potency but may have different effects on bone and heart. The two agents are being compared in a prospective randomized prevention trial (the STAR trial).

NONINVASIVE BREAST CANCER Breast cancer develops as a series of molecular changes in the epithelial cells that lead to ever more malignant behavior. Increased use of mammography has led to more frequent diagnosis of noninvasive breast cancer. These lesions fall into two groups: ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (lobular neoplasia). The management of both entities is controversial.

Ductal Carcinoma in Situ Proliferation of cytologically malignant breast epithelial cells within the ducts is termed *DCIS*. Significant disagreement can occur in differentiating atypical hyperplasia from DCIS. At least one-third of the cases of untreated DCIS progress to invasive breast cancer within 5 years. For many years, the standard treatment for this disease was mastectomy. However, since treatment of this condition by lumpectomy and radiation therapy gives survival that is as good as the survival for invasive breast cancer by mastectomy, it appears paradoxical to recommend more aggressive therapy for a "less" malignant disease. In one randomized trial, the combination of wide excision plus irradiation for DCIS caused a substantial reduction in the local recurrence rate as compared with wide excision alone with negative margins, though survival was identical in the two arms. No studies have compared either of these regimens to mastectomy. Addition of tamoxifen to any DCIS surgical/radiation therapy regimen further improves local control.

Several prognostic features may help to identify patients at high risk for local recurrence after either lumpectomy alone or lumpectomy with radiation therapy. These include extensive disease; age < 40; and cytologic features such as necrosis, poor nuclear grade, and comedo subtype with overexpression of *erbB2*. Some data suggest that adequate excision with careful determination of pathologically clear margins is associated with a low recurrence rates. When surgery is combined with radiation therapy, recurrence (which is usually in the same quadrant) occurs with a frequency of ≤10%. Given the fact that half of these recurrences will be invasive, about 5% of the initial cohort will eventually develop invasive breast cancer. A reasonable expectation of mortality for these patients is about 1%, a figure that approximates the mortality rate for DCIS managed by mastectomy. Although this train of reasoning has not formally been proved valid, it is reasonable at present to recommend that patients who desire breast preservation, and in whom DCIS appears to be reasonably localized, be managed by adequate surgery with meticulous pathologic evaluation, followed by breast irradiation and tamoxifen. For patients with localized DCIS, axillary lymph node dissection is unnecessary. More controversial is the question of what management is optimal when there is any degree of invasion. Because of a significant likelihood (10 to

15%) of axillary lymph node involvement even when the primary lesion shows only microscopic invasion, it is prudent to do at least a level 1 and 2 axillary lymph node dissection for all patients with any degree of invasion; sentinel node biopsy may be substituted. Further management is dictated by the presence of nodal spread.

Lobular Neoplasia Proliferation of cytologically malignant cells within the lobules is termed *lobular neoplasia*. Nearly 30% of patients who have had adequate local excision of the lesion develop breast cancer (usually infiltrating ductal cell carcinoma) over the next 15 to 20 years. Ipsilateral and contralateral disease are equally common. Therefore, lobular neoplasia may be a premalignant lesion that suggests an elevated risk of subsequent breast cancer, rather than a form of malignancy itself, and aggressive local management seems unreasonable. Most patients should be treated with tamoxifen for 5 years and followed with careful annual mammography and semiannual physical examinations. Additional molecular analysis of these lesions may make it possible to discriminate between patients who are at risk of further progression and who require additional therapy and those in whom simple follow-up is adequate.

MALE BREAST CANCER Breast cancer is about 1/150th as frequent in men as in women. It usually presents as a unilateral lump in the breast and is frequently not diagnosed promptly. Given the small amount of soft tissue and the unexpected nature of the problem, locally advanced presentations are somewhat more common. When male breast cancer is matched to female breast cancer by age and stage, its overall prognosis is identical. Although gynecomastia may initially be unilateral or asymmetric, any unilateral mass in a man over the age of 40 should receive a careful workup all the way through biopsy. On the other hand, bilateral symmetric breast development rarely represents breast cancer and is almost invariably due to endocrine disease or a drug effect. It should be kept in mind, nevertheless, that the risk of cancer is much greater in men with gynecomastia; in such men, gross asymmetry of the breasts should arouse suspicion of cancer. Male breast cancer is best managed by mastectomy and axillary lymph node dissection (modified radical mastectomy). Patients with locally advanced disease or positive nodes should also be treated with irradiation. Approximately 90% of male breast cancers contain estrogen receptors, and approximately 60% of cases with metastatic disease respond to endocrine therapy. No randomized studies have evaluated adjuvant therapy for male breast cancer. Two historic experiences suggest that the disease responds well to adjuvant systemic therapy, and, if not medically contraindicated, the same criteria for the use of adjuvant therapy in women should be applied to men.

The sites of relapse and spectrum of response to chemotherapeutic drugs are virtually identical for breast cancers in the two sexes.

FOLLOW-UP OF BREAST CANCER PATIENTS Despite the availability of sophisticated and expensive imaging techniques and a wide range of serum tumor marker tests, no studies document that survival is influenced by early diagnosis of relapse. Surveillance guidelines are given in Table 76-5.

77 GASTROINTESTINAL TRACT CANCER

Robert J. Mayer

The gastrointestinal tract is the second most common noncutaneous site for cancer and the second major cause of cancer-related mortality in the United States.

ESOPHAGEAL CANCER

INCIDENCE AND ETIOLOGY Cancer of the esophagus is a relatively uncommon but extremely lethal malignancy. The diagnosis was made in 14,250 Americans in 2004 and led to 13,300 deaths. Worldwide, the incidence of esophageal cancer varies strikingly. It occurs frequently within a geographic region extending from the southern shore of the Caspian Sea on the west to northern China on the east and encompassing parts of Iran, Central Asia, Afghanistan, Siberia, and Mongolia. High-incidence "pockets" of the disease are also present in such disparate locations as Finland, Iceland, Curaçao, southeastern Africa, and northwestern France. In North America and western Europe, the disease is more common in blacks than whites and in males than females; it appears most often after age 50 and seems to be associated with a lower socioeconomic status.

A variety of causative factors have been implicated in the development of the disease (Table 77-1). In the United States, esophageal cancer cases are either squamous cell carcinomas or adenocarcinomas. The etiology of squamous cell esophageal cancer is related to excess alcohol consumption and/or cigarette smoking. The relative risk increases with the amount of tobacco smoked or alcohol consumed, with these factors acting synergistically. The consumption of whiskey is linked to a higher incidence than the consumption of wine or beer. Squamous cell esophageal carcinoma has also been associated with the ingestion of nitrites, smoked opiates, and fungal toxins in pickled vegetables, as well as mucosal damage caused by such physical insults as long-term exposure to extremely hot tea, the ingestion of lye, radiation-induced strictures, and chronic achalasia. The presence of an esophageal web in association with glossitis and iron deficiency (i.e.,

TABLE 77-1 Some Etiologic Factors Believed to Be Associated with Esophageal Cancer

Excess alcohol consumption
Cigarette smoking
Other ingested carcinogens
Nitrates (converted to nitrites)
Smoked opiates
Fungal toxins in pickled vegetables
Mucosal damage from physical agents
Hot tea
Lye ingestion
Radiation-induced strictures
Chronic achalasia
Host susceptibility
Esophageal web with glossitis and iron deficiency (i.e., Plummer-Vinson or Paterson-Kelly syndrome)
Congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris)
? Dietary deficiencies molybdenum, zinc, vitamin A
? Celiac sprue
Chronic gastric reflux (i.e., Barrett's esophagus) for adenocarcinoma

Plummer-Vinson or Paterson-Kelly syndrome) and congenital hyperkeratosis and pitting of the palms and soles (i.e., tylosis palmaris et plantaris) have each been linked with squamous cell esophageal cancer, as have dietary deficiencies of molybdenum, zinc, and vitamin A.

For unclear reasons, the incidence of squamous cell esophageal cancer has decreased somewhat in both the black and white population in the United States over the past 25 years, while the rate of adenocarcinoma has risen dramatically, particularly in white males. Adenocarcinomas arise in the distal esophagus in the presence of chronic gastric reflux and gastric metaplasia of the epithelium (Barrett's esophagus), which is more common in obese persons. Adenocarcinomas arise within dysplastic columnar epithelium in the distal esophagus. Even before frank neoplasia is detectable, aneuploidy and p53 mutations are found in the dysplastic epithelium. These adenocarcinomas behave clinically like gastric adenocarcinoma and now account for >50% of esophageal cancers.

CLINICAL FEATURES About 15% of esophageal cancers occur in the upper third of the esophagus (cervical esophagus), 35% in the middle third, and 50% in the lower third. Squamous cell carcinomas and adenocarcinomas of the esophagus cannot be distinguished radiographically or endoscopically.

Progressive dysphagia and weight loss of short duration are the initial symptoms in the vast majority of patients. Dysphagia initially occurs with solid foods and gradually progresses to include semisolids and liquids. By the time these symptoms develop, the disease is usually incurable, since difficulty in swallowing does not occur until >60% of the esophageal circumference is infiltrated with cancer. Dysphagia may be associated with pain on swallowing (odynophagia), pain radiating to the chest and/or back, regurgitation or vomiting, and aspiration pneumonia. The disease most commonly spreads to adjacent and supraclavicular lymph nodes, liver, lungs, and pleura. Tracheoesophageal fistulas may develop as the disease advances, leading to severe suffering. As with other squamous cell carcinomas, hypercalcemia may occur in the absence of osseous metastases, probably from parathormone-related peptide secreted by tumor cells (Chap. 86).

DIAGNOSIS Attempts at endoscopic and cytologic screening for carcinoma in patients with Barrett's esophagus, while effective as a means of detecting high-grade dysplasia, have not yet been shown to improve the prognosis in individuals found to have a carcinoma. Routine contrast radiographs effectively identify esophageal lesions large enough to cause symptoms. In contrast to benign esophageal leiomyomas, which result in esophageal narrowing with preservation of a normal mucosal pattern, esophageal carcinomas characteristically cause ragged, ulcerating changes in the mucosa in association with deeper infiltration, producing a picture resembling achalasia. Smaller, potentially resectable tumors are often poorly visualized despite technically adequate esophagograms. Because of this, esophagoscopy should be performed in all patients suspected of having an esophageal abnormality, to visualize the tumor and to obtain histopathologic confirmation of the diagnosis. Because the population of persons at risk for squamous cell carcinoma of the esophagus (i.e., smokers and drinkers) also has a high rate of cancers of the lung and the head and neck region, endoscopic inspection of the larynx, trachea, and bronchi should also be done. A thorough examination of the fundus of the stomach (by retroflexing the endoscope) is imperative as well. Endoscopic biopsies of esophageal tumors fail to recover malignant tissue in one-third of cases because the biopsy forceps cannot penetrate deeply enough through normal mucosa pushed in front of the carcinoma. Cytologic examination of tumor brushings frequently complements standard biopsies and should be performed routinely. The extent of tumor spread to the mediastinum and paraaortic lymph nodes should also be assessed by computed tomography (CT) scans of the chest and abdomen and by endoscopic ultrasound. Positron emission tomography (PET) scanning may also provide useful assessment of resectability.

TREATMENT

The prognosis for patients with esophageal carcinoma is poor. Fewer than 5% of patients are alive 5 years after the diagnosis; thus, management focuses on symptom control. Surgical resection of all gross tumor (i.e., total resection) is feasible in only 45% of cases, with residual tumor cells frequently present at the resection margins. Such esophagectomies have been associated with a postoperative mortality rate of 5 to 10% due to anastomotic fistulas, subphrenic abscesses, and respiratory complications. About 20% of patients who survive a total resection live 5 years. The outcome of primary radiation therapy (5500 to 6000 cGy) for squamous cell carcinomas is similar to that of radical surgery, sparing patients perioperative morbidity but often resulting in less satisfactory palliation of obstructive symptoms. The evaluation of chemotherapeutic agents in patients with esophageal carcinoma has been hampered by ambiguity in the definition of "response" (i.e., benefit) and the debilitated physical condition of many treated individuals. Nonetheless, significant reductions in the size of measurable tumor masses have been reported in 15 to 25% of patients given single-agent treatment and in 30 to 60% of patients treated with drug combinations that include cisplatin. Combination chemotherapy and radiation therapy as the initial therapeutic approach, either alone or followed by an attempt at operative resection, may be of benefit. When administered along with radiation therapy, chemotherapy produces a better survival outcome than radiation therapy alone. The use of preoperative chemotherapy and radiation therapy followed by esophageal resection appears to prolong survival as compared with historic controls, but randomized trials have produced inconsistent results.

For the incurable, surgically unresectable patient with esophageal cancer, dysphagia, malnutrition, and the management of tracheoesophageal fistulas loom as major issues. Approaches to palliation include repeated endoscopic dilatation, the surgical placement of a gastrostomy or jejunostomy for hydration and feeding, and endoscopic placement of an expansive metal stent to bypass the tumor. Endoscopic fulguration of the obstructing tumor with lasers appears to be the most promising of these techniques.

TUMORS OF THE STOMACH

GASTRIC ADENOCARCINOMA ■ Incidence and Epidemiology For unclear reasons, the incidence and mortality rates for gastric cancer have decreased markedly during the past 65 years. The mortality rate from gastric cancer in the United States has dropped in men from 28 to 5.0 per 100,000 population, while in women, the rate has decreased from 27 to 2.3 per 100,000. Nonetheless, 22,710 new cases of stomach cancer were diagnosed in the United States and 11,780 Americans died of the disease in 2004. Gastric cancer incidence has decreased worldwide but remains high in Japan, China, Chile, and Ireland.

The risk of gastric cancer is greater among lower socioeconomic classes. Migrants from high- to low-incidence nations maintain their susceptibility to gastric cancer, while the risk for their offspring approximates that of the new homeland. These findings suggest that an environmental exposure, probably beginning early in life, is related to the development of gastric cancer, with dietary carcinogens considered the most likely factor(s).

Pathology About 85% of stomach cancers are adenocarcinomas, with 15% due to lymphomas and gastrointestinal stromal tumors (GIST, formerly called *leiomyosarcomas*). Gastric adenocarcinomas may be subdivided into two categories: a *diffuse type* in which cell cohesion is absent, so that individual cells infiltrate and thicken the stomach wall without forming a discrete mass; and an *intestinal type* characterized by cohesive neoplastic cells that form glandlike tubular structures. The diffuse carcinomas occur more often in younger patients, develop throughout the stomach (including the cardia), result in a loss of distensibility of the gastric wall (so-called linitis plastica or "leather bottle" appearance), and carry a poorer prognosis. Intestinal-type lesions are frequently ulcerative, more commonly appear in the antrum and lesser curvature of the stomach, and are often preceded by a prolonged precancerous process. While the incidence of diffuse carcinomas is similar in most populations, the intestinal type tends to predominate in the high-risk geographic regions and is less likely to be found in areas where the frequency of gastric cancer is declining. Thus, different etiologic factor(s) may be involved in these two subtypes. In the United States, the distal stomach is the site of origin of ~30% of gastric cancers, ~20% arise in the midportion of the stomach, and ~37% originate in the proximal third of the stomach. The remaining 13% involve the entire stomach.

Etiology The long-term ingestion of high concentrations of nitrates in dried, smoked, and salted foods appears to be associated with a higher risk. The nitrates are thought to be converted to carcinogenic nitrites by bacteria (Table 77-2). Such bacteria may be introduced exogenously through the ingestion of partially decayed foods, which are consumed in abundance worldwide by the lower socioeconomic classes. Bacteria such as *Helicobacter pylori* may also contribute to this effect by causing chronic gastritis, loss of gastric acidity, and bacterial growth in the stomach. The effect of *H. pylori* eradication on the subsequent risk for gastric cancer in high-incidence areas is under investigation. Loss of acidity may occur when acid-producing cells of the gastric antrum have been removed surgically to control benign peptic ulcer disease or when achlorhydria, atrophic gastritis, and even pernicious anemia develop in the elderly. Serial endoscopic examinations of the stomach in patients with atrophic gastritis have documented replacement of the usual gastric mucosa by intestinal-type cells. This process of intestinal metaplasia may lead to cellular atypia and eventual neoplasia. Since the declining incidence of gastric cancer in the United States primarily reflects a decline in distal, ulcerating, intestinal-type lesions, it is conceivable that better food preservation and the availability of refrigeration to all socioeconomic classes have decreased the dietary ingestion of exogenous bacteria.

Several additional etiologic factors have been associated with gastric carcinoma. Gastric ulcers and adenomatous polyps have occasionally been so linked, but data regarding a cause-and-effect relationship are unconvincing. The inadequate clinical distinction between benign gastric ulcers and small ulcerating carcinomas may, in part, account for this presumed association. The presence of extreme hypertrophy of gastric rugal folds (i.e., Ménétrier's disease), giving the impression of polypoid lesions, has been associated with a striking frequency of malignant transformation; such hypertrophy, however, does not represent the presence of true adenomatous polyps. Individuals with blood group A have a higher incidence of gastric cancer than persons with blood group O; this observation may be related to differences in the mucous secretion leading to altered mucosal protection from carcinogens. A germline mutation in the E-cadherin gene, inherited in an autosomal dominant pattern and coding for a cell adhesion protein, has been linked to a high incidence of occult gastric cancers in young asymptomatic carriers. Duodenal ulcers are not associated with gastric cancer.

