Meningitis Except during outbreaks of meningococcal infection, *S. pneumoniae* is the most common cause of bacterial meningitis in adults. Because of the remarkable success of *H. influenzae* type b vaccine, *S. pneumoniae* now predominates among cases in infants and toddlers as well (but not among those in newborns). Meningitis develops either by the direct extension of infection from the sinuses or the middle ear or as a result of seeding of meningeal endothelial cells or the choroid plexus during bacteremia. Favoring the former pathogenesis are the association between acute otitis media or sinusitis and meningitis and the role of *S. pneumoniae* as the most common cause of recurrent meningitis associated with head trauma, cerebrospinal fluid (CSF) leak, and/or dural tear. Favoring the latter are the association between pneumococcal bacteremia from any source and meningitis as well as an autopsy study of temporal bone from children who died of bacterial meningitis, which yielded no evidence of extension from the middle ear. In adults, meningitis is usually a complication of bacteremia, which in turn is attributable, in the great majority of cases, to pneumonia.

In the meninges and subarachnoid space, pneumococcal peptidoglycan stimulates an intense inflammatory response mediated by the release of proinflammatory cytokines such as IL-8 and macrophage inflammatory protein (MIP)-1, which are detectable in the CSF of patients with meningitis. The ensuing inflammatory response results in raised intracranial pressure, brain edema, and decreased blood flow leading to meningismus, drowsiness, or coma. Activated leukocytes migrate across the blood-brain barrier and release matrix metalloproteases and reactive oxygen and nitrogen species that damage neurons. Focal neurologic signs may result from vasculitis with venous or arterial thrombosis, cranial neuropathy due to entrapment or infarction, local cerebritis, subdural effusion, or brain herniation (Chap. 360).

No distinctive clinical or laboratory feature differentiates meningitis due to *S. pneumoniae* from that due to other bacteria. Patients note the sudden onset of fever, headache, and stiffness or pain in the neck. Without treatment, there is a progression over 24 to 48 h to confusion and then obtundation. On physical examination, the patient looks acutely ill and has a rigid neck. In such cases lumbar puncture should not be delayed for CT of the head unless papilledema or focal neurologic signs are evident. Typical CSF findings consist of pleocytosis (500 to 10,000 cells/μL) with ≥85% PMNs, an elevated protein level (100 to 500 mg/dL), and a decrease in glucose content (<30 mg/dL). If antibiotics have not been given, large numbers of pneumococci can be seen in a Gram-stained specimen of CSF in all cases, and specific therapy can be administered, although, because of its similar appearance, *Listeria* may be misidentified as the pneumococcus. If an effective antibiotic has already been given, the number of bacteria may be greatly decreased and microscopic examination of a Gram-stained specimen may yield negative results. In this situation, immunologic methods for the detection of pneumococcal capsule in the CSF may be positive in up to two-thirds of cases, although these methods have fallen out of favor.

OTHER SYNDROMES The appearance of pneumococcal infection at other, ordinarily sterile body sites indicates hematogenous spread, usually during frank pneumonia or, in a small proportion of cases, from an inapparent focus of infection. A case of pneumococcal endocarditis is seen every few years at large tertiary-care hospitals. Purulent pericarditis, occurring as a separate entity or together with endocarditis, is even rarer. Septic arthritis can arise spontaneously in a natural or prosthetic joint or as a complication of rheumatoid arthritis. Osteomyelitis in adults tends to involve vertebral bones. Pneumococcal peritonitis occurs by one of three pathogenetic pathways: (1) hematogenous spread when ascites or other preexisting peritoneal disease is present; (2) local spread from a perforated viscus (usually appendicitis or perforated ulcer); or (3) transit via the fallopian tubes. Salpingitis may be recognized with or without accompanying peritonitis. Epidural and brain abscesses arise as a complication of sinusitis or mastoiditis. Cellulitis develops most often in persons who have connective tissue diseases or HIV infection. The appearance of any of these unusual pneumococcal infections may suggest that tests for HIV infection should be undertaken. Finally, for reasons that are unclear, unencap-

sulated (but not encapsulated) pneumococci cause sporadic or epidemic conjunctivitis.

TREATMENT

Antibiotic Susceptibility β-Lactam antibiotics, the cornerstone of therapy for serious pneumococcal infection, bind covalently to the active site and thereby block the action of enzymes (endo-, trans-, and carboxypeptidases) needed for cell-wall synthesis. Because these enzymes were identified by their reaction with radiolabeled penicillin, they are called *penicillin-binding proteins*. In the 1960s, virtually all clinical isolates of *S. pneumoniae* were susceptible to penicillin (i.e., were inhibited in vitro by concentrations of <0.06 μg/mL). During the past two decades, an increasing number of isolates have shown some degree of resistance to penicillin. Resistance results when spontaneous mutation or acquisition of new genetic material alters penicillin-binding proteins in a manner that reduces their affinity for penicillin, thereby necessitating a higher concentration of penicillin for their saturation. The genetic information that renders pneumococci resistant to penicillin is generally acquired from oral streptococci and conveys resistance to other antibiotics as well. Selection of antibiotic-resistant strains in the United States—especially in areas of high antibiotic use, such as day-care centers—and importation of strains from other countries where antibiotics are available without prescription have contributed to the prevalence of multidrug resistance.

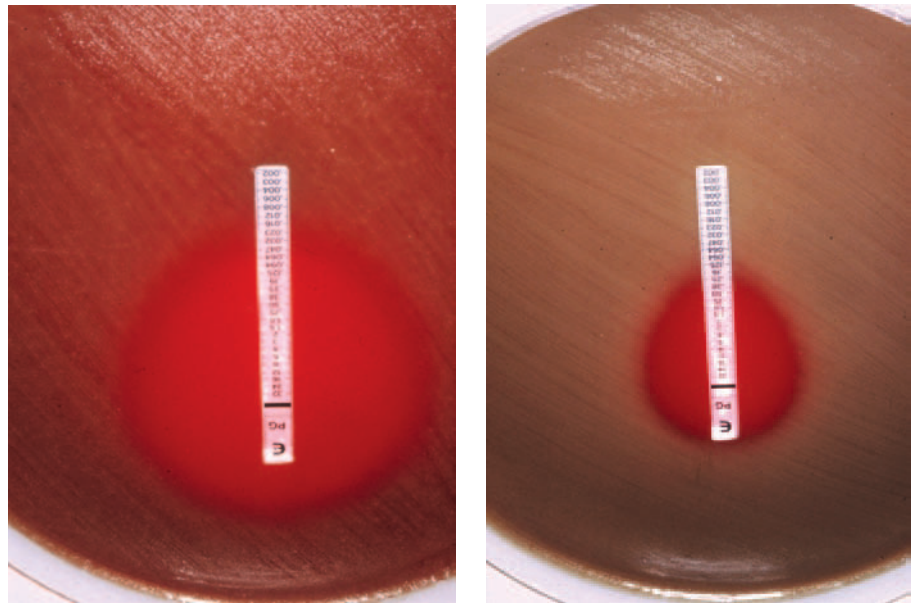

FIGURE 119-3 The e-strip method currently used by most laboratories to determine the susceptibility of *S. pneumoniae* to antibiotics. After the plate is streaked with a suspension of pneumococci, a strip that has been impregnated with graded concentrations of the antibiotic under study (penicillin in the example shown) is placed on the surface, and the plate is incubated overnight at 37°C. The organism on the left is inhibited by a penicillin concentration of 0.016 μg/mL and is fully susceptible to this drug. The organism on the right is inhibited only by a penicillin concentration of 0.25 μg/mL and is intermediately resistant to this agent.

At present, ~20% of pneumococcal isolates in the United States are intermediately susceptible to penicillin [minimal inhibitory concentration (MIC) 0.1 to 1.0 μg/mL], and 15% are resistant (MIC ≥2.0 μg/mL; Fig. 119-3). These definitions were based on drug levels achievable in CSF during treatment of meningitis, whereas levels reached in the bloodstream, lungs, and sinuses are actually much higher. Thus the MIC needs to be interpreted in light of the infection being treated. Pneumonia caused by a penicillin-resistant strain is likely to respond to 24 million units of penicillin daily, whereas meningitis will not. The recently revised definition of amoxicillin resistance (susceptible, MIC ≤2 μg/mL; intermediately resistant, MIC = 4 μg/mL; resistant, MIC ≥8 μg/mL) is based on serum levels, assuming that no physician would knowingly treat meningitis with this oral medication. Pneumonia due to an intermediately amoxicillin-resistant strain may not respond to treatment with this drug, and that due to a resistant strain is likely not to respond. On the assumption that antibiotic concentrations in middle-ear fluid or sinus cavities approach those in serum, similar inferences can be made about the treatment of otitis or sinusitis.

Penicillin-susceptible pneumococci are susceptible to all commonly used cephalosporins. Penicillin-intermediate strains tend to be resistant to all first- and many second-generation cephalosporins (of which cefuroxime retains the best efficacy), but most are susceptible to certain third-generation cephalosporins, including cefotaxime, ceftriaxone, cefepime, and cefpodoxime. One-half of highly penicillin-resistant pneumococci are also resistant to cefotaxime, ceftriaxone, and cefepime, and nearly all are resistant to cefpodoxime. Just as in the case of penicillin, susceptibility to cefotaxime and ceftriaxone is defined on the basis of achievable CSF levels. Thus pneumonia caused by intermediately resistant strains (MIC = 2 μg/mL) will respond well to usual doses of these drugs, and pneumonia due to a resistant organism (MIC ≥ 4 μg/mL) is likely to respond. Meningitis due to intermediately resistant strains may not respond, and meningitis due to a resistant strain is likely not to respond to treatment with cefotaxime or ceftriaxone.

About one-quarter of all pneumococcal isolates in the United States are resistant to erythromycin and the newer macrolides, including azithromycin and clarithromycin, with much higher rates of resistance in penicillin-resistant strains. This resistance will certainly affect empirical therapy for bronchitis, sinusitis, and pneumonia. In the United States, the majority of macrolide-resistant pneumococci bear the so-called M phenotype (erythromycin MIC = 1 to 8 μg/mL) and are susceptible to clindamycin. In this case, resistance is mediated by an efflux pump mechanism; to some extent, M-type resistance can be overcome by clinically achievable levels of macrolides. In Europe, most macrolide resistance is due to a mutation in *ermB*, which confers high-level resistance not only to macrolides but also to clindamycin; more than 90% of pneumococcal isolates in the United States are susceptible to clindamycin. Rates of doxycycline resistance among pneumococci of varying susceptibility to penicillin are similar to those observed for macrolides. One-third of pneumococcal isolates exhibit reduced susceptibility to trimethoprim-sulfamethoxazole. The newer fluoroquinolones remain highly effective against pneumococci, with equal efficacy against penicillin-susceptible and -resistant strains; the rate of resistance is generally <1% but approaches 2 to 3% in areas where quinolones are widely used and is increasing. Ketolides appear to be uniformly effective against pneumococci, as does vancomycin, although it is feared that the acquisition of vancomycin resistance by enterococci and other gram-positive bacteria may eventually lead to pneumococcal transformation to resistance. Oxazolidinones and glycopeptides also appear to be effective in vitro, with MICs no higher for drug-resistant *S. pneumoniae* strains than for penicillin-susceptible strains. Resistance to streptogramins parallels that to macrolides, limiting the usefulness of these drugs for the treatment of pneumonia.

Pneumococcal susceptibility patterns vary greatly between and even within individual communities, and the data are in a state of flux. It does appear, however, that the constant trend is toward more widespread antibiotic resistance.

Otitis Media and Acute Sinusitis (Table 119-4) Current treatment recommendations for otitis media and acute sinusitis—conditions whose pathogenesis and microbial etiology are similar—are based on the

TABLE 119-4 *Regimens for the Treatment of Pneumococcal Otitis Media or Sinusitis in Adults*[a]

Regimen	Drug, Dose	Duration	Comments
First-line	Amoxicillin, 1 g q8h	Otitis: 3–5 days after clinical response, not to exceed 7 days total; sinusitis: 7–10 days after clinical response, not to exceed 2 weeks total	If this regimen fails, try second-line regimen.
Second-line	Amoxicillin, 1 g q8h, plus clavulanic acid[b]	Same as above	If this regimen fails, try third-line regimen.
Third-line	Ceftriaxone, 1 g qd	3–5 days for otitis; longer for sinusitis	If this regimen fails, consider complications; consult otolaryngologist and/or infectious disease specialist.

[a] Treatment for otitis media or sinusitis is empirical, since aspiration of the involved area to establish an etiologic diagnosis is rarely undertaken, except under the conditions of a research protocol.
[b] Give half as amoxicillin alone and half as amoxicillin with clavulanic acid.

following points: (1) Acute otitis media is the most common infection for which antibiotics are prescribed in the United States. (2) As noted above, *S. pneumoniae* is the most likely treatable cause; taken together, *H. influenzae* and *M. catarrhalis*, many strains of which produce β-lactamases, are implicated nearly as frequently as pneumococci. (3) In the absence of diagnostic tympanocentesis, the etiologic diagnosis is nearly always presumptive. (4) Because penetration into a closed space is required, high serum levels of an effective antibiotic are required to treat otitis caused by intermediately or fully resistant pneumococci. (5) *S. pneumoniae* is more likely than *Haemophilus* to cause progression to serious complications without specific therapy. (6) Antibiotics that are effective against pneumococci and yet resist β-lactamases tend to be very expensive compared with amoxicillin.

As a result of these considerations, the Otitis Media Working Group of the Centers for Disease Control and Prevention (CDC) recommended that initial therapy be amoxicillin in a high dosage—e.g., 80 to 90 mg/kg per day in two or three divided doses for infants and toddlers or 1 g three times daily for adults. If this regimen fails, highly penicillin-resistant pneumococci or β-lactamase-producing bacteria may be responsible, and amoxicillin may be given at the same total dosage but with one-half of the dose in the form of amoxicillin/clavulanic acid. If this regimen fails, three doses of ceftriaxone at daily intervals are likely to be curative. A quinolone or ketolide may also be tried in adults. Patients must be monitored closely for a response. Despite the detection (by molecular analysis) of pneumococcal DNA in middle-ear fluid, chronic serous otitis ("glue ear") is probably not due to active infection and does not require antibiotic therapy. Treatment for otitis is recommended for a total of 5 to 7 days; treatment for acute sinusitis is given for 10 to 14 days.

Pneumonia (Table 119-5) This section will deal primarily with the treatment of pneumonia that is known to be due to *S. pneumoniae*. The broader issue of empirical therapy for community-acquired pneumonia is covered in detail elsewhere (Chap. 239). However, a few general comments on empirical therapy apply. Without a good sputum sample that can be Gram-stained and examined microscopically, the etiologic agent is not known at the time when treatment needs to be initiated and is not likely to become known later. Empirical therapy in such cases must be effective against *S. pneumoniae*, which remains the most likely causative agent of community-acquired pneumonia, unless epidemiologic, clinical, and radiologic findings strongly favor another etiologic entity. In the past, when pneumococci were uniformly susceptible to nearly all antibiotics, it did not matter which drug was selected. Now that pneumococci are resistant, it clearly makes a difference. If a good sputum sample reveals only organisms consistent with *S. pneumoniae*, therapy can be focused on this organism, although additional treatment may be added for organisms that are not visualized microscopically—e.g., influenza virus in a patient hospitalized during an influenza outbreak. Even if the pneumococcus is suspected, a certain degree of empiricism is required, because the antibiotic susceptibility of the strain involved will not be known for 1 or 2 days.

There has been increased emphasis on outpatient therapy in patients who are at low risk (as determined by PORT score according to criteria described by the Pneumonia Outcomes Research Team; Chap. 239). This approach appears to be safe. However, if the physician is in doubt about the severity of illness, the social circumstances, or the likelihood of compliance with the prescribed antibiotic regimen, it may be best to hospitalize the patient, at least briefly. Predictions based on PORT score have been validated for pneumococcal pneumonia.

OUTPATIENT THERAPY Amoxicillin (1 g three times daily) effectively treats all cases of pneumococcal pneumonia except those caused by the most highly penicillin-resistant isolates. Neither cefuroxime nor cefpodoxime offers any advantages over amoxicillin since these drugs are less likely, even at high dosages, to be active against highly resistant pneumococcal strains. One of the newer fluoroquinolones or a ketolide in an accepted dosage for pneumonia is highly likely to be effective. Clindamycin will be effective in 90% and doxycycline, azithromycin, or clarithromycin in 75% of cases—levels of resistance that make their use questionable unless the organism is known to be susceptible. Because one-third of all isolates are now resistant to trimethoprim-sulfamethoxazole, this agent can no longer be recommended. Since none of these therapies ensures the kind of antibiotic coverage that it would have in the past, patients should be instructed to remain in close contact with the prescribing physician, especially if there is any deterioration in their condition.

INPATIENT THERAPY Pneumonia caused by penicillin-susceptible or intermediately penicillin-resistant pneumococcal isolates is readily treatable with β-lactam antibiotics. The dosages that follow are acceptable against intermediately resistant strains and against many or most fully resistant isolates, although they are excessive for use against susceptible isolates. Lower doses, however, cannot be recommended initially because susceptibility is usually not known until 48 to 72 h after treatment is begun. Patients who are sick enough to be hospitalized should

TABLE 119-5 *Regimens for the Treatment of Pneumococcal Pneumonia in Adults*[a]

Route, Drug	Dose, Schedule[b]
ORAL THERAPY	
Amoxicillin	1 g q8h
Quinolone, e.g., gatifloxacin	400 mg q24h
PARENTERAL THERAPY	
Penicillin[c]	3–4 mU q4h
Ampicillin[d]	1–2 g q6h
Ceftriaxone	1 g q12–24h
Cefotaxime	1–2 g q6–8h
Quinolone, e.g., gatifloxacin	400 mg q24h
Imipenem	500 mg q6h
Vancomycin[e]	500 mg q6h

[a] These regimens are recommended for treatment after a presumptive diagnosis is made on the basis of examination of a Gram-stained sputum sample or as a replacement for more broad-spectrum empirical therapy after a diagnosis of pneumococcal pneumonia is proven by culture. When a valid sputum specimen cannot be obtained, concern for other likely pathogens should prompt the selection of more all-inclusive therapeutic regimens.
[b] Therapy should continue for 5 days after defervescence, not to exceed 7–10 days total. A switch from parenteral to oral drug administration may be made as soon as the patient can tolerate oral medications.
[c] This regimen is listed more for historic than for practical reasons. The spectrum is overly narrow, although perfectly acceptable if a Gram-stained sputum specimen shows only pneumococci. However, the need for frequent administration, mandated by the short half-life of penicillin, renders this regimen impractical.
[d] Usually given in the form of ampicillin/sulbactam.
[e] Not proven to be effective by the extensive clinical experience that applies to the other regimens.

be treated promptly. Most physicians favor parenteral antibiotics, although oral administration of well-absorbed drugs may be acceptable if the patient is not vomiting or hypotensive. Recommended regimens include ceftriaxone (1 g every 12 to 24 h) or cefotaxime (1 to 2 g every 6 to 8 h); the lower doses should suffice except against highly resistant strains. Ampicillin (1 to 2 g every 6 h) is also widely used, usually in the form of ampicillin/sulbactam. Quinolones are effective against all but a small percentage of pneumococcal strains and can be given parenterally or orally. Clindamycin is effective against ~90% of isolates. On the basis of in vitro considerations, vancomycin (500 mg every 6 h) is likely to be uniformly effective against pneumococci, and this drug or a quinolone should be used together with a third-generation cephalosporin for initial therapy in a patient who is likely to be infected with a highly antibiotic-resistant strain or in one who has had a severe allergic reaction to penicillins and cephalosporins. As noted above, there have always been treatment failures unrelated to the antimicrobial susceptibility of the organism; nevertheless, the failure of a patient to respond promptly should raise the question of resistance, and another drug should be given until the susceptibility of the infecting strain has been documented. Of course, evidence for loculated infections (such as empyema) and/or other causes of fever should be sought and addressed appropriately.

DURATION OF THERAPY The optimal duration of treatment for pneumococcal pneumonia is uncertain. Penicillin-susceptible strains begin to disappear from the sputum within several hours of the first dose of penicillin, and a single dose of procaine penicillin, which results in the maintenance of an effective antimicrobial level for 24 h, was said to cure pneumococcal pneumonia in otherwise-healthy young adults at the time when all isolates were susceptible. Most older physicians treated pneumococcal pneumonia for 5 to 7 days. In the absence of reports of therapy failure, younger physicians have tended to treat the infection for 10 to 14 days. Prolongation of therapy is a two-edged sword, especially in debilitated patients, because the risk of complications increases with each day of antibiotic treatment, particularly in the hospital setting. A few days of close observation and parenteral therapy followed by an oral antibiotic—with the entire course of treatment continuing for no more than 5 days after the patient becomes afebrile—may be the best approach.

Meningitis (Table 119-6) Pneumococcal meningitis should be treated initially with ceftriaxone (1 to 2 g every 12 h) plus vancomycin (500 mg every 6 h or 1 g every 12 h). At this time, studies in experimental animals suggest benefits of the addition of rifampin, but in vitro studies indicate antagonism between this drug and ceftriaxone or vancomycin. This author does not recommend that rifampin be added. Two drugs are given initially because the cephalosporin is likely to be effective against most isolates and readily penetrates the blood-brain barrier, whereas, although all isolates are susceptible to vancomycin, this drug has a somewhat unpredictable capacity to cross the blood-brain barrier. If the isolate is shown to be susceptible or intermediately resistant, treatment can be continued with ceftriaxone, and vancomycin may be discontinued. If the organism is resistant, continued treatment with two drugs is indicated. Cefotaxime (2 g every 6 h) may be used instead of ceftriaxone. Imipenem (500 mg every 6 h) may be used in patients who have had life-threatening reactions to β-lactam antibiotics. As noted above, the author of this chapter does not recommend the addition of rifampin. The total duration of therapy for pneumococcal meningitis is 10 days. Consistent with the central pathogenic role of inflammation in meningitis, a recent study demonstrates clear benefit from the addition of glucocorticoids; heretofore, relevant data were conflicting (Chap. 360). Meningitis should be treated in an intensive care unit and with the participation of appropriate consultants, generally including a neurologist and a specialist in infectious diseases.

Endocarditis Pneumococcal endocarditis is associated with rapid destruction of heart valves. Pending results of susceptibility studies, treatment should be initiated with ceftriaxone or cefotaxime; as the prevalence of highly resistant strains increases, it might be prudent to add vancomycin until results of susceptibility studies are available.

TABLE 119-6 *Treatment of Pneumococcal Meningitis*

Circumstance	Appropriate Course[a]
Diagnosis of pneumococcal meningitis; antibiotic susceptibility unknown	Treat with ceftriaxone, 1–2 g q12h, plus vancomycin, 500 mg q6h, until antibiotic susceptibility of organism is known.
Susceptibility results available	Continue treatment with ceftriaxone alone if organism is susceptible or intermediate; continue both ceftriaxone and vancomycin if organism is resistant.
Life-threatening penicillin allergy	Treat with imipenem, 500 mg q6h, rather than a β-lactam antibiotic.

[a] Treatment should be administered for 5–7 days after defervescence or for a total of 10 days.

There is no clear evidence that adding another antibiotic to the regimen is beneficial; aminoglycosides are somewhat synergistic and rifampin or quinolones are antagonistic with β-lactams. Patients with endocarditis should probably be treated in an intensive care unit in collaboration with an infectious disease consultant, a cardiologist, and a cardiovascular surgeon.

Other Therapeutic Modalities A variety of agents that block the action of TNF-α, IL-1, or platelet-activating factor have conferred no benefit and may even have had a detrimental effect on pneumococcal sepsis. Similar results have been obtained with glucocorticoids except in cases of meningitis.

PREVENTION Pneumococcal polysaccharide vaccine contains 25 μg of capsular polysaccharide from the 23 most prevalent serotypes of *S. pneumoniae*; vaccination stimulates antibody to most serotypes in most recipients. In adults <55 years old, protection rates are at least 85% even 5 years or longer after vaccination (Table 119-7). The level and duration of protection decrease with advancing age, perhaps because of a diminished avidity of the antibody for the capsular polysaccharide. As a result, 50% of persons in their eighties are protected for up to 3 years, with very little or no protection thereafter. In subgroups of the population at high risk (e.g., debilitated elderly persons and individuals with severe chronic lung disease), vaccine has not been shown conclusively to be effective. Persons who most need the vaccine because of poor IgG responses are not likely to respond to immunization with significant increases in antibody level. Nevertheless, in light of the safety and low cost of the vaccine, some experts believe that the poor average rate of response should not deter physicians from administering vaccine to individual patients who are at increased risk of pneumococcal infection.

The CDC's Immunization Practices Advisory Committee has broadened its recommendations for pneumococcal vaccination to include all persons over the age of 2 years who are at substantially increased risk of developing pneumococcal infection and/or of having

TABLE 119-7 *Protective Efficacy of Polyvalent Pneumococcal Polysaccharide Vaccine*[a]

Age, Years	No. of Subject Pairs	Years since Last Vaccination		
		<3	3–5	>5
<55	125	93	89	85
55–64	149	88	82	75
65–74	213	80	71	58
75–84	188	67	53	32
≥85	133	46	22	−13

[a] Results of a case-control study involving all cases of invasive pneumococcal disease in Connecticut during 7 years (1984–1990). Vaccinated subjects were matched with controls, and the rate of invasive pneumococcal disease was related to age and time since vaccination. The data, showing protective efficacy, suggest that, within 5 years of vaccination, protection rates decline with age—i.e., from ~90% in persons <65 years of age to <50% in persons ≥85 years old. Protection also declines with increasing time from vaccination to infection, and this decline is more prominent in older patients.

Source: *Data adapted Ed Shapiro et al: N Engl J Med 325:1453, 1991; with permission.*

a serious complication of such an infection. Perhaps most important are those with anatomical or functional asplenia who are at risk for overwhelming, life-threatening infections. Others who might fall within these recommendations are persons (1) over the age of 65; (2) with CSF leak, diabetes mellitus, alcoholism, cirrhosis, chronic renal insufficiency, chronic pulmonary disease, or advanced cardiovascular disease; (3) who have an immunocompromising condition associated with increased risk of pneumococcal disease, such as multiple myeloma, lymphoma, Hodgkin's disease, HIV infection, organ transplantation, or chronic use of glucocorticoids; (4) who are genetically at increased risk, such as Native Americans and Alaskans; or (5) who live in environments where outbreaks are particularly likely to occur, such as nursing homes.

Recommendations regarding revaccination seem to be somewhat inconsistent. A single revaccination is advocated for persons over the age of 65 if more than 5 years have transpired since the first vaccination. Since antibody levels decline and there is no anamnestic response, it seems more reasonable simply to recommend revaccination at 5-year intervals, especially in persons over the age of 65, who tend to have almost no adverse reaction to vaccination, and in splenectomized patients, who are most in need.

Pneumococcal polysaccharide vaccine is not useful in children <2 years of age, whose immune system does not respond well to polysaccharide antigens. Conjugating the polysaccharide to a protein alters the form in which the antigen is presented to immune-processing cells, yielding an effective immunogen. A heptavalent protein-conjugate pneumococcal polysaccharide vaccine, approved for use in 2000, protects infants and young children against pneumococcal otitis media, pneumonia, bacteremia, and meningitis; efficacy for serotypes contained in the vaccine, which are responsible for about two-thirds of all cases of pneumococcal disease in young children, is 67% for otitis and 97% for bacteremia and meningitis. The rate of nasopharyngeal carriage of vaccine serotypes is also reduced. By its "herd effect" (i.e., the effect on nonvaccinated members of the population), widespread use of this vaccine appears to have decreased the overall incidence of invasive pneumococcal disease in the population. Protein conjugate vaccines that contain antigen from the 11 most common infecting serotypes are being studied. The usefulness of these products may ultimately be limited because they may lead to replacement of serotypes contained in the vaccine with nonvaccine serotypes. Vaccines that contain surface-expressed proteins present in all pneumococci, such as pneumococcal surface protein A (PspA) and surface adhesin A (PsaA), are in the early phases of investigation. Conjugate vaccines do not appear to offer any advantage over polysaccharide vaccine in healthy or diseased adults, although a subpopulation of persons who, on a genetic basis, fail to respond to pneumococcal polysaccharide vaccine may respond to a conjugate vaccine.

120 STAPHYLOCOCCAL INFECTIONS

Franklin D. Lowy

Staphylococcus aureus, the most virulent of the many staphylococcal species, has demonstrated its versatility by remaining a major cause of morbidity and mortality despite the availability of numerous effective antistaphylococcal antibiotics. *S. aureus* is a pluripotent pathogen, causing disease through both toxin-mediated and non-toxin-mediated mechanisms. This organism is responsible for both nosocomial and community-based infections that range from relatively minor skin and soft tissue infections to life-threatening systemic infections.

The "other" staphylococci, collectively designated *coagulase-negative staphylococci* (CoNS), are considerably less virulent than *S. aureus* but remain important pathogens in selected clinical settings. These include but are not limited to infections associated with prosthetic devices.

MICROBIOLOGY AND TAXONOMY

The 33 staphylococcal species (with additional staphylococcal species under review) are pathogenic members of the family Micrococcaceae. A simple strategy for identification of the more clinically important species is outlined in Fig. 120-1. Automated diagnostic systems as well as kits are available for biochemical characterization of all the staphylococcal species. 16S ribosomal RNA analysis has proved a reliable method for distinguishing among species. With few exceptions, *S. aureus* is distinguished from other staphylococcal species by its production of coagulase, a surface enzyme that converts fibrinogen to fibrin. Most other clinically relevant staphylococci are coagulase-negative. *S. aureus* also ferments mannitol, is positive for protein A, and produces DNase. On blood agar plates, *S. aureus* tends to form golden β-hemolytic colonies; in contrast, CoNS produce white nonhemolytic colonies.

Staphylococci are gram-positive cocci that form grapelike clusters on Gram's stain (Fig. 120-2). They are catalase-positive (unlike streptococcal species), nonmotile, aerobic, and facultatively anaerobic. These hardy organisms are capable of prolonged survival on environmental surfaces in varying conditions.

Determining whether multiple isolates (especially of CoNS) from a particular patient are the same or different is often an important factor in distinguishing contaminants from genuine pathogens. Determining whether multiple isolates from different patients are the same or different is relevant when there is concern that a nosocomial outbreak may have been due to a common point source (e.g., a contaminated medical instrument). Biochemical tests, often performed in conjunction with antimicrobial susceptibility testing, have been used as a relatively simple means of distinguishing among staphylococcal species or strains. More discriminating molecular typing techniques, such as pulsed-field gel electrophoresis, have also been used for this purpose.

S. AUREUS INFECTIONS

EPIDEMIOLOGY *S. aureus* is a part of the normal human flora. The anterior nares is the most frequent site of human colonization, although the skin (especially when damaged), vagina, axilla, perineum, and oropharynx may also be colonized. Approximately 25 to 50% of healthy persons may be persistently or transiently colonized with *S. aureus*. The rate of colonization is higher among insulin-dependent diabetics, HIV-infected patients, injection drug users, patients under-

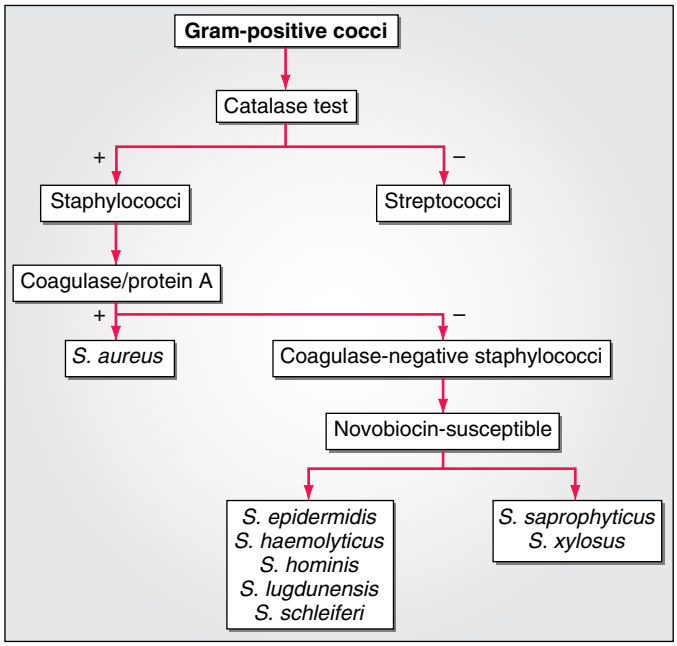

FIGURE 120-1 Biochemical characterization of staphylococci: algorithm of biochemical tests used to discriminate among the clinically important staphylococci. Additional tests are necessary to identify all of the different species.

going hemodialysis, and individuals with skin damage. Sites of colonization serve as a reservoir of strains for future *S. aureus* infections, and persons colonized with *S. aureus* are at greater risk of subsequent infection (with their colonizing strain) than are uncolonized individuals.

Overall, *S. aureus* is a leading cause of nosocomial infections. It is the most common cause of surgical wound infections and is second only to CoNS as a cause of primary bacteremia. Increasingly, nosocomial isolates are resistant to multiple drugs. In the community, *S. aureus* remains an important cause of skin and soft tissue infections, respiratory infections, and (among injection drug users) infective endocarditis. As the number of patients receiving home infusion therapy increases, so does the number of community-acquired staphylococcal infections.

Several reports have described community-acquired infections (in both rural and urban settings) caused by methicillin-resistant *S. aureus* (MRSA) in individuals with no prior medical exposure. In contrast to hospital-acquired MRSA strains, these community isolates have remained susceptible to many non-β-lactam antibiotics. Of concern has been the apparent capacity of community-acquired MRSA strains to cause serious disease in immunocompetent individuals. This ability may be due to the presence of different toxin-producing genes in these strains as well as the use of β-lactam agents for empirical treatment of patients infected with these strains.

FIGURE 120-2 Gram's stain of *S. aureus* in a sputum sample with polymorphonuclear leukocytes. (*From Lowy, 1998; with permission of the New England Journal of Medicine. Copyright 1998 Massachusetts Medical Society. All rights reserved.*)

Most individuals who develop *S. aureus* infections do so with their own colonizing strains. However, *S. aureus* may also be acquired from other people or from environmental exposures. Transmission most frequently results from transient colonization of the hands of hospital personnel, who then transfer strains from one patient to another. Spread of staphylococci in aerosols of respiratory or nasal secretions from heavily colonized individuals has also been reported.

PATHOGENESIS ■ General Concepts *S. aureus* is a pyogenic pathogen known for its capacity to induce abscess formation at sites of both local and metastatic infections. This classic pathologic response to *S. aureus* defines the framework within which the infection will progress. The bacteria elicit an inflammatory response characterized by an initial intense polymorphonuclear leukocyte (PMN) response and the subsequent infiltration of macrophages and fibroblasts. Either the host cellular response (including the deposition of fibrin and collagen) contains the infection, or infection spreads to the adjoining tissue or the bloodstream.

In toxin-mediated staphylococcal disease, the clinical infection is not invariably present. For example, once toxin has been elaborated into food, staphylococcal food poisoning can develop in the absence of viable bacteria. In the staphylococcal toxic shock syndrome (TSS), conditions that allow elaboration of toxin at sites of colonization (e.g., the presence of a superabsorbent tampon) are sufficient for initiation of clinical illness.

The *S. aureus* Genome The entire genome has been sequenced for several strains of *S. aureus*. Among the interesting revelations are the following: (1) There is a high degree of nucleotide sequence similarity among the different strains. (2) A relatively large amount of genetic information is acquired by horizontal transfer from other bacterial species. (3) *S. aureus* contains a number of unique "pathogenicity" or "genomic" islands. These islands are mobile genetic elements that contain clusters of enterotoxin and exotoxin genes or antimicrobial resistance determinants. (4) Among the genes contained in these islands are those carrying *mecA*, the gene responsible for methicillin resistance. These methicillin resistance–containing islands have been designated *staphylococcal cassette chromosomes* (SCC*mec*) and range in size from ~20 to 60 kb. To date, four SCC*mec*s have been identified. The type 4 SCC*mec* has been associated with the community-acquired MRSA strains that have been responsible for numerous outbreaks.

Regulation of Virulence Gene Expression In both toxin-mediated and non-toxin-mediated diseases due to *S. aureus*, the expression of virulence determinants associated with infection is dependent on a series of regulatory genes [e.g., accessory gene regulator (*agr*) and staphylococcal accessory regulator (*sar*)] that coordinately control the expression of the virulence genes. The regulatory gene *agr* is part of a quorum-sensing signal transduction pathway that senses and responds to bacterial density. Staphylococcal surface proteins are synthesized during the bacterial exponential growth phase in vitro. In contrast, secreted proteins, such as α toxin, the enterotoxins, and assorted enzymes, are released during the postexponential growth phase.

It has been hypothesized that these regulatory genes serve a similar function in vivo. Successful invasion requires the sequential expression of these different bacterial elements. Bacterial adhesins are needed to initiate colonization of host tissue surfaces. The subsequent release of various enzymes enables the colony to obtain nutritional support and permits bacteria to spread to adjacent tissues. Studies using mutant

strains with these regulatory genes inactivated show reduced virulence in several animal models of *S. aureus* infection.

Pathogenesis of Invasive *S. aureus* Infection Staphylococci are opportunists. For these organisms to invade the host and cause infection, some or all of the following steps are necessary: inoculation and local colonization of tissue surfaces, invasion, evasion of the host response, and metastatic spread. The initiation of staphylococcal infection requires a breach in cutaneous or mucosal barriers. Colonizing strains or strains transferred from other individuals are inoculated into damaged skin, a wound, or the bloodstream. Except under these circumstances, staphylococci generally persist as harmless commensals.

In *S. aureus* infections, recurrences develop relatively frequently, apparently because of the capacity of these pathogens to survive, to persist in a quiescent state in various tissues, and then to cause recrudescent infections when suitable conditions arise.

Nasal Colonization The anterior nares are the principal site of staphylococcal colonization in humans. Surprisingly little is known about the biology of this colonization process. It appears to involve the attachment of *S. aureus* to both nasal mucin and keratinized epithelial cells of the anterior nares. Other factors that may contribute to colonization include the influence of other resident nasal flora and their bacterial density, nasal mucosal damage (e.g., that resulting from inhalational drug use), the antimicrobial properties of nasal secretions, and host genetic factors [e.g., human leukocyte antigen (HLA) type].

Inoculation and Colonization of Tissue Surfaces Staphylococci may be introduced into tissue as a result of minor abrasions, administration of medications such as insulin, or establishment of intravenous access with catheters. After their introduction into a tissue site, bacteria replicate and colonize the host tissue surface. A family of structurally related *S. aureus* surface proteins referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) plays an important role as a mediator of adherence to these sites. MSCRAMMs such as fibronectin-binding protein, clumping factor, and collagen-binding protein enable the bacteria to colonize different tissue surfaces; these proteins contribute to the pathogenesis of invasive infections such as endocarditis and arthritis by facilitating the adherence of *S. aureus* to surfaces with exposed fibronectin, fibrinogen, or collagen.

Although CoNS are classically known for their ability to elaborate a biofilm and colonize prosthetic devices, *S. aureus* also possesses the genes responsible for biofilm formation—the intercellular adhesion (*ica*) locus. Binding to these devices often involves staphylococcal adherence to serum constituents that have coated the device surface. As a result, *S. aureus* is frequently isolated from biomedical-device infections.

Invasion After colonization, staphylococci replicate at the initial site of infection, elaborating enzymes that include serine proteases, hyaluronidases, thermonucleases, and lipases. These enzymes facilitate bacterial survival and local spread across tissue surfaces, although their precise role in infections is still not well defined. The lipases may also facilitate survival in lipid-rich areas such as the hair follicles, where *S. aureus* infections are often initiated. The *S. aureus* toxin Panton-Valentine leukocidin is cytolytic to PMNs, macrophages, and monocytes. Strains elaborating this toxin have been epidemiologically linked with cutaneous infections such as furuncles and carbuncles as well as with serious pulmonary infections in adolescents.

Constitutional findings may result from either localized or systemic infections. The cell wall—consisting of alternating N-acetyl muramic acid and N-acetyl glucosamine units in combination with an additional cell wall component, lipoteichoic acid—can initiate an inflammatory response that includes the sepsis syndrome. Staphylococcal α toxin, which causes pore formation in various eukaryotic cells, can also initiate an inflammatory response with findings suggestive of sepsis.

Evasion of Host Defense Mechanisms Evasion of host defense mechanisms is critical to invasion. Staphylococci possess an antiphagocytic polysaccharide microcapsule. Most human *S. aureus* infections are due to capsular types 5 and 8. The *S. aureus* capsule also appears to play an important role in the induction of abscess formation. The capsular polysaccharides are characterized by a zwitterionic charge pattern (the presence of both negatively and positively charged molecules) that is critical to abscess formation. Protein A, an MSCRAMM unique to *S. aureus*, acts as an Fc receptor. This protein can bind the Fc portion of IgG subclasses 1, 2, and 4, preventing opsonophagocytosis by PMNs.

An additional mechanism of *S. aureus* evasion of the host response is its capacity for intracellular survival. Both professional and nonprofessional phagocytes are capable of internalizing staphylococci. Staphylococcal internalization by endothelial cells provides a sanctuary that protects bacteria against the host's defenses. It also results in cellular changes, such as the expression of integrins and Fc receptors and the release of cytokines. These cellular changes may contribute to systemic manifestations of disease, including sepsis and vasculitis.

The intracellular environment favors the phenotypic expression of *S. aureus* small-colony variants. These menadione and hemin auxotrophic mutants are generally deficient in α toxin and are able to persist within endothelial cells. Small-colony variants are often selected after aminoglycoside therapy and are more commonly found in sites of persistent infections (e.g., chronic bone infections) and in respiratory secretions from patients with cystic fibrosis. These variants represent another mechanism for prolonged staphylococcal survival that may enhance the likelihood of recurrences. Finally, *S. aureus* can survive within PMNs and may use these cells to spread and to seed other tissue sites.

Host Response to *S. aureus* Infection The primary host response to *S. aureus* infection is the PMN. PMNs are attracted to sites of infection by bacterial components such as formylated peptides or peptidoglycan. These cells are also attracted by the cytokines tumor necrosis factor (TNF) and interleukins (ILs) 1 and 6, which are released by activated macrophages and endothelial cells.

Although most individuals have antistaphylococcal antibodies, it is not clear that the antibody levels are qualitatively or quantitatively sufficient to protect against infection. Anticapsular and anti-MSCRAMM antibodies facilitate opsonization in vitro and have been protective against infection in several animal models.

Groups at Increased Risk of Infection Some diseases appear to entail multiple risk factors for *S. aureus* infection; diabetes, for example, entails an increased rate of colonization with *S. aureus*, the use of injectable insulin, and the possibility of impaired leukocyte function. Individuals with congenital or acquired qualitative or quantitative defects in PMNs are at increased risk of *S. aureus* infections; these include neutropenic patients (e.g., those receiving chemotherapeutic agents), individuals with defective intracellular killing of staphylococci (e.g., chronic granulomatous disease), and persons with Job's syndrome or Chédiak-Higashi syndrome. Other groups at risk include individuals with abnormalities of the skin (e.g., eczema) and those with prosthetic devices.

Pathogenesis of Toxin-Mediated Disease *S. aureus* produces three types of toxin: cytotoxins (discussed above), pyrogenic-toxin superantigens, and exfoliative toxins. Both epidemiologic and animal data suggest that the presence of antitoxin antibodies is protective against illness in TSS, staphylococcal food poisoning, and staphylococcal scalded-skin syndrome (SSSS). Illness develops after synthesis and absorption of the toxin followed by the toxin-initiated host response.

Enterotoxin and Toxic Shock Syndrome Toxin 1 (TSST-1) The pyrogenic toxin superantigens are a family of small-molecular-size, structurally similar proteins that are responsible for two diseases: TSS and food poisoning. TSS results from the ability of enterotoxins and TSST-1 to function as T cell mitogens. In the normal process of antigen presentation, the antigen is first processed within the cell, and peptides are then presented in the major histocompatibility complex (MHC) class II groove, initiating a measured T cell response. In contrast, enterotoxins bind directly to the invariant region of MHC—outside the MHC class II groove. The enterotoxins can then bind T cell receptors via the vβ

chain, resulting in a dramatic overexpansion of T cell clones (up to 20% of the total T cell population).

As a result of this T cell expansion, there is the equivalent of a "cytokine storm," with the release of inflammatory mediators that include interferon (IFN) γ, IL-1, IL-6, TNF-α, and TNF-β. The result is a multisystem disease that produces a constellation of findings, including myalgias, fever, rash, and hypotension. These findings mimic those found in endotoxin shock; however, the pathogenic mechanisms differ. It has been hypothesized that a contributing factor to TSS is the release of endotoxin from the gastrointestinal tract, which may synergistically enhance the effects of the toxin.

A different region of the enterotoxin molecule is responsible for the symptoms of food poisoning. The enterotoxins are heat stable and can survive conditions that kill the bacteria. Illness results from the ingestion of preformed toxin. As a result, the incubation period is short (1 to 6 h). The toxin stimulates the vagus nerve and the vomiting center of the brain. It also appears to stimulate intestinal peristaltic activity.

Exfoliative Toxins and the Staphylococcal Scalded-Skin Syndrome The exfoliative toxins are responsible for SSSS. The toxins that produce disease in humans have been divided into two serotypes: ETA and ETB. These toxins disrupt the desmosomes that link adjoining cells. Although the mechanism of this disruption remains uncertain, studies suggest that the toxins possess serine protease activity, which—through as-yet-undefined mechanisms—triggers exfoliation. The result is a split in the epidermis at the granular level, and this event is responsible for the superficial desquamation of the skin that typifies this illness.

DIAGNOSIS *S. aureus* infections are readily diagnosed by Gram's stain (Fig. 120-2) and microscopic examination of abscess contents or of infected tissue. Staphylococci appear as large gram-positive cocci that are present singly, in pairs, or in clusters. Routine culture of infected material usually yields positive results, and blood cultures are sometimes positive even when infections are localized to extravascular sites. Polymerase chain reaction (PCR)–based assays have been applied to the rapid diagnosis of *S. aureus* infection and are increasingly being used in clinical microbiology laboratories. To date, serologic assays have not proved useful for the diagnosis of staphylococcal infections. Determining whether patients with documented *S. aureus* bacteremia also have infective endocarditis or a metastatic focus of infection remains a diagnostic challenge (see "Bacteremia, Sepsis, and Infective Endocarditis," below).

CLINICAL SYNDROMES (Table 120-1) ■ **Skin and Soft Tissue Infections** *S. aureus* causes a variety of cutaneous infections. Common predisposing factors include skin diseases, damage to the skin (e.g., insect bites, minor trauma), injections (e.g., in diabetes, injection drug use), and poor personal hygiene. These infections are characterized by the formation of pus-containing blisters, which often begin in hair follicles and spread to adjoining tissues. *Folliculitis* is a superficial infection that involves the hair follicle, with a central area of purulence (pus) surrounded by induration and erythema. *Furuncles* (boils) are more extensive, painful lesions that tend to occur in hairy, moist regions of the body and extend from the hair follicle to become a true abscess with an area of central purulence. *Carbuncles* are most often located in the lower neck and are even more severe and painful, resulting from the coalescence of other lesions that extend to a deeper layer of the subcutaneous tissue. In general, furuncles and carbuncles are readily apparent, with pus often expressible or discharging from the abscess.

Mastitis develops in 1 to 3% of nursing mothers. The infection, which generally presents within 2 to 3 weeks after delivery, is characterized by findings that range from cellulitis to abscess formation. Systemic signs, such as fever and chills, are often present in more severe cases.

Other cutaneous *S. aureus* infections include impetigo, cellulitis, and hidradenitis suppurativa (recurrent follicular infections in regions such as the axilla). *S. aureus* is also one of the most common causes of surgical wound infection.

TABLE 120-1 *Common Illnesses Caused by* **Staphylococcus aureus**

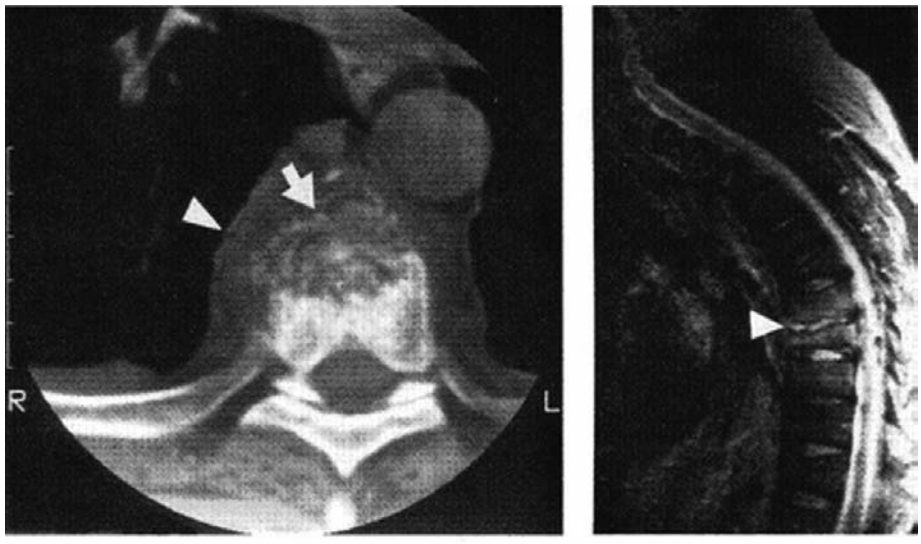
Skin and Soft Tissue Infections
Folliculitis
Furuncle, carbuncle
Cellulitis
Impetigo
Mastitis
Surgical wound infections
Hidradenitis suppurativa
Musculoskeletal Infections
Septic arthritis
Osteomyelitis
Pyomyositis
Psoas abscess
Respiratory Tract Infections
Ventilator-associated or nosocomial pneumonia
Septic pulmonary emboli
Postviral pneumonia (e.g., influenza)
Empyema
Bacteremia and Its Complications
Sepsis, septic shock
Metastatic foci of infection (kidney, joints, bone, lung)
Infective endocarditis
Infective Endocarditis
Injection drug use–associated
Native-valve
Prosthetic-valve
Nosocomial
Device-Related Infections (e.g., intravascular catheters, prosthetic joints)
Toxin-Mediated Illnesses
Toxic shock syndrome
Food poisoning
Staphylococcal scalded-skin syndrome

Musculoskeletal Infections *S. aureus* is among the most common causes of bone infections—both those resulting from hematogenous dissemination and those arising from contiguous spread from a soft tissue site.

Hematogenous osteomyelitis in children most often involves the long bones. Infections present with fever and bone pain or with a child's reluctance to bear weight. The white blood cell count and erythrocyte sedimentation rate are often elevated. Blood cultures are positive in ~50% of cases. When necessary, bone biopsies for culture and histopathologic examination are usually diagnostic. Routine x-rays may be normal for up to 14 days after the onset of symptoms. ^{99m}Tc-phosphonate scanning often detects early evidence of infection. Magnetic resonance imaging (MRI) is more sensitive than other techniques in establishing a radiologic diagnosis.

In adults, hematogenous osteomyelitis involving the long bones is less common. However, *vertebral osteomyelitis* is among the more common clinical presentations. These infections are most often seen in patients with endocarditis, those undergoing hemodialysis, diabetics, and injection drug users. Vertebral bone infections may present with intense back pain and fever but may also be clinically occult, presenting with chronic back pain and low-grade fever. *S. aureus* is the most common cause of epidural abscess, a complication that can result in neurologic compromise. Patients complain of difficulty voiding or walking and of radicular pain in addition to the symptoms associated with their osteomyelitis. Surgical intervention in this setting often constitutes a medical emergency. MRI most reliably establishes the diagnosis (Fig. 120-3).

Bone infections that result from contiguous spread tend to develop from soft tissue infections, such as those associated with diabetic or vascular ulcers, surgery, or trauma. Exposure of bone, a draining fistulous tract, failure to heal, or continued drainage suggests involvement of underlying bone. Bone involvement is established by bone culture and histopathologic examination. Contamination of culture material from adjacent tissue can make the diagnosis of osteomyelitis difficult in the absence of pathologic confirmation. In addition, it is



A B

FIGURE 120-3 *S. aureus* vertebral osteomyelitis involving the thoracic disk between T8 and T9 in a 63-year-old man. *A*. The lower end plate is damaged (*arrow*), and there is an adjacent paraspinal mass (*arrowhead*). *B*. Sagittal T2-weighted magnetic resonance image of the spine, illustrating anterior wedging of the body of T8. (*From MA Artinian et al: Images in clinical medicine. Vertebral osteomyelitis. N Engl J Med 329:399, 1993. Copyright 1993 Massachusetts Medical Society. All rights reserved. Reprinted with permission.*)

sometimes difficult to distinguish radiologically between osteomyelitis and overlying soft tissue infection with underlying osteitis.

S. aureus is the most common cause of *septic arthritis* in children. This infection is rapidly progressive and may be associated with extensive joint destruction if left untreated. It presents with intense pain on motion of the affected joint, swelling, and fever. Aspiration of the joint reveals turbid fluid, with >50,000 PMNs/μL and gram-positive cocci in clusters on Gram's stain. In adults, arthritis may result from trauma, surgery, or hematogenous dissemination. The most commonly involved joints include the knees, shoulders, hips, and phalanges. Infection frequently develops in joints previously damaged by osteoarthritis or rheumatoid arthritis. Iatrogenic infections resulting from aspiration or injection of agents into the joint also occur. In these settings, the patient experiences increased pain and swelling in the involved joint in association with fever.

Pyomyositis is an unusual infection of skeletal muscles that is seen primarily in tropical climates. In addition to occurring in seriously immunocompromised patients, it has recently been reported in HIV-infected individuals. Pyomyositis presents with fever, swelling, and pain overlying the involved muscle. Aspiration of fluid from the involved tissue reveals pus containing numerous white blood cells and gram-positive bacteria in clusters. Although a history of trauma may be associated with the infection, its pathogenesis is poorly understood.

Respiratory Tract Infections Respiratory tract infections caused by *S. aureus* occur in selected clinical settings. *S. aureus* is a cause of serious infections in newborns and infants; these infections present with shortness of breath, fever, and respiratory failure. Chest x-ray may reveal pneumatoceles (shaggy, thin-walled cavities). Pneumothorax and empyema are recognized complications of this type of infection.

In adults, nosocomial *S. aureus* pulmonary infections are commonly seen in intubated patients on intensive care units. The clinical presentation is no different from that encountered in pulmonary infections of other bacterial etiologies. Patients produce increased volumes of purulent sputum and develop respiratory distress, fever, and new pulmonary infiltrates. Distinguishing bacterial pneumonia from other causes of respiratory failure or new pulmonary infiltrates in critically ill patients is often difficult and relies on a constellation of clinical, radiologic, and laboratory findings.

Community-acquired respiratory tract infections due to *S. aureus* are most commonly seen as postviral infections or as a result of septic pulmonary emboli (e.g., in injection drug users). Influenza is the most common cause of the former type of presentation. Patients may present with fever, bloody sputum production, and midlung field pneumatoceles or multiple, patchy pulmonary infiltrates. Diagnosis is made by sputum Gram's stain and culture. Blood cultures, although useful, are usually negative.

Bacteremia, Sepsis, and Infective Endocarditis *S. aureus* bacteremia may be complicated by sepsis, endocarditis, vasculitis, or metastatic seeding (establishment of suppurative collections at other tissue sites). The frequency of metastatic seeding during bacteremia has been estimated to be as high as 31%. Among the more commonly seeded tissue sites are bones, joints, kidneys, and lungs.

Recognition that these complications have developed is often difficult if clinical and laboratory diagnostic methods alone are used. Comorbid conditions that are frequently seen in association with *S. aureus* bacteremia and that increase the risk of complications include diabetes, HIV infection, and renal insufficiency. Other host factors associated with an increased risk of complications include presentation with community-acquired *S. aureus* bacteremia (except in injection drug users), lack of an identifiable primary focus, and presence of prosthetic devices.

Clinically, *S. aureus* sepsis presents in a manner similar to that documented for sepsis due to other bacteria. The well-described progression of hemodynamic changes—beginning with respiratory alkalosis and clinical findings of hypotension and fever—is commonly seen. The microbiologic diagnosis is established by positive blood cultures.

The overall incidence of *S. aureus* endocarditis has increased over the past 20 years. Depending on the series, *S. aureus* now accounts for 25 to 35% of all cases of bacterial endocarditis. This increase is due, at least in part, to the increased use of intravascular devices; the incidence of infective endocarditis among patients with *S. aureus* bacteremia and intravascular catheters was 25% when studied with transesophageal echocardiography. Other factors associated with an increased risk of endocarditis are injection drug use, hemodialysis, the presence of intravascular prosthetic devices, and immunosuppression. Despite the availability of effective antibiotics, mortality from these infections continues to range from 20 to 40%, depending on both the host and the nature of the infection. Complications of *S. aureus* endocarditis include cardiac valvular insufficiency, peripheral emboli, metastatic seeding, and central nervous system involvement. *S. aureus* brain abscess is a recognized complication of left-sided endocarditis.

S. aureus endocarditis is encountered in four clinical settings: (1) right-sided endocarditis in association with injection drug use, (2) left-sided native-valve endocarditis, (3) prosthetic-valve endocarditis, and (4) nosocomial endocarditis. In each of these settings, the diagnosis is established by recognition of clinical stigmata suggestive of endocarditis. These findings include cardiac manifestations such as new or changing cardiac valvular murmurs; cutaneous evidence of endocarditis such as vasculitic lesions, Osler's nodes, or Janeway lesions; evidence of embolic disease; and a history suggesting a risk for *S. aureus* bacteremia. In the absence of antecedent antibiotic therapy, blood cultures are almost uniformly positive. Transthoracic echocardiography, while less sensitive than transesophageal echocardiography, is less invasive and often establishes the presence of valvular vegetations.

Acute right-sided tricuspid valvular *S. aureus* endocarditis is most often seen in injection drug users. The classic presentation includes a high fever, a toxic clinical appearance, pleuritic chest pain, and the production of purulent (sometimes bloody) sputum. Chest x-rays re-

veal evidence of septic pulmonary emboli (small, peripheral, circular lesions that may cavitate with time). A high percentage of the affected patients have no history of antecedent valvular damage. At the outset of their illness, patients may present with fever alone, without cardiac or other localizing findings. As a result, a high index of clinical suspicion is essential to the diagnosis.

Individuals with antecedent cardiac valvular damage more commonly present with left-sided native-valve endocarditis involving the previously affected valve. These patients tend to be older than those with right-sided endocarditis, their prognosis is worse, and their incidence of complications (including peripheral emboli, cardiac decompensation, and metastatic seeding) is higher.

S. aureus is one of the more common causes of prosthetic-valve endocarditis. This infection is especially fulminant in the early postoperative period and is associated with a high mortality rate. In most instances, medical therapy alone is not sufficient and urgent valve replacement is necessary. Patients are prone to develop valvular insufficiency or myocardial abscesses originating from the region of valve implantation.

The increased frequency of nosocomial endocarditis (15 to 30% of cases, depending on the study) reflects in part the increased use of intravascular devices. This form of endocarditis is most commonly caused by *S. aureus*; because patients often are critically ill, are receiving antibiotics for various other indications, and have comorbid conditions, the diagnosis is not easily recognized.

Urinary Tract Infections Urinary tract infections are infrequently caused by *S. aureus*. In contrast with that of most other urinary pathogens, the presence of *S. aureus* in the urine is suggestive of hematogenous dissemination. Ascending *S. aureus* infections occasionally result from instrumentation of the genitourinary tract.

Prosthetic Device–Related Infections *S. aureus* accounts for a large proportion of prosthetic device–related infections. These infections often involve intravascular catheters, prosthetic valves, orthopedic devices, peritoneal or intraventricular catheters, and vascular grafts. Recently, *S. aureus* isolates have also been responsible for a sizable proportion of infections of left-ventricular-assist devices. In contrast with the more indolent presentation of CoNS infections, *S. aureus* device-related infections often present more acutely, with both localized and systemic manifestations. The latter infections also tend to be more rapidly progressive. It is relatively common for a pyogenic collection to be present at the device site. Aspiration of these collections and performance of blood cultures are important components in establishing a diagnosis. *S. aureus* infections tend to occur more commonly in the early postimplantation period unless the device is used for access (e.g., intravascular or hemodialysis catheters). In the latter instance, infections can occur as long as the device is used. As in most prosthetic-device infections, successful therapy usually involves removal of the device. Left in place, the device is a potential nidus for either persistent or recurrent infections.

Toxin-Mediated Diseases ■ *Toxic Shock Syndrome* TSS was first recognized as a disease in children in 1978. The disease gained national attention in the early 1980s, when a nationwide outbreak occurred among young, otherwise healthy, menstruating women. Epidemiologic investigation demonstrated that these cases were strongly associated with menstruation and the use of a highly absorbent tampon that had recently been introduced to the market. Subsequent studies established the role of TSST-1 in these illnesses. Withdrawal of the tampon from the market resulted in a rapid decline in the incidence of this disease. However, menstrual and nonmenstrual cases continue to be reported.

The clinical presentation is similar in menstrual and nonmenstrual TSS, although the nature of the risk clearly differs. Evidence of a clinical *S. aureus* infection is not a prerequisite for the development of the illness. TSS results from the elaboration of an enterotoxin or the structurally related enterotoxin-like TSST-1. More than 90% of menstrual cases are caused by TSST-1, whereas a high percentage of nonmenstrual cases are caused by enterotoxins.

TSS begins with relatively nonspecific flulike symptoms. In menstrual cases, the onset usually comes 2 or 3 days after the start of menstruation. Patients present with fever, hypotension, and erythroderma of variable intensity. Mucosal involvement is common (e.g., conjunctival hyperemia). The illness can rapidly progress to symptoms that include vomiting, diarrhea, confusion, myalgias, and abdominal pain. These symptoms reflect the multisystemic nature of the disease, with involvement of the liver, kidneys, gastrointestinal tract, and/or central nervous system. Desquamation of the skin occurs during convalescence, usually 1 or 2 weeks after the onset of illness. Laboratory findings may include azotemia, leukocytosis, hypoalbuminemia, thrombocytopenia, and liver function abnormalities.

Diagnosis of TSS still depends on the presence of a constellation of findings rather than on one specific finding (Table 120-2). Part of the case definition is the absence of laboratory evidence of other illnesses that are often included in the differential (e.g., Rocky Mountain spotted fever, rubeola, leptospirosis). Other diagnoses to be considered are drug toxicities, viral exanthems, sepsis, and Kawasaki disease. Illness occurs only in persons who lack antibody to TSST-1. Recurrences are possible if antibody fails to develop after the illness.