TABLE 77-2 *Nitrate-Converting Bacteria as a Factor in the Causation of Gastric Carcinoma*[a]

Exogenous sources of nitrate-converting bacteria:
Bacterially contaminated food (common in lower socioeconomic classes, who have a higher incidence of the disease; diminished by improved food preservation and refrigeration)
? *Helicobacter pylori* infection
Endogenous factors favoring growth of nitrate-converting bacteria in the stomach:
Decreased gastric acidity
Prior gastric surgery (antrectomy) (15- to 20-year latency period)
Atrophic gastritis and/or pernicious anemia
? Prolonged exposure to histamine H_2-receptor antagonists

[a] Hypothesis: Dietary nitrates are converted to carcinogenic nitrites by bacteria.

Clinical Features Gastric cancers, when superficial and surgically curable, usually produce no symptoms. As the tumor becomes more extensive, patients may complain of an insidious upper abdominal discomfort varying in intensity from a vague, postprandial fullness to a severe, steady pain. Anorexia, often with slight nausea, is very common but is not the usual presenting complaint. Weight loss may eventually be observed, and nausea and vomiting are particularly prominent with tumors of the pylorus; dysphagia may be the major symptom caused by lesions of the cardia. There are no early physical signs. A palpable abdominal mass indicates long-standing growth and predicts regional extension.

Gastric carcinomas spread by direct extension through the gastric wall to the perigastric tissues, occasionally adhering to adjacent organs such as the pancreas, colon, or liver. The disease also spreads via lymphatics or by seeding of peritoneal surfaces. Metastases to intra-abdominal and supraclavicular lymph nodes occur frequently, as do metastatic nodules to the ovary (Krukenberg's tumor), periumbilical region ("Sister Mary Joseph node"), or peritoneal cul-de-sac (Blumer's shelf palpable on rectal or vaginal examination); malignant ascites may also develop. The liver is the most common site for hematogenous spread of tumor.

The presence of iron-deficiency anemia in men and of occult blood in the stool in both sexes mandates a search for an occult gastrointestinal tract lesion. A careful assessment is of particular importance in patients with atrophic gastritis or pernicious anemia. Unusual clinical features associated with gastric adenocarcinomas include migratory thrombophlebitis, microangiopathic hemolytic anemia, and acanthosis nigricans.

Diagnosis A double-contrast radiographic examination is the simplest diagnostic procedure for the evaluation of a patient with epigastric complaints. The use of double-contrast techniques helps to detect small lesions by improving mucosal detail. The stomach should be distended at some time during every radiographic examination, since decreased distensibility may be the only indication of a diffuse infiltrative carcinoma. Although gastric ulcers can be detected fairly early, distinguishing benign from malignant lesions is difficult. The anatomic location of an ulcer is not in itself an indication of the presence or absence of a cancer.

Gastric ulcers that appear benign by radiography present special problems. Some physicians believe that gastroscopy is not mandatory if the radiographic features are typically benign, if complete healing can be visualized by x-ray within 6 weeks, and if a follow-up contrast radiograph obtained several months later shows a normal appearance. However, we recommend gastroscopic biopsy and brush cytology for all patients with a gastric ulcer in order to exclude a malignancy. Malignant gastric ulcers must be recognized before they penetrate into surrounding tissues, because the rate of cure of early lesions limited to the mucosa or submucosa is >80%. Since gastric carcinomas are

TABLE 77-3 *Staging System for Gastric Carcinoma*

Stage	TNM	Features	Data from ACS: No. of Cases, %	Data from ACS: 5-Year Survival, %

difficult to distinguish clinically or radiographically from gastric lymphomas, endoscopic biopsies should be made as deeply as possible, due to the submucosal location of lymphoid tumors.

The staging system for gastric carcinoma is shown in Table 77-3.

TREATMENT

Complete surgical removal of the tumor with resection of adjacent lymph nodes offers the only chance for cure. However, this is possible in fewer than a third of patients. A subtotal gastrectomy is the treatment of choice for patients with distal carcinomas, while total or near-total gastrectomies are required for more proximal tumors. The inclusion of extended lymph node dissection to these procedures appears to confer an added risk for complications without enhancing survival. The prognosis following complete surgical resection depends on the degree of tumor penetration into the stomach wall and is adversely influenced by regional lymph node involvement, vascular invasion, and abnormal DNA content (i.e., aneuploidy), characteristics found in the vast majority of American patients. As a result, the probability of survival after 5 years for the 25 to 30% of patients able to undergo complete resection is ~20% for distal tumors and <10% for proximal tumors, with recurrences continuing to occur for at least 8 years after surgery. In the absence of ascites or extensive hepatic or peritoneal metastases, even patients whose disease is believed to be incurable by surgery should be offered resection of the primary lesion. Reduction of tumor bulk is the best form of palliation and may enhance the probability of benefit from chemotherapy and/or radiation therapy.

Gastric adenocarcinoma is a relatively radioresistant tumor, and adequate control of the primary tumor requires doses of external beam irradiation that exceed the tolerance of surrounding structures, such as bowel mucosa and spinal cord. As a result, the major role of radiation therapy in patients has been palliation of pain. Radiation therapy alone after a complete resection does not prolong survival. In the setting of surgically unresectable disease limited to the epigastrium, patients treated with 3500 to 4000 cGy did not live longer than similar patients not receiving radiotherapy; however, survival was prolonged slightly when 5-fluorouracil (5-FU) was given in combination with radiation therapy. In this clinical setting, the 5-FU may well be functioning as a radiosensitizer.

The administration of combinations of cytotoxic drugs to patients with advanced gastric carcinoma has been associated with partial responses in 30 to 50% of cases, providing significant benefit to individuals who respond to treatment. Such drug combinations have generally included 5-FU and doxorubicin together with either mitomycin-C or cisplatin. Despite this encouraging response rate, complete remissions are uncommon, the partial responses are transient, and the overall influence of multidrug therapy on survival has been a source of debate. The use of adjuvant chemotherapy alone following the complete resection of a gastric cancer has only minimally improved survival. However, postoperative chemotherapy combined with radiation therapy has been shown to reduce the recurrence rate and prolong survival.

PRIMARY GASTRIC LYMPHOMA Primary lymphoma of the stomach is relatively uncommon, accounting for <15% of gastric malignancies and about 2% of all lymphomas. The stomach is, however, the most frequent extranodal site for lymphoma, and gastric lymphoma has increased in frequency during the past 25 years. The disease is difficult to distinguish clinically from gastric adenocarcinoma; both tumors are most often detected during the sixth decade of life; present with epigastric pain, early satiety, and generalized fatigue; and are usually characterized by ulcerations with a ragged, thickened mucosal pattern demonstrated by contrast radiographs. The diagnosis of lymphoma of the stomach may occasionally be made through cytologic brushings of the gastric mucosa but usually requires a biopsy at gastroscopy or laparotomy. Failure of gastroscopic biopsies to detect lymphoma in a given case should not be interpreted as being conclusive, since superficial biopsies may miss the deeper lymphoid infiltrate. The macroscopic pathology of gastric lymphoma may also mimic adenocarcinoma, consisting of either a bulky ulcerated lesion localized in the corpus or antrum or a diffuse process spreading throughout the entire gastric submucosa and even extending into the duodenum. Microscopically, the vast majority of gastric lymphoid tumors are non-Hodgkin's lymphomas of B cell origin; Hodgkin's disease involving the stomach is extremely uncommon. Histologically, these tumors may range from well-differentiated, superficial processes [mucosa-associated lymphoid tissue (MALT)] to high-grade, large-cell lymphomas. Infection with *H. pylori*, the same bacterium associated with the development of gastric adenocarcinoma, appears to increase the risk for gastric lymphoma in general and MALT lymphomas in particular. Gastric lymphomas spread initially to regional lymph nodes (often to Waldeyer's ring) and may then disseminate. Gastric lymphomas are staged like other lymphomas (Chap. 97).

TREATMENT

Primary gastric lymphoma is a far more treatable disease than adenocarcinoma of the stomach, a fact that underscores the need for making the correct diagnosis. Antibiotic treatment to eradicate *H. pylori* infection has led to regression of about 75% of gastric MALT lymphomas and should be considered before surgery, radiation therapy, or chemotherapy are undertaken in patients having such tumors. A lack of response to such antimicrobial treatment has been linked to a specific chromosomal abnormality, i.e., t(11;18). Responding patients should undergo periodic endoscopic surveillance because it remains unclear whether the neoplastic clone is eliminated or merely suppressed. Subtotal gastrectomy, usually followed by combination chemotherapy, has led to 5-year survival rates of 40 to 60% in patients with localized high-grade lymphomas. The need for a major surgical procedure is not clear, particularly in patients with preoperative radiographic evidence of nodal involvement, for whom chemotherapy alone [CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) plus rituximab] is effective therapy. A role for radiation therapy is not defined because most recurrences develop at sites distant from the epigastrium. If widespread disease is discovered at the time of laparotomy, combination chemotherapy should be used.

GASTRIC (NONLYMPHOID) SARCOMA Leiomyosarcomas and GISTs make up 1 to 3% of gastric neoplasms. They most frequently involve the anterior and posterior walls of the gastric fundus and often ulcerate and bleed. Even those lesions that appear benign on histologic ex-

amination may behave in a malignant fashion. These tumors rarely invade adjacent viscera and characteristically do not metastasize to lymph nodes, but they may spread to the liver and lungs. The treatment of choice is surgical resection. Combination chemotherapy should be reserved for patients with metastatic disease. All such tumors should be analyzed for a mutation in the c-*kit* receptor. GISTs are unresponsive to conventional chemotherapy; ~50% of patients with such tumors, however, experience objective response when treated with imatinib mesylate (Gleevec), a selective inhibitor of the c-*kit* tyrosine kinase.

COLORECTAL CANCER

INCIDENCE Cancer of the large bowel is second only to lung cancer as a cause of cancer death in the United States; 146,940 new cases occurred in 2004, and 56,730 deaths were due to colorectal cancer. The incidence rate has remained relatively unchanged during the past 30 years while the mortality rate has decreased, particularly in females. Colorectal cancer generally occurs in individuals ≥50 years.

POLYPS AND MOLECULAR PATHOGENESIS Most colorectal cancers, regardless of etiology, arise from adenomatous polyps. A polyp is a grossly visible protrusion from the mucosal surface and may be classified pathologically as a nonneoplastic hamartoma (*juvenile polyp*), a hyperplastic mucosal proliferation (*hyperplastic polyp*), or an adenomatous polyp. Only adenomas are clearly premalignant, and only a minority of such lesions ever develop into cancer. Population-screening studies and autopsy surveys have revealed that adenomatous polyps may be found in the colons of >30% of middle-aged or elderly people; however, <1% of polyps ever become malignant. Most polyps produce no symptoms and remain clinically undetected. Occult blood in the stool may be found in <5% of patients with such lesions.

A number of molecular changes have been described in DNA obtained from adenomatous polyps, dysplastic lesions, and polyps containing microscopic foci of tumor cells (carcinoma in situ), which are thought to represent a multistep process in the evolution of normal colonic mucosa to life-threatening invasive carcinoma. These developmental steps towards carcinogenesis include, but are not restricted to, point mutations in the K-*ras* protooncogene; hypomethylation of DNA, leading to gene activation; loss of DNA ("allelic loss") at the site of a tumor-suppressor gene [the adenomatous polyposis coli (*APC*) gene] on the long arm of chromosome 5 (5q21); allelic loss at the site of a tumor-suppressor gene located on chromosome 18q [the deleted in colorectal cancer (*DCC*) gene]; and allelic loss at chromosome 17p, associated with mutations in the p53 tumor-suppressor gene (Fig. 68-2). Thus, the altered proliferative pattern of the colonic mucosa, which results in progression to a polyp and then to carcinoma, may involve the mutational activation of an oncogene followed by and coupled with the loss of genes that normally suppress tumorigenesis. It remains uncertain whether the genetic aberrations always occur in a defined order. Based on this model, however, cancer is believed to develop only in those polyps in which all of these mutational events take place.

Clinically, the probability of an adenomatous polyp becoming a cancer depends on the gross appearance of the lesion, its histologic features, and its size. Adenomatous polyps may be pedunculated (stalked) or sessile (flat-based). Cancers develop more frequently in sessile polyps. Histologically, adenomatous polyps may be tubular, villous (i.e., papillary), or tubulovillous. Villous adenomas, most of which are sessile, become malignant more than three times as often as tubular adenomas. The likelihood that any polypoid lesion in the large bowel contains invasive cancer is related to the size of the polyp, being negligible (<2%) in lesions <1.5 cm, intermediate (2 to 10%) in lesions 1.5 to 2.5 cm in size, and substantial (10%) in lesions >2.5 cm.

Following the detection of an adenomatous polyp, the entire large bowel should be visualized endoscopically or radiographically, since synchronous lesions are present in about one-third of cases. Colonoscopy should then be repeated periodically, even in the absence of a previously documented malignancy, since such patients have a 30 to 50% probability of developing another adenoma and are at a higher-than-average risk for developing a colorectal carcinoma. Adenomatous polyps are thought to require >5 years of growth before becoming clinically significant; colonoscopy need not be carried out more frequently than every 3 years.

ETIOLOGY AND RISK FACTORS Risk factors for the development of colorectal cancer are listed in Table 77-4.

Diet The etiology for most cases of large-bowel cancer appears to be related to environmental factors. The disease occurs more often in upper socioeconomic populations who live in urban areas. Mortality from colorectal cancer is directly correlated with per capita consumption of calories, meat protein, and dietary fat and oil as well as elevations in the serum cholesterol concentration and mortality from coronary artery disease. Geographic variations in incidence are unrelated to genetic differences, since migrant groups tend to assume the large-bowel cancer incidence rates of their adopted countries. Furthermore, population groups such as Mormons and Seventh Day Adventists, whose lifestyle and dietary habits differ somewhat from those of their neighbors, have significantly lower-than-expected incidence and mortality rates for colorectal cancer. Colorectal cancer has increased in Japan since that nation has adopted a more "western" diet. At least two hypotheses have been proposed to explain the relationship to diet, neither of which is fully satisfactory.

ANIMAL FATS One hypothesis is that the ingestion of animal fats such as are found in red meats and processed meat leads to an increased proportion of anaerobes in the gut microflora, resulting in the conversion of normal bile acids into carcinogens. This provocative hypothesis is supported by several reports of increased amounts of fecal anaerobes in the stools of patients with colorectal cancer. Diets high in animal (but not vegetable) fats are also associated with high serum cholesterol, which is also associated with enhanced risk for the development of colorectal adenomas and carcinomas.

INSULIN RESISTANCE The enhanced number of calories inherent in "western" diets coupled with physical inactivity have been associated with a higher prevelance of obesity. Persons with such excess weight gain develop insulin resistance with increased circulating levels of insulin, leading to higher circulating concentrations of insulin-like growth factor type I (IGF-I). This growth factor appears to stimulate proliferation of the intestinal mucosa.

FIBER Contrary to one hypothesis, the results of randomized trials and case-controlled studies have failed to show any value for dietary fiber or diets high in fruits and vegatables in preventing the recurrence of colorectal adenomas or the development of colorectal cancer. The weight of epidemiologic evidence, however, implicates diet as being the major etiologic factor for colorectal cancer, particularly diets high in animal fat and in calories.

HEREDITARY FACTORS AND SYNDROMES As many as 25% of patients with colorectal cancer have a family history of the disease, suggesting a hereditary predisposition. Inherited large-bowel cancers can be divided into two main groups: the well-studied but uncommon polyposis syndromes and the more common nonpolyposis syndromes (Table 77-5).

Polyposis Coli Polyposis coli (familial polyposis of the colon) is a rare condition characterized by the appearance of thousands of adenomatous polyps throughout the large bowel. It is transmitted as an autosomal dominant trait; the occasional patients with no family history

TABLE 77-5 *Hereditable (Autosomal Dominant) Gastrointestinal Polyposis Syndromes*

Syndrome	Distribution of Polyps	Histologic Type	Malignant Potential	Associated Lesions
Familial adenomatous polyposis	Large intestine	Adenoma	Common	None
Gardner's syndrome	Large and small intestines	Adenoma	Common	Osteomas, fibromas, lipomas, epidermoid cysts, ampullary cancers, congenital hypertrophy of retinal pigment epithelium
Turcot's syndrome	Large intestine	Adenoma	Common	Brain tumors
Nonpolyposis syndrome (Lynch syndrome)	Large intestine (often proximal)	Adenoma	Common	Endometrial and ovarian tumors
Peutz-Jeghers syndrome	Small and large intestines, stomach	Hamartoma	Rare	Mucocutaneous pigmentation; tumors of the ovary, breast, pancreas, endometrium
Juvenile polyposis	Large and small intestines, stomach	Hamartoma, rarely progressing to adenoma	Rare	Various congenital abnormalities

probably developed the condition due to a spontaneous mutation. Polyposis coli is associated with a deletion in the long arm of chromosome 5 (including the *APC* gene) in both neoplastic (somatic mutation) and normal (germline mutation) cells. The loss of this genetic material (i.e., allelic loss) results in the absence of tumor-suppressor genes whose protein products would normally inhibit neoplastic growth. The presence of soft tissue and bony tumors, congenital hypertrophy of the retinal pigment epithelium, mesenteric desmoid tumors, and of ampullary cancers in addition to the colonic polyps characterizes a subset of polyposis coli known as *Gardner's syndrome*. The appearance of malignant tumors of the central nervous system accompanying polyposis coli defines *Turcot's syndrome*. The colonic polyps in all these conditions are rarely present before puberty but are generally evident in affected individuals by age 25. If the polyposis is not treated surgically, colorectal cancer will develop in almost all patients before age 40. Polyposis coli results from a defect in the colonic mucosa leading to an abnormal proliferative pattern and an impaired DNA repair following exposure to radiation or ultraviolet light. Once the multiple polyps that constitute polyposis coli are detected, patients should undergo a total colectomy. The ileoanal anastomotic technique allows removal of the entire bowel while retaining the anal sphincter; this appears to be the best treatment. Medical therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) such as sulindac and cyclooxygenase-2 inhibitors such as celecoxib can decrease the number and size of polyps in patients with polyposis coli; however, this effect on polyps is only temporary. Colectomy remains the primary therapy. The offspring of patients with polyposis coli, who often are prepubertal when the diagnosis is made in the parent, have a 50% risk for the development of this premalignant disorder and should be carefully screened by annual flexible sigmoidoscopy until age 35. Proctosigmoidoscopy is a sufficient screening procedure because polyps tend to be evenly distributed from cecum to anus, making more-invasive and expensive techniques such as colonoscopy or barium enema unnecessary. Testing for occult blood in the stool is an inadequate screening maneuver. An alternative method for identifying carriers is testing DNA from peripheral blood mononuclear cells for the presence of a mutated *APC* gene. The detection of such a germline mutation can lead to a definitive diagnosis before the development of polyps.

Hereditary Nonpolyposis Colon Cancer Hereditary nonpolyposis colon cancer (HNPCC), also known as *Lynch syndrome*, is another autosomal dominant trait. It is characterized by the presence of three or more relatives with histologically documented colorectal cancer, one of whom is a first-degree relative of the other two; one or more cases of colorectal cancer diagnosed before age 50 in the family; and colorectal cancer involving at least two generations. In contrast to polyposis coli, HNPCC is associated with an unusually high frequency of cancer arising in the proximal large bowel. The median age for the appearance of an adenocarcinoma is <50 years, 10 to 15 years younger than the median age for the general population. Despite having a poorly differentiated histologic appearance, the proximal colon tumors in HNPCC have a better prognosis than sporadic tumors from patients of similar age. Families with HNPCC often include individuals with multiple primary cancers; the association of colorectal cancer with either ovarian or endometrial carcinomas is especially strong in women. It has been recommended that members of such families undergo biennial colonoscopy beginning at age 25 years, with intermittent pelvic ultrasonography and endometrial biopsy offered for potentially afflicted women; such a screening strategy has not yet been validated. HNPCC is associated with germline mutations of several genes, particularly *hMSH2* on chromosome 2 and *hMLH1* on chromosome 3. These mutations lead to errors in DNA replication and are thought to result in DNA instability because of defective repair of DNA mismatches, resulting in abnormal cell growth and tumor development. Testing tumor cells for "microsatellite instability" (sequence changes reflecting defective mismatch repair) in patients under age 50 with colorectal cancer and a positive family history for colorectal or endometrial cancer may identify probands with HNPCC.

INFLAMMATORY BOWEL DISEASE (See also Chap. 276) Large-bowel cancer is increased in incidence in patients with long-standing inflammatory bowel disease (IBD). Cancers develop more commonly in patients with ulcerative colitis than in those with granulomatous colitis, but this impression may result in part from the occasional difficulty of differentiating these two conditions. The risk of colorectal cancer in a patient with IBD is relatively small during the initial 10 years of the disease, but then it appears to increase at a rate of ~0.5 to 1% per year. Cancer may develop in 8 to 30% of patients after 25 years. The risk is higher in younger patients with pancolitis.

Cancer surveillance in patients with IBD is unsatisfactory. Symptoms such as bloody diarrhea, abdominal cramping, and obstruction, which may signal the appearance of a tumor, are similar to the complaints caused by a flare-up of the underlying disease. In patients with a history of IBD lasting ≥15 years who continue to experience exacerbations, the surgical removal of the colon can significantly reduce the risk for cancer and also eliminate the target organ for the underlying chronic gastrointestinal disorder. The value of such surveillance techniques as colonoscopy with mucosal biopsies and brushings for less symptomatic individuals with chronic IBD is uncertain. The lack of uniformity regarding the pathologic criteria that characterize dysplasia and the absence of data that such surveillance reduces the development of lethal cancers have made this costly practice an area of controversy.

OTHER HIGH-RISK CONDITIONS ■ *Streptococcus bovis* Bacteremia For unknown reasons, individuals who develop endocarditis or septicemia from this fecal bacteria have a high incidence of occult colorectal tumors and, possibly, upper gastrointestinal cancers as well. Endoscopic or radiographic screening appears advisable.

Ureterosigmoidostomy Colon cancer develops in 5 to 10% of people 15 to 30 years after ureterosigmoidostomy to correct congenital extrophy

of the bladder. Neoplasms characteristically are found at a site distal to the ureteral implant where colonic mucosa is chronically exposed to both urine and feces.

Tobacco Use Cigarette smoking is linked to the development of colorectal adenomas, particularly after >35 years of tobacco use. No biologic explanation for this association has yet been proposed.

PRIMARY PREVENTION Several orally administered compounds have been assessed as possible inhibitors of colon cancer. The most effective class of these chemopreventive agents is aspirin and other NSAIDs, which are thought to suppress cell proliferation by inhibiting prostaglandin synthesis. Regular aspirin use reduces the risk for colonic adenomas and carcinomas as well as for death from large-bowel cancer; such use also appears to diminish the likelihood for developing additional premalignant adenomas following treatment for a prior colon carcinoma. This inhibiting effect of aspirin on colon carcinogenesis appears to increase with the duration of drug use. Oral folic acid supplements and oral calcium supplements reduce the risk of adenomatous polyps and colorectal cancers in case-controlled studies. While antioxidant vitamins such as ascorbic acid, tocopherols, and β-carotene are present in diets rich in fruits and vegetables, which have been associated with lower rates of colorectal cancer, they are ineffective at reducing the incidence of subsequent adenomas in patients who have undergone the removal of a colon adenoma. Estrogen-replacement therapy has been associated with a reduction in the risk of colorectal cancer in women, conceivably by an effect on bile acid synthesis and composition or by decreasing synthesis of IGF-I. The otherwise unexplained reduction in colorectal cancer mortality in women may be a result of the widespread use of estrogen replacement in postmenopausal individuals.

SCREENING The rationale for colorectal cancer screening programs is that the earlier detection of localized, superficial cancers in asymptomatic individuals will increase the surgical cure rate. Such screening programs are important for individuals having a family history of the disease in first-degree relatives. The relative risk for developing colorectal cancer increases to 1.75 in such individuals and may be even higher if the relative was afflicted before age 60. The prior use of proctosigmoidoscopy as a screening tool was based on the observation that 60% of early lesions are located in the rectosigmoid. For unexplained reasons, however, the proportion of large-bowel cancers arising in the rectum has been decreasing during the past several decades, with a corresponding increase in the proportion of cancers in the more proximal descending colon. As such, the potential for rigid proctosigmoidoscopy to detect a sufficient number of occult neoplasms to make the procedure cost-effective has been questioned. Flexible, fiberoptic sigmoidoscopes permit trained operators to visualize the colon for up to 60 cm, which enhances the capability for cancer detection. However, this technique still leaves the proximal half of the large bowel unscreened.

Most programs directed at the early detection of colorectal cancers have focused on digital rectal examinations and fecal occult blood testing. The digital examination should be part of any routine physical evaluation in adults older than age 40, serving as a screening test for prostate cancer in men, a component of the pelvic examination in women, and an inexpensive maneuver for the detection of masses in the rectum. The development of the Hemoccult test has greatly facilitated the detection of occult fecal blood. Unfortunately, even when performed optimally, the Hemoccult test has major limitations as a screening technique. About 50% of patients with documented colorectal cancers have a negative fecal Hemoccult test, consistent with the intermittent bleeding pattern of these tumors. When random cohorts of asymptomatic persons have been tested, 2 to 4% have Hemoccult-positive stools. Colorectal cancers have been found in <10% of these "test-positive" cases, with benign polyps being detected in an additional 20 to 30%. Thus, a colorectal neoplasm will not be found in most asymptomatic individuals with occult blood in their stool. Nonetheless, persons found to have Hemoccult-positive stool routinely undergo further medical evaluation, including sigmoidoscopy, barium enema, and/or colonoscopy—procedures that are not only uncomfortable and expensive but also associated with a small risk for significant complications. The added cost of these studies would appear justifiable if the small number of patients found to have occult neoplasms because of Hemoccult screening could be shown to have an improved prognosis and prolonged survival. Prospectively controlled trials showed a statistically significant reduction in mortality from colorectal cancer for individuals undergoing annual screening. However, this benefit only emerged after >13 years of follow-up and was extremely expensive to achieve, since all positive tests (most of which were false-positive) were followed by colonoscopy. Moreover, these colonoscopic examinations quite likely provided the opportunity for cancer prevention through the removal of potentially premalignant adenomatous polyps since the eventual development of cancer was reduced by 20% in the cohort undergoing annual screening.

Screening techniques for large-bowel cancer in asymptomatic persons remain unsatisfactory. Compliance with any screening strategy within the general population is poor. At present, the American Cancer Society suggests fecal Hemoccult screening annually and flexible sigmoidoscopy every 5 years beginning at age 50 for asymptomatic individuals having no colorectal cancer risk factors. The American Cancer Society has proposed a "total colon examination" (i.e., colonoscopy or double-contrast barium enema) every 10 years as an alternative to Hemoccult testing with periodic flexible sigmoidoscopy. Colonoscopy has been shown to be superior to double-contrast barium enema and also to have a higher sensitivity for detecting villous or dysplastic adenomas or cancers than the strategy employing occult fecal blood testing and flexible sigmoidoscopy. Whether colonoscopy performed every 10 years beginning after age 50 will prove to be cost-effective and whether it may be supplanted as a screening maneuver by sophisticated radiographic techniques ("virtual colonoscopy") remains unclear. More effective techniques for screening are needed, perhaps taking advantage of the molecular changes that have been described in these tumors. Analysis of stool for mutation in the *APC* tumor-suppressor gene is being tested.

CLINICAL FEATURES ■ Presenting Symptoms Symptoms vary with the anatomic location of the tumor. Since stool is relatively liquid as it passes through the ileocecal valve into the right colon, cancers arising in the cecum and ascending colon may become quite large without resulting in any obstructive symptoms or noticeable alterations in bowel habits. Lesions of the right colon commonly ulcerate, leading to chronic, insidious blood loss without a change in the appearance of the stool. Consequently, patients with tumors of the ascending colon often present with symptoms such as fatigue, palpitations, and even angina pectoris and are found to have a hypochromic, microcytic anemia indicative of iron deficiency. Since the cancer may bleed intermittently, a random fecal occult blood test may be negative. As a result, the unexplained presence of iron-deficiency anemia in any adult (with the possible exception of a premenopausal, multiparous woman) mandates a thorough endoscopic and/or radiographic visualization of the entire large bowel (Fig. 77-1).

Since stool becomes more concentrated as it passes into the transverse and descending colon, tumors arising there tend to impede the passage of stool, resulting in the development of abdominal cramping, occasional obstruction, and even perforation. Radiographs of the abdomen often reveal characteristic annular, constricting lesions ("apple-core" or "napkin-ring") (Fig. 77-2).

Cancers arising in the rectosigmoid are often associated with hematochezia, tenesmus, and narrowing of the caliber of stool; anemia is an infrequent finding. While these symptoms may lead patients and their physicians to suspect the presence of hemorrhoids, the development of rectal bleeding and/or altered bowel habits demands a prompt digital rectal examination and proctosigmoidoscopy.

Staging, Prognostic Factors, and Patterns of Spread The prognosis for individuals having colorectal cancer is related to the depth of tumor

FIGURE 77-1 Double-contrast air-barium enema revealing a sessile tumor of the cecum in a patient with iron-deficiency anemia and guaiac-positive stool. The lesion at surgery was a stage B adenocarcinoma.

penetration into the bowel wall and the presence of both regional lymph node involvement and distant metastases. These variables are incorporated into the staging system introduced by Dukes and applied to a TNM classification method, in which T represents the depth of tumor penetration, N the presence of lymph node involvement, and M the presence or absence of distant metastases (Table 77-6). Superficial lesions that do not penetrate into the muscularis or involve regional lymph nodes are designated as *stage A* (T1N0M0) disease; tumors that penetrate more deeply but have not spread to lymph nodes are *stage B* disease [subclassified as stage B_1 (T2N0M0) if lesions are restricted to the muscularis and as stage B_2 (T3N0M0) if lesions involve or penetrate the serosa]; regional lymph node involvement defines *stage C* (TxN1M0) disease; and metastatic spread to sites such as liver, lung, or bone indicates *stage D* (TxNxM1) disease. Unless gross evidence of metastatic disease is present, disease stage cannot be determined accurately before surgical resection and pathologic analysis of the operative specimens. It is not clear whether the detection of nodal metastases by special immunohistochemical molecular techniques has the same prognostic implications as disease detected by routine light microscopy.

FIGURE 77-2 Annular, constricting adenocarcinoma of the descending colon. This radiographic appearance is referred to as an "apple-core" lesion and is always highly suggestive of malignancy.

TABLE 77-6 *Staging of and Prognosis for Colorectal Cancer*

Stage				Approximate 5-Year Survival, %
Dukes	TNM	Numerical	Pathologic Description	
A	T1N0M0	I	Cancer limited to mucosa and submucosa	>90
B_1	T2N0M0	I	Cancer extends into muscularis	85
B_2	T3N0M0	II	Cancer extends into or through serosa	70–80
C	TxN1M0	III	Cancer involves regional lymph nodes	35–65
D	TxNxM1	IV	Distant metastases (i.e., liver, lung)	5

Most recurrences after a surgical resection of a large-bowel cancer occur within the first 4 years, making 5-year survival a fairly reliable indicator of cure. The likelihood for 5-year survival in patients with colorectal cancer is stage-related (Table 77-6). That likelihood has improved during the past several decades when similar surgical stages have been compared. The most plausible explanation for this improvement appears to be more thorough intraoperative and pathologic staging. In particular, more exacting attention to pathologic detail has revealed that the prognosis following the resection of a colorectal cancer is not related merely to the presence or absence of regional lymph node involvement. Prognosis may be more precisely gauged by the number of involved lymph nodes (one to four lymph nodes versus five or more lymph nodes). Other predictors of a poor prognosis after a total surgical resection include tumor penetration through the bowel wall into pericolic fat, poorly differentiated histology, perforation and/or tumor adherence to adjacent organs (increasing the risk for an anatomically adjacent recurrence), and venous invasion by tumor (Table 77-7). Regardless of the clinicopathologic stage, a preoperative elevation of the plasma carcinoembryonic antigen (CEA) level predicts eventual tumor recurrence. The presence of aneuploidy and specific chromosomal deletions, such as allelic loss in chromosome 18q (involving the *DCC* gene) in tumor cells, appears to predict a higher risk for metastatic spread, particularly in patients with stage B_2 (T3N0M0) disease. Conversely, the detection of microsatellite instability in tumor tissue has been associated with a more favorable outcome. In contrast to most other cancers, the prognosis in colorectal cancer is not influenced by the size of the primary lesion when adjusted for nodal involvement and histologic differentiation.

TABLE 77-7 *Predictors of Poor Outcome Following Total Surgical Resection of Colorectal Cancer*

Tumor spread to regional lymph nodes
Number of regional lymph nodes involved
Tumor penetration through the bowel wall
Poorly differentiated histology
Perforation
Tumor adherence to adjacent organs
Venous invasion
Preoperative elevation of CEA titer (>5.0 ng/mL)
Aneuploidy
Specific chromosomal deletion (e.g., allelic loss on chromosome 18q)

Note: CEA, carcinoembryonic antigen.

Cancers of the large bowel generally spread to regional lymph nodes or to the liver via the portal venous circulation. The liver represents the most frequent visceral site of metastatic dissemination; it is the initial site of distant spread in one-third of recurring colorectal cancers and is involved in more than two-thirds of such patients at the time of death. In general, colorectal cancer rarely metastasizes to the lungs, supraclavicular lymph nodes, bone, or brain without prior spread to the liver. A major exception to this rule occurs in patients having primary tumors in the distal rectum, from which tumor cells may spread through the paravertebral venous plexus, escaping the portal venous system and thereby reaching the lungs or supraclavicular lymph nodes without hepatic involvement. The median survival after the detection of distant metastases is 6 to 9 months (hepatomegaly, abnormal liver chemistries) to 24 to 30 months (small liver nodule initially identified by elevated CEA level and subsequent CT scan).