Food Poisoning *S. aureus* is among the most common causes of foodborne outbreaks of infection in the United States. *S. aureus* food poisoning results from the inoculation of toxin-producing *S. aureus* into food by colonized food handlers. Toxin is then elaborated in such growth-promoting food as custards, potato salad, or processed meats. Even if the bacteria are killed by warming, the heat-stable toxin is not destroyed. The onset of illness is rapid and explosive, occurring within 1 to 6 h of ingestion. The illness is characterized by nausea and vomiting, although diarrhea, hypotension, and dehydration may also occur. The differential diagnosis includes diarrhea of other etiologies, especially that caused by similar toxins (e.g., the toxins elaborated by *Bacillus cereus*). The rapidity of onset, the absence of fever, and the epidemic nature of the presentation arouse suspicion regarding this diagnosis. Symptoms generally resolve within 8 to 10 h. The diagnosis can be established by the demonstration of bacteria or the documentation of enterotoxin in the implicated food. Treatment is entirely supportive.

Staphylococcal Scalded-Skin Syndrome SSSS most often affects newborns and children. The illness may vary from localized blister formation to exfoliation of much of the skin surface. The skin is usually fragile and often tender, with thin-walled, fluid-filled bullae. Gentle pressure results in rupture of the lesions, leaving denuded underlying skin (Ni-

TABLE 120-2 *Case Definition of* S. aureus *Toxic Shock Syndrome*

1. Fever: temperature of ≥38.9°C (≥102°F)
2. Hypotension: systolic blood pressure of ≤90 mmHg, or orthostatic hypotension (orthostatic drop in diastolic blood pressure by ≥15 mmHg, orthostatic syncope, or orthostatic dizziness)
3. Diffuse macular rash with subsequent desquamation in 1 to 2 weeks after onset (including the palms and soles)
4. Multisystem involvement
   a. Hepatic: bilirubin or aminotransferase levels ≥2 times normal
   b. Hematologic: platelet count ≤100,000/μL)
   c. Renal: blood urea nitrogen or serum creatinine level ≥2 times the normal upper limit
   d. Mucous membranes: vaginal, oropharyngeal, or conjunctival hyperemia
   e. Gastrointestinal: vomiting or diarrhea at onset of illness
   f. Muscular: severe myalgias or serum creatine phosphokinase level ≥2 times the upper limit
   g. Central nervous system: disorientation or alteration in consciousness without focal neurologic signs and in the absence of fever and hypotension
5. Negative serologic or other tests for measles, leptospirosis, and Rocky Mountain spotted fever as well as negative blood or cerebrospinal fluid cultures for organisms other than *S. aureus*

Source: M Wharton et al: Case definitions for public health surveillance. MMWR 39:1, 1990; with permission.

kolsky's sign; Fig. 120-4). The mucous membranes are usually spared. In more generalized infection, there are often constitutional symptoms, including fever, lethargy, and irritability with poor feeding. Significant amounts of fluid can be lost in more extensive cases. Illness usually follows localized infection at one of a number of possible sites. SSSS is much less common among adults but can follow infections caused by exfoliative toxin–producing strains.

PREVENTION Prevention of the spread of *S. aureus* infections in the hospital setting involves hand washing and careful attention to appropriate isolation procedures. Through strict isolation practices, some Scandinavian countries have been remarkably successful at preventing the introduction and dissemination of MRSA in hospitals. Other countries, such as the United States and Great Britain, have been less successful.

The use of topical antimicrobial agents (e.g., mupirocin) to eliminate nasal colonization with *S. aureus* and to prevent subsequent infection has been investigated in a number of clinical settings. Elimination of nasal carriage of *S. aureus* has reduced the incidence of infections among patients undergoing hemodialysis and peritoneal dialysis. A randomized, placebo-controlled study attempted to reduce rates of wound infection among patients undergoing surgery with the prophylactic application of topical mupirocin to the nares. The results failed to demonstrate an overall benefit from the use of mupirocin but did suggest that the incidence of infections might be reduced if the use of mupirocin were limited to patients nasally colonized with *S. aureus*.

The ability of a capsular polysaccharide–protein conjugate vaccine to prevent staphylococcal infections in hemodialysis patients was studied. The results, while inconclusive, did show promise. Other potential vaccine candidates, including those incorporating the ligand-binding domains of several MSCRAMMs, are also under investigation.

COAGULASE-NEGATIVE STAPHYLOCOCCAL INFECTIONS

CoNS, although considerably less virulent than *S. aureus*, are among the most common causes of prosthetic-device infections. Approximately half of the 32 identified CoNS species have been associated with human infections. Of these species, *S. epidermidis* is the most common human pathogen overall; this component of the normal human flora is found on the skin (where it is the most abundant bacterial species) as well as in the oropharynx and vagina. *S. saprophyticus*, a novobiocin-resistant species, is a pathogen in urinary tract infections.

PATHOGENESIS Among CoNS, *S. epidermidis* is the species most commonly associated with prosthetic-device infections. Infection is a two-step process, with initial adhesion to the device followed by colonization. *S. epidermidis* is uniquely adapted to colonize these devices by its capacity to elaborate the extracellular polysaccharide (slime) that facilitates formation of a protective biofilm on the device surface.

FIGURE 120-4 Evidence of staphylococcal scalded-skin syndrome in a 6-year-old boy. Nikolsky's sign, with separation of the superficial layer of the outer epidermal layer, is visible. (*From LA Schenfeld et al: Images in clinical medicine. Staphylococcal scalded skin syndrome. N Engl J Med 42:1178, 2000. Copyright 2000 Massachusetts Medical Society. All rights reserved. Reprinted with permission.*)

Implanted prosthetic material is often coated with host serum or tissue constituents such as fibrinogen or fibronectin. These molecules serve as potential bridging ligands, facilitating bacterial attachment to the device surface. The surface-associated staphylococcal enzyme autolysin (AtlE) may play a role in attachment to either modified or unmodified prosthetic surfaces. In addition to AtlE, other surface molecules, such as fibrinogen-binding protein and cell wall teichoic acid, appear to mediate adherence to fibrinogen and fibronectin, respectively. The polysaccharide intercellular adhesin facilitates subsequent staphylococcal colonization and accumulation on the device surface. The genes responsible for synthesis of this polysaccharide (the *ica* genes) are also present in *S. aureus*, although their role in the two species may differ. In *S. epidermidis*, the *ica* genes are more commonly found in strains associated with device infections than in strains associated with colonization of mucosal surfaces. Biofilm appears to act as a barrier protecting bacteria from host defense mechanisms as well as from antibiotics, while providing a suitable environment for bacterial survival.

Two additional staphylococcal species, *S. lugdunensis* and *S. schleiferi*, produce more serious infections (native-valve endocarditis and osteomyelitis) than do other CoNS. The basis for this enhanced virulence is not known, although both species appear to share more virulence determinants with *S. aureus* (e.g., clumping factor and lipase) than do other CoNS.

The capacity of *S. saprophyticus* to cause urinary tract infections in young women appears to be related to its enhanced capacity to adhere to uroepithelial cells. A 160-kDa hemagglutinin/adhesin may contribute to this affinity.

DIAGNOSIS While the detection of CoNS at sites of infection or in the bloodstream is not difficult by standard microbiologic culture methods, interpretation of these results is frequently problematic. Since these organisms are present in large numbers on the skin, they often contaminate cultures. It has been estimated that only 10 to 25% of blood cultures positive for CoNS reflect true bacteremia. Similar problems arise with cultures of other sites. Among the clinical findings suggestive of true bacteremia are fever, evidence of local infection (e.g., erythema or purulent drainage at the intravenous catheter site), leukocytosis, and systemic signs of sepsis. Laboratory findings suggestive of true bacteremia include multiple positive cultures of the same strain (i.e., the same species with the same antibiogram or a closely related DNA fingerprint) from separate cultures, growth of the strain within 48 h, and bacterial growth in both aerobic and anaerobic bottles.

CLINICAL SYNDROMES CoNS cause diverse prosthetic device–related infections, including those that involve prosthetic cardiac valves and joints, vascular grafts, intravascular devices, and central nervous system shunts. In all of these settings, the clinical presentation is similar. The signs of localized infection are often subtle, the rate of disease progression is slow, and the systemic findings are often limited. Signs of infection such as purulent drainage, pain at the site, or loosening of prosthetic implants are sometimes evident. Fever is frequently but not always present, and there may be mild leukocytosis.

Infections that are not associated with prosthetic devices are infrequent, although native-valve endocarditis due to CoNS has accounted for ~5% of cases in some reviews. *S. lugdunensis* appears to be a more aggressive pathogen in this setting, causing greater mortality and rapid valvular destruction with abscess formation.

Rx TREATMENT

General Principles of Therapy In addition to the selection of appropriate antimicrobial therapy for staphylococcal infections, surgical incision and drainage of all suppurative collections are necessary. Prosthetic-device infections are unlikely to be successfully managed unless the device is removed. In the limited number of situations in which re-

moval is not possible or the infection is due to CoNS, an initial attempt at medical therapy without device removal may be warranted. Because of the well-recognized risk of complications associated with *S. aureus* bacteremia, therapy is generally prolonged (4 to 8 weeks) unless the patient is identified as being one of the small percentage of individuals who are at low risk for complications—e.g., immunocompetent patients and patients whose *S. aureus* infection is associated with a removable focus (such as an intravenous catheter) and whose device is promptly removed.

Duration of Antimicrobial Therapy Debate continues regarding the duration of therapy for bacteremic *S. aureus* infections. No carefully controlled, prospective study has addressed this question. A meta-analysis reviewing studies relevant to this issue concluded that insufficient information was currently available to determine which patients were candidates for short-course therapy (2 weeks rather than 4 to 8 weeks).

Among the findings associated with an increased risk of complicated bacteremia are persistently positive blood cultures 48 to 96 h after institution of therapy, acquisition of the infection in the community, a removable focus of infection (i.e., intravascular catheters) that is not removed, and cutaneous or embolic manifestations of infection. In those immunocompetent patients for whom short-course therapy is planned, a transesophageal echocardiogram to rule out endocarditis is warranted since neither clinical nor laboratory findings are adequate to detect cardiac involvement. In addition, an aggressive radiologic investigation to identify potential metastatic collections is indicated. All symptomatic sites need to be carefully evaluated.

Choice of Antimicrobial Agents The choice of antimicrobial agents to treat both coagulase-positive staphylococcal and CoNS infections has become increasingly problematic because of the prevalence of multidrug-resistant strains. Data collected by the Centers for Disease Control and Prevention from intensive care units in the United States (1988 to 1998) show a dramatic increase in the number of isolates that are now susceptible only to vancomycin. This trend is even more apparent with CoNS: more than 80% of nosocomial isolates are resistant to methicillin, and these MRSA strains are usually resistant to most other antibiotics as well. Because the selection of antimicrobial agents for the treatment of *S. aureus* infections is similar to that for CoNS infections, treatment options for these pathogens are discussed together and are summarized in Table 120-3.

As a result of the widespread dissemination of plasmids containing the enzyme penicillinase, few strains of staphylococci (<5%) remain susceptible to penicillin. However, against susceptible strains, penicillin remains the drug of choice. Penicillin-resistant isolates are treated with semisynthetic penicillinase-resistant penicillins (SPRPs) such as oxacillin or nafcillin. Methicillin, the first of the SPRPs, is now used infrequently. Cephalosporins are alternative therapeutic agents for these infections. Second- and third-generation cephalosporins do not have a therapeutic advantage over first-generation cephalosporins for the treatment of staphylococcal infections. The carbapenem imipenem has excellent activity against methicillin-sensitive *S. aureus* (MSSA) but not MRSA.

The isolation of MRSA was reported within 1 year of the introduction of methicillin. The prevalence of MRSA has since increased steadily. In many hospitals, 40 to 50% of *S. aureus* isolates are now resistant to methicillin. Resistance to methicillin indicates resistance to all SPRPs as well as all cephalosporins. Many MRSA isolates are also resistant to other antimicrobial families, including aminoglycosides, quinolones, and macrolides.

Production of a novel penicillin-binding protein (PBP 2a or 2′) is responsible for methicillin resistance. This protein is synthesized by the *mecA* gene, which (as stated above) is part of a large mobile genetic element—a pathogenicity or genomic island—called the staphylococcal cassette chromosome (SCC*mec*). It is hypothesized that acquisition of this genetic material resulted from horizontal transfer from a related staphylococcal species, such as *S. sciuri*. Phenotypic expression of methicillin resistance may be constitutive (i.e., expressed in all organisms in a population) or heterogeneous (i.e., displayed by only a proportion of the total organism population). Detection of methicillin resistance in the clinical microbiology laboratory can be difficult if the strain expresses heterogeneous resistance. Therefore, susceptibility studies are routinely performed at reduced temperatures (30° to 35°C for 24 h), with increased concentrations of salt in the medium to enhance the expression of resistance. In addition to PCR-based techniques, a number of rapid methods for the detection of methicillin resistance have recently been developed.

Vancomycin is the drug of choice for the treatment of methicillin-resistant staphylococcal infections. Because it is less bactericidal than the β-lactams, it should be used only after careful consideration in patients with a history of β-lactam allergies. In 1997, an *S. aureus* strain with reduced susceptibility to vancomycin (VISA) was reported from Japan. Subsequently, additional clinical isolates of VISA were reported from geographically disparate locations. These strains were all resistant to methicillin and many other antimicrobial agents. The VISA strains appear to evolve (under vancomycin selective pressure) from strains that are susceptible to vancomycin but are heterogeneous, with a small proportion of the bacterial population expressing the resistance phenotype. The mechanism of VISA resistance is uncertain but appears to be an abnormal cell wall, which was first noted by electron microscopy. Vancomycin is trapped by the abnormal peptidoglycan cross-linking and is unable to gain access to its target site.

In 2002, the first clinical isolate of fully vancomycin-resistant *S. aureus* was reported. Resistance in this and one subsequently reported clinical isolate was due to the presence of *vanA*, the gene responsible for expression of vancomycin resistance in enterococci. This observation suggested that resistance was acquired as a result of horizontal conjugal transfer from a vancomycin-resistant strain of *Enterococcus faecalis*. The patients had both MRSA and vancomycin-resistant enterococci cultured from sites of infection. The isolates remained susceptible to chloramphenicol, linezolid, minocycline, quinupristin/dalfopristin, and trimethoprim-sulfamethoxazole (TMP-SMX). The *vanA* gene is responsible for the synthesis of the dipeptide D-Ala-D-Lac in place of D-Ala-D-Ala. Vancomycin is not able to bind to the altered peptide.

Alternatives to the β-lactams and vancomycin have less antistaphylococcal activity. Although the quinolones have reasonable in vitro activity against staphylococci, the frequency of fluoroquinolone resistance has increased progressively, especially among methicillin-resistant isolates. Methicillin-susceptible staphylococci have remained more susceptible to the fluoroquinolones than have methicillin-resistant strains. Of particular concern in methicillin-resistant strains is the possible emergence of quinolone resistance during therapy. Resistance to the quinolones is most commonly chromosomal and results from mutations of the topoisomerase IV or DNA gyrase genes, although multidrug efflux pumps may also contribute. While the newer quinolones exhibit increased in vitro activity against staphylococci, it is uncertain whether this increase translates into enhanced in vivo activity. Other antibiotics such as minocycline and TMP-SMX have been successfully used to treat methicillin-resistant staphylococcal infections in the face of vancomycin toxicity or intolerance.

Among the newer antistaphylococcal agents, the parenteral streptogramin quinupristin/dalfopristin displays bactericidal activity against all staphylococci, including VISA strains. This drug has been used successfully to treat serious MRSA infections. In cases of erythromycin or clindamycin resistance, it is bacteriostatic against staphylococci.

Linezolid—the first member of a new drug family, the oxazolidinones—is bacteriostatic against staphylococci, has been well tolerated, and offers the advantage of comparable bioavailability after oral or parenteral administration. Cross-resistance with other inhibitors of protein synthesis has not been reported. Resistance to linezolid has been limited, although at least one resistant clinical isolate has been reported. The efficacy of linezolid in the treatment of deep-seated infections such as osteomyelitis has not yet been established. There are currently insufficient data on the efficacy of either quinupristin/dalfopristin or linezolid for the treatment of infective endocarditis. Dap-

TABLE 120-3 *Antimicrobial Therapy for Serious* S. aureus *Infections*[a]

Sensitivity/Resistance of Isolate	Drug of Choice	Alternative(s)	Comments
Sensitive to penicillin	Penicillin G (4 mU q4h)	Nafcillin (2 g q4h) or oxacillin (2 g q4h), cefazolin (2 g q8h), vancomycin (1 g q12h[b])	Fewer than 5% of isolates are sensitive to penicillin.
Sensitive to methicillin	Nafcillin or oxacillin (2 g q4h)	Cefazolin (2 g q8h[b]), vancomycin (1 g q12h[b])	Patients with penicillin allergy can be treated with a cephalosporin if the allergy does not involve an anaphylactic or accelerated reaction; vancomycin is the alternative. Desensitization to β-lactams may be indicated in selected cases of serious infection where maximal bactericidal activity is needed (e.g., prosthetic-valve endocarditis[c]). Type A β-lactamase may rapidly hydrolyze cefazolin and reduce its efficacy in endocarditis.
Resistant to methicillin	Vancomycin (1 g q12h[b])	TMP-SMX (TMP, 5 mg/kg q12h[b]), minocycline (100 mg PO q12h[b]), ciprofloxacin (400 mg q12h[b]), levofloxacin (500 mg q24h[b]), quinupristin/dalfopristin (7.5 mg/kg q8h), linezolid (600 mg q12h *except*: 400 mg q12h for uncomplicated skin infections); daptomycin (4 mg/kg q24h[b]) for complicated skin infections; investigational drugs: oritavancin, tigecycline	Sensitivity testing is necessary before an alternative drug is used. Adjunctive drugs (those that should be used only in combination with other antimicrobial agents) include gentamicin (1 mg/kg q8h[b]), rifampin (300 mg PO q8h), and fusidic acid (500 mg q8h; not readily available in the United States). Quinupristin/dalfopristin is bactericidal against methicillin-resistant isolates unless the strain is resistant to erythromycin or clindamycin. The newer quinolones may retain in vitro activity against ciprofloxacin-resistant isolates; resistance may develop during therapy. The efficacy of adjunctive therapy is not well established in many settings. Both linezolid and quinupristin/dalfopristin have had in vitro activity against most VISA and VRSA strains. See footnote for treatment of prosthetic-valve endocarditis.[c]
Resistant to methicillin with intermediate or complete resistance to vancomycin[d]	Uncertain	Same as for methicillin-resistant strains; check antibiotic susceptibilities	Same as for methicillin-resistant strains; check antibiotic susceptibilities
Not yet known (i.e., empirical therapy)	Vancomycin (1 g q12h)	—	Empirical therapy is given when the susceptibility of the isolate is not known. Vancomycin with or without an aminoglycoside is recommended for suspected community- or hospital-acquired *S. aureus* infections because of the increased frequency of methicillin-resistant strains in the community.

[a] Recommended dosages are for adults with normal renal and hepatic function. The route of administration is intravenous unless otherwise indicated.
[b] The dosage must be adjusted in patients with reduced creatinine clearance.
[c] For the treatment of prosthetic-valve endocarditis, the addition of gentamicin (1 mg/kg q8h) and rifampin (300 mg PO q8h) is recommended, with adjustment of the gentamicin dosage if the creatinine clearance rate is reduced.
[d] Vancomycin-resistant *S. aureus* isolates from clinical infections have recently been reported.

Source: Modified with permission of the *New England Journal of Medicine* (Lowy, 1998).

Note: TMP-SMX, trimethoprim-sulfamethoxazole; VISA, vancomycin-intermediate *S. aureus*; VRSA, vancomycin-resistant *S. aureus*.

tomycin, a new parenteral bactericidal agent with antistaphylococcal activity, was recently approved for the treatment of complicated skin infections. This drug disrupts the cytoplasmic membrane. Oritavancin, a new glycopeptide, is undergoing clinical trials.

Combinations of antistaphylococcal agents are sometimes used to enhance bactericidal activity in the treatment of serious infections such as endocarditis or osteomyelitis. In selected instances (e.g., right-sided endocarditis), drug combinations are also used to shorten the duration of therapy. Among the antimicrobial agents used in combinations are rifampin, aminoglycosides (e.g., gentamicin), and fusidic acid (which is not readily available in the United States). While these agents are not effective singly because of the frequent emergence of resistance, they have proved useful in combination with other agents because of their bactericidal activity against staphylococci.

In vitro studies have demonstrated synergy against staphylococci with the following combinations: (1) β-lactams and aminoglycosides; (2) vancomycin and gentamicin; (3) vancomycin, gentamicin, and rifampin (against CoNS); and (4) vancomycin and rifampin. In several instances, these in vitro observations have been supported by studies using the experimental animal model of endocarditis.

Antimicrobial Therapy for Selected Settings For uncomplicated skin and soft tissue infections, the use of oral antistaphylococcal agents is usually successful. For other infections, parenteral therapy is indicated.

S. aureus endocarditis is usually an acute, life-threatening infection. Thus blood cultures need to be obtained promptly and followed by the immediate institution of empirical antimicrobial therapy. For *S. aureus* native-valve endocarditis, a combination of antimicrobial agents is often used. In a large prospective study, an SPRP combined with an aminoglycoside did not alter the clinical outcome but did reduce the duration of *S. aureus* bacteremia. As a result, many clinicians begin therapy for life-threatening infections with a 3- to 5-day course of a β-lactam and an aminoglycoside (gentamicin, 1 mg/kg intravenously every 8 h). If a MRSA strain is isolated, vancomycin (30 mg/kg every 24 h, given in two equal doses up to a total of 2 g) is recommended. Patients are treated for 4 to 6 weeks, depending on the clinical response.

In prosthetic-valve endocarditis, surgery in addition to antibiotic therapy is often necessary. The combination of a β-lactam agent—or, if the isolate is β-lactam resistant, vancomycin (30 mg/kg every 24 h, given in two equal doses up to a total of 2 g)—with an aminoglycoside (gentamicin, 1 mg/kg intravenously every 8 h) and rifampin (300 mg orally every 8 h) is recommended. This combination is used to avoid the possible emergence of rifampin resistance during therapy if only two drugs are used.

For hematogenous osteomyelitis or septic arthritis in children, a 4-week course of therapy is usually adequate. In adults, treatment is often more prolonged. For chronic forms of osteomyelitis, surgical debridement is necessary in combination with antimicrobial therapy. For joint infections, a critical component of therapy is the repeated aspiration or arthroscopy of the affected joint to prevent damage from leukocytes.

The combination of rifampin with ciprofloxacin has been used successfully to treat prosthetic-joint infections, especially when the device cannot be removed. The efficacy of this combination may reflect the enhanced activity against staphylococci in biofilms as well as the attainment of effective intracellular concentrations.

The choice of empirical therapy for staphylococcal infections depends in part on susceptibility data for the local geographic area. Increasingly, vancomycin (in combination with an aminoglycoside or rifampin for serious infections) is the drug of choice for both community- and hospital-acquired infections.

Therapy for Toxic Shock Syndrome Supportive therapy with reversal of hypotension is the mainstay of therapy for TSS. Both fluids and pressors may be necessary. Tampons or other packing material should be promptly removed. The role of antibiotics is less clear. Some investigators recommend a combination of clindamycin and a semisynthetic penicillin. Clindamycin is advocated because, as a protein synthesis inhibitor, it reduces toxin synthesis in vitro. A semisynthetic penicillin is suggested to eliminate any potential focus of infection as well as to eradicate persistent carriage that might increase the likelihood of recurrent illness. Anecdotal reports document the successful use of intravenous immunoglobulin to treat TSS. The role of glucocorticoids in the treatment of this disease is uncertain at present.

Therapy for Other Toxin-Mediated Diseases Therapy for staphylococcal food poisoning is entirely supportive. For SSSS, antistaphylococcal therapy targets the primary site of infection.

121 STREPTOCOCCAL AND ENTEROCOCCAL INFECTIONS

Michael R. Wessels

Many varieties of streptococci are found as part of the normal human flora colonizing the respiratory, gastrointestinal, and genitourinary tracts. Several species are important causes of human disease. Group A *Streptococcus*, or *S. pyogenes*, is responsible for streptococcal pharyngitis, one of the most common bacterial infections of school-age children, and for the postinfectious syndromes of acute rheumatic fever and poststreptococcal glomerulonephritis. Group B *Streptococcus*, or *S. agalactiae*, is the leading cause of bacterial sepsis and meningitis in newborns and a major cause of endometritis and fever in parturient women. Enterococci are important causes of urinary tract infection, nosocomial bacteremia, and endocarditis. Viridans streptococci are the most common cause of bacterial endocarditis.

Streptococci are gram-positive bacteria of spherical to ovoid shape that characteristically form chains when grown in liquid media. Most streptococci that cause human infections are facultative anaerobes, although some are strict anaerobes. Streptococci are relatively fastidious organisms, requiring enriched media for growth in the laboratory. No single scheme for classification of streptococci is entirely satisfactory. Consequently, clinicians and clinical microbiologists often identify streptococci by any of several classification systems, including hemolytic pattern, Lancefield group, species name, and common or trivial name. Many of the streptococci associated with human infection produce a zone of complete hemolysis around the bacterial colony when cultured on blood agar, a pattern known as β *hemolysis*. The β-hemolytic streptococci can be classified by the Lancefield system, a serologic grouping based on the reaction of specific antisera with cell-wall carbohydrate antigens of the bacteria. With rare exceptions, organisms belonging to Lancefield groups A, B, C, and G are all β-hemolytic streptococci, and each is associated with characteristic patterns of human infection. Other streptococci produce a zone of partial (α) hemolysis, often imparting a greenish appearance to the agar. These α-hemolytic streptococci are further identified by biochemical testing and include *S. pneumoniae*, an important cause of pneumonia, meningitis, and other infections, and several species of streptococci referred to collectively as the *viridans streptococci*, which are part of the normal oral flora and are important as agents of subacute bacterial endocarditis. Finally, some streptococci are nonhemolytic, a pattern sometimes called γ *hemolysis*. The classification of the major groups of streptococci responsible for human infections is outlined in Table 121-1. Among the organisms classified serologically as group D streptococci, the enterococci are now considered to constitute a separate genus on the basis of DNA homology studies. Thus species previously designated as *S. faecalis* and *S. faecium* have been renamed *Enterococcus faecalis* and *E. faecium*, respectively. →***For further discussion of pneumococcal infections, see Chap. 119.***

GROUP A STREPTOCOCCI

Lancefield's group A consists of a single species, *S. pyogenes*. As its species name implies, this organism is associated with a variety of suppurative infections. In addition, group A streptococci can trigger the postinfectious syndromes of acute rheumatic fever (which is uniquely associated with *S. pyogenes* infection; Chap. 302) and poststreptococcal glomerulonephritis (Chap. 264).

PATHOGENESIS Group A streptococci elaborate a number of cell-surface components and extracellular products important both in the pathogenesis of infection and in the immune response of the human host. The cell wall contains a carbohydrate antigen that may be released by treatment with acid. The reaction of such acid extracts with group A–specific antiserum is the basis for the definitive identification of a streptococcal strain as *S. pyogenes*. The major surface protein of group A streptococci is M protein, which occurs in more than 100 antigenically distinct types and is the basis for the serotyping of strains with specific antisera. The M protein molecules are fibrillar structures anchored in the cell wall of the organism that extend as hairlike projections away from the cell surface. The amino acid sequence of the distal or amino-terminal portion of the M protein molecule is quite variable, accounting for the antigenic variation of the different M types, while more proximal regions of the protein are relatively conserved. A newer technique for assignment of M type to group A streptococcal isolates uses the polymerase chain reaction to amplify the

TABLE 121-1 *Classification of Streptococci*

Lancefield Group	Representative Species	Hemolytic Pattern	Typical Infections
A	*S. pyogenes*	β	Pharyngitis, impetigo, cellulitis, scarlet fever
B	*S. agalactiae*	β	Neonatal sepsis and meningitis, puerperal infection, urinary tract infection, diabetic ulcer infection, endocarditis
C	*S. equisimilis*	β	Cellulitis, bacteremia, endocarditis
D	Enterococci: *E. faecalis*; *E. faecium*	Usually nonhemolytic	Urinary tract infection, nosocomial bacteremia, endocarditis
	Nonenterococci: *S. bovis*	Usually nonhemolytic	Bacteremia, endocarditis
G	*S. canis*	β	Cellulitis, bacteremia, endocarditis, septic arthritis
Variable or nongroupable	Viridans streptococci: *S. sanguis*; *S. mitis*	α	Endocarditis, dental abscess, brain abscess
	Intermedius, *milleri*, or *anginosus* group: *S. intermedius*, *S. anginosus*, *S. constellatus*	Variable	Brain abscess, visceral abscess
	Anaerobic streptococci: *Peptostreptococcus magnus*	Usually nonhemolytic	Sinusitis, pneumonia, empyema, brain abscess, liver abscess

variable region of the M protein gene. DNA sequence analysis of the amplified gene segment can be compared with an extensive database [developed at the Centers for Disease Control and Prevention (CDC)] for assignment of M type. This method eliminates the need for typing sera, which are available in only a few reference laboratories. The presence of M protein on a group A streptococcal isolate correlates with its capacity to resist phagocytic killing in fresh human blood; this phenomenon appears to be due, at least in part, to the binding of plasma fibrinogen to M protein molecules on the streptococcal surface, which interferes with complement activation and deposition of opsonic complement fragments on the bacterial cell. This resistance to phagocytosis may be overcome by M protein–specific antibodies; thus individuals with antibodies to a given M type acquired as a result of prior infection are protected against subsequent infection with organisms of the same M type but not against that with different M types.

Group A streptococci also elaborate, to varying degrees, a polysaccharide capsule composed of hyaluronic acid. The production of large amounts of hyaluronic acid capsule by certain strains lends a characteristic mucoid appearance to the bacterial colonies. The capsular polysaccharide also plays an important role in protecting the organisms from ingestion and killing by phagocytes. In contrast to M protein, the hyaluronic acid capsule is a weak immunogen, and antibodies to hyaluronate have not been shown to be important in protective immunity; the presumed explanation is the apparent structural identity between streptococcal hyaluronic acid and the hyaluronic acid of mammalian connective tissues. The capsular polysaccharide may also play a role in group A streptococcal colonization of the pharynx by binding to CD44, a hyaluronic acid–binding protein expressed on human pharyngeal epithelial cells.

Group A streptococci produce a large number of extracellular products that may be important in local and systemic toxicity and in the spread of infection through tissues. These products include streptolysins S and O, toxins that damage cell membranes and account for the hemolysis produced by the organisms; streptokinase; DNases; protease; and pyrogenic exotoxins A, B, and C. The pyrogenic exotoxins, previously known as erythrogenic toxins, cause the rash of scarlet fever. Since the mid-1980s, pyrogenic exotoxin–producing strains of group A *Streptococcus* have been linked to unusually severe invasive infections, including necrotizing fasciitis and a systemic syndrome termed the *streptococcal toxic shock syndrome*. Several extracellular products stimulate specific antibody responses useful in the serodiagnosis of recent streptococcal infection. Tests for these antibodies are used primarily for the detection of preceding streptococcal infection in cases of suspected acute rheumatic fever or poststreptococcal glomerulonephritis.

CLINICAL MANIFESTATIONS ■ Pharyngitis

Although seen in patients of all ages, group A streptococcal pharyngitis is one of the most common bacterial infections of childhood, accounting for 20 to 40% of all cases of exudative pharyngitis in children; it is rare among those under the age of 3. Younger children may manifest streptococcal infection with a syndrome of fever, malaise, and lymphadenopathy without exudative pharyngitis. Infection is acquired through contact with another individual carrying the organism. Respiratory droplets are the usual mechanism of spread, although other routes, including food-borne outbreaks, have been well described.

The incubation period is 1 to 4 days. Symptoms include sore throat, fever and chills, malaise, and sometimes abdominal complaints and vomiting, particularly in children. Both symptoms and signs are quite variable, ranging from mild throat discomfort with minimal physical findings to high fever and severe sore throat associated with intense erythema and swelling of the pharyngeal mucosa and the presence of purulent exudate over the posterior pharyngeal wall and tonsillar pillars. Enlarged, tender anterior cervical lymph nodes commonly accompany exudative pharyngitis.

The differential diagnosis of streptococcal pharyngitis includes the many other bacterial and viral causes of pharyngitis (Table 121-2). Streptococcal infection is unlikely to be the cause of pharyngitis when symptoms and signs suggestive of viral infection are prominent (conjunctivitis, coryza, cough, hoarseness, or discrete ulcerative lesions of

TABLE 121-2 *Infectious Etiologies of Acute Pharyngitis*

Organism	Associated Clinical Syndrome(s)
VIRUSES	
Rhinovirus	Common cold
Coronavirus	Common cold
Adenovirus	Pharyngoconjunctival fever
Influenza virus	Influenza
Parainfluenza virus	Cold, croup
Coxsackievirus	Herpangina, hand-foot-and-mouth disease
Herpes simplex virus	Gingivostomatitis (primary infection)
Epstein-Barr virus	Infectious mononucleosis
Cytomegalovirus	Mononucleosis-like syndrome
HIV	Acute (primary) infection syndrome
BACTERIA	
Group A streptococci	Pharyngitis, scarlet fever
Group C or G streptococci	Pharyngitis
Mixed anaerobes	Vincent's angina
Arcanobacterium haemolyticum	Pharyngitis, scarlatiniform rash
Neisseria gonorrhoeae	Pharyngitis
Treponema pallidum	Secondary syphilis
Francisella tularensis	Pharyngeal tularemia
Corynebacterium diphtheriae	Diphtheria
Yersinia enterocolitica	Pharyngitis, enterocolitis
Yersinia pestis	Plague
Chlamydiae	
Chlamydia pneumoniae	Bronchitis, pneumonia
Chlamydia psittaci	Psittacosis
Mycoplasmas	
Mycoplasma pneumoniae	Bronchitis, pneumonia

the buccal or pharyngeal mucosa). Other infections commonly producing exudative pharyngitis include infectious mononucleosis and adenovirus infection. Now rare in the United States, the pseudomembrane of diphtheria may give a similar appearance. The coryneform organism *Arcanobacterium haemolyticum* may cause pharyngitis, often in association with a scarlet fever–like rash (Chap. 122). Other causes of pharyngitis, usually without a purulent exudate, include coxsackievirus, influenza virus, mycoplasmas, and *Neisseria gonorrhoeae* and acute infection with HIV. Because of the range of clinical presentations of streptococcal pharyngitis and the large number of other agents that can produce the same clinical picture, diagnosis of streptococcal pharyngitis on clinical grounds alone is not reliable.

The throat culture remains the diagnostic "gold standard." Culture of a throat specimen that is properly collected (i.e., by vigorous rubbing of a sterile swab over both tonsillar pillars) and properly processed is the most sensitive and specific means available to make a definitive diagnosis. A rapid diagnostic kit for latex agglutination or enzyme immunoassay of swab specimens can serve as a useful adjunct to the throat culture. While precise figures on sensitivity and specificity vary among studies, the rapid diagnostic kits generally are >95% specific. Thus a positive result can be relied upon for definitive diagnosis and eliminates the need for a throat culture. However, because the rapid diagnostic tests are less sensitive than throat culture (with a relative sensitivity ranging from 55 to 90% in comparative studies), a negative result should be confirmed with a throat culture.

TREATMENT

In the usual course of uncomplicated streptococcal pharyngitis, symptoms resolve after 3 to 5 days. The course is shortened little by treatment, which is given primarily to prevent suppurative complications and rheumatic fever. Prevention of rheumatic fever depends on eradication of the organism from the pharynx, not simply on resolution of symptoms, and requires 10 days of penicillin treatment—either a single intramuscular dose of benzathine penicillin G or a 10-day course of oral penicillin (Table 121-3). Erythromycin may be substituted for penicillin in the treatment of individuals allergic to penicillin. Once-daily azithromycin is a more convenient but expensive alternative. Although azithromycin is approved for a 5-day course of treatment, only limited data support equivalent efficacy to a standard 10-day treatment course. Resistance to erythromycin and other macrolides is common in isolates from several countries, including Spain, Italy, Finland, Japan, and Korea. Macrolide resistance may be becoming more prevalent elsewhere with the increasing use of this class of antibiotics. In areas in which resistance rates exceed 5 to 10%, macrolides should be avoided unless results of susceptibility testing are known. Follow-up culture after treatment is no longer routinely recommended but may be warranted in selected cases, such as those involving patients or families with frequent streptococcal infections or those occurring in situations in which the risk of rheumatic fever is thought to be high (e.g., when cases of rheumatic fever have recently been reported in the community).

TABLE 121-3 *Treatment of Group A Streptococcal Infections*

Infection	Treatment[a]
Pharyngitis	Benzathine penicillin G, 1.2 mU IM; *or* penicillin V, 250 mg PO tid or 500 mg PO bid × 10 days (Children <27 kg: Benzathine penicillin G, 600,000 units IM; *or* penicillin V, 250 mg PO bid or tid × 10 days)
Impetigo	Same as pharyngitis
Erysipelas/cellulitis	Severe: Penicillin G, 1–2 mU IV q4h Mild to moderate: Procaine penicillin, 1.2 mU IM bid
Necrotizing fasciitis/myositis	Surgical debridement; *plus* penicillin G, 2–4 mU IV q4h; *plus* clindamycin,[b] 600–900 mg q8h
Pneumonia/empyema	Penicillin G, 2–4 mU IV q4h; *plus* drainage of empyema
Streptococcal toxic shock syndrome	Penicillin G, 2–4 mU IV q4h; *plus* clindamycin,[b] 600–900 mg q8h; *plus* intravenous immunoglobulin,[b] 2 g/kg as a single dose

[a] Penicillin allergy: Erythromycin (10 mg/kg PO qid up to a maximum of 250 mg per dose) may be substituted for oral penicillin. Alternative agents for parenteral therapy include first-generation cephalosporins—if the nature of the allergy is not an immediate hypersensitivity reaction (anaphylaxis or urticaria) or another potentially life-threatening manifestation (e.g., severe rash and fever)—or vancomycin.

[b] Efficacy unproven, but recommended by several experts. See text for discussion.

COMPLICATIONS Suppurative complications of streptococcal pharyngitis have become uncommon with the widespread use of antibiotics for most cases of symptomatic streptococcal infection. The complications result from the spread of infection from the pharyngeal mucosa to deeper tissues by direct extension or by the hematogenous or lymphatic route and may include cervical lymphadenitis, peritonsillar or retropharyngeal abscess, sinusitis, otitis media, meningitis, bacteremia, endocarditis, and pneumonia. Local complications, such as abscess formation in the peritonsillar or parapharyngeal space, should be considered in a patient with unusually severe or prolonged symptoms or localized pain associated with high fever and a toxic appearance. Nonsuppurative complications include acute rheumatic fever (Chap. 302) and poststreptococcal glomerulonephritis (Chap. 264), both of which are thought to result from immune responses to streptococcal infection. Penicillin treatment of streptococcal pharyngitis has been shown to reduce the likelihood of acute rheumatic fever but not that of poststreptococcal glomerulonephritis.

Bacteriologic Treatment Failure and the Asymptomatic Carrier State Surveillance cultures have shown that up to 20% of individuals in certain populations may have asymptomatic pharyngeal colonization with group A streptococci. There are no definitive guidelines for management of these asymptomatic carriers or of asymptomatic individuals who still have a positive throat culture after a full course of treatment for symptomatic pharyngitis. A reasonable course of action is to give a single 10-day course of penicillin for symptomatic pharyngitis and, if positive cultures persist, not to re-treat unless symptoms recur. Studies of the natural history of streptococcal carriage and infection have shown that the risk both of developing rheumatic fever and of transmitting infection to others is substantially lower among asymptomatic carriers than among individuals with symptomatic pharyngitis. Therefore, overly aggressive attempts to eradicate carriage are probably not justified under most circumstances. An exception is the situation in which an asymptomatic carrier is a potential source of infection to others. Outbreaks of food-borne infection and nosocomial puerperal infection have been traced to asymptomatic carriers who may harbor the organisms in the throat, on the skin, or in the vagina or anus.

TREATMENT

In cases in which a carrier is transmitting infection to others, attempts to eradicate carriage are warranted, although data are limited on the best regimen to use to clear the organism after penicillin alone has failed. The combination of penicillin V (500 mg four times daily for 10 days) and rifampin (600 mg twice daily for the last 4 days) has been used to eliminate pharyngeal carriage. A 10-day course of oral vancomycin (250 mg four times daily) and rifampin (600 mg twice daily) has eradicated rectal colonization. However, experience is not extensive with any regimen.

Scarlet Fever Scarlet fever consists of streptococcal infection, usually pharyngitis, accompanied by a characteristic rash (Fig. 121-1). The rash arises from the effects of one of three toxins, currently designated streptococcal pyrogenic exotoxins A, B, and C, and previously known as erythrogenic or scarlet fever toxins. In the past, scarlet fever was thought to reflect infection of an individual lacking toxin-specific immunity with a toxin-producing strain of group A *Streptococcus*. Susceptibility to scarlet fever was correlated with results of the Dick test, in which a small amount of erythrogenic toxin injected intradermally produced local erythema in susceptible individuals but elicited no re-

FIGURE 121-1 Scarlet fever exanthem. Finely punctated erythema has become confluent (scarlatiniform); petechiae can occur and have a linear configuration within the exanthem in body folds (Pastia's lines). *(From Fitzpatrick, Johnson, Wolff: Color Atlas and Synopsis of Clinical Dermatology, 4th ed., New York, McGraw-Hill, 2001, with permission.)*

action in those with specific immunity. Subsequent studies have suggested that development of the scarlet fever rash may reflect a hypersensitivity reaction requiring prior exposure to the toxin. For reasons that are not clear, scarlet fever has become less common in recent years, although strains of group A streptococci that produce pyrogenic exotoxins continue to be prevalent in the population.

The symptoms of scarlet fever are the same as those of pharyngitis alone. The rash typically begins on the first or second day of illness over the upper trunk, spreading to involve the extremities but sparing the palms and soles. The rash is made up of minute papules, giving a characteristic "sandpaper" feel to the skin. Associated findings include circumoral pallor, "strawberry tongue" (enlarged papillae on a coated tongue, which later may become denuded), and accentuation of the rash in the skin folds (Pastia's lines). Subsidence of the rash in 6 to 9 days is followed after several days by desquamation of the palms and soles. The differential diagnosis of scarlet fever includes other causes of fever and generalized rash, such as measles and other viral exanthems, Kawasaki disease, toxic shock syndrome, and systemic allergic reactions (e.g., drug eruptions).

Skin and Soft Tissue Infections Group A streptococci—and occasionally other streptococcal species—cause a variety of infections involving the skin, subcutaneous tissues, muscles, and fascia. While several clinical syndromes, recognized according to the tissues involved, offer a useful means for classification of skin and soft tissue infections, not all cases fit exactly into a single category. The classic syndromes should be considered as general guides to predicting the level of tissue involvement in a particular patient, the probable clinical course, and the likelihood that surgical intervention or aggressive life-support will be required.

IMPETIGO (PYODERMA) Impetigo is a superficial infection of the skin caused primarily by group A streptococci and occasionally by other streptococci or by *Staphylococcus aureus*. Impetigo is seen most often in young children, tends to occur during the warmer months, and is more common in semitropical or tropical climates than in cooler regions. Infection is more common among children living under conditions of poor hygiene. Prospective studies have shown that colonization of unbroken skin with group A streptococci precedes the development of clinical infection. Minor trauma, such as a scratch or an insect bite, may then serve to inoculate organisms into the skin. Impetigo is best prevented, therefore, by attention to adequate hygiene. The usual sites of involvement are the face (particularly around the nose and mouth) and the legs, although lesions may occur at other locations. Individual lesions begin as red papules, which evolve quickly into vesicular and then pustular lesions that break down and coalesce to form characteristic honeycomb-like crusts (Fig. 121-2). Lesions are generally not painful, and patients do not appear ill. Fever is not a feature of impetigo and, if present, suggests either infection extending to deeper tissues or another diagnosis.

The classic presentation of impetigo usually poses little diagnostic difficulty. Cultures of impetiginous lesions often yield *S. aureus* as well as group A streptococci, but longitudinal studies have shown that, in almost all cases, streptococci can be isolated initially, with staphylococci appearing later, presumably as secondary colonizing flora. In the past, penicillin was nearly always effective against these infections; in recent years, however, penicillin treatment failures have become more common, an observation suggesting that *S. aureus* infection may have become more prominent as a cause of impetigo. *Bullous impetigo* due to *S. aureus* is distinguished from typical streptococcal infection by the presence of more extensive, bullous lesions that break down and leave thin paper-like crusts instead of the thick amber crusts of streptococcal impetigo. Other skin lesions that may be confused with impetigo include herpetic lesions—either those of orolabial herpes simplex or those of chickenpox or zoster. Herpetic lesions can generally be distinguished by their appearance as more discrete, grouped vesicles and by a positive Tzanck test. In difficult cases, cultures of vesicular fluid should yield group A streptococci in impetigo and the responsible virus in *Herpesvirus* infections.

TREATMENT

Treatment of streptococcal impetigo is the same as that for streptococcal pharyngitis. In view of evidence that *S. aureus* has become a relatively frequent cause of impetigo, empirical regimens should cover both streptococci and *S. aureus*. For example, either dicloxacillin or cephalexin can be given at a dose of 250 mg four times daily for 10 days. Topical mupirocin ointment is also effective. Rheumatic fever is not a sequela to streptococcal skin infections, although poststreptococcal glomerulonephritis may follow either skin or throat infection. The reason for this difference is not known. One hypothesis is that the immune response necessary for development of rheumatic fever occurs only after infection of the pharyngeal mucosa. In addition, the strains of group A streptococci that cause pharyngitis are generally of different M protein types than those associated with skin infections; thus the strains that cause pharyngitis may have rheumatogenic potential, while the skin-infecting strains may not.

FIGURE 121-2 Impetigo contagiosa is a superficial streptococcal or *Staphylococcus aureus* infection consisting of honey-colored crusts and erythematous weeping erosions. Occasionally, bullous lesions may be seen. *(Courtesy of Mary Spraker, MD.)*

CELLULITIS Inoculation of organisms into the skin may lead to infection involving the skin and subcutaneous tissues, or *cellulitis*. The portal of entry may be a traumatic or surgical wound, an insect bite, or any other break in skin integrity. Often, no entry site is apparent.

One form of streptococcal cellulitis, *erysipelas*, is characterized by a bright red appearance of the involved skin, which forms a plateau sharply demarcated from surrounding normal skin (Fig. 121-3). The lesion is warm to the touch, may be tender, and appears shiny and swollen. The skin often has a *peau d' orange* texture, which is thought to reflect involvement of superficial lymphatics; superficial blebs or bullae may form, usually 2 or 3 days after onset. The lesion typically develops over a few hours and is associated with fever and chills. Erysipelas tends to occur in certain characteristic locations: the malar area of the face (often with extension over the bridge of the nose to the contralateral malar region) and the lower extremities. After one episode, recurrence at the same site—sometimes years later—is not uncommon.

Classic cases of erysipelas, with the typical features described above, are almost always due to β-hemolytic streptococci, usually those of group A and occasionally those of group C or G. Often, however, the appearance of streptococcal cellulitis is not sufficiently distinctive to permit a specific diagnosis on clinical grounds. The area of involvement may not be one of the typical sites for erysipelas, the lesion may be less intensely red than usual and may fade into surrounding skin, and/or the patient may appear only mildly ill. In such cases, it is prudent to broaden the spectrum of empiric antimicrobial therapy to include other pathogens, particularly *S. aureus*, that can produce cellulitis with the same appearance. Staphylococcal infection should be suspected if cellulitis develops around a wound or an ulcer.

Streptococcal cellulitis tends to develop at anatomic sites in which normal lymphatic drainage has been disrupted, such as sites of prior episodes of cellulitis, the arm ipsilateral to a mastectomy and axillary lymph node dissection, a lower extremity previously involved in deep venous thrombosis or chronic lymphedema, or the leg from which a saphenous vein has been harvested for coronary artery bypass grafting. The organism may enter via a breach in the dermal barrier at a location some distance from the eventual site of clinical cellulitis. For example, some patients with recurrent episodes of leg cellulitis following saphenous vein removal stop having recurrent episodes only after treatment of tinea pedis on the affected extremity. Fissures in the skin presumably serve as a portal of entry for streptococci, which then produce infection more proximally in the leg at the site of previous injury. Streptococcal cellulitis may also involve recent surgical wounds. Group A streptococci are among the few bacterial pathogens that typically produce signs of wound infection and surrounding cellulitis within the first 24 h after surgery. These wound infections are usually associated with a thin exudate and may spread rapidly, either as cellulitis in the skin and subcutaneous tissue or as a deeper tissue infection (see below). Streptococcal wound infection or localized cellulitis may also be associated with *lymphangitis*, manifested by red streaks extending proximally along superficial lymphatics from the site of infection.

FIGURE 121-3 Erysipelas is a streptococcal infection of the superficial dermis and consists of well-demarcated, erythematous, edematous, warm plaques.

TREATMENT

See Table 121-3 and Chap. 110.

Deep Soft-Tissue Infections *Necrotizing fasciitis*, also referred to as *hemolytic streptococcal gangrene*, is an infection involving the superficial and/or deep fascia investing the muscles of an extremity or the trunk. The source of the infection is either the skin, with organisms introduced into the tissue as a result of trauma (sometimes trivial), or the bowel flora, with organisms released during abdominal surgery or from an occult enteric source, such as a diverticular or appendiceal abscess. The site of inoculation in both forms of necrotizing fasciitis may be inapparent and is often some distance from the site of clinical involvement; e.g., the introduction of organisms via minor trauma to the hand may be associated with clinical infection of the tissues overlying the shoulder or chest. In cases associated with the bowel flora, the infection is usually polymicrobial, involving a mixture of anaerobic bacteria (such as *Bacteroides fragilis* or anaerobic streptococci) and facultative organisms (usually gram-negative bacilli). Cases unrelated to contamination from bowel organisms are most commonly caused by group A streptococci, either alone or in combination with other organisms (most often *S. aureus*). Overall, group A streptococci are implicated in about 60% of cases of necrotizing fasciitis. The onset of symptoms is usually quite acute and is marked by severe pain at the site of involvement, malaise, fever, chills, and a toxic appearance. The physical findings, particularly early in the illness, may not be striking, with only minimal erythema of the overlying skin. Pain and tenderness are usually severe; in contrast, in more superficial cellulitis, the skin appearance is more abnormal, but pain and tenderness are only mild or moderate. As the infection progresses (often in a matter of several hours), the severity and extent of symptoms worsen, and skin changes become more evident, with the appearance of dusky or mottled erythema and edema. The marked tenderness of the involved area may evolve into anesthesia as the spreading inflammatory process produces infarction of cutaneous nerves.

Although myositis is more commonly due to *S. aureus* infection, group A streptococci occasionally produce abscesses in skeletal muscles (*streptococcal myositis*), with little or no involvement of the surrounding fascia or overlying skin. The presentation is usually subacute, but a fulminant form has been described in association with severe systemic toxicity, bacteremia, and a high mortality rate. The fulminant form may reflect the same basic disease process as that seen in necrotizing fasciitis, but with the necrotizing inflammatory process extending into the muscles themselves rather than remaining limited to the fascial layers.

TREATMENT

Once necrotizing fasciitis is suspected, early surgical exploration is both diagnostically and therapeutically indicated. Surgery reveals necrosis and inflammatory fluid tracking along the fascial planes above and between muscle groups, without involvement of the muscles themselves. The process usually extends beyond the area of clinical involvement, and extensive debridement is required. Drainage and debridement are central to the management of necrotizing fasciitis; antibiotic treatment is a useful adjunct (Table 121-3), but surgery is life-saving.

Treatment for streptococcal myositis consists of surgical drainage—usually by an open procedure that permits evaluation of the extent of the infection and ensures adequate debridement of involved tissues—and high-dose penicillin (Table 121-3).

Pneumonia and Empyema Group A streptococci are an occasional cause of pneumonia, generally in previously healthy individuals. The onset of symptoms may be abrupt or gradual. Pleuritic chest pain, fever, chills, and dyspnea are the characteristic symptoms. Cough is usually present but may not be prominent. Approximately one-half of patients

with group A streptococcal pneumonia have an accompanying pleural effusion. In contrast to the sterile parapneumonic effusions typical of pneumococcal pneumonia, those complicating streptococcal pneumonia are almost always infected. The empyema fluid is usually visible by chest radiography on initial presentation and may enlarge rapidly. These pleural collections should be drained early, as they tend to become loculated rapidly, resulting in a chronic fibrotic reaction that may require thoracotomy for removal.

Bacteremia, Puerperal Sepsis, and Streptococcal Toxic Shock Syndrome Group A streptococcal bacteremia is usually associated with an identifiable local infection. Bacteremia occurs rarely with otherwise uncomplicated pharyngitis, occasionally with cellulitis or pneumonia, and relatively frequently with necrotizing fasciitis. Bacteremia without an identified source raises the possibility of endocarditis, an occult abscess, or osteomyelitis. A variety of focal infections may arise secondarily from streptococcal bacteremia, including endocarditis, meningitis, septic arthritis, osteomyelitis, peritonitis, and visceral abscesses.

Group A streptococci are occasionally implicated in infectious complications of childbirth, usually endometritis and associated bacteremia. In the preantibiotic era, puerperal sepsis was commonly caused by group A streptococci, but currently it is more often caused by group B streptococci. Several nosocomial outbreaks of puerperal infection due to group A streptococci have been traced to an asymptomatic carrier, usually an individual present at the delivery of the infant. The site of carriage may be the skin, throat, anus, or vagina.

Beginning in the late 1980s, several reports described patients who had group A streptococcal infections associated with shock and multisystem organ failure. This syndrome has been called the streptococcal toxic shock syndrome (TSS) because it shares certain features with staphylococcal TSS. In 1993, a case definition for group A streptococcal TSS was formulated by a group of clinicians, microbiologists, and epidemiologists in conjunction with the CDC (Table 121-4). The general features of the illness include fever, hypotension, renal impairment, and respiratory distress syndrome. Various types of rash have been described, but rash usually does not develop. Laboratory abnormalities include a marked shift to the left in the white blood cell differential, with many immature granulocytes; hypocalcemia; hypoalbuminemia; and thrombocytopenia, which usually becomes more pronounced on the second or third day of illness. In contrast to those with staphylococcal TSS, the majority of patients with streptococcal TSS are bacteremic. The most common associated infection is a soft tissue infection—necrotizing fasciitis, myositis, or cellulitis—although a variety of other associated local infections have been described, including pneumonia, peritonitis, osteomyelitis, and myometritis. Streptococcal TSS is associated with a mortality rate of 30%, with most deaths secondary to shock and respiratory failure. Because of its rapidly progressive and lethal course, early recognition of the syndrome is essential. Patients should be given aggressive supportive care in the form of fluid resuscitation, pressors, and mechanical ventilation in addition to antimicrobial therapy and, in cases associated with necrotizing fasciitis, surgical debridement. Exactly why certain patients develop this fulminant syndrome is not known. Early studies of the streptococcal strains isolated from these patients demonstrated a strong association with the production of pyrogenic exotoxin A. This association has been inconsistent in subsequent cases series. Pyrogenic exotoxin A and several other streptococcal exotoxins act as superantigens to trigger release of inflammatory cytokines from T lymphocytes. Fever, shock, and organ dysfunction in streptococcal TSS may reflect, in part, the systemic effects of superantigen-mediated cytokine release.

TABLE 121-4 *Proposed Case Definition for the Streptococcal Toxic Shock Syndrome*[a]

I. Isolation of group A streptococci (*Streptococcus pyogenes*)
  A. From a normally sterile site (e.g., blood, cerebrospinal fluid, pleural or peritoneal fluid, tissue biopsy, surgical wound)
  B. From a nonsterile site (e.g., throat, sputum, vagina, superficial skin lesion)
II. Clinical signs of severity
  A. Hypotension: Systolic blood pressure of ≤90 mmHg in adults or in the 5th percentile for age in children *and*
  B. Two or more of the following signs:
    1. Renal impairment: Serum creatinine level of ≥177 μmol/L (≥2 mg/dL) for adults or at least twice the upper limit of normal for age; in patients with preexisting renal disease, elevation over baseline by a factor of at least 2
    2. Coagulopathy: Platelet count of ≤100×10^9/L (100,000/μL) *or* disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
    3. Liver involvement: Alanine aminotransferase (SGOT), aspartate aminotransferase (SGPT), or total bilirubin level at least twice the upper limit of normal for age; in patients with preexisting liver disease, elevation over baseline by a factor of at least 2
    4. Adult respiratory distress syndrome, defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure; *or* evidence of diffuse capillary leak manifested by acute onset of generalized edema; *or* pleural or peritoneal effusions with hypoalbuminemia
    5. Generalized erythematous macular rash that may desquamate
    6. Soft tissue necrosis, including necrotizing fasciitis or myositis; *or* gangrene

[a] An illness fulfilling criteria IA, IIA, and IIB is defined as a *definite* case. An illness fulfilling criteria IB, IIA, and IIB is defined as a *probable* case if no other etiology for the illness is identified.

Source: Working Group on Severe Streptococcal Infections, 1993.

TREATMENT

In light of the possible role of pyrogenic exotoxins or other streptococcal toxins in streptococcal TSS, treatment of the affected patients with clindamycin has been advocated by some authorities, who argue that, through its direct action on protein synthesis, clindamycin is more effective in rapidly terminating toxin production than penicillin—a cell-wall agent (Table 121-3). Support for this view comes from studies of an experimental model of streptococcal myositis, in which mice treated with clindamycin had a higher rate of survival than those given penicillin. Comparable data on the treatment of human infections are not available. Although clindamycin resistance in group A streptococci is uncommon (<2% among U.S. isolates), it has been documented. Thus, if clindamycin is used for initial treatment of a critically ill patient, penicillin should be given as well until the antibiotic susceptibility of the streptococcal isolate is known.

Intravenous immunoglobulin has been used as adjunctive therapy for streptococcal TSS; pooled immunoglobulin preparations contain antibodies capable of neutralizing the effects of streptococcal toxins (Table 121-3). Anecdotal reports and case series have suggested favorable clinical responses to intravenous immunoglobulin, but no prospective controlled trials of this modality of therapy have yet been reported.

STREPTOCOCCI OF GROUPS C AND G

Group C and group G streptococci are β-hemolytic bacteria that occasionally cause human infections similar to those caused by group A streptococci, including pharyngitis, cellulitis and soft-tissue infections, pneumonia, bacteremia, endocarditis, and septic arthritis. Puerperal sepsis, meningitis, epidural abscess, intraabdominal abscess, urinary tract infection, and neonatal sepsis have also been reported. Group C streptococci are a common cause of infection in domesticated animals, especially horses and cattle, and some human infections have been acquired through contact with animals or through consumption of unpasteurized milk. Bacteremia and septic arthritis more frequently involve group G than group C streptococci. Group C or G streptococcal bacteremia occurs most often in patients who are elderly or chronically ill and, in the absence of an obvious local infection, is likely to reflect endocarditis. Septic arthritis, sometimes involving multiple joints, may complicate endocarditis or develop in its absence.

TREATMENT

Penicillin is the drug of choice for treatment of infections due to group C or G streptococci. Antibiotic treatment is the same as for patients with similar syndromes due to group A *Streptococcus* (Table 121-3). Patients with bacteremia or septic arthritis should receive intravenous penicillin (2 to 4 mU every 4 h). All group C and G streptococci are sensitive to penicillin; nearly all are inhibited in vitro by concentrations of ≤0.03 μg/mL. Occasional isolates exhibit tolerance: although inhibited by low concentrations of penicillin, they are killed only by significantly higher concentrations. The clinical significance of tolerance is unknown. Because of the poor clinical response of some patients to penicillin alone, the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) is recommended by some authorities for treatment of endocarditis or septic arthritis due to group C or G streptococci; however, combination therapy has not been shown to be superior to treatment with penicillin alone. Patients with joint infections often require repeated aspiration or open drainage and debridement for cure; the response to treatment may be slow, particularly in debilitated patients and those with involvement of more than one joint. Infection of prosthetic joints almost always requires removal of the prosthesis in addition to antibiotic therapy.

GROUP B STREPTOCOCCI

Identified first as a cause of mastitis in cows, streptococci belonging to Lancefield's group B have since been recognized as a major cause of sepsis and meningitis in human neonates. Group B streptococci are also a frequent cause of peripartum fever in women and an occasional cause of serious infection in nonpregnant adults. Lancefield group B consists of a single species, *S. agalactiae*, which is definitively identified with specific antiserum to the group B cell wall–associated carbohydrate antigen. A streptococcal isolate can be classified presumptively as belonging to group B on the basis of biochemical tests, including hydrolysis of sodium hippurate (in which 99% of isolates are positive), hydrolysis of bile esculin agar (in which 99 to 100% are negative), bacitracin susceptibility (in which 92% are resistant), and production of CAMP factor (in which 98 to 100% are positive). CAMP factor is a phospholipase produced by group B streptococci that results in synergistic hemolysis with β lysin produced by certain strains of *S. aureus*. Its presence can be demonstrated by cross-streaking of the test isolate and an appropriate staphylococcal strain on a blood agar plate. Group B streptococci causing human infections are encapsulated by one of nine antigenically distinct polysaccharides. The capsular polysaccharide has been shown experimentally to be important in the virulence of the organism. Antibodies to the capsular polysaccharide afford protection against group B streptococci of the same (but not of a different) capsular type.

INFECTION IN NEONATES Two general types of group B streptococcal infection in infants are defined by the age of the patient at presentation. *Early-onset infections* occur within the first week of life, with a median age of 20 h at the onset of illness. Approximately half of these infants have signs of group B streptococcal disease at birth. The infection is acquired during or shortly before birth from organisms colonizing the maternal genital tract. Surveillance studies have shown that 5 to 40% of women are vaginal or rectal carriers of group B streptococci. Approximately 50% of infants delivered vaginally by carrier mothers become colonized, although only 1 to 2% of those colonized develop clinically evident infection. Prematurity and maternal risk factors (prolonged labor, obstetric complications, and maternal fever) are often involved. The presentation of early-onset infection is the same as that of other forms of neonatal sepsis. Typical findings include respiratory distress, lethargy, and hypotension. Essentially all infants with early-onset disease are bacteremic, one-third to one-half have pneumonia and/or respiratory distress syndrome, and one-third have meningitis.

Late-onset infections occur in infants between 1 week and 3 months of age, with a mean age at onset of 3 to 4 weeks. The infecting organism may be acquired during delivery (as in early-onset cases) or during later contact with a colonized mother, nursery personnel, or another source. Meningitis is the most common manifestation of late-onset infection and in most cases is associated with a strain of capsular type III of the organism. Infants present with fever, lethargy or irritability, poor feeding, and seizures. The various other types of late-onset infection include bacteremia without an identified source, osteomyelitis, septic arthritis, and facial cellulitis associated with submandibular or preauricular adenitis.

TREATMENT

Penicillin is the treatment of choice for all group B streptococcal infections. Empiric broad-spectrum therapy for suspected bacterial sepsis, consisting of ampicillin and gentamicin, is generally administered until culture results become available. If cultures yield group B streptococci, many pediatricians continue to administer gentamicin, along with ampicillin or penicillin, for a few days until clinical improvement becomes evident. Infants with bacteremia or soft-tissue infection should receive penicillin at a dosage of 200,000 units/kg per day in divided doses; those with meningitis should receive 400,000 units/kg per day. Meningitis should be treated for at least 14 days because of the risk of relapse with shorter courses.

Prevention The incidence of group B streptococcal infection is unusually high among infants of women with risk factors: preterm delivery, early rupture of membranes (>24 h before delivery), prolonged labor, fever, or chorioamnionitis. Because the usual source of the organisms infecting a neonate is the mother's birth canal, efforts have been made to prevent group B streptococcal infections by the identification of high-risk carrier mothers and their treatment with various forms of antibiotic or immunoprophylaxis. Prophylactic administration of ampicillin or penicillin to such patients during delivery has been shown to reduce the risk of infection in the newborn. This approach has been hampered by the logistical difficulties of identifying colonized women before delivery, since the results of vaginal cultures early in pregnancy are poor predictors of carrier status at delivery. The CDC has recommended that women be screened for anogenital colonization at 35 to 37 weeks of pregnancy by means of a swab culture of the lower vagina and anorectum; intrapartum chemoprophylaxis is recommended for women who are culture-positive and to all women, regardless of culture status, who have previously given birth to an infant with group B streptococcal infection or who have a history of group B streptococcal bacteriuria during pregnancy. Women whose culture status is unknown and who develop premature labor (<37 weeks), prolonged rupture of membranes (>18 h), or intrapartum fever should also receive intrapartum chemoprophylaxis. The recommended regimen for chemoprophylaxis is 5 million units of penicillin G followed by 2.5 million units every 4 h until delivery. Cefazolin is an alternative for women with a history of penicillin allergy who are thought not to be at high risk for anaphylaxis. For women with a history of an immediate hypersensitivity reaction, clindamycin or erythromycin may be substituted, but only if the colonizing isolate has been demonstrated to be susceptible. If susceptibility testing results are not available or indicate resistance, vancomycin should be used in this situation.

Treatment of all pregnant women who are colonized or who have risk factors for neonatal infection will result in exposure of 15 to 25% of pregnant women and newborns to antibiotics, with the attendant risks of allergic reactions and selection for resistant organisms. Although still in the developmental stages, a group B streptococcal vaccine may ultimately offer a better solution to prevention. Because transplacental passage of maternal antibodies produces protective antibody levels in the newborn, efforts are under way to develop a vaccine against group B streptococci that can be given to childbearing women before or during pregnancy. Results of phase 1 clinical trials of group B streptococcal capsular polysaccharide–protein conjugate vaccines suggest that a multivalent conjugate vaccine would be safe and highly immunogenic.

INFECTION IN ADULTS The majority of group B streptococcal infections in adults are related to pregnancy and parturition. Peripartum fever, the most common manifestation, is sometimes accompanied by symptoms and signs of endometritis or chorioamnionitis (abdominal distention and uterine or adnexal tenderness). Blood cultures are often positive, as are cultures of vaginal swabs. Bacteremia is usually transitory but occasionally results in meningitis or endocarditis. Infections in adults that are not associated with the peripartum period generally involve individuals who are elderly or have some underlying chronic illness, such as diabetes mellitus or a malignancy. Among the infections that develop with some frequency in adults are cellulitis and soft tissue infection (including infected diabetic skin ulcers), urinary tract infection, pneumonia, endocarditis, and septic arthritis. Other reported infections include meningitis, osteomyelitis, and intraabdominal or pelvic abscesses.

℞ TREATMENT

Group B streptococci are less sensitive to penicillin than group A organisms, requiring somewhat higher doses. Adults with serious localized infections (pneumonia, pyelonephritis, abscess) should receive doses in the range of 12 million units of penicillin G daily, while patients with endocarditis or meningitis should receive 18 to 24 million units per day in divided doses. Vancomycin is an acceptable alternative for patients allergic to penicillin.

ENTEROCOCCI AND NONENTEROCOCCAL GROUP D STREPTOCOCCI

ENTEROCOCCI Lancefield group D includes the enterococci, organisms now classified in a separate genus from other streptococci, and nonenterococcal group D streptococci. Enterococci are distinguished from nonenterococcal group D streptococci by their ability to grow in the presence of 6.5% sodium chloride and by the results of other biochemical tests. The enterococcal species that are significant pathogens for humans are *E. faecalis* and *E. faecium*. These organisms tend to produce infection in patients who are elderly or debilitated or in whom mucosal or epithelial barriers have been disrupted or the balance of the normal flora altered by antibiotic treatment. Urinary tract infections due to enterococci are quite common, particularly among patients who have received antibiotic treatment or undergone instrumentation of the urinary tract. Enterococci are a frequent cause of nosocomial bacteremia in patients with intravascular catheters. These organisms account for 10 to 20% of cases of bacterial endocarditis on both native and prosthetic valves. The presentation of enterococcal endocarditis is usually subacute but may be acute, with rapidly progressive valve destruction. Enterococci are frequently cultured from bile and are involved in infectious complications of biliary surgery and in liver abscesses. Moreover, enterococci are often isolated from polymicrobial infections arising from the bowel flora (e.g., intraabdominal abscesses), from abdominal surgical wounds, and from diabetic foot ulcers. While such mixed infections are frequently cured by antimicrobials not active against enterococci, specific therapy directed against enterococci is warranted when these organisms are the predominant species or are isolated from blood cultures.

℞ TREATMENT

Unlike streptococci, enterococci are not reliably killed by penicillin or ampicillin alone at concentrations achieved clinically in the blood or tissues. Ampicillin reaches sufficiently high urinary concentrations to constitute adequate monotherapy for uncomplicated urinary tract infections. Because in vitro testing has shown evidence of synergistic killing of most enterococcal strains by the combination of penicillin or ampicillin with an aminoglycoside, combined therapy is recommended for enterococcal endocarditis and meningitis; the regimen is penicillin (3 to 4 million units every 4 h) or ampicillin (2 g every 4 h) plus moderate-dose gentamicin (1 mg/kg every 8 h for patients with normal renal function). Enterococcal endocarditis should be treated for a minimum of 4 weeks and for 6 weeks if symptoms have been present for ≥3 months or if the infection involves a prosthetic heart valve. For nonendocarditis bacteremia and other serious enterococcal infections, it is not known whether the efficacy of single-agent β-lactam therapy is improved by the addition of gentamicin, but many infectious disease specialists use combination therapy for such infections, especially in critically ill patients. Vancomycin, in combination with gentamicin, may be substituted for penicillin in allergic patients. Enterococci are resistant to all cephalosporins; therefore, this class of antibiotics should not be used for treatment of enterococcal infections.

Antimicrobial susceptibility testing should be performed routinely on enterococcal isolates from patients with serious infections, and therapy should be adjusted according to the results (Table 121-5). Most enterococci are resistant to streptomycin, and this drug should not be used for treatment of enterococcal infection unless in vitro testing of the strain indicates susceptibility. Though less widespread than streptomycin resistance, high-level resistance to gentamicin—with a minimum inhibitory concentration (MIC) of >2000 μg/mL—has become common. Gentamicin-resistant enterococci should be tested for susceptibility to streptomycin; occasional gentamicin-resistant enterococci are sensitive to streptomycin. If the isolate is resistant to all aminoglycosides, treatment with penicillin or ampicillin alone may be successful. The prolonged administration (i.e., for at least 6 weeks) of high-dose ampicillin (e.g., 12 g/d) is recommended for endocarditis due to these highly resistant enterococci.

Enterococci may be resistant to penicillins via two distinct mechanisms. The first is the production of β-lactamase (mediating resistance to penicillin and ampicillin), which has been reported for *E. faecalis* isolates from several locations in the United States and other countries. Because the amount of β-lactamase produced by enterococci may be insufficient for detection by routine antibiotic susceptibility testing, isolates from serious infections should be screened specifically for β-lactamase production with use of a chromogenic cephalosporin or by another method. For the treatment of β-lactamase-producing strains, vancomycin, ampicillin/sulbactam, amoxicillin/clavulanate, or imipenem may be used in combination with gentamicin.

The second mechanism of penicillin resistance is not mediated by β-lactamase and may be due to altered penicillin-binding proteins. This intrinsic penicillin resistance is common among *E. faecium* isolates, which routinely are more resistant to β-lactam antibiotics than are isolates of *E. faecalis*. Moderately resistant enterococci (MICs of penicillin and ampicillin, 16 to 64 μg/mL) may be susceptible to high-dose penicillin or ampicillin plus gentamicin, but strains with MICs of ≥200 μg/mL must be considered resistant to clinically achievable levels of β-lactam antibiotics, including imipenem. Vancomycin plus gentamicin is the recommended regimen for infections due to enterococci with high-level intrinsic resistance to β-lactams.

Vancomycin-resistant enterococci, first reported from clinical sources in the late 1980s, have become common in many hospitals.

TABLE 121-5 *Treatment Options for Antibiotic-Resistant Enterococcal Infections*

Resistance Pattern	Recommended Therapy
β-Lactamase production	Gentamicin plus ampicillin/sulbactam, amoxicillin/clavulanate, imipenem, or vancomycin
β-Lactam resistance, but no β-lactamase production	Gentamicin plus vancomycin
High-level gentamicin resistance	Streptomycin-sensitive isolate: Streptomycin plus ampicillin or vancomycin Streptomycin-resistant isolate: No proven therapy (continuous-infusion ampicillin, prolonged treatment)
Vancomycin resistance	Ampicillin plus gentamicin
Vancomycin and β-lactam resistance	No uniformly bactericidal drugs; linezolid (all enterococci) or quinupristin/dalfopristin (*E. faecium* only)

Three major vancomycin resistance phenotypes have been described: VanA, VanB, and VanC. The VanA phenotype is associated with high-level resistance to vancomycin and to teicoplanin, a related glycopeptide antibiotic not currently available in the United States. VanB and VanC strains are resistant to vancomycin but susceptible to teicoplanin, although teicoplanin resistance may develop during treatment in VanB strains. For enterococci resistant to both vancomycin and β-lactams, there are no established therapies that provide uniformly bactericidal activity. Regimens that have been tried with some success in individual cases or experimentally include ciprofloxacin plus rifampin plus gentamicin; ampicillin plus vancomycin (particularly if in vitro testing shows synergistic bacteriostatic activity); and chloramphenicol or tetracycline (if the strain is susceptible in vitro). Two newer agents with activity against vancomycin-resistant enterococci are quinupristin/dalfopristin and linezolid, which were approved for use in the United States in 1999 and 2000, respectively. Quinupristin/dalfopristin is a streptogramin combination with in vitro bacteriostatic activity against *E. faecium*, including vancomycin-resistant isolates, but not against *E. faecalis* or other enterococcal species. Favorable clinical responses have been obtained in approximately three-quarters of patients treated with this agent. Linezolid is an oxazolidinone antibiotic with good bacteriostatic activity against nearly all enterococci, including vancomycin-resistant enterococci. Limited clinical experience suggests that linezolid is at least as efficacious as quinupristin/dalfopristin.

OTHER GROUP D STREPTOCOCCI The main nonenterococcal group D streptococcal species that causes human infections is *S. bovis*. *S. bovis* endocarditis is often associated with neoplasms of the gastrointestinal tract—most frequently a colon carcinoma or polyp—but is also reported in association with other bowel lesions. When occult gastrointestinal lesions are carefully sought, abnormalities are found in ≥60% of patients with *S. bovis* endocarditis. In contrast to the enterococci, nonenterococcal group D streptococci like *S. bovis* are reliably killed by penicillin as a single agent, and penicillin is the treatment of choice for *S. bovis* infections.

VIRIDANS AND OTHER STREPTOCOCCI

VIRIDANS STREPTOCOCCI Consisting of multiple species of α-hemolytic streptococci, the viridans streptococci are a heterogeneous group of organisms that are important as agents of bacterial endocarditis (Chap. 109). Several species of viridans streptococci, including *S. salivarius*, *S. mitis*, *S. sanguis*, and *S. mutans*, are part of the normal flora of the mouth, where they live in close association with the teeth and gingiva. Some species contribute to the development of dental caries. The transient viridans streptococcal bacteremia induced by eating, tooth-brushing, flossing, and other sources of minor trauma, together with adherence to biologic surfaces, is thought to account for the predilection of these organisms to cause endocarditis (see Fig. 109-1). Viridans streptococci are also isolated, often as part of a mixed flora, from sites of sinusitis, brain abscess, and liver abscess.

Viridans streptococcal bacteremia occurs relatively frequently in neutropenic patients, particularly after bone marrow transplantation or high-dose chemotherapy for cancer. Some of these patients develop a sepsis syndrome with high fever and shock. Risk factors for viridans streptococcal bacteremia include chemotherapy with high-dose cytosine arabinoside, prior treatment with trimethoprim-sulfamethoxazole or a fluoroquinolone, treatment with antacids or histamine antagonists, mucositis, and profound neutropenia.

The *S. milleri* group (also referred to as the *S. intermedius* or *S. anginosus* group) includes three species that cause human disease: *S. intermedius*, *S. anginosus*, and *S. constellatus*. These organisms are often considered viridans streptococci, although they differ somewhat from other viridans streptococci in both their hemolytic pattern (they may be α-, β-, or nonhemolytic) and the disease syndromes they cause. This group commonly produces suppurative infections, particularly abscesses of brain and abdominal viscera, and infections related to the oral cavity or respiratory tract, such as peritonsillar abscess, lung abscess, and empyema.

TREATMENT

Isolates from neutropenic patients with bacteremia are often resistant to penicillin; thus these patients should be treated presumptively with vancomycin until the results of susceptibility testing become available. Viridans streptococci isolated in other clinical settings usually are sensitive to penicillin.

ABIOTROPHIA SPECIES (NUTRITIONALLY VARIANT STREPTOCOCCI)

Occasional isolates cultured from the blood of patients with endocarditis fail to grow when subcultured on solid media. These *nutritionally variant streptococci* require supplemental thiol compounds or active forms of vitamin B_6 (pyridoxal or pyridoxamine) for growth in the laboratory. The nutritionally variant streptococci are generally grouped with the viridans streptococci because they cause similar types of infections. However, they have been reclassified on the basis of 16S ribosomal RNA sequence comparisons into a separate genus, *Abiotrophia*, with two species: *A. defectivus* and *A. adjacens*.

TREATMENT

Treatment failure and relapse appear to be more common in cases of endocarditis due to nutritionally variant streptococci than in those due to the usual viridans streptococci. Thus the addition of gentamicin (1 mg/kg every 8 h for patients with normal renal function) to the penicillin regimen is recommended in therapy for endocarditis due to the nutritionally variant organisms.

OTHER STREPTOCOCCI

S. suis is an important pathogen in swine and has been reported to cause meningitis in humans, usually in individuals with occupational exposure to pigs. Strains of *S. suis* associated with human infections have generally reacted with Lancefield group R typing serum and sometimes with group D typing serum as well. Isolates may be α- or β-hemolytic and are sensitive to penicillin. *S. iniae*, a pathogen of fish, has been associated with infections in humans who have handled live or freshly killed fish. Cellulitis of the hand is the most common form of human infection, although bacteremia and endocarditis have been reported. *Anaerobic streptococci*, or *peptostreptococci*, are part of the normal flora of the oral cavity, bowel, and vagina. Infections caused by the anaerobic streptococci are discussed in Chap. 148.

122 DIPHTHERIA AND OTHER CORYNEBACTERIAL INFECTIONS

Randall K. Holmes

DIPHTHERIA

DEFINITION Diphtheria is a localized infection of mucous membranes or skin that is caused by *Corynebacterium diphtheriae* and may be associated with a characteristic pseudomembrane at the site of infection (Fig. 122-1). Some strains of *C. diphtheriae* produce diphtheria toxin, a protein that can cause myocarditis, polyneuropathy, and other systemic toxic effects. Respiratory diphtheria is usually caused by toxinogenic (tox$^+$) *C. diphtheriae*, but infections of the skin (cutaneous diphtheria) and other anatomical sites are often caused by nontoxinogenic (tox$^-$) *C. diphtheriae*. Respiratory diphtheria caused by either tox$^+$ or tox$^-$ isolates of *C. diphtheriae*—but not cutaneous diphtheria—is a nationally notifiable infectious disease in the United States.

ETIOLOGY *C. diphtheriae* is an aerobic, nonmotile, nonsporulating, irregularly staining, gram-positive rod. The bacteria are club-shaped and are often arranged in clusters (*Chinese letters*) or parallel arrays (*palisades*). Selective media containing either tellurite or colisitin plus nalidixic acid are recommended for cultivation of *C. diphtheriae*. The gravis, mitis, and intermedius biotypes are distinguished by colonial morphology and laboratory tests. Both tox$^+$ and tox$^-$ strains are infectious, but tox$^+$ strains can produce toxemic diphtheria and are more likely to cause pseudomembranes. Diphtheria toxin is encoded by specific corynephages, and tox$^-$ *C. diphtheriae* (or other *Corynebacterium* species, such as *C. ulcerans* and *C. pseudotuberculosis*) can acquire the ability to produce diphtheria toxin by infection with tox$^+$ phages (*phage conversion*). Growth of *C. diphtheriae* under low-iron conditions that mimic the environment of host tissues induces production of diphtheria toxin and expression of systems for siderophore-dependent iron uptake, utilization of iron from heme, and several other iron-regulated functions.

IMMUNOLOGY Treatment of diphtheria toxin with formaldehyde converts it to a nontoxic but immunogenic product (*diphtheria toxoid*). Immunization with toxoid elicits antibody (*antitoxin*) that neutralizes the toxin and prevents diphtheria. The attack rate and mortality rate for diphtheria are low in immune individuals with antitoxin titers of >0.01 unit per milliliter. Antitoxin neither prevents colonization by *C. diphtheriae* nor eradicates the *carrier state*. When most individuals in a population have protective levels of antitoxin (*herd immunity*), the carrier rate for tox$^+$ strains of *C. diphtheriae* falls to a low level, and the risk that susceptible individuals will be exposed to tox$^+$ *C. diphtheriae* decreases dramatically. Susceptible individuals may contract diphtheria if they travel to regions where the disease is present or if tox$^+$ strains of *C. diphtheriae* are introduced into their community.

FIGURE 122-1 Pseudomembrane of diphtheria. Diphtheria is now a rare cause of exudative pharyngitis in the United States, but outbreaks continue to occur in under-immunized countries and regions. The pharyngitis has an acute onset, is characterized by severe dysphagia, and is accompanied by a thick, tenacious, gray-white exudate on the tonsils, uvula, and pharynx. As the exudate coagulates, it forms a so-called pseudomembrane, which may result in respiratory obstruction. *[From Upper Respiratory and Head and Neck Infections, Vol. IV, I. Brook (ed), in Atlas of Infectious Diseases, GL Mandell (ed). Philadelphia, Current Medicine, Inc., with permission.]*

EPIDEMIOLOGY AND IMMUNITY Humans are the principal reservoir for *C. diphtheriae*. Transmission occurs primarily by close personal contact. The risk that *C. diphtheriae* will be transmitted to susceptible individuals from patients with diphtheria is greater than the risk that it will be transmitted to them from carriers. The incubation period for respiratory diphtheria is typically 2 to 5 days (range, 1 to 10 days). Cutaneous diphtheria is usually a secondary infection whose signs develop an average of 7 days (range, 1 to >21 days) after the appearance of other primary dermatologic lesions.

In temperate climates, diphtheria primarily involves the respiratory tract. It occurs throughout the year, with a peak incidence in colder months, and it is usually caused by tox$^+$ *C. diphtheriae*. Before immunization was introduced, diphtheria was primarily a disease of children; it affected up to 10% of individuals in this group and sometimes caused devastating epidemics. Most young infants were immune because of transplacental transfer of maternal IgG antitoxin, but children became susceptible by 6 to 12 months of age. Approximately 75% of individuals became immune by 10 years of age as a result of contact with *C. diphtheriae*. Mortality rates of 30 to 40% were common in untreated disease and were sometimes >50% in epidemics. Treatment with antitoxin reduced the case-fatality rate to 5 to 10%.

Routine immunization of children in the United States resulted in a progressive decrease of diphtheria from the peak of 206,939 cases (incidence rate, 191 cases per 100,000 population) in 1921 to ≤5 cases per year since 1980. Circulation of tox$^+$ strains of *C. diphtheriae* among the population decreased dramatically throughout this period, but endemic foci of clonally related tox$^+$ and tox$^-$ strains, belonging predominantly to the ET215 complex, have persisted for the past 25 years in South Dakota and Ontario. As the incidence of diphtheria decreased, a higher proportion of cases occurred in older persons (who were never immunized or whose immunity waned because they did not receive booster doses of vaccine or did not have contact with *C. diphtheriae*), but the case-fatality ratio remained unchanged at 5 to 10%. High rates of immunization are achieved by school entry (>96%), but immunization rates for younger children are substantially lower. Immunity to diphtheria among adults declines gradually with increasing age, and only 30% of men in the 60- to 69-year-old age group have protective levels of diphtheria antitoxin. Among adults immunity to diphtheria is typically lower among women than among men; likewise, it is lower among Mexican-Americans than among other racial or ethnic groups. The most recent large diphtheria outbreak in the United States (about 1100 cases) occurred in Seattle, Washington, between 1972 and 1982. Alcoholism, low socioeconomic status, crowded living conditions, and Native-American ethnic background were significant risk factors in this outbreak.

A massive diphtheria epidemic (>157,000 cases and >5000 deaths) occurred during the 1990s in Russia and the newly independent states of the former Soviet Union and accounted for >80% of diphtheria cases reported worldwide during that decade. The epidemic began in 1990 with 1436 cases (0.49 per 100,000 population) and peaked in 1995 with 50,425 cases (17.29 per 100,000 population). Clonally related tox$^+$ *C. diphtheriae* stains of the ET8 complex, which constituted only a small percentage of archival *C. diphtheriae* isolates from Russia before that epidemic, increased dramatically in prevalence, ac-

counting for >80% of isolates by 1994. Molecular analysis of *tox* gene alleles from isolates of the ET8 complex demonstrated that the existing diphtheria toxoid vaccine remained appropriate for ongoing use as a protective immunogen, and a mass vaccination program succeeded in reducing the number of cases to 2720 in 1998 (0.93 per 100,000 population). A majority of cases throughout this epidemic occurred in persons ≥15 years old, and adults from 40 to 49 years old had very high incidence and death rates. In 1994, case-fatality rates varied from 2.8% in the Russian Federation to 23% in Lithuania and Turkmenistan. Factors that facilitated the spread of this epidemic included large-scale population movements, socioeconomic instability, deteriorating health infrastructure, delayed implementation of aggressive control measures in response to the epidemic, inadequate information for physicians and the public, and frequent shortages of supplies for prevention and treatment of the disease. The most important risk factor for diphtheria in the Republic of Georgia was lack of vaccination (matched odds ratio, 19.2), but household diphtheria exposure, exposure to skin lesions, the presence of tonsils, a history of eczema, preceding fever with myalgia, sharing a bed, sharing glasses and cups, and taking a bath less often than weekly were also significant risk factors. Although small numbers of imported cases from this epidemic occurred in western European countries, none resulted in secondary transmission of diphtheria, notwithstanding a high proportion of susceptible adults in countries with imported cases. Inadequate primary immunization of children in the states of the former Soviet Union in the years preceding the epidemic, along with failure to maintain adequate immunity in adults by booster immunization, appear to have been primary factors in the development of the massive diphtheria epidemic in this region.

In the tropics, cutaneous diphtheria is more common than respiratory diphtheria, occurs throughout the year, and often develops as a secondary infection complicating other dermatoses. Isolates of *C. diphtheriae* from skin lesions are more often tox^- than tox^+. Cutaneous diphtheria is increasingly recognized in temperate climates and accounted for 86% of the 1100 cases in the Seattle epidemic of 1972 to 1982. Since 1980, cutaneous diphtheria has not been a reportable disease in the United States, and recent health statistics include only respiratory diphtheria.

During the 1990s, tox^- strains of *C. diphtheriae* were associated with new types of infections. In the United Kingdom, these strains caused symptomatic pharyngitis, predominantly among homosexual men, that was sometimes accompanied by tonsillar exudate. In Switzerland, strains with a high potential for invasiveness were isolated from 38 intravenous drug users and shown by ribotyping to be clonally related. The latter strains caused infections of the skin (15 cases), respiratory tract (10 cases), and blood (13 cases). Among the patients with bloodstream infections, 9 had endocarditis, and 4 of these 9 patients died.

PATHOLOGY AND PATHOGENESIS *C. diphtheriae* infects mucous membranes, most commonly in the respiratory tract, and also invades open skin lesions resulting from insect bites or trauma. In infections caused by tox^+ *C. diphtheriae*, initial edema and hyperemia are often followed by epithelial necrosis and acute inflammation. Coagulation of the dense fibrinopurulent exudate produces a pseudomembrane (Fig. 122-1), and the inflammatory reaction accompanied by vascular congestion extends into the underlying tissues. The pseudomembrane contains large numbers of *C. diphtheriae* organisms, but the bacteria are rarely isolated from the blood or internal organs.

Diphtheria toxin acts both locally and systemically, and the lethal dose for humans is ~0.1 μg/kg. Toxin contributes locally to pseudomembrane formation; systemically, it can cause myocarditis, polyneuropathy, and focal necrosis in various organs, including the kidneys, liver, and adrenal glands. Changes in the myocardium include cloudy swelling of muscle fibers and interstitial edema. These changes are followed within weeks by hyaline and granular degeneration (sometimes with fatty degeneration), progressing to myolysis and finally to the replacement of lost muscle by fibrosis. Thus, diphtheria can cause permanent cardiac damage. In diphtheritic polyneuropathy, pathologic changes include patchy breakdown of myelin sheaths in peripheral and autonomic nerves, but recovery of nerve damage is the rule if the patient survives.

Diphtheria toxin is produced by *C. diphtheriae* as an extracellular polypeptide. Proteolytic cleavage of the intact toxin forms nicked toxin consisting of fragments A and B. Fragment B binds to a plasma-membrane receptor (a precursor of a heparin-binding growth factor resembling epidermal growth factor), and the bound toxin is internalized by receptor-mediated endocytosis. Fragment A is translocated across the membrane of acidified endosomes and released into the cytoplasm, where it catalyzes the transfer of the adenosine diphosphate ribose moiety from nicotinamide adenine dinucleotide (NAD) to a modified histidine residue (diphthamide) on elongation factor 2 (EF-2), thereby inactivating EF-2 and inhibiting protein synthesis. One molecule of fragment A in the cytoplasm can kill a cell. Other metabolic alterations are secondary to inhibition of protein synthesis.

CLINICAL MANIFESTATIONS ■ Respiratory Diphtheria The current epidemiologic case definition of diphtheria used by the Centers for Disease Control and Prevention (CDC) is based on both a clinical syndrome [upper respiratory tract illness with sore throat, low-grade fever, and an adherent membrane of the tonsil(s), pharynx, and/or nose] and laboratory criteria (isolation of *C. diphtheriae* from a clinical specimen or a histopathologic diagnosis of diphtheria). Clinically compatible cases are classified as *confirmed* if they are either confirmed by the laboratory or epidemiologically linked to a laboratory-confirmed case and as *probable* if they are neither confirmed by the laboratory nor linked to a laboratory-confirmed case. By these criteria, both asymptomatic individuals and patients with respiratory findings but no pseudomembrane are classified as *carriers* if *C. diphtheriae* is isolated from the respiratory tract. On clinical grounds, diphtheria is graded as *tonsillar* if pseudomembranes are localized to the tonsils, as *combined types* or *delayed diagnosis* if more extensive pseudomembranes are present, and as *severe* if cervical adenopathy or cervical edema is also present. Onset is often gradual, but most patients seek medical care within a few days of becoming ill. Fever [a temperature of 37.8° to 38.9°C (100° to 102°F)], sore throat, and weakness are the most common symptoms, while dysphagia, headache, and change of voice occur in fewer than half of patients. Neck edema and difficulty breathing are noted in ≤10% of patients and are associated with an increased risk of death. Systemic manifestations are due primarily to toxic effects of diphtheria toxin. Patients without toxicity exhibit discomfort and malaise associated with local infection, whereas severely toxic patients may develop listlessness, pallor, and tachycardia that can progress rapidly to vascular collapse.

Primary infection in the respiratory tract is most often tonsillopharyngeal but may also be (in decreasing order of frequency) laryngeal, nasal, and tracheobronchial. Multiple sites are frequently involved, and secondary spread of pharyngeal infection upward to the nasal mucosa or downward to the larynx and tracheobronchial tree is much more common than primary infection at those sites. Systemic toxicity is usually most severe when extensive pseudomembrane extends from the tonsils and pharynx into contiguous regions. A small percentage of patients present with malignant or "bull-neck" diphtheria, with extensive pseudomembrane formation, foul breath, massive swelling of the tonsils and uvula, thick speech, cervical lymphadenopathy, striking edematous swelling of the submandibular region and anterior neck, and severe toxicity.

In tonsillopharyngeal diphtheria, isolated spots of gray or white exudate may appear first. These spots often extend and coalesce within a day to form a confluent, sharply demarcated pseudomembrane (Fig. 122-1) that becomes progressively thicker, more tightly adherent to the underlying tissue, and darker gray in color. Unlike the exudate in streptococcal pharyngitis, the diphtheritic pseudomembrane often extends beyond the margin of the tonsils onto the tonsillar pillars, palate, or uvula. Dislodging the membrane is likely to cause bleeding. Laryn-

geal diphtheria often presents as hoarseness and cough. Demonstration of laryngeal pseudomembrane by laryngoscopy helps distinguish diphtheria from other infectious forms of laryngitis. Patients with nasal diphtheria may present with unilateral or bilateral serosanguineous nasal discharge associated with irritation of the nares or lip. Primary or secondary diphtheritic infection occasionally involves other mucous membranes, including the conjunctiva and the membranes of the genitourinary and gastrointestinal tracts.

Cutaneous Diphtheria Cutaneous diphtheria usually presents as an infection by *C. diphtheriae* of preexisting dermatoses involving the lower extremities, upper extremities, head, or trunk. The clinical features are similar to those of other secondary cutaneous bacterial infections. In the tropics, cutaneous diphtheria may present as a primary cutaneous lesion, typically with morphologically distinct "punched-out" ulcers that are covered by necrotic slough or membrane and have well-demarcated edges.

Other Clinical Presentations *C. diphtheriae* is an occasional cause of invasive infections, including endocarditis and septic arthritis. Risk factors for such infections include preexisting cardiac abnormalities, abuse of intravenous drugs, and alcoholic cirrhosis.

COMPLICATIONS Obstruction of the respiratory tract can be caused by extensive pseudomembrane formation and swelling early in the disease or by sloughed pseudomembrane that becomes lodged in the airways later in the disease. The risk is greater when infection involves the larynx or the tracheobronchial tree and in children because of the small size of the airways.

Myocarditis and polyneuropathy are the prominent toxic manifestations of diphtheria. The risk of each is proportional to the severity of local disease. Myocarditis occurred in 22% and neuropathy in 5% of 656 hospitalized patients (54% female, 70% ≥15 years old) with diphtheria in the Kyrgyz Republic in 1995; 7% of patients with myocarditis and 2% of patients without myocarditis died. The median interval from hospitalization to death was 4.5 days (range, 0 to 13 days). Manifestations of diphtheritic myocarditis include various dysrhythmias, conduction disturbances, and dilated cardiomyopathy. Although complete heart block from diphtheritic myocarditis was almost always fatal before temporary cardiac pacemakers were developed, approximately one-fourth of patients with this complication have recently been treated successfully.

Polyneuropathy typically begins 3 to 5 weeks after onset of diphtheria and has a slow course. It appears earliest in patients who experience the most severe and prolonged neurologic abnormalities. The initial presentation commonly involves gingival, lingual, or facial numbness as well as dysphonia, dysphagia, and paresthesias of the extremities. These findings may be followed by cranial motor nerve pareses, respiratory and abdominal muscle weakness that may require artificial ventilation, quadriparesis or quadriplegia, peripheral sensory disturbances, sensory ataxia, pain in the extremities, and a variety of autonomic disturbances. Cranial nerve dysfunction typically appears earlier than motor disturbances of the trunk and extremities. In severely affected patients, paresis or paralysis of the trunk and extremities may become worse during the second month, as cranial nerve dysfunction is improving, and peak at 7 to 9 weeks after the onset of polyneuropathy. Severe arterial hypotension attributable to autonomic dysfunction may occur from 4 to 7 weeks after the onset of polyneuropathy and last from 3 to 10 days. Polyneuropathy usually resolves completely in patients who survive.

Pneumonia occurs in more than one-half of fatal cases of diphtheria. Less common complications include renal failure, encephalitis, cerebral infarction, pulmonary embolism, and bacteremia or endocarditis due to invasive infection by *C. diphtheriae*. Serum sickness may result from antitoxin therapy.

COURSE AND PROGNOSIS Most cases of diphtheria develop in nonimmunized patients. The attack rate, severity of disease, and risk of complications are much lower in immunized patients. The pseudomembrane may continue to increase in size during the first day after administration of antitoxin. During the next several days to a week, it becomes softer, less adherent, and nonconfluent and eventually disappears. In the preantibiotic era, *C. diphtheriae* persisted in the throat for ~2 weeks in one-half of patients and for ≥1 month in about one-fifth. Mortality increases with the severity of local disease, the extent of pseudomembrane formation, and the delay between onset of local disease and administration of antitoxin. The death rate is highest during the first week of illness; among patients with bull-neck diphtheria; among patients with myocarditis who develop ventricular tachycardia, atrial fibrillation, or complete heart block; among patients with laryngeal or tracheobronchial involvement; among infants and patients >60 years of age; and among alcoholics. Both the mortality rate and the risk of myocarditis or peripheral neuropathy are significantly lower in cutaneous diphtheria than in respiratory diphtheria.

DIAGNOSIS A characteristic pseudomembrane (Fig. 122-1) on the mucosa of the tonsils, palate, oropharynx, nasopharynx, nose, or larynx suggests diphtheria but is not uniformly present. Diphtheritic pseudomembrane must be distinguished from other pharyngeal exudates, including those of group A β-hemolytic streptococcal infections, infectious mononucleosis, viral pharyngitis, fusospirochetal infection, and candidiasis. Diphtheria should be considered in patients with sore throat, cervical adenopathy or swelling, and low-grade fever, especially when these manifestations are accompanied by systemic toxicity, hoarseness, stridor, palatal paralysis, or serosanguineous nasal discharge with or without demonstrable pseudomembrane. Treatment with diphtheria antitoxin should begin as soon as the clinical diagnosis of diphtheria is made.

Definitive diagnosis of respiratory diphtheria is based on compatible clinical findings supported by the isolation of *C. diphtheriae* from local lesions or by histopathology. Rarely, respiratory diphtheria may be caused by infection with tox^+ *C. ulcerans*, and such cases should be managed like cases caused by *C. diphtheriae*. *C. pseudodiphtheriticum*, a tox^- organism that is often part of the normal throat flora, can be associated with pseudomembranous pharyngitis or lower respiratory tract infection; however, unlike. *C. diphtheriae*, it does not pose a significant risk to contacts of infected patients. Specimens from the nose, throat, and membrane (and, when possible, from beneath the membrane) should be submitted for culture. The laboratory should be notified that diphtheria is suspected to ensure that one appropriate selective medium, such as cysteine-tellurite blood agar or Tinsdale medium, is used in addition to a nonselective medium (e.g., sheep blood agar) for primary plating of the specimens. Biochemical tests needed to differentiate *C. diphtheriae* from corynebacteria of the normal flora (diphtheroids) require several days. Group A β-hemolytic streptococci and *Staphylococcus aureus* are also isolated frequently from patients with diphtheria. All laboratory isolates of *C. diphtheriae*, whether or not they are associated with disease, should be submitted to the Diphtheria Laboratory, National Center for Infectious Diseases, CDC, for confirmation of biotype and toxinogenicity and for other specialized tests.

Cutaneous diphtheria may present as a characteristic "punched-out" ulcer with a membrane, but it is more often indistinguishable from other inflammatory dermatoses. Diagnosis depends on a high degree of suspicion and on culture of cutaneous lesions on laboratory media appropriate for isolation of *C. diphtheriae*. Throat samples from all patients with cutaneous diphtheria should be cultured for *C. diphtheriae*.

℞ TREATMENT

Administration of diphtheria antitoxin is the most import element in the treatment of respiratory diphtheria. The decision to administer diphtheria antitoxin must be based on the clinical diagnosis of respiratory diphtheria, without waiting for definitive laboratory confirmation. Since antitoxin cannot neutralize toxin that is already bound to tissues, each day of delay in initiating treatment with antitoxin is associated with a significant increase in mortality risk. Because diphthe-

ria antitoxin is produced in horses, it is necessary to question patients about possible allergy to horse serum and to perform a conjunctival or intracutaneous test with diluted antitoxin for immediate hypersensitivity. Epinephrine must be available for immediate administration to patients with severe allergic reactions. Patients with immediate hypersensitivity should be desensitized before a full therapeutic dose of antitoxin is given. The risk of serum sickness associated with administration of equine antitoxin is acceptable because of the established therapeutic value of antitoxin in decreasing mortality from respiratory diphtheria. Since 1997, diphtheria antitoxin has been available in the United States only from the CDC and is distributed under an Investigational New Drug (IND) protocol. Physicians should promptly notify their state health departments of suspected diphtheria cases. To obtain diphtheria antitoxin and consultation on its use, physicians should promptly contact staff at the National Immunization Program at (404) 639-8255 during office hours from 8:00 A.M. to 4:30 P.M. eastern standard time or through the CDC operator at (404) 639-2889 or (404) 639-2888 at any time.

Antibiotics have little demonstrated effect on the healing of local infection in diphtheria patients treated with antitoxin. The primary goal of antibiotic therapy for patients or carriers is therefore to eradicate *C. diphtheriae* and prevent its transmission from the patient to susceptible contacts. Regimens currently recommended by the CDC for the treatment of patients with respiratory diphtheria are erythromycin given orally or by injection for 14 days (40 mg/kg per day; maximum, 2 g/d) or procaine penicillin G given intramuscularly for 14 days (300,000 U/d for patients weighing ≤10 kg and 600,000 U/d for those weighing >10 kg). Rifampin or clindamycin has also been used successfully and is an acceptable alternative for treating patients who cannot take penicillin G or erythromycin. Eradication of *C. diphtheriae* should be documented by negative cultures of samples taken on two or three successive days at least 24 h after the completion of antibiotic therapy. Some authorities also recommend a repeat throat culture 2 weeks later. The small percentage of patients who continue to be infected with *C. diphtheriae* after treatment with penicillin or erythromcyin should receive an additional 10-day course of oral erythromycin followed by a repeat culture for *C. diphtheriae*. Plasmid-mediated resistance to erythromycin emerged transiently in *C. diphtheriae* during the Seattle epidemic, but its frequency declined dramatically after the routine use of erythromycin was discontinued.

Patients with respiratory or cutaneous diphtheria caused by tox^+ *C. diphtheriae* or by *C. diphtheriae* strains of unknown toxinogenicity should be hospitalized, kept in bed initially, handled with isolation procedures appropriate for the site of infection, and given supportive care as needed. Respiratory and cardiac function must be monitored closely. Early intubation or tracheostomy is recommended when the larynx is involved or signs of impending airway obstruction are detected. Tracheobronchial membrane can sometimes be removed mechanically via the endotracheal tube or tracheostomy. Primary or secondary pneumonia should be diagnosed and treated promptly. Sedative or hypnotic drugs that may mask respiratory symptoms are contraindicated. Close electrocardiographic monitoring, treatment of arrhythmias, and electrical pacing for heart block are essential. Congestive heart failure should be treated as described in Chap. 216. Glucocorticoids do not reduce the risk of diphtheritic myocarditis or polyneuropathy. Ulcerative or ecthymatous cutaneous lesions should be treated with Burow's solution applied on wet compresses after debridement of necrotic areas, and treatment for associated conditions such as pediculosis, scabies, or underlying dermatoses should be instituted. Recovery from diphtheria does not always confer active immunity, and initiation of an immunization regimen for diphtheria that is appropriate for the patient's age should be an integral part of the treatment plan.

PREVENTION DTaP (diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed) is currently recommended for all doses in the primary immunization schedule for children up to age 7 years who do not have contraindications. Td (tetanus and diphtheria toxoids adsorbed; for adult use) is currently recommended for routine booster immunizations at 10-year intervals in adults who do not have contraindications. Td is also recommended for adults who require prophylactic booster immunizations for tetanus-prone wounds. Currently recommended schedules for primary immunization of children and adults against diphtheria and for maintenance of immunity by periodic booster doses of appropriate vaccines throughout life are summarized in Chap. 107.

Close contacts of patients with respiratory diphtheria, especially household contacts, should have throat and nasal specimens collected and cultured for *C. diphtheriae*, should receive a 7- to 10-day course of either benzathine penicillin G (600,000 U for persons <6 years old or 1,200,000 U for persons ≥6 years old) or oral erythromycin (40 mg/kg per day for children and 1 g/d for adults), and should promptly receive diphtheria antitoxin if they become ill. Contacts whose immunization status is inadequate should receive a booster dose of diphtheria toxoid appropriate for their age. In situations where surveillance of contacts cannot be maintained, the benzathine penicillin G regimen should be used for treatment to ensure compliance. Contacts of patients with cutaneous diphtheria should be treated similarly, except that ongoing investigation of contacts can be discontinued if the strain of *C. diphtheriae* from the patient is found to be nontoxinogenic. Identified carriers of *C. diphtheriae* in the community should also be treated with the recommended regimen for contacts.

OTHER CORYNEBACTERIAL INFECTIONS

DEFINITION Medically important coryneform bacteria include 36 of 59 currently recognized species in the genus *Corynebacterium* plus numerous other taxonomically related organisms that share specific 16S rDNA signature nucleotides and belong to the high-guanosine-plus-cytosine lineage of gram-positive bacteria. They include environmental organisms and members of the normal flora that cause opportunistic infections, human pathogens of relatively low virulence, and animal pathogens that cause zoonotic infections. Reported infections caused by coryneform bacteria have increased substantially in number over the past several decades. Isolates of *C. jeikeium* and *C. urealyticum* are often resistant to multiple antibiotics.

ETIOLOGY AND LABORATORY DIAGNOSIS Because coryneform bacteria are potential pathogens, it is important not to dismiss them arbitrarily as components of the normal flora or as contaminants when they are found in clinical specimens. Coryneform bacteria should be identified to the species level when they are isolated from normally sterile body sites (unless only one of several specimens is positive for growth), when they represent the predominant organisms in appropriately collected clinical specimens, and when they are present as the only organism in urine at a count of $>10^4$/mL or as the predominant organisms in urine with a total bacterial count of $>10^5$/mL.

The coryneform bacteria are a large, heterogeneous group of gram-positive, pleomorphic, irregularly staining bacilli or coccobacilli that superficially resemble *C. diphtheriae*, have widely varying guanosine-plus-cytosine contents (from 46 to 74% guanosine plus cytosine) for members of the genus *Corynebacterium*, and are often difficult to identify and classify. Club-shaped rod forms are observed only for true *Corynebacterium* species. The genus *Corynebacterium* is currently divided into three groups: the nonlipophilic, fermentative corynebacteria (including *C. diphtheriae*, *C. ulcerans*, *C. pseudotuberculosis*, *C. xerosis*, *C. striatum*, *C. minutissimum*, and others); the nonlipophilic, nonfermentative corynebacteria (including *C. pseudodiphtheriticum* and others); and the lipophilic corynebacteria (including *C. jeikeium*, *C. urealyticum*, and others). The coryneform group includes additional genera, such as *Arcanobacterium* and *Rhodococcus*. Classification of coryneform bacteria is based on routine and molecular genetics–based diagnostic methods; these methods are often supplemented by chemotaxonomic methods that include identification of the short-chain mycolic acids present in most *Corynebacterium* species but absent in other coryneform bacteria, determination of the specific diamino acid present in peptidoglycan, and characterization of the major cellular

fatty acids. The classification system for coryneform bacteria is evolving rapidly, with 14 new species defined in the past 5 years. All coryneform bacteria that are clinically significant but cannot be readily identified in routine diagnostic laboratories should be submitted to an appropriate reference laboratory experienced in this area.

ECOLOGY AND EPIDEMIOLOGY Humans are the probable natural reservoir for *C. xerosis*, *C. pseudodiphtheriticum*, *C. striatum*, *C. minutissimum*, *C. jeikeium*, *C. urealyticum*, and *Arcanobacterium haemolyticum*. Animals are the probable natural reservoir for *Arcanobacterium pyogenes* (cows, sheep, pigs), *C. ulcerans* (cows, horses), and *C. pseudotuberculosis* (sheep, horses, goats, cattle). The natural reservoir for *Rhodococcus equi* is soil. The ecologic niches for many other coryneform bacteria of medical importance are not well defined.

Corynebacterial species that are found frequently as components of the normal human flora include *C. pseudodiphtheriticum* (pharynx, skin), *C. xerosis* (conjunctival sac, nasopharynx, skin), *C. auris* (external auditory canal), and *C. striatum* (anterior nares, skin). Corynebacterial species that commonly colonize the skin of hospitalized patients include *C. jeikeium* (axilla, groin, perineum) and *C. urealyticum*. *C. jeikeium* most often colonizes patients with malignancies or severe immunodeficiency; it is also isolated from environmental sources (surfaces, air) in hospitals and from the hands of ward staff. *C. ulcerans* infections are acquired by consumption of raw milk. *C. pseudotuberculosis* infections are acquired by contact with animals or animal products or by consumption of raw milk.

PATHOGENESIS AND CLINICAL MANIFESTATIONS *C. ulcerans* infections of humans usually present as pharyngitis and can mimic respiratory diphtheria, whereas infections caused by *C. pseudotuberculosis* typically present as suppurative granulomatous lymphadenitis. Some strains of *C. ulcerans* and *C. pseudotuberculosis* can produce diphtheria toxin, but infections of humans with tox^- strains have been reported only for *C. ulcerans*. *C. ulcerans* infections that are presumed on clinical grounds to be caused by tox^+ strains should be managed like diphtheria, and diphtheria antitoxin should be administered. *C. pseudodiphtheriticum*, a tox^- commensal of low virulence, is an uncommon cause of pneumonia in men with AIDS and of pharyngitis. It has also been associated with necrotizing tracheitis, tracheobronchitis, endocarditis, and urinary tract infection in patients without known immune deficiencies. Pharyngeal infections associated with *C. pseudodiphtheriticum* can be confused with diphtheria until the bacteriologic diagnosis is established; however, unlike diphtheria, these infections do not pose a danger to contacts. *C. xerosis* and *C. striatum* are constituents of the normal human flora that are of low virulence and rarely cause human infections.

C. jeikeium causes severe infections primarily in patients with hematologic malignancies and neutropenia. Skin colonization precedes clinical infection. Risk factors for nosocomial *C. jeikeium* sepsis include prolonged hospitalization, breaks in the integument, chronic intravascular catheterization, and prior treatment with broad-spectrum antibiotics. Other presentations of *C. jeikeium* infection include endocarditis, device-related infections, pulmonary infiltrates, cutaneous septic emboli, soft tissue infections, and rashes. Endocarditis due to *C. jeikeium* occurs primarily in patients with prosthetic heart valves. *C. jeikeium* is a rare cause of central nervous system infections in patients with ventricular shunts.

C. urealyticum is a significant cause of nosocomial urinary tract infections, including acute and chronic cystitis and pyelonephritis. The organism closely resembles *C. jeikeium* but differs from the latter by producing urease and failing to convert glucose to acidic metabolites. Hydrolysis of urea by urease causes alkalinization of the urine and formation of ammonium magnesium phosphate (struvite) stones. *C. urealyticum* is a cause of alkaline-encrusted cystitis in patients with preexisting bladder lesions that serve as foci for precipitation of struvite crystals. Risk factors associated with symptomatic urinary tract infections include preexisting immunosuppression, recent urologic procedures (including renal transplantation), underlying disorders of the genitourinary tract, and a history of urinary tract infections.

C. minutissimum is frequently isolated from the lesions of erythrasma, a common superficial skin infection characterized by the presence in intertriginous areas of reddish-brown, scaly, pruritic, macular patches that exhibit coral-red fluorescence under a Wood's light. The etiology of erythrasma appears to be polymicrobial; infection of the skin by *C. minutissimum* follows the onset of maceration and scaling. Deep infections caused by *C. minutissimum*, which are rare, include abscesses, bacteremia, endocarditis, peritonitis, pyelonephritis, and infection of central venous catheters.

A. haemolyticum causes pharyngitis and chronic skin ulcers. Less frequently, it causes a variety of deep tissue infections, septicemia, and endocarditis. Some 90% of *A. haemolyticum* infections occur in patients between 10 and 30 years old. *A. haemolyticum* pharyngitis in this age group is 5 to 13% as frequent as *Streptococcus pyogenes* pharyngitis. An erythematous rash is present in 30 to 67% of cases. The rash is usually scarlatiniform and most pronounced on the trunk and proximal extremities, but it sometimes resembles urticaria or erythema multiforme. Because rash is more frequent in *A. haemolyticum* infections than in *S. pyogenes* infections, *A. haemolyticum* should be considered as a possible etiology in older children and adults who present with the scarlet fever syndrome. Infection due to *A. haemolyticum* can also present as extensive pharyngeal exudate and can mimic diphtheria. *A. haemolyticum* occasionally causes peritonsillar abscess, sepsis, endocarditis, or meningitis.

A. pyogenes causes bovine mastitis, a disease transmitted by flies. Yearly epidemics of leg ulcers infected with *A. pyogenes* among schoolchildren in Thailand occurred between 1979 and 1984 and were postulated to have resulted from introduction of the organism into traumatic skin lesions by flies. Reported *A. pyogenes* infections in adults in Denmark have included abscesses, cystitis, intraabdominal infections, and mastoiditis with bacteremia.

R. equi, which causes bronchopneumonia in horses and occasional infections in other animals, has emerged as an important intracellular opportunistic pathogen in immunocompromised patients. Most reported cases are necrotizing pulmonary infections that resemble tuberculosis or nocardiosis in patients with severely defective cell-mediated immunity, including those with AIDS.

DIAGNOSIS Pharyngitis caused by tox^+ strains of *C. ulcerans* may be clinically indistinguishable from diphtheria. The presentations of infections caused by other coryneform bacteria are not pathognomonic, and diagnosis of these infections is based on a high index of suspicion, identification of the organism by culture in appropriate clinical specimens, and exclusion of other likely causes of infection. Sheep blood agar containing fosfomycin (100 μg/mL) or colistin–nalidixic acid blood agar is useful as a selective medium for most coryneform bacteria, and medium containing 0.1 to 1% Tween 80 is useful for isolation of lipophilic coryneform bacteria.

Since *C. urealyticum* is often undetected by routine urine cultures; it is necessary to incubate cultures for 24 to 48 h on blood agar or on special media for selected patients (especially elderly men with preexisting genitourinary abnormalities) with alkaline urine, ammonium magnesium phosphate stones, gram-positive bacilli in the urine, or negative standard urine cultures despite clinical evidence of bacteriuria. Other microbes that can cause urinary tract infections with alkaline urine include *Proteus*, *Ureaplasma*, and some staphylococci and streptococci. Alkaline-encrusted cystitis is an anatomic diagnosis made by cystoscopy.

The differential diagnosis of *A. haemolyticum* pharyngitis with rash includes scarlet fever; rubella; staphylococcal and streptococcal toxic shock syndromes; infections caused by Epstein-Barr virus, cytomegalovirus, and enteroviruses (especially coxsackieviruses); disseminated gonococcal infection; secondary syphilis; and drug allergy. Routine diagnostic methods for throat cultures are not ideal for the detection of *A. haemolyticum*, nor is this organism detected by the rapid tests for *S. pyogenes* that are sometimes substituted for throat cultures. Pharyngitis caused by *A. haemolyticum* in adolescents and

adults is likely to remain underdiagnosed until improved tests for the organism are developed and used by diagnostic laboratories.

Erythrasma is diagnosed clinically. Because of uncertainty about the etiologic role of *C. minutissimum*, culture of erythrasma lesions is not currently recommended.

TREATMENT

Since prediction of susceptibility patterns on the basis of isolate identification to the species level is not necessarily reliable, antimicrobial susceptibility testing should be performed on all isolates of clinically significant coryneform bacteria. In light of the emergence and spread of vancomycin resistance in several gram-positive bacterial species as well as the observation of intrinsic vancomycin resistance in some species of coryneform bacteria (e.g., *Microbacterium resistens*), some authorities have recently recommended that glycopeptide antibiotics not be used as first-line agents to treat infections caused by coryneform bacteria. Physicians treating infections caused by coryneform bacteria that are likely to exhibit resistance to multiple antibiotics should obtain expert consultation concerning current treatment recommendations.

Strains of *C. jeikeium* are typically resistant to most antibiotics. Vancomycin has been recommended most often as the drug of choice for empirical treatment of infections caused by this organism, although antimicrobial susceptibility testing may reveal other antibiotic options for some isolates. For device-related *C. jeikeium* infections, removal of the infected device is usually required in addition to appropriate antibiotic therapy.

C. urealyticum is often resistant to the antibiotics used commonly for the treatment of urinary tract infections. Empirical treatment with vancomycin has often been recommended pending the results of antimicrobial susceptibility testing. Several courses of antibiotic therapy may be necessary for bacteriologic cure. Patients with alkaline-encrusted cystitis require resection of the encrusted lesions in addition to antibiotic therapy.

No controlled trials of treatment for *A. haemolyticum* infections have been performed. In vitro tests usually demonstrate susceptibility to penicillins, erythromycin, azithromycin, clindamycin, doxycycline, ciprofloxacin, and vancomycin, but treatment failures have been reported with appropriate doses of penicillins. Limited data suggest that the clinical course of *A. haemolyticum* pharyngitis may be shortened by treatment with erythromycin.

Infections with *C. ulcerans* that present like diphtheria or are known to be caused by tox$^+$ strains should be treated like diphtheria. Oral erythromycin is usually effective for treatment of erythrasma. For infections caused by *R. equi*, vancomycin has often been recommended as the drug of choice. Possible alternatives include erythromycin, rifampin, aminoglycosides, and chloramphenicol; the combination of erythromycin and rifampin is attractive because of possible synergy. Penicillins should not be used, because *R. equi* rapidly develops resistance. Many weeks of antibiotic treatment, sometimes supplemented by surgical intervention, are often needed for infections caused by *R. equi*. Suppressive therapy with antibiotics should be continued indefinitely in patients with AIDS after initial treatment of infections caused by *R. equi*. Initial treatment of infections caused by other coryneform bacteria should be based on the identity of the organism and published data regarding antibiotic susceptibility. Therapy should be modified, when necessary, in light of the results of antibiotic susceptibility tests.

123 INFECTIONS CAUSED BY *LISTERIA MONOCYTOGENES*

Anne Schuchat, Claire V. Broome

Listeria monocytogenes is a gram-positive rod that can be isolated from soil, vegetation, and many animal reservoirs. Human disease due to *L. monocytogenes* generally occurs in the setting of pregnancy or of immunosuppression caused by illness or medication. Increasing evidence suggests that a substantial portion of cases of human listeriosis are attributable to the food-borne transmission of *L. monocytogenes*. Unlike most food-borne pathogens, which cause primarily gastrointestinal illness, *L. monocytogenes* causes invasive syndromes, such as meningitis, sepsis, chorioamnionitis, and stillbirth.

ETIOLOGY Listeriae are aerobic or facultatively anaerobic, nonsporulating gram-positive bacilli that grow at 1 to 45°C and typically have tumbling motility when cultured at 20 to 25°C. Characteristics that help distinguish *L. monocytogenes* from other *Listeria* spp. include the formation of a narrow zone of β hemolysis on sheep blood agar and the production of acid from glucose, maltose, L-rhamnose, and α-methyl-D-mannoside but not from D-xylose. Determination of the serotype of *L. monocytogenes* is based on somatic (O) and flagellar (H) antigens. Most cases of human disease are caused by serotypes 1/2a, 1/2b, and 4b. Subtyping, especially by pulsed-field gel electrophoresis, has made it easier to discriminate among strains of *Listeria* and thus to link environmental or food isolates with clinical infections.

PATHOGENESIS *L. monocytogenes* is an intracellular pathogen&mdash characteristic consistent with its predilection for causing illness in persons with deficient cell-mediated immunity. The organism can be found as part of the gastrointestinal flora in healthy individuals. Lack of gastric acidity and abnormal gastrointestinal functioning may increase the risk of invasive disease following exposure to the organism in the gastrointestinal tract. The increased risk of *L. monocytogenes* infection in pregnant women may be due to both systemic and local immunologic changes associated with pregnancy. For example, local immunosuppression at the maternal-fetal interface of the placenta may facilitate intrauterine infection following transient maternal bacteremia.

The molecular pathogenesis of *L. monocytogenes* has been elucidated. The cell-surface protein internalin interacts with specific receptors to induce phagocytosis. Both listeriolysin O and phospholipases permit the organism to escape from the phagosome into the cytosol while avoiding intracellular killing. Through the surface protein Act A, *L. monocytogenes* uses actin-based motility to move to the cell membrane. Efficient cell-to-cell spread is accomplished by both actin filament formation and phospholipase production. Genetic determinants of these proteins have been characterized. Because the organism is adapted for both intracellular survival and direct cell-to-cell spread, it is not eliminated by antibodies.

EPIDEMIOLOGY Long recognized as a veterinary pathogen, *L. monocytogenes* causes basilar meningitis ("circling disease") and stillbirth in sheep and cattle. The occurrence of listeriosis among humans has received increasing attention as the role of contaminated foods in the pathogenesis of epidemic listeriosis has been recognized and reports of disease associated with the expanding immunosuppressed population have accumulated.

Invasive listeriosis—confirmed by culture of blood or cerebrospinal fluid (CSF)—occurs in approximately 3 to 5 individuals per million population annually in the United States. Perinatal listeriosis complicates 9 births per 100,000. A 40% decline in incidence since the period from 1986 through 1990 may be attributable to aggressive food regulation and industrial clean-up efforts. Incidence further declined by 35% from 1996 through 2001. Multistate surveillance for sporadic listeriosis suggests that 20% of infections are fatal or result in stillbirth, although higher case-fatality rates have been reported during listeriosis epidemics and were described in early series. Most cases of disease due to *L. monocytogenes* are sporadic; however, investigation of several outbreaks of listeriosis since 1980 has demonstrated common-source food-borne transmission as a cause of human illness and has shown that the incubation period for disease following consumption of contaminated food can be 2 to 6 weeks. The largest North American outbreak, which took place in Los Angeles in 1985, involved more than 100 cases and 48 deaths or stillbirths. A nationwide outbreak in France in 1992 involved 279 cases and 63 deaths. Foods implicated in outbreaks of listeriosis include contaminated coleslaw, pasteurized milk, soft cheeses, pâté, ready-to-eat turkey and pork products, hot dogs, butter, and prepared salads; epidemiologic studies have implicated undercooked chicken, uncooked hot dogs, soft cheeses, and food from store delicatessen counters in sporadic disease. Listerial contamination of foods is relatively common. Among foods contaminated with the organism, those that are purchased ready to eat, are contaminated with serotype 4b, and are contaminated at a relatively high level may be the most likely to cause illness. The long incubation period associated with listeriosis contributes to the difficulty of implicating specific foods as the cause of either common-source outbreaks or sporadic cases.

Although food-borne transmission appears to be the foremost cause of epidemic and sporadic disease, several clusters of late-onset neonatal infection suggest nosocomial transmission of *L. monocytogenes*. Contaminated multiuse materials and equipment have been suggested as causes of some nosocomial clusters. Listeriosis has been reported in veterinarians and other persons in close contact with infected animals.

CLINICAL PRESENTATION *Pregnancy-associated listeriosis* may occur during any stage of pregnancy, although most infections are detected during the third trimester, possibly because of failure to obtain specimens for bacterial culture earlier during gestation in instances of abortion and stillbirth. One-half to two-thirds of pregnant women with perinatal listeriosis experience a mild illness characterized by fever, myalgias, malaise, and backache, which sometimes are accompanied by diarrhea, abdominal pain, nausea, and/or vomiting during the bacteremic phase. Blood cultures should be used for diagnosis. Transplacental spread of the organism results in intrauterine infection, which can lead to chorioamnionitis, premature labor, intrauterine fetal demise, or early-onset disease of the newborn. Women with listeriosis diagnosed during pregnancy have a favorable clinical outcome after antibiotic therapy or delivery. Although often included in the differential diagnosis of recurrent spontaneous abortion, infection with *L. monocytogenes* appears to cause fewer than 2% of stillbirths.

Neonatal listeriosis can be classified under the same categories used for group B streptococcal infection (Chap. 121), with early-onset disease evident during the first week of life and late-onset disease developing thereafter. Infants may be symptomatic at birth; most infants with early-onset disease are symptomatic by the second day of life. Aspiration of infected amniotic fluid contributes to pathogenesis. Early-onset disease may include sepsis, respiratory distress, skin lesions, and the syndrome called *granulomatosis infantisepticum*, which is characterized by disseminated abscesses involving the liver, spleen, adrenal glands, lungs, and other sites. Infants with late-onset neonatal disease are more likely than those with early-onset disease to develop meningitis. While early-onset disease is often associated with obstetric complications such as premature delivery and chorioamnionitis, late-onset disease typically affects infants born at term by uncomplicated deliveries. Infants may acquire *L. monocytogenes* during passage through the birth canal; except in several clusters of late-onset neonatal infections linked to nosocomial transmission, the pathogenesis of late-onset disease is not well understood.

Listeriosis not associated with pregnancy usually affects persons with immunosuppressive conditions, although invasive disease can also affect immunocompetent adults, particularly elderly persons. The most common underlying conditions in nonpregnant adults with listeriosis are chronic glucocorticoid therapy, solid or hematologic malignancies (particularly in fludarabine-treated patients), diabetes mellitus, renal disease, liver disease, and AIDS. Although the prevalence of listeriosis among persons infected with HIV is much higher than that in the general population, listeriosis is a relatively uncommon opportunistic infection in AIDS.

Sepsis Clinical studies have shown that bacteremic infection without an evident focus is the most common clinical manifestation of listeriosis among immunocompromised hosts, while infection of the central nervous system (CNS) ranks second in frequency. Listerial sepsis cannot be distinguished clinically from bacteremia involving other organisms. Patients are usually febrile, often appear extremely ill, and may have prodromal symptoms including myalgia, nausea, vomiting, and diarrhea. Immunocompromised patients with listeriosis are less likely than other *Listeria*-infected adults to present with CNS infection, possibly because they are more likely to have blood cultured during febrile episodes and thus to have transient listerial bacteremia recognized.