TREATMENT

Total resection of tumor is the optimal treatment when a malignant lesion is detected endoscopically or radiographically in the large bowel. An evaluation for the presence of metastatic disease, including a thorough physical examination, chest radiograph, biochemical assessment of liver function, and measurement of the plasma CEA level, should be performed before surgery. When possible, a colonoscopy of the entire large bowel should be performed to identify synchronous neoplasms and/or polyps. The detection of metastases should not preclude surgery in patients with tumor-related symptoms such as gastrointestinal bleeding or obstruction, but it often prompts the use of a less radical operative procedure. At the time of laparotomy, the entire peritoneal cavity should be examined, with thorough inspection of the liver, pelvis, and hemidiaphragm and careful palpation of the full length of the large bowel. Following recovery from a complete resection, patients should be observed carefully for 5 years by semiannual physical examinations and yearly blood chemistry measurements. If a complete colonoscopy was not performed preoperatively, it should be carried out within the first several postoperative months. Some authorities favor measuring plasma CEA levels at 3-month intervals because of the sensitivity of this test as a marker for otherwise undetectable tumor recurrence. Subsequent endoscopic or radiographic surveillance of the large bowel, probably at triennial intervals, is indicated, since patients who have been cured of one colorectal cancer have a 3 to 5% probability of developing an additional bowel cancer during their lifetime and a >15% risk for the development of adenomatous polyps. Anastomotic ("suture-line") recurrences are infrequent in colorectal cancer patients provided the surgical resection margins were adequate and free of tumor. Periodic CT screening, chest radiographs, or more frequent colonoscopic examinations do not affect prognosis and add unnecessary costs to postoperative surveillance.

Radiation therapy to the pelvis is recommended for patients with rectal cancer because it reduces the 20 to 25% probability of regional recurrences following complete surgical resection of stage B_2 or C tumors, especially if they have penetrated through the serosa. This alarmingly high rate of local disease recurrence is believed to be due to the fact that the contained anatomic space within the pelvis limits the extent of the resection and because the rich lymphatic network of the pelvic side wall immediately adjacent to the rectum facilitates the early spread of malignant cells into surgically inaccessible tissue. The use of sharp rather than blunt dissection of rectal cancers ("total mesorectal excision") appears to reduce the likelihood of local disease recurrence to ~10%. Radiation therapy, either pre- or postoperatively, reduces the likelihood of pelvic recurrences but does not appear to prolong survival. Preoperative radiotherapy is indicated for patients with large, potentially unresectable rectal cancers; such lesions may shrink enough to permit subsequent surgical removal. Radiation therapy is not effective in the primary treatment of colon cancer.

Chemotherapy in patients with advanced colorectal cancer has proven to be of only marginal benefit. 5-FU is the most effective single agent for this disease. Partial responses are obtained in 15 to 20% of patients. The probability of tumor response appears to be somewhat greater for patients with liver metastases when chemotherapy is infused directly into the hepatic artery, but intraarterial treatment is costly and toxic and does not appear to prolong survival. The concomitant administration of folinic acid (leucovorin) improves the efficacy of 5-FU in patients with advanced colorectal cancer, presumably by enhancing the binding of 5-FU to its target enzyme, thymidylate synthase. A threefold improvement in the partial response rate is noted when folinic acid is combined with 5-FU; however, the effect on survival is marginal, and the optimal dose schedule remains to be defined. 5-FU is generally administered intravenously but may also be given orally in the form of capecitabine with seemingly similar efficacy.

Irinotecan (CPT-11), a topoisomerase 1 inhibitor, prolongs survival when compared to supportive care in patients whose disease has progressed on 5-FU. Furthermore, the addition of irinotecan to 5-FU and leucovorin (LV) improves response rates and survival of patients with metastatic disease. The *FOLFIRI regimen* is as follows: irinotecan, 180 mg/m^2 as a 90-min infusion day 1; LV, 400 mg/m^2 as a 2-h infusion during irinotecan, immediately followed by 5-FU bolus, 400 mg/m^2 and 46-h continuous infusion of 2.4 to 3 g/m^2 every 2 weeks. Oxaliplatin, a platinum analogue, also improves the response rate when added to 5-FU and LV as initial treatment of patients with metastatic disease. The *FOLFOX regimen* is the following: 2-h infusion of LV (200 mg/m^2 per day) followed by a 5-FU bolus (400 mg/m^2 per day) and 22-h infusion (600 mg/m^2 per day) for 2 consecutive days every 2 weeks, together with oxaliplatin, 85 mg/m^2 as a 2-h infusion on day 1.

Patients with solitary hepatic metastases without clinical or radiographic evidence of additional tumor involvement should be considered for partial liver resection, because such procedures are associated with 5-year survival rates of 25 to 30% when performed on selected individuals by experienced surgeons.

The administration of 5-FU and LV for 6 months after resection of tumor in patients with stage C disease leads to a 40% decrease in recurrence rates and 30% improvement in survival. Patients with stage B_2 tumors do not appear to benefit from adjuvant therapy. In rectal cancer, the delivery of postoperative (and probably preoperative) combined modality therapy (5-FU plus radiation therapy) reduces the risk of recurrence and increases the chance of cure for patients with stages B_2 and C tumors. The 5-FU acts as a radiosensitizer when delivered together with radiation therapy. A surprising lack of use of life-extending adjuvant therapy has been documented in patients over age 65 years. This age bias is completely inappropriate as the benefits of adjuvant therapy have been documented in patients over age 65 years.

TUMORS OF THE SMALL INTESTINE

Small-bowel tumors comprise <5% of gastrointestinal neoplasms. Because of their rarity, a correct diagnosis is often delayed. Abdominal symptoms are usually vague and poorly defined, and conventional radiographic studies of the upper and lower intestinal tract often appear normal. Small-bowel tumors should be considered in the differential diagnosis in the following situations: (1) recurrent, unexplained episodes of crampy abdominal pain; (2) intermittent bouts of intestinal obstruction, especially in the absence of IBD or prior abdominal surgery; (3) intussusception in the adult; and (4) evidence of chronic intestinal bleeding in the presence of negative conventional contrast radiographs. A careful small-bowel barium study is the diagnostic procedure of choice; the diagnostic accuracy may be improved by infusing barium through a nasogastric tube placed into the duodenum (enteroclysis).

BENIGN TUMORS The histology of benign small-bowel tumors is difficult to predict on clinical and radiologic grounds alone. The symptomatology of benign tumors is not distinctive, with pain, obstruction, and hemorrhage being the most frequent symptoms. These tumors are usually discovered during the fifth and sixth decades of life, more often in the distal rather than the proximal small intestine. The most common benign tumors are adenomas, leiomyomas, lipomas, and angiomas.

Adenomas These tumors include those of the islet cells and Brunner's glands as well as polypoid adenomas. *Islet cell adenomas* are occasionally located outside the pancreas; the associated syndromes are discussed in Chap. 329. *Brunner's gland adenomas* are not truly neoplastic but represent a hypertrophy or hyperplasia of submucosal duodenal glands. These appear as small nodules in the duodenal mucosa that secrete a highly viscous alkaline mucus. Most often, this is an incidental radiographic finding not associated with any specific clinical disorder.

Polypoid Adenomas About 25% of benign small-bowel tumors are polypoid adenomas (Table 77-5). They may present as single polypoid lesions or, less commonly, as papillary villous adenomas. As in the colon, the sessile or papillary form of the tumor is sometimes associated with a coexisting carcinoma. Occasionally, patients with Gardner's syndrome develop premalignant adenomas in the small bowel; such lesions are generally in the duodenum. Multiple polypoid tumors may occur throughout the small bowel (and occasionally the stomach and colorectum) in the Peutz-Jeghers syndrome. The polyps are usually hamartomas (juvenile polyps) having a low potential for malignant degeneration. Mucocutaneous melanin deposits as well as tumors of the ovary, breast, pancreas, and endometrium are also associated with this autosomal dominant condition.

Leiomyomas These neoplasms arise from smooth-muscle components of the intestine and are usually intramural, affecting the overlying mucosa. Ulceration of the mucosa may cause gastrointestinal hemorrhage of varying severity. Cramping, intermittent abdominal pain is frequently encountered.

Lipomas These tumors occur with greatest frequency in the distal ileum and at the ileocecal valve. They have a characteristic radiolucent appearance, are usually intramural and asymptomatic, but on occasion cause bleeding.

Angiomas While not true neoplasms, these lesions are important because they frequently cause intestinal bleeding. They may take the form of telangiectasia or hemangiomas. Multiple intestinal telangiectasias occur in a nonhereditary form confined to the gastrointestinal tract or as part of the hereditary Osler-Rendu-Weber syndrome. Vascular tumors may also take the form of isolated hemangiomas, most commonly in the jejunum. Angiography, especially during bleeding, is the best procedure for evaluating these lesions.

MALIGNANT TUMORS While rare, small-bowel malignancies occur in patients with long-standing regional enteritis and celiac sprue as well as in individuals with AIDS. Malignant tumors of the small bowel are frequently associated with fever, weight loss, anorexia, bleeding, and a palpable abdominal mass. After ampullary carcinomas (many of which arise from biliary or pancreatic ducts), the most frequently occurring small-bowel malignancies are adenocarcinomas, lymphomas, carcinoid tumors, and leiomyosarcomas.

Adenocarcinomas The most common primary cancers of the small bowel are adenocarcinomas, accounting for ~50% of malignant tumors. These cancers occur most often in the distal duodenum and proximal jejunum, where they tend to ulcerate and cause hemorrhage or obstruction. Radiologically, they may be confused with chronic duodenal ulcer disease or with Crohn's disease if the patient has long-standing regional enteritis. The diagnosis is best made by endoscopy and biopsy under direct vision. Surgical resection is the treatment of choice.

Lymphomas Lymphoma in the small bowel may be primary or secondary. A diagnosis of a primary intestinal lymphoma requires histologic confirmation in a clinical setting in which palpable adenopathy and hepatosplenomegaly are absent and no evidence of lymphoma is seen on chest radiograph, CT scan, or peripheral blood smear or on bone marrow aspiration and biopsy. Symptoms referable to the small bowel are present, usually accompanied by an anatomically discernible lesion. Secondary lymphoma of the small bowel consists of involvement of the intestine by a lymphoid malignancy extending from involved retroperitoneal or mesenteric lymph nodes (Chap. 97).

Primary intestinal lymphoma accounts for ~20% of malignancies of the small bowel. These neoplasms are non-Hodgkin's lymphomas; they usually have a diffuse, large-cell histology and are of T cell origin. Intestinal lymphoma involves the ileum, jejunum, and duodenum, in decreasing frequency, a pattern that mirrors the relative amount of normal lymphoid cells in these anatomic areas. The risk of small-bowel lymphoma is increased in patients with a prior history of malabsorptive conditions (e.g., celiac sprue), regional enteritis, and depressed immune function due to congenital immunodeficiency syndromes, prior organ transplantation, autoimmune disorders, or AIDS.

The development of localized or nodular masses that narrow the lumen results in periumbilical pain (made worse by eating) as well as weight loss, vomiting, and occasional intestinal obstruction. The diagnosis of small-bowel lymphoma may be suspected from the appearance on contrast radiographs of patterns such as infiltration and thickening of mucosal folds, mucosal nodules, areas of irregular ulceration, or stasis of contrast material. The diagnosis can be confirmed by surgical exploration and resection of involved segments. Intestinal lymphoma can occasionally be diagnosed by peroral intestinal mucosal biopsy, but since the disease mainly involves the lamina propria, full-thickness surgical biopsies are usually required.

Resection of the tumor constitutes the initial treatment modality. While postoperative radiation therapy has been given to some patients following a total resection, most authorities favor short-term (three cycles) systemic treatment with combination chemotherapy. The frequent presence of widespread intraabdominal disease at the time of diagnosis and the occasional multicentricity of the tumor often make a total resection impossible. The probability of sustained remission or cure is ~75% in patients with localized disease but is ~25% in individuals with unresectable lymphoma. In patients whose tumors are not resected, chemotherapy may lead to bowel perforation.

A unique form of small-bowel lymphoma, diffusely involving the entire intestine, was first described in oriental Jews and Arabs and is referred to as *immunoproliferative small intestinal disease* (IPSID), *Mediterranean lymphoma,* or *α-heavy chain disease*. This is a B cell tumor. The typical presentation includes chronic diarrhea and steatorrhea associated with vomiting and abdominal cramps; clubbing of the digits may be observed. A curious feature in many patients with IPSID is the presence in the blood and intestinal secretions of an abnormal IgA that contains a shortened α-heavy chain and is devoid of light chains. It is suspected that the abnormal α chains are produced by plasma cells infiltrating the small bowel. The clinical course of patients with IPSID is generally one of exacerbations and remissions, with death frequently resulting from either progressive malnutrition and wasting or the development of an aggressive lymphoma. The use of oral antibiotics such as tetracycline appears to be beneficial in the early phases of the disorder, suggesting a possible infectious etiology. Combination chemotherapy has been administered during later stages of the disease, with variable results. Results are better when antibiotics and chemotherapy are combined.

Carcinoid Tumors Carcinoid tumors arise from argentaffin cells of the crypts of Lieberkühn and are found from the distal duodenum to the ascending colon, areas embryologically derived from the midgut. More than 50% of intestinal carcinoids are found in the distal ileum, with most congregating close to the ileocecal valve. Most intestinal carcinoids are asymptomatic and of low malignant potential, but invasion and metastases may occur, leading to the carcinoid syndrome (Chap. 329).

Leiomyosarcomas Leiomyosarcomas often are >5 cm in diameter and may be palpable on abdominal examination. Bleeding, obstruction, and perforation are common. Such tumors should be analyzed for the expression of mutant c-*kit* receptor (defining GIST), and in the presence of metastatic disease, justifying treatment with imatinib mesylate (Gleevec).

CANCERS OF THE ANUS

Cancers of the anus account for 1 to 2% of the malignant tumors of the large bowel. Most such lesions arise in the anal canal, the anatomic area extending from the anorectal ring to a zone approximately halfway between the pectinate (or dentate) line and the anal verge. Carcinomas arising proximal to the pectinate line (i.e., in the transitional zone between the glandular mucosa of the rectum and the squamous epithelium of the distal anus) are known as basaloid, cuboidal, or cloacogenic tumors; about one-third of anal cancers have this histologic pattern. Malignancies arising distal to the pectinate line have a squamous cell histology, ulcerate more frequently, and constitute ~55% of anal cancers. The prognosis for patients with basaloid and squamous cell cancers of the anus is identical when corrected for tumor size and the presence or absence of nodal spread.

The development of anal cancer is associated with infection by human papillomavirus, the same organism etiologically linked to cervical cancer. The virus is sexually transmitted. The infection may lead to anal warts (condyloma accuminata), which may progress to anal intraepithelial neoplasia and on to squamous cell carcinoma. The risk for anal cancer is increased among homosexual males, presumably related to anal intercourse. Anal cancer risk is increased in both men and women with AIDS, possibly because their immunosuppressed state permits more severe papillomavirus infection. Anal cancers occur most commonly in middle-aged persons and are more frequent in women than men. At diagnosis, patients may experience bleeding, pain, sensation of a perianal mass, and pruritus.

Radical surgery (abdominal-perineal resection with lymph node sampling and a permanent colostomy) used to be the treatment of choice for this tumor type. The 5-year survival rate after such a procedure was 55 to 70% in the absence of spread to regional lymph nodes and <20% if nodal involvement was present. An alternative therapeutic approach combining external beam radiation therapy with concomitant chemotherapy has resulted in biopsy-proven disappearance of all tumor in >80% of patients whose initial lesion was <3 cm in size. Tumor has recurred in <10% of these patients, and ~70% of patients with anal cancers can be cured with nonoperative treatment. Surgery should be reserved for the minority of individuals who are found to have residual tumor after being managed initially with radiation therapy combined with chemotherapy.

78 TUMORS OF THE LIVER AND BILIARY TRACT

Jules L. Dienstag, Kurt J. Isselbacher

BENIGN LIVER TUMORS

HEPATOCELLULAR ADENOMAS Hepatocellular adenomas are benign tumors of the liver found predominantly in women in their third and fourth decades. Their preponderance in women suggests a hormonal influence in their pathogenesis, and oral contraceptives are thought to contribute. The risk of liver adenomas is increased among those who take anabolic steroids and exogenous androgens. Multiple hepatic adenomas have been associated with glycogen storage disease type I.

Hepatic adenomas occur predominantly in the right lobe of the liver, may be multiple, and are often quite large (>10 cm). Microscopically, they consist of normal or slightly atypical hepatocytes. These cells contain increased glycogen, making them appear paler and larger than normal. Clinical features include pain and the presence of a palpable mass or features of intratumor hemorrhage (pain and circulatory collapse). The diagnosis is usually made by a combination of techniques: sonography, computed tomography (CT), magnetic resonance imaging (MRI), selective hepatic arteriography, and radionuclide scans. The angiographic appearance is typically hypervascular but often also includes hypovascular regions. Technetium 99m scans usually show a defect, because phagocytosing Kupffer cells are absent. Like hepatocellular carcinomas, adenomas have a T_1-intense MRI appearance. The risk of malignant change is small; the risk is higher for large (>10 cm) and multiple adenomas.