CNS Infection The most common presentation of CNS infection due to *L. monocytogenes* is meningitis, which can present as either an acute or (less often) a subacute illness. Presenting symptoms include fever, headache, and an altered level of consciousness. Examination of CSF usually reveals pleocytosis, increased protein concentrations, and normal glucose levels, although other patterns are sometimes found. Gram's stain is positive in only 25% of cases. The diagnosis is made when *L. monocytogenes* is identified on culture. Despite its name, *L. monocytogenes* is rarely associated with monocytosis of either CSF or blood. Other syndromes seen in CNS infection include meningoencephalitis; cerebritis; and brainstem, spinal cord, or intracranial abscesses. The unusual syndrome of rhombencephalitis includes asymmetric cranial-nerve palsies, altered consciousness, cerebellar signs, and motor or sensory loss. Symptoms of other nonmeningitic CNS infections include fever, ataxia, seizures, personality changes, and coma. Nuchal rigidity is rare in nonmeningitic infections. CSF cultures may be sterile; blood cultures are usually diagnostic.

Endocarditis Like most forms of bacterial endocarditis, listerial endocarditis typically occurs in patients with prosthetic or previously damaged valves. The organism has a predilection for the left side of the heart. Endocarditis due to *L. monocytogenes* is often associated with systemic embolization.

Focal Infections Other focal infections that can follow unrecognized bacteremia include endophthalmitis, peritonitis, osteomyelitis, visceral abscess, pleuropulmonary infection, and cholecystitis. Cutaneous lesions may develop without systemic involvement and have been reported in veterinarians and poultry workers.

Gastrointestinal Illness Several common-source outbreaks of acute febrile gastroenteritis suggest that *L. monocytogenes* can cause an acute diarrheal syndrome in persons without immunocompromising conditions. The importance of *L. monocytogenes* in sporadic diarrheal illness is unclear. Although the organism is not identified by the culture methods routinely used for stool specimens, studies using selective enrichment media for evaluation of consecutive specimens from patients hospitalized with acute diarrhea have suggested that *L. monocytogenes* is not a major cause of sporadic diarrhea.

Recurrences Recurrent infection with *L. monocytogenes* has been reported but is rare. Many recurrences are due to the subtype responsible for the initial infection. The implication is that such recurrences result either from insufficient treatment of a focus of primary infection or from repeated exposure to a persistently contaminated source.

DIAGNOSIS Invasive listeriosis is diagnosed when the organism is cultured from a site that is usually sterile, such as blood, CSF, or amniotic fluid. The organism grows readily within 36 h on routine culture media, but morphologic similarities between *Listeria* and diphtheroids make it necessary to use biochemical tests to identify the species. Serologic assays with whole-cell antigens have not been useful for the diagnosis of listeriosis, both because exposure to the organism (and thus the presence of antibody) may be common and because infected individuals may not produce antibody. Assays for antibody to listeriolysin O have been applied in epidemiologic investigations and, retrospectively, in the diagnosis of culture-negative CNS infection. Culture of the organism from nonsterile sites such as the vagina and rectum is not useful for clinical diagnosis, as the organism may be carried at these sites by ~5% of healthy individuals.

Differential diagnosis of prematurity, spontaneous abortion, or stillbirth includes infectious diseases such as group B streptococcal infection, congenital syphilis, and toxoplasmosis; pathogens such as group B streptococci and *Escherichia coli* are more common than *L. monocytogenes* as causes of meningitis and sepsis in the newborn period. Listerial infection should always be considered in the differential diagnosis of meningitis in immunosuppressed persons, particularly transplant recipients and others undergoing glucocorticoid treatment, patients with hematologic malignancy, and HIV-infected patients. Among healthy adults, meningitis is much more likely to be caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, or viral pathogens than by *L. monocytogenes*.

TREATMENT

The treatment of choice for listeriosis is intravenous administration of either ampicillin or penicillin, often in combination with an aminoglycoside for synergy. Trimethoprim-sulfamethoxazole is bactericidal against *L. monocytogenes* and has been used successfully in the treatment of patients with penicillin allergy. *L. monocytogenes* is susceptible in vitro to penicillin G, ampicillin, erythromycin, trimethoprim-sulfamethoxazole, chloramphenicol, rifampin, tetracyclines, aminoglycosides, and imipenem. However, chloramphenicol and rifampin may antagonize the bactericidal effect of penicillins. Because *L. monocytogenes* is not sensitive to cephalosporins, these agents should not be used for single-agent empirical treatment of neonatal sepsis or of meningitis in newborns or immunocompromised hosts.

Dosages and durations of therapy have not been subjected to controlled trials. For nonpregnant adults with listeriosis, the regimen of choice is either ampicillin (12 g intravenously per day in six divided doses) or penicillin G (15 to 20 million units intravenously per day in six divided doses); for immunosuppressed patients with meningitis, some experts add gentamicin (1.3 mg/kg intravenously every 8 h) for synergy. Penicillin-allergic patients may be treated with trimethoprim-sulfamethoxazole (15/75 mg/kg intravenously per day in three equal portions every 8 h). Meningitis in an immunocompetent patient may require 2 to 3 weeks of antibiotic therapy after defervescence. Meningitis, bacteremia, endocarditis, and nonmeningitic listeriosis in immunosuppressed patients should be treated longer, probably for 4 to 6 weeks. Neonatal listeriosis can be treated with a 2-week course of ampicillin. Infants weighing <2000 g should receive 100 mg/kg per day in two equal doses during the first week of life and 150 mg/kg per day during the second week. Infants weighing ≥2000 g should receive 150 mg/kg per day in three equal doses during the first week of life and 200 mg/kg per day during the second week. The addition of an aminoglycoside should be considered for neonatal infection (gentamicin, 5 mg/kg per day in two divided doses during the first week of life; 7.5 mg/kg per day in three equal doses during the second week). For listeriosis in pregnant women, a 2-week course of ampicillin (4 to 6 g per day in four equal doses) is recommended. During the last month of pregnancy, infected women with serious penicillin allergies may be treated with erythromycin.

TABLE 123-1 *Dietary Recommendations for the Prevention of Food-Borne Listeriosis*

Recommendations to all individuals
1. Thoroughly cook raw food from animal sources, such as beef, pork, and poultry.
2. Wash raw vegetables thoroughly before eating them.
3. Keep uncooked meats separate from vegetables and from cooked and ready-to-eat foods.
4. Avoid raw (unpasteurized) milk or foods made from raw milk.
5. Wash hands, knives, and cutting boards after handling uncooked foods.

Additional recommendations to high-risk individuals[a]
6. Avoid soft cheeses such as Mexican-style, feta, Brie, Camembert, and blue-veined cheese. There is no need to avoid hard cheeses, cream cheese, cottage cheese, or yogurt.
7. Leftover foods or ready-to-eat foods, such as hot dogs, should be reheated until steaming hot before being eaten.
8. Although the risk of listeriosis associated with foods from delicatessen counters is relatively low and poorly characterized, pregnant women and immunosuppressed persons may choose to avoid these foods or to thoroughly reheat cold cuts before eating them.

[a] Persons immunocompromised by illness or medications; pregnant women.

PROGNOSIS Treatment of maternal bacteremia during pregnancy can prevent neonatal infection. Antibiotic therapy for the newborn can limit sequelae, although the widely disseminated disease characteristic of granulomatosis infantisepticum is frequently fatal regardless of treatment. Early-onset disease carries a higher mortality risk than late-onset infection, and immunocompromised hosts have a worse prognosis than do otherwise-healthy adults with listeriosis.

PREVENTION *L. monocytogenes* is frequently isolated from food; the Food and Drug Administration, the U.S. Department of Agriculture, and manufacturers are pursuing further measures to reduce *L. monocytogenes* contamination of foods that have been subjected to listericidal processing. Prevention of listeriosis requires dietary counseling of persons at increased risk of disease (Table 123-1). There is no role for the administration of prophylaxis to contacts of patients with listeriosis. Clinicians are encouraged to report cases of listeriosis to local or state health departments. Case reporting and subtyping of clinical isolates can facilitate early recognition of outbreaks and prevention of subsequent cases.

124 TETANUS

Elias Abrutyn

DEFINITION Tetanus is a neurologic disorder, characterized by increased muscle tone and spasms, that is caused by tetanospasmin, a powerful protein toxin elaborated by *Clostridium tetani*. Tetanus occurs in several clinical forms, including generalized, neonatal, and localized disease.

ETIOLOGIC AGENT *C. tetani* is an anaerobic, motile gram-positive rod that forms an oval, colorless, terminal spore and thus assumes a shape resembling a tennis racket or drumstick. The organism is found worldwide in soil, in the inanimate environment, in animal feces, and occasionally in human feces. Spores may survive for years in some environments and are resistant to various disinfectants and to boiling for 20 min. Vegetative cells, however, are easily inactivated and are susceptible to several antibiotics (metronidazole, penicillin, and others).

Tetanospasmin is formed in vegetative cells under plasmid control. It is a single polypeptide chain. With autolysis, the single-chain toxin is released and cleaved to form a heterodimer consisting of a heavy chain (100 kDa), which mediates binding to nerve-cell receptors and entry into these cells, and a light chain (50 kDa), which acts to block neurotransmitter release. The genome sequence of *C. tetani* has been reported. The amino acid structures of the two most powerful toxins known, botulinum toxin and tetanus toxin, are partially homologous.

EPIDEMIOLOGY Tetanus occurs sporadically and almost always affects nonimmunized persons, partially immunized persons, or fully immunized individuals who fail to maintain adequate immunity with booster doses of vaccine. Although tetanus is entirely preventable by immunization, the burden of disease is large worldwide. The disease is common in areas where soil is cultivated, in rural areas, in warm climates, during summer months, and among males. In countries without a comprehensive immunization program, tetanus occurs predominantly in neonates and other young children. It is noteworthy that international programs to eliminate neonatal tetanus have been in place for some time. In the United States and other nations with successful immunization programs, neonatal tetanus is rare (only one case was reported in the United States during the period 1998–2000), and the disease affects other age groups and groups inadequately covered by immunization (such as nonwhites). The success of immunization in the United States is depicted in Fig. 124-1. Since 1976, fewer than 100 cases have been reported yearly; this figure contrasts remarkably with that of 500 to 600 cases reported annually in the late 1940s, when vaccine administration became routine and tetanus became notifiable. In 1947, the incidence of tetanus was 3.9 cases per 1 million population. In contrast, the average annual incidence rate for 1998–2000 was 0.16 per 1 million population. The risk for the development of tetanus is highest among the elderly. A large-scale national serologic survey for tetanus and diphtheria antibody performed in 1988–1994 showed that, overall, 72% of Americans over the age of 6 years were protected against tetanus. Whereas 91% of children 6 to 11 years old were protected, the percentage protected fell with age: only 30% of persons >70 years old (men, 45%; women, 21%) had adequate antibody levels. Notably, individuals 20 to 49 years old now account for a large proportion of cases, because fewer cases occurred in the elderly without a similar reduction among young and middle-aged adults.

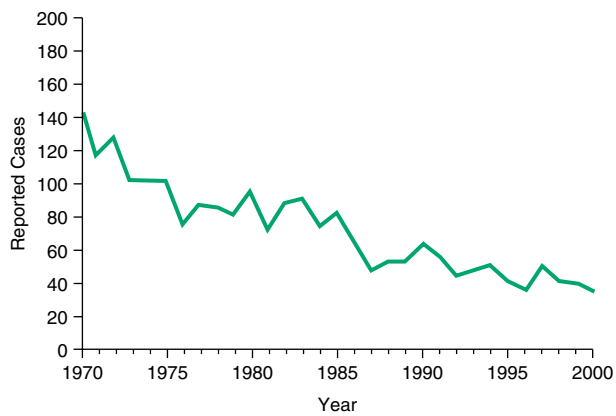

FIGURE 124-1 Tetanus: Reported cases by year—United States, 1970–2000. *[From Centers for Disease Control and Prevention: Summary of notifiable diseases, United States, 2000. MMWR 49(53):74, 2000.]*

In the United States, most cases of tetanus follow an acute injury, such as a puncture wound, laceration, or abrasion. Tetanus is acquired indoors or during farming, gardening, and other outdoor activities. The injury may be major but often is trivial, so that medical attention is not sought; in some instances no injury can be identified. The disease may complicate chronic conditions such as skin ulcers, abscesses, and gangrene. Tetanus is also associated with burns, frostbite, middle-ear infection, surgery, abortion, childbirth, body piercing, and drug abuse, notably "skin popping." In some patients no portal of entry for the organism can be identified.

PATHOGENESIS Contamination of wounds with spores of *C. tetani* is probably a frequent occurrence. Germination and toxin production, however, take place only in wounds with low oxidation-reduction potential, such as those with devitalized tissue, foreign bodies, or active infection. *C. tetani* does not itself evoke inflammation, and the portal of entry retains a benign appearance unless infection with other organisms is present.

Toxin released in the wound binds to peripheral motor neuron terminals, enters the axon, and is transported to the nerve-cell body in the brainstem and spinal cord by retrograde intraneuronal transport. The toxin then migrates across the synapse to presynaptic terminals, where it blocks release of the inhibitory neurotransmitters glycine and γ-aminobutyric acid (GABA). The blocking of neurotransmitter release by tetanospasmin, a zinc metalloprotease, involves the cleavage of protein(s) critical to proper function of the synaptic vesicle release apparatus. With diminished inhibition, the resting firing rate of the α motor neuron increases, producing rigidity. With lessened activity of reflexes that limit polysynaptic spread of impulses (a glycinergic activity), agonists and antagonists may be recruited rather than inhibited, with the consequent production of spasms. Loss of inhibition may also affect preganglionic sympathetic neurons in the lateral gray matter of the spinal cord and produce sympathetic hyperactivity and high circulating catecholamine levels. Tetanospasmin, like botulinum toxin, may block neurotransmitter release at the neuromuscular junction and produce weakness or paralysis; recovery requires sprouting of new nerve terminals.

In local tetanus, only the nerves supplying the affected muscles are involved. Generalized tetanus occurs when toxin released in the wound enters the lymphatics and bloodstream and is spread widely to distant nerve terminals; the blood-brain barrier blocks direct entry into the central nervous system. If it is assumed that intraneuronal transport times are equal for all nerves, short nerves are affected before long nerves: this fact explains the sequential involvement of nerves of the head, trunk, and extremities in generalized tetanus.

CLINICAL MANIFESTATIONS *Generalized tetanus*, the most common form of the disease, is characterized by increased muscle tone and generalized spasms. The median time of onset after injury is 7 days; 15% of cases occur within 3 days and 10% after 14 days.

Typically, the patient first notices increased tone in the masseter muscles (trismus, or lockjaw). Dysphagia or stiffness or pain in the neck, shoulder, and back muscles appears concurrently or soon thereafter. The subsequent involvement of other muscles produces a rigid abdomen and stiff proximal limb muscles; the hands and feet are relatively spared. Sustained contraction of the facial muscles results in a grimace or sneer (risus sardonicus), and contraction of the back mus-

cles produces an arched back (opisthotonos). Some patients develop paroxysmal, violent, painful, generalized muscle spasms that may cause cyanosis and threaten ventilation. These spasms occur repetitively and may be spontaneous or provoked by even the slightest stimulation. A constant threat during generalized spasms is reduced ventilation or apnea or laryngospasm. The severity of illness may be mild (muscle rigidity and few or no spasms), moderate (trismus, dysphagia, rigidity, and spasms), or severe (frequent explosive paroxysms). The patient may be febrile, although many have no fever; mentation is unimpaired. Deep tendon reflexes may be increased. Dysphagia or ileus may preclude oral feeding.

Autonomic dysfunction commonly complicates severe cases and is characterized by labile or sustained hypertension, tachycardia, dysrhythmia, hyperpyrexia, profuse sweating, peripheral vasoconstriction, and increased plasma and urinary catecholamine levels. Periods of bradycardia and hypotension may also be documented. Sudden cardiac arrest sometimes occurs, but its basis is unknown. Other complications include aspiration pneumonia, fractures, muscle rupture, deep-vein thrombophlebitis, pulmonary emboli, decubitus ulcer, and rhabdomyolysis.

Neonatal tetanus usually occurs as the generalized form and is usually fatal if left untreated. It develops in children born to inadequately immunized mothers, frequently after unsterile treatment of the umbilical cord stump. Its onset generally comes during the first 2 weeks of life. Poor feeding, rigidity, and spasms are typical features of neonatal tetanus. *Local tetanus* is an uncommon form in which manifestations are restricted to muscles near the wound. The prognosis is excellent. *Cephalic tetanus*, a rare form of local tetanus, follows head injury or ear infection. Trismus and dysfunction of one or more cranial nerves, often the seventh nerve, are found. The incubation period is a few days and the mortality is high.

DIAGNOSIS The diagnosis of tetanus is based entirely on clinical findings. Tetanus is unlikely if a reliable history indicates the completion of a primary vaccination series and the receipt of appropriate booster doses. Wounds should be cultured in suspected cases. However, *C. tetani* can be isolated from wounds of patients without tetanus and frequently cannot be recovered from wounds of those with tetanus. The leukocyte count may be elevated. Cerebrospinal fluid examination yields normal results. Electromyograms may show continuous discharge of motor units and shortening or absence of the silent interval normally seen after an action potential. Nonspecific changes may be evident on the electrocardiogram. Muscle enzyme levels may be raised. Serum antitoxin levels of ≥0.15 U/mL are considered protective and make tetanus unlikely, although cases developing despite protective antitoxin levels have been reported.

The differential diagnosis includes local conditions also producing trismus, such as alveolar abscess, strychnine poisoning, dystonic drug reactions (e.g., to phenothiazines and metoclopramide), and hypocalcemic tetany. Other conditions sometimes confused with tetanus include meningitis/encephalitis, rabies, and an acute intraabdominal process (because of the rigid abdomen). Markedly increased tone in central muscles (face, neck, chest, back, and abdomen) with superimposed generalized spasms and relative sparing of the hands and feet strongly suggests tetanus.

Rx TREATMENT

General Measures The goals of therapy are to eliminate the source of toxin, neutralize unbound toxin, and prevent muscle spasms, monitoring the patient's condition and providing support—especially respiratory support—until recovery. Patients should be admitted to a quiet room in an intensive care unit, where observation and cardiopulmonary monitoring can be maintained continuously but stimulation can be minimized. Protection of the airway is vital. Wounds should be explored, carefully cleansed, and thoroughly debrided.

Antibiotic Therapy Although of unproven value, antibiotic therapy is administered to eradicate vegetative cells—the source of toxin. The use of penicillin (10 to 12 million units intravenously, given daily for 10 days) has been recommended, but metronidazole (500 mg every 6 h or 1 g every 12 h) is preferred by some experts on the basis of this drug's excellent antimicrobial activity, a survival rate higher than that obtained with penicillin in one nonrandomized trial, and the absence of activity antagonistic to GABA, as seen with penicillin. Clindamycin and erythromycin are also alternatives for the treatment of penicillin-allergic patients. Additional specific antimicrobial therapy should be given for active infection with other organisms.

Antitoxin Given to neutralize circulating toxin and unbound toxin in the wound, antitoxin effectively lowers mortality; toxin already bound to neural tissue is unaffected. Human tetanus immune globulin (TIG) is the preparation of choice and should be given promptly. The dose is 3000 to 6000 units intramuscularly, usually in divided doses because the volume is large. The optimal dose is not known, however, and results from one study indicated that a 500-unit dose was as effective as higher doses. Pooled intravenous immunoglobulin may be an alternative to TIG, but the specific antitoxin concentration in this formulation is not standardized. It may be best to administer antitoxin before manipulating the wound; the value of injecting a dose proximal to the wound or infiltrating the wound is unclear. Additional doses are unnecessary because the half-life of antitoxin is long. Antibody does not penetrate the blood-brain barrier. Intrathecal administration should be considered experimental. Equine tetanus antitoxin (TAT) is not available in the United States but is used elsewhere. It is cheaper than human antitoxin, but its half-life is shorter and its administration commonly elicits hypersensitivity and serum sickness.

Control of Muscle Spasms Many agents, alone and in combination, have been used to treat the muscle spasms of tetanus, which are painful and can threaten ventilation by causing laryngospasm or sustained contraction of ventilatory muscles. The ideal therapeutic regimen would abolish spasmodic activity without causing oversedation and hypoventilation. Diazepam, a benzodiazepine and GABA agonist, is in wide use. The dose is titrated, and large doses (≥250 mg/d) may be required. Lorazepam, with a longer duration of action, and midazolam, with a short half-life, are other options. Barbiturates and chlorpromazine are considered second-line agents. Therapeutic paralysis with a nondepolarizing neuromuscular blocking agent and mechanical ventilation may be required for the treatment of spasms unresponsive to medication or spasms that threaten ventilation. However, prolonged paralysis after the discontinuation of therapy with such agents has been described, and both the need for continued paralysis and the occurrence of complications should be assessed daily. Alternative agents include propofol, which is expensive; dantrolene and intrathecal baclofen, which are being investigated in the hope of shortening the period of therapeutic paralysis; succinylcholine, which has been associated with hyperkalemia; and magnesium sulfate, which requires monitoring of neurologic (patellar reflex) and respiratory function as well as daily measurement of serum magnesium levels.

Respiratory Care Intubation or tracheostomy, with or without mechanical ventilation, may be required for hypoventilation due to oversedation or laryngospasm or for the avoidance of aspiration by patients with trismus, disordered swallowing, or dysphagia. The need for these procedures should be anticipated, and they should be undertaken electively and early.

Autonomic Dysfunction The optimal therapy for sympathetic overactivity has not been defined. Agents that have been considered include labetalol (an α- and β-adrenergic blocking agent that is recommended by some experts but that reportedly has caused sudden death), esmolol administered by continuous infusion (a beta blocker whose short half-life may be advantageous in the event of severe hypertension from unopposed α-adrenergic activity), clonidine (a central-acting antiadrenergic drug), and morphine sulfate. Parenteral magnesium sulfate

and continuous spinal or epidural anesthesia have been used but may be more difficult to administer and monitor. The relative efficacy of these modalities has yet to be determined. Hypotension or bradycardia may require volume expansion, use of vasopressors or chronotropic agents, or pacemaker insertion.

Vaccine Patients recovering from tetanus should be actively immunized (see below) because immunity is not induced by the small amount of toxin that produces disease.

Additional Measures Additional therapeutic measures include hydration to control insensible and other fluid losses, which may be significant; the meeting of the patient's increased nutritional requirements by enteral or parenteral means; physiotherapy to prevent contractures; and administration of heparin or another anticoagulant to prevent pulmonary emboli. Bowel, bladder, and renal function must be monitored. Gastrointestinal bleeding and decubitus ulcers must be prevented, and intercurrent infection should be treated.

PREVENTION ■ Active Immunization All partially immunized and unimmunized adults should receive vaccine, as should those recovering from tetanus. The primary series for adults consists of three doses: the first and second doses are given 4 to 8 weeks apart, and the third dose is given 6 to 12 months after the second. A booster dose is required every 10 years and may be given at mid-decade ages—35, 45, and so on. Combined tetanus and diphtheria toxoid, adsorbed (Td, for adult use)—rather than single-antigen tetanus toxoid—is preferred for persons >7 years of age. Adsorbed vaccine is preferred because it produces more persistent antibody titers than fluid vaccine. In response to a vaccine shortage in 2001, the Centers for Disease Control and Prevention recommended that routine booster doses of Td for adolescents and adults be deferred until 2002, pending a better supply, but that all other existing recommendations for vaccine use be followed.

Wound Management Proper wound management requires consideration of the need for (1) passive immunization with TIG and (2) active immunization with vaccine, preferably Td in persons over age 7 (Table 124-1). The dose of TIG for passive immunization of persons with wounds of average severity is 250 units intramuscularly, which produces a protective antibody level in the serum for at least 4 to 6 weeks; the appropriate dose of TAT, an equine-derived product, is 3000 to 6000 units. Vaccine and TAT should be administered at separate sites with separate syringes.

Neonatal Tetanus Measures aimed at preventing neonatal tetanus include maternal vaccination, even during pregnancy; efforts to increase the proportion of births that take place in the hospital; and the provision of training for nonmedical birth attendants.

PROGNOSIS The application of methods to monitor and support oxygenation has markedly improved the prognosis in tetanus; mortality rates as low as 10% have been reported from units accustomed to handling such cases. In the United States during the periods 1995–1997 and 1998–2000, the case-fatality rates were 11% and 16%, respectively. In the latter period, there were 20 deaths among the 113 cases with known outcome (total, 130 cases). The outcome is poor in neonates and the elderly and in patients with a short incubation period, a short interval from the onset of symptoms to admission, or a short period from the onset of symptoms to the first spasm (period of onset). Outcome is also related to the extent of prior vaccination.

The course of tetanus extends over 4 to 6 weeks, and patients may require prolonged ventilator support. Increased tone and minor spasms can last for months, but recovery is usually complete.

TABLE 124-1 *Wound Care: Administration of Tetanus Toxoid and Tetanus Immune Globulin*

History of Adsorbed Tetanus Toxoid	Clean Minor Wound		All Other Wounds[a]	
	Td[b]	TIG	Td[b]	TIG
Unknown or <3 doses	Yes	No	Yes	Yes
3 doses[c]	No, unless >10 years since last dose	No	No, unless >5 years since last dose	No

[a] Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missile or crushing injuries, burns, and frostbite.
[b] For children <7 years old, DTP (or DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. Td is preferred to tetanus toxoid alone in adults.
[c] If only three doses of fluid toxoid have been received, then a fourth dose of toxoid—preferably an adsorbed toxoid—should be given.
Note: DT, diphtheria and tetanus vaccine; DTP, diphtheria, tetanus, and pertussis vaccine; Td, tetanus-diphtheria toxoid, adsorbed; TIG, tetanus immune globulin.

125 BOTULISM

Elias Abrutyn

DEFINITION Botulism is a paralytic disease caused by potent protein neurotoxins elaborated by *Clostridium botulinum*. Illness begins with cranial nerve involvement, and progression proceeds caudally to involve the extremities. Cases may be classified as (1) *food-borne botulism*, from ingestion of preformed toxin in food contaminated with *C. botulinum*; (2) *wound botulism*, from toxin produced in wounds contaminated with the organism; and (3) *intestinal botulism*, from ingestion of spores and production of toxin in the intestine of infants (infant botulism) or adults. Botulinum toxin, because of its extraordinary potency, has long been considered a threat as an agent of bioterrorism or biological warfare (see Chap. 205).

ETIOLOGIC AGENT *C. botulinum*, a species encompassing a heterogeneous group of anaerobic gram-positive organisms that form subterminal spores, is found in soil and marine environments throughout the world and elaborates the most potent bacterial toxin known. Organisms of types A through G have been distinguished by the antigenic specificities of their toxins; a classification system based on physiologic characteristics has also been described. Rare strains of other clostridial

species—*C. butyricum* and *C. baratii*—have also been found to produce toxin. *C. botulinum* strains with proteolytic activity can digest food and produce a spoiled appearance; nonproteolytic types leave the appearance of food unchanged.

Of the eight distinct toxin types described (A, B, C_1, C_2, D, E, F, and G), all except C_2 are neurotoxins; C_2 is a cytotoxin of unknown clinical significance. Botulinum neurotoxin, whether ingested, inhaled, or produced in the intestine or a wound, enters the vascular system and is transported to peripheral cholinergic nerve terminals, including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The central nervous system is not involved. Active neurotoxin (150 kDa) is composed of a heavy chain (a 100-kDa fragment responsible for neurospecific binding and translocation in the nerve cell) and a light chain (a 50-kDa fragment responsible for intracellular catalytic activity). The steps involved in neurotoxin activity include (1) specific binding to presynaptic nerve cells at the myoneural junction, (2) internalization of the toxin inside the nerve cell in endocytic vesicles, (3) translocation of the toxin into the cytosol, and (4) proteolysis by toxin (a zinc endopeptidase) of components of the neuroexocytosis apparatus curtailing release of the neurotransmitter acetylcholine. Cure follows sprouting of new nerve terminals.

Toxin is heat-labile, but spores are highly heat-resistant; both can be inactivated under appropriate conditions (see "Prevention," below). In the gastrointestinal tract, toxin is complexed with nontoxin proteins and resists degradation. Toxin types A, B, E, and (rarely) F cause human disease; type G (from *C. argentinense*) has been associated with sudden death, but not with neuroparalytic illness, in a few patients in Switzerland; and types C and D cause animal disease.

EPIDEMIOLOGY Human botulism occurs worldwide. In the United States, the geographic distribution of cases by toxin type parallels the distribution of organism types found in the environment. Type A predominates west of the Rocky Mountains; type B is generally distributed but is more common in the East; and type E is found in the Pacific Northwest, Alaska, and the Great Lakes area. In the United States, food-borne botulism has been associated primarily with home-canned food, particularly vegetables, fruit, and condiments, and less commonly with meat and fish. Type E outbreaks are frequently associated with fish products. Commercial products occasionally cause outbreaks, but some of these outbreaks have resulted from improper handling after purchase. Outbreaks in restaurants, schools, and private homes have been traced to uncommon sources (commercial potpies, beef stew, turkey loaf, sautéed onions, baked potatoes, and chopped garlic in oil). Food-borne botulism can occur when (1) a food to be preserved is contaminated with spores, (2) preservation does not inactivate the spores but kills other putrefactive bacteria that might inhibit growth of *C. botulinum* and provides anaerobic conditions at a pH and temperature that allow germination and toxin production, and (3) food is not heated to a temperature that destroys toxin before being eaten.

CLINICAL MANIFESTATIONS ■ Food-Borne Botulism After ingestion of food containing toxin, illness varies from a mild condition for which no medical advice is sought to very severe disease that can result in death within 24 h. The incubation period is usually 18 to 36 h but, depending on toxin dose, can extend from a few hours to several days. Symmetric descending paralysis is characteristic and can lead to respiratory failure and death. Cranial nerve involvement, which almost always marks the onset of symptoms, usually produces diplopia, dysarthria, dysphonia, and/or dysphagia. Weakness progresses, often rapidly, from the head to involve the neck, arms, thorax, and legs; occasionally, weakness is asymmetric. Nausea, vomiting, and abdominal pain may precede or follow the onset of paralysis. Dizziness, blurred vision, dry mouth, and very dry, occasionally sore throat are common. Patients are generally alert and oriented, but they may be drowsy, agitated, and anxious. Typically, they have no fever. Ptosis is frequent; the pupillary reflexes may be depressed, and fixed or dilated pupils are noted in half of patients. The gag reflex may be suppressed, and deep tendon reflexes may be normal or decreased. Sensory findings are usually absent. Paralytic ileus, severe constipation, and urinary retention are common.

Wound Botulism Wound botulism occurs when the spores contaminating a wound germinate and form vegetative organisms that produce toxin. This rare condition resembles food-borne illness except that the incubation period is longer, averaging about 10 days, and gastrointestinal symptoms are lacking. Wound botulism has been documented after traumatic injury involving contamination with soil; in injection drug users, for whom black-tar heroin use has been identified as a risk factor; and after cesarean delivery. The illness has occurred even after antibiotics have been given to prevent wound infection. When present, fever is probably attributable to concurrent infection with other bacteria. The wound may appear benign.

Intestinal Botulism In intestinal botulism, toxin is produced in and absorbed from the intestine after the germination of ingested spores. Infant botulism is the most common form of botulism. The severity ranges from mild illness with failure to thrive to fulminant severe paralysis with respiratory failure. Infant botulism may be one cause of sudden infant death. The identification of contaminated honey as one source of spores has led to the recommendation that honey not be fed to children <12 months of age. Most cases cannot be attributed to a particular food source. The factors permitting intestinal colonization with *C. botulinum* are not fully defined, but cases usually involve infants <6 months of age; susceptibility may decrease as the normal intestinal flora develops. Intestinal botulism involving adults is uncommon. The patient may have a history of gastrointestinal disease, gastrointestinal surgery, or recent antibiotic therapy. Toxin and organisms may be identified in the stool.

Bioterrorism and Biological Warfare (See also Chap. 205) Botulinum toxin could be dispersed as an aerosol (producing inhalational botulism) or as a contaminant in material to be ingested (producing food-borne botulism). Inhalational botulism resembles food-borne illness, but gastrointestinal symptoms are absent. Botulism follows adsorption of toxin from mucosal surfaces (gut, lung) and wounds, but the toxin does not penetrate intact skin. As a toxin-mediated illness, botulism is noncommunicable, and standard isolation precautions are sufficient unless bacterial meningitis is being considered. Features suggestive of an outbreak due to deliberate release of botulinum toxin are shown in Table 125-1.

DIAGNOSIS A diagnosis of botulism must be considered in patients with symmetric descending paralysis who are afebrile and mentally intact. The bulbar musculature is involved initially, but sensory findings are absent and, early on, deep tendon reflexes remain intact. The differential diagnosis of botulism and differentiating features are listed in Table 125-2.

The demonstration of toxin in serum by bioassay in mice is definitive, but this test may be negative, particularly in wound and infant botulism. It is performed only by specific laboratories, which can be identified through regional public health authorities. Other assays are

TABLE 125-1 Features of Outbreaks Suggesting Deliberate Release of Botulinum Toxin[a]

- Outbreak of large number of cases of acute flaccid paralysis with prominent bulbar palsies
- Outbreak with an unusual botulinum toxin type (i.e., type C, D, F, or G or type E toxin not associated with food of aquatic origin)
- Outbreak with a common geographic factor among cases (e.g., airport, work location) but without a common dietary exposure (i.e., features suggesting an aerosol attack)
- Multiple simultaneous outbreaks with no common source

[a] A careful travel and activity history, as well as a dietary history, should be taken in any suspected botulism outbreak. Patients should also be asked whether they know of other persons with similar symptoms.

TABLE 125-2 *Selected Mimics That May Lead to Misdiagnosis of Botulism*

Condition	Features Distinguishing Condition from Botulism
COMMON MISDIAGNOSES	
Guillain-Barré syndrome[a] and its variants, especially Miller-Fisher variant	History of antecedent infection; paresthesias; often ascending paralysis; early areflexia; eventual CSF protein increase; EMG findings
Myasthenia gravis[a]	Recurrent paralysis; EMG findings; sustained response to anticholinesterase
Stroke[a]	Paralysis often asymmetric; abnormal CNS image
Intoxication with depressants (e.g., acute alcohol intoxication), organophosphates, carbon monoxide, or nerve gas	History of exposure; excessive drug levels detected in body fluids
Lambert-Eaton syndrome	Increased strength with sustained contraction; evidence of lung carcinoma; EMG findings similar to botulism
Tick paralysis	Paresthesias; ascending paralysis; tick attached to skin
OTHER MISDIAGNOSES	
Poliomyelitis	Antecedent febrile illness; asymmetric paralysis; CSF pleocytosis
CNS infections, especially of the brainstem	Mental status changes; CSF and EEG abnormalities
CNS tumor	Paralysis often asymmetric; abnormal CNS image
Streptococcal pharyngitis[b]	Absence of bulbar palsies; positive rapid antigen test result or throat culture
Psychiatric illness[a]	Normal EMG in conversion paralysis
Viral syndrome[a]	Absence of bulbar palsies and flaccid paralysis
Inflammatory myopathy[a]	Elevated creatine kinase level
Diabetic complications[a]	Sensory neuropathy; few cranial nerve palsies
Hyperemesis gravidarum[a]	Absence of bulbar palsies and acute flaccid paralysis
Hypothyroidism[a]	Abnormal thyroid function tests
Laryngeal trauma[a]	Absence of flaccid paralysis; dysphonia without flaccid paralysis
Overexertion[a]	Absence of bulbar palsies and acute flaccid paralysis

[a] Misdiagnoses made in a large outbreak of botulism (St. Louis ME et al: Botulism from chopped garlic: Delayed recognition of a major outbreak. Ann Intern Med 108:363, 1988).
[b] Pharyngeal erythema can occur in botulism.
Note: CNS, central nervous system; CSF, cerebrospinal fluid; EEG, electroencephalogram; EMG, electromyogram.

being developed and remain experimental. The demonstration of the organism or its toxin in vomitus, gastric fluid, or stool is strongly suggestive of the diagnosis, because intestinal carriage is rare. Isolation of the organism from food without toxin is insufficient grounds for the diagnosis. Wound cultures yielding the organism are suggestive of botulism. The edrophonium chloride (Tensilon) test for myasthenia gravis may be falsely positive in botulism but is usually less dramatically positive than in the former condition. Nerve conduction velocity is normal, but compound muscle action potentials on routine nerve stimulation studies are decreased with a supramaximal stimulus, and facilitation is evident after repetitive stimulation at high frequency. Single-fiber electromyography may be helpful. The white blood cell count and erythrocyte sedimentation rate are normal.

TREATMENT

Patients should be hospitalized and monitored closely, both clinically and by spirometry, pulse oximetry, and measurement of arterial blood gases for incipient respiratory failure. Intubation and mechanical ventilation should be strongly considered when the vital capacity is <30% of predicted, especially when paralysis is progressing rapidly and hypoxemia with absolute or relative hypercarbia is documented (Chap. 252). Serial measurements of the maximal static inspiratory pressure may be useful in predicting respiratory failure.

In food-borne illness, equine antitoxin should be administered as soon as possible after specimens are obtained for laboratory analysis. Treatment should not await laboratory analyses, which may take days. The previous trivalent antitoxin (types A, B, and E) preparation is no longer available. Instead, a bivalent preparation containing toxin types A and B and an investigational monovalent type E preparation can be obtained. The bivalent preparation is given routinely; monovalent type E antitoxin is given in addition when exposure to type E toxin is suspected (after seafood ingestion, for example). In the United States, antitoxin as well as help in clinical management and laboratory confirmation are available at *any* time from state health departments or from the Centers for Disease Control and Prevention (CDC: 404-639-2206; emergency number, 404-639-2888). A limited supply of an investigational heptavalent antitoxin (types A through G) is maintained by the U.S. military for emergency use.

After testing for hypersensitivity to horse serum, antitoxin is given as recommended by the CDC; repeated doses are not considered necessary. Anaphylaxis and serum sickness are risks inherent in use of the equine product, and desensitization of allergic patients may be required. If there is no ileus, cathartics and enemas may be given to purge the gut of toxin; emetics or gastric lavage can also be used if the time since ingestion is brief (only a few hours). Neither the use of antibiotics to eliminate an intestinal source for possible continued toxin production nor the administration of guanidine hydrochloride and other drugs to reverse paralysis is of proven value.

Treatment of infant botulism requires supportive care and administration of human botulism immune globulin (obtainable at all times from the California Department of Health Services at 510-540-2646). Neither equine antitoxin nor antibiotics have been shown to be beneficial. In wound botulism, equine antitoxin is administered. The wound should be thoroughly explored and debrided, and an antibiotic such as penicillin should be given to eradicate *C. botulinum* from the site, even though the benefit of this therapy is unproven. Results of wound cultures should guide the use of other antibiotics.

Botulinum toxins have been approved for therapeutic use. Botulinum toxin type A has been approved for the treatment of strabismus, blepharospasm, cervical dystonia, and glabellar lines; therapy appears safe and effective. Botulinum toxin type B has been approved for the treatment of cervical dystonia. The value of these preparations in many other conditions is being evaluated. Generalized botulism-like weakness complicating therapy has been reported but is rare.

PROGNOSIS Type A disease is generally more severe than type B, and mortality from botulism is higher among patients above age 60 than among younger patients. With improved respiratory and intensive care, the case-fatality rate in food-borne illness has been reduced to ~7.5% and is low in infant botulism as well. Artificial respiratory support may be required for months in severe cases. Some patients experience residual weakness and autonomic dysfunction for as long as a year after disease onset.

PREVENTION A pentavalent vaccine (A–E) is available for use in highly exposed individuals. Spores can be inactivated by exposure to high temperature (116° to 121°C) and pressure, as in steam sterilizers or pressure cookers used in accordance with the manufacturer's instructions. Toxin can be inactivated by exposure to a temperature of 100°C for 10 min. Newly identified cases should be reported immediately to public health authorities.

126 GAS GANGRENE AND OTHER CLOSTRIDIAL INFECTIONS

Dennis L. Kasper, Lawrence C. Madoff

DEFINITION Bacteria of the genus *Clostridium* are gram-positive, spore-forming, obligate anaerobes that are ubiquitous in nature. There are >60 recognized species of clostridia, many of which are generally considered saprophytic. Some of these species are pathogenic for humans and animals, particularly under conditions of lowered oxidation-reduction potential. Infections associated with these organisms range from localized wound contamination to overwhelming systemic disease. The four major disease categories for which clostridia are responsible are intestinal disorders, suppurative deep-tissue infections, skin and soft tissue infections, and bacteremia. Toxins play a major role in some of these syndromes. →***Colitis caused by C. difficile is discussed in Chap. 114.***

ETIOLOGY In humans, clostridia normally reside in the gastrointestinal tract and in the female genital tract, although they occasionally are isolated from the skin or the mouth. Of the known species of the genus *Clostridium*, at least 30 have been isolated from human infections. Like several other pathogenic anaerobic bacterial species, clostridia are quite aerotolerant, but they do not grow on artificial media in the presence of oxygen. Clostridia characteristically produce abundant gas in artificial media and form subterminal endospores. *C. perfringens*, one of the most important species, is encapsulated and nonmotile and rarely sporulates in artificial media; the spores can usually be destroyed by boiling. →***C. tetani and C. botulinum are discussed in detail in Chaps. 124 and 125, respectively.***

Clostridia are present in the normal colonic flora at concentrations of 10^9 to 10^{10}/g. Of the ≥30 species that normally colonize humans, *C. ramosum* is the most abundant and is followed in frequency by *C. perfringens*. These organisms are universally present in soil at concentrations of up to 10^4/g. *C. perfringens* strains are classified (on the basis of their production of several lethal toxins) into five types, designated A through E. Type A predominates in fecal flora of humans as well as in soil, whereas the habitats of types B through E are thought to be the intestinal tracts of other animals. Although clostridia are gram-positive organisms, many species may appear to be gram-negative in clinical specimens or stationary-phase cultures. Therefore, the results of Gram's staining of cultures or clinical material should be interpreted with great care.

C. perfringens is the most common of the clostridial species isolated from tissue infections and bacteremias; next in frequency are *C. novyi* and *C. septicum*. In the category of enteric infections, *C. difficile* is an important cause of antibiotic-associated colitis, and *C. perfringens* is associated with food poisoning (type A) and enteritis necroticans (type C).

PATHOGENESIS Despite the isolation of clostridial species from many serious traumatic wounds, the prevalence of severe infections due to these organisms is low. Two factors that appear to be essential to the development of severe disease are tissue necrosis and a low oxidation-reduction potential. *C. perfringens* requires about 14 amino acids and at least 6 additional growth factors for optimal growth. These nutrients are not found in appreciable concentrations in normal body fluids but are present in necrotic tissue. When *C. perfringens* grows in necrotic tissue, a zone of tissue damage due to the toxins elaborated by the organism allows progressive growth. In contrast, when only a few bacteria leak into the bloodstream from a small defect in the intestinal wall, the organisms do not have the opportunity to multiply rapidly because blood as a medium for growth is relatively deficient in certain amino acids and growth factors. Therefore, in a patient without tissue necrosis, bacteremia is usually benign.

C. perfringens possesses at least 17 possible virulence factors, including 12 active tissue toxins and enterotoxins. The enterotoxins include four major lethal toxins: α, β, ϵ, and ι. The *α toxin* is a phospholipase C (lecithinase) that splits lecithin into phosphorylcholine and diglyceride. It has been associated with gas gangrene and is known to be hemolytic, to destroy platelets and polymorphonuclear leukocytes (PMNs), and to cause widespread capillary damage. When injected intravenously, it causes massive intravascular hemolysis and damages liver mitochondria. The α toxin may be important in the initiation of muscle infections that may progress to gas gangrene. Experimentally, the higher the concentration of α toxin in the culture fluid, the smaller the dose of *C. perfringens* required to produce infection. The protective effect of antiserum is directly proportional to its content of α antitoxin. Studies suggest that *θ toxin*, a thiol-activated cytolysin that is also called *perfringolysin O*, may also play an important role in pathogenesis by promoting vascular leukostasis, endothelial cell injury, and regional tissue hypoxia. The resulting perfusion defects extend the anaerobic environment and contribute to rapidly advancing tissue destruction. A characteristic pathologic finding in gas gangrene is the near absence of PMNs despite extensive tissue destruction. Experimental data indicate that both α and θ toxins are essential in the leukocyte aggregation that occurs at the margins of tissue injury instead of the expected infiltration of these cells into the area of damage. Genetically altered strains induce less leukocyte aggregation when α toxin is absent and none when θ toxin is missing. The other major toxins, β, ϵ, and ι, are known to increase capillary permeability.

CLINICAL MANIFESTATIONS ■ **Intestinal Disorders** ■ *FOOD POISONING*

C. perfringens, primarily type A, is the second or third most common cause of food poisoning in the United States (Chap. 113). The responsible toxin is thought to be a cytotoxin produced by >75% of strains isolated from cases of foodborne disease. The cytotoxin binds to a receptor on the small-bowel brush border and induces a calcium ion–dependent alteration in permeability. The associated loss of ions alters intracellular metabolism, resulting in cell death. Outbreaks generally have resulted from problems in the cooling and storage of food cooked in bulk. The food sources primarily involved are meat, meat products, and poultry. Generally, the implicated meats have been cooked, allowed to cool, and then recooked the following day, often in a stew or hash. Strains of *C. perfringens* that contaminate meat manage to survive initial cooking. During reheating, the organisms sporulate and germinate. The disease is associated with an attack rate that is often as high as 70%. Symptoms of food poisoning from type A strains develop 8 to 24 h after ingestion of foods heavily contaminated with the organism. The primary symptoms include epigastric pain, nausea, and watery diarrhea usually lasting 12 to 24 h. Fever and vomiting are

uncommon. Molecular methods including ribotyping and pulsed-field gel electrophoresis have been used to detect fecal cytotoxin in outbreaks of food poisoning caused by *C. perfringens*.

C. perfringens has also been implicated in a more severe form of diarrhea than that of classic food poisoning. This more severe disease tends to occur in the elderly and has been associated with antibiotic use in hospitalized populations. In this form of disease, diarrhea is generally more profuse, of longer duration, and accompanied by abdominal pain. Blood and mucus have been detected in the feces of the affected patients. In one hospital-based study of a cluster of cases, widespread environmental contamination with *C. perfringens* spores was documented.

ENTERITIS NECROTICANS Necrotizing enteritis (enteritis necroticans, or *pigbel*) is caused by β toxin produced by type C strains of *C. perfringens* following ingestion of a high-protein meal in conjunction with trypsin inhibitors (e.g., in sweet potatoes) by a susceptible host who has limited intestinal proteolytic activity. This disease has been reported among children and adults in New Guinea. A similar disease, *darmbrand*, was epidemic in Germany after World War II. Clinical features of pigbel include acute abdominal pain, bloody diarrhea, vomiting, shock, and peritonitis; 40% of patients die. Pathologic studies reveal an acute ulcerative process of the bowel restricted to the small intestine. The mucosa is lifted off the submucosa, with the formation of large denuded areas. Pseudomembranes composed of sloughed epithelium are common, and gas may dissect into the submucosa. The source of the organisms may be the patient's own intestinal flora; cultures of ingested pork have failed to yield the organism. Antibodies to the β toxin of *C. perfringens* have been of considerable benefit in changing the course of established disease. In a large-scale trial, children immunized with *C. perfringens* β toxoid were protected.

NEUTROPENIC ENTEROCOLITIS (TYPHLITIS) See Chaps. 72 and 148.

Suppurative Deep Tissue Infections Clostridia are frequently recovered from various suppurative conditions in conjunction with other anaerobic and aerobic bacteria but can also be the only organisms isolated. These suppurative conditions, which exist with severe local inflammation but usually without the characteristic systemic signs induced by clostridial toxins, include intraabdominal sepsis, empyema, pelvic abscess, subcutaneous abscess, frostbite with gas gangrene, infection of a stump in an amputee, brain abscess, prostatic abscess, perianal abscess, conjunctivitis, infection of a renal cell carcinoma, and infection of an aortic graft.

Clostridia are isolated from approximately two-thirds of patients with intraabdominal infections resulting from intestinal perforation. *C. ramosum*, *C. perfringens*, and *C. bifermentans* are the most commonly isolated species. The presence of clostridial species does not affect the clinical presentation or outcome of these infections (Chap. 148).

An association has been made between malignancy and the isolation of *C. septicum* in the absence of grossly contaminated deep traumatic wounds. A major site for such a malignancy is the gastrointestinal tract, particularly the colon. An association with leukemia or with other solid tumors has also been noted, and one case of fatal myonecrosis has been reported in a patient with ovarian cancer. Some of these patients present with *C. septicum* bacteremia; these cases have a fulminant clinical course (discussed below). Others develop localized suppurative infection in the abdomen or the abdominal wall without bacteremia. Presumably, this infection arises from a silent perforation that leads to intraabdominal abscess formation.

Clostridia have been isolated from suppurative infections of the female genital tract, particularly tuboovarian and pelvic abscesses. The major species involved has been *C. perfringens*. Most of these are mild suppurative infections without evidence of uterine gangrene. *C. perfringens* has been isolated from as many as 20% of diseased gallbladders at surgery. One clinical syndrome, *emphysematous cholecystitis*, is caused by clostridial species at least 50% of the time. In this syndrome, gas forms in the biliary radicles and the wall of the gallbladder. Emphysematous cholecystitis is seen most often in diabetic patients. Although the mortality rate in this entity is higher than in more common forms of cholecystitis, there is no evidence of myonecrosis.

Clostridia are among the many organisms found in empyema fluid or isolated by transtracheal aspiration from patients with lung abscesses. There is no unique clinical clue to the presence of clostridia (as opposed to other organisms) in these infections. *C. perfringens* has been reported as a cause of empyema arising from aspiration pneumonia, pulmonary emboli, and infarction. However, the majority of cases of clostridial empyema are secondary to trauma.

Skin and Soft Tissue Infections Various categories of traumatic wound infections due to clostridia have been described: simple contamination, anaerobic cellulitis, fasciitis with or without systemic manifestations, and anaerobic myonecrosis.

SIMPLE CONTAMINATION Clostridia are cultured most often from wounds in the absence of clinical signs of sepsis. As many as 30% of battle wounds are contaminated by clostridia without signs of suppuration, and 16% of penetrating abdominal wounds yield clostridia on culture despite treatment with cephalothin and kanamycin. In cases of trauma, clostridia are isolated with equal frequency from suppurative and well-healing wounds. Thus the diagnosis of clostridial infection should be based on clinical rather than bacteriologic criteria.

LOCALIZED INFECTION OF THE SKIN AND SOFT TISSUE WITHOUT SYSTEMIC SIGNS This condition, originally referred to as *anaerobic cellulitis*, is a localized infection involving the skin and soft tissue and is due to clostridia alone or with other bacteria. There are no systemic signs of toxicity, although the infection may invade locally, producing necrosis. These infections tend to be relatively indolent, spreading slowly to contiguous areas. Localized infections are relatively free of pain and edema. Perhaps because of the lack of edema, gas that is limited to the wound and the immediately surrounding tissue may be more evident than in gas gangrene. In these localized infections, gas is never found intramuscularly. Cellulitis, perirectal abscesses, and diabetic foot ulcers are typical infections from which clostridial species can be isolated. If inadequately treated, these localized infections advance by extension through subcutaneous tissue and fascial planes into muscle and may produce severe systemic disease with signs of toxemia.

A localized form of suppurative myositis has been described in heroin addicts. These patients develop local pain and tenderness in discrete areas (particularly the thigh and forearm), with the subsequent appearance of fluctuance and crepitance that require surgical drainage. The unusual aspect of these infections is that they remain localized without systemic signs of toxicity. Moreover, the affected local areas are not necessarily sites of trauma or heroin injection. Pathologic examination reveals subcutaneous abscesses, purulent myositis, and fasciitis from which clostridia are recovered in pure culture; on occasion, mixed infections involving aerobes and anaerobes are found. Wound botulism has been reported in association with the injection of black tar heroin.

SPREADING CELLULITIS AND FASCIITIS WITH SYSTEMIC TOXICITY This condition involves diffuse spreading cellulitis and fasciitis, without myonecrosis and with only mild inflammation in muscle. Patients present with the abrupt onset of a syndrome that progresses rapidly (within hours) through the fascial planes. In cases with suppuration and gas in soft tissues as well as overwhelming toxemia, the infection is rapidly fatal. On physical examination there is subcutaneous crepitation but little localized pain. Surgery is of no proven value because there are no discretely involved tissues amenable to resection, as may be the case in myonecrosis. However, in rapidly advancing fasciitis, incision of the affected area is still the cornerstone of therapy. The initial local lesion may be quite innocuous and arises from an area involved by tumor or other infection and not by injury. The systemic toxic effects include hemolysis and injury of capillary membranes. Usually, this infection is fatal within 48 h, despite intensive therapy involving antitoxin and exchange transfusion. This syndrome is seen most commonly in patients with carcinoma, especially of the sigmoid or the

cecum. Presumably, the tumor invades the fascia, and colonic contents leak into the abdominal wall. Patients present with extreme toxicity and occasionally with total-body crepitation. The syndrome differs from necrotizing fasciitis caused by other organisms in three respects: (1) rapid mortality, (2) rapid tissue invasion, and (3) the systemic effects of the toxin, typified by massive hemolysis.

GAS GANGRENE (CLOSTRIDIAL MYONECROSIS) Gas gangrene is characterized by rapid and extensive necrosis of muscle accompanied by gas formation and systemic toxicity and occurs when bacteria invade healthy muscle from adjacent traumatized muscle or soft tissue. The infection originates in a wound contaminated with clostridia. Although >30% of deep wounds are infected with clostridia, the incidence of clostridial myonecrosis is quite low. These infections occur in both military and civilian settings. An essential factor in the genesis of gas gangrene appears to be trauma, particularly involving deep muscle laceration. The entity of clostridial myonecrosis is relatively uncommon after simple, through-and-through bullet wounds without shattering of bone and is relatively common following shrapnel fragmentation wounds, particularly when deep muscle is involved. In civilian cases, gas gangrene can follow trauma, surgery, or intramuscular injection. The trauma need not be severe; however, the wound must be deep, necrotic, and without communication to the surface.

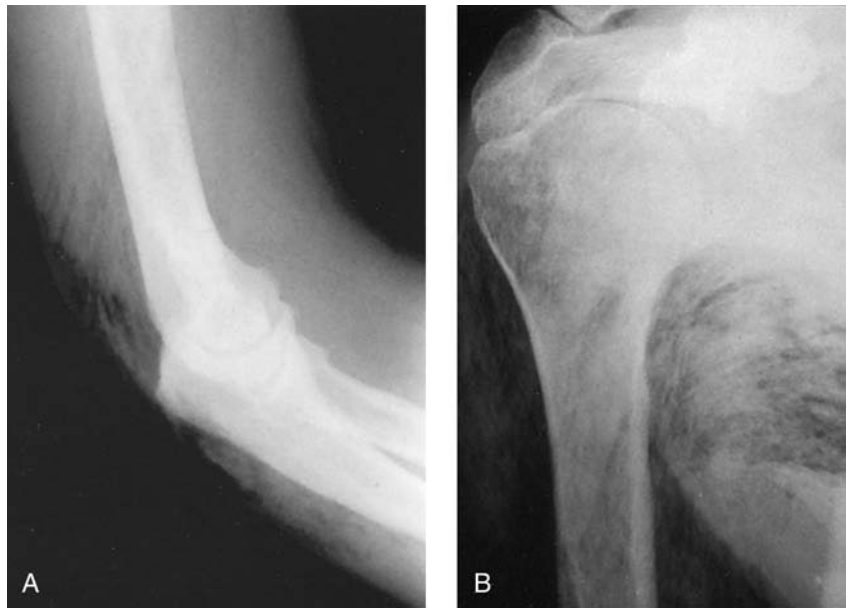

FIGURE 126-1 Spontaneous gas gangrene. Radiographs of the elbow (*A*) and shoulder (*B*) show gas in tissue. The patient developed spontaneous gas gangrene of the hand, which spread rapidly up the arm and onto the thorax. *C. septicum* was grown from blood and necrotic tissue of the arm. *[Reprinted with permission from DL Stevens (ed): Atlas of Infectious Diseases, vol II: Skin, Soft Tissue, Bone and Joint Infections. Philadelphia, Current Medicine, 1995.]*

The incubation period of gas gangrene is usually short: almost always <3 days and frequently <24 h. Some 80% of cases are caused by *C. perfringens*, while *C. novyi*, *C. septicum*, and *C. histolyticum* cause most of the remaining cases. Typically, gas gangrene begins with the sudden onset of pain in the region of the wound, which helps to differentiate it from spreading cellulitis. Once established, the pain increases steadily in severity but remains localized to the infected area and spreads only if the infection spreads. Soon after pain develops, local swelling and edema—accompanied by a thin, often hemorrhagic exudate—appear. Patients frequently develop marked tachycardia, but elevation in temperature may be only minimal. Gas is usually not obvious at this early stage and may be completely absent. Frothiness of the wound exudate may be noted. The skin is tense, white, often marbled with blue, and cooler than normal. The symptoms progress rapidly; swelling, edema, and toxemia increase, and a profuse serous discharge, which may have a peculiar sweetish smell, appears. Gram's staining of the wound exudate shows many gram-positive rods with relatively few inflammatory cells.

At surgery, muscle may appear pale because of the intensity of edema, but it does not contract when probed with a scalpel. When dissected, the muscle is beefy red and nonviable and can progress to become black, friable, and gangrenous. It is important to establish a diagnosis early, preferably by frozen-section biopsy of muscle.

Despite hypotension, renal failure, and (often) body crepitation, patients with myonecrosis frequently have a heightened awareness of their surroundings until just before death, when they lapse into toxic delirium and coma. In untreated cases, as the local wounds progress, the skin becomes bronzed; bullae appear, become filled with dark red fluid, and are accompanied by dark patches of cutaneous gangrene. Gas appears in later phases (Fig. 126-1) but may not be as obvious as in anaerobic cellulitis. Jaundice is rare in wound gas gangrene (in contrast to uterine infections) and, when it does appear, is almost invariably associated with hemoglobinuria, hemoglobinemia, and septicemia. Cases of clostridial myonecrosis without a history of trauma have been reported. These patients have bullous lesions and crepitation of the skin; they present with a rapidly worsening course that includes myonecrosis, especially of the extremities.

Bacteremia and Clostridial Sepsis The relatively common entity of transient clostridial bacteremia can arise in any hospitalized patient but is most common with a predisposing focus in the gastrointestinal tract, biliary tract, or uterus. Fever frequently resolves within 24 to 48 h without therapy. Despite the finding of clostridial bacteremia following septic abortions and the frequent isolation of clostridia from the lochia, most of the patients involved do not have evidence of sepsis. In one series of 60 patients with clostridial bacteremia, half had an infected site that could be associated with the bacteremia, while the other half had a totally unrelated illness, such as tuberculous pneumonia, meningitis, or benign gastroenteritis. By the time blood culture reports are returned, patients frequently are completely well and sometimes have been discharged. Therefore, when a blood culture is positive for clostridia, the patient must be assessed clinically rather than simply treated on the basis of the culture result.

Clostridial sepsis is an uncommon but almost invariably fatal illness following clostridial infection—primarily that of the uterus, colon, or biliary tract. This entity must be differentiated from transient clostridial bacteremia, which is much more common. *C. perfringens* causes the majority of cases of both sepsis and transient bacteremia. *C. septicum*, *C. sordellii*, and *C. novyi* account for most of the remainder of cases. Clostridia account for 1 to 2.5% of all positive blood cultures in major hospital centers.

The majority of cases of clostridial sepsis originate from the female genital tract and follow septic abortion. Introduction of a foreign body is a common antecedent event. In the uterus, residual necrotic fetal and placental tissues and traumatized endometrium may allow the growth of clostridia. Only a small fraction of cases of septic abortion (1%) are followed by serious sepsis. In these patients, sepsis, fever, and chills begin from 1 to 3 days after the attempted abortion. The initial signs are malaise, headache, severe myalgias, abdominal pain, nausea, vomiting, and occasionally diarrhea. Frequently, a bloody or brown vaginal discharge is noted. Patients may rapidly develop oliguria, hypotension, jaundice, and hemoglobinuria. The hemolysis, which is secondary to *C. perfringens* α toxin, causes a characteristic bronzing of the skin. As in myonecrosis, the mental status of severely ill patients is characterized by increased alertness and apprehension. Local examination of the pelvis reveals foul cervical discharge, occasionally with gas. Frequently, laceration marks around the cervix or perforation of the cervical segment is evident. If the infection involves

the myometrium or has spread to the adnexa, extreme tenderness, guarding, and an adnexal mass may be found.

Laboratory studies in patients with sepsis reveal an elevated white blood cell count and may show pink, hemoglobin-tinged plasma. Anemia is proportional to the degree of hemolysis, and the hematocrit may be extremely low. Platelet counts may be reduced, and there is often evidence of disseminated intravascular coagulation (DIC). Oliguria or anuria, increasingly refractory hypotension, and hemorrhage and bruising may develop.

Clostridia may enter the bloodstream from the gastrointestinal or biliary tract. This occurrence is associated with ulcerative lesions or obstruction of the small or large intestine, necrotic or infiltrating malignancy, bowel surgery, or various abdominal catastrophes. The patient may present with an acute febrile illness, with chills and fever but no other signs of localized infection. Intravascular hemolysis occurs in as many as half of such cases. Biliary or gastrointestinal symptoms, if present, may be the only clue to the etiology. Positive blood cultures provide the definitive clue to the diagnosis.

Patients with malignant disease can also develop rapidly fatal clostridial sepsis, particularly from a gastrointestinal focus. The most common species in this setting is *C. septicum*. Characteristic signs and symptoms include fever, tachycardia, hypotension, abdominal pain or tenderness, nausea, vomiting, and (preterminally) coma. The tachycardia may be out of proportion to the fever. Only ~20 to 30% of patients develop hemolysis. A striking feature of this syndrome is the rapidity of death, which frequently occurs in <12 h.

DIAGNOSIS The diagnosis of clostridial disease, in association with positive cultures, must be based primarily on clinical findings. Because of the presence of clostridia in many wounds, their mere isolation from any site, including the blood, does not necessarily indicate severe disease. Smears of wound exudates, uterine scrapings, or cervical discharge may show abundant large gram-positive rods as well as other organisms. Cultures should be placed in selective media and incubated anaerobically for identification of clostridia. The diagnosis of clostridial myonecrosis can be established by frozen-section biopsy of muscle.

The urine of patients with severe clostridial sepsis may contain protein and casts, and some patients may develop severe uremia. Profound alterations of circulating erythrocytes are seen in severely toxemic patients. Patients have hemolytic anemia, which develops extremely rapidly, along with hemoglobinemia, hemoglobinuria, and elevated levels of serum bilirubin. Spherocytosis, increased osmotic and mechanical red blood cell fragility, erythrophagocytosis, and methemoglobinemia have been described. DIC may develop in patients with severe infection. In patients with severe sepsis, Wright's or Gram's staining of a smear of peripheral blood or buffy coat may demonstrate clostridia.

X-ray examination sometimes provides an important clue to the diagnosis by revealing gas in muscles, subcutaneous tissue, or the uterus. However, the finding of gas is not pathognomonic for clostridial infection. Other anaerobic bacteria, frequently mixed with aerobic organisms, may produce gas.

Rx TREATMENT (Table 126-1)

Traumatic wounds should be thoroughly cleansed and debrided. Traditionally, the antibiotic treatment of choice for severe clostridial infection has been penicillin G (20 million units per day in adults). Penicillin G treatment of gas gangrene has become more controversial because of increasing resistance to this drug and data obtained from animal models of infection. In a mouse model of gas gangrene, antibiotics inhibiting toxin synthesis appeared to be preferable to cell wall–active drugs; clindamycin treatment enhanced survival more than therapy with penicillin; and the combination of clindamycin and penicillin was superior to penicillin alone. For severe clostridial sepsis, clindamycin may be used at a dose of 600 mg every 6 h in combination with high-dose penicillin (3 to 4 million units every 4 h). Although no clinical trials validate this choice, it is gaining acceptance in the infectious disease community.

In cases of penicillin sensitivity or allergy, other antibiotics should be considered, but all should be tested for in vitro activity because of the occasional isolation of resistant strains. Clostridia are frequently, but not universally, susceptible in vitro to cefoxitin, carbenicillin, chloramphenicol, clindamycin, metronidazole, doxycycline, imipenem, minocycline, tetracycline, third-generation cephalosporins, and vancomycin. For severe clostridial infections, sensitivity testing should be done before an antimicrobial agent with unpredictable activity is used. Simple contamination of a wound with clostridia should not be treated with antibiotics. Localized skin and soft tissue infection can be managed by debridement rather than with systemic antibiotics. Drugs are required when the process extends into adjacent tissue or when fever and systemic signs of sepsis are present. Surgery is a mainstay of therapy for gas gangrene. Amputation is often required for rapidly spreading infection involving a limb, as the process frequently fails to respond to antibiotics. Hysterectomy is required for uterine myonecrosis. Abdominal wall myonecrosis usually continues despite initial aggressive surgery and antibiotic therapy and requires repeated surgical debridement of all involved muscle.

Suppurative infections should be treated with antibiotics. Frequently, broad-spectrum antibiotics must be used because of the mixed flora involved in these infections. Aminoglycosides can be used for the aerobic gram-negative bacteria involved in mixed infections.

The use of a polyvalent gas gangrene antitoxin is still recommended by some authorities. At present, no such antitoxin is produced in the United States, and most centers have discontinued its use in the management of patients with suspected gas gangrene or clostridial postabortion sepsis because of questionable efficacy and the substantial risk of hypersensitivity to horse serum, from which the antitoxin is derived.

The use of hyperbaric oxygen in the treatment of gas gangrene is also controversial. Studies in humans are not well designed to an-

TABLE 126-1 *Treatment of Clostridial Infections*[a]

Condition	Antibiotic Treatment	Penicillin Allergy	Adjunctive Treatment/Note
Contamination	None	—	—
Gas gangrene	Penicillin, 3 to 4 million units IV q4h, *plus* Clindamycin, 600 mg IV q6h	Chloramphenicol, metronidazole, imipenem, doxycycline (see text)[b]	Surgical debridement with wide excision is essential; consider hyperbaric oxygen
Clostridial sepsis	Penicillin, 3 to 4 million units IV q4h, *plus* Clindamycin, 600 mg IV q6h	Chloramphenicol, metronidazole, imipenem, doxycycline (see text)[b]	Transient bacteremia may be clinically insignificant
Suppurative deep-tissue infections (e.g., abdominal wall, gynecologic)	Penicillin, 3 to 4 million units IV q4h, *plus* Gentamicin, 5 mg/kg IV q24h, *or* A third-generation cephalosporin (e.g., ceftriaxone, 2 g (IV q12h)	As above, plus gentamicin or a quinolone	Empirical therapy should be given; therapy should be based on Gram's stain and culture results when available

[a] Treatment recommendations for *C. difficile* colitis, tetanus, and botulism are found in Chaps. 114, 124, and 125, respectively.
[b] Perform sensitivity testing; consider desensitization.

swer questions on efficacy, but several knowledgeable authors believe that hyperbaric oxygen therapy has contributed to dramatic clinical improvement. Such therapy may, however, be associated with untoward effects due to oxygen toxicity and high atmospheric pressure. Some centers without hyperbaric chambers have reported acceptable mortality rates; thus expert surgical and medical management and control of complications are probably the most important factors in the treatment of gas gangrene. Fasciotomy should not be delayed for hyperbaric oxygen therapy.

ACKNOWLEDGMENT

Section 6 Diseases Caused by Gram-Negative Bacteria

127 MENINGOCOCCAL INFECTIONS

David S. Stephens, Robert S. Munford, Lee M. Wetzler

DEFINITION *Neisseria meningitidis* is the etiologic agent of two life-threatening diseases: meningococcal meningitis and fulminant meningococcemia. Meningococci also cause pneumonia, septic arthritis, pericarditis, urethritis, and conjunctivitis. Most cases are potentially preventable by vaccination.

ETIOLOGIC AGENT Meningococci are gram-negative aerobic diplococci. Unlike the other neisseriae, they have a polysaccharide capsule. They are transmitted among humans—their only known habitat—via respiratory secretions. Colonization of the nasopharynx or pharynx is much more common than invasive disease.

MICROBIOLOGY AND CLASSIFICATION On the basis of genome sequencing, *N. meningitidis* is categorized as a β-proteobacterium related to *Bordetella*, *Burkholderia*, *Kingella*, and *Methylomonas* and—more distantly—to *Vibrio*, *Haemophilus*, and *Escherichia coli*. Meningococci are traditionally classified by serologic typing systems based on structural differences in capsule (serogroup), major outer-membrane protein (OMP) porins (serotype), other OMPs (serosubtype), and lipooligosaccharide (LOS; immunotype). Thus, the meningococcal strain designation B:2b:P1.5:L3,7,9 reflects the serogroup (B), serotype (2b), serosubtype (P1.5), and immunotype (L3,7,9).

Meningococci are classified into serogroups according to the antigenicity of their capsular polysaccharides, which reflects structural differences in these carbohydrates. Five serogroups (A, B, C, Y, and W-135) are responsible for >90% of cases of meningococcal disease worldwide. Serogroup A strains, which caused most of the large epidemics of meningococcal disease during the first half of the twentieth century, are now associated with recurring epidemics in sub-Saharan Africa and other locales in the developing world. Serogroups B and C cause most cases of sporadic and epidemic meningococcal disease in industrialized countries. In the United States and Canada during the 1990s, serogroup B was the most common cause of sporadic disease, while serogroup C was a more frequent cause of outbreaks. Serogroup Y has recently been isolated from almost one-third of cases of meningococcal disease in the United States. In general, patients with serogroup Y disease are older and more likely to be African American or to have a chronic underlying illness than are patients with disease caused by other serogroups. Serogroups Y and W-135 are isolated more often than the other serogroups from patients with pneumonia.

One limitation of the serogroup classification is that the genes for capsule biosynthesis can be transferred from one strain to another, with consequent changes in the capsule structure of the recipient strain and therefore in its serogroup. Other methods for tracking meningococcal strains have thus become increasingly useful. Meningococcal serotypes and subtypes are defined by antigenic differences in specific OMPs, whereas multilocus enzyme electrophoresis classifies bacteria into electrophoretic types (ETs). Other techniques for establishing strain identity or nonidentity are pulsed-field gel electrophoresis and amplification of bacterial genomic sequences by polymerase chain reaction (PCR). These techniques are used for the identification of the strains associated with outbreaks of disease. For example, the virulent III-1 clonal complex of serogroup A was first recognized in Nepal in 1983 to 1984; it spread to Mecca, then to sub-Saharan Africa, and subsequently to temperate Africa. The serogroup B ET-5 complex was first identified in Norway in the 1970s and later caused outbreaks in Europe, Cuba, and South and North America (most recently, in the Pacific Northwest). Serogroup C ET-24 (the ET-37 complex) has caused sporadic cases and outbreaks in Canada and the United States; in some analyses, it has been associated with high rates of mortality and morbidity.

EPIDEMIOLOGY Meningococcal disease occurs worldwide as isolated (sporadic) cases, institution- or community-based outbreaks, and large epidemics. Despite effective antibiotics and partially effective vaccines, *N. meningitidis* is still a leading global cause of meningitis and rapidly fatal sepsis, often in otherwise-healthy individuals.

N. meningitidis is unique among the major bacterial agents of meningitis in that it causes epidemic as well as endemic (sporadic) disease. In all, 300,000 to 500,000 cases of meningococcal disease occur worldwide each year—numbers that frequently are increased by large epidemics. The annual incidence of meningococcal disease is 1 to 2 cases per 100,000 population for sporadic disease, 5 to 10 per 100,000 for hypersporadic disease (localized outbreaks and case clusters), and 10 to >1000 per 100,000 for pandemic and epidemic disease (e.g., serogroup A epidemics). The African meningitis belt (i.e., sub-Saharan Africa) continues to have high levels of sporadic disease and major outbreaks. In the largest meningococcal epidemic outbreak recorded, >300,000 cases and 30,000 deaths occurred in sub-Saharan Africa in 1996 to 1997 due to serogroup A *N. meningitidis*. Large serogroup B epidemics and/or outbreaks of serogroup A or C meningococcal disease have also occurred in Europe, the United States, Canada, China, Nepal, Mongolia, New Zealand, Cuba, Brazil, Chile, Saudi Arabia, and South Africa since 1980. In 2000, 2001, and 2002, worldwide epidemics of serogroup W-135 meningococcal disease occurred in association with the Muslim pilgrimage to Mecca (the Hajj) and in the meningitis belt of sub-Saharan Africa.

In the United States, the attack rate for sporadic meningococcal disease is ~1 case per 100,000 persons per year. Disease attack rates are highest among infants 3 to 9 months of age (10 to 15 cases per

100,000 infants per year). Attack rates are higher among children than among adults, and there is a second peak of incidence among teenagers, in whom outbreaks have often been tied to residence in barracks, dormitories, or other crowded conditions. Although the age-specific incidence is much lower among adults (<1 case per 100,000 persons per year), one-third to one-half of all cases of sporadic meningococcal disease occur in individuals ≥18 years of age. Peak disease incidence coincides with the winter peak of respiratory viral illnesses. During epidemics, disease incidence increases disproportionately among teenagers and young adults. In sub-Saharan Africa, epidemic outbreaks occur with the dry season and the coming of the dry dusty winds of the harmattan.

Meningococcal disease occurs more commonly among the household contacts of primary cases than in the general population. The secondary attack rate is 400 to 1000 per 100,000 household members. School-based clusters of cases have also been described; the attack rate among school contacts of cases has been estimated at 2 to 4 cases per 100,000 exposed individuals. In outbreaks on college campuses, attack rates have been highest among students living in dormitories. Most secondary cases occur within 2 weeks of the primary case, although some cases may develop as long as several months later. Secondary cases account for <2% of all cases reported each year in the United States.

Meningococcal colonization of the nasopharynx (asymptomatic carriage) can persist for months. In nonepidemic periods, ~10% of healthy individuals are colonized. Factors that predispose individuals to colonization with *N. meningitidis* include residence in the same household with a person who has meningococcal disease or is a carrier, household or institutional crowding, active or passive exposure to tobacco smoke, and a recent history of a viral upper respiratory infection. These factors have also been associated with an increased risk of meningococcal disease.

PATHOGENESIS (Fig. 127-1) Meningococci that colonize the upper respiratory tract are internalized by nonciliated mucosal cells and may traverse them to enter the submucosa, from which they can make their way into the bloodstream. While meningococcal colonization occurs often in healthy humans, bloodstream infection is an infrequent event that is not essential for the organisms' survival and spread. The production of human disease has no obvious evolutionary advantage for either pathogen or host. Although some strains of *N. meningitidis* are thought to cause more severe disease in humans than do other strains, the basis for this difference is not understood. Meningococci may undergo important phenotypic changes when they adapt to growth in vivo; presumed virulence traits include the antiphagocytic capsular polysaccharide, an ability to sialylate LOS so that it mimics host-cell carbohydrate moieties, the secretion of IgA protease, and mechanisms for iron acquisition. The ET-5 strain of serogroup B *N. meningitidis* has been associated with high case-fatality rates in some populations but not in others; this discrepancy suggests that host factors also contribute importantly to disease pathogenesis.

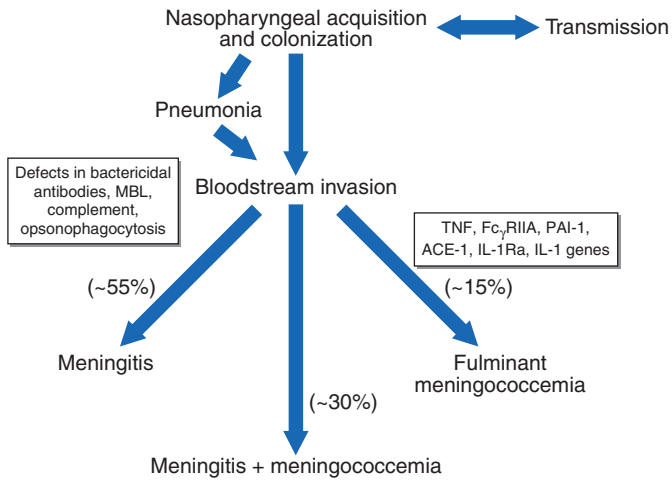

FIGURE 127-1 Meningococcal disease pathogenesis, susceptibility, and severity. After human-to-human transmission, environmental factors (smoking, coinfections), polymorphisms in innate immunity or other genes, and absence of mucosal antibodies may confer susceptibility to meningococcal invasion from the nasopharynx into the bloodstream. In individuals who lack bactericidal antibodies, terminal or alternative pathway complement-deficiency states and other genetic polymorphisms may influence the severity of the ensuing host response and the clinical presentation. Although each of these gene associations has been reported, most of them require confirmation in different ethnic groups. MBL, mannose-binding lectin; TNF, tumor necrosis factor; FcγRIIA, FCγRIIA R131 allele; PAI-1, plasminogen activator inhibitor 1; ACE-1, angiotensin-converting enzyme 1; IL, interleukin.

A meningococcus that enters the bloodstream from the nasopharynx and survives host defenses generally has one of two fates. If multiplication occurs slowly, the bacteria eventually may seed local sites, such as the meninges and/or (less commonly) the joints or the pericardium. More rapid multiplication in the bloodstream is associated with the clinical features of meningococcemia, with petechiae, purpura, disseminated intravascular coagulation (DIC), and shock, which usually causes symptoms before local sites become infected. Thus compartmentalization of bacterial growth and host inflammation either in the blood or at a local site (usually the meninges) can occur.

Outer-Membrane Components Associated with Virulence Invasive meningococcal strains are characterized by the expression of capsular polysaccharide and other outer-membrane structures, including LOS (endotoxin). Outer-membrane blebbing, meningococcal autolysis, molecular mimicry, genome plasticity, horizontal DNA exchange, and phase and/or antigenic variation are all important in meningococcal virulence.

CAPSULE The polysaccharide capsule is a major—if not the major—virulence factor of *N. meningitidis*. As stated above, meningococci isolated from the blood or cerebrospinal fluid (CSF) of patients with invasive meningococcal disease most often express capsules of serogroups A, B, C, Y, and W-135. Isolates from asymptomatic nasopharyngeal carriers are nongroupable or express B, Y, X, Z, or 29E capsular serogroups. Capsules impart antiphagocytic and antibactericidal properties to the meningococcus and thus enhance meningococcal survival during invasion of the bloodstream or CSF. Capsules also provide protective properties (e.g., preventing desiccation and phagocytic killing) and antiadherent properties; these properties promote meningococcal transmission, spread, and survival externally and within intracellular compartments such as phagocytic vacuoles.

Except in serogroup A, the major meningococcal capsular polysaccharides associated with invasive disease are composed of sialic acid (*N*-acetyl neuraminic acid, NANA) derivatives. The serogroup B capsule is composed of (α2→8)-linked NANA, the serogroup C capsule of (α2→9)-linked NANA, the serogroup Y capsule of alternating D-glucose and NANA, and the serogroup W-135 capsule of D-galactose and NANA. The differences in sialic acid capsule composition are derived from the distinct polysialyltransferases encoded by the fourth gene of the capsule biosynthesis operon, which is also used as a basis for capsule-specific PCR diagnosis. A four-gene operon encoding the capsule transport apparatus (ctr) is conserved among different serogroups and is also used in PCR diagnosis. The serogroup A capsule is composed of repeating units of (α)-linked *N*-acetyl-mannosamine-1-phosphate and is encoded by a four-gene biosynthesis cassette unique for this serogroup.

OUTER-MEMBRANE PROTEINS Meningococci isolated from sites of colonization or invasive disease are piliated. Pili are complex outer-membrane, protein-based organelles that facilitate adhesion—the first step in meningococcal host-cell interactions. Meningococci express two major OMP porins, PorA and PorB. Human opsonins and bactericidal antibodies induced during meningococcal disease have been shown to recognize PorA and PorB. Vaccines based on PorA-containing outer-membrane vesicles are under development. Another OMP, Opc, is involved in cell attachment and is also a target of bactericidal antibodies. Meningococci encounter iron-restricted environments during infection. The majority of host iron is presented intracellularly as he-

moglobin and extracellularly as human transferrin and lactoferrin. Meningococci have evolved systems for acquisition of these iron-carrying molecules.

LIPOOLIGOSACCHARIDE Meningococcal LOS is structurally related to the lipopolysaccharide (LPS) expressed by many gram-negative bacilli. However, LOS does not have repeating O-antigen subunits of sugars. The lipid A moiety of LOS, which has been classically termed *endotoxin* (as opposed to the bacterial exotoxins), is the portion that mediates the induction of inflammatory cytokines often seen in disease. The effect of lipid A is due to an interaction with the innate immune receptor Toll-like receptor 4 (TLR4) in association with the membrane protein MD2. TLR4 and MD2 are found mainly on macrophages/monocytes, dendritic cells, and other phagocytes. The morbidity and mortality of meningococcal bacteremia and meningitis have been directly correlated with the amount of circulating meningococcal endotoxin.

Other Virulence Mechanisms The outer-membrane components of *N. meningitidis* (e.g., pili, LOS, Opa proteins, Opc, capsule) vary in expression or structure at high frequencies (10^{-2} to 10^{-4} per cell per generation). Variation is the result of genetic switches that turn expression of a component on or off, regulate the amount of a component, or alter the structure of a component. Genetic events leading to phase and structural variation allow immune escape and create variability in the structures that are important in pathogenesis (on and off expression of attachment ligands, protection against serum killing, invasion determinants). The serogroup B capsule provides an example of how meningococci downregulate the human immune response through the expression of host-like antigens. The (α2→8)-linked polysialic acid capsule of serogroup B meningococci is identical to structures on the human neural cell adhesion molecule N-CAM. Meningococci are also characterized by frequent vesiculation (blebbing) of the outer membrane, and the amount of blebbing may vary between strains. Blebs may contribute to the rapid initiation of the inflammatory and clotting cascades. They may also be related to the natural autolysis of meningococci that results in DNA release and facilitates genetic transformation.

Specific disease manifestations of meningococcal infections have specific virulence and pathogenic mechanisms as described below for fulminant meningococcemia and meningitis.

Fulminant Meningococcemia (Purpura Fulminans) Fulminant meningococcemia is perhaps the most rapidly lethal form of septic shock experienced by humans. It differs from most other forms of septic shock by the prominence of hemorrhagic skin lesions (petechiae, purpura; see Fig. 46-5) and the consistent development of DIC.

The dominant proinflammatory molecule in the meningococcal cell wall is the endotoxin or LOS, and the outer membrane that contains it is poorly tethered to the underlying peptidoglycan. This structural peculiarity seems to account for the fact that meningococci shed LOS-containing membrane blebs as they grow. The bacteria can multiply to very high concentrations in the blood. The concentrations of endotoxin detected in the blood of patients with fulminant meningococcemia are 10- to 1000-fold higher than those found in the blood of patients with bacteremia due to other gram-negative bacteria. The bacteria and endotoxin-containing blebs stimulate monocytes, neutrophils, and endothelial cells, which then release cytokines and other mediators that can activate many distant targets, including other leukocytes, platelets, and endothelial cells. In addition, meningococci can invade the vascular endothelium. When activated, the endothelium produces molecules that can be procoagulant as well as adhesive for leukocytes.

Patients with fulminant meningococcemia usually have extremely high blood levels of both proinflammatory mediators—i.e., tumor necrosis factor (TNF), interleukin (IL) 1, interferon γ, and IL-8—and anti-inflammatory mediators—i.e., IL-1 receptor antagonist (IL-1Ra), soluble IL-1 receptors, soluble TNF receptors, and IL-10. The plasma of patients with meningococcal shock can decrease the responses of normal leukocytes to stimuli such as LOS; the implication is that anti-inflammatory mediators predominate in the blood late in infection.

Procoagulant, antifibrinolytic forces are also active in the blood of patients with fulminant meningococcemia (Fig. 127-2). Monocytes express large amounts of tissue factor. Fibrinopeptide A and thrombin-antithrombin levels are high, reflecting active clotting, while antithrombin and fibrinogen levels are low. Although the tissue factor–regulated ("extrinsic") arm of coagulation predominates, the contact system (factors XII and XI, prekallikrein, high-molecular-weight kininogen) is also activated. Striking deficiencies of antithrombin and proteins C and S can occur; studies have found a strong negative correlation between protein C activity and both the size of purpuric skin lesions and the mortality rate. Plasminogen levels are decreased, while plasmin-antiplasmin complexes and plasminogen activator inhibitor 1 (PAI-1) levels in the blood are very high. PAI-1 levels have been correlated with mortality risk.

Fibrin deposition is therefore favored both by the procoagulant tendency (promoted through activation of tissue factor and deficiencies of proteins C and S and antithrombin) and by an antifibrinolytic tendency (favored by excessive PAI-1). Both platelets and leukocytes doubtless contribute to the formation of microthrombi and to the vascular injury that ensues. Thrombosis of small to mid-sized arteries can produce peripheral necrosis and gangrene necessitating limb or digit amputation.

Meningitis Meningococcal bacteremia can result in the seeding of the meninges, pericardium, and large joints. Up to one-third of patients with meningococcal disease present with meningitis or other closed-space infections without signs of sepsis. How meningococci traverse the blood-brain barrier and enter the CSF or reach other closed sites is unclear. Meningococci have been shown to invade endothelial cells both experimentally and in vivo. The choroid plexus is also a potential site of meningococcal entry into the CSF. Meningococcal pili may bind CD46, a complement-regulatory protein that is expressed by the choroid plexus and meningeal epithelia. Upon meningococcal entry into the CSF, a vigorous local inflammatory response ensues, probably triggered by endotoxin-containing meningococcal membranes. Both bacterial growth and the inflammatory response occur within the CSF, where levels of endotoxin, IL-6, TNF, IL-1β, IL-1Ra, and IL-10 exceed the concentrations found in plasma by 100- to 1000-fold. The inflammatory response is largely confined to the subarachnoid space and contiguous structures. The inflammatory cytokines TNF and IL-1 released in meningococcal bacteremia may also enhance the permeability of the blood-brain barrier. Meningitis and other closed-space infections (e.g., arthritis, pericarditis) are the result of bacterial survival and multiplication at these sites. For example, meningitis and its sequelae are due to the induction of local inflammatory cytokines and other mediators (e.g., nitric oxide), leukocyte infiltration across the blood-brain barrier, breakdown of the blood-brain barrier with edema,

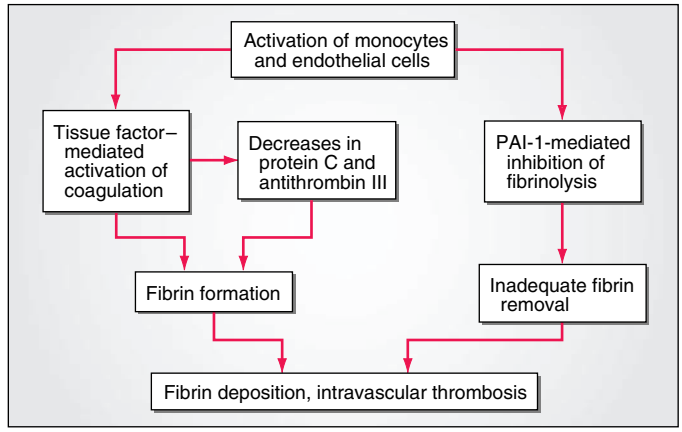

FIGURE 127-2 The pathogenesis of fibrin deposition in patients with fulminant meningococcemia. PAI-1, plasminogen activator inhibitor 1. (*Adapted from M Levi et al: Eur J Clin Invest 27:3, 1997.*)

release of metalloproteases, induction of cellular apoptosis, coagulation of vessels, and ischemia.

Patients who develop meningitis without meningococcemia may be individuals in whom meningococci do not grow rapidly in or have been cleared from the blood; may have antibodies or phagocytes that slow meningococcal growth; or may lack the (unknown) factors that allow *N. meningitidis* to multiply rapidly in vivo. If disease is recognized early, the prognosis of patients with meningococcal meningitis is substantially better than that of patients with fulminant meningococcemia.

HOST DEFENSE MECHANISMS Preventing meningococcal growth in blood requires bactericidal and opsonic antibodies, complement, and phagocytes (Fig. 127-3). The major bactericidal antibodies are IgM and IgG, which (except for serogroup B) bind to the capsular polysaccharide. Immunity to meningococci is therefore serogroup specific. Antibodies to other surface (subcapsular) antigens may confer cross-serogroup protection. PorA, PorB, Opc, and LOS appear to be major targets of cross-reactivity and of serogroup B bactericidal antibodies. Infants are protected from meningococcal disease during the first months of life by passively transferred maternal IgG antibodies. As maternal antibody levels wane, the attack rate increases, peaking from 3 to 9 months of age. Disease incidence declines as protective antibodies are induced by colonization with nonpathogenic bacteria that have cross-reactive antigens. In addition to *Neisseria lactamica*, which frequently colonizes young children, some enteric bacteria have antigens that cross-react with those of meningococci. One theory relates the occurrence of some cases of meningococcal disease to the presence of high levels of IgA antibodies to meningococci, since these antibodies can block the bactericidal activity of IgM.

Complement is required for bactericidal activity and for efficient opsonophagocytosis. Individuals deficient in any of the late complement components (C5 to C9) cannot assemble the membrane-attack complex (MAC) needed to kill *Neisseria*. These persons typically develop less severe meningococcal disease than complement-sufficient individuals, do so at an older age, and tend to have disease due to uncommon serogroups (W-135, X, Y, Z, and 29E). Although only one-half of individuals with known late-complement-component deficiency ever experience meningococcal disease, some affected persons have several episodes. Deficiency of each of the terminal complement components is inherited in an autosomal recessive fashion. Properdin deficiency, in contrast, is X-linked; some affected males develop overwhelming meningococcal disease, an observation indicating that the alternative complement pathway is also needed for antimeningococcal host defense. Disease onset in properdin-deficient individuals typically occurs in the teens or twenties. There is also recent evidence that inherited differences in the mannose-binding lectin (MBL) pathway of complement activation may influence the risk of acquiring meningococcal disease in childhood. Alleles that decrease MBL synthesis have been associated with increased risk in the few studies reported to date.

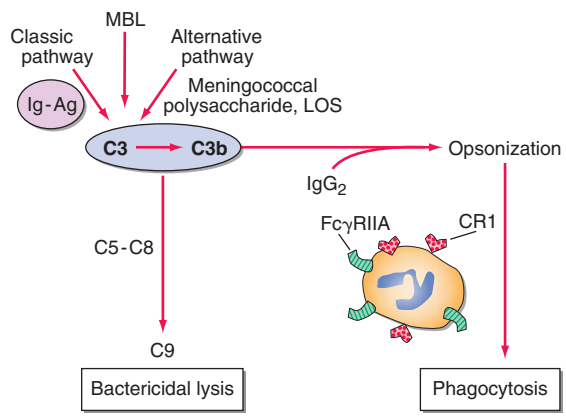

FIGURE 127-3 Protection from meningococcal disease involves both antimeningococcal immunoglobulins and complement. Activation of complement by antimeningococcal IgM or IgG promotes bacterial lysis via the membrane attack complex (C5–C9), while C3b [produced by alternative, mannose-binding lectin (MBL), or classic pathway activation] and antimeningococcal IgG_2 cooperate to produce effective opsonophagocytosis. A neutrophil defect in binding IgG_2 (the FcγRIIA R131 allele) has been associated with more severe meningococcal disease. CR1, complement receptor 1; LOS, lipooligosaccharide.

Activation of the classic pathway of complement by antigen-antibody complexes or of the alternative pathway by LOS or capsular polysaccharide is important for producing and maintaining C3b (Fig. 127-3). Without C3b, neither bactericidal lysis nor phagocytosis can proceed effectively. When C3b is generated, meningococcal growth is probably checked by the MAC, which produces bacterial lysis, and by robust phagocytosis. Most IgG antibodies to the meningococcal polysaccharide are of the IgG_2 isotype; a phagocytic cell defect (the FcγRIIA R131 allele) that impairs the phagocytosis of IgG_2-coated particles has been associated with more severe meningococcal disease. This allele has also been associated with a more severe clinical course in patients with late-complement-component deficiency; thus effective phagocytosis may contribute to the relatively mild meningococcal disease usually observed in these individuals.

The available studies of gene polymorphism–disease associations are summarized in Figs. 127-1 and 127-3. In individuals who lack bactericidal antibodies, protection from acquiring meningococcal bacteremia may be provided, at least in part, by innate immune mechanisms such as the MBL pathway for activating complement, complement factor C4b, and the TLR4 pathway for LOS recognition. Other genes may influence meningococcal survival in vivo [FcγIIA (CD32)], while still others seem to regulate the host inflammatory (IL-1β, IL-1Ra, TNF, angiotensin-converting enzyme) and clotting (PAI-1) responses to invading meningococci. Although many of these associations await confirmation in other populations of patients, in sum they point to important genetic influences on the acquisition and severity of meningococcal disease. This conclusion is supported by the overrepresentation of ABO blood group nonsecretors among patients with meningococcal disease and by the striking variability in meningococcal disease incidence among different racial groups.

CLINICAL MANIFESTATIONS ■ Upper Respiratory Tract Infections Although many patients who develop meningococcal meningitis or meningococcemia report having had throat soreness or other upper respiratory symptoms during the preceding week, it is uncertain whether these symptoms are due to infection with meningococci. Meningococcal pharyngitis is rarely diagnosed. Adult patients with *N. meningitidis* bacteremia more often have clinically apparent disease of the respiratory tract (pneumonia, sinusitis, tracheobronchitis, conjunctivitis) than do younger patients.

Meningococcemia Patients with meningococcal disease may have both meningococcemia and meningitis. These conditions have a wide clinical spectrum, with many overlapping features.

Approximately 10 to 30% of patients with meningococcal disease have meningococcemia without clinically apparent meningitis. Although meningococcal bacteremia may occasionally be transient and asymptomatic, in most individuals it is associated with fever, chills, nausea, vomiting, and myalgias. Prostration is common. The most distinctive feature is rash. Erythematous macules rapidly become petechial and, in severe cases, purpuric (see Fig. 46-5). Although the lesions are typically found on the trunk and lower extremities, they may also occur on the face, arms, and mucous membranes. The petechiae may coalesce into hemorrhagic bullae or may undergo necrosis and ulcerate. Patients with severe coagulopathy may develop ischemic extremities or digits, often with a sharp line of demarcation between normal and ischemic tissue.

In many patients with fulminant meningococcemia, the CSF may be normal and the CSF culture negative. Indeed, the absence of meningitis in a patient with meningococcemia is a poor prognostic sign; it suggests that the bacteria have multiplied so rapidly in the blood that meningeal seeding has not yet occurred or had time to elicit in-

flammation in the CSF. Most of these patients also lack evidence of an acute-phase response; i.e., the erythrocyte sedimentation rate is normal, and the C-reactive protein concentration in blood is low.

The *Waterhouse-Friderichsen syndrome* is a dramatic example of DIC-induced microthrombosis, hemorrhage, and tissue injury. Although overt adrenal failure is infrequently documented in patients with fulminant meningococcemia, patients may have partial adrenal insufficiency and be unable to mount the normal hypercortisolemic response to severe stress or cosyntropin stimulation. Almost all patients who die from fulminant meningococcemia have adrenal hemorrhages at autopsy.

Chronic meningococcemia (Fig. 127-4) is a rare syndrome of episodic fever, rash, and arthralgias that can last for weeks to months. The rash may be maculopapular; it is occasionally petechial. Splenomegaly may develop. If untreated or if treated with glucocorticoids, chronic meningococcemia may evolve into meningitis, fulminant meningococcemia, or (rarely) endocarditis.

Meningitis (See also Chap. 360) Patients with meningococcal meningitis have usually been sick for ≥24 h before they seek medical attention. Common presenting symptoms include nausea and vomiting, headache, neck stiffness, lethargy, and confusion. The symptoms and signs of meningococcal meningitis cannot be distinguished from those elicited by other meningeal pathogens. Many patients with meningococcal meningitis have concurrent meningococcemia, however, and petechial or purpuric skin lesions (Fig. 46-5) may suggest the correct diagnosis. CSF findings are consistent with those of purulent meningitis: hypoglycorrhachia, an elevated protein concentration, and a neutrophilic leukocytosis. A Gram's stain of CSF is usually positive (see "Diagnosis," below); when this finding is unaccompanied by CSF leukocytosis, the prognosis for normal recovery is often poor.

Other Manifestations Arthritis occurs in ~10% of patients with meningococcal disease. When arthritis develops during the first few days of the patient's illness, it usually reflects direct meningococcal invasion of the joint. Arthritis that begins later in the course is thought to be due to immune complex deposition. Primary meningococcal pneumonia occurs principally in adults, often in military populations, and is often due to serogroup Y. While meningococcal pericarditis is occasionally seen, endocarditis due to *N. meningitidis* is now exceedingly rare. Primary meningococcal conjunctivitis can be complicated by meningococcemia; systemic therapy is therefore warranted when this condition is diagnosed. Meningococcal urethritis has been reported in individuals who practice oral sex.

Complications Patients with meningococcal meningitis may develop cranial nerve palsies, cortical venous thrombophlebitis, and cerebral edema. Children may develop subdural effusions. Permanent sequelae can include mental retardation, deafness, and hemiparesis. The major long-term morbidity of fulminant meningococcemia is the loss of skin, limbs, or digits that results from ischemic necrosis and infarction.

FIGURE 127-4 Erythematous papular lesions are seen on the leg of this patient with chronic meningococcemia. (*Courtesy of Kenneth M. Kaye, M.D., and Elaine T. Kaye, M.D.*)

DIAGNOSIS Few clinical clues help the physician distinguish the patient with early meningococcal disease from patients with other acute systemic infections. The most useful clinical finding is the petechial or purpuric rash (see Fig. 46-5), but it must be differentiated from the petechial lesions seen with gonococcemia (see Fig. 128-1), Rocky Mountain spotted fever (see Fig. 158-1), hypersensitivity vasculitis (see Fig. 46-4), endemic typhus, and some viral infections. In one case series, one-half of the adults with meningococcal bacteremia had neither meningitis nor a rash.

The definitive diagnosis is established by recovering *N. meningitidis*, its antigens, or its DNA from normally sterile body fluids, such as blood, CSF, or synovial fluid, or from skin lesions. Meningococci grow best on Mueller-Hinton or chocolate blood agar at 35°C in an atmosphere that contains 5 to 10% CO_2. Specimens should be plated without delay. *N. meningitidis* bacteria are oxidase-positive, gram-negative diplococci that typically utilize maltose and glucose.

A Gram's stain of CSF reveals intra- or extracellular organisms in ~85% of patients with meningococcal meningitis. The latex agglutination test for meningococcal polysaccharides is less sensitive. PCR amplification of DNA in buffy coat or CSF samples is more sensitive than either of these tests; like the latex agglutination test, this method is unaffected by prior antibiotic therapy.

Throat or nasopharyngeal specimens should be cultured on Thayer-Martin medium, which suppresses the competing oral flora. Throat or nasopharyngeal cultures are recommended only for research or epidemiologic purposes, since a positive result merely confirms the carrier state and does not establish the existence of systemic disease.

℞ TREATMENT (Table 127-1)

A third-generation cephalosporin, such as cefotaxime (2 g intravenously every 4 h) or ceftriaxone (2 g intravenously every 12 h), is preferred for initial therapy. One of these cephalosporins in combination with other agents may cover other bacteria (such as *Streptococcus pneumoniae* and *Haemophilus influenzae*) that can cause the same syndromes (Chap. 360). Penicillin G (18 to 24 million units intravenously per day) remains an acceptable alternative for confirmed invasive meningococcal disease in most countries. However, the prevalence of meningococci with reduced susceptibility to penicillin has been increasing, and high-level penicillin resistance has been reported. Other options include meropenem (1 g intravenously every 8 h). In the patient who is allergic to β-lactam drugs, chloramphenicol (75 to 100 mg/kg per day) is a suitable alternative; chloramphenicol-resistant meningococci have been reported from Vietnam and France. The newer fluoroquinolones gatifloxacin, moxifloxacin, and gemifloxacin have excellent in vitro activity against *N. meningitidis*, with measurable CNS penetration, and appear promising in animal models. Patients with meningococcal meningitis should be given antimicrobial therapy for at least 5 days. While glucocorticoid therapy for meningitis in adults is controversial, many experts administer dexamethasone, beginning if possible before antibiotic therapy is initiated; the schedule is 10 mg intravenously 15 to 20 min before the first antibiotic dose and then every 6 h for 4 days.

Patients with fulminant meningococcemia often experience diffuse leakage of fluid into extravascular spaces, shock, and multiple-organ dysfunction (Chaps. 253 and 254). Myocardial depression may be prominent. Supportive therapy, although never studied in randomized, placebo-controlled trials, is recommended. Standard measures include vigorous fluid resuscitation (often requiring several liters over the first 24 h), elective ventilation, and pressors. Some authorities recommend early hemodialysis or hemofiltration. Fresh-frozen plasma is often given to patients who are bleeding extensively or who have severely deranged clotting parameters. Many European experts have adminis-

TABLE 127-1 Antibiotic Treatment, Chemoprophylaxis, and Vaccinations for Invasive Meningococcal Disease

ANTIBIOTIC TREATMENT[a]
1. Ceftriaxone 2 g IV q12h (100 mg/kg per day) or cefotaxime 2 g IV q4h
2. For penicillin-sensitive *N. meningitidis*: Penicillin G 18–24 million units per day in divided doses q4h (250,000 units/kg per day)
3. Chloramphenicol 75–100 mg/kg per day in divided doses q6h
4. Meropenem 1.0 g (children, 40 mg) IV q8h
5. In an outbreak setting in developing countries: Long-acting chloramphenicol in oil suspension (Tifomycin), single dose
Adults: 3.0 g (6 mL)
Children 1–15 years old: 100 mg/kg
Children <1 year old: 50 mg/kg
CHEMOPROPHYLAXIS[b]
Rifampin (oral)
Adults: 600 mg bid for 2 days
Children ≥1 month old: 10 mg/kg bid for 2 days
Children <1 month old: 5 mg/kg bid for 2 days
Ciprofloxacin (oral)
Adults: 500 mg, 1 dose
Ofloxacin (oral)
Adults: 400 mg, 1 dose
Ceftriaxone (IM)
Adults: 250 mg, 1 dose
Children <15 years old: 125 mg, 1 dose
Azithromycin (oral)
500 mg, 1 dose
VACCINATION[c]
A, C, Y, W-135 vaccine (Memomune, Aventis Pasteur) or A, C vaccine
Single 0.5-mL subcutaneous injection
New C; A, C; and A, C, Y, W-135 meningococcal conjugate vaccines[d]

[a] Patients with meningococcal meningitis should receive antimicrobial therapy for at least 5 days.
[b] Use is recommended for close contacts of cases.
[c] At present, use is generally limited to the control of epidemics and to individuals with increased risk of meningococcal disease. Vaccine efficacy wanes after 3–5 years, and vaccine is not effective in recipients <2 years of age.
[d] These vaccines appear to provide immunity in young children, a prolonged immune response, and herd immunity (decreased transmission and colonization).

tered antithrombin III to such patients. Patients with fulminant meningococcemia in whom shock persists despite vigorous fluid resuscitation should receive supplemental glucocorticoid treatment (hydrocortisone, 1 mg/kg every 6 h) pending tests of adrenal reserve.

Although it has not been formally tested in patients with fulminant meningococcemia, activated protein C (drotrecogin alfa, Xigris) is approved for use in patients with severe sepsis and dysfunction of more than one organ (APACHE II score, >25). Because of the pathophysiology, patients with meningococcemia may represent a group most likely to benefit from administration of activated protein C. The recommended dose is 24 μg/kg per hour, given as a continuous intravenous infusion for 96 h. Drotrecogin alfa is contraindicated when the peripheral-blood platelet count is <50,000/μL, however, and when there is active bleeding or a high risk of bleeding. Clotting parameters should be monitored closely while the drug is being infused; its administration should be discontinued 4 to 6 h before the performance of an invasive procedure. Drotrecogin alfa should not be used in patients with meningitis pending further evidence that it does not induce intracranial bleeding when the meninges are inflamed.

PROGNOSIS When patients are first evaluated, the clinical features most strongly associated with a fatal outcome are shock, a purpuric or ecchymotic rash, a low or normal blood leukocyte count, an age of ≥60 years, and coma. The absence of meningitis, the presence of thrombocytopenia, low blood concentrations of antithrombin or proteins S and C, high blood levels of PAI-1, and a low erythrocyte sedimentation rate (or C-reactive protein level) have also been associated with increased mortality from meningococcal disease. In contrast, the receipt of antibiotics before hospital admission has been associated with lower mortality rates in some studies.

PREVENTION ■ Meningococcal Polysaccharide Vaccines A single injection of quadrivalent meningococcal polysaccharide vaccine (serogroups A, C, W-135, and Y) immunizes ~80 to 95% of immunocompetent adults (Table 127-1). Children ≥3 months of age can be vaccinated to prevent serogroup A disease, but multiple doses are required; the vaccine is otherwise ineffective in children <2 years old. The duration of vaccine-induced immunity in adults is probably <5 years. There is currently no vaccine for serogroup B; its polysaccharide is a sialic acid homopolymer that is poorly immunogenic in humans. In addition to individuals with late-complement-component or properdin deficiency, persons with sickle cell anemia, asplenia, or splenectomy should receive the quadrivalent vaccine. Vaccination is also recommended for military recruits, pilgrims on the Hajj, and individuals traveling to sub-Saharan Africa during the dry months (June to December) or to other areas with epidemic meningococcal disease. The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends vaccination of incoming college freshmen who will live in dormitories. In general, the vaccine should be given only to persons >2 years of age.

New meningococcal capsular oligosaccharide and polysaccharide conjugate vaccines (C; A and C; A, C, Y, and W-135) are being developed; some are currently undergoing clinical trials, and some are now in use in Europe and Canada. These vaccines are based on the approach used for the highly successful *H. influenzae* type b conjugate vaccines. Covalent linkage of the polysaccharide to a carrier protein converts the polysaccharide to a thymus-dependent antigen enhancing IgG anticapsular antibodies and memory B cells. Because levels of antibody in mucosal secretions are much higher after the administration of a conjugate vaccine than after vaccination with an unconjugated preparation, a major benefit of these vaccines may be the introduction of herd immunity. Memory response to meningococcal polysaccharide also appears to be an important effect of the conjugate vaccines. Meningococcal conjugate vaccines are not yet licensed in the United States. However, in the United Kingdom, serogroup C conjugate vaccines introduced in 2000 have had a marked impact on the incidence of serogroup C disease in the population vaccinated. If conjugate meningococcal vaccines prove to be capable of providing durable antibody or memory responses (particularly in infants and young children), their integration into the routine childhood immunization schedule would appear warranted. Vaccines for serogroup B meningococcal disease remain elusive; none of the group B vaccines studied in clinical trials has proven to be broadly effective, but these products have a role in the control of serogroup B epidemics. The identification of new meningococcal protective antigens and the development of better meningococcal vaccines are areas of continued research and hold promise for the prevention of diseases due to *N. meningitidis*.

Screening tests for complement-component deficiency should be conducted in patients who have a family history of meningococcal or disseminated gonococcal disease; in patients who have a recurrence; in patients whose first case occurs at ≥15 years of age; in patients with cases caused by serogroups other than A, B, or C; and in family members of patients found to have a complement deficiency.

Antimicrobial Chemoprophylaxis The attack rate for meningococcal disease among household or other close contacts of cases is >400-fold greater than that in the population as a whole. Close contacts of cases should receive chemoprophylaxis with rifampin, ciprofloxacin, ofloxacin, or azithromycin (Table 127-1). A single intramuscular injection of ceftriaxone is also effective. Close contacts include persons who live in the same household, day-care center contacts, and anyone directly exposed to a patient's oral secretions. Casual contacts are not at increased risk. Chemoprophylaxis should be administered as soon as possible after the case is identified.

Isolation Precautions The CDC recommends that patients with meningococcal disease who are hospitalized be placed in respiratory isolation for the first 24 h.

Outbreak Control An organization- or community-based outbreak of meningococcal disease is defined as the occurrence of three or more cases within ≤3 months in persons who have a common affiliation or reside in the same area but who are not close contacts of one another; in addition, the primary disease attack rate must exceed 10 cases per 100,000 persons, and the case strains of *N. meningitidis* must be of the same molecular type. Mass vaccination should be considered when such outbreaks occur, and mass chemoprophylaxis may be used to control school- or other institution-based outbreaks. Consultation with public health authorities is recommended when such campaigns are contemplated.

128 GONOCOCCAL INFECTIONS

Sanjay Ram, Peter A. Rice

DEFINITION Gonorrhea is a sexually transmitted infection of epithelium and commonly manifests as cervicitis, urethritis, proctitis, and conjunctivitis. If untreated, infections at these sites can lead to local complications such as endometritis, salpingitis, tuboovarian abscess, bartholinitis, peritonitis, and perihepatitis in the female; periurethritis and epididymitis in the male; and ophthalmia neonatorum in the newborn. Disseminated gonococcemia is an uncommon event whose manifestations include skin lesions, tenosynovitis, arthritis, and (in rare cases) endocarditis or meningitis.

Neisseria gonorrhoeae is a gram-negative, nonmotile, non-spore-forming organism that grows in pairs (diplococci). Each individual organism is shaped like a coffee bean, with adjacent concave sides seen on Gram's stain. Gonococci, like all other *Neisseria* spp., are oxidase positive. They are distinguished from other neisseriae by their ability to grow on selective media and to utilize glucose but not maltose, sucrose, or lactose.

EPIDEMIOLOGY The incidence of gonorrhea has declined significantly in the United States, but there were still ~362,000 newly reported cases in 2002. Gonorrhea remains a major public health problem worldwide, is a significant cause of morbidity in developing countries, and may play a role in enhancing transmission of HIV.

Gonorrhea predominantly affects young, nonwhite, unmarried, less educated members of urban populations. The number of reported cases probably represents half of the true number of cases—a discrepancy resulting from underreporting, self-treatment, and nonspecific treatment without a culture-proven diagnosis. The number of reported cases of gonorrhea in the United States rose from ~250,000 in the early 1960s to a high of 1.01 million in 1978. The peak recorded incidence of gonorrhea in modern times was reported in 1975, with 468 cases per 100,000 population in the United States. This peak was attributable to the interaction of several variables, including improved accuracy of diagnosis, changes in patterns of contraceptive use, and changes in sexual behavior. The incidence of the disease has since gradually declined and is currently estimated at 120 cases per 100,000, a figure that is still the highest among industrialized countries. A further decline in the overall incidence of gonorrhea in the United States over the past decade may reflect increased condom use resulting from public health efforts to curtail HIV transmission. Presently, the attack rate in the United States is highest in the 20- to 24-year age group, in which 75% of all cases occur. With adjustment for sexual experience, the risk is highest among sexually active 15- to 19-year-old women. In terms of ethnicity, rates are highest among African Americans and lowest among persons of Asian or Pacific Island descent.

The incidence of gonorrhea is highest in developing countries. The exact incidence of any of the sexually transmitted diseases (STDs) is difficult to ascertain in developing countries because of limited surveillance and variable diagnostic criteria. For example, in Kenya, it was estimated in 1987 that 10% of all live births were adversely affected by STDs, and gonococcal ophthalmia neonatorum reportedly affected 4% of all live-born infants. The median prevalence of gonorrhea in unselected populations of pregnant women has been estimated at 10% in Africa, 5% in Latin America, and 4% in Asia. Studies in Africa have clearly demonstrated that nonulcerative STDs such as gonorrhea are an independent risk factor for the transmission of HIV (Chap. 173).

Gonorrhea is transmitted from males to females more efficiently than in the opposite direction. The rate of transmission to a woman following a single unprotected sexual encounter with an infected man is on the order of 40 to 60%. Oropharyngeal gonorrhea occurs in ~20% of women who practice fellatio with infected partners. Transmission in either direction by cunnilingus is rare.

There exists in any population a small minority of individuals who have high rates of new-partner acquisition. These "core-group members" or "high-frequency transmitters" are vital in sustaining STD transmission at the population level. Another instrumental factor in sustaining gonorrhea in the population is the large number of infected individuals who are asymptomatic or have minor symptoms that are ignored. These persons, unlike symptomatic individuals, do not cease sexual activity and therefore continue to transmit the disease. This situation underscores the importance of contact tracing and empirical treatment of sex partners of index cases.

PATHOGENESIS, IMMUNOLOGY, AND ANTIMICROBIAL RESISTANCE ■ Outer-Membrane Proteins ■ *Pili* Fresh clinical isolates of *N. gonorrhoeae* initially form piliated (fimbriated) colonies distinguishable on translucent agar. Pilus expression is rapidly switched off with unselected subculture because of rearrangements in pilus genes. This change is a basis for phase variation of gonococci. Piliated strains adhere better to cells derived from human mucosal surfaces and are more virulent in organ culture models and human inoculation experiments than nonpiliated variants. In a fallopian tube explant model, pili mediate gonococcal attachment to nonciliated columnar epithelial cells. This event initiates gonococcal phagocytosis and transport through these cells to intercellular spaces near the basement membrane or directly into the subepithelial tissue. Damage to nearby ciliated columnar epithelial cells, which is caused by the release of cytokines, results in loss of cilia and sloughing of ciliated cells and diminishes the integrity of the fallopian tube. Nonpiliated gonococci cause epithelial damage at a much slower rate. CD46 (membrane cofactor protein) is present on urogenital epithelial cells in both men and women and has been determined to be a receptor for PilC; this subunit is located at the tip of the pilus molecule

and is critical in mediating adherence. Pili are also essential for genetic competence and transformation of *N. gonorrhoeae*, which permit horizontal transfer of genetic material between different gonococcal lineages in vivo.

OPACITY-ASSOCIATED PROTEIN Another gonococcal surface protein that is important in adherence to epithelial cells is opacity-associated protein (Opa, formerly called protein II). Opa contributes to intergonococcal adhesion, which is responsible for the opaque nature of gonococcal colonies on translucent agar and the organism's adherence to a variety of eukaryotic cells, including polymorphonuclear leukocytes (PMNs). Certain Opa variants promote invasion of epithelial cells, and this effect has been linked with the ability of Opa to bind vitronectin, glycosaminoglycans, and several members of the carcinoembryonic antigen–related cell adhesion molecule (CEACAM, previously known as CD66) receptor family. Each strain of *N. gonorrhoeae* possesses as many as 11 different *opa* genes, but usually no more than three types are expressed at any given time. Isolates from normally sterile sites such as the fallopian tube and synovial fluid usually fail to express Opa, while isolates from mucosal sites usually form opaque colonies. Female commercial sex workers with antibodies to Opa may be less likely to develop pelvic inflammatory disease (PID) than women without such antibodies. *N. gonorrhoeae* Opa proteins that bind CEACAM 1, which is expressed by primary CD4+ T lymphocytes, suppress the activation and proliferation of these lymphocytes. This phenomenon may serve to explain the transient decrease in CD4+ T-lymphocyte counts associated with gonococcal infection.

PORIN Porin (previously designated protein I) is the most abundant gonococcal surface protein, accounting for >50% of the organism's total outer-membrane protein. Porin molecules exist as trimers that provide anion aqueous channels through the otherwise-hydrophobic outer membrane. Porin shows stable interstrain antigenic variation and forms the basis for gonococcal serotyping. Two main serotypes have been identified: Por1A strains are often associated with disseminated gonococcal infection (DGI), while Por1B strains usually cause local genital infections only. DGI strains are generally resistant to the killing action of normal human serum, do not incite a significant local inflammatory response, and therefore may not cause symptoms at genital sites. These characteristics may be related to the ability of Por1A strains to bind to complement-downregulatory molecules, resulting in a diminished inflammatory response. Porin can translocate to the cytoplasmic membrane of host cells—a process that could initiate gonococcal endocytosis and invasion. In addition, porin is an immunologic target of bactericidal and opsonophagocytic antibodies that may arise in response to immune stimulation resulting from infection or immunization with porin-containing vaccine candidates.

OTHER OUTER-MEMBRANE PROTEINS Other notable outer-membrane proteins include H.8, a lipoprotein that is present in high concentration on the surface of all gonococcal strains and is an excellent target for antibody-based diagnostic testing. Transferrin-binding proteins (Tbp1 and Tbp2) and lactoferrin-binding protein are required for scavenging iron from transferrin and lactoferrin in vivo. Transferrin and iron have been shown to increase attachment of iron-deprived *N. gonorrhoeae* to human endometrial cells. Studies with volunteers have demonstrated that gonococci deficient in transferrin- and lactoferrin-binding proteins cannot establish infection in men. IgA1 protease is produced by *N. gonorrhoeae* and may protect the organism from the action of mucosal IgA.

Lipooligosaccharide Gonococcal lipooligosaccharide (LOS) consists of a lipid A and a core oligosaccharide that lacks the repeating O-carbohydrate antigenic side chain seen in other gram-negative bacteria (Chap. 105). Gonococcal LOS possesses marked endotoxic activity and contributes to the local cytotoxic effect in the fallopian tube model. LOS core sugars undergo a high degree of antigenic variation under different conditions of growth; this variation reflects genetic regulation and expression of glycotransferase genes that dictate the carbohydrate structure of LOS. These phenotypic changes may affect interactions of *N. gonorrhoeae* with elements of the humoral immune system (antibodies and complement) and may also influence direct binding of organisms to both professional phagocytes and nonprofessional phagocytes (epithelial cells). For example, gonococci that are sialylated at their LOS sites bind complement factor H and downregulate the alternative pathway of complement. LOS sialylation may also mask bactericidal antibody–binding epitopes on LOS and porin and may decrease opsonophagocytosis and inhibit the oxidative burst in PMNs. While sialylation of LOS confers on the bacteria the ability to attenuate the inflammatory response and evade the innate immune system, experiments in male volunteers suggest that sialylated gonococci may be less capable of establishing infection than their unsialylated counterparts. This difference could be explained by the observation that the unsialylated terminal lactosamine residue of LOS binds to an asialoglycoprotein receptor on male epithelial cells that would otherwise facilitate binding and subsequent gonococcal invasion of these cells.

Host Factors In addition to gonococcal structures that interact with epithelial cells, host factors seem to be important in mediating entry of gonococci into nonphagocytic cells. Activation of phosphatidylcholine-specific phospholipase C and acidic sphingomyelinase by *N. gonorrhoeae*, which results in the release of diacylglycerol and ceramide, is a requirement for the entry of *N. gonorrhoeae* into epithelial cells. Ceramide accumulation within cells leads to apoptosis, which may disrupt epithelial integrity and facilitate entry of gonococci into subepithelial tissue. Release of chemotactic factors as a result of complement activation contributes to inflammation, as does the toxic effect of LOS in provoking the release of inflammatory cytokines.

The importance of humoral immunity in host defenses against neisserial infections is best illustrated by the predisposition of persons deficient in terminal complement components (C5 through C9) to recurrent bacteremic gonococcal infections and to recurrent meningococcal meningitis or meningococcemia. Gonococcal porin induces T cell–proliferative responses in persons with urogenital gonococcal disease. A significant increase in porin-specific interleukin (IL) 4–producing CD4+ as well as CD8+ lymphocytes is seen in individuals with mucosal gonococcal disease. A portion of these lymphocytes that show a porin-specific T_H2-type response could traffic to mucosal surfaces and play a role in immune protection against the disease. Few data clearly indicate that protective immunity is acquired from a previous gonococcal infection, although bactericidal and opsonophagocytic antibodies to porin and LOS may offer partial protection. On the other hand, women who are infected and acquire high levels of antibody to another outer-membrane protein, Rmp (reduction modifiable protein, formerly called protein III), may be especially likely to become reinfected with *N. gonorrhoeae* because Rmp antibodies block the effect of bactericidal antibodies to porin and LOS. Rmp shows little, if any, interstrain antigenic variation; therefore, Rmp antibodies potentially may block antibody-mediated killing of all gonococci. The mechanism of blocking has not been fully characterized, but Rmp antibodies noncompetitively inhibit binding of porin and LOS antibodies because of the proximity of these structures in the gonococcal outer membrane. Less well understood is how blocking antibody may divert complement binding to the gonococcal surface or otherwise hasten inactivation of complement. In male volunteers who have no history of gonorrhea, the net effect of these events may influence the outcome of experimental challenge with *N. gonorrhoeae*. Because Rmp bears extensive homology to enterobacterial OmpA and meningococcal class 4 proteins, it is possible that these blocking antibodies result from prior exposure to cross-reacting proteins from these species and also play a role in first-time infection with *N. gonorrhoeae*.

Gonococcal Resistance to Antimicrobial Agents It is no surprise that *N. gonorrhoeae*, with its remarkable capacity to alter its antigenic structure and adapt to changes in the microenvironment, has become resistant to numerous antibiotics. The first effective agents against gonorrhea were the sulfonamides, which were introduced in the 1930s. Within a

decade, antibiotic resistance emerged, resulting in treatment failures in one-third of patients. Penicillin was then employed as the drug of choice for the treatment of gonorrhea. By 1965, 42% of gonococcal isolates had developed low-level resistance to penicillin G. To prevent treatment failures, the Centers for Disease Control and Prevention (CDC) at that time recommended doubling the dose of penicillin for the treatment of gonorrhea. Resistance due to the production of penicillinase arose later.

Gonococci become fully resistant to antibiotics either by chromosomal mutations or by acquisition of R factors (plasmids). Two types of chromosomal mutations have been described. The first type, which is drug specific, is a single-step mutation leading to high-level resistance. The second type involves mutations at several chromosomal loci that combine to determine the level as well as the pattern of resistance. Strains with mutations in chromosomal genes were first observed in the late 1950s. As recently as 1997, strains with chromosomal resistance (CMRNG) accounted for resistance to penicillin, tetracycline, or both in ~20% of strains surveyed in the United States.

β-Lactamase (penicillinase)–producing strains of *N. gonorrhoeae* (PPNG) carrying plasmids with the Pc^r determinant were seen almost simultaneously in the United States, England, western Africa, and the Philippines in the late 1970s. PPNG strains have since spread worldwide and by the early 1980s accounted for >50% of all gonococcal isolates in some parts of the developing world. The average prevalence of PPNG in the United States dropped by two-thirds after most penicillin use was discontinued and is now on the order of 4%, with higher rates reported from certain areas. *N. gonorrhoeae* strains with plasmid-borne tetracycline resistance (TRNG) can mobilize some β-lactamase plasmids, and PPNG and TRNG occur together, sometimes along with CMRNG. Penicillin, ampicillin, and tetracycline are no longer reliable agents for the treatment of gonorrhea and should not be used. Third-generation cephalosporins have remained highly effective as single-dose therapy for gonorrhea. Even though the minimal inhibitory concentrations (MICs) of ceftriaxone for certain strains may reach 0.015 to 0.125 mg/L (higher than MICs of 0.0001 to 0.008 mg/L for fully susceptible strains), these levels are greatly exceeded in blood, the urethra, and the cervix when the routinely recommended ceftriaxone and cefixime regimens are administered (see below). These regimens almost always result in an effective cure.

Quinolone-containing regimens are also recommended for treatment of gonococcal infections; the fluoroquinolones offer the advantage of antichlamydial activity when administered for 7 days. Serum concentrations following therapeutic dosages of the quinolones exceed the MIC for *N. gonorrhoeae* by ~100-fold. However, quinolone-resistant *N. gonorrhoeae* (QRNG) appeared soon after these agents were first used to treat gonorrhea, particularly in Southeast Asia. QRNG strains have been reported recently in the United States, mostly in the far western states. Alterations in DNA gyrase and topoisomerase IV have been implicated as mechanisms of fluoroquinolone resistance.

Resistance to spectinomycin, which is used as an alternative agent, has been reported, but resistance to this agent is usually not associated with resistance to other antibiotics. Therefore, spectinomycin can be reserved for use against multiresistant strains of *N. gonorrhoeae*. Nevertheless, outbreaks caused by strains resistant to spectinomycin have been documented in Korea and England when the drug was used as a primary agent to treat gonorrhea.

CLINICAL MANIFESTATIONS ■ Gonococcal Infection in Males Acute urethritis is the most common clinical manifestation of gonorrhea in males. The usual incubation period following exposure is 2 to 7 days, although the interval can be longer and some men remain asymptomatic. Strains of the Por1A serotype, with nutritional requirements for arginine, hypoxanthine, and uracil (i.e., the AHU auxotype), tend to cause a greater proportion of cases of mild and asymptomatic urethritis than Por1B strains. Urethral discharge and dysuria, usually without urinary frequency or urgency, are the major symptoms. The discharge initially is scant and mucoid but becomes profuse and purulent within a day or two. The clinical manifestations of gonococcal urethritis are usually more severe and overt than those of nongonococcal urethritis, including urethritis caused by *Chlamydia trachomatis* (Chap. 160); however, exceptions are common, and it is often impossible to differentiate the causes of urethritis on clinical grounds alone. The majority of cases of urethritis seen in the United States today are not caused by *N. gonorrhoeae* and/or *C. trachomatis*. Although a number of other organisms may be responsible, most cases do not have a specific etiologic agent identified. Most symptomatic males with gonorrhea seek treatment and cease to be infectious. The remaining men, who are largely asymptomatic, accumulate in number over time and constitute about two-thirds of all infected men at any point in time. Together with men incubating the organism (who shed the organism but are asymptomatic), they serve as the source of spread of infection. Prior to the antibiotic era, symptoms of urethritis persisted for about 8 weeks. Epididymitis is now an uncommon complication, and gonococcal prostatitis occurs rarely, if at all. Other unusual local complications of gonococcal urethritis include edema of the penis due to dorsal lymphangitis or thrombophlebitis, submucous inflammatory "soft" infiltration of the urethral wall, periurethral abscess or fistulae, inflammation or abscess of Cowper's gland, and seminal vesiculitis. Balanitis may develop in uncircumcised men. After a decline in gonococcal infections among homosexual men early in the era of AIDS, a disturbing increase in gonorrhea was observed among young homosexual men in the 1990s, probably related to decreased condom use. The clinical features of anorectal and pharyngeal gonorrhea are discussed below.