Management involves imaging surveillance for small tumors. If the lesion is large (8 to 10 cm), near the surface, and resectable, surgical removal is appropriate. A patient with liver adenoma should stop taking oral contraceptives. Surgical resection may be required for tumors that do not shrink after oral contraceptives are stopped. Pregnancy increases the risk of hemorrhage and should be avoided in women with large adenomas. Patients with multiple large adenomas (e.g., those with glycogen-storage disease) may benefit from liver transplantation.

FOCAL NODULAR HYPERPLASIA Focal nodular hyperplasia is a benign tumor often identified incidentally on imaging studies or at laparoscopy done for other reasons. Like hepatic adenomas, it occurs predominantly in women; however, oral contraceptives are not implicated, and hemorrhage and necrosis are rare. The risk of hemorrhage, however, appears to be higher in women taking oral contraceptives. Typically, the lesion is a solid tumor, often in the right lobe, with a fibrous core and stellate projections. The fibrous projections contain atypical hepatocytes, biliary epithelium, Kupffer cells, and inflammatory cells. A technetium scan will usually show a hot spot because of the presence of Kupffer cells. The lesion appears vascular on angiography, and septations may be detectable by angiography, helical CT scan, and, most reliably, MRI, but only rarely by ultrasound. Surgery is indicated only for symptomatic lesions.

HEMANGIOMA AND OTHER BENIGN TUMORS *Hemangiomas* are the most common benign liver tumors, occurring predominantly in women and usually detected incidentally. The prevalence in the general population is in the range of 0.5 to 7.0%. These asymptomatic vascular lesions can be identified by MRI, contrast-enhanced CT, labeled red blood cell nuclide scans, or hepatic angiography. They do not need to be removed unless they are large and are producing a mass effect. Hemorrhage is rare, and malignant change does not occur.

Nodular regenerative hyperplasia consists of multiple hepatic nodules resulting from periportal hepatocyte regeneration with surrounding atrophy. It may be associated with an underlying condition such as malignancy or connective tissue disease. Portal hypertension (in the absence of cirrhosis) is the most common clinical manifestation. Other less common benign hepatic lesions include *bile duct adenomas* and *cystadenomas*.

CARCINOMAS OF THE LIVER

HEPATOCELLULAR CARCINOMA ■ Epidemiology and Etiology Primary hepatocellular carcinoma (HCC) is one of the most common tumors in the

world and the third most frequent cause of cancer mortality. It is especially prevalent in regions of Asia and sub-Saharan Africa, where the annual incidence is up to 500 cases per 100,000 population. In the United States and western Europe, it is much less common; however, the annual incidence in the United States has increased from 1.4 per 100,000 during 1976 to 1980 to 2.4 per 100,000 in the 1990s. HCC is up to 4 times more common in men than in women and usually arises in a cirrhotic liver. The incidence peaks in the fifth to sixth decades of life in western countries but 1 to 2 decades earlier in regions of Asia and Africa with a high prevalence of liver carcinoma.

The principal reason for the high incidence of HCC in parts of Asia and Africa is the frequency of chronic infection with *hepatitis B virus* (HBV) and *hepatitis C virus* (HCV). These chronic infections frequently lead to cirrhosis, which itself is an important risk factor for HCC (the risk of liver cancer in a cirrhotic liver is ~3% per year); 60 to 90% of these tumors occur in patients with macronodular cirrhosis. Studies in regions of Asia where HCC and HBV infection are prevalent have shown that the incidence of this cancer is about 100-fold higher in individuals with evidence of HBV infection than in noninfected controls, particularly in those with markers of high-level HBV replication, e.g., hepatitis B e antigen (HBeAg) (Chap. 285). In China, the lifetime risk of HCC in patients with chronic hepatitis B approaches 40%. In patients with HBV infection and HCC, HBV DNA may be integrated into host genomic DNA, both in the tumor cells and in adjacent, uninvolved hepatocytes. In addition, modifications of cellular gene expression occur by insertional mutagenesis, chromosomal rearrangements, or the transcriptional transactivating activity of the X and the pre-S2 regions of the HBV genome.

HCV also leads to HCC. HCV genetic material does not become integrated into host genomic DNA. Therefore, the mechanism of HCV carcinogenesis is unclear. Whether the ability of the HCV NS3 domain or the core protein to transform cells in vitro contributes to HCC in humans remains conjectural; alternatively, repeated cycles of liver regeneration and repair common in cirrhosis may permit the emergence of a malignant clone. In Europe and Japan, HCV appears to be substantially more prevalent than HBV in cases of HCC. Both HBV and HCV can be demonstrated in some patients, but the clinical course of liver malignancy in these patients does not appear to differ from that when only one virus is implicated. One distinction in high-prevalence areas between HCC associated with HBV infection and that associated with HCV infection is in the timing of onset. In Asia, HBV is acquired at birth via perinatal transmission, whereas HCV infection is acquired primarily during adulthood from transfused blood and injections. Correspondingly, the onset of HCC occurs one to two decades earlier in those with lifelong hepatitis B than in persons with adult-acquired hepatitis C. Retrospective analysis indicates that HCC occurs on average approximately 30 years after HCV infection and almost exclusively in patients with cirrhosis. The annual incidence of HCC in cirrhotic patients with chronic hepatitis C is 1.5 to 4%. Over the last decade, the frequency of HCC in Japan has increased substantially, primarily in patients with cirrhosis associated with chronic hepatitis C. The same trend is beginning to emerge in the United States and Europe; based on the known frequency of HCV-associated cirrhosis in these populations, the incidence of new HCC cases is expected to increase more than 250-fold over the next decade.

Any agent or factor that contributes to chronic, low-grade liver cell damage and mitosis makes hepatocyte DNA more susceptible to genetic alterations. Thus, as indicated above, *chronic liver disease* of any type is a risk factor and predisposes to the development of HCC. These conditions include alcoholic liver disease, α_1-antitrypsin deficiency, hemochromatosis, tyrosinemia, primary biliary cirrhosis, and even cirrhosis associated with nonalcoholic steatohepatitis. In Africa and southern China, *aflatoxin* B_1 is an important public health hazard. This mycotoxin appears to induce a very specific G-to-T mutation at codon 249 in the tumor suppressor gene p53.

The loss, inactivation, or mutation of the p53 gene has been implicated in tumorigenesis and is the most common genetic derangement present in human cancers. Thus HBV and aflatoxin B_1 have been implicated in the pathogenesis of HCC in regions of Africa and southern China where both agents are prevalent.

In view of the male predominance of HCC, hormonal factors may also play a role. HCC may occur with long-term androgenic steroid administration, with exposure to thorium dioxide or vinyl chloride (see below), and possibly with exposure to estrogens in the form of oral contraceptives.

Clinical and Laboratory Features HCC initially may escape clinical recognition because it occurs in patients with underlying cirrhosis, and the symptoms and signs may suggest progression of the underlying disease. The most common presenting features are abdominal *pain* with detection of an abdominal mass in the right upper quadrant. A *friction rub* or *bruit* may be heard over the liver. Blood-tinged ascites occurs in about 20% of cases. Jaundice is rare, unless significant deterioration of liver function or mechanical obstruction of the bile ducts occurs. Serum elevations of alkaline phosphatase and α fetoprotein (AFP) are common (see below). An abnormal type of prothrombin, des-γ-carboxy prothrombin, is made and correlates with AFP elevations.

A small percentage of patients with HCC have a *paraneoplastic syndrome*; erythrocytosis may result from erythropoietin-like activity produced by the tumor; hypercalcemia may result from secretion of a parathyroid-like hormone. Other manifestations may include hypercholesterolemia, hypoglycemia, polymyositis, acquired porphyria, dysfibrinogenemia, cryofibrinogenemia, and vasoactive peptide-associated diarrhea.

Imaging procedures to detect liver tumors include ultrasound, CT, MRI, and hepatic artery angiography (Chap. 271). Ultrasound is frequently used to screen high-risk populations and should be the first test if HCC is suspected; it is less costly than scans, is relatively sensitive, and can detect most tumors >3 cm. Helical CT and MRI (hyperintense T2-weighted imaging) scans are being used with increasing frequency and have higher sensitivities.

AFP levels >500 μg/L are found in about 70 to 80% of patients with HCC. Lower levels may be found in patients with large metastases from gastric or colonic tumors and in some patients with acute or chronic hepatitis. High levels of serum AFP (>500 to 1000 μg/L) in an adult with liver disease and without an obvious gastrointestinal tumor strongly suggest HCC. A rising level suggests progression of the tumor or recurrence after hepatic resection or therapeutic approaches such as ablation or chemoembolization (see below). The presence of an arterially enhancing liver mass >2 cm documented with two imaging procedures or with one imaging technique together with an AFP >400 ng/mL is highly suggestive of HCC.

Percutaneous *liver biopsy* can be diagnostic if the sample is taken from an area localized by ultrasound or CT. Because these tumors tend to be vascular, percutaneous biopsies should be done with caution. Another possible risk of liver biopsy is seeding the needle track with tumor; however, despite anecdotal reports, the likelihood of needle-track seeding is estimated to be as low as 0.006% and as high as 1%. Cytologic examination of ascitic fluid is invariably negative for tumor cells. Occasionally, *laparoscopy* or *minilaparotomy*, to permit liver biopsy under direct vision, may be used. This approach has the additional advantage of sometimes identifying patients who have a localized resectable tumor suitable for partial hepatectomy.

TREATMENT

Staging of HCC is based on four criteria: tumor size (< or > 50% of the liver), ascites (absent or present), bilirubin (< or > 3 mg/dL), and albumin (< or >3 g/dL) to establish Okuda stages I (no positive criteria), II (1or 2 positives), and III (3 or 4 positives). The Okuda system predicts clinical course better than the American Joint Cancer Commission TNM system. The natural history of each stage without treatment is as follows: stage I, 8 months; stage II, 2 months; stage III, less than 1 month. Several newly proposed staging systems take additional

variables into account; however, none of the new systems has been validated. As screening for HCC has detected earlier tumors, survival has increased. Surgery alone can produce survivals of 54% at 1 year, 40% at 2 years, and 28% at 3 years when cancers are detected before symptoms appear.

The course of *clinically apparent* disease is rapid; if untreated, most patients die within 3 to 6 months of diagnosis. When HCC is detected very early by serial screening of AFP and ultrasound, survival is 1 to 2 years after resection. In selected cases, therapy may prolong life. *Surgical resection* offers a chance for cure; however, few patients have a resectable tumor at the time of presentation, because of underlying cirrhosis, involvement of both hepatic lobes, or distant metastases (common sites are lung, brain, bone, and adrenal), and the 5-year survival is low. Even after successful "curative" resection of HCC, the predisposing primary liver disorder (e.g., cirrhosis, hepatitis B) persists and new cancers can arise in the residual liver.

Screening for HCC in High-risk Patients Because 20 to 30% of patients with early HCC do not have elevated levels of circulating AFP, ultrasonographic screening is recommended along with AFP determination. In a study in the Far East, persons positive for hepatitis B surface antigen, with or without liver disease, were screened serially; a number of patients with small, subclinical tumors were identified and surgical resection was performed. Follow-up observation revealed a 5-year survival rate of 70% in this group and a 10-year survival rate of 50%. These Asian patients, however, were unusual in that they had minimal or no liver disease, and their tumors tended to be unifocal or encapsulated. In another study, AFP screening every 6 months (without ultrasound) among remote Native Alaskan populations of noncirrhotic patients with chronic hepatitis B led to improved survival rates compared with historic outcomes. These findings are in contrast with those of a study in a large population of Italian patients with cirrhosis, associated in most cases with chronic HBV and/or HCV infections. Screening every 3 to 12 months permitted the detection of a 3% annual incidence of cancer in this cohort but in most cases failed to achieve the goal of early detection of surgically treatable disease. No randomized study has yet shown a survival benefit for screening patients at high risk of HCC, but most clinicians screen high-risk patients with twice-annual AFP and ultrasound.

Liver transplantation may be considered as a therapeutic option; tumor recurrence or metastases are the major problems. Patients who have a single lesion $\leq$5 cm or three or fewer lesions $\leq$3 cm have survival after liver transplantation that is the same as survival after transplantation for nonmalignant liver disease (Chap. 291). Other approaches are primarily palliative and include (1) hepatic artery embolization and chemotherapy (chemoembolization), (2) alcohol or radiofrequency ablation via ultrasound-guided percutaneous injection, and (3) ultrasound-guided cryoablation. Radiofrequency ablation and surgical resection have been equally effective for potentially resectable HCC in some studies; 5-year survival >50% has been seen. Thus, some consider radiofrequency ablation as potentially curative. Unresectable HCC is usually managed by chemoembolization ("transcatheter arterial embolization"), but results have been mixed. Some randomized trials have shown no survival advantage. Two studies (from Hong Kong and Spain) showed >20% improvement in survival with chemoembolization compared to supportive care. The Hong Kong study mainly involved patients with hepatitis B given cisplatin chemotherapy. Survival at 1 (57%), 2 (31%), and 3 years (26%) was better than that seen in the supportive care group (32, 11, and 3%, respectively). The Spanish study mainly involved patients with hepatitis C given doxorubicin chemotherapy. Survival at 1 (82%) and 2 years (63%) in the chemoembolization group was superior to survival for supportive care (63 and 27%, respectively). Outcome is related to the experience of the treating institution; highly specialized centers obtain better results than those doing fewer procedures and those using less stringent criteria for intervention. The procedure may be complicated by a postembolization syndrome (fever, chills, abdominal pain, nausea, vomiting, leukocytosis) and transient (but occasionally irreversible) hepatic decompensation.

Treatment options for unresectable disease are limited. The liver cannot tolerate high doses of radiation and the disease is not responsive to chemotherapy. Investigative immunotherapy and gene therapy techniques have not yet been successful. Based on the presence of hormone receptors on the tumor, tamoxifen has been tested, but without success, and octreotide has shown some modest activity. In patients with resectable tumors, polyprenoic acid (a retinoic acid formulation) and intra-arterial ^{131}I-labeled lipiodol have been reported to reduce the rate of recurrence.

Prevention is the preferred strategy. Hepatitis B vaccine can prevent infection and its sequelae, and a reduction in HCC has been seen in Taiwan with the introduction of universal vaccination of children. Interferon treatment reduces the incidence of hepatic failure, death, and HCC in HBV-infected patients. Whether antiviral therapy with lamivudine, adefovir, or other agents (Chap. 287) will reduce the risk of HCC in HBV-infected cirrhotic patients is unknown. Interferon may lower the risk of HCC in patients with hepatitis C–related cirrhosis, but the evidence is mainly from retrospective studies that are confounded by lead-time bias. Prospective trials have produced conflicting results. Interferon may also reduce the risk of HCV-associated HCC recurrence after resection or percutaneous ablation.

OTHER MALIGNANT LIVER TUMORS

Fibrolamellar carcinoma differs from typical HCC in that it tends to occur in young adults without underlying cirrhosis. This tumor is nonencapsulated but well circumscribed and contains fibrous lamellae; it grows slowly and is associated with a longer survival if treated. Surgical resection has resulted in 5-year survivals >50%; if the lesion is nonresectable, liver transplantation is an option, and the outcome far exceeds that observed in the nonfibrolamellar variety of HCC. *Hepatoblastoma* is a tumor of infancy that typically is associated with very high serum AFP levels. The lesions are usually solitary, may be resectable, and have a better 5-year survival than that of HCC. *Angiosarcoma* consists of vascular spaces lined by malignant endothelial cells. Etiologic factors include prior exposure to thorium dioxide, polyvinyl chloride, arsenic, and androgenic anabolic steroids. *Epithelioid hemangioendothelioma* is of borderline malignancy; most cases are benign, but bone and lung metastases occur. This tumor occurs in early adulthood, presents with right upper quadrant pain, and is heterogeneous on sonography, hypodense on CT, and without neovascularity on angiography. Immunohistochemical staining reveals expression of factor VIII antigen. In the absence of extrahepatic metastases, these lesions can be treated by surgical resection or liver transplantation.

METASTATIC TUMORS Metastatic tumors of the liver are common, ranking second only to cirrhosis as a cause of fatal liver disease. In the United States, the incidence of metastatic carcinoma is at least 20 times greater than that of primary carcinoma. At autopsy, hepatic metastases occur in 30 to 50% of patients dying from malignant disease.

Pathogenesis The liver is uniquely vulnerable to invasion by tumor cells. Its size, high rate of blood flow, double perfusion by the hepatic artery and portal vein, and Kupffer cell filtration function combine to make it the next most common site of metastases after the lymph nodes. In addition, local tissue factors or endothelial membrane characteristics appear to enhance metastatic implants. Virtually all types of neoplasms except those primary in the brain may metastasize to the liver. The most common primary tumors are those of the gastrointestinal tract, lung, and breast, as well as melanomas. Less common are metastases from tumors of the thyroid, prostate, and skin.