Gonococcal Infections in Females ■ *GONOCOCCAL CERVICITIS* Mucopurulent cervicitis is the most common STD diagnosis in American women and may be caused by *N. gonorrhoeae*, *C. trachomatis*, and other organisms. Cervicitis may coexist with candidal or trichomonal vaginitis. *N. gonorrhoeae* primarily infects the cervical os but can also infect more peripheral areas of the cervix where columnar epithelium meets stratified squamous epithelium. Except in rare instances, the vaginal mucosa, which is lined by stratified squamous epithelium, does not become infected. Bartholin's glands occasionally become infected.

Women infected with *N. gonorrhoeae* usually develop symptoms. However, the women who either remain asymptomatic or have only minor symptoms may delay in seeking medical attention. These symptoms may include scant discharge from the vagina that may issue forth from the inflammed cervix (not vaginitis or vaginosis per se) and dysuria (often without urgency or frequency) that may be associated with gonococcal urethritis. Although the incubation period of gonorrhea is less well defined in women than in men, symptoms usually develop within 10 days of infection and are more acute and intense than those of chlamydial cervicitis.

The physical examination may reveal a mucopurulent discharge (mucopus) issuing from the cervical os. The examiner may check for mucopurulent discharge by swabbing a sample of mucus from the endocervix and observing its color against the white background of the swab; yellow or green mucus suggests mucopus. However, only 35% of women with gonococcal cervicitis actually have a mucopurulent discharge defined by these criteria. Because Gram's stain is not sensitive for the diagnosis of gonorrhea in women, specimens should be submitted for culture or a nonculture assay (see below). Edematous and friable cervical ectopy as well as endocervical bleeding induced by gentle swabbing are more often seen in chlamydial infection.

N. gonorrhoeae may be recovered from the urethra and rectum of women with cervicitis, but these are rarely the sole infected sites. Urethritis in women may produce symptoms of internal dysuria, which is often attributed to "cystitis." Pyuria in the absence of bacteriuria seen on Gram's stain of unspun urine, accompanied by urine cultures that fail to yield $>10^5$ colonies of bacteria usually associated with urinary tract infection, signifies the possibility of urethritis due to *C. trachomatis*. Urethral infection with *N. gonorrhoeae* may also occur in this

context, but in this instance urethral cultures will usually be positive. Compression of the urethra through the anterior vaginal wall against the symphysis pubis may express urethral exudate.

COMPLICATIONS OF GONOCOCCAL CERVICITIS Gonococcal infection may extend deep enough to produce dyspareunia and lower abdominal or back pain. In such cases, it is imperative to consider a diagnosis of PID and to administer treatment for that disease (Chap. 115). Ascending infection of the genital tract follows ~20% of cases of gonococcal cervicitis and may result in acute endometritis accompanied by abnormal menstrual bleeding, midline lower abdominal pain and tenderness, and dyspareunia. Spread to the fallopian tubes results in acute salpingitis, whose symptoms may be accompanied by signs of cervical motion tenderness and abnormal adnexal mass on pelvic examination. Patients may be febrile, and leukocytosis and an elevated erythrocyte sedimentation rate or C-reactive protein level may be detected. Co-infection with *C. trachomatis* may increase the risk of PID, which is the clinical counterpart of endometritis and salpingitis. Tubal scarring leading to infertility is the most devastating sequela of salpingitis; the increased risk of ectopic pregnancy is also significant. Prompt and appropriate antibiotic therapy for gonococcal salpingitis (prior to the development of an adnexal mass) can prevent tubal infertility in nearly all cases. Bilateral tubal damage occurs in ~20% of women with an adnexal mass. More than half of women with tubal infertility give no history of PID. These women with "silent salpingitis" may report abdominal or pelvic discomfort (such as dysmenorrhea or dyspareunia) that may be attributed to other diagnoses (such as endometriosis). Spread of infection to the pelvis may result in pelvic peritonitis characterized by nausea and vomiting. Spread of gonococci—or, more commonly, of chlamydiae—via the peritoneal cavity to the upper abdomen may cause perihepatitis (Fitz-Hugh–Curtis syndrome; Chap. 115).

GONOCOCCAL VAGINITIS The vaginal mucosa of healthy women is lined by stratified squamous epithelium and is usually not infected by *N. gonorrhoeae*. However, gonococcal vaginitis can occur in anestrogenic women (e.g., prepubertal girls and postmenopausal women), in whom the vaginal stratified squamous epithelial layers are often thinned down to the basilar layer, which can be infected by *N. gonorrhoeae*. The intense inflammation of the vagina makes the physical (speculum and bimanual) examination extremely painful. The vaginal mucosa is red and edematous, and an abundant purulent discharge is present. Infection in the urethra and in Skene's and Bartholin's glands often accompanies gonococcal vaginitis. Inflamed cervical erosion or abscesses in nabothian cysts may also occur. Coexisting cervicitis may result in pus in the cervical os.

Differential Diagnosis of Genital Gonococcal Infections The clinical features of uncomplicated gonococcal infections closely resemble those of genital infections caused by *C. trachomatis*. Although the symptoms produced by chlamydial infections tend to be milder, the two infections are often indistinguishable on clinical grounds alone. Co-infection with *N. gonorrhoeae* and *C. trachomatis* is seen in up to 40% of cases. →***The differential diagnosis of urethritis, epididymitis, and proctitis in men; of cervicitis and PID in women; and of vaginitis in prepubertal girls is discussed in Chap. 115.***

Anorectal Gonorrhea Because the female anatomy permits the spread of cervical exudate to the rectum, *N. gonorrhoeae* is sometimes recovered from the rectum of women with uncomplicated gonococcal cervicitis. The rectum is the sole site of infection in only 5% of women with gonorrhea. Such women are usually asymptomatic but occasionally have acute proctitis manifested by anorectal pain or pruritus, tenesmus, purulent rectal discharge, and rectal bleeding. Among homosexual men, the frequency of gonococcal infection, including rectal infection, fell by ≥90% throughout the United States in the early 1980s, but a resurgence of gonorrhea among homosexual men was documented in several cities during the 1990s. Gonococcal isolates from the rectum of homosexual men tend to be more resistant than other gonococcal isolates to antimicrobials. Gonococcal isolates with a mutation in mtrR (multiple transferable resistance repressor) or in the promoter region of the gene that encodes for this transcriptional repressor develop increased resistance to antimicrobial hydrophobic agents such as bile acids and fatty acids in feces and thus are found with increased frequency in homosexual men. The mutation, which curtails the production of a DNA-binding protein called MtrR, results in derepression of the expression of other *mtr* genes that encode the production of an energy-dependent efflux pump, thereby resulting in increased resistance to hydrophobic agents. This situation may have been responsible for higher rates of failure of treatment for rectal gonorrhea with older regimens consisting of penicillin or tetracyclines.

Pharyngeal Gonorrhea Pharyngeal gonorrhea is usually mild or asymptomatic, although symptomatic pharyngitis does occasionally occur with cervical lymphadenitis. The mode of acquisition is oral-genital sexual exposure, with fellatio being a more efficient means of transmission than cunnilingus. It is important to solicit a sexual history as part of the evaluation of pharyngitis so that appropriate cultures for *N. gonorrhoeae* can be performed. Acute HIV infection should also be considered in the differential diagnosis of pharyngitis in persons with appropriate risk factors. Most cases resolve spontaneously, and transmission from the pharynx to sexual contacts is rare. Pharyngeal infection almost always coexists with genital infection. Swabs from the pharynx should be plated directly onto gonococcal selective media. Because pharyngeal colonization with *N. meningitidis* needs to be differentiated from that with other *Neisseria* species, the diagnosis of pharyngeal gonorrhea is more expensive and difficult than that of anogenital gonorrhea.

Ocular Gonorrhea in Adults Ocular gonorrhea in an adult usually results from autoinoculation from an infected genital site. As in genital infection, the manifestations range from severe to occasionally mild or asymptomatic disease. The variability in clinical manifestations may result from differences in the ability of the infecting strain to elicit an inflammatory response.

Infection may result in a markedly swollen eyelid, severe hyperemia and chemosis, and a profuse purulent discharge. The massively inflamed conjunctiva may be draped over the cornea and limbus. Lytic enzymes from the infiltrating PMNs occasionally cause corneal ulceration and rarely cause perforation.

Prompt recognition and treatment of this condition are of paramount importance. Gram's stain and culture of the purulent discharge establish the diagnosis. Genital cultures should also be performed.

Gonorrhea in Pregnant Women, Neonates, and Children Gonorrhea in pregnancy can have serious consequences for both the mother and the infant. Therefore, early detection and eradication of the disease in the mother are extremely important. Recognition of gonorrhea early in pregnancy also identifies a population at risk for other STDs, particularly chlamydial infection and syphilis. These women should be monitored closely for these infections throughout pregnancy. The incidence of gonorrhea in pregnancy ranges from rare to ~10%, depending upon the population surveyed. Salpingitis and PID can occur during the first trimester and are associated with a high rate of fetal loss. In the second and third trimesters, the relative impermeability of the cervical mucus (under the influence of progesterone) and the obliteration of the intrauterine cavity (resulting from the attachment of the chorion to the endometrial decidua by around the twelfth week of gestation) pose physical barriers that usually prevent ascending infection. Pharyngeal infection, most often asymptomatic, may be more common during pregnancy because of altered sexual practices. Acquisition of gonococcal infection late in pregnancy can adversely affect labor and delivery as well as the well-being of the fetus. Prolonged rupture of the membranes, premature delivery, chorioamnionitis, funisitis (infection of the umbilical cord stump), and sepsis in the infant (with *N. gonorrhoeae* detected in the gastric aspirate of the newborn during delivery) are common complications of maternal gonococcal infection at term. Hazards to the fetus include spontaneous abortion, perinatal death, premature delivery, perinatal distress, and premature

rupture of membranes. Other microorganisms and conditions, including *Mycoplasma hominis*, *Ureaplasma urealyticum*, *C. trachomatis*, and bacterial vaginosis, have been associated with similar complications.

The most common form of gonorrhea in neonates is ophthalmia neonatorum, which results from exposure to infected cervical secretions during parturition. Ocular neonatal instillation of a prophylactic agent (e.g., 1% silver nitrate eyedrops or ophthalmic preparations containing erythromycin or tetracycline) is a cost-effective measure for the prevention of ophthalmia neonatorum but is not effective for its treatment, which requires systemic antibiotics. The clinical manifestations are acute and begin 2 to 5 days after birth. A small inoculum of organisms, low virulence of the infecting strain, or partial suppression by ophthalmic prophylaxis can result in a more indolent course. Therefore, gonococcal infection must be ruled out by culture in every case of conjunctivitis in infants. An initial nonspecific conjunctivitis with a serosanguineous discharge is followed by tense edema of both eyelids, chemosis, and a profuse, thick, purulent discharge. Corneal ulcerations that result in nebulae or perforation may lead to anterior synechiae, anterior staphyloma, panophthalmitis, and blindness. Infections described at other mucosal sites in infants, including vaginitis, rhinitis, and anorectal infection, are likely to be asymptomatic. Pharyngeal colonization has been demonstrated in 35% of infants with gonococcal ophthalmia, and coughing is the most prominent symptom in these cases. Septic arthritis (see below) is the most common manifestation of systemic infection or DGI in the newborn. The primary focus of DGI in most of these cases is uncertain. The onset usually comes at 3 to 21 days of age, and polyarticular involvement is common. Sepsis, meningitis, and pneumonia are seen in rare instances.

Any STD in children beyond the neonatal period raises the possibility of sexual abuse. In most cases of abuse, the perpetrator is a male assailant known to the child. Gonococcal vulvovaginitis is the most common manifestation of gonococcal infection in children beyond infancy. Anorectal and pharyngeal infections are common in these children and are frequently asymptomatic. The urethra, Bartholin's and Skene's glands, and the upper genital tract are rarely involved. All children with gonococcal infection should also be evaluated for chlamydial infection, syphilis, and possibly HIV infection. All cases of suspected and confirmed child abuse should be reported to the appropriate social service agency in the county where the child resides.

Gonococcal Arthritis (DGI) DGI or gonococcal arthritis results from gonococcal bacteremia. In the 1970s, DGI occurred in ~0.5 to 3% of persons with untreated gonococcal mucosal infection. The lower incidence at present is probably attributable to a decline in the prevalence of particular strains that are likely to disseminate and has resulted in fewer cases that present in the bacteremic stage of the disease (see below). DGI strains resist the bactericidal action of human serum and generally do not incite inflammation at genital sites, probably because of limited generation of chemotactic factors. These strains are often of the Por1A serotype, are highly susceptible to penicillin, and have special growth requirements (i.e., the AHU auxotype) that makes the organism more fastidious and more difficult to isolate. Menstruation is a risk factor for dissemination, and approximately two-thirds of cases of DGI are in women. In about half of affected women, symptoms of DGI begin within 7 days of onset of menses. Complement deficiencies, especially of the components involved in the assembly of the membrane attack complex (C5 through C9), predispose to neisserial bacteremia. Up to 13% of patients with DGI have complement deficiencies, and persons with more than one episode of DGI should be screened with an assay for total hemolytic complement activity.

The clinical manifestations of DGI have sometimes been classified into two stages: a bacteremic stage, which is less common today, and a joint-localized stage with suppurative arthritis. A clear-cut progression usually is not evident. Patients in the bacteremic stage have higher temperatures, and their fever is more frequently accompanied by chills. Painful joints are common and often occur in conjunction with tenosynovitis and skin lesions. Polyarthralgias usually include the knees, elbows, and more distal joints; the axial skeleton is generally spared. Skin lesions are seen in ~75% of patients and include papules and pustules, often with a hemorrhagic component (Fig. 128-1). These lesions are usually on the extremities and number between 5 and 40. The differential diagnosis of the bacteremic stage of DGI includes Reiter's syndrome, acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g., hepatitis B and acute HIV infection). The distribution of joint symptoms in Reiter's syndrome differs from DGI (Fig. 128-2), as do the skin and genital manifestations (Chap. 305).

FIGURE 128-1 Disseminated gonococcemia in the skin is seen as hemorrhagic papules and pustules with purpuric centers in a centrifugal distribution.

Suppurative arthritis involves one or two joints, most often (in decreasing order of frequency) the knees, wrists, ankles, and elbows. The occurrence of arthritis in the absence of signs and symptoms of the bacteremic stage has led to the suggestion that these are separate syndromes. Other joints, such as the small joints of the hands and feet and the sternoclavicular and temporomandibular joints, are occasionally involved. Most patients who develop gonococcal septic arthritis do so without prior polyarthralgias or skin lesions; in the absence of symptomatic genital infection, this disease cannot be distinguished from septic arthritis caused by other pathogens. The differential diagnosis of acute arthritis in young adults is discussed in Chap. 314. Rarely, osteomyelitis complicates septic arthritis involving small joints of the hand.

Although it has been postulated that the initial arthritis and skin lesions are due to direct tissue invasion by *N. gonorrhoeae*, the organism has been recovered from <5% of skin lesions cultured. This low isolation rate has been attributed to either a small inoculum of infecting organisms or the fastidious growth requirements of *N. gon-*

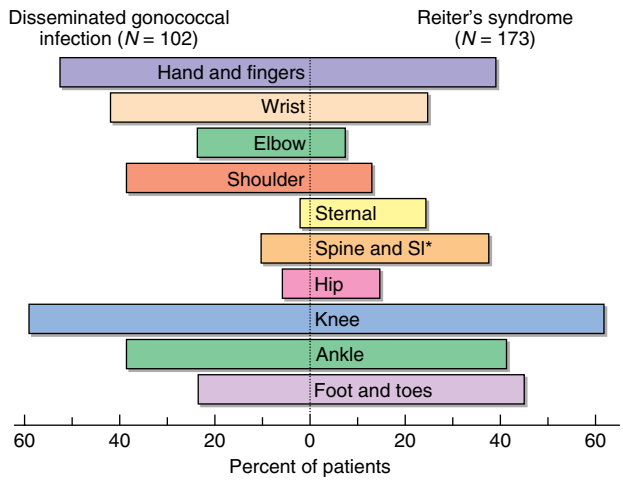

FIGURE 128-2 Distributions of joints with arthritis in 102 patients with disseminated gonococcal infection and 173 patients with Reiter's syndrome. "Sternal" includes the sternoclavicular joints. *SI denotes the sacroiliac joint. (*Reprinted with permission from M Kousa et al: Sex Transm Dis 5:57, 1978; with permission.*)

orrhoeae strains that disseminate. Gonococcal antigens have been identified in "sterile" skin lesions by immunofluorescent staining techniques. There is also evidence that immune-mediated or hypersensitivity phenomena caused by gonococcal antigens account for skin lesions. Other manifestations of noninfectious dermatitis, such as nodular lesions, urticaria, and erythema multiforme, have been described. Gonococcal endocarditis, although rare today, was relatively common in the preantibiotic era, causing about one-quarter of reported cases of endocarditis. Another unusual complication of DGI is meningitis.

Gonococcal Infection in HIV-Infected Persons The association between gonorrhea and the acquisition of HIV has been demonstrated in several well-controlled studies, mainly in Kenya and Zaire. The nonulcerative STDs enhance the transmission of HIV by three- to fivefold, possibly because of increased viral shedding in persons with urethritis or cervicitis (Chap. 173). HIV has been detected by polymerase chain reaction (PCR) more commonly in ejaculates from HIV-positive men with gonococcal urethritis than in those from HIV-positive men with nongonococcal urethritis. PCR positivity diminishes by twofold following appropriate therapy for urethritis. Not only does gonorrhea enhance the transmission of HIV, it may also increase the individual's risk for acquisition of HIV. A proposed mechanism is the significantly greater number of CD4+ lymphocytes and dendritic cells that can be infected by HIV in endocervical secretions of women with nonulcerative STDs than in those of women with ulcerative STDs.

LABORATORY DIAGNOSIS A rapid diagnosis of gonococcal infection in men may be obtained by Gram's staining of urethral exudates. The detection of gram-negative intracellular diplococci is usually highly specific and sensitive in diagnosing gonococcal urethritis in symptomatic males but is only ~50% sensitive in diagnosing gonococcal cervicitis. Samples should be collected with Dacron or rayon swabs. Part of the sample should be inoculated onto a plate of modified Thayer-Martin or other gonococcal selective medium for culture. It is important to process all samples immediately because gonococci do not tolerate drying. If plates cannot be incubated immediately, they can be held safely for several hours at room temperature in candle extinction jars prior to incubation. If processing is to occur within 6 h, transport of specimens may be facilitated by the use of nonnutritive swab transport systems such as Stuart or Amies medium. For longer holding periods (e.g., when specimens for culture are to be mailed), culture media with self-contained CO_2-generating systems (such as the JEMBEC or Gono-Pak systems) may be used. Specimens should also be obtained for the diagnosis of chlamydial infection.

PMNs are often seen in the endocervix on a Gram's stain, and an abnormally increased number [≥30 PMNs per field in five 1000X oil-immersion (microscopic) fields] establishes the presence of an inflammatory discharge. Unfortunately, the presence or absence of gram-negative intracellular diplococci in cervical smears does not accurately predict which patients have gonorrhea, and the diagnosis in this setting should be made by culture or another suitable nonculture diagnostic method. The sensitivity of a single endocervical culture is ~80 to 90%, with the precise figure depending on the quality of the medium and the adequacy of the clinical specimen. The yield can be enhanced by culture of a second cervical specimen. If a history of rectal sex is elicited, a rectal wall swab (uncontaminated with feces) should be cultured. A presumptive diagnosis of gonorrhea cannot be made on the basis of gram-negative diplococci in smears from the pharynx, where other *Neisseria* species are components of the normal flora.

Nucleic acid probe tests are sometimes substituted for culture for the direct detection of *N. gonorrhoeae* in urogenital specimens. A common assay employs a nonisotopic chemiluminescent DNA probe that hybridizes specifically with gonococcal 16S ribosomal RNA. Studies assessing the utility of the nucleic acid probe system in high-risk outpatients undergoing screening for STDs have revealed that it is at least as sensitive as conventional culture techniques and may be a cost-effective alternative to culture, especially in high-risk males. A disadvantage of non-culture-based assays in general is that specimens submitted in probe-transport systems cannot be cultured subsequently. Therefore, a culture-confirmatory test is not possible, and formal antimicrobial susceptibility testing, if needed, cannot be performed. Low-cost point-of-care tests are under development for use in resource-poor settings, where specific diagnosis often gives way to syndromic management. Nucleic acid amplification tests (NAATs, including Roche Amplicor, Gen-Probe APTIMA, and BDProbeTec) have been cleared by the U.S. Food and Drug Administration (FDA) and offer the advantage of testing urine samples with a sensitivity similar to that of culture and other non-NAATs on urethral or cervical swab samples.

Because of the legal implications, the preferred method for the diagnosis of gonococcal infection in children is a standardized culture. Two positive NAATs, each targeting a different nucleic acid sequence, may be substituted for culture of the cervix or the urethra as legal evidence of infection; however, cervical specimens are not recommended for prepubertal girls. Nonculture tests for gonococcal infection have not been approved by the FDA for use with specimens obtained from the pharynx and rectum of infected children. Cultures should be obtained from the pharynx and anus of both girls and boys, the vagina of girls, and the urethra of boys. For boys with a urethral discharge, a meatal specimen of the discharge is adequate for culture. Presumptive colonies of *N. gonorrhoeae* should be identified definitively by at least two independent methods (e.g., biochemical, enzyme substrate, or serologic).

Blood should be cultured in suspected cases of DGI. The use of Isolator blood culture tubes may enhance the yield. The probability of positive blood cultures decreases after 48 h of illness. Synovial fluid should be inoculated into blood culture broth medium and plated onto chocolate agar rather than selective medium because this fluid is not likely to be contaminated with commensal bacteria. Gonococci are infrequently recovered from early joint effusions containing <20,000 leukocytes/μL but may be recovered from effusions containing >80,000 leukocytes/μL. The organisms are seldom recovered from blood and synovial fluid of the same patient.

Rx TREATMENT

Although clinical isolates of *N. gonorrhoeae* vary in their antimicrobial susceptibility patterns in different parts of the world, they remain susceptible to a wide variety of agents. Because failure of treatment can lead to continued transmission and the emergence of antibiotic resistance, the importance of adequate treatment with a regimen that the patient will adhere to cannot be overemphasized. Thus highly effective single-dose regimens have been developed for the treatment of uncomplicated gonococcal infections. The 2002 CDC treatment guidelines for gonococcal infections are summarized in Table 128-1; the recommendations for uncomplicated gonorrhea apply to HIV-infected as well as HIV-uninfected patients.

The third-generation cephalosporins cefixime (given orally) and ceftriaxone (given intramuscularly), both as a single dose, have been the mainstay of therapy with this class of antibiotics for uncomplicated gonococcal infection of the urethra, cervix, rectum, or pharynx. The recent discontinuation of cefixime production in the United States has prompted further examination of alternative oral options for urogenital and pharyngeal gonococcal infections. To be considered as a recommended treatment for uncomplicated gonorrhea, an antimicrobial regimen should cure >95% of urogenital infections. (The therapeutic efficacy for anorectal infection is typically comparable to that for urogenital infection.) Studies documenting efficacy should have sufficient sample size so that the lower limit of the confidence interval (CI) of the cure rate is also >95%. The available data do not demonstrate that any single-dose oral antimicrobial regimen other than cefixime or a fluoroquinolone (see below) meets these efficacy criteria for urogenital gonococcal infection; published data on the efficacy of alternative oral regimens in treating pharyngeal gonococcal infection are even more

limited. Single doses of ciprofloxacin, ofloxacin, or levofloxacin are effective first-line regimens. Other quinolones, such as gatifloxacin, norfloxacin, and lomefloxacin, are probably efficacious for treating uncomplicated gonorrhea, but data regarding their use are also limited, and they offer no advantage over the other recommended quinolones. Because of resistance to fluoroquinolones in several parts of Asia and the Pacific (including Hawaii), these agents should not be used to treat gonorrhea acquired in these regions. Several states, including California, are now recommending the curtailment of quinolone treatment for gonorrhea infection altogether, and in these regions ceftriaxone should be used.

Because co-infection with *C. trachomatis* occurs frequently, initial treatment regimens must incorporate an agent (e.g., azithromycin or doxycycline) effective against chlamydial infection. Routine dual therapy without testing for *Chlamydia* can be cost-effective for populations where chlamydial infection accompanies 10 to 30% of gonococcal infections. Pregnant women with gonorrhea should receive concurrent treatment with a macrolide antibiotic for possible chlamydial infection; doxycycline should not be used during pregnancy. A single 1-g dose of azithromycin, which is effective therapy for uncomplicated chlamydial infections, results in an unacceptably low cure rate (93%) for gonococcal infections and should not be used alone.

Uncomplicated gonococcal infections in penicillin-allergic persons who cannot tolerate quinolones may be treated with a single dose of spectinomycin.

Persons with uncomplicated infections who receive a recommended regimen need not return for a test of cure. Cultures for *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen, and any gonococci isolated should be tested for antimicrobial susceptibility.

Symptomatic gonococcal pharyngitis is more difficult to eradicate than genital infection. Few regimens result in cure rates of >90%. Persons who cannot tolerate cephalosporins or quinolones can be treated with spectinomycin, but this agent results in a cure rate of ≤52%. Therefore, persons given spectinomycin should have a pharyngeal culture performed 3 to 5 days after treatment as a test of cure.

TABLE 128-1 *Recommended Treatment for Gonococcal Infections: 2002 Guidelines of the Centers for Disease Control and Prevention*

Diagnosis	Treatment of Choice
Uncomplicated gonococcal infection of the cervix, urethra, pharynx, or rectum[a]	
First-line regimens	Ceftriaxone (125 mg IM, single dose) *or* Ciprofloxacin (500 mg PO, single dose)[b] *or* Ofloxacin (400 mg PO, single dose)[b] *or* Levofloxacin (250 mg PO, single dose)[b] *or* Cefixime (400 mg PO, single dose)[c] *plus* If chlamydial infection is not ruled out: Azithromycin (1 g PO, single dose) *or* Doxycycline (100 mg PO bid for 7 days)
Alternative regimens	Spectinomycin (2 g IM, single dose) *or* Ceftizoxime (500 mg IM, single dose) *or* Cefotaxime (500 mg IM, single dose) *or* Cefotetan (1 g IM, single dose) plus probenecid (1 g PO, single dose) *or* Cefoxitin (2 g IM, single dose) plus probenecid (1 g PO, single dose)
Epididymitis	See Chap. 115
Pelvic inflammatory disease	See Chap. 115
Gonococcal conjunctivitis in an adult	Ceftriaxone (1 g IM, single dose)[d]
Ophthalmia neonatorum[e]	Ceftriaxone (25–50 mg/kg IV, single dose, not to exceed 125 mg)
Disseminated gonococcal infection[f]	
Initial therapy[g]	
Patient tolerant of β-lactam drugs	Ceftriaxone (1 g IM or IV q24h; recommended) *or* Cefotaxime (1 g IV q8h) *or* Ceftizoxime (1 g IV q8h)
Patients allergic to β-lactam drugs	Ciprofloxacin (500 mg IV q12h)[b] *or* Ofloxacin (400 mg IV q12h)[b] *or* Levofloxacin (500 mg IV q24h)[b] *or* Spectinomycin (2 g IM q12h)
Continuation therapy	Ciprofloxacin (500 mg PO bid)[b] *or* Ofloxacin (400 mg PO bid)[b] *or* Levofloxacin (500 mg PO qd)[b] *or* Cefixime (400 mg PO bid)[c]
Meningitis or endocarditis	See text[h]

[a] True failure of treatment with a recommended regimen is rare and should prompt an evaluation for reinfection or consideration of an alternative diagnosis. In cases of quinolone failure, the isolate should be tested for drug resistance if possible.
[b] Quinolones should not be used for infections acquired in Asia or the Pacific, including Hawaii and California. The use of quinolones is also inadvisable for treating infections acquired in other areas where the prevalence of quinolone-resistant *N. gonorrhoeae* (QRNG) is >1%, or in areas that are reporting increasing numbers of QRNG strains.
[c] Cefixime, a first-line recommendation for treatment of uncomplicated gonococcal infection (or continuation therapy for DGI), is currently unavailable in the United States.
[d] Plus lavage of the infected eye with saline solution (once).
[e] Prophylactic regimens are discussed in the text.
[f] Hospitalization is indicated if the diagnosis is uncertain, if the patient has frank arthritis with an effusion, or if the patient cannot be relied on to adhere to treatment.
[g] All initial regimens should be continued for 24 to 48 h after clinical improvement begins, at which time therapy may be switched to one of the continuation regimens to complete a full week of antimicrobial treatment.
[h] Hospitalization is indicated to exclude suspected meningitis or endocarditis.

Treatments for gonococcal epididymitis and PID are discussed in Chap. 115. Ocular gonococcal infections in older children and adults should be managed with a single dose of ceftriaxone combined with saline irrigation of the conjunctivae (both undertaken expeditiously), and patients should undergo a careful ophthalmologic evaluation that includes a slit-lamp examination.

DGI may require higher dosages and longer durations of therapy (Table 128-1). Hospitalization is indicated if the diagnosis is uncertain, if the patient has localized joint disease that requires aspiration, or if the patient cannot be relied on to comply with treatment. Open drainage is necessary only occasionally—e.g., for management of hip infections that may be difficult to drain percutaneously. Nonsteroidal anti-inflammatory agents may be indicated to alleviate pain and hasten improvement of affected joints. Gonococcal meningitis and endocarditis should be treated in the hospital with high-dose intravenous ceftriaxone (1 to 2 g every 12 h); therapy should continue for 10 to 14 days for meningitis and for at least 4 weeks for endocarditis. All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

PREVENTION AND CONTROL Condoms, if properly used, provide effective protection against the transmission and acquisition of gonorrhea as well as other infections that are transmitted to and from genital mucosal surfaces. Spermicidal preparations used with a diaphragm or cervical sponges impregnated with nonoxynol 9 offer some protection against gonorrhea and chlamydial infection. However, the frequent use of preparations that contain nonoxynol 9 is associated with mucosal disruption that paradoxically may enhance the risk of HIV infection

in the event of exposure. All patients should be instructed to refer sex partners for evaluation and treatment. All sex partners of persons with gonorrhea should be evaluated and treated for *N. gonorrhoeae* and *C. trachomatis* infections if their last contact with the patient took place within 60 days before the onset of symptoms or the diagnosis of infection in the patient. If the patient's last sexual encounter was >60 days before onset of symptoms or diagnosis, the patient's most recent sex partner should be treated. Patients should be instructed to abstain from sexual intercourse until therapy is completed and until they and their sex partners no longer have symptoms. Greater emphasis must be placed on prevention by public health education, individual patient counseling, and behavior modification. Sexually active persons, especially adolescents, should be offered screening for STDs. For males, a NAAT on urine or a urethral swab may be used for screening. Preventing the spread of gonorrhea may help reduce the transmission of HIV. No effective vaccine for gonorrhea is yet available, but efforts to test a porin vaccine candidate are under way.

ACKNOWLEDGMENT

129 *MORAXELLA CATARRHALIS* AND OTHER *MORAXELLA* SPECIES

Daniel M. Musher

MORAXELLA CATARRHALIS

The gram-negative coccus *Moraxella catarrhalis* is a component of the normal bacterial flora of the upper airways and has been increasingly recognized as a cause of otitis media, sinusitis, and bronchopulmonary infection. Over the past several decades, this organism has been variously designated as *Micrococcus catarrhalis*, *Neisseria catarrhalis*, and *Branhamella catarrhalis*.

BACTERIOLOGY AND IMMUNITY On Gram's staining, *M. catarrhalis* organisms appear as gram-negative cocci, sometimes occurring in pairs and retaining the side-by-side kidney-bean configuration of *Neisseria* (Fig. 129-1). These cocci tend to retain crystal violet during the decolorizing step and may be confused with *Staphylococcus aureus*. *Moraxella* colonies grow well on blood or chocolate agar but may be overlooked because of their resemblance to *Neisseria* spp. (a major component of the normal pharyngeal flora). *Moraxella* is readily distinguishable from *Neisseria* spp. by biochemical tests.

Strains of *M. catarrhalis* show a surprising degree of homogeneity in terms of their outer-membrane proteins. Antibody to some of these proteins is generally present in serum of children >4 years old; however, colonizing or disease-causing isolates may survive in serum despite this naturally present antibody and complement. Bactericidal antibody emerges after natural infection and may be directed against one or more conserved outer-membrane proteins—a property of potential value in vaccine development. The presence of certain outer-membrane proteins is associated with virulence in mice, and antibody may be protective. Antibody to lipooligosaccharide may also provide some degree of protection. These and other bacterial constituents are under investigation for use as vaccines.

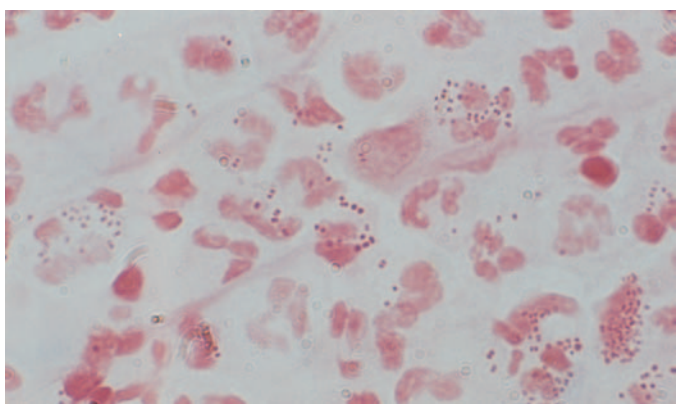

FIGURE 129-1 Gram-stained sputum from a patient with acute purulent tracheobronchitis. Many polymorphonuclear neutrophils and a few macrophages are seen along with many gram-negative cocci (*Moraxella catarrhalis*), a few of which appear as pairs. Nearly all organisms are cell associated and probably have been taken up by phagocytes, consistent with the notion that *Moraxella* is a lower-grade pathogen than organisms such as *Streptococcus pneumoniae*.

EPIDEMIOLOGY With repeated cultures and the use of selective media, *M. catarrhalis* can be isolated from the upper respiratory tract or saliva of 50% of healthy schoolchildren and of up to 7% of healthy adults. When conventional microbiologic techniques are used, *Moraxella* can be isolated from sputum of about 10% of persons who have chronic bronchitis and 25% of those who have bronchiectasis in the absence of acute infection. Investigators in both the northern and southern hemispheres have reported a striking seasonal variation in the isolation of this organism from clinical specimens, with a peak in late winter/early spring and a nadir in late summer/early fall. Direct contact has not been shown to contribute to community-acquired infection, but nosocomial spread of infection has been documented occasionally.

CLINICAL MANIFESTATIONS ■ Otitis Media and Sinusitis *M. catarrhalis* has repeatedly been shown to be the third most common bacterial isolate from middle-ear fluid of children who have otitis media, being surpassed only by *Streptococcus pneumoniae* and nontypable *Haemophilus influenzae*. Recent studies have shown that this organism is also a prominent isolate from sinus cavities in acute and chronic sinusitis.

Purulent Tracheobronchitis and Pneumonia *M. catarrhalis* causes acute exacerbations of chronic bronchitis (increased production and/or purulence of sputum), purulent tracheobronchitis (the latter also involving fever and leukocytosis), and pneumonia; acquisition of a new bacterial strain is often responsible. The great majority of infected persons are >50 years old and have a long history of cigarette smoking and underlying chronic obstructive pulmonary disease (COPD); many have lung cancer as well. In one study, 76% of affected persons had COPD (severe in many cases), and one-third of those with COPD had lung cancer; most patients also had clinical evidence of malnutrition. In one extensive series of cases, *M. catarrhalis* pneumonia did not occur in otherwise-healthy hosts.

Symptoms of *M. catarrhalis* infection have been regarded as modest in severity. Both cough and the amount and purulence of sputum are usually increased above baseline. Chills are reported in one-quarter

of patients, pleuritic pain in one-third, and malaise in 40%. Most patients have peak temperatures of <38.3°C (<101°F), and peripheral white blood cell counts are <10,000/μL in nearly one-quarter of cases. Microscopic examination of a good sputum specimen following Gram's staining regularly reveals profuse organisms, and quantitative culture yields ~ 2×10^8 colony-forming units per milliliter. The radiologic appearance is variable; in one study, 43% of subjects had segmental or lobar infiltrates, and the remainder had a mixed pattern of subsegmental, segmental, interstitial, and diffuse involvement. These clinical, laboratory, and radiographic findings do not differ from those of pneumococcal or *Haemophilus* pneumonia in an older patient population. However, a far lesser degree of bloodstream invasion occurs in *M. catarrhalis* infection; in one series, none of 25 patients with *M. catarrhalis* pneumonia had bacteremia. Nevertheless, pneumonia due to *M. catarrhalis* is a marker for severe underlying disease: nearly half of patients die within 3 months of onset.

Other Syndromes Local extension causing empyema is very uncommon, and, as might be inferred from the low rate of bacteremia, metastatic complications of *M. catarrhalis* pneumonia, such as septic arthritis, are exceedingly rare. As of 1995, 58 cases of bacteremic infection due to *M. catarrhalis* had been reported, mainly in children <10 years old or adults >60 years old; most of these patients had severe underlying lung disease and/or were immunocompromised. The syndromes reported have included bacteremia with no apparent focus, pneumonia, endocarditis, and meningitis. A petechial or purpuric rash, reminiscent of that observed in meningococcal sepsis and associated with disseminated intravascular coagulation, has been described in a few cases.

DIAGNOSIS Microscopic examination of Gram-stained sputum yields characteristic findings (Fig. 129-1). The presence of many polymorphonuclear leukocytes without epithelial cells indicates that the sputum sample is of good quality; since most patients with *Moraxella* infection have chronic lung disease, it is usually not difficult to obtain a good specimen. Large numbers of *Moraxella* organisms are seen as gram-negative cocci, often lining up side by side and thus resembling pairs of kidneys.

TREATMENT

Treatment of *M. catarrhalis* infection with a penicillin/clavulanic acid combination seems highly appropriate. Penicillin resistance first appeared in isolates in the mid-1970s and is now found in 94% of clinical isolates. Resistance is mediated by two closely related β-lactamases, BRO-1 and BRO-2, which are present in 90% and 10% of resistant isolates, respectively. These enzymes are active against penicillin, ampicillin, and amoxicillin but less so against cephalosporins, especially third-generation cephalosporins, and they bind avidly to clavulanic acid and sulbactam. Thus a β-lactam/β-lactamase inhibitor combination offers an effective mode of treatment. Cephalosporins, especially those of the second and third generations, are effective alternatives. Isolates in the United States are also nearly uniformly susceptible to tetracycline, newer macrolides, ketolides, trimethoprim-sulfamethoxazole (TMP-SMX), quinolones, and chloramphenicol. A 5-day course of therapy has been shown to cure respiratory infection, although a longer course is required in sinusitis.

Treatment of sinusitis or otitis media is empirical, as appropriate specimens are usually obtained only in research studies. In the treatment of pneumonia during the period between the identification of gram-negative cocci in a Gram-stained specimen and the final identification of the organisms by culture, the severity of the condition and the potential presence of other infecting organisms should guide antibiotic selection. For example, an exacerbation of bronchitis caused by *M. catarrhalis* might be treated with tetracycline or TMP-SMX; however, in a patient with pneumonia, the possibility that pneumococci resistant to these agents also might be present dictates the choice of ampicillin/sulbactam, a third-generation cephalosporin, or a quinolone, at least until culture results become available.

TABLE 129-1 *Moraxella Species*

Moraxella Species	*Number of Isolates*	*Common Sites/ Clinical Association*	*Number (Percent) for Each Site*
M. osloensis[a]	199	Blood	44 (22)
		CSF	18 (9)
		Urine	17 (9)
		Respiratory tract	24 (12)
M. nonliquefaciens	356	Blood	27 (8)
		CSF	6 (2)
		Respiratory tract	196 (55)
M. canis	74	Dog-bite wound	53 (72)
M-6	47	Blood, bone	15 (32)
M. lacunata	33	Conjunctivitis, keratitis	23 (70)
M. urethralis	28	Urine	16 (57)
		Genital tract	3 (11)
M. phenylpyruvica	73	Blood	19 (26)
		CSF	8 (11)
		Urine	12 (16)
M. atlantae	44	Blood	20 (45)
		CSF	5 (11)

[a] Some of these isolates would now be distinguished as a new species, *Moraxella lincolnii*.
Note: CSF, cerebrospinal fluid.

OTHER *MORAXELLA* SPECIES

Other *Moraxella* species cause a wide range of infections, including bronchitis, pneumonia, empyema, endocarditis, meningitis, conjunctivitis, endophthalmitis, urinary tract infection, septic arthritis, and wound infection. In a report on all *Moraxella* isolates submitted to the Centers for Disease Control and Prevention (CDC) between 1953 and 1980, certain clinical associations were apparent (Table 129-1). *M. osloensis* and *M. nonliquefaciens*, the most commonly isolated species, were cultured from a wide range of normally sterile body sites, including blood, cerebrospinal fluid, and joints. *M. osloensis* was the *Moraxella* species most frequently isolated from blood; *M. nonliquefaciens* tended to be isolated from the ears, nose, or throat (47%) or the sputum (8%) and has since been implicated as a cause of conjunctivitis and keratitis. *M. urethralis* was isolated most often from urine and the genital tract and probably represents the *Moraxella* species implicated previously in urethritis. More than half of isolates of *M. phenylpyruvica* and *M. atlantae* were obtained from normally sterile sites. A recent study found *Moraxella* spp., including *M. catarrhalis*, in 35% of infected wounds following cat bites and in 10% of those following dog bites. The clinical features of infections due to *Moraxella* spp. other than *M. catarrhalis* and the nature of the hosts in which they occur have not been fully characterized.

130 *HAEMOPHILUS* INFECTIONS

Timothy F. Murphy

HAEMOPHILUS INFLUENZAE

MICROBIOLOGY *Haemophilus influenzae* was first recognized in 1892 by Pfeiffer, who erroneously concluded that the bacterium was the cause of influenza. The bacterium is a small (1- by 0.3-μm) gram-negative organism of variable shape; hence, it is often described as a pleomorphic coccobacillus. In clinical specimens such as cerebrospinal fluid (CSF) and sputum, it frequently stains only faintly with phenosafranin and therefore can easily be overlooked.

H. influenzae grows both aerobically and anaerobically. Its aerobic growth requires two factors: hemin (X factor) and nicotinamide adenine dinucleotide (V factor). These requirements are used in the clinical laboratory to identify the bacterium. Six major serotypes of *H. influenzae* have been identified; designated *a* through *f*, they are based on antigenically distinct polysaccharide capsules. In addition, some strains lack a polysaccharide capsule and are referred to as *nontypable* strains. Type b and nontypable strains are the most relevant strains clinically (Table 130-1), although encapsulated strains other than type b can cause disease. *H. influenzae* was the first free-living organism to have its entire genome sequenced.

The antigenically distinct type b capsule is a linear polymer composed of ribosyl-ribitol phosphate. Strains of *H. influenzae* type b (Hib) cause disease primarily in infants and children under the age of 6 years. Nontypable strains are primarily mucosal pathogens, although these strains occasionally cause invasive disease.

EPIDEMIOLOGY AND TRANSMISSION *H. influenzae* is an exclusively human pathogen. The organism is spread by airborne droplets or by direct contact with secretions or fomites. Nontypable strains colonize the upper respiratory tract of up to three-fourths of healthy adults. Colonization with nontypable *H. influenzae* is a dynamic process; new strains are acquired and other strains are replaced periodically.

The widespread use of Hib conjugate vaccines has resulted in striking decreases in the rate of nasopharyngeal colonization by Hib and the incidence of Hib infection (Fig. 130-1). Invasive Hib disease now occurs predominantly in underimmunized children and in infants who have not completed the primary immunization series.

Certain population groups have a higher incidence of invasive Hib disease than the general population. The incidence of meningitis due to Hib has been three to four times higher among black children than among white children in several studies. In some Native American groups, the incidence of invasive Hib disease is 10 times higher than that in the general population. Although this increased incidence has not yet been accounted for, several factors may be relevant, including age at exposure to the bacterium, socioeconomic conditions, and genetic differences in the ability to mount an immune response.

PATHOGENESIS Hib strains cause systemic disease by invasion and hematogenous spread to distant sites such as the meninges, bones, and joints. The type b polysaccharide capsule is an important virulence factor affecting the bacterium's ability to avoid opsonization and cause systemic disease.

Nontypable strains cause disease by local invasion of mucosal surfaces. Otitis media results when bacteria reach the middle ear by way of the eustachian tube. Adults with chronic bronchitis experience recurrent lower respiratory tract infection due to nontypable strains. The incidence of invasive disease caused by nontypable strains is low.

TABLE 130-1 *Characteristics of Type b and Nontypable Strains of Haemophilus influenzae*

Feature	*Type b Strains*	*Nontypable Strains*
Capsule	Ribosyl-ribitol phosphate	Unencapsulated
Pathogenesis	Invasive infections due to hematogenous spread	Mucosal infections due to contiguous spread
Clinical manifestations	Meningitis and invasive infections in incompletely immunized infants and children	Otitis media in infants and children; lower respiratory tract infections in adults with chronic bronchitis
Evolutionary history	Basically clonal	Genetically diverse
Vaccine	Highly effective conjugate vaccines	None available; under development

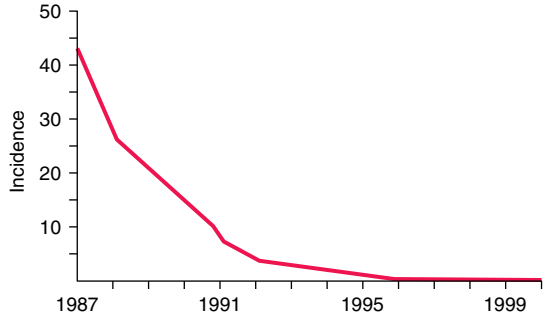

FIGURE 130-1 Estimated incidence (rate per 100,000) of invasive disease due to *Haemophilus influenzae* type b among children <5 years of age: 1987–2000. (*Data from the Centers for Disease Control and Prevention.*)

IMMUNE RESPONSE Antibody to capsule is important in protection from infection by Hib strains. The level of (maternally acquired) serum antibody to the capsular polysaccharide, which is a polymer of polyribitol ribose phosphate (PRP), declines from birth to 6 months of age and, in the absence of vaccination, remains low until around 2 or 3 years of age. The age at the antibody nadir correlates with that of the peak incidence of type b disease. Antibody to PRP then appears partly as a result of exposure to Hib or cross-reacting antigens. Systemic Hib disease is unusual after the age of 6 years because of the presence of protective antibody. Vaccines in which PRP is conjugated to protein carrier molecules have been developed and are now used widely. These vaccines generate an antibody response to PRP in infants and are effective in preventing invasive infections in infants and children.

Since nontypable strains lack a capsule, the immune response to infection is directed at noncapsular antigens. These noncapsular antigens of *H. influenzae* have generated considerable interest as targets of the human immune response and as potential vaccine components. The human immune response to nontypable strains appears to be strain-specific, accounting in part for the propensity of these strains to cause recurrent otitis media and recurrent exacerbations of chronic bronchitis in immunocompetent hosts.

CLINICAL MANIFESTATIONS ■ Hib The most serious manifestation of infection with Hib is meningitis. The age of peak incidence varies somewhat among populations, depending in part on the use of vaccine, but this infection primarily affects infants <2 years of age. The clinical manifestations of meningitis caused by Hib are similar to those of meningitis caused by other bacterial pathogens. Fever and altered central nervous system function are the most common features at presentation. Nuchal rigidity may or may not be evident. Subdural effusion, the most common complication, is suspected when, despite 2 or 3 days of appropriate antibiotic therapy, the infant has seizures, hemiparesis, or continued obtundation. The overall mortality from meningitis caused by Hib is ~5%, and the rate of morbidity is high. Of survivors, 6% have permanent sensorineural hearing loss, and about one-fourth have a significant handicap of some type. If more subtle handicaps are sought, up to half of survivors are found to have some neurologic sequelae, such as partial hearing loss and delay in language development.

Epiglottitis is a life-threatening infection involving cellulitis of the epiglottis and supraglottic tissues. It can lead to acute upper airway obstruction. Its unique epidemiologic features are its occurrence in an older age group (2 to 7 years old) than other Hib infections and its absence among Navajo Indians and Alaskan Eskimos. Sore throat and

fever rapidly progress to dysphagia, drooling, and airway obstruction. Epiglottitis also occurs in adults.

Cellulitis due to Hib occurs in young children. The most common location is on the head or neck, and the involved area sometimes takes on a characteristic bluish-red color. Most patients have bacteremia, and 10% have an additional focus of infection.

Hib causes *pneumonia* in infants. The infection is clinically indistinguishable from other types of bacterial pneumonia (e.g., pneumococcal pneumonia) except that Hib is more likely to involve the pleura.

Several less common invasive conditions can be important clinical manifestations of Hib infection in children. These include osteomyelitis, septic arthritis, pericarditis, orbital cellulitis, endophthalmitis, urinary tract infection, abscesses, and bacteremia without an identifiable focus. As has already been mentioned, infections due to Hib are unusual among patients older than 6 years.

Nontypable *H. influenzae* Nontypable *H. influenzae* is a common cause of community-acquired bacterial pneumonia in adults. Nontypable *H. influenzae* pneumonia is especially common among patients with chronic obstructive pulmonary disease (COPD) or AIDS. The clinical features of pneumonia due to *H. influenzae* are similar to those of other types of bacterial pneumonia (including pneumococcal pneumonia). Patients present with fever, cough, and purulent sputum, usually of several days' duration. Chest radiography reveals alveolar infiltrates in a patchy or lobar distribution. Gram-stained sputum contains a predominance of small, pleomorphic, coccobacillary gram-negative bacteria.

Exacerbations of COPD caused by nontypable *H. influenzae* are characterized by increased cough, sputum production, and shortness of breath. Fever is low-grade, and no infiltrates are evident on chest x-ray.

Nontypable *H. influenzae* is one of the three most common causes of childhood otitis media (the other two being *Streptococcus pneumoniae* and *Moraxella catarrhalis*). Infants are febrile and irritable, while older children report ear pain. Symptoms of viral upper respiratory infection often precede otitis media. The diagnosis is made by pneumatic otoscopy. An etiologic diagnosis, although not routinely sought, can be established by tympanocentesis and culture of middle-ear fluid.

Nontypable *H. influenzae* also causes puerperal sepsis and is an important cause of neonatal bacteremia. These nontypable strains tend to be of biotype IV and cause invasive disease after colonizing the female genital tract.

Nontypable *H. influenzae* causes sinusitis in adults and children. In addition, the bacterium is a less common cause of various invasive infections that are reported primarily as small-series descriptions and case reports. These infections include empyema, adult epiglottitis, pericarditis, cellulitis, septic arthritis, osteomyelitis, endocarditis, cholecystitis, intraabdominal infections, urinary tract infections, mastoiditis, aortic graft infection, and bacteremia without a detectable focus.

DIAGNOSIS The most reliable method for establishing a diagnosis of Hib infection is recovery of the organism in culture. The CSF of a patient in whom meningitis is suspected should be subjected to Gram's staining and culture. The presence of gram-negative coccobacilli in Gram-stained CSF is strong evidence for Hib meningitis. Recovery of the organism from CSF confirms the diagnosis. Cultures of other normally sterile body fluids, such as blood, joint fluid, pleural fluid, pericardial fluid, and subdural effusion, are confirmatory in other infections.

Detection of PRP is an important adjunct to culture in rapid diagnosis. Immunoelectrophoresis, latex agglutination, coagglutination, and enzyme-linked immunosorbent assay are effective in detecting PRP. These assays are particularly helpful when patients have received prior antimicrobial therapy and thus are especially likely to have negative cultures.

Before the early 1980s, nontypable strains of *H. influenzae* were frequently misidentified as Hib because of their autoagglutination when serotypes were determined in agglutination assays. Since nontypable *H. influenzae* is primarily a mucosal pathogen, it is a component of a mixed flora; this situation makes etiologic diagnosis challenging. Nontypable *H. influenzae* infection is strongly suggested by the predominance of gram-negative coccobacilli among abundant polymorphonuclear leukocytes in a Gram-stained sputum specimen from a patient in whom pneumonia or tracheobronchitis is suspected. A sputum culture is helpful when interpreted along with the results of Gram's staining. Although bacteremia is detectable in a small proportion of patients with pneumonia due to nontypable *H. influenzae*, most such patients have negative blood cultures.

A diagnosis of otitis media is based on the detection by pneumatic otoscopy of fluid in the middle ear. An etiologic diagnosis requires tympanocentesis but is not routinely sought. An invasive procedure is also required to determine the etiology of sinusitis; thus, treatment is often empirical once the diagnosis is suspected in light of clinical symptoms and sinus radiographs.

Rx TREATMENT

Initial therapy for meningitis due to Hib should consist of a cephalosporin such as ceftriaxone or cefotaxime. For children, the dosage of ceftriaxone is 75 to 100 mg/kg daily given in two doses 12 h apart. The pediatric dosage of cefotaxime is 200 mg/kg daily given in four doses 6 h apart. Adult dosages are 2 g every 12 h for ceftriaxone and 2 g every 4 to 6 h for cefotaxime. An alternative regimen for initial therapy is ampicillin (200 to 300 mg/kg daily in four divided doses) plus chloramphenicol (75 to 100 mg/kg daily in four divided doses). Therapy should continue for a total of 1 to 2 weeks.

Administration of glucocorticoids to patients with Hib meningitis reduces the incidence of neurologic sequelae. The presumed mechanism is reduction of the inflammation induced by bacterial cell-wall mediators of inflammation when cells are killed by antimicrobial agents. Dexamethasone (0.6 mg/kg per day intravenously in four divided doses for 2 days) is recommended for the treatment of Hib meningitis in children >2 months of age.

Invasive infections other than meningitis are treated with the same antimicrobial agents. For epiglottitis, the dosage of ceftriaxone is 50 mg/kg daily, and the dosage of cefotaxime is 150 mg/kg daily, given in three divided doses 8 h apart. Epiglottitis constitutes a medical emergency, and maintenance of an airway is critical. The duration of therapy is determined by the clinical response. A course of 1 to 2 weeks is usually appropriate.

Many infections caused by nontypable strains of *H. influenzae*, such as otitis media, sinusitis, and exacerbations of COPD, can be treated with oral antimicrobial agents. Approximately 25% of nontypable strains produce β-lactamase and are resistant to ampicillin. Infections caused by ampicillin-resistant strains can be treated with a variety of agents, including trimethoprim-sulfamethoxazole, amoxicillin/clavulanic acid, various extended-spectrum cephalosporins, and newer macrolides (azithromycin and clarithromycin). Fluoroquinolones are highly active against *H. influenzae* but are not currently recommended for the treatment of children or pregnant women because of possible effects on articular cartilage.

PREVENTION ■ Vaccination (See also Chap. 107) The development of conjugate vaccines that prevent invasive infections with Hib in infants and children has been a dramatic success. Three such vaccines are licensed in the United States. In addition to eliciting protective antibody, these vaccines prevent disease by reducing pharyngeal colonization with Hib.

All children should be immunized with an Hib conjugate vaccine, receiving the first dose at ~2 months of age, the rest of the primary series between 2 and 6 months of age, and a booster dose at 12 to 15 months of age. Specific recommendations vary for the different conjugate vaccines. The reader is referred to the recommendations of the American Academy of Pediatrics. Currently, no vaccines are available for the prevention of disease caused by nontypable *H. influenzae*.

Chemoprophylaxis The risk of secondary disease is greater than normal among household contacts of patients with Hib disease. The attack rate is as high as 4% among susceptible infants. Therefore, all children and adults (except pregnant women) in households with at least one contact <4 years of age who is incompletely immunized should receive prophylaxis with oral rifampin. (This rule does not apply when all household contacts under the age of 4 years have been completely immunized with conjugate vaccine.) Children <12 years old should receive rifampin at a dose of 20 mg/kg once daily for 4 days, and adults should receive 600 mg daily for 4 days. The index case should receive rifampin before or at the time of discharge from the hospital because antimicrobial agents used for the treatment of meningitis do not reliably eradicate Hib from the nasopharynx.

When two or more cases of invasive Hib disease have occurred within 60 days at a child-care facility attended by incompletely vaccinated children, administration of rifampin to all attendees and personnel is indicated, as is recommended for household contacts. Chemoprophylaxis is not indicated in nursery and child-care contacts of a single index case. The reader is referred to the recommendations of the American Academy of Pediatrics.

HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS

H. influenzae biogroup aegyptius was formerly called *Haemophilus aegyptius* because of phenotypic characteristics distinct from those of *H. influenzae*. However, later studies involving DNA hybridization and DNA transformation demonstrated that *H. aegyptius* and *H. influenzae* are members of the same species.

H. influenzae biogroup aegyptius has long been associated with conjunctivitis. Moreover, this strain is now known to be the cause of Brazilian purpuric fever (BPF), which was first recognized in 1984 in the rural Brazilian town of Promissao. The sharing of many phenotypic and genotypic characteristics by the various strains of *H. influenzae* biogroup aegyptius that cause BPF indicates that these strains represent a clone of *H. influenzae*. The age of peak incidence of BPF is 1 to 4 years, with a range of 3 months to 8 years. The illness can occur sporadically or in outbreaks. Typically, after an episode of purulent conjunctivitis, high fever occurs in association with vomiting and abdominal pain. Within 12 to 48 h after onset, the patient develops petechiae, purpura, and peripheral necrosis and experiences vascular collapse. The characteristic laboratory features are thrombocytopenia, prolonged prothrombin time, uniformly unrevealing CSF findings, and blood cultures positive for *H. influenzae* biogroup aegyptius. Initial reports cited high mortality (70%), but subsequent studies have indicated that milder forms of the illness exist. Most patients have resolved or resolving purulent conjunctivitis, and culture of the conjunctiva is positive in approximately one-third of cases. BPF has been seen in several towns in Brazil and on two occasions in Australia.

HAEMOPHILUS DUCREYI

Haemophilus ducreyi is the etiologic agent of chancroid (Chap. 115), a sexually transmitted disease characterized by genital ulceration and inguinal adenitis. *H. ducreyi* poses a significant health problem in developing countries. Although this infection is less common in the United States, its incidence has increased dramatically in the past several years. In addition to being a cause of morbidity in itself, chancroid is associated with infection with HIV because of the role of genital ulceration in the transmission of HIV.

MICROBIOLOGY *H. ducreyi* is a highly fastidious coccobacillary gram-negative bacterium whose growth requires X factor (hemin). Although, in light of this requirement, the bacterium has been classified in the genus *Haemophilus*, DNA homology and chemotaxonomic studies have established substantial differences between *H. ducreyi* and other *Haemophilus* species. Taxonomic reclassification of the organism is likely in the future but awaits further study.

The histology of the genital ulcer of chancroid is characterized by perivascular and interstitial infiltrates of macrophages and of CD4+ and CD8+ lymphocytes. The appearance is consistent with a delayed-type hypersensitivity, cell-mediated immune response. The presence of CD4+ cells and macrophages in the ulcer may explain, in part, the facilitation of transmission of HIV in patients with chancroid.

EPIDEMIOLOGY AND PREVALENCE Chancroid is a common cause of genital ulcers in developing countries. In the United States, chancroid is now endemic in some regions, and several large outbreaks have occurred since 1981. Recurring epidemiologic themes have been apparent in these outbreaks: (1) transmission has been predominantly heterosexual; (2) males have outnumbered females by ratios of 3:1 to 25:1; (3) prostitutes have been important in transmission of the infection; and (4) chancroid has been strongly associated with illicit drug use. The incidence of chancroid in the United States will likely increase in the coming years, and the genital ulcers associated with this infection will continue to play a role in the transmission of HIV.

CLINICAL MANIFESTATIONS Infection is acquired as the result of a break in the epithelium during sexual contact with an infected individual. After an incubation period of 4 to 7 days, the initial lesion—a papule with surrounding erythema—appears. In 2 to 3 days, the papule evolves into a pustule, which spontaneously ruptures and forms a sharply circumscribed ulcer that is generally not indurated (Fig. 130-2). The ulcers are painful and bleed easily; little or no inflammation of the surrounding skin is evident. Approximately half of patients develop enlarged, tender inguinal lymph nodes, which frequently become fluctuant and spontaneously rupture. Patients usually seek medical care after 1 to 3 weeks of painful symptoms.

The presentation of chancroid does not usually include all of the typical clinical features and is sometimes atypical. Multiple ulcers can coalesce to form giant ulcers. Ulcers can appear and then resolve, with inguinal adenitis (Fig. 130-2) and suppuration following 1 to 3 weeks later; this clinical picture can be confused with that of lymphogranuloma venereum. Multiple small ulcers can resemble folliculitis. Other differential diagnostic considerations include the various infections causing genital ulceration, such as primary syphilis, condyloma latum of secondary syphilis, genital herpes, and donovanosis. In rare cases chancroid lesions become secondarily infected with bacteria; the result is extensive inflammation.

DIAGNOSIS Clinical diagnosis of chancroid is often inaccurate, and laboratory confirmation should be attempted in suspected cases. Gram's staining of a swab of the lesion may reveal a predominance of characteristic gram-negative coccobacilli, but the presence of other bacteria often makes it difficult to interpret this result. An accurate diagnosis of chancroid relies on cultures of *H. ducreyi* from the lesion. In addition, aspiration and culture of suppurative lymph nodes should be considered. Since the organism can be difficult to grow, the use of selective and supplemented media is necessary. A new multiplex

FIGURE 130-2 Chancroid with characteristic penile ulcers and associated left inguinal adenitis (bubo).

polymerase chain reaction (PCR) assay has been developed to amplify simultaneously DNA targets from *H. ducreyi*, *Treponema pallidum*, and herpes simplex virus types 1 and 2. When this assay becomes commercially available, it will be a useful diagnostic method with which to identify the etiology of genital ulcers.

TREATMENT

The treatment regimen recommended by the Centers for Disease Control and Prevention is a single 1-g oral dose of azithromycin. Alternative regimens include ceftriaxone (250 mg intramuscularly in a single dose), ciprofloxacin (500 mg orally twice a day for 3 days), or erythromycin base (500 mg orally three times a day for 7 days). Isolates from patients who do not respond promptly to treatment should be tested for antimicrobial susceptibility. In patients with HIV infection, healing may be slow and longer courses of treatment may be necessary. Clinical treatment failure in HIV-seropositive patients may reflect co-infection, especially with herpes simplex virus. Contacts of patients with chancroid should be identified and treated whether or not symptoms are present if they had sexual contact with the patient during the 10 days preceding the patient's onset of symptoms.

OTHER *HAEMOPHILUS* SPECIES

Haemophilus species are often recovered as components of the flora of the normal human upper respiratory tract. However, these bacteria are infrequent causes of infection because of their low pathogenic potential. *Haemophilus* species have fastidious growth requirements and are generally rather slow-growing. The species implicated in human infections include *H. parainfluenzae*, *H. aphrophilus*, and *H. paraphrophilus* (Chap. 131); *H. parahaemolyticus*; *H. haemolyticus*; and *H. segnis*. *Haemophilus* species are differentiated from one another by several characteristics, primarily their requirements for X and V factors. Species designated *para-* require V factor but not X factor for growth, whereas the others require either X and V or X only.

Haemophilus species, particularly *H. parainfluenzae*, are an increasingly recognized cause of endocarditis and should be considered as such, especially when initial blood cultures are negative but clinical suspicion of endocarditis is high. Blood cultures should be incubated for 2 weeks to increase the likelihood of isolating slow-growing *Haemophilus* species. Endocarditis due to *Haemophilus* species usually presents with a subacute course, but the presentation varies.

A variety of other infections involving almost all organ systems can be caused by *Haemophilus* species. Most of these unusual manifestations have been reported as single cases and small series.

TREATMENT

The antimicrobial susceptibility characteristics of other *Haemophilus* species are similar to those of *H. influenzae*. Some strains produce β-lactamase and are thereby resistant to ampicillin. Other strains are sensitive to ampicillin, and this agent has been used successfully to treat many infections. Alternative agents with good activity against most *Haemophilus* species include trimethoprim-sulfamethoxazole, third-generation cephalosporins, tetracycline, chloramphenicol, and aminoglycosides. Endocarditis caused by ampicillin-sensitive strains should be treated with ampicillin plus an aminoglycoside.

131 INFECTIONS DUE TO HACEK GROUP AND MISCELLANEOUS GRAM-NEGATIVE BACTERIA

Dennis L. Kasper, Tamar F. Barlam

HACEK GROUP ORGANISMS

HACEK organisms are a group of fastidious, slow-growing, gram-negative bacteria whose growth requires an atmosphere of carbon dioxide. Species belonging to this group include several ***H****aemophilus* species, ***A****ctinobacillus actinomycetemcomitans*, ***C****ardiobacterium hominis*, ***E****ikenella corrodens*, and ***K****ingella kingae*. HACEK bacteria normally reside in the oral cavity and have been associated with local infections in the mouth. They are also known to cause severe systemic infections, most often bacterial endocarditis (Chap. 109).

Of the HACEK group, the *Haemophilus* species, *A. actinomycetemcomitans*, and *C. hominis* are most frequently associated with endocarditis, which can develop on either native or prosthetic valves. In large series, up to 3% of cases of infective endocarditis are attributable to HACEK organisms. The clinical course of HACEK endocarditis tends to be subacute; however, embolization is common. The overall prevalence of major emboli associated with HACEK endocarditis ranges from 28 to 71% in different series. On echocardiography, valvular vegetations are seen in up to 85% of patients. The vegetations are frequently large, although vegetation size has not been directly correlated with risk of embolization. Cultures of blood from patients with suspected HACEK endocarditis may require up to 30 days to become positive, and the microbiology laboratory should be alerted if a HACEK organism is being considered. However, most cultures that ultimately yield a HACEK organism become positive within the first week, especially with improved culture systems such as BACTEC. In addition, polymerase chain reaction techniques are facilitating the diagnosis of HACEK infections. Because of the organisms' slow growth, antimicrobial testing may be difficult, and strains producing β-lactamase may not be identified accurately. This factor should be considered in the selection of a therapeutic regimen. E-test methodology may improve the accuracy of susceptibility testing.

Native-valve endocarditis should be treated for 4 weeks with antibiotics, whereas prosthetic-valve endocarditis requires 6 weeks of therapy. The cure rates for HACEK prosthetic-valve endocarditis appear to be high. Unlike prosthetic-valve endocarditis caused by other gram-negative organisms, HACEK endocarditis is often cured with antibiotic treatment alone—i.e., without surgical intervention. Recommendations for the treatment of HACEK endocarditis are presented in Table 131-1.

***HAEMOPHILUS* SPECIES** *Haemophilus* species cause more than half of all cases of HACEK endocarditis. *H. aphrophilus* and *H. parainfluenzae* are most common; *H. paraphrophilus* is less common. Up to 50%

TABLE 131-1 *Treatment of Endocarditis Caused by HACEK Group Organisms*[a]

Organism	Initial Therapy	Alternative Agents	Comments
Haemophilus species	Ceftriaxone (2 g/d)	Fluoroquinolones,[b] ampicillin/sulbactam	Ampicillin ± aminoglycoside can be used if organism does not produce β-lactamase.
Actinobacillus actinomycetemcomitans	Ceftriaxone (2 g/d)	Semisynthetic penicillins (e.g., mezlocillin), TMP-SMX, fluoroquinolones,[b] azithromycin	Limited data exist on efficacy of regimens other than semisynthetic penicillins or third-generation cephalosporins.
Cardiobacterium hominis	Penicillin (16–18 mU/d in 6 divided doses) ± gentamicin (5–6 mg/kg/d in 3 divided doses)	Ceftriaxone, ampicillin/sulbactam	Value of aminoglycoside has not been proven. Organism is usually pan-sensitive, but high-level resistance to penicillin has been reported.
Eikenella corrodens	Ampicillin (2 g q4h)	Ceftriaxone, fluoroquinolones[b]	Organism is resistant to clindamycin and metronidazole.
Kingella kingae	Ceftriaxone (2 g/d) or ampicillin/sulbactam (3 g of ampicillin q6h)	Fluoroquinolones,[b] vancomycin, clindamycin, macrolides, TMP-SMX	Prevalence of β-lactamase-producing strains is increasing. Efficacy for invasive infections is best demonstrated for first-line treatments.

[a] Susceptibility testing should be performed to guide therapy.
[b] Fluoroquinolones are not recommended for treatment of children <17 years of age.

Note: TMP-SMX, trimethoprim-sulfamethoxazole.

of patients with native-valve endocarditis due to *Haemophilus* species report a history of cardiac valvular disease, 60% have been ill for <2 months before presentation, and 50% are anemic at presentation. Some 19% to 50% of these patients develop congestive heart failure. Mortality rates as high as 30% to 50% have been reported in older series, with most deaths attributed to cerebral embolism; however, recent studies have documented mortality rates of <5%. In rare cases, *H. parainfluenzae* has been isolated from other infections, such as meningitis; brain, dental, and liver abscess; pneumonia; and septicemia.

TREATMENT

See Table 131-1.

ACTINOBACILLUS ACTINOMYCETEMCOMITANS *A. actinomycetemcomitans*, another slow-growing inhabitant of the oral cavity, can be isolated from soft tissue infections and abscesses in association with *Actinomyces israelii*. About 30% of actinomycotic lesions also yield *A. actinomycetemcomitans* on culture. *A. actinomycetemcomitans* has been associated with severe destructive periodontal disease, characterized by loss of alveolar bone of the molars and incisors, in both children and adults. Patients who develop endocarditis with this organism typically have severe periodontal disease and underlying cardiac valvular damage as well as high rates of embolic phenomena. *A. actinomycetemcomitans* has been isolated from patients with brain abscess, meningitis, parotitis, osteomyelitis, urinary tract infection, pneumonia, and empyema, among other infections.

TREATMENT

See Table 131-1.

CARDIOBACTERIUM HOMINIS *C. hominis* primarily causes endocarditis in patients with underlying valvular heart disease or with prosthetic valves. Unlike other HACEK bacteria, *C. hominis* most frequently affects the aortic valve. Many patients have signs and symptoms of long-standing infection before diagnosis and have evidence of arterial embolization, vasculitis, cerebrovascular accidents, immune complex glomerulonephritis, or arthritis at presentation. As in endocarditis due to other HACEK organisms, embolization, mycotic aneurysms, and congestive heart failure are frequent.

TREATMENT

See Table 131-1.

EIKENELLA CORRODENS *E. corrodens*, a fastidious, facultative gram-negative organism, is part of the endogenous flora of the mouth and nasopharynx. It is most frequently recovered from sites of infection in conjunction with other bacterial species. Clinical sources of *E. corrodens* include sites of human bite wounds (clenched-fist injuries), endocarditis, soft tissue infections of the head and neck, soft tissue infections in injection drug users, osteomyelitis, respiratory infections, chorioamnionitis, gynecologic infections associated with intrauterine devices, meningitis and brain abscesses, and visceral abscesses.

TREATMENT

See Table 131-1.

KINGELLA KINGAE *K. kingae* is a β-hemolytic, fastidious, nonmotile gram-negative rod. Because of improved microbiologic methodology, isolation of this organism is increasingly common. In recent series, *K. kingae* was the cause of up to half of all cases of previously undiagnosed osteomyelitis and septic arthritis in children <2 years old. *K. kingae* has been the third most common cause of septic arthritis in children <24 months of age; staphylococcal and streptococcal species remain most prevalent. In children <4 years of age, there is evidence for prolonged nasopharyngeal colonization, with carriage rates of 10%. Invasive *K. kingae* infections with bacteremia are associated with stomatitis. Both *K. kingae* colonization and primary herpes—a major cause of stomatitis—peak in children 6 to 48 months of age. *K. kingae* bacteremia can present with a petechial rash similar to that seen with *Neisseria meningitidis* sepsis.

Infective endocarditis, unlike other infections with *K. kingae*, occurs in older children and adults. The majority of patients have preexisting valvular disease. As in endocarditis caused by the other HACEK organisms, there is a high incidence of complications, including arterial emboli, cerebrovascular accidents, tricuspid insufficiency, and congestive heart failure with cardiovascular collapse.

TREATMENT

See Table 131-1.

OTHER GRAM-NEGATIVE BACTERIA

***ACINETOBACTER* SPECIES** See Chap. 134.

ACHROMOBACTER XYLOSOXIDANS Previously known as *Alcaligenes xylosoxidans*, this gram-negative bacillus is probably part of the endogenous intestinal flora and has been isolated from water sources. Immunocompromised hosts appear to be at increased risk for infection with this organism. Nosocomial sources to which outbreaks of infection with *A. xylosoxidans* have been attributed include contaminated intravenous fluids, pressure transducers, and disinfectants. Clinical illness has been associated with isolates from many sites, including blood (often in the setting of infected intravascular devices), urine, respiratory secretions, cerebrospinal fluid, peritoneal and pleural fluids, and

endocarditic prosthetic valves. Community-acquired bacteremia with *A. xylosoxidans* usually occurs in the setting of pneumonia. Metastatic skin lesions are present in one-fifth of cases. The reported mortality rate is 67%, similar to rates for other bacteremic gram-negative pneumonias.

TREATMENT

In vitro susceptibility testing of all clinically relevant isolates is essential to the selection of appropriate therapy.

AGROBACTERIUM RADIOBACTER (TUMEFACIENS) This organism has been associated with intravascular catheter–related infections in immunocompromised hosts, especially individuals infected with HIV. Clinically important infections associated with *A. radiobacter* include prosthetic-joint and prosthetic-valve infections, bacteremia, peritonitis, and urinary tract infections.

TREATMENT

Antibiotic sensitivity testing is essential in the choice of therapy.

***CAPNOCYTOPHAGA* SPECIES** This genus of fusiform, long, thin, gram-negative coccobacilli is facultatively anaerobic and requires an atmosphere enriched in carbon dioxide for optimal growth. *C. ochracea*, *C. gingivalis*, and *C. sputigena* are inhabitants of the healthy human oral cavity and have been isolated from the female genital tract. Their isolation has also been reported from blood, cerebrospinal fluid, and respiratory fluids (including pleural collections). These organisms have been associated with sepsis in immunocompromised hosts; particularly at risk are neutropenic patients with acute myelogenous leukemia or acute lymphocytic leukemia. In the immunocompetent host, these three species probably play a role in localized juvenile periodontitis; however, they have been isolated from many other sites as well, usually as part of a polymicrobial infection. In vitro sensitivity testing of these organisms is difficult because they are slow-growing and fastidious.

C. canimorsus and *C. cynodegmi* are endogenous to the canine mouth. Patients infected with these species frequently have a history of dog bites or of exposure to dogs without scratches or bites. Asplenia, glucocorticoid therapy, and alcohol abuse are predisposing conditions and are associated with relatively fulminant infections. The interval from dog bite to presentation averages 5 days but ranges from 1 day to 1 month. *C. canimorsus* causes a wide range of infections, including severe sepsis with shock and disseminated intravascular coagulation, meningitis, endocarditis, cellulitis, and septic arthritis. In the asplenic individual who has recently sustained a dog bite, infection with this organism must be considered early because of a potentially rapid progression to death.

TREATMENT

Although penicillin has been considered first-line therapy for infections due to *C. ochracea*, *C. gingivalis*, and *C. sputigena*, an increasing number of isolates reportedly produce β-lactamase. Fluoroquinolone resistance is also increasing. Clindamycin (600 to 900 mg every 6 to 8 h) or drug combinations including a penicillin derivative plus a β-lactamase inhibitor—such as ampicillin/sulbactam (1.5 to 3.0 g of ampicillin every 6 h)—are currently recommended for empirical therapy. Penicillin (12 to 18 million units daily in 6 divided doses) is the drug of choice for documented infections with *C. canimorsus*. This regimen or ampicillin/sulbactam should also be given prophylactically to asplenic patients sustaining dog-bite injuries. Patients with suspected infection due to *C. canimorsus* should be treated empirically, because identification of this organism and determination of its antibiotic sensitivity can take many days. Other drugs to which *C. canimorsus* is reportedly susceptible include clindamycin, imipenem, quinolones, and third-generation cephalosporins.

CHROMOBACTERIUM VIOLACEUM This organism is rarely a human pathogen but reportedly has been responsible for life-threatening infections with severe sepsis and metastatic abscesses, particularly in children. A slender, slightly curved, gram-negative rod that is facultatively anaerobic, *C. violaceum* inhabits tropical water and soil and causes infection after contamination of skin wounds. Patients with defective neutrophil function (e.g., those with chronic granulomatous disease) are infected by this organism with unusual frequency. The mortality rate in the United States from infection with *C. violaceum* has been reported at >60%.

TREATMENT

C. violaceum is generally susceptible to ciprofloxacin (500 mg every 12 h orally or 400 mg every 12 h intravenously), trimethoprim-sulfamethoxazole (TMP-SMX), gentamicin, and chloramphenicol.

***CHRYSEOBACTERIUM* SPECIES** *C. meningosepticum* and *C. indologenes* were previously classified as *Flavobacterium* species. *C. meningosepticum* is a ubiquitous organism and an important cause of nosocomial infections. It has been associated with outbreaks due to contaminated fluids, such as disinfectants, arterial catheter flush solutions, and aerosolized antibiotics, and with sporadic infections due to indwelling devices, vials, sink traps, feeding tubes, and other fluid-associated apparatus. Patients with nosocomial *C. meningosepticum* infection usually have underlying immunosuppression (e.g., related to malignancy). *C. meningosepticum* has been reported to cause meningitis (primarily in neonates), sepsis, endocarditis, bacteremia, soft tissue infections, and pneumonia. *C. indologenes* has caused bacteremia, sepsis, and pneumonia, typically in immunocompromised patients with indwelling devices.

TREATMENT

Antibiotic treatment should be based on susceptibility results because of the high likelihood that a *C. meningosepticum* isolate will produce β-lactamase. Early reports suggested that vancomycin might be efficacious, but more recent data refute this conclusion.

PLESIOMONAS SHIGELLOIDES This freshwater organism is a cause of acute diarrhea (Chap. 113) and occasionally of serious extraintestinal disease. *P. shigelloides* is transmitted to humans via contaminated water or food. This motile, facultatively anaerobic gram-negative rod most often produces mild, watery diarrhea. Severe extraintestinal infections have been reported, most commonly in immunocompromised hosts, and include bacteremia, cellulitis, neonatal sepsis and meningitis, and septic arthritis.

TREATMENT

There is great variability among strains in terms of antibiotic sensitivity patterns, and isolates must be tested before appropriate therapy can be selected.

***AEROMONAS* SPECIES** Five species of *Aeromonas* are known to be associated with disease in humans, but more than 85% of these *Aeromonas* infections are caused by *A. hydrophila*, *A. caviae*, and *A. veronii* biovar *sobria*. *Aeromonas* proliferates in potable and fresh water and in soil. It remains controversial whether *Aeromonas* is a cause of bacterial gastroenteritis. Although many case reports have associated *Aeromonas* with gastroenteritis, no clear outbreaks with a single isolate have been documented, no conclusive animal model exists, and asymptomatic colonization of the intestinal tract with *Aeromonas* occurs frequently. However, rare cases of hemolytic-uremic syndrome following bloody diarrhea have been shown to be secondary to the presence of *Aeromonas*. In addition, identification of an enterotoxin (different from the Shiga-like toxin produced by *Escherichia coli* O157:H7) in these cases supports the hypothesis that *Aeromonas* causes gastroenteritis.

Aeromonas causes sepsis and bacteremia in infants with multiple medical problems and in immunocompromised hosts, particularly those with cancer or hepatobiliary disease. *Aeromonas* infection and sepsis can occur in trauma patients with myonecrosis or in burn patients exposed to *Aeromonas* by environmental contamination of their wounds from fresh water or soil sources. Mortality ranges from 25% among immunocompromised adults with sepsis to >90% among patients with myonecrosis. *Aeromonas* can produce skin lesions resembling the ecthyma gangrenosum lesions seen in *Pseudomonas aeruginosa* infection. These lesions are hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration.

Aeromonas wound infections can occur in healthy adults who sustain minor trauma with environmental contamination, usually water-related; after severe trauma and crush injuries with sepsis and environmental exposure, usually to soil; and in nosocomial infections related to catheters, surgical incisions, or use of leeches. Other clinical manifestations include meningitis, peritonitis, pneumonia, and ocular infections.

Rx TREATMENT

Treatment should be guided by antimicrobial susceptibility testing. *Aeromonas* species are generally susceptible to fluoroquinolones (e.g., ciprofloxacin at a dosage of 500 mg every 12 h orally or 400 mg every 12 h intravenously), TMP-SMX (at a trimethoprim dosage of 10 mg/kg per day in 3 or 4 divided doses), third-generation cephalosporins, and aminoglycosides. However, resistance is increasing.

MISCELLANEOUS ORGANISMS Many other gram-negative rods have been reported to cause occasional infections in hosts who are immunologically unprepared to deal with relatively avirulent organisms or who are unfortunate enough to encounter an exceptionally large inoculum. Such organisms include *Weeksella* species; various CDC groups, such as EF-4, Ve-2 (*Flavimonas* species), IVc-2, NO-1, WO-1, and Gilardi Group WO-1; *Sphingobacterium* species; *Protomonas* species; *Ochrobactrum anthropi*; *Oligella urethralis*; and *Shewanella putrefaciens*. The reader is advised to consult subspecialty texts and references for further guidance on these organisms.

132 *LEGIONELLA* INFECTION

Feng-Yee Chang, Victor L. Yu

DEFINITION *Legionellosis* refers to the two clinical syndromes caused by bacteria of the genus *Legionella*. *Pontiac fever* is an acute, febrile, self-limited illness that has been serologically linked to *Legionella* species, whereas *Legionnaires' disease* is the designation for pneumonia caused by these species.

HISTORY Legionnaires' disease was first recognized in 1976, when an outbreak of pneumonia took place at a hotel in Philadelphia during the American Legion Convention. The causative agent proved to be a newly discovered bacterium, *Legionella pneumophila*, that was isolated from lung specimens obtained from the victims at autopsy.

MICROBIOLOGY The family Legionellaceae comprises 41 species with 64 serogroups. The species *L. pneumophila* causes 80 to 90% of human infections and includes at least 14 serogroups; serogroups 1, 4, and 6 are most commonly implicated in human infections. To date, 17 species other than *L. pneumophila* have been associated with human infections, among which *L. micdadei* (Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, and *L. longbeachae* are the most common.

Members of the Legionellaceae are aerobic gram-negative bacilli that do not grow on routine microbiologic media. Buffered charcoal yeast extract (BCYE) agar is the medium used to grow *Legionella*. Antibiotics added to the medium suppress the growth of competing flora from nonsterile sites, and dyes color the colonies and assist in identification.

The direct fluorescent antibody (DFA) test can definitively identify a number of individual species. In *L. pneumophila*, lipopolysaccharide is a prominent constituent of the outer membrane, and the serogroup-specific antigen and antibodies detected by immunofluorescence are directed primarily at the lipopolysaccharide. Both polyclonal and monoclonal DFA reagents are commercially available. The monoclonal antibody reagent is less cross-reactive but is specific for *L. pneumophila*.

ECOLOGY AND TRANSMISSION The natural habitats for *L. pneumophila* are aquatic bodies, including lakes and streams. *L. longbeachae* has been isolated from soil. *Legionella* can survive under a wide range of environmental conditions; for example, the organisms can live for years in refrigerated water samples. Natural bodies of water contain only small numbers of *Legionella*. However, once the organisms enter human-constructed aquatic reservoirs (such as water-distribution systems), they can grow and proliferate. Factors known to enhance colonization by and amplification of legionellae include warm temperatures (25° to 42°C), stagnation, and scale and sediment. *L. pneumophila* can form microcolonies within biofilms; its eradication from water-distribution systems requires disinfectants that can penetrate the biofilm. The presence of symbiotic microorganisms, including algae, amebas, ciliated protozoa, and other water-dwelling bacteria, promotes the growth of *L. pneumophila*. *Legionella* can invade and multiply within free-living protozoa.

Hot-water tanks colonized with *L. pneumophila* are significantly more likely than uncolonized tanks to be cooler, to have a vertical configuration, to be older, and to have higher concentrations of calcium and magnesium. Vertical tanks, especially those that are electric coil–heated rather than gas-heated, have a pronounced temperature stratification and thick sediment accumulation at the bottom.

The source of *Legionella* is water. Early investigations that implicated cooling towers antedated the discovery that the organism could also exist in potable-water distribution systems. It is now known that, in most previously reported outbreaks, cases of Legionnaires' disease continued to occur despite disinfection of cooling towers and the potable water supply was the actual source. Koch's postulates have been fulfilled in epidemiologic studies using molecular fingerprinting methods to link potable water sources (rather than cooling towers) to *Legionella* infection in humans. Community-acquired Legionnaires' disease has also been linked to colonization of residential and industrial water supplies.

Multiple modes of transmission of *Legionella* to humans exist, including aerosolization, aspiration, and direct instillation into the lung during respiratory tract manipulations. Aspiration is the predominant

mode of transmission, but it is unclear whether *Legionella* enters the lung via oropharyngeal colonization or directly via the drinking of contaminated water. Nasogastric tubes have been linked to nosocomial Legionnaires' disease in several reports; microaspiration of contaminated water was the hypothesized mode of transmission. Surgery with general anesthesia is a known risk factor that is consistent with aspiration. Especially compelling is the reported 30% incidence of postoperative *Legionella* pneumonia among patients undergoing head and neck surgery at a hospital with a contaminated water supply; aspiration is a recognized sequela in such cases. Studies of patients with hospital-acquired Legionnaires' disease have shown that these individuals underwent endotracheal intubation significantly more often and for a significantly longer duration than patients with nosocomial pneumonia of other etiologies.

Aerosolization of *Legionella* by devices filled with tap water, including nebulizers and humidifiers, has been implicated in disease causation. An ultrasonic mist machine in the produce section of a grocery store was implicated in a community outbreak. Pontiac fever has been linked to *Legionella*-containing aerosols from water-using machinery, a cooling tower, air-conditioners, and whirlpools.

EPIDEMIOLOGY The incidence of Legionnaires' disease depends on the degree of contamination of the aquatic reservoir, the immune status of the persons exposed to water from that reservoir, the intensity of exposure, and the availability of specialized laboratory tests on which the correct diagnosis can be based.

Numerous prospective studies have ranked *Legionella* among the top four microbial causes of community-acquired pneumonia (with *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Chlamydia pneumoniae* usually ranked first, second, and third, respectively), accounting for 3 to 15% of cases. On the basis of a multihospital study of community-acquired pneumonia in Ohio, it is estimated that only 3% of sporadic cases of Legionnaires' disease are correctly diagnosed. *Legionella* is responsible for 10 to 50% of nosocomial pneumonias when a hospital's water system is colonized with the organisms. One situation in which the diagnosis of Legionnaires' disease should be considered is that in which the presenting patient has been hospitalized within 10 days before the onset of symptoms.

The most common risk factors for Legionnaires' disease are cigarette smoking, chronic lung disease, advanced age, and immunosuppression (including receipt of glucocorticoids). However, in a large prospective study of community-acquired pneumonia, 28% of patients with Legionnaires' disease did not have these classic risk factors. Surgery is a prominent predisposing factor in hospital-acquired infection, with transplant recipients at highest risk. Hospital-acquired cases are now being recognized among neonates and children with immunosuppression or underlying pulmonary disease.

Pontiac fever occurs in epidemics. The high attack rate (>90%) reflects airborne transmission.

PATHOGENESIS AND IMMUNITY *Legionella* enters the lungs through aspiration or direct inhalation. Attachment of the bacteria to host cells is mediated by type IV pili, heat-shock protein Hsp60, and the major outer-membrane protein. *Legionella* binds to complement CR1 and CR3 integrin receptors on the surface of the host cell. Because the organisms possess pili that may mediate adherence to respiratory tract epithelial cells, conditions that impair mucociliary clearance, including cigarette smoking, lung disease, or alcoholism, predispose to Legionnaires' disease.

Cell-mediated immunity is the primary mechanism of host defense against *Legionella*, as it is against other intracellular pathogens, including *Mycobacterium tuberculosis*, *Listeria*, and *Toxoplasma*. Alveolar macrophages readily phagocytose *Legionella*. The attachment of the bacteria to phagocytes is mediated via Fc receptors and complement receptors, which attach to the bacterial major outer-membrane protein. Binding to these receptors promotes phagocytosis but fails to trigger an oxidative burst. The *L. pneumophila* phagosome resists acidification and evades fusion with late endocytic compartments and lysosomes. Although many *Legionella* organisms are killed, some proliferate intracellularly until the cells rupture; the bacteria are then phagocytosed again by newly recruited phagocytes, and the cycle begins anew.

Two general types of bacterial virulence genes required for intracellular growth have been identified: those that affect trafficking of the bacterial phagosome (establishment factors) and those that affect replication after trafficking (maintenance factors). Establishment factor mutants exhibit severe intracellular-growth defects because they cannot alter phagosome trafficking to inhibit fusion with lysosomes. Genes of the *L. pneumophila* chromosome that harbor this phenotype, referred to as *dot* (defective organelle trafficking) or *icm* (intracellular multiplication) genes, play an essential role in redirecting phagosome trafficking and establishing an intracellular site for bacterial growth. The Dot/Icm apparatus is hypothesized to be a translocase that exports effector molecules into host cells. *Legionella* does not require this transporter for growth once a replicative niche has been established. Among the *L. pneumophila* maintenance factors is the macrophage infectivity potentiator protein (Mip), which is exported to the bacterial surface and is involved in establishing intracellular infection. *L. pneumophila* Mip mutants have macrophage uptake and replicative phagosome formation kinetics that are similar to those of wild-type bacteria. However, these activities are delayed once the replicative phagosome is established.

Legionnaires' disease is more common and its manifestations are more severe among patients with depressed cell-mediated immunity, including transplant recipients, patients infected with HIV, and patients receiving glucocorticoids. The disease also occurs with unusual frequency among patients with hairy cell leukemia (which is characterized by monocyte deficiency and dysfunction) but not among patients with other types of leukemia.

The role of neutrophils in immunity appears to be minimal: neutropenic patients are not predisposed to Legionnaires' disease. Although *L. pneumophila* is susceptible to oxygen-dependent microbiologic systems in vitro, it resists killing by neutrophils.

The humoral immune system is active against *Legionella*. Type-specific IgM and IgG antibodies are measurable within weeks of infection. In vitro, antibodies promote killing of *Legionella* by phagocytes (neutrophils, monocytes, and alveolar macrophages). Immunized animals develop a specific antibody response, with subsequent resistance to *Legionella* challenge. However, antibodies neither enhance lysis by complement nor inhibit intracellular multiplication within phagocytes.

Some *L. pneumophila* strains are clearly more virulent than others, although the precise factors mediating virulence remain uncertain. For example, although multiple strains may colonize water-distribution systems, only a few cause disease in patients exposed to water from these systems. At least one surface epitope of *L. pneumophila* serogroup 1 is associated with virulence. *L. pneumophila* serogroup 6 is more commonly involved in hospital-acquired Legionnaires' disease and is more likely to be associated with a poor outcome.

PATHOLOGY The consistent pathologic features of Legionnaires' disease are confined to the lungs. Multifocal pneumonia with patchy lobular inflammation and extensive multilobar consolidation has been observed. Visible abscesses with central necrosis were seen in 20% of autopsied cases in one study. On histologic examination, fibrinopurulent pneumonia with intensive alveolitis and bronchiolitis is evident. Lesions of longer standing can have a nodular appearance with a central area of necrosis surrounded by macrophages and other cells. The alveoli are filled with fibrin, neutrophils, and alveolar macrophages. The direct fluorescent stain is not only specific but also the most sensitive option for visualization of the organism in tissues. Polyvalent DFA stains but not monoclonal DFA stain can be used for formalinized specimens. Culture is the preferred method for diagnosis based on clinical specimens.

CLINICAL AND LABORATORY FEATURES ■ Pontiac Fever Pontiac fever is an acute, self-limiting, flulike illness with a 24- to 48-h incubation period. Pneumonia does not develop. Malaise, fatigue, and myalgias are the most frequent symptoms, occurring in 97% of cases. Fever (usually with chills) develops in 80 to 90% of cases and headache in 80%. Other symptoms (seen in fewer than 50% of cases) include arthralgias, nausea, cough, abdominal pain, and diarrhea. Modest leukocytosis with a neutrophilic predominance is sometimes detected. Complete recovery takes place within only a few days without antibiotic therapy; a few patients may experience lassitude for many weeks thereafter. The diagnosis is established by antibody seroconversion.

Legionnaires' Disease (Pneumonia) Legionnaires' disease is often included in the differential diagnosis of "atypical pneumonia," along with infection due to *C. pneumoniae*, *Chlamydia psittaci*, *Mycoplasma pneumoniae*, *Coxiella burnetii*, and some viruses. The clinical similarities among these types of pneumonia include a relatively nonproductive cough and a low incidence of grossly purulent sputum. However, the clinical manifestations of Legionnaires' disease are usually more severe than those of most "atypical" pneumonias, and the course and prognosis of *Legionella* pneumonia more closely resemble those of bacteremic pneumococcal pneumonia than those of pneumonia due to other "atypical" pathogens. Patients with community-acquired Legionnaires' disease are significantly more likely than patients with pneumonia of other etiologies to be admitted to an intensive care unit on presentation.

The incubation period for Legionnaires' disease is 2 to 10 days. The symptoms and signs may range from a mild cough and a slight fever to stupor with widespread pulmonary infiltrates and multisystem failure. Nonspecific symptoms—malaise, fatigue, anorexia, and headache—are seen early in the illness. Myalgias and arthralgias are uncommon but are prominent in a few patients. Upper respiratory symptoms, including coryza, are rare.

The mild cough of Legionnaires' disease is only slightly productive. Sometimes the sputum is streaked with blood. Chest pain—either pleuritic or nonpleuritic—can be a prominent feature and, when coupled with hemoptysis, can lead to an incorrect diagnosis of pulmonary embolism. Shortness of breath is reported by one-third to one-half of patients.

Gastrointestinal difficulties are often pronounced; abdominal pain, nausea, and vomiting affect 10 to 20% of patients. Diarrhea (watery rather than bloody) is reported in 25 to 50% of cases. The most common neurologic abnormalities are confusion or changes in mental status; however, the multitudinous neurologic symptoms reported range from headache and lethargy to encephalopathy.

Patients with Legionnaires' disease virtually always have fever. Temperatures in excess of 40.5°C (104.9°F) were recorded in 20% of the cases in one series. Relative bradycardia has been overemphasized as a useful diagnostic finding; it occurs primarily in older patients with severe pneumonia. Chest examination reveals rales early in the course and evidence of consolidations as the disease progresses. Abdominal examination may reveal generalized or local tenderness.

Although the clinical manifestations often considered classic for Legionnaires' disease (Table 132-1) may suggest the diagnosis, prospective comparative studies have shown that clinical manifestations are generally nonspecific and that Legionnaires' disease is not readily distinguishable from pneumonia of other etiologies. In a review of 13 studies of community-acquired pneumonia, clinical manifestations that occurred significantly more often in Legionnaires' disease included diarrhea, neurologic findings (including confusion), and a temperature of >39°C. Hyponatremia, elevated values in liver function tests, and hematuria also occurred more frequently in Legionnaires' disease. Other laboratory abnormalities include creatine phosphokinase elevation, hypophosphatemia, serum creatinine elevation, and proteinuria.

TABLE 132-1 Clinical Clues Suggestive of Legionnaires' Disease

Diarrhea
High fever (>40°C or >104°F))
Numerous neutrophils but no organisms revealed by Gram's staining of respiratory secretions
Hyponatremia (serum sodium level of <131 meq/L)
Failure to respond to β-lactam drugs (penicillins or cephalosporins) and aminoglycoside antibiotics
Occurrence of illness in an environment in which the potable water supply is known to be contaminated with *Legionella*
Onset of symptoms within 10 days after discharge from the hospital

Extrapulmonary Legionellosis Since the portal of entry for *Legionella* is the lung in virtually all cases, extrapulmonary manifestations usually result from bloodborne dissemination from the lung. In a prospective survey of patients with Legionnaires' disease diagnosed by isolation of the organism from sputum, *Legionella* was isolated from the blood by a special culture method in 38% of cases.

Legionella has been identified in lymph nodes, spleen, liver, or kidneys in autopsied cases of Legionnaires' disease. The most common extrapulmonary site of legionellosis is the heart; numerous reports have described myocarditis, pericarditis, postcardiotomy syndrome, and prosthetic-valve endocarditis. Most cases have been hospital-acquired. In some patients who have not had overt evidence of pneumonia, the organisms may have gained entry through a postoperative sternal wound exposed to contaminated tap water or through a mediastinal-tube insertion site. Sinusitis, peritonitis, pyelonephritis, skin and soft tissue infection, septic arthritis, and pancreatitis have been seen predominantly in immunosuppressed patients.

Chest Radiographic Abnormalities Virtually all patients with Legionnaires' disease have abnormal chest radiographs showing pulmonary infiltrates at the time of clinical presentation. In a few cases of hospital-acquired disease, fever and respiratory tract symptoms have preceded the appearance of the infiltrate on chest radiography. Findings on chest radiography are useful for assessing the severity of illness in that they identify multilobar involvement and permit monitoring of disease progression. However, these findings are nonspecific and do not serve to distinguish Legionnaires' disease from pneumonias of other etiologies. Pleural effusion is evident in 28 to 63% of cases on hospital admission. In immunosuppressed patients, especially those receiving glucocorticoids, distinctive rounded nodular opacities may be seen; these lesions may expand and cavitate (Fig. 132-1). Likewise, pulmonary abscesses can occur in immunosuppressed hosts. The progression of infiltrates and pleural effusion on chest radiography despite appropriate antibiotic therapy within the first week is common, and radiographic improvement lags behind clinical improvement by several days. Complete clearing of infiltrates requires 1 to 4 months.

DIAGNOSIS The diagnosis of Legionnaires' disease requires special microbiologic tests (Table 132-2). The sensitivity of bronchoscopy specimens is approximately the same as that of sputum samples for culture on selective media; if sputum is not available, bronchoscopy specimens may yield the organism. Bronchoalveolar lavage fluid gives higher yields than bronchial wash specimens. Thoracentesis should be performed if pleural effusion is found, and the fluid should be evaluated by DFA staining, culture, and the antigen assay designed for use with urine.

Staining Gram's staining of material from normally sterile sites, such as pleural fluid or lung tissue, occasionally suggests the diagnosis; efforts to detect *Legionella* in sputum by Gram's staining typically reveal numerous leukocytes but no organisms. When they are visualized, the organisms appear as small, pleomorphic, faint, gram-negative bacilli. *L. micdadei* organisms can be detected as weakly or partially acid-fast bacilli in clinical specimens. Modified acid-fast staining substitutes 1% sulfuric acid for the traditional 3% hydrochloric acid; the less aggressive decolorizer increases the yield of *L. micdadei*. *Legionella*-infected patients have occasionally been treated empirically with

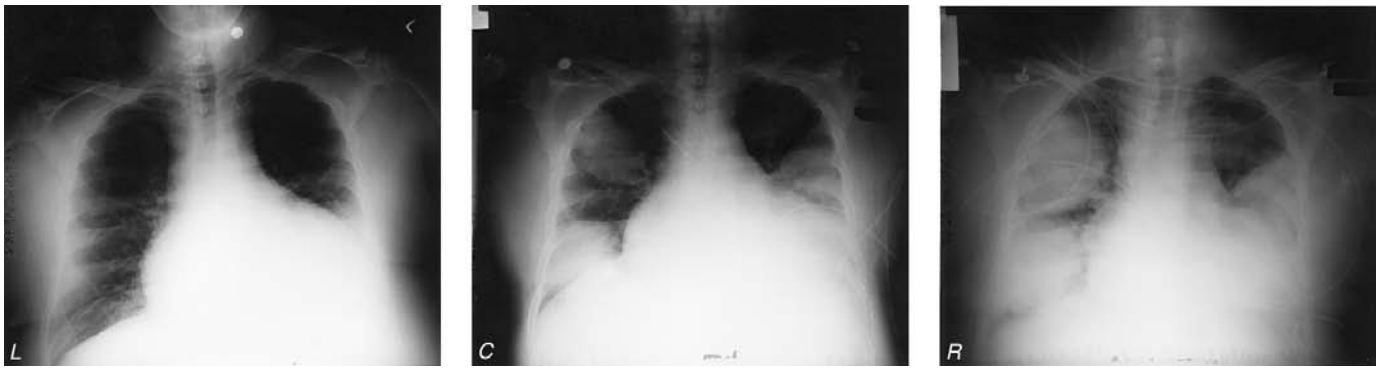

FIGURE 132-1 Chest radiographic findings in a 52-year-old man who presented with pneumonia subsequently diagnosed as Legionnaires' disease. The patient was a cigarette smoker with chronic obstructive pulmonary disease and alcoholic cardiomyopathy; he had received glucocorticoids. *L. pneumophila* was identified by DFA staining and culture of sputum. *Left:* Baseline chest radiograph showing long-standing cardiomegaly. *Center:* Admission chest radiograph showing new rounded opacities. *Right:* Chest radiograph taken 3 days after admission, during treatment with erythromycin.

antituberculosis medications because of false-positive acid-fast smears.

The DFA test is rapid and highly specific but is less sensitive than culture because large numbers of organisms are required for microscopic visualization. This test is more likely to be positive in advanced than in early disease.

Culture The definitive method for diagnosis of *Legionella* infection is isolation of the organism from respiratory secretions or other specimens. Multiple selective BCYE media are required for maximal sensitivity. Colonies grow slowly, requiring 3 to 5 days to become grossly visible. When culture plates are overgrown with other microflora, pretreatment of the specimen with acid or heat can markedly improve the yield. *L. pneumophila* is often isolated from sputum that is not grossly or microscopically purulent; sputum containing more than 25 epithelial cells per high-power field (a finding that classically suggests contamination) may still yield *L. pneumophila*.

Antibody Detection Antibody testing of both acute- and convalescent-phase sera is necessary. A fourfold rise in titer is diagnostic; 12 weeks are often required for the detection of an antibody response. A single titer of 1:128 in a patient with pneumonia constitutes presumptive (but not definitive) evidence for Legionnaires' disease. Serology is of use primarily in epidemiologic studies. The specificity of serology for *Legionella* species other than *L. pneumophila* is uncertain; there is cross-reactivity with *Legionella* spp. and some gram-negative bacilli.

Urinary Antigen The assay for *Legionella* soluble antigen in urine (Binax, Portland, ME) is rapid, relatively inexpensive, easy to perform, second only to culture in terms of sensitivity, and highly specific. Its use in every clinical laboratory is recommended. The test is available only for *L. pneumophila* serogroup 1, which, as has been mentioned, causes about 80% of *Legionella* infections. Cross-reactivity with other *L. pneumophila* serogroups and other *Legionella* species has been detected in up to 22% of urine samples from patients with culture-proven cases. Antigen in urine is detectable 3 days after the onset of clinical disease, and urinary antigen positivity persists for several weeks. The test is not affected by antibiotic administration.

Molecular Methods Polymerase chain reaction (PCR) with DNA probes is theoretically more sensitive and specific than other methods, but the results have been disappointing to date. PCR has proved useful in the identification of *Legionella* from environmental water specimens.

TABLE 132-2 *Utility of Special Laboratory Tests for the Diagnosis of Legionnaires' Disease*

Test	Sensitivity, %	Specificity, %
Culture		
Sputum[a]	80	100
Transtracheal aspirate	90	100
DFA staining of sputum	50–70	96–99
Urinary antigen testing[b]	70	100
Antibody serology[c]	40–60	96–99

[a] Use of multiple selective media with dyes.
[b] Serogroup 1 only.
[c] IgG and IgM testing of both acute- and convalescent-phase sera. A single titer of ≥1:256 is considered presumptive, while fourfold seroconversion is considered definitive.

TREATMENT

Since *Legionella* is an intracellular pathogen, antibiotics that can reach intracellular concentrations exceeding the minimal inhibitory concentration are most likely to be efficacious in the clinical setting. The dosages for various drugs used in the treatment of *Legionella* infection are listed in Table 132-3.

The newer macrolides (especially azithromycin) and respiratory tract quinolones (levofloxacin, gemifloxacin, moxifloxacin) are now the antibiotics of choice and are effective as monotherapy. Compared with erythromycin, the newer macrolides have superior in vitro activity, display greater intracellular activity, and reach higher concentrations in respiratory secretions and in lung tissue. The pharmacokinetics of the newer macrolides and quinolones also allow once- or twice-daily dosing. Finally, the large fluid volume required for intravenous administration, symptomatic ototoxicity, and gastrointestinal side effects have rendered erythromycin obsolete for the treatment of *Legionella* infection. Quinolones are the preferred antibiotics for transplant recipients because both macrolides and rifampin interact

TABLE 132-3 *Antibiotic Therapy for* Legionella *Infection*

Antimicrobial Agent	Dosage[a]
Macrolides	
Azithromycin	500 mg[b] PO or IV[c] q24h
Clarithromycin	500 mg PO or IV[c] q12h
Quinolones	
Levofloxacin	750 mg IV q24h
	500 mg[b] PO q24h
Ciprofloxacin	400 mg IV q8h
	750 mg PO q12h
Ofloxacin	400 mg PO or IV q12h
Moxifloxacin	400 mg[b] PO q24h
Tetracyclines	
Doxycycline	100 mg[b] PO or IV q12h
Minocycline	100 mg[b] PO or IV q12h
Tetracycline	500 mg PO or IV q6h
Others	
Trimethoprim-sulfamethoxazole	160/800 mg IV q8h
	160/800 mg PO q12h
Rifampin[d]	300–600 mg PO or IV q12h

[a] Dosages are derived from clinical experience.
[b] We recommend doubling the first dose.
[c] Intravenous formulation is not available in some countries.
[d] Rifampin should be used only in combination with a macrolide or a quinolone.

pharmacologically with cyclosporine and tacrolimus. One uncontrolled retrospective study has suggested that complications are fewer and clinical response is more rapid in patients receiving quinolones than in those receiving macrolides. Alternative agents include tetracycline and its analogues doxycycline and minocycline. Anecdotal reports have described both successes and failures with trimethoprim-sulfamethoxazole, imipenem, and clindamycin. For severely ill patients with extensive pulmonary infiltrates, a combination of rifampin with a newer macrolide or quinolone can be used for initial treatment.

Initial therapy should be given by the intravenous route. A clinical response usually occurs within 3 to 5 days, after which oral therapy can be substituted. The total duration of therapy in the immunocompetent host is 10 to 14 days; a longer course (3 weeks) may be appropriate for immunosuppressed patients and those with advanced disease. For azithromycin, with its long half-life, a 5- to 10-day course is sufficient.

Pontiac fever requires only symptom-based treatment, not antimicrobial therapy.

PROGNOSIS Mortality rates for Legionnaires' disease vary, depending on the patient's underlying disease and its severity, the patient's immune status, the severity of pneumonia, and the timing of administration of appropriate antimicrobial therapy. Mortality rates are highest (80%) among immunosuppressed patients who do not receive appropriate antimicrobial therapy early in the course of illness. With appropriate and timely antibiotic treatment, mortality from community-acquired Legionnaires' disease among immunocompetent patients ranges from 0 to 11%; without treatment, the figure may be as high as 31%. In an observational study of survivors of an outbreak of community-acquired Legionnaires' disease, sequelae of fatigue, neurologic symptoms, and weakness were found in 63% to 75% of patients 17 months after receipt of antibiotics.

PREVENTION Routine environmental culture of the hospital water supply is recommended as an approach to the prevention of hospital-acquired Legionnaires' disease. Positive cultures from the water supply mandate the use of specialized laboratory tests (especially culture on selective media and urinary antigen assay) for patients with hospital-acquired pneumonia. Studies have shown that neither a high degree of outward cleanliness nor routine application of maintenance measures decreases the frequency or intensity of *Legionella* colonization. Thus, engineering guidelines and building codes, although routinely advocated as preventive measures, have little impact on *Legionella* colonization.

Disinfection of the water supply is now feasible. Two methods have proven reliable and cost-effective. The superheat-and-flush method requires heating of the water so that the distal-outlet temperature is 70 to 80°C and flushing of the distal outlets with hot water for at least 30 min. This method is ideal for emergency situations. A commercial copper and silver ionization method has proved effective in numerous hospitals. Hyperchlorination is no longer recommended because of its expense, carcinogenicity, corrosive effects on piping, and unreliable efficacy.

133 PERTUSSIS AND OTHER *BORDETELLA* INFECTIONS

Scott A. Halperin

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis*. The name *pertussis* means "violent cough," which aptly describes the most consistent and prominent feature of the illness. The inspiratory sound made at the end of an episode of paroxysmal coughing gives rise to the common name for the illness, "whooping cough"; however, this feature is variable, being uncommon in infants ≤6 months of age and frequently absent in older children and adults. The Chinese name for pertussis is "the 100-day cough," which accurately describes the clinical course of the illness. The identification of *B. pertussis* was first reported by Bordet and Gengou in 1906, and vaccines were produced over the following two decades.

MICROBIOLOGY Six species have been identified in the genus *Bordetella*: *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. holmesii*, and *B. hinzii*. *B. pertussis* infects only humans and is the most important *Bordetella* species causing human disease. *B. parapertussis* causes an illness in humans that is similar to pertussis but is typically milder; coinfections with *B. parapertussis* and *B. pertussis* have been documented. *B. bronchiseptica* is an important pathogen of domestic animals that causes kennel cough in dogs, atrophic rhinitis and pneumonia in pigs, and pneumonia in cats. Both respiratory infection and opportunistic infection are occasionally reported in humans. *B. avium* is an important cause of respiratory illness in turkeys. The remaining two species, *B. hinzii* and *B. holmesii*, have been recognized as unusual causes of bacteremia. Both of these species have been isolated from patients with sepsis, most often from those who are immunocompromised.

Bordetella species are gram-negative pleomorphic aerobic bacilli that share common genotypic characteristics. *B. pertussis* and *B. parapertussis* are the most similar of the species but differ in that *B. parapertussis* does not express the gene coding for pertussis toxin. *B. pertussis* is a slow-growing fastidious organism that requires selective medium and forms small glistening bifurcated colonies. Suspicious colonies are presumptively identified as *B. pertussis* by direct fluorescent antibody testing or by agglutination with species-specific antiserum. *B. pertussis* is further differentiated from other *Bordetella* species by biochemical and motility characteristics.

B. pertussis produces a wide array of toxins and biologically active products that are important in its pathogenesis and in immunity. Most of these virulence factors are under the control of a single genetic locus that regulates their production, resulting in antigenic modulation and phase variation. Although these processes occur both in vitro and in

vivo, their importance in the pathobiology of the organism is unknown; they may play a role in intracellular persistence and person-to-person spread. The organism's most important virulence factor is *pertussis toxin*, which is composed of a B oligomer–binding subunit and an enzymatically active A protomer that ADP-ribosylates a guanine nucleotide-binding regulatory protein (G protein) in target cells, producing a variety of biologic effects. Pertussis toxin has important mitogenic activity, affects the circulation of lymphocytes, and serves as an adhesin for bacterial binding to respiratory ciliated cells. In animal models, the toxin's effects include histamine sensitization, lymphocytosis promotion, and insulin secretion. Another virulence factor is *filamentous hemagglutinin*, a component of the cell wall and a bacterial adhesin. *Pertactin* is an outer-membrane protein and another important adhesin. *Fimbriae* are bacterial appendages that also play a role in bacterial attachment; they are the major antigens against which agglutinating antibodies are directed. These agglutinating antibodies have historically been the primary means of serotyping *B. pertussis* strains. Other virulence factors include tracheal cytotoxin, which causes respiratory epithelial damage; adenylate cyclase toxin, which impairs host immune-cell function; dermonecrotic toxin, which may contribute to respiratory mucosal damage; and lipooligosaccharide, which has properties similar to those of other gram-negative bacterial endotoxins.

PATHOGENESIS Infection with *B. pertussis* is initiated by attachment of the organism to the ciliated epithelial cells of the nasopharynx. Attachment is mediated by surface adhesins (e.g., pertactin and filamentous hemagglutinin), which bind to the integrin family of cell-surface proteins, probably in conjunction with pertussis toxin. The role of fimbriae in adhesion or maintenance of infection has not been fully delineated. At the site of attachment, the organism multiplies, producing a variety of other toxins that cause local mucosal damage (tracheal cytotoxin, dermatonecrotic toxin). Impairment of host defense by *B. pertussis* is mediated by pertussis toxin and adenylate cyclase toxin. There is local cellular invasion, with intracellular bacterial persistence; however, systemic dissemination does not occur. Systemic manifestations (lymphocytosis) result from the effects of the toxins.

The pathogenesis of the clinical manifestations of pertussis is poorly understood. It is not known what causes the paroxysmal cough that is the hallmark of pertussis. A pivotal role for pertussis toxin has been proposed. Proponents of this position point to the efficacy of preventing clinical symptoms with a vaccine containing only pertussis toxoid. Detractors counter that pertussis toxin is not the critical factor because paroxysmal cough also occurs in patients infected with *B. parapertussis*, which does not produce pertussis toxin. It is thought that the neurologic events observed in pertussis, such as seizures and encephalopathy, are due to hypoxia from coughing paroxysms or apnea rather than to the effects of specific bacterial products. *B. pertussis* pneumonia, which occurs in up to 10% of infants with pertussis, is usually a diffuse bilateral primary infection. In older children and adults with pertussis, pneumonia is often due to secondary bacterial infection with streptococci or staphylococci.

IMMUNITY Both humoral and cell-mediated immunity are thought to be important in pertussis. Antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae are all protective in animal models. Pertussis agglutinins were correlated with protection in early studies of whole-cell pertussis vaccines. Serologic correlates of protection conferred by acellular pertussis vaccines have not been established, although antibody to pertactin, fimbriae, and (to a lesser degree) pertussis toxin correlated best with protection in two acellular pertussis vaccine efficacy trials. The duration of immunity after whole-cell pertussis vaccination is short-lived, with little protection remaining after 10 to 12 years. Data on the duration of protection after acellular pertussis vaccination are still being collected. Although immunity after natural infection has been said to be lifelong, seroepidemiologic evidence suggests that it may not be and that subsequent episodes of clinical pertussis are prevented by intermittent subclinical infection.

EPIDEMIOLOGY Pertussis is a highly communicable disease, with attack rates of 80 to 100% among unimmunized household contacts and 20% within households in well-immunized populations. The infection has a worldwide distribution, with cyclical outbreaks every 3 to 5 years (a pattern that has persisted despite widespread immunization). Pertussis occurs in all months; however, in North America, pertussis activity peaks in the summer and autumn.

Before the institution of widespread immunization programs, pertussis was one of the most common infectious causes of morbidity and death. In the United States prior to the 1940s, between 115,000 and 270,000 cases of pertussis were reported annually, with an average yearly rate of 150 cases per 100,000 population. With universal childhood immunization, the number of reported cases fell by >95%, with even more dramatic decreases in mortality. Only 1010 cases of pertussis were reported in 1976. Since that time, however, rates have slowly increased. In 2000, more than 7800 cases of pertussis were reported in the United States.

Although thought of as a disease of childhood, pertussis can affect people of all ages and is increasingly being identified as a cause of prolonged coughing illness in adolescents and adults. In unimmunized populations, pertussis incidence peaks in the preschool years, and well over half of children have the disease before reaching adulthood. In highly immunized populations such as those in North America, the peak incidence is among infants <1 year of age who have not completed the three-dose primary immunization series. Recent trends, however, show an increasing incidence of pertussis among adolescents and adults. In the United States in 2000, 24% of patients were <7 months of age, 36% were adolescents, and 20% were adults. The figures for adolescents and adults are probably underestimates because of a greater degree of underrecognition and underreporting in these age groups. A number of studies of prolonged coughing illness suggest that pertussis may be the etiologic agent in 12 to 30% of adults with cough that does not improve within 2 weeks. In a recent study of the efficacy of an acellular pertussis vaccine in adolescents and adults, the incidence of pertussis in the placebo group was 3.7 to 4.5 cases per 1000 person-years. Although this prospective cohort study yielded a lower estimate than the studies of cough illness, its results still translate to between 600,000 and 800,000 cases of pertussis in adults annually in the United States. Severe morbidity and mortality, however, are virtually restricted to infants. In Canada, there were 10 deaths from pertussis between 1991 and 1998; all those who died were infants ≤6 months of age. Although school-age children are the source of infection for most households, adults are the likely source for high-risk infants and may serve as the reservoir of infection between epidemic years. In developing countries, pertussis remains an important cause of infant morbidity and mortality. The World Health Organization estimated that in 1995 over 40 million people worldwide were infected by *B. pertussis* and that 355,000 children died of pertussis.

CLINICAL MANIFESTATIONS Pertussis is a prolonged coughing illness with clinical manifestations that vary by age (Table 133-1). Classic pertussis is most often seen in preschool and school-age children, although it is not uncommon among adolescents and adults. After an incubation

TABLE 133-1 *Clinical Features of Pertussis, by Age Group and Diagnostic Status*

	Percentage of Patients		
	Adolescents and Adults		
Feature	Laboratory Confirmation	No Laboratory Confirmation	Children
Cough	95–100	95–100	95–100
Prolonged	60–80	60–80	60–95
Paroxysmal	60–90	50–90	80–95
Sleep-disturbing	50–80	50–80	90–100
Whoop	10–40	5–30	40–80
Posttussive vomiting	20–50	5–30	80–90

period averaging 7 to 10 days, an illness develops that is indistinguishable from the common cold and is characterized by coryza, lacrimation, mild cough, low-grade fever, and malaise. After 1 to 2 weeks, this *catarrhal phase* evolves into the *paroxysmal phase*: the cough becomes more frequent and spasmodic with repetitive bursts of 5 to 10 coughs, often within a single expiration. Posttussive vomiting is frequent, with a mucous plug occasionally expelled at the end of an episode. The episode may be terminated by an audible whoop, which occurs upon rapid inspiration against a closed glottis at the end of a paroxysm. During a spasm, there may be impressive neck-vein distension, bulging eyes, tongue protrusion, and cyanosis. Paroxysms may be precipitated by noise, eating, or physical contact. Between attacks, the patient's appearance is normal but increasing fatigue is evident. The frequency of paroxysmal episodes varies widely, from several per hour to 5 to 10 per day. Episodes are often worse at night and interfere with sleep. Weight loss is not uncommon as a result of the illness's interference with eating. Most complications occur during the paroxysmal stage. Fever is uncommon and suggests bacterial superinfection.

After 2 to 4 weeks, the coughing episodes become less frequent and less severe—changes heralding the onset of the *convalescent phase*. This phase can last from 1 to 3 months and is characterized by a gradual resolution of the coughing episodes. For 6 months to a year, intercurrent viral infections may be associated with a recrudescence of paroxysmal cough.

Not all individuals who develop pertussis have classic disease. The clinical manifestations in adolescents and adults are more often atypical. In a German study of pertussis in adults, more than two-thirds had paroxysmal cough and more than one-third had whoop. Adult illness in North America differs from this experience: the cough may be severe and prolonged but is less frequently paroxysmal, and a whoop is uncommon. Vomiting with cough is the best predictor of a diagnosis of pertussis as the cause of a prolonged cough in adults. Other features predictive of this diagnosis are a cough at night and exposure to other individuals with a prolonged coughing illness.

COMPLICATIONS Complications are frequently associated with pertussis and are more common among infants than among older children or adults. Subconjunctival hemorrhages, abdominal and inguinal hernias, pneumothoraces, and facial and truncal petechiae can result from increased intrathoracic pressure generated by severe fits of coughing. Weight loss can follow decreased caloric intake. In a series of more than 1100 children <2 years of age who were hospitalized with pertussis, 27.1% had apnea, 9.4% had pneumonia, 2.6% had seizures, and 0.4% had encephalopathy; 10 children (0.9%) died. Pneumonia is reported in $<5\%$ of adolescents and adults and increases in frequency after 50 years of age. In contrast to the primary *B. pertussis* pneumonia that develops in infants, pneumonia in adolescents and adults with pertussis is usually caused by a secondary infection with encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. Pneumothorax, severe weight loss, inguinal hernia, rib fracture, carotid artery aneurysm, and cough syncope have all been reported in adolescents and adults with pertussis.

DIAGNOSIS If the classic symptoms of pertussis are present, clinical diagnosis is not difficult. However, particularly in older children and adults, it is difficult to differentiate infections caused by *B. pertussis* and *B. parapertussis* from other respiratory tract infections on clinical grounds. Therefore, laboratory confirmation should be attempted in all cases. Lymphocytosis (absolute lymphocyte count, $>10 \times 10^9$/L) is common among young children (in whom it is unusual with other infections) but not among adolescents and adults. Culture of nasopharyngeal secretions remains the "gold standard" of diagnosis; the best specimen is collected by nasopharyngeal aspiration, in which a fine flexible plastic catheter attached to a 10-mL syringe is passed into the nasopharynx and withdrawn while gentle suction is applied. Since *B. pertussis* is highly sensitive to drying, secretions should be inoculated without delay onto appropriate media (Bordet-Gengou or Regan-Lowe) or the catheter should be flushed with a phosphate-buffered saline solution. An alternative is a nasopharyngeal culture with a calcium alginate swab; again, inoculation of culture plates should be immediate or an appropriate transport medium (such as Regan-Lowe charcoal medium) should be used. Cultures become positive by day 5 of incubation, and *B. pertussis* and *B. parapertussis* can be differentiated by agglutination with specific antisera or by direct immunofluorescence.

Nasopharyngeal cultures in untreated pertussis remain positive for a mean of 3 weeks after the onset of illness; these cultures become negative within 5 days of the institution of appropriate antimicrobial therapy. Since much of the period during which the organism can be recovered from the nasopharynx falls into the catarrhal phase, when the etiology of the infection is not suspected, there is only a small window of opportunity for culture-proven diagnosis. Cultures from infants and young children are more frequently positive than those from older children and adults; this difference may reflect earlier presentation of the former age group for medical care. The increasing availability of the polymerase chain reaction for pertussis in diagnostic laboratories is enhancing the sensitivity of the organism's detection. This method may further laboratory confirmation but does not solve problems related to the long delays in specimen procurement that often are encountered in pertussis cases. Direct fluorescent antibody tests of nasopharyngeal secretions for direct diagnosis may still be available in some laboratories but should not be used because of poor sensitivity and specificity.

As a result of the difficulties with laboratory diagnosis of pertussis in adolescents, adults, and any patient who has been symptomatic for >4 weeks, increasing attention is being given to serologic diagnosis. Enzyme immunoassays detecting IgA and IgG antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae have been developed and assessed for reproducibility. Two- or fourfold increases in antibody titer are suggestive of pertussis, although cross-reactivity of some antigens (such as filamentous hemagglutinin and pertactin) among *Bordetella* species makes it difficult to depend diagnostically on seroconversion involving a single type of antibody. Late presentation for medical care and prior immunization also complicate serologic diagnosis because the first sample obtained may in fact be a convalescent-phase specimen. Proposed criteria for serologic diagnosis based on a single serum specimen call for comparison of the patient's antibody levels with established population values; for example, a patient with serologically confirmed pertussis might be required to have a titer greater than two or three standard deviations above the mean titer for a normal population. However, at present, no antibody test is widely or commercially available, and no specific serologic criteria are universally accepted.

DIFFERENTIAL DIAGNOSIS A child presenting with paroxysmal cough, posttussive vomiting, and whoop is likely to have an infection caused by *B. pertussis* or *B. parapertussis*; lymphocytosis increases the likelihood of a *B. pertussis* etiology. Viruses such as respiratory syncytial virus and adenovirus have been isolated from patients with clinical pertussis but probably represent coinfection. In adolescents and adults, among whom paroxysmal cough and whoop are frequently absent, the differential diagnosis of a prolonged coughing illness is more extensive. Pertussis should be suspected in anyone with a cough that does not improve within 14 days, a paroxysmal cough of any duration, or any respiratory symptoms after contact with a laboratory-confirmed case of pertussis. Other etiologies to consider include infections caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenovirus, influenza virus, and other respiratory viruses. Use of angiotensin-converting enzyme (ACE) inhibitors, reactive airway disease, and gastroesophageal reflux disease are well-described noninfectious causes of prolonged cough in adults.

Rx TREATMENT

Antibiotics The purpose of antibiotic therapy for pertussis is to eradicate the infecting bacteria from the nasopharynx; therapy does not

substantially alter the clinical course unless given early in the catarrhal phase. Macrolide antibiotics are the drugs of choice for treatment of pertussis (Table 133-2); a macrolide-resistant *B. pertussis* strain has been reported from a single case in an outbreak in Arizona. Trimethoprim-sulfamethoxazole is recommended as an alternative for individuals allergic to macrolides.