Clinical Features Most patients with metastases to the liver present with symptoms referable only to the primary tumor, and the asymptomatic hepatic involvement is discovered in the course of clinical evaluation. Sometimes hepatic involvement is reflected by nonspecific symptoms of weakness, weight loss, fever, sweating, and loss of appetite. Rarely, features indicating active hepatic disease, especially abdominal pain, hepatomegaly, or ascites, are present. Patients with widespread meta-

static liver involvement usually have clinical signs suggestive of cancer and hepatic enlargement. Some have localized induration or tenderness, and, occasionally, a friction rub may be found over tender areas of the liver.

Results of liver biochemical tests are often abnormal, but the elevations in marker levels are often only mild and nonspecific. These signs reflect the effects of fever and wasting as well as those of the infiltrating neoplastic process itself. An increase in serum alkaline phosphatase is the most common and frequently the only abnormality. Hypoalbuminemia, anemia, and occasionally a mild elevation of aminotransferase levels may also be found with more widespread disease. Substantially elevated serum levels of carcinoembryonic antigen are usually found when the metastases are from primary malignancies in the gastrointestinal tract, breast, or lung.

Diagnosis Evidence of metastatic invasion of the liver should be sought actively in any patient with a primary malignancy, especially of the lung, gastrointestinal tract, or breast, before resection of the primary lesion. An elevated level of alkaline phosphatase or a mass apparent on ultrasound, CT, or MRI examination of the liver may provide a presumptive diagnosis. Blind percutaneous needle biopsy of the liver will result in a positive diagnosis of metastatic disease in only 60 to 80% of cases with hepatomegaly and elevated alkaline phosphatase levels. Serial sectioning of specimens, two or three repeated biopsies, or cytologic examination of biopsy smears may increase the diagnostic yield by 10 to 15%. The yield is increased when biopsies are directed by ultrasound or CT or obtained during laparoscopy.

TREATMENT

Most metastatic carcinomas respond poorly to all forms of treatment, which is usually only palliative. Rarely a single, large metastasis can be removed surgically. Systemic chemotherapy may slow tumor growth and reduce symptoms, but it does not alter the prognosis. Chemoembolization, intrahepatic chemotherapy, and alcohol or radiofrequency ablation may provide palliation.

CHOLANGIOCARCINOMA Benign tumors of the extrahepatic bile ducts are extremely rare causes of mechanical biliary obstruction. Most of these are papillomas, adenomas, or cystadenomas and present with obstructive jaundice or hemobilia. Adenocarcinoma of the extrahepatic ducts is more common. There is a slight male preponderance (60%), and the incidence peaks in the fifth to seventh decades. Apparent predisposing factors include (1) some chronic hepatobiliary parasitic infestations, (2) congenital anomalies with ectactic ducts, (3) sclerosing cholangitis and chronic ulcerative colitis, and (4) occupational exposure to possible biliary tract carcinogens (employment in rubber or automotive plants). Cholelithiasis is not clearly a predisposing factor for cholangiocarcinoma. The lesions of cholangiocarcinoma may be diffuse or nodular. Nodular lesions often arise at the bifurcation of the common bile duct (Klatskin tumors) and are usually associated with a *collapsed gallbladder*, a finding that mandates cholangiography to view proximal hepatic ducts.

Patients with cholangiocarcinoma usually present with biliary obstruction, painless jaundice, pruritus, weight loss, and acholic stools. A deep-seated, vaguely localized right upper quadrant pain may be noted. Hepatomegaly and a palpable, distended gallbladder (unless the lesion is high in the duct) are frequent accompanying signs. Fever is unusual unless associated with ascending cholangitis. Because the obstructing process is gradual, the cholangiocarcinoma is often far advanced by the time it presents clinically. The diagnosis is most frequently made by cholangiography following ultrasound demonstration of dilated intrahepatic bile ducts. Any focal strictures of the bile ducts should be considered malignant until proven otherwise. Endoscopic cholangiography permits obtaining specimens for cytology (sensitivity ~60%) and insertion of stents for biliary drainage. Survival of 1 to 2 years is possible in some cases. Perhaps 20% of patients have surgically resectable tumors, but 5-year survival is only 10 to 30%. The high recurrence rate limits the value of liver transplantation. Photodynamic therapy (intravenous hematoporphyrin with cholangioscopically delivered light) has been used with promising early results.

CARCINOMA OF THE PAPILLA OF VATER The ampulla of Vater may be involved by extension of tumor arising elsewhere in the duodenum or may itself be the site of origin of a sarcoma, carcinoid tumor, or adenocarcinoma. Papillary adenocarcinomas are associated with slow growth and a more favorable clinical prognosis than diffuse, infiltrative cancers of the ampulla, which are more frequently widely invasive. The presenting clinical manifestation is usually obstructive jaundice. Endoscopic retrograde cannulation of the pancreatic duct is the preferred diagnostic technique when ampullary carcinoma is suspected, because it allows for direct endoscopic inspection and biopsy of the ampulla and for pancreatography to exclude a pancreatic malignancy. Cancer of the papilla is usually treated by wide surgical excision. Lymph node or other metastases are present at the time of surgery in approximately 20% of cases, and the 5-year survival rate following surgical therapy in this group is only 5 to 10%. In the absence of metastases, radical pancreaticoduodenectomy (the Whipple procedure) is associated with 5-year survival rates as high as 40%.

CANCER OF THE GALLBLADDER Most cancers of the gallbladder develop in conjunction with stones rather than polyps. In patients with gallstones, the risk for developing gallbladder cancer, while increased, is still quite low. In one study, gallbladder cancer developed in only 5 of 2583 patients with gallstones followed for a median of 13 years. In the United States, adenocarcinomas make up the vast majority of the estimated 6500 new cases of gallbladder cancer diagnosed each year. The female/male ratio is 4:1, and the mean age at diagnosis is approximately 70 years. The clinical presentation is most often one of unremitting right upper quadrant pain associated with weight loss, jaundice, and a palpable right upper quadrant mass. Cholangitis may supervene. The preoperative diagnosis of the condition has been facilitated by ultrasound and CT, which are also useful in guiding fine-needle aspiration and biopsy. The presence on imaging of a calcified ("porcelain") gallbladder can suggest gallbladder carcinoma; however, cancer is associated with <25% of patients with porcelain gallbladder.

Once symptoms have appeared, spread of the tumor outside the gallbladder by direct extension or by lymphatic or hematogenous routes is almost invariable. Over 75% of gallbladder carcinomas are unresectable at the time of surgery, the exceptions being tumors discovered incidentally at laparotomy. If the tumor is found by the pathologist, no additional therapy is required. If the tumor is noted by the surgeon on routine cholecystectomy, a second operation is generally performed to resect the adjacent liver, bile duct, and local lymph nodes. Incidental resectable gallbladder tumors have a 50% 5-year survival. The 1-year mortality rate for unresectable disease is about 95%, and <5% of patients survive 5 years. Radical operative resection does not appear to improve survival. Trials of radiation and chemotherapy in patients with gallbladder cancer have been disappointing.

79 PANCREATIC CANCER

Robert J. Mayer

INCIDENCE AND ETIOLOGY The incidence of pancreatic carcinoma in the United States has increased as the median life expectancy of the American population has lengthened. The tumor results in the death of >98% of afflicted patients. In 2004, 31,270 individuals died of pancreatic cancer making it the fourth most common cause of cancer-related mortality. The disease is more common in males than in females and in blacks than in whites. It rarely develops before the age of 50.

Little is known about the causes of pancreatic cancer. Cigarette smoking is the most consistent risk factor, with the disease being two to three times more common in heavy smokers than in nonsmokers. Whether this association is due to a direct carcinogenic effect of tobacco metabolites on the pancreas or an as yet undefined exposure that occurs more frequently in cigarette smokers is uncertain. Patients with chronic pancreatitis are at increased risk of pancreatic cancer, as are persons with long-standing diabetes mellitus. Obesity is a risk factor for pancreatic cancer; risk is directly related to increased calorie intake. Alcohol abuse or cholelithiasis are not risk factors for pancreatic cancer. Nor is pancreatic cancer associated with coffee consumption. Mutations in K-*ras* genes have been found in >85% of specimens of human pancreatic cancer. Pancreatic cancer has been associated with mutation of the $p16^{INK4}$ gene located on chromosome 9p21, a gene also implicated in the pathogenesis of malignant melanoma, as well as mutations of the *p53*, *DPC4*, and *BRCA2* tumor suppressor genes. A series of molecular events involving a sequence of these mutations has been proposed to occur as the normal pancreatic duct progresses through dysplasia to infiltrating carcinoma.

CLINICAL FEATURES More than 90% of pancreatic cancers are ductal adenocarcinomas, with islet cell tumors constituting the remaining 5 to 10%. Pancreatic cancers occur twice as frequently in the pancreatic head (70% of cases) as in the body (20%) or tail (10%) of the gland.

With the exception of jaundice, the initial symptoms associated with pancreatic cancer are often insidious and are usually present for >2 months before the cancer is diagnosed (Table 79-1). Pain and weight loss are present in >75% of patients. The pain typically has a gnawing, visceral quality, occasionally radiating from the epigastrium to the back. Pain is often a more severe problem in lesions arising in the body or tail of the gland, as such tumors may become quite large before being detected. Characteristically, the pain improves somewhat when the patient bends forward. The development of significant pain suggests retroperitoneal invasion and infiltration of the splanchnic nerves, indicating that the primary lesion is advanced and is not surgically resectable. Rarely, such pain may be transient and associated with hyperamylasemia, indicative of acute pancreatitis caused by ductal obstruction by tumor. The weight loss observed in most patients is primarily the result of anorexia, although in the initial period of the disease, subclinical malabsorption may also be a contributing factor.

Jaundice due to biliary obstruction is found in >80% of patients having tumors in the pancreatic head and is typically accompanied by dark urine, a claylike appearance of stool, and pruritus. In contrast to the "painless jaundice" sometimes observed in patients having carcinomas of the bile ducts, duodenum, or periampullary regions, most icteric individuals with ductal carcinomas of the pancreatic head will complain of significant abdominal discomfort. Although the gallbladder is usually enlarged in patients with carcinoma of the head of the pancreas, it is palpable in <50% (Courvoisier's sign). However, the presence of an enlarged gallbladder in a jaundiced patient without biliary colic should suggest malignant obstruction of the extrahepatic biliary tree.

Glucose intolerance, presumably a direct consequence of the tumor, often develops within 2 years of the clinical diagnosis. Other initial manifestations include venous thrombosis and migratory thrombophlebitis (Trousseau's syndrome), gastrointestinal hemorrhage from varices due to compression of the portal venous system by tumor, and splenomegaly caused by cancerous encasement of the splenic vein.

TABLE 79-1 *Presenting Signs and Symptoms of Pancreatic Carcinoma*

Frequent	Infrequent
Abdominal pain	Glucose intolerance
Weight loss	Palpable gallbladder
Jaundice (lesions of pancreatic head only)	Migratory thrombophlebitis
	Gastrointestinal hemorrhage
	Splenomegaly

DIAGNOSTIC PROCEDURES (Fig. 79-1) Despite the availability of serologic tests for tumor-associated antigens such as the carcinoembryonic antigen (CEA) and CA 19-9 and noninvasive imaging techniques such as computed tomography (CT) and ultrasonography, the early diagnosis of a potentially resectable pancreatic carcinoma remains extremely difficult. The nonspecificity of the initial symptoms and the poor sensitivity of both serologic assays and noninvasive techniques have frustrated the development of effective screening procedures. When the disease is clinically suspected in a patient having vague, persistent abdominal complaints, ultrasound should be performed to visualize the gallbladder and the pancreas, as should upper gastrointestinal contrast radiographs to rule out a hiatal hernia or a peptic ulcer. If these studies fail to provide an explanation for the symptoms, a CT scan should be considered. It should encompass not only the pancreas but also the liver, retroperitoneal lymph nodes, and pelvis, as pancreatic cancer frequently spreads within the abdomen. While more costly than ultrasonography, CT is technically simpler and more reproducible, provides better definition of the body and tail of the pancreas, and requires less interpretive skill. CT generally detects a malignant pancreatic lesion in >80% of cases; in 5 to 15% of patients with proven pancreatic carcinoma, the CT scan shows only generalized pancreatic enlargement suggesting pancreatitis rather than malignancy. False-positive results occur in about 5 to 10% of cases in which no tumor was found on laparotomy. Magnetic resonance imaging (MRI), while not superior to CT in the evaluation of pancreatic lesions, may occasionally distinguish benign from malignant neoplasms. The value of positron emission tomography (PET) has not been determined. When clinical circumstances dictate additional diagnostic evaluation, endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic ultrasonography (EUS) may clarify the cause of ambiguous CT or ultrasound findings. The characteristic findings are stenosis or obstruction of either the pancreatic or the common bile duct; both duct systems are abnormal in over half of cases. Carcinoma and chronic pancreatitis can be difficult to distinguish by ERCP, particularly if both diseases are present. False-negative results with ERCP are infrequent (<5%) and usually occur in the setting of islet cell, rather than ductal, carcinomas.

Angiography, once a commonly utilized means of detecting carcinomas in the body and tail of the pancreas, has been largely replaced as a diagnostic and staging procedure by spiral CT scanning with contrast imaging. This high-resolution technology predicts the resectability of the tumor if no disease is found outside the pancreas, obstruction of the superior mesenteric-portal vein confluence is absent, or tumor extension to the celiac axis and superior mesenteric arteries is not found. Radiographic staging criteria are shown in Table 79-2.

Regardless of the results of the above diagnostic studies, a histologic confirmation of pancreatic cancer is mandatory; similar radiographic and endoscopic findings can result from other neoplasms such as islet cell tumor or lymphoma, for which the therapeutic approach and prognosis differ from those for ductal carcinoma. In patients with unresectable disease or medical contraindications to surgical resection, tissue may be obtained through a percutaneous needle aspiration biopsy of the pancreas with CT or ultrasonographic guidance.

Unfortunately, however, even laparotomy may not provide a definitive diagnosis, because chronic pancreatitis may also produce a hard mass in the head of the pancreas indistinguishable from carcinoma by

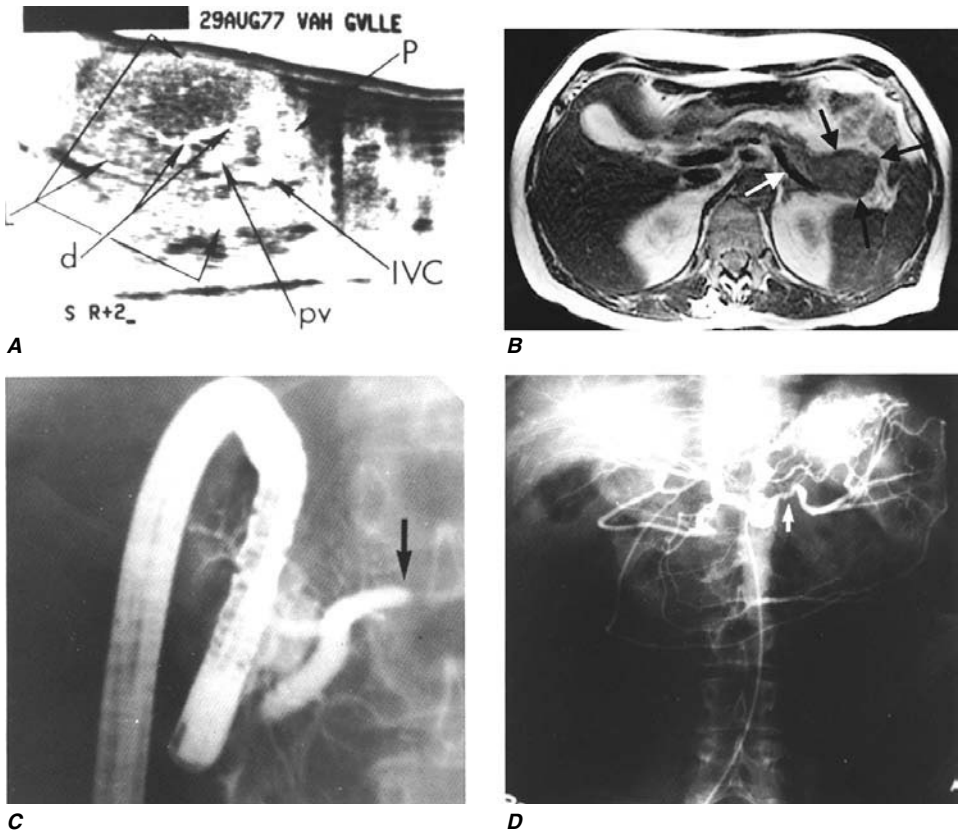

FIGURE 79-1 Carcinoma of the pancreas. *A*. Sonogram showing pancreatic carcinoma (P), dilated intrahepatic bile ducts (d), dilated portal vein (pv), and inferior vena cava (IVC). *B*. Computed tomography scan showing pancreatic carcinoma (*dark arrows*). *C*. Endoscopic retrograde showing abrupt cutoff of the duct of Wirsung (*arrow*). *D*. Arteriogram showing sheathing of splenic artery by tumor encasement (*arrow*).

palpation. Furthermore, a superficial biopsy of such a mass may not show neoplastic tissue, revealing only evidence of pancreatitis, as the cancer is often surrounded by edematous, inflamed, and fibrotic tissue (i.e., chronic pancreatitis).

TREATMENT

Complete surgical resection of pancreatic tumors offers the only effective treatment for this disease. Unfortunately, such "curative" operations are only possible in 10 to 15% of patients with pancreatic cancer, usually those individuals with a tumor in the pancreatic head in whom jaundice was the initial symptom. Patients considered for such a procedure should have no evidence of metastatic spread on a chest radiograph and abdominal-pelvic CT scan and should be operated on by an experienced surgeon, as mortality rates of >15% have been associated with this procedure. Curative resection is usually preceded by laparoscopic inspection of the abdomen to confirm absence of occult disease spread to the omentum, peritoneum, or liver, which would preclude curative resection. Although the potential for cure in patients with pancreatic cancer is restricted to the few who are able to undergo a complete surgical resection, the 5-year survival rate following such operations is only 10%. Nonetheless, the procedure is worth attempting, particularly for lesions in the pancreatic head, since ductal carcinomas often cannot be distinguished preoperatively from ampullary, duodenal, and distal bile duct tumors or pancreatic cyst adenocarcinomas, all of which have far higher rates of resectability and cure. Furthermore, patients who undergo resection and eventually experience disease recurrence survive three to four times longer than those whose tumor is not excised, indicating that such operations have a palliative effect. The risk for tumor recurrence is not affected by the type of operative procedure—i.e., total pancreatectomy versus pancreaticoduodenectomy ("Whipple resection")—but it is increased by the presence of lymph node metastases or tumor invasion into adjacent viscera. As a rule, pancreaticoduodenectomy or distal pancreatectomy seems preferable to total pancreatectomy because of the retention of exocrine function and avoidance of brittle diabetes.

The median survival for patients whose pancreatic cancers are surgically unresectable is 6 months. Management is directed at palliation of symptoms. Ambulatory patients having tumors in the pancreatic head should be considered for surgical diversion of the biliary system. If jaundice has already developed, therapeutic options include either nonoperative biliary decompression by endoscopic or percutaneous, transhepatic biliary drainage or surgical biliary bypass. External beam radiation in patients with unresectable tumors that have not spread beyond the pancreas does not appear to prolong survival, although a sufficient reduction in tumor size may lead to palliation of pain. However, the addition of chemotherapy with fluorouracil (5-FU) or gemcitabine to external beam irradiation has increased the survival time for these patients, presumably because the drugs act as radiosensitizing agents. In a small patient population, a combination of radiation therapy and 5-FU prolonged the survival and increased the cure rate compared to an untreated control group who had a complete surgical resection of their pancreatic cancer. Attempts at confirming this observation have resulted in controversial outcomes. The possibility of administering such chemoradiation therapy at diagnosis and before surgery (neoadjuvant treatment) to increase the potential for resectability is under investigation. Intraoperative radiation therapy has the potential to deliver higher doses of radiation to the tumor while sparing neighboring tissues but does not give better results than external beam treatment.

Chemotherapy in the management of patients with widely metastatic pancreatic cancer has been disappointing. Gemcitabine, a deoxycytidine analogue, produces improvement in the quality of life for patients with advanced pancreatic cancer. However, duration of survival is only modestly improved. Newer forms of treatment, including combining gemcitabine with other cytotoxic agents or therapies directed at specific molecular targets, such as the epidermal growth fac-

TABLE 79-2 *Clinical (Radiographic) Staging of Pancreatic Cancer*

Stage	Clinical/Radiographic Criteria
I	Resectable (T1–T2, selected T3,[a] NX, M0) No encasement of celiac axis or SMA Patent SMPV confluence No extrapancreatic disease
II	Locally advanced (T3, NX–1, M0) Arterial encasement (celiac axis or SMA) or venous occlusion (SMV or portal vein) No extrapancreatic disease
III	Metastatic (T1–3, NX–1, M1) Metastases typically to liver, peritoneum, and occasionally lung

[a] Resectable T3 lesions include those with isolated involvement of the SMV, portal vein, or hepatic artery without encasement of the celiac axis or SMA.

Note: T1, restricted to pancreas; T2, extension to duodenum, bile duct, or peripancreatic tissues; T3, extension to stomach, spleen, colon, or adjacent large vessels; NX, nodal status unknown; N0, regional nodes uninvolved; N1, regional nodes involved; M0, metastases absent; M1, metastases present; SMA, superior mesenteric artery; SMPV, superior mesenteric vein confluence with portal vein; SMV, superior mesenteric vein

tor receptor or the vascular endothelial growth factor receptor are being evaluated. Experimental therapy should constitute the initial treatment for consenting, ambulatory patients. →***Pancreatic endocrine tumors are discussed in Chap. 329.***

80 BLADDER AND RENAL CELL CARCINOMAS

Howard I. Scher, Robert J. Motzer

BLADDER CANCER

A transitional cell epithelium lines the urinary tract from the renal pelvis to the ureter, urinary bladder, and the proximal two-thirds of the urethra. Cancers can occur at any point: 90% of malignancies develop in the bladder, 8% develop in the renal pelvis, and the remaining 2% develop in the ureter or urethra. Bladder cancer is the fourth most common cancer in men and the tenth in women, with an estimated 60,240 new cases and 12,710 deaths predicted for the year 2004. The almost 5:1 ratio of incidence to mortality reflects the higher frequency of the less lethal superficial variants compared to the more lethal invasive and metastatic variants. The incidence is four times higher in men than in women, and twofold higher in whites than blacks, with a median age at diagnosis of 65 years. Once diagnosed, urothelial tumors exhibit polychronotropism—the tendency to recur over time and in new locations in the urothelial tract. As long as urothelium is present, continuous monitoring of the tract is required.

EPIDEMIOLOGY Cigarette smoking is believed to contribute to up to 50% of the diagnosed urothelial cancers in men and up to 40% in women. The risk of developing a urothelial malignancy in male smokers is increased two- to fourfold relative to nonsmokers and continues for 10 years or longer after cessation. Other implicated agents include the aniline dyes, the drugs phenacetin and chlornaphazine, and external beam radiation. Chronic cyclophosphamide exposure may also increase risk, whereas vitamin A supplements appear to be protective. Exposure to *Schistosoma haematobium*, a parasite found in many developing countries, is associated with an increase in both squamous and transitional cell carcinomas of the bladder.

PATHOLOGY More than 95% of urothelial tumors in the United States are transitional cell in origin. Pure squamous cancers with keratinization constitute 3%, adenocarcinomas 2%, and small cell tumors (with paraneoplastic syndromes) <1%. Adenocarcinomas develop primarily in the urachal remnant in the dome of the bladder or in the periurethral tissues; some assume a signet cell histology. Lymphomas or melanomas are rare. Clinical subtypes are grouped into three categories: 75% are superficial, 20% invade muscle, and 5% present with de novo metastatic disease. Of the transitional cell tumors, low-grade papillary lesions that grow on a central stalk are most common. These tumors are very friable, have a tendency to bleed, are at high risk for recurrence, and yet rarely progress to the more lethal invasive variety. About half of all invasive tumors progressed from a superficial stage. In contrast, carcinoma in situ (CIS) is a high-grade tumor that is considered a precursor of the more lethal muscle-infiltrating cancers. Tumors are rated by histologic type and grade. Grade I lesions (highly differentiated tumors) rarely progress to a higher stage, whereas grade III tumors do.

PATHOGENESIS The multicentric nature of the disease and high rate of recurrence has led to the hypothesis of a field defect in the urothelium. Molecular genetic analyses suggest that the superficial and invasive lesions develop along distinct pathways in which primary tumorigenic aberrations precede secondary changes associated with progression to a more advanced stage. Deletions of 9q are an early event; 3p and 5q deletions occur more frequently in invasive lesions. Deletions at the *TP53* locus on 17p, the *DCC* locus in 18q, and the *RB* locus on 13q24 have been seen only in invasive disease. Deletions of 3p and 11p occur in both superficial and invasive tumors. Within all clinical stages, including Tis, T1, and T2 or greater lesions, tumors with altered *TP53* have a higher risk of metastasis and death from disease.

CLINICAL PRESENTATION, DIAGNOSIS, AND STAGING Hematuria occurs in 80 to 90% of patients and often reflects exophytic tumors. Irritative symptoms are the next most common presentation and may reflect in situ disease. The bladder is the most common source of gross hematuria (40%), but benign cystitis (22%) is a more common cause than bladder cancer (15%) (Chap. 40). Microscopic hematuria is more commonly of prostate origin (25%); only 2% of bladder cancers produce microscopic hematuria. Once hematuria is documented, a urinary cytology, visualization of the urothelial tract by computed tomography (CT) or intravenous pyelogram (IVP), and cystoscopy are recommended, if no other etiology is found. Screening asymptomatic individuals for hematuria increases the diagnosis of tumors at an early stage but has not been shown to prolong life. Obstruction of the ureters may cause flank pain. Symptoms of metastatic disease are rarely the first presenting sign.

The endoscopic evaluation includes an examination under anesthesia to determine whether a palpable mass is present. A flexible endoscope is inserted into the bladder, and a bladder barbotage is performed. The visual inspection includes mapping the location, size, and number of lesions, as well as a description of the growth pattern (solid vs papillary). An intraoperative video is often recorded. All visible tumors should be resected, and a sample of the muscle underlying the tumor should be obtained to assess the depth of invasion. Normal mucosal areas are biopsied at random to ensure no field defect. A notation is made as to whether a tumor was completely or incompletely resected. Selective catheterization and visualization of the upper tracts should be performed if the cytology is positive and no disease is visible in the bladder. Ultrasonography, CT, and/or magnetic resonance imaging (MRI) may help to determine whether a tumor extends to perivesical fat (T3), and to document nodal spread. Distant metastases are assessed by CT of the chest and abdomen, MRI, or radionuclide imaging of the skeleton. Ta lesions grow as exophytic lesions; CIS lesions start on the surface and tend to invade. The revised tumor, node, metastasis (TNM) staging system is illustrated in Fig. 80-1.

℞ TREATMENT

Management depends on whether the tumor invades muscle and whether there is spread to the regional lymph nodes and beyond. The probability of spread increases with increasing T stage. At a minimum, the management of a superficial tumor is a complete endoscopic re-

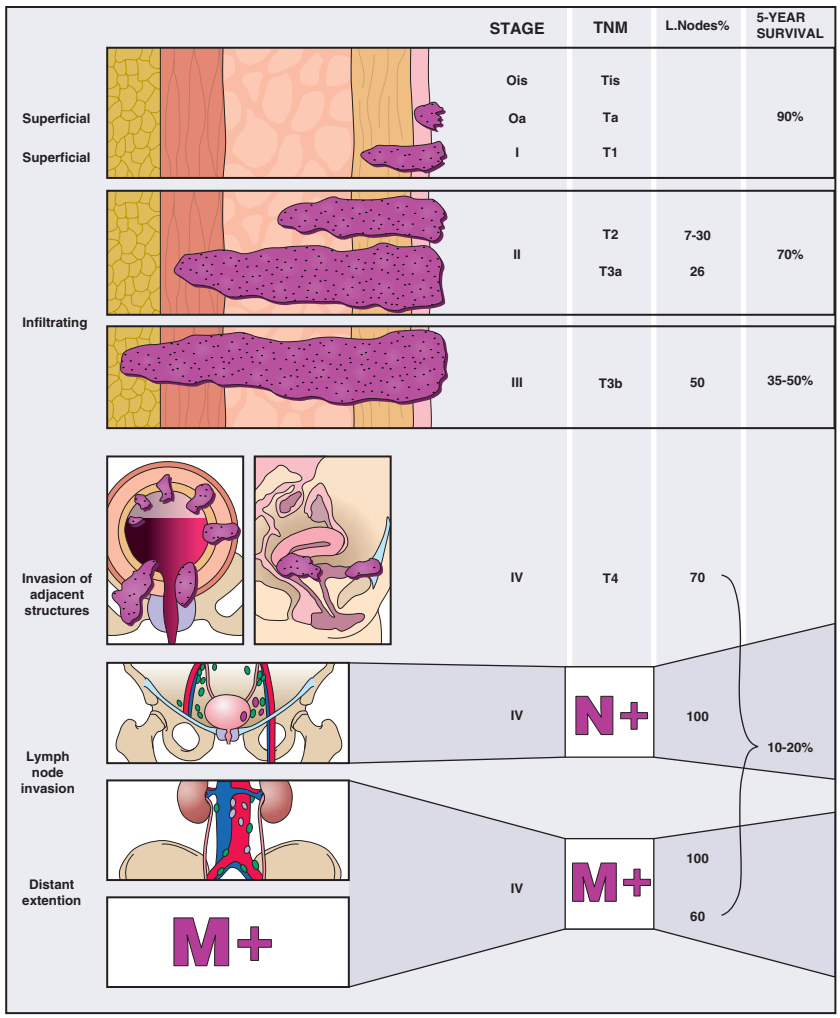

FIGURE 80-1 Bladder staging. TNM, tumor, node, metastasis.

section with or without intravesical therapy. The decision to recommend intravesical therapy depends on the histologic subtype, number of lesions, depth of invasion, and presence or absence of CIS. Recurrences develop in upwards of 50% of cases, and 5 to 20% progress to a more advanced stage. Solitary papillary lesions are generally managed by transurethral surgery alone. CIS and recurrent disease are treated by transurethral surgery followed by intravesical therapy. Radical cystectomy is the standard treatment for a tumor that has invaded muscle, either at the time of diagnosis or following treatment for superficial disease. The decision to administer systemic therapy is then based on the pathologic findings.

Superficial Disease Intravesical therapies are used in two general contexts: as an adjuvant to a complete endoscopic resection to prevent recurrence or, less commonly, to eliminate disease that cannot be controlled by endoscopic resection alone. Intravesical treatments are advised for patients with recurrent disease, >40% involvement of the bladder surface by tumor, the presence of diffuse CIS, or T1 disease. Bacillus Calmette-Guerin (BCG) in six weekly instillations, followed by maintenance, is considered standard based on randomized comparisons. Other agents with activity include mitomycin-C and interferon (IFN). The side effects include dysuria, urinary frequency, and, depending on the drug, myelosuppression or a contact dermatitis. Rarely, intravesical BCG may produce a systemic illness associated with granulomatous infections in multiple sites that requires antituberculin therapy.

Following the endoscopic resection, patients are monitored for recurrence at 3-month intervals during the first year. Those with persistent disease or new tumors are generally considered for a second course of BCG or for intravesical chemotherapy with valrubicin or gemcitabine. In some cases cystectomy is recommended, although the specific indications vary. Recurrence may develop anywhere along the urothelial tract including the renal pelvis, ureter, or urethra. A consequence of the "successful" treatment of tumors in the bladder is an increase in the frequency of extravesical recurrences. Tumors in the ureter or renal pelvis are typically managed by resection during retrograde examination or, in some cases, by instillation through the renal pelvis. Tumors of the prostatic urethra may require cystectomy if a complete resection cannot be achieved.

Invasive Disease The treatment of a tumor that has invaded muscle can be separated into control of the primary tumor and, depending on the pathologic findings at surgery, systemic chemotherapy. Radical cystectomy is the standard, although in selected cases a bladder-sparing approach that includes a complete endoscopic resection, partial cystectomy, or a combination of resection, systemic chemotherapy, and external beam radiation therapy is used. Indications for cystectomy include muscle-invading tumors not suitable for segmental resection, low-stage tumors unsuitable for conservative management (e.g., due to multicentric and frequent recurrences resistant to intravesical instillations), high-grade tumors (T1G3) associated with CIS, and bladder symptoms such as frequency or hemorrhage that impair quality of life. In some countries, external beam radiation therapy is considered standard. In the United States, its role is limited to those patients deemed unfit for cystectomy and those with unresectable local disease, and as part of an experimental approach that seeks to spare the bladder.

Radical cystectomy is major surgery that requires appropriate preoperative evaluation and management. The procedure involves removal of the bladder and pelvic lymph nodes, and creation of a conduit or reservoir for urinary flow. Grossly abnormal lymph nodes are evaluated by frozen section. If metastases are confirmed, the procedure is often aborted. In males, radical cystectomy involves the removal of the bladder, prostate and seminal vesicles, and proximal urethra. Impotence is universal unless the nerves responsible for erectile function are preserved. In females, the procedure includes removal of the bladder, urethra, uterus, fallopian tubes, ovaries, anterior vaginal wall, and surrounding fascia. Previously, urine flow was managed by directing the ureters to the abdominal wall, where it was collected in an external appliance. Currently, most patients receive a continent cutaneous reservoir that is constituted from detubularized bowel, or an orthotopic neobladder. Some 70% of men receive a neobladder. With a continent reservoir, 65 to 85% of men will be continent at night and 85 to 90% during the day. Cutaneous reservoirs are drained by intermittent catheterization; orthotopic neobladders are drained more naturally. Contraindications to a neobladder include renal insufficiency, an inability to self-catheterize, or the presence of an exophytic tumor or CIS in the urethra. Diffuse CIS in the bladder is a relative contraindication based on the risk of a urethral recurrence. Concurrent diseases in the bowel such as ulcerative colitis or Crohn's disease may hinder the use of resected bowel.

A partial cystectomy may be considered when the disease is limited to the dome of the bladder, a minimum of a 2-cm margin can be achieved, there is no CIS in other sites, and the bladder capacity is adequate after the tumor has been removed. This occurs in 5 to 10% of cases. Carcinomas in the ureter or in the renal pelvis are treated with nephroureterectomy with a bladder cuff to remove the tumor.

The probability of recurrence following surgery is predicted on the basis of pathologic stage, presence or absence of lymphatic or vascular

invasion, and nodal spread. Among those who recur, the recurrence develops in a median of 1 year (range, 0.04 to 11.1 years). Long-term outcomes vary by pathologic stage and histology (Table 80-1). The number of lymph nodes removed is also prognostic whether or not tumor was in the nodes.

Metastatic Disease The primary goal of treatment for metastatic disease is to achieve a complete remission with chemotherapy alone, or with a combined-modality approach of chemotherapy followed by surgical resection of residual disease, as is done routinely for the treatment of germ cell tumors. One can define a goal in terms of cure or palliation on the basis of the probability of achieving a complete response to chemotherapy using prognostic factors, such as Karnofsky Performance Status (<80%), and whether the pattern of spread is nodal or visceral (liver, lung, or bone). For those with zero, 1, or 2 risk factors, the probability of a complete remission is 38, 25, and 5%, respectively, and median survival is 33, 13.4, and 9.3 months, respectively. Toxicities also vary as a function of risk. Treatment-related mortality has been reported in 3 to 4% of cases using some combinations. Patients with a compromised performance status, visceral disease, or bone metastases are rarely cured with chemotherapy alone; in these cases, median survivals rarely exceed 6 months.

A number of chemotherapeutic drugs have shown activity as single agents; cisplatin, paclitaxel, and gemcitabine are considered most active. Standard therapy consists of two-, three-, or four-drug combinations. Overall response rates of >50% have been reported using combinations such as methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC); cisplatin and paclitaxel (PT); gemcitabine and cisplatin (GC); or gemcitabine, paclitaxel, and cisplatin (GTC). M-VAC was considered standard, but the toxicities of neutropenia and fever, mucositis, diminished renal and auditory function, and peripheral neuropathy led to the development of alternative regimens. A comparative trial of M-VAC versus GC showed less neutropenia and fever, less mucositis, and more anemia and thrombocytopenia with the two-drug regimen.

Chemotherapy has also been evaluated in the neoadjuvant and adjuvant settings. In a randomized trial, patients receiving three cycles of neoadjuvant M-VAC followed by cystectomy had significantly better median (6.2 years) and 5-year survival (57%) compared to cystectomy alone (median survival, 3.8 years; 5-year survival, 42%). Adjuvant therapy with cisplatin, methotrexate, and vinblastine (CMV) (three cycles) appears to reduce the risk of recurrence by 15%. Additional trials are studying taxane- and gemcitabine-based combinations.

Chemotherapy has a role in invasive disease; however, for the majority of patients, chemotherapy alone is inadequate to clear the bladder of disease. Experimental studies are evaluating combined-modality approaches using chemotherapy and radiation therapy together in patients whose tumors were endoscopically removed.

The recommendation to administer adjuvant therapy is based on the risk of recurrence following cystectomy. Indications include the presence of nodal disease, extravesical tumor extension, or vascular invasion in the resected specimen. Adjuvant therapy (four cycles of combination chemotherapy) delays recurrence, although an effect on survival is less clear.

The management of bladder cancer is summarized in Table 80-2.

RENAL CELL CARCINOMA

Renal cell carcinomas account for 90 to 95% of malignant neoplasms arising from the kidney. Notable features include refractoriness to cytotoxic agents, infrequent but reproducible responses to biologic response modifiers such as IFN-α and interleukin 2 (IL-2), and a variable clinical course for patients with metastatic disease, including anecdotal reports of spontaneous regression.

TABLE 80-1 *Survival Following Surgery for Bladder Cancer*

Pathologic Stage	5-Year Survival, %	10-Year Survival, %
T2,N0	89	87
T3a,N0	78	76
T3b,N0	62	61
T4,N0	50	45
Any T,N1	35	34

TABLE 80-2 *Management of Bladder Cancer*

Nature of Lesion	Management Approach
Superficial	Endoscopic removal, usually with intravesical therapy
Invasive disease	Cystectomy ± systemic chemotherapy (before or after surgery)
Metastatic disease	Curative or palliative chemotherapy (based on prognostic factors) ± surgery

EPIDEMIOLOGY AND ETIOLOGY The annual incidence of renal cell carcinoma continues to rise and now includes nearly 36,000 cases annually in the United States resulting in 12,500 deaths. The male:female ratio is 2:1. Incidence peaks between the ages of 50 to 70, although this malignancy may be diagnosed at any age. Many environmental factors have been investigated as possible contributing causes; the strongest association is with cigarette smoking (accounting for 20 to 30% of cases) and obesity. Risk is also increased for patients who have acquired cystic disease of the kidney associated with end-stage renal disease, and for those with tuberous sclerosis. Most cases are sporadic, although familial forms have been reported. One is associated with von Hippel-Lindau (VHL) syndrome, which predisposes to renal cell carcinomas, retinal hemangioma, hemangioblastoma of the spinal cord and cerebellum, and pheochromocytoma. Roughly 35% of individuals with VHL disease develop renal cell cancer. An increased incidence has also been reported for first-degree relatives. Most renal cancers arise from the epithelial cells of the proximal tubules. A number of genetic alterations have been described; 97% show allelic loss at 3p. Deletions of 3p21–26 (where the *VHL* gene maps) have been identified in familial as well as sporadic tumors.

PATHOLOGY Renal cell neoplasia represents a heterogeneous group of tumors with distinct histopathologic, genetic, and clinical features ranging from benign to high-grade malignant (Table 80-3). They are classified on the basis of morphology and histology. Categories include clear cell carcinoma (60% of cases), papillary (5 to 15%), chromophobic tumors (5 to 10%), oncocytomas (5 to 10%), and collecting or Bellini duct tumors (<1%). Clear cell tumors have clear cytoplasm and usually show chromosome 3p deletions. Papillary tumors tend to be bilateral and multifocal and show trisomy 7 or 17. Chromophobic tumors are characterized by multiple chromosomal losses but do not exhibit 3p deletions and have a more indolent clinical course. Oncocytomas have a characteristic morphology including a deeply eosinophilic cytoplasm, do not exhibit 3p deletions or trisomy 7 or 17, and are considered benign neoplasms. In contrast, Bellini duct carcinomas are very rare and are thought to arise from the collecting ducts within the renal medulla. They tend to affect younger patients and are very aggressive tumors.

TABLE 80-3 *Classification of Epithelial Neoplasms Arising from the Kidney*

Carcinoma Type	Growth Pattern	Cell of Origin	Cytogenetics
Clear cell	Acinar or sarcomatoid	Proximal tubule	3p−
Papillary	Papillary or sarcomatoid	Proximal tubule	+7, +17, −Y
Chromophobic	Solid, tubular, or sarcomatoid	Cortical collecting duct	Hypodiploid
Oncocytic	Tumor nests	Cortical collecting duct	Undetermined
Collecting duct	Papillary or sarcomatoid	Medullary collecting duct	Undetermined

CLINICAL PRESENTATION The presenting signs and symptoms include hematuria, abdominal pain, and a flank or abdominal mass. This classic triad occurs in 10 to 20% of patients. Other symptoms are fever, weight loss, anemia, and a varicocele (Table 80-4). The tumor can also be found incidentally on a radiograph. Widespread use of radiologic cross-sectional imaging procedures (CT, ultrasound, MRI) contributes to earlier detection, including incidental renal masses detected during evaluation for other medical conditions. The increasing number of incidentally discovered low-stage tumors contributes to an improved 5-year survival for patients with renal cell carcinoma and increased use of nephron-sparing surgery (partial nephrectomy).

A spectrum of paraneoplastic syndromes has been associated with these malignancies, including erythrocytosis, hypercalcemia, nonmetastatic hepatic dysfunction (Stauffer syndrome), and acquired dysfibrinogenemia. Erythrocytosis is noted at presentation in only about 3% of patients. Anemia, a sign of advanced disease, is more common.

The standard evaluation of patients with suspected renal cell tumors includes a CT scan of the abdomen and pelvis, a chest radiograph, urine analysis, and urine cytology. A CT of the chest is warranted if metastatic disease is suspected from the chest radiograph, as it will detect significantly smaller lesions, and their presence may influence the approach to the primary tumor. MRI is useful in evaluating the inferior vena cava in cases of suspected tumor involvement or invasion by thrombus, as well as for patients in whom contrast cannot be administered owing to either allergy or renal dysfunction. In clinical practice, any solid renal masses should be considered malignant until proven otherwise; a definitive diagnosis is required. If no metastases are demonstrated, surgery is indicated, even if the renal vein is invaded. The differential diagnosis of a renal mass includes cysts, benign neoplasms (adenoma, angiomyolipoma, oncocytoma), inflammatory lesions (pyelonephritis or abscesses), and other primary or metastatic malignant neoplasms. Other malignancies that may involve the kidney include transitional cell carcinoma of the renal pelvis, sarcoma, lymphoma, Wilms' tumor, and metastatic disease, especially from melanoma. All of these are less common causes of renal masses than is renal cell cancer.

STAGING AND PROGNOSIS Two staging systems used commonly are the Robson classification and the American Joint Committee on Cancer (AJCC) staging system. According to the Robson system, stage I tumors are confined to the kidney; stage II tumors extend through the renal capsule but are confined to Gerota's fascia; stage III tumors involve the renal vein or vena cava (stage III A) or the hilar lymph nodes (stage III B); and stage IV disease includes tumors that are locally invasive to adjacent organs (excluding the adrenal gland) or distant metastases. The rate of 5-year survival varies by stage: 66% for stage I, 64% for stage II, 42% for stage III, and 11% for stage IV. The prognosis for patients with stage IIIA lesions is similar to that of stage II disease; 5-year survival for patients with stage IIIB disease is only 20%, closer to that of stage IV.

TABLE 80-4 Signs and Symptoms in Patients with Renal Cell Cancer

Presenting Sign or Symptom	Incidence, %
Classic triad: hematuria, flank pain, flank mass	10–20
Hematuria	40
Flank pain	40
Palpable mass	25
Weight loss	33
Anemia	33
Fever	20
Hypertension	20
Abnormal liver function	15
Hypercalcemia	5
Erythrocytosis	3
Neuromyopathy	3
Amyloidosis	2
Increased erythrocyte sedimentation rate	55

TREATMENT

Localized Tumors The standard management for stage I or II tumors and selected cases of stage III disease is radical nephrectomy. This procedure involves en bloc removal of Gerota's fascia and its contents including the kidney, the ipsilateral adrenal gland, and adjacent hilar lymph nodes. The role of a regional lymphadenectomy is controversial. Extension into the renal vein or inferior vena cava, stage III disease, does not preclude resection even if cardiopulmonary bypass is required. Half of these patients have prolonged survival if the tumor is resected. Stauffer syndrome describes the rare patient with no detectable metastatic disease who has hepatic dysfunction. These patients are also candidates for renal resection because the hepatopathy is often reversible after the primary is removed.

In selected patients who have only one kidney—depending on the size and location of the lesion—nephron-sparing approaches may be used via an open or laparoscopic approach. A nephron-sparing approach can also be used for patients with bilateral tumors, accompanied by a radical nephrectomy on the opposite side. Partial nephrectomy techniques are being applied electively to resect small masses for patients with a normal contralateral kidney. Adjuvant chemotherapy, immunotherapy, and radiation therapy are not useful following surgery, even in cases with a poor prognosis.

Advanced Disease Investigational therapy is first-line treatment for metastatic disease as no immune approach or chemotherapeutic agent has shown significant antitumor activity. The prognosis is highly variable; in one analysis, no prior nephrectomy, a Karnofsky performance status <80, low hemoglobin, high corrected calcium, and abnormal lactate dehydrogenase (LDH) were poor prognostic factors. Patients with zero, one or two, and three or more factors had a median survival of 24, 12, and 5 months, respectively. These tumors often follow an unpredictable and protracted clinical course. In one study, 10% of patients with established metastatic disease did not progress after 1 year of observation. It may be best to document progression before considering potentially toxic treatment approaches.

Surgery has a limited role for patients with metastatic disease. One indication for nephrectomy is to alleviate pain or hemorrhage of a primary tumor. Nephrectomy is not indicated to induce tumor regression (occurs in $<1\%$ of cases) or to increase sensitivity to cytokine therapy. However, long-term survival may occur in patients who relapse after nephrectomy in a solitary site that can be removed.

IFN-α and IL-2 produce regressions in 10 to 20% of patients but these are rarely durable. IL-2 was approved on the observation of durable complete remission in a small proportion of cases. IFN has also been evaluated as an adjuvant to cytoreductive surgery. In one study, patients were randomized to surgery plus IFN (5×10^6 IU/m^2, 3 times per week) versus IFN alone. The median time to progression was 5 versus 3 months, and median survival was 17 versus 7 months (hazard ratio, .54) in favor of the combined-modality approach. A second trial with a similar design showed a 3-month difference in median survival (11.1 versus 8.1 months) in favor of the combined approach. Newer cytokines and novel biologic agents are under investigation, and promising results have been reported using an inhibitor of vascular endothelial growth factor.

CARCINOMA OF THE RENAL PELVIS AND URETER

About 2500 cases of renal pelvis and ureter cancer occur each year; nearly all are transitional cell carcinomas similar to bladder cancer in biology and appearance. This tumor also is associated with chronic phenacetin abuse and with Balkan nephropathy, a chronic interstitial nephritis endemic in Bulgaria, Greece, Bosnia-Herzegovina, and Romania.

The most common symptom is painless gross hematuria, and the disease usually is detected on IVP during the workup for hematuria. Patterns of spread are like those in bladder cancer. For disease localized to the renal pelvis and ureter, nephroureterectomy (including excision of the distal ureter with a portion of the bladder) is associated

with a 5-year survival of 80 to 90% for low-grade lesions. More invasive or histologically poorly differentiated tumors are more likely to recur locally and metastasize. Metastatic disease is treated with the chemotherapy used in bladder cancer, and the outcome is similar to that of metastatic transitional cell cancer of bladder origin.

81 HYPERPLASTIC AND MALIGNANT DISEASES OF THE PROSTATE

Howard I. Scher

The frequency of both benign and malignant changes in the prostate increase with age. Autopsies of men in the eighth decade of life show hyperplastic changes in >90% and malignant changes in >70% of individuals. The high prevalence of these diseases in an elderly population with competing causes of morbidity and mortality mandates a risk-adapted approach to diagnosis and treatment. This can be achieved by considering these diseases as a series of states. Each state represents a distinct clinical milestone for which intervention(s) may be recommended based on the presence or risk of developing symptoms or death from disease in a given time frame (Fig. 81-1). For benign proliferative disorders, symptoms of urinary frequency, infection, and potential for obstruction are weighed against the side effects and complications of medical or surgical therapy. For prostate malignancies, the risk of developing the disease, symptoms, or death from cancer are balanced against the morbidities of interventions recommended and preexisting comorbid conditions.

In 2004, around 230,000 prostate cancer cases were diagnosed, of whom 29,900 succumbed. The absolute number of prostate cancer deaths has decreased in the past 5 years; this has been attributed by some to the widespread use of detection strategies based on monitoring prostate-specific antigen (PSA). However, screening has not been proven to improve survival in prospective randomized trials. The paradox of management is that although the disease remains the second leading cause of cancer deaths in men, the almost 8:1 ratio in incidence to prostate cancer–specific mortality shows that the majority of men do not die of their disease.

ANATOMY AND PATHOLOGY

The prostate is located in the pelvis and is surrounded by the rectum, the bladder, the periprostatic and dorsal vein complexes that are responsible for erectile function, and the urinary sphincter that is responsible for passive urinary control. The prostate is composed of branching tubuloalveolar glands arranged in lobules and surrounded by a stroma. The acinal unit includes an epithelial compartment made up of epithelial, basal, and neuroendocrine cells and a stromal compartment that includes fibroblasts and smooth-muscle cells. The compartments are separated by a basement membrane. PSA and acid phosphatase (ACP) are produced in the epithelial cells. Both cell types express androgen receptors and depend on androgens for growth. Testosterone, the major circulating androgen, is converted by the enzyme 5-α reductase to dihydrotestosterone in the gland. Changes in prostate size occur during puberty and after the age of 55 in the periurethral portion of the gland. Most cancers develop in the peripheral zone, which can often be palpated by a digital rectal examination (DRE). Nonmalignant growth occurs predominantly in the transition zone around the urethra.