TABLE 133-2 *Antimicrobial Therapy for Pertussis*

Drug	Adult Daily Dose	Frequency	Duration (Days)	Comments
Erythromycin estolate	1–2 g	3 divided doses	7–14	Frequent gastrointestinal side effects
Clarithromycin	500 mg	2 divided doses	7	
Azithromycin	500 mg on day 1, 250 mg subsequently	1 daily dose	5	
Trimethoprim-sulfamethoxazole	160 mg of trimethoprim, 800 mg of sulfamethoxazole	2 divided doses	14	For patients allergic to macrolides; data on effectiveness limited

Supportive Care Young infants have the highest rates of complication and death from pertussis; therefore, most infants and older children with severe disease should be hospitalized. A quiet environment may decrease the stimulation that can trigger paroxysmal episodes. Use of β-adrenergic agonists and/or glucocorticoids has been advocated by some authorities but has not been proved to be effective. Cough suppressants are not effective and play no role in the management of pertussis.

Infection Control Measures Hospitalized patients with pertussis should be placed in respiratory isolation, with the use of precautions appropriate for pathogens spread by large respiratory droplets. Isolation should continue for 5 days after initiation of erythromycin therapy or for 3 weeks (i.e., until nasopharyngeal cultures are consistently negative) in those individuals unable to tolerate antimicrobial therapy.

PREVENTION ■ Chemoprophylaxis Because the risk of transmission of *B. pertussis* within households is high, chemoprophylaxis is widely recommended for household contacts of pertussis cases. The effectiveness of chemoprophylaxis, although unproven, is supported by several epidemiologic studies of institutional and community outbreaks of pertussis. In the only randomized placebo-controlled study, erythromycin estolate (50 mg/kg per day in three divided doses; maximum dose, 1 g/d) was effective in reducing the incidence of bacteriologically confirmed pertussis by 67%; however, there was no decrease in the incidence of clinical disease. Despite these disappointing results, many authorities continue to recommend chemoprophylaxis, particularly in households with members at high risk of severe disease (children <1 year of age). Data are not yet available on use of the newer macrolides for chemoprophylaxis.

Immunization (See also Chap. 107) The mainstay of pertussis prevention is active immunization. Pertussis vaccine has been available for over 70 years and became widely used in North America after 1940; reported cases of pertussis have since fallen by $>90\%$. Whole-cell pertussis vaccines are prepared through the heating, chemical inactivation, and purification of whole *B. pertussis* organisms. Although effective (average efficacy estimate, 85%, with results in various studies of different products ranging from 30 to 100%), whole-cell pertussis vaccines are associated with adverse events—both common (fever; injection-site pain, erythema, and swelling; irritability) and uncommon (febrile seizures, hypotonic hyporesponsive episodes). Alleged associations of whole-cell pertussis vaccine with encephalopathy, sudden infant death syndrome, and autism, although not substantiated, have spawned an active anti-immunization lobby. The development of acellular pertussis vaccines, which are effective but less reactogenic, has greatly alleviated concerns about the inclusion of pertussis vaccine in the combined infant immunization series. Although whole-cell vaccines are still extensively used worldwide, acellular pertussis vaccines are used exclusively for childhood immunization in the United States and elsewhere (Canada, Sweden, Germany, Japan). In North America, acellular pertussis vaccines are given as a three-dose primary series at 2, 4, and 6 months of age, with a reinforcing dose between 15 and 18 months of age and a booster dose at 4 to 6 years of age.

A wide variety of acellular pertussis vaccines have been developed, although not all are available in every country. All acellular pertussis vaccines currently available contain pertussis toxoid. Only one monovalent pertussis toxoid vaccine has been licensed in the United States; the remainder of the fully developed vaccines contain filamentous hemagglutinin as well as toxoid. At least four acellular pertussis vaccines also contain pertactin, and two products also contain one or more types of fimbriae. All of the licensed acellular pertussis vaccines have undergone phase 3 efficacy testing. Although differences in study design make direct comparisons difficult, an effort to standardize case definitions and the similarity of some of the studies, which used common vaccine arms to allow "bridging" of the data between studies, have permitted some general conclusions. Even though some would still disagree, most experts have concluded that two-component acellular pertussis vaccines are more effective than monocomponent vaccines and that the addition of pertactin further increases efficacy. The further addition of fimbriae appears to provide some additional protective efficacy against milder disease. In two studies, protection against pertussis by vaccines correlated best with the production of antibody to pertactin, fimbriae, and pertussis toxin.

The development of acellular pertussis vaccines has sparked interest in the potential for control of pertussis in adolescents and adults and in the possibility that pertussis control in those groups will enhance the protection of infants too young to be immunized. Whole-cell pertussis vaccine is contraindicated in individuals ≥ 7 years of age because of their poor toleration of possible adverse events. However, adult formulations of acellular pertussis vaccines, both alone and in combination with adult-formulation diphtheria-tetanus toxoid, have been demonstrated to be safe, immunogenic, and efficacious in clinical trials in adolescents and adults and are now recommended for routine immunization of adolescents in several countries. Further epidemiologic studies will help public health authorities and advisory committees determine the role of pertussis immunization in the control of pertussis in adults.

134 DISEASES CAUSED BY GRAM-NEGATIVE ENTERIC BACILLI

Thomas A. Russo

Extraintestinal infections are the predominant presentation of disease caused by gram-negative bacilli (GNB) belonging to medically important genera of the family Enterobacteriaceae (*Escherichia*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, and *Edwardsiella*) and by the genus *Acinetobacter* from the family Neisseriaceae. However, certain strains of *Escherichia coli* have evolved to be strictly intestinal pathogens, causing gastroenteritis by a variety of unique pathogenic mechanisms. The virulence traits of intestinal pathogenic *E. coli* are for the most part distinct from those of extraintestinal pathogenic *E. coli* and other GNB that cause disease outside the bowel. This difference reflects site-dependent differences in host environments and defense mechanisms.

E. COLI AS AN INTESTINAL PATHOGEN

Certain strains of *E. coli* are capable of causing intestinal infection. Other important intestinal pathogens are discussed in Chaps. 113, 126, and 137–140.

ETIOLOGY, EPIDEMIOLOGY, AND MANIFESTATIONS Intestinal pathogenic strains of *E. coli* are rarely encountered in the fecal flora of healthy hosts and instead appear to be essentially obligate pathogens. These strains have evolved a special ability to cause enteritis, enterocolitis, and colitis whenever ingested in sufficient quantities by a naive host. At least six distinct "pathotypes" of intestinal pathogenic *E. coli* exist: (1) Shiga toxin–producing *E. coli* (STEC)/enterohemorrhagic *E. coli* (EHEC), (2) enterotoxigenic *E. coli* (ETEC), (3) enteropathogenic *E. coli* (EPEC), (4) enteroinvasive *E. coli* (EIEC), (5) enteroaggregative *E. coli* (EAEC), and (6) diffusely adherent *E. coli* (DAEC). Organisms of these pathotypes are acquired via the fecal-oral route. Transmission occurs predominantly via contaminated food and water for ETEC, STEC, EIEC, EAEC, and DAEC and by person-to-person spread for EPEC (and occasionally STEC). Humans appear to be the major reservoir (except for STEC), since the host range appears to be dictated by species-specific attachment factors. Although there is some overlap, each pathotype possesses a unique combination of virulence traits that results in a distinctive intestinal pathogenic mechanism (Table 134-1); however, these strains are largely incapable of causing disease outside the intestinal tract. Except in the case of STEC, disease due to this group of pathogens occurs primarily in developing countries.

Shiga Toxin–Producing *E. coli* STEC strains constitute an emerging group of pathogens that can cause hemorrhagic colitis and the hemolytic-uremic syndrome (HUS). Several large outbreaks resulting from the consumption of undercooked ground beef and other foods have received significant attention from the media. O157:H7 is the most prominent serotype, but O6, O26, O55, O91, O103, O111, O113, and OX3 have also been associated with these syndromes. The ability to produce Shiga toxins (Stx2 and/or Stx1) or related toxins is the critical factor dictating whether a bacterium can cause the STEC syndrome. *Shigella dysenteriae* strains that produce the closely related Shiga toxin Stx can cause the same syndrome. Stx2 appears to be more important than Stx1 in the development of HUS and other severe disease. All Shiga toxins studied to date consist of an enzymatically active A subunit and five identical B subunits that mediate binding to globoceramides. The A subunit cleaves an adenine from the 28S rRNA, which irreversibly inhibits ribosomal function. Therefore, Shiga toxins belong to the class of toxins known as *ribosome-inactivating proteins* (RIPs).

Additional factors, such as acid tolerance and adherence, are necessary for maximal pathogenicity of STEC. The genomes of the majority of isolates responsible for disease possess the locus for enterocyte effacement (LEE). This pathogenicity island was first described in EPEC strains and contains genes that mediate adherence to intestinal epithelial cells. It has been proposed that the subgroup of STEC strains that possess stx_1 and/or stx_2 as well as LEE be termed *enterohemorrhagic E. coli* (EHEC).

Domesticated ruminant animals, particularly cattle and young calves, serve as the major reservoir for STEC. Ground beef—the most common food source of STEC strains—is often contaminated during processing. Furthermore, manure from cattle or other animals that is used as fertilizer can contaminate produce (potatoes, lettuce, sprouts, fallen apples) and water (fecal runoff). It is estimated that $<10^3$ CFU (colony-forming units) of STEC can cause disease. Therefore, not only can low levels of food or environmental contamination (e.g., in water swallowed while swimming) result in disease, but person-to-person transmission (e.g., at day-care centers and in institutions) becomes an important vehicle for secondary spread. Laboratory-associated infections also take place. Both outbreaks and sporadic cases are attributable to this group of pathogens, with a seasonal peak in the summer months.

In contrast to the other pathotypes, STEC causes infections more frequently in developed countries, where the consumption of processed foods is more common than in developing regions. O157 strains are the fourth most commonly reported cause of bacterial diarrhea in the United States (after *Campylobacter*, *Salmonella*, and *Shigella*). Colonization of the colon and perhaps the ileum results in symptoms after an incubation period of 3 or 4 days. Colonic edema and an initial secretory diarrhea may develop into the STEC syndrome's hallmark trait of grossly bloody diarrhea (detected by history or examination) in >90% of cases. Significant abdominal pain and fecal leukocytes are commonly present (70% of cases), but fever is usually absent. Occasionally, *Clostridium difficile*, *Campylobacter*, and *Salmonella* infection present in a similar fashion, as do noninfectious diseases (e.g., inflammatory bowel disease). STEC disease is usually self-limited, lasting 5 to 10 days. This infection can be complicated by HUS, which occurs 2 to 14 days after diarrhea in 2 to 8% of cases, most often affecting the very young and the elderly. It is estimated that >50% of all cases of HUS in the United States are caused by STEC. This complication is probably mediated by the systemic translocation of Shiga toxins. Erythrocytes may serve as carriers of Stx to small-vessel renal and cerebral endothelial cells. The subsequent development of thrombotic microangiopathy (perhaps with direct toxin-mediated effects on various cells) most commonly results in some combination of fever, thrombocytopenia, renal failure, and encephalopathy. Although the mortality rate with dialysis support is <10%, residual renal dysfunction and neurologic sequelae may persist.

Enterotoxigenic *E. coli* In tropical or developing countries, ETEC is a major cause of endemic diarrhea. After weaning, children experience several episodes of ETEC infection during the first 3 years of life. The incidence of disease diminishes with age, a pattern that correlates with the development of mucosal immunity to colonization factors. In industrialized countries, infection usually follows travel to endemic areas. ETEC is the most common agent of traveler's diarrhea, causing 25 to 75% of cases. The incidence of infection is decreased by the prudent avoidance of potentially contaminated fluids and foods (Chap. 108). ETEC infection is uncommon in the United States, but outbreaks secondary to consumption of food products imported from endemic areas have occurred. A large inoculum (10^6 to 10^{10} CFU) is needed to produce disease. After ingestion of contaminated water or food (particularly items poorly cooked, unpeeled, or unrefrigerated), colonization factor–mediated intestinal adherence occurs over 12 to 72 h.

Disease is mediated primarily by heat-labile toxin (LT-1) and/or a heat-stable toxin (STa) that causes net fluid secretion via activation of adenylate cyclase (LT-1) and/or guanylate cyclase (STa) in the jejunum and ileum; the result is watery diarrhea accompanied by cramps. LT-1 consists of an A and a B subunit and is structurally and functionally similar to cholera toxin. Strong binding of the B subunit to

the GM_1 ganglioside leads to the intracellular translocation of the A subunit, which functions as an ADP-ribosyltransferase. The mature STa toxin is an 18- or 19-amino-acid secreted peptide whose biologic activity is mediated by binding to the guanylate cyclase C found in the brush-border membrane of intestinal epithelial cells; this binding results in increased intracellular concentrations of cyclic GMP. Characteristically absent are histopathologic changes of the small bowel; mucus, blood, and inflammatory cells in stool; and fever. The disease spectrum ranges from a mild illness to a life-threatening cholera-like illness. Although symptoms are usually self-limited (typically lasting for 3 days), infection may result in significant morbidity and mortality when health care is poor and when small and/or undernourished children are affected.

TABLE 134-1 *Intestinal Pathogenic* E. coli

Pathotype[a]	*Clinical Syndrome(s)*[b]	*Defining Molecular Trait*	*Responsible Genetic Element*[c]
STEC	Hemorrhagic colitis, hemolytic-uremic syndrome	Shiga toxin	Lambda-like Stx1 or Stx2 encoding bacteriophage
ETEC	Traveler's diarrhea	Heat-stable and -labile enterotoxins, colonization factors	Virulence plasmid(s)
EPEC	Watery diarrhea in young children	Localized adherence, attaching and effacing lesion on intestinal epithelium	EPEC adherence factor plasmid pathogenicity island (locus for enterocyte effacement)
EIEC	Dysentery	Invasion of colonic epithelial cells, intracellular multiplication, cell-to-cell spread	Multiple genes contained primarily in large virulence plasmid
EAEC/DAEC	Traveler's diarrhea, persistent diarrhea	Aggregative/diffuse adherence	Chromosomal or plasmid-associated adherence genes

[a] STEC, Shiga toxin–producing *E. coli*; ETEC, enterotoxigenic *E. coli*; EPEC, enteropathogenic *E. coli*; EIEC, enteroinvasive *E. coli*; EAEC, enteroaggregative *E. coli*; DAEC, diffusely adherent *E. coli*.
[b] Classic syndromes; see text for details on spectrum of disease.
[c] Pathogenesis is multigenic and requires genes in addition to those listed.

Enteropathogenic *E. coli* EPEC causes disease primarily in young children, including neonates. The first *E. coli* pathotype recognized as an agent of diarrheal disease, EPEC was responsible for outbreaks of infantile diarrhea (including some outbreaks in hospital nurseries) in industrialized countries in the 1940s and 1950s. At present, however, infection due to EPEC is uncommon in developed countries. In contrast, EPEC is an important cause of infant diarrhea (both sporadic and epidemic) in developing countries. Breast-feeding diminishes the incidence of EPEC infection. Rapid person-to-person spread may occur. Upon colonization of the small bowel, symptoms develop after a brief incubation period (1 or 2 days). Initial localized adherence leads to a characteristic effacement of microvilli, with the formation of cuplike, actin-rich pedestals. Diarrheal stool often contains mucus but not blood. Although usually self-limited (lasting for 5 to 15 days), EPEC diarrhea may persist for weeks.

Enteroinvasive *E. coli* EIEC, a relatively uncommon cause of diarrhea, is rarely identified in the United States, although a few food-related outbreaks have been described. In developing countries, sporadic disease is infrequently recognized in children and travelers. EIEC shares many genetic and clinical features with *Shigella*; however, unlike *Shigella*, EIEC produces disease only at a large inoculum (10^8 to 10^{10} CFU), with onset generally occurring after an incubation period of 1 to 3 days. Initially, enterotoxins are believed to induce secretory small-bowel diarrhea. Subsequently, colonization and invasion of the colonic mucosa, followed by replication therein and cell-to-cell spread, result in the development of inflammatory colitis characterized by fever, abdominal pain, tenesmus, and scant stool containing mucus, blood, and inflammatory cells. Symptoms are usually self-limited (7 to 10 days).

Enteroaggregative and Diffusely Adherent *E. coli* EAEC and DAEC have been described primarily in developing countries and in young children. These strains can cause traveler's diarrhea. A large inoculum is required for infection. In vitro, the organisms exhibit a diffuse or "stacked-brick" adherence pattern. Clinical disease has been associated with prolonged watery diarrhea.

DIAGNOSIS A practical approach to the evaluation of diarrhea is to distinguish noninflammatory from inflammatory cases (Chap. 113). ETEC, EPEC, EAEC, and DAEC are uncommon causes of noninflammatory diarrhea in the United States. Their diagnosis requires specialized assays that are not routinely available and whose use is rarely indicated since these diseases are self-limited. ETEC causes the majority of cases of noninflammatory traveler's diarrhea; EAEC and DAEC cause a minority of these cases. Definitive diagnosis generally is not necessary, and empirical antimicrobial treatment is a reasonable approach. If diarrhea persists despite treatment, *Giardia* or *Cryptosporidium* should be sought. The diagnosis of infection with EIEC, a rare cause of inflammatory diarrhea in the United States, also requires specialized assays. However, evaluation for STEC infection, particularly when bloody diarrhea is reported or observed, is appropriate. Although screening for *E. coli* strains that do not ferment sorbitol and subsequent serotyping for O157 constitute the most common method presently used to detect STEC, testing for Shiga toxins or toxin genes is more sensitive, specific, and rapid. The latter approach offers another advantage as well: it detects both non-O157 strains and sorbitol-fermenting strains of O157, which otherwise are difficult to identify. DNA-based, enzyme-linked immunosorbent, and cytotoxicity assays are in various stages of development and are likely to emerge as the diagnostic standards in time.

TREATMENT

The mainstay of treatment for all diarrheal syndromes is the appropriate replacement of water and electrolytes (Chap. 113). The use of prophylactic antibiotics to prevent traveler's diarrhea should be discouraged, especially in light of high rates of antibiotic resistance. When stools are free of mucus and blood, early patient-initiated treatment of traveler's diarrhea with a quinolone decreases the duration of illness, and the use of loperamide may halt symptoms within a few hours (Chap. 113). Although dysentery caused by EIEC is self-limited, treatment hastens the resolution of symptoms, particularly in severe cases. Treatment of STEC infection should be avoided since antibiotics may increase the incidence of HUS (possible via increased release of Stx).

EXTRAINTESTINAL PATHOGENS

GENERAL FEATURES AND PRINCIPLES ■ Epidemiology Extraintestinal pathogenic *E. coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, *Edwardsiella*, and *Acinetobacter* are components of the normal animal and human colonic flora and/or of the flora of a variety of environmental habitats (including long-term-care facilities and hospitals). In healthy humans, *E. coli* is the predominant gram-negative bacillus in the colonic flora. GNB (primarily *E. coli*, *Klebsiella*, and *Proteus*) only transiently colonize the oropharynx and skin of healthy individuals. In contrast, in long-term-care and hospital settings, a variety of GNB emerge as the dominant colonizing flora of both mucosal and skin surfaces, particularly with antimicrobial use, severe illness, and extended length of stay. Acquisition of the GNB (from various reservoirs) leads to infection.

Pathogenesis Multiple bacterial traits are required for various aspects of the pathogenesis of GNB. The possession of specialized virulence genes is what defines pathogens and enables them to infect the host efficiently. As more is learned about these genes, it is becoming clear

TABLE 134-2 *Interactions of Extraintestinal Pathogenic* E. coli *with the Human Host: A Paradigm for Extracellular, Extraintestinal Gram-Negative Bacterial Pathogens*

Bacterial Goal	*Host Obstacle*	*Bacterial Solution*
Extraintestinal attachment	Flow of urine, mucociliary blanket	Multiple adhesins (e.g., type 1 fimbriae, Sfa/Foc, P pili)
Nutrient acquisition for growth	Nutrient sequestration (e.g., iron via intracellular storage and extracellular scavenging via lactoferrin and transferrin)	Cellular lysis (e.g., hemolysin); multiple mechanisms for competing for extracellular iron (e.g., siderophores) and other nutrients
Initial avoidance of host bactericidal activity	Complement, phagocytic cells, antimicrobial peptides	Capsular polysaccharide, lipopolysaccharide
Transmission	?	Irritant tissue damage resulting in increased excretion (e.g., toxins such as hemolysin)
Late avoidance of host bactericidal activity	Acquired immunity (e.g., specific antibodies), treatment with antibiotics	? Cell entry, acquisition of antimicrobial resistance

that hosts and their cognate pathogens have been coadapting throughout evolutionary history. In fact, it has been speculated that infection is just a point on the spectrum of evolutionary development between microbes and hosts. At one end of this spectrum is a commensal/symbiotic interaction (e.g., mitochondria—formerly bacteria—within eukaryotic cells); at the other end is a lethal outcome that results in a "dead-end relationship" (e.g., Ebola virus). During this host-pathogen "chess match" over time, various and redundant solutions have emerged both in pathogens and in their hosts that enable these partners to maintain their coexistence (Table 134-2).

Extraintestinal pathogenic strains of *E. coli* (ExPEC) and the other genera discussed in this chapter cause infection outside the bowel. All are extracellular pathogens and therefore share certain pathogenic features. Innate defense systems (complement, antimicrobial peptides, professional phagocytes) and humoral immunity are the most critical host-defense components. As a result, both susceptibility to and severity of infection are increased with dysfunction or deficiencies of these components (e.g., neutrophils) (Chap. 104).

A given pathogen usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type 1 fimbriae, Sfa/Foc, P pili). Nutrient acquisition (e.g., iron via siderophores) requires many genes that are necessary but not sufficient for pathogenesis. The ability to resist the bactericidal activity of complement and professional phagocytes in the absence of antibody [e.g., conferred by capsule or O antigen of lipopolysaccharide (LPS)] is one of the defining traits of an extracellular pathogen. Tissue damage (e.g., hemolysis in the case of *E. coli*) may facilitate spread. Many important virulence genes await identification, and our understanding of many aspects of the pathogenesis of GNB is in its infancy (Chap. 105).

The ability to induce septic shock is another defining feature of these genera. GNB are the most common cause of this dangerous complication. The lipid A moiety of LPS (via interaction with host Toll-like receptors) and probably other bacterial factors as well (including capsule) stimulate a proinflammatory host response, which, if overexuberant, results in shock (Chap. 254).

Lastly, many serotypes exist in most genera of GNB; for example, there are >100 O-specific antigens and >80 capsular antigens in *E. coli*. This antigenic variability, which permits immune evasion and successful recurrent infection by strains of the same species, has also impeded vaccine development (Chap. 107).

Infectious Syndromes Depending on both the host and the pathogen, nearly every organ or body cavity can be infected with GNB. *E. coli* and, to a lesser degree, *Klebsiella* and *Proteus* account for the majority of infections and are the most virulent pathogens of this group. However, the other genera are becoming increasingly important, particularly among persons in long-term care and hospitalized patients. This expanding role is in large part due to the innate or acquired resistance of these organisms to antimicrobial agents and to the increasing number of immunocompromised hosts. The mortality rate is significant in many GNB infections and correlates with the severity of illness. Especially problematic are pneumonia and bacteremia from any source complicated by severe sepsis (with or without shock); these conditions have associated mortality rates of 20 to 50%.

Diagnosis Isolation of GNB from ordinarily sterile sites almost always implies infection. Their isolation from nonsterile sites, particularly from soft-tissue and respiratory cultures, requires clinical correlation to differentiate colonization from infection. Results of an assessment of lactose fermentation (described for each genus below) are usually available before final identification of the organism and its antimicrobial susceptibilities and may assist in guiding empirical therapy.

TREATMENT

The antimicrobial resistance of GNB is variable and is influenced by both geographic location and regional antibiotic use. Empirical antimicrobial choices should be based on local susceptibility patterns. Extended-spectrum β-lactamases (ESBLs, class A) and AmpC β-lactamases (class C) are responsible for the majority of multidrug resistance in GNB. The acquisition of ESBLs via transferable plasmids is increasing. To date, ESBLs are most prevalent in *Klebsiella* and *E. coli*, but they have also been described (and are probably underrecognized) in *Enterobacter* and other enteric GNB. Plasmids encoding for ESBLs confer resistance to third-generation cephalosporins and aztreonam and frequently contain linked resistance determinants for aminoglycosides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX). Up to 50% of strains expressing ESBLs have associated fluoroquinolone resistance. Outbreaks due to strains possessing ESBLs have been associated with extensive institutional use of third-generation cephalosporins, particularly ceftazidime. The carbapenems (e.g., imipenem) are the only β-lactam agents that are reliably efficacious against strains expressing an ESBL.

Derepression of inducible chromosomal AmpC β-lactamases, another important resistance mechanism, may be preexisting or may develop during therapy. This determinant confers resistance to second- and third-generation cephalosporins, to aztreonam, and often to β-lactam/β-lactamase inhibitor combinations. Chromosomal AmpC β-lactamases occur in *Enterobacter*, *Serratia*, *Citrobacter*, *Proteus vulgaris*, *Proteus penneri*, *Providencia*, *Morganella*, and *Acinetobacter*. In addition, some strains of *E. coli*, *Klebsiella pneumoniae*, and other Enterobacteriaceae that carry chromosomal AmpC β-lactamases have acquired plasmids that contain AmpC β-lactamases.

Although relevant data are suboptimal or conflicting, combination therapy may increase antibiotic efficacy (particularly for serious infections, such as pneumonia) and diminish the emergence of resistance. Furthermore, drainage of abscesses and removal of infected foreign bodies are often needed for cure.

GNB are commonly involved in polymicrobial infections, in which it is difficult to determine the role of each specific pathogen (Chap. 148). Although some GNB are more pathogenic than others, it is usually prudent, if possible, to design an antimicrobial regimen that includes activity against all of the GNB identified, since each is capable of pathogenicity in its own right.

Prevention Diligent hand hygiene by health care personnel and avoidance of inappropriate antimicrobial use are key in preventing infection and the further development of antimicrobial resistance.

***ESCHERICHIA COLI* INFECTIONS ■ Commensal Strains** Commensal *E. coli* variants, which constitute the major portion of the normal facultative intestinal flora in most humans, for the most part confer benefits (such as resistance to colonization) to their hosts. These strains generally

lack the specialized virulence traits that enable intestinal and extraintestinal pathogenic *E. coli* strains to cause disease within and outside the gastrointestinal tract, respectively. However, commensal *E. coli* are sometimes involved in extraintestinal infections when an aggravating factor is present, such as a foreign body (e.g., a urinary catheter), host compromise (e.g., local anatomical or functional abnormalities such as urinary or biliary tract obstruction or immunocompromise), or an inoculum that is large or contains a mixture of bacterial species (e.g., fecal contamination of the peritoneal cavity).

Extraintestinal Pathogenic Strains (ExPEC) The majority of *E. coli* isolates from symptomatic infections of the urinary tract, bloodstream, cerebrospinal fluid, respiratory tract, and peritoneum (spontaneous bacterial peritonitis) are distinct from commensal and intestinal pathogenic strains of *E. coli* by virtue of their functionally similar virulence factor profiles (Table 134-2) and clonal background. It has recently been proposed that these extraintestinal strains of *E. coli* be termed *ExPEC*. Evaluation of a limited number of strains has established that ExPEC can also cause surgical wound infection, osteomyelitis, and myositis, but the number of cases evaluated to date is too small for a reliable assessment of proportions. Studies on the nature of *E. coli* strains responsible for other extraintestinal infections are in progress.

Like commensal *E. coli* (but in contrast to intestinal pathogenic *E. coli*), ExPEC strains are often found in the normal intestinal flora and do not cause gastroenteritis in humans. Although acquisition of an ExPEC strain by the host is a prerequisite for ExPEC infection, it is not the rate-limiting step, which instead is entry of a colonizing ExPEC strain from its site of colonization (e.g., the colon, vagina, or oropharynx) into a normally sterile extraintestinal site (e.g., the urinary tract, peritoneal cavity, or lungs). ExPEC strains have acquired genes encoding diverse extraintestinal virulence factors that enable the bacteria to cause infections outside the gastrointestinal tract in both normal and compromised hosts (Table 134-2). These virulence genes are, for the most part, distinct from those that enable intestinal pathogenic strains to cause intestinal disease. All age groups, all types of hosts, and nearly all organs and sites are susceptible to infection by ExPEC. Previously healthy hosts infected with ExPEC can become severely ill and even die; however, adverse outcomes are more prevalent in the presence of coincidental disease and abnormalities in host defenses. *E. coli* is the most common enteric gram-negative species to cause extraintestinal infection in ambulatory, long-term-care, and hospital settings. The diversity and the medical and economic impact of ExPEC infections are evident from a review of the following specific syndromes.

Infectious Syndromes ■ *URINARY TRACT INFECTION (UTI)* The urinary tract is the site most frequently infected by ExPEC. A common infection among ambulatory patients, UTI accounts for 1% of ambulatory care visits in the United States and is second only to lower respiratory tract infection among infections responsible for hospitalization. UTIs are best considered by clinical syndrome (e.g., uncomplicated cystitis, catheter-associated) within the context of specific hosts (e.g., premenopausal women, compromised host; Chap. 269). *E. coli* is the single most prevalent pathogen for all UTI syndrome/host group combinations. Each year in the United States, for example, *E. coli* causes 85 to 95% of an estimated 6 to 8 million episodes of uncomplicated cystitis in premenopausal women, with an estimated $1 billion in direct health care costs. Furthermore, 20% of women with an initial infection develop frequent recurrences (0.3 to >20 per year). Except in the first year of life, acceptance of the diagnosis of UTI in males requires clear documentation since such infection is unusual in the absence of a history of instrumentation or anal intercourse.

Uncomplicated urethritis or cystitis occurs most commonly and is characterized by symptoms of dysuria, frequency, and suprapubic pain. Fever and/or back pain suggests progression to pyelonephritis. Pregnant women are at unusually high risk for this complication, which can adversely affect the outcome of pregnancy. As a result, prenatal screening for bacteriuria, with treatment when the results are positive, is the standard of care. Fever may take 5 to 7 days to resolve completely in appropriately treated patients with pyelonephritis but should fall over time. Persistently elevated or increasing fever and neutrophil counts should prompt evaluation for intrarenal or perinephric abscess and/or obstruction. Renal parenchymal damage and loss of renal function occur primarily in the setting of obstruction. Prostatic infection is generally a complication of UTI in men with a history of instrumentation and/or prostatic hypertrophy. The diagnosis and treatment of UTI are detailed in Chap. 269 and are tailored according to the individual host, the nature and site of infection, and the local pattern of antimicrobial susceptibility.

ABDOMINAL AND PELVIC INFECTION The abdomen/pelvis is the second most frequent site of extraintestinal infection due to *E. coli*. A wide variety of clinical syndromes occur in this location, including acute peritonitis secondary to fecal contamination, spontaneous bacterial peritonitis, peritoneal dialysis–associated peritonitis, diverticulitis, appendicitis, intraperitoneal or visceral abscesses (hepatic, pancreatic, splenic), infected pancreatic pseudocysts, and septic cholangitis and/or cholecystitis. In intraabdominal infections, *E. coli* can be isolated either alone or (as is often the case) along with other facultative and/or anaerobic members of the intestinal flora (Chap. 112).

PNEUMONIA *E. coli* is not usually considered a cause of pneumonia (Chap. 239). Indeed, enteric GNB account for only 2 to 5% of cases of community-acquired pneumonia (CAP), in part because these organisms only transiently colonize the oropharynx of a minority of healthy individuals. In contrast, rates of oral colonization with *E. coli* and other GNB increase with the severity of illness and with antibiotic use. Thus, GNB are a common cause of pneumonia among residents of long-term-care institutions and are the most frequent cause (60 to 70% of cases) of hospital-acquired pneumonia (Chap. 116), particularly among postoperative and intensive care patients. Infection is usually acquired by small-volume aspiration but occasionally occurs via hematogenous spread, in which case multifocal nodular infiltrates can be seen. Tissue necrosis, probably due to cytotoxins produced by GNB, is common. Despite significant institutional variation, *E. coli* is generally the third or fourth most commonly isolated gram-negative bacillus in these settings, accounting for 5 to 8% of episodes in both U.S.- and European-based studies. Regardless of the host, pneumonia due to enteric GNB is a serious disease, with high crude and attributable mortality rates (20 to 60% and 10 to 20%, respectively).

MENINGITIS (See also Chap. 360) *E. coli* is one of the two leading causes of neonatal meningitis (the other being group B *Streptococcus*). The majority of responsible strains possess the K1 capsular serotype. Outside this setting, meningitis due to *E. coli* is uncommon, occurring predominantly in the setting of disruption of the meninges due to craniotomy or trauma or in the presence of cirrhosis. In these instances, the meninges are presumably seeded from poorly cleared portal-source episodes of bacteremia or via direct extension from an otogenic or sinus source.

CELLULITIS/MUSCULOSKELETAL INFECTION Infections of decubitus ulcers and the lower extremities in diabetic patients (or other hosts with neurovascular compromise) are usually polymicrobial. *E. coli* contributes frequently to decubitus infections and occasionally to lower-extremity infections in these patients. In addition, *E. coli* may occasionally cause cellulitis or burn-site or surgical-wound infection, particularly when the infection originates close to the perineum. Osteomyelitis secondary to contiguous spread can occur in these settings. Hematogenously acquired osteomyelitis, particularly of vertebral bodies, is more commonly caused by *E. coli* than is generally appreciated; this organism accounts for 10% of cases in some series (Chap. 111). *E. coli* occasionally causes orthopedic device–associated infection or septic arthritis and is a rare cause of hematogenously acquired myositis. Myositis or fasciitis of the upper leg should prompt an evaluation for an abdominal source with contiguous spread.

ENDOVASCULAR INFECTION Despite being one of the most common causes of bacteremia, *E. coli* rarely seeds native heart valves and is an uncommon cause of prosthetic-valve endocarditis. Likewise, *E. coli* infections of aneurysms and vascular grafts are uncommon.

MISCELLANEOUS INFECTIONS *E. coli* can cause infection in nearly every organ and site. It is responsible for 8% of surgical site infections (superficial, deep tissue, or organ/space—e.g., mediastinitis), occasional cases of complicated sinusitis, and uncommon cases of endophthalmitis or brain abscess.

BACTEREMIA *E. coli* bacteremia can arise from primary infection at any extraintestinal site. In addition, primary *E. coli* bacteremia can arise from percutaneous intravascular devices or can result from the increased intestinal mucosal permeability seen in neonates and in the settings of neutropenia and chemotherapy-induced mucositis, trauma, and burns. Roughly equal proportions of bacteremia cases originate in the community and in the hospital. *E. coli* and *Staphylococcus aureus* are the most common clinically significant blood isolates; *E. coli*, which is isolated in 17 to 37% of cases, is the gram-negative bacillus most often isolated from the blood in the ambulatory setting as well as in most long-term-care and hospital settings. Isolation of *E. coli* from the blood is almost always clinically significant and typically is accompanied by the sepsis syndrome, severe sepsis (sepsis-induced dysfunction of at least one organ or system), or septic shock (Chap. 254). Calculations based on a conservative estimate for severe *E. coli* sepsis (i.e., 17% of all cases of severe sepsis) translate into an estimated 40,000 deaths among the affected patients in the United States in 2001.

The urinary tract is the most common source of *E. coli* bacteremia, accounting for two-thirds of episodes. Bacteremia from a urinary tract source is particularly common with pyelonephritis, urinary tract obstruction, or instrumentation in the presence of infected urine. The abdomen is the second most common source, accounting for 25% of episodes. Although obstructive biliary tract disease (stones, tumor) and overt disruption of bowel are responsible for many of these cases, some abdominal sources (e.g., abscesses) are remarkably silent clinically and require identification via imaging studies (e.g., computed tomography). Therefore, the physician should be cautious in designating the urinary tract as the source of *E. coli* bacteremia in the absence of appropriate signs and symptoms. Soft tissue, bone, and pulmonary infections are the next most common sources for bacteremia.

Diagnosis Strains of *E. coli* that cause extraintestinal infections usually grow both aerobically and anaerobically within 24 h on standard diagnostic media and are easily identified by the clinical microbiology laboratory according to standard biochemical criteria. More than 90% of ExPEC strains are rapid lactose fermenters.

TREATMENT

In the past, *E. coli* has typically been highly susceptible to antibiotics and readily eradicated with antibiotic therapy. Unfortunately, this situation has changed. In general, the frequency of ampicillin resistance precludes its empirical use, even in community-acquired infections. Rates of resistance to first-generation cephalosporins and TMP-SMX are increasing among community-acquired strains in the United States (with current rates of 10 to 40%) and are even higher in Europe and developing countries. Until recently, TMP-SMX was the drug of choice for the treatment of uncomplicated cystitis in many locales. Although continued empirical use of TMP-SMX will predictably result in ever-diminishing cure rates, a wholesale switch to alternative agents (e.g., fluoroquinolones) will just as predictably accelerate the widespread emergence of resistance to these antimicrobial classes, as has already occurred in some areas. It is not surprising that rates of resistance among isolates from long-term-care facilities and hospitals are particularly high. Significant resistance (30 to 40%) to amoxicillin/clavulanic acid and piperacillin has been increasingly reported. Fortunately, rates of resistance to cephalosporins (second-, third-, and fourth-generation), quinolones, monobactams (e.g., aztreonam), carbapenems (e.g., imipenem), and aminoglycosides are generally $<10\%$. [The mean rate of resistance to third-generation cephalosporins was 3.2% among isolates reported to the National Nosocomial Infections Surveillance (NNIS) system in 1998.] An exception involves settings where extensive use of quinolone prophylaxis has led to the emergence of significant quinolone resistance (e.g., in patients with leukemia, transplant recipients, and patients with cirrhosis). Whatever the current rates, the frequency of acquisition of plasmids containing ESBLs and other resistance determinants is likely to increase.

***KLEBSIELLA* INFECTIONS** *K. pneumoniae* is the most important *Klebsiella* species from a medical standpoint, causing community-acquired, long-term-care, and nosocomial infections. *K. oxytoca* is primarily a pathogen in long-term-care and hospital settings. *K. rhinoscleromatis* and *K. ozaenae* are usually isolated from patients in tropical climates. *Klebsiella* species are broadly prevalent in the environment and colonize mucosal surfaces of mammals. In healthy humans, *K. pneumoniae* colonization rates range from 5 to 35% in the colon and from 1 to 5% in the oropharynx; the skin is usually colonized only transiently. In long-term-care facilities and hospitals, colonization occurs with *K. oxytoca* as well, and carriage rates are significant among both workers and patients. Person-to-person spread is thought to be the predominant mode of acquisition. Classically, *Klebsiella* is associated with CAP, primarily in alcoholics. However, the majority of *Klebsiella* infections now occur in long-term-care facilities and hospitals. *Klebsiella* causes a spectrum of extraintestinal infections similar to that caused by *E. coli*. However, extraintestinal infections due to *Klebsiella* occur at a lower incidence in all sites except the respiratory tract. These variances in infection rates are probably due to differences in colonization and site-specific virulence traits. Antibiotic-resistant strains have been responsible for a number of nosocomial outbreaks of infection in intensive care units (ICUs) and neonatal nurseries. The most common clinical syndromes are pneumonia, UTI, abdominal infection, surgical site infection, soft tissue infection, and subsequent bacteremia. *K. rhinoscleromatis* is the causative agent of rhinoscleroma, a slowly progressive (months to years) mucosal upper respiratory infection that causes necrosis and occasional obstruction of the nasal passages. *K. ozaenae* has been implicated as a cause of chronic atrophic rhinitis.

Infectious Syndromes ■ *PNEUMONIA* *K. pneumoniae* causes only a small proportion of cases of CAP (Chap. 239). This infection occurs primarily in hosts with underlying disease, such as alcoholics, diabetics, and individuals with chronic lung disease. As in all pneumonias due to enteric GNB, purulent sputum production and "airspace" disease on x-ray are typical. Presentation with earlier, less extensive infection is more common than that with the classic lobar infiltrate with a bulging fissure. Pulmonary necrosis, pleural effusion, and empyema occur with progression. Pulmonary infection in residents of long-term-care facilities and in hospitalized patients is especially frequent because of increased oropharyngeal colonization rates. Mechanical ventilation is an important risk factor.

UTI The incidence of *K. pneumoniae* UTI among healthy adults is only 1 to 2%. However, in complicated UTIs (including those associated with indwelling bladder catheters), the incidence of *Klebsiella* infection increases to 5 to 17%.

ABDOMINAL INFECTION *Klebsiella* causes a spectrum of abdominal infections similar to that caused by *E. coli* but is less frequently isolated from these infections.

OTHER INFECTIONS *Klebsiella* cellulitis or soft tissue infection occurs most frequently in devitalized tissue (e.g., decubitus ulcers, diabetes, burn sites) or in immunocompromised hosts. *Klebsiella* causes a significant minority of surgical site infections, hematogenously derived endophthalmitis cases, and nosocomial sinusitis cases as well as occasional cases of osteomyelitis contiguous to soft tissue infection, temperate myositis, and neonatal meningitis or meningitis associated with neurosurgery.

BACTEREMIA *Klebsiella* infection at any site can result in bacteremia. Infections of the urinary tract, respiratory tract, and abdomen each account for 15 to 30% of *Klebsiella* bacteremias. Intravascular device–related infection is another important source (5 to 15%). Surgical site infection and other miscellaneous infections account for the rest. *Klebsiella* is one of the agents that causes sepsis neonatorum and bacteremia with fever and neutropenia. Like enteric GNB in general, *Klebsiella* rarely causes endocarditis or endovascular infection.

Diagnosis Except for *K. rhinoscleromatis* and *K. ozaenae*, klebsiellae are readily isolated and identified by the laboratory and usually ferment lactose.

TREATMENT

K. pneumoniae and *K. oxytoca* have similar antibiotic resistance profiles. They are intrinsically resistant to ampicillin and ticarcillin. NNIS data from 1998 indicated that 10.7% of ICU patients were infected with strains resistant to third-generation cephalosporins. This increasing degree of resistance is primarily mediated by plasmids containing genes that encode ESBLs. In addition, these plasmids usually possess linked resistance determinants for aminoglycosides, tetracyclines, and TMP-SMX. In specific hospitals or geographic locales (e.g., Brooklyn, NY), the prevalence of ESBL-containing isolates is significantly higher. Resistance to β-lactam/β-lactamase inhibitor combinations and second-generation cephalosporins independent of ESBL-containing plasmids has also been increasingly described. Up to 50% of ESBL-containing strains have displayed associated fluoroquinolone resistance. At this time, rates of resistance to quinolones, cephamycins (e.g., cefoxitin), fourth-generation cephalosporins (e.g., cefepime), and amikacin are generally $<$10%, but these rates will probably increase. Carbapenems (e.g., imipenem) remain the most active antibiotic class against *Klebsiella*.

***PROTEUS* INFECTIONS** *P. mirabilis* causes 90% of *Proteus* infections. These infections occur in the community, in long-term-care facilities, and in hospitals. *P. vulgaris* and *P. penneri* are isolated primarily from infections contracted in long-term-care facilities or hospitals. *Proteus* species are part of the colonic flora of a wide variety of mammals, birds, fish, and reptiles. Their ability to generate histamine from contaminated fish has implicated these GNB in the pathogenesis of scombroid (fish) poisoning (Chap. 378). *P. mirabilis* colonizes healthy humans (prevalence, 50%), but *P. vulgaris* and *P. penneri* are isolated primarily from individuals with underlying disease. The urinary tract is overwhelmingly the favored site of *Proteus* infection, with adhesins, flagella, IgA protease, and urease as the important virulence factors. However, *Proteus* less commonly causes infection in a variety of extraintestinal sites.

Infectious Syndromes ■ *UTI* *P. mirabilis* causes only 1 to 2% of cases of UTI in healthy women, and *Proteus* species cause only 5% of cases of hospital-acquired UTI. However, *Proteus* is responsible for 10 to 15% of cases of complicated UTI, primarily those associated with catheterization; in the setting of long-term catheterization, their prevalence rate ranges from 20 to 45%. This high prevalence is due in part to the ability of *Proteus* to produce high levels of urease, which hydrolyzes urea to ammonia and results in alkalization of the urine. This situation, in turn, leads to precipitation of organic and inorganic compounds, with the formation of struvite and carbonate-apatite crystals, biofilm formation on catheters, and/or the development of calculi. *Proteus* becomes associated with the stones and can usually be eradicated only by complete stone removal. Over time, staghorn calculi may form and lead to obstruction and renal failure. Therefore, an unexplained alkaline urine should be cultured for *Proteus*, and identification of a *Proteus* species should prompt an evaluation for calculi.

OTHER INFECTIONS Although the majority of *Proteus* infections arise from the urinary tract, these bacteria occasionally cause pneumonia (primarily in long-term-care or hospitalized patients), nosocomial sinusitis, intraabdominal abscesses, biliary tract infection, surgical site infection, soft tissue infection (especially decubitus and diabetic ulcers), and osteomyelitis (primarily contiguous); they rarely cause temperate myositis. In addition, *Proteus* occasionally causes neonatal meningitis (with the umbilicus often implicated as the source), which is often complicated by the development of a cerebral abscess. Otogenic brain abscess is also seen.

BACTEREMIA The majority of *Proteus* bacteremias originate from the urinary tract; however, any of the less common sites of infection are also potential sources. Infection of intravascular devices should also be considered. Endovascular infection is rare. *Proteus* species are occasional agents of sepsis neonatorum and bacteremia with fever and neutropenia.

Diagnosis *Proteus* is readily isolated and identified by the laboratory. The majority of strains are lactose negative, and most demonstrate characteristic "swarming" motility on agar plates.

TREATMENT

P. mirabilis remains susceptible to most antimicrobial agents except tetracycline. Resistance to ampicillin and first-generation cephalosporins has been acquired by 10 to 50% of strains. Overall, 5% of *P. mirabilis* isolates in the United States now possess an ESBL. *P. vulgaris* and *P. penneri* are more resistant than *P. mirabilis*. Resistance to ampicillin and first-generation cephalosporins is the rule for these species. Derepression of an inducible chromosomal AmpC β-lactamase (not present in *P. mirabilis*) occurs in up to 30% of strains. Imipenem, fourth-generation cephalosporins (e.g., cefepime), aminoglycosides, TMP-SMX, and quinolones have excellent activity (90 to 100%).

***ENTEROBACTER* INFECTIONS** *E. cloacae* and *E. aerogenes* are responsible for most *Enterobacter* infections (65 to 75% and 15 to 25%, respectively); *E. agglomerans*, *E. sakazakii*, and *E. gergoviae* are less commonly isolated (5%, 1%, and $<$1%, respectively). These organisms cause primarily health care–related or hospital-related infections. They are widely prevalent in foods, environmental sources (including health care facility equipment), and a wide variety of animals. Only a minority of healthy humans are colonized, but the percentage increases significantly in the setting of long-term care or hospitalization. Although colonization is an important prelude to infection, direct introduction via intravenous lines (e.g., contaminated intravenous fluids, pressure monitors) also occurs. Significant antibiotic resistance has developed in *Enterobacter* species and has contributed to their emergence as prominent nosocomial pathogens. Individuals who have received prior antibiotic treatment, who have comorbid disease, and who are patients in ICUs are at greatest risk for infection. *Enterobacter* causes a spectrum of extraintestinal infections similar to that described for other GNB in this chapter.

Infectious Syndromes Pneumonia, UTI (particularly catheter-related), intravascular device–related infection, surgical site infection, and abdominal infection (primarily postoperative or device-related—e.g., biliary stents) are the most common syndromes encountered. Nosocomial sinusitis, meningitis related to neurosurgical procedures (including use of pressure monitors), osteomyelitis, and endophthalmitis after eye surgery are less frequent. *E. sakazakii* is commonly responsible for neonatal meningitis/sepsis (particularly in premature infants); contaminated formula has been implicated as a source of this infection, which is often complicated by brain abscess or ventriculitis. Bacteremia can result from infection at any of these sites. In the setting of *Enterobacter* bacteremia, contamination of intravenous fluids or medications, blood components or plasma derivatives, catheter-flushing fluids, pressure monitors, and dialysis equipment should always be considered, particularly with epidemic infection. *Enterobacter* can also cause bacteremia in patients with fever and neutropenia. *Enterobacter*

endocarditis is rare, occurring primarily in association with intravenous drug abuse or prosthetic valves.

Diagnosis *Enterobacter* is readily isolated and identified by the laboratory. Most strains are lactose positive.

TREATMENT

Significant antimicrobial resistance exists among *Enterobacter* strains. Ampicillin and the first- and second-generation cephalosporins have little or no activity. The extensive use of third-generation cephalosporins has resulted in the selection of strains that produce high levels of AmpC β-lactamase, which confers resistance to second- and third-generation cephalosporins, monobactams (e.g., aztreonam), and (frequently) β-lactam/β-lactamase inhibitor combinations. Resistant isolates may emerge during therapy; their presence should be considered a possibility when clinical deterioration follows several days of improvement. A 34% resistance rate to third-generation cephalosporins was reported in ICU isolates in 1998 (NNIS data). Imipenem, fourth-generation cephalosporins (e.g., cefepime), aminoglycosides (amikacin > gentamicin), TMP-SMX, and quinolones have retained excellent activity (90 to 99%). However, increasing resistance to quinolones, in conjunction with the increased use of these agents, is a concern.

***ACINETOBACTER* INFECTIONS** *A. baumannii* is responsible for the majority of *Acinetobacter* infections; a minority are due to *A. calcoaceticus*, *A. junii*, and *Acinetobacter* genospecies 3 and 13TU. *Acinetobacter* is highly prevalent in the environment. It is found in most water and soil samples and has a wide habitat. *Acinetobacter* has been cultured from the moist skin of healthy humans; increased colonization of the skin and the respiratory and gastrointestinal tracts occurs in individuals in long-term-care facilities and hospitals. Reservoirs for acquisition in these settings include health care personnel, medical equipment, food, and the surrounding environment. The overwhelming majority of infections are acquired in the hospital or in long-term-care facilities. The spectrum of extraintestinal infections caused by *Acinetobacter* is similar to that caused by other GNB. *Acinetobacter* species account for 1 to 3% of hospital-acquired infections and primarily affect immunocompromised hosts and patients with comorbid disease. ICUs are a prominent site of *Acinetobacter* infection. In some centers, the incidence of *Acinetobacter* infections, particularly those due to antibiotic-resistant strains, is increasing. Both sporadic and epidemic infections occur, usually after the first week of hospitalization.

Infectious Syndromes The respiratory tract (particularly in ventilated patients) and intravascular devices (particularly for non–*A. baumannii* species) are the favored sites of infection. *A. baumannii* uncommonly causes severe CAP, usually in compromised hosts (e.g., alcoholics), with the preponderance of cases reported from warm, humid geographic locales. Infections of a catheterized urinary tract, postoperative sites, burn sites, biliary stents, and sinuses (with tube-related ostial obstruction) are less common, as are neurosurgical infections (site- or device-associated—e.g., pressure monitors). Uncommon infections include contiguous osteomyelitis, peritonitis associated with continuous ambulatory peritoneal dialysis, and ophthalmic infection. The respiratory tract and intravascular devices are the most common sources for bacteremia.

Diagnosis On Gram's stain, *Acinetobacter* organisms usually appear as short GNB or coccobacilli. They are strictly aerobic, nonfermenting, and readily isolated and identified.

TREATMENT

Many strains of *Acinetobacter* are highly resistant to antimicrobial agents. Empirical combination therapy is prudent pending susceptibility studies. Ampicillin, aztreonam, and the first- and second-generation cephalosporins possess little or no activity against these species. Resistance rates are 20 to 50% for mezlocillin, piperacillin, quinolones, third-generation cephalosporins, and gentamicin. Imipenem is presently the most active antimicrobial (>95% sensitivity); β-lactam/β-lactamase inhibitor combinations, cefepime, and amikacin are often active.

***SERRATIA* INFECTIONS** *S. marcescens* causes the majority of *Serratia* infections (>90%), and *S. liquefaciens* is occasionally isolated. Serratiae are found primarily in the environment (including health care institutions) and particularly in moist foci. Although strains have been isolated from a variety of animals, healthy humans are rarely colonized. In long-term-care facilities or hospitals, diverse reservoirs for the organisms include health care personnel, food, milk in neonatal units, sinks, respiratory and other hospital equipment, pressure monitors, intravenous solutions, multiply accessed medication vials, blood products (e.g., platelets), lotions, irrigation solutions, and even disinfectants. Infection results from either direct inoculation (e.g., via intravenous fluid) or colonization (primarily of the respiratory tract) and subsequent infection. Sporadic infection is most common, but occasional epidemics and common-source outbreaks occur. The spectrum of extraintestinal infections caused by *Serratia* is similar to that for other GNB. *Serratia* species account for 1 to 3% of hospital-acquired infections.

Infectious Syndromes The respiratory tract, the genitourinary tract, intravascular devices, and surgical wounds are the most common sites of *Serratia* infection and sources of *Serratia* bacteremia. Soft tissue infections, including myositis, osteomyelitis, abdominal and biliary tract infection (postprocedural), contact lens–associated keratitis, endophthalmitis, septic arthritis (primarily with intraarticular injections), and infusion-related bacteremias occur less commonly. Serratiae are uncommon causes of neonatal or postsurgical meningitis and bacteremia associated with fever and neutropenia. Endocarditis is rare.

Diagnosis Serratiae are readily cultured and identified by the laboratory and are usually lactose negative. A minority of *S. marcescens* strains are red-pigmented.

TREATMENT

A high proportion of *Serratia* strains (>80%) are resistant to ampicillin and the first-generation cephalosporins. Although derepression of inducible chromosomal AmpC β-lactamases may be preexistent or may develop during therapy, >90% of isolates are susceptible to other GNB-appropriate antibiotics.

***CITROBACTER* INFECTIONS** *C. freundii* and *C. koseri* (formerly *C. diversus*) cause the majority of human *Citrobacter* infections, which are similar epidemiologically and clinically to *Enterobacter* and *Acinetobacter* infections. *Citrobacter* organisms are commonly present in water, food, soil, and the intestinal tracts of animals. *Citrobacter* is part of the normal fecal flora in a minority of healthy humans, but colonization rates increase in long-term-care facilities and hospitals—the settings in which nearly all infections occur. *Citrobacter* species account for 1 to 2% of nosocomial infections. The affected hosts are usually immunocompromised or have comorbid disease. *Citrobacter* causes extraintestinal infections whose spectrum is similar to that described for other GNB.

Infectious Syndromes The urinary tract is the site of 40 to 50% of infections due to *Citrobacter*. Less commonly infected sites include the biliary tree (particularly with stones or obstruction), the respiratory tract, surgical sites, soft tissue (e.g., decubitus ulcers), the peritoneum, and intravascular devices. Osteomyelitis (usually contiguous), neurosurgery-related infection, and myositis occur rarely. *Citrobacter* is also an uncommon cause of neonatal meningitis; *C. koseri* accounts for 90% of cases due to this genus. A frequent and devastating complication of this infection (occurring in 50 to 80% of cases) is the development of brain abscesses. Bacteremia is most commonly due to UTI, biliary or abdominal infection, or intravascular devices. *Citrobacter* is an uncommon cause of bacteremia in the setting of fever and neutropenia. Endocarditis or endovascular infection is rare.

Diagnosis *Citrobacter* species are readily isolated and identified, often as part of a polymicrobial culture; 35 to 50% of isolates are lactose positive.

TREATMENT

C. freundii is generally more resistant to antibiotics than *C. koseri*. Ampicillin and the first- and second-generation cephalosporins display poor activity against *Citrobacter*. Resistance is variable but increasing to ticarcillin, mezlocillin, piperacillin, aztreonam, quinolones, gentamicin, and third-generation cephalosporins; such resistance may evolve during therapy. The β-lactamase inhibitors usually do not improve susceptibility to β-lactam agents. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with >90% of strains sensitive.

***MORGANELLA* AND *PROVIDENCIA* INFECTIONS** *M. morganii* (formerly *Proteus morganii*), *P. stuartii*, and (less frequently) *P. rettgeri* (formerly *Proteus rettgeri*) are the members of these genera that are responsible for human infections. The epidemiologic, pathogenic, and clinical manifestations of these organisms are similar to those of *Proteus* species; however, *Morganella* and *Providencia* are almost exclusively pathogens of persons in long-term-care facilities and, to a lesser degree, hospitalized patients.

Infectious Syndromes These species are primarily urinary tract pathogens, most often associated with long-term (>30-day) catheterization. UTI in uncatheterized or short-term-catheterized individuals is uncommon. Biofilm formation or encrustation of the catheter usually develops and may lead to catheter obstruction. Likewise, infection may result in the development of struvite bladder or renal stones, which, in turn, may lead to renal obstruction and serve as foci for relapse. Other infectious syndromes occur less commonly but include surgical site infection, soft tissue infection (primarily decubitus and diabetic ulcers), burn site infection, pneumonia (particularly ventilator-associated), intravascular device infection, and intraabdominal infection. Rarely, the other extraintestinal infections described for GNB also occur. Bacteremia is uncommon; although any infected site can serve as the source, the urinary tract accounts for the majority of cases, with surgical site and soft tissue infections less frequently responsible.

Diagnosis *M. morganii* and *Providencia* are readily isolated and identified. Nearly all isolates are unable to ferment lactose.

TREATMENT

Morganella and *Providencia* may be highly resistant to antimicrobial agents. Ampicillin and the first-generation cephalosporins exhibit poor activity against these organisms. Of *Providencia* isolates, 40% are resistant to fluoroquinolones. Variable resistance is emerging (and may evolve during therapy) against ticarcillin, mezlocillin, piperacillin, aztreonam, gentamicin, TMP-SMX, and the second- and third-generation cephalosporins. The β-lactamase inhibitor tazobactam (but not sulbactam or clavulanic acid) somewhat improves susceptibility to β-lactam agents. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with >90% of strains susceptible. Removal of an infected catheter or stones is critical for eradication of the organisms from the urinary tract.

***EDWARDSIELLA* INFECTION** *E. tarda* is the only member of this genus associated with human disease. This organism is found predominantly in both freshwater and marine environments and in the animals that live in these environments. Human acquisition occurs primarily during interaction with these reservoirs. *E. tarda* infection is rare in the United States; most recently reported cases are from Southeast Asia. This pathogen shares some of the clinical features of both *Salmonella* species and *Vibrio vulnificus*.

Infectious Syndromes Gastroenteritis is the predominant infectious syndrome reported (50 to 80% of infections). Self-limiting watery diarrhea is most frequent; however, cases of severe colitis responding to therapy have also been described. The most common extraintestinal infection is wound infection due to direct inoculation, which is often associated with freshwater, marine, or snake-related injuries. Other infectious syndromes appear to be due to invasion of the gastrointestinal tract and subsequent bacteremia. The majority of afflicted hosts have either liver disease or an iron-overload state (e.g., sickle cell disease). A primary bacteremic syndrome, sometimes complicated by meningitis, has been described and has a 40% case-fatality rate. Visceral (primarily hepatic) or intraperitoneal abscesses have also been reported.

Diagnosis Although *E. tarda* can readily be isolated and identified, most laboratories do not routinely identify it from stool.

TREATMENT

E. tarda is sensitive to most GNB-appropriate antimicrobial agents. Gastroenteritis is generally self-limiting, but treatment with TMP-SMX or a quinolone may expedite its resolution. In the setting of overwhelming sepsis, quinolones, third- or fourth-generation cephalosporins, imipenem, and aminoglycosides—alone or in combination—are the safest choices pending susceptibility information.

INFECTIONS CAUSED BY MISCELLANEOUS GENERA Species from genera of GNB such as *Hafnia*, *Kluyvera*, *Cedecea*, *Pantoea*, and *Ewingella* are occasionally isolated from a variety of clinical specimens, including blood, sputum, cerebrospinal fluid, joint fluid, biliary drainage, and wounds. Although their role in disease has not always been defined, these strains appear to be rare and usually opportunistic human pathogens. The primary medical literature should be consulted for details on their potential role as infectious agents.

135 *HELICOBACTER PYLORI* INFECTIONS

John C. Atherton, Martin J. Blaser

DEFINITION *Helicobacter pylori* persistently colonizes the human stomach and is of etiologic importance in peptic ulcer disease (Chap. 274) and gastric malignancy (Chap. 77). Other gastric *Helicobacter* species colonize animals, some with a narrow range and others with a broad range of host species specificity. Those with broad specificity are occasionally found in humans, probably as zoonoses. The two most common of these species among isolates from humans are *Helicobacter bizzozeronii* (formerly known as *Helicobacter heilmannii* or *Gastrospirillum hominis*) and *Helicobacter felis*. It is unclear whether these helicobacters cause human disease. Numerous species of non-gastric helicobacters are found in humans and animals and have been increasingly recognized as causes of human disease, especially in immunocompromised hosts.

ETIOLOGIC AGENT *H. pylori* is a gram-negative, spiral, flagellated bacillus that has naturally colonized humans for at least tens of thousands of years. It is noninvasive, living in gastric mucus; a small proportion of the bacterial cells are adherent to the mucosa. Its spiral shape and flagella render *H. pylori* motile in the mucus environment. This organism has several acid-resistance mechanisms, most notably a highly expressed urease that catalyzes urea hydrolysis to produce buffering ammonia. In vitro, *H. pylori* is microaerophilic and slow-growing and requires complex growth media. Publication of the complete genomic sequence of *H. pylori* in 1997 led to significant advances in the understanding of the organism's biology.

EPIDEMIOLOGY The prevalence of *H. pylori* is ~30% in the United States and other developed countries as opposed to >80% in most developing countries. In the United States, prevalence varies with age: ~50% of 60-year-old persons and 20% of 30-year-old persons are colonized. *H. pylori* is usually acquired in childhood. The age association is due mostly to a birth-cohort effect whereby current 60-year-olds were more commonly colonized as children than current 30-year-olds. Spontaneous acquisition or loss of the bacterium in adulthood is uncommon. Other than age, the main risk factor for *H. pylori* positivity is low socioeconomic status; crowding and markers of poor hygiene in childhood are particularly strong risk factors. Thus, the falling incidence among children is likely due, at least in part, to improvements in living standards and increased use of antibiotics.

Humans are the only important reservoir of *H. pylori*. Members of a family may carry the same strain, and colonization is particularly common in childhood institutions. These findings imply direct person-to-person spread, but whether transmission takes place by the fecal-oral or the oral-oral route is unknown. *H. pylori* is easily cultured from vomitus and gastroesophageal refluxate and is less easily cultured from stool.

PATHOLOGY AND PATHOGENESIS *H. pylori* colonization induces chronic superficial gastritis, which includes both mononuclear and polymorphonuclear cell infiltration of the mucosa. (The term *gastritis* should be used specifically to describe histologic features; it also has been used to describe endoscopic appearances and even symptoms, which do not correlate closely with microscopic findings or with the presence of *H. pylori*.) The immune response to *H. pylori* includes both the production of antibody (local and systemic) and a cell-mediated response but is ineffective in clearing the bacterium. The pattern of gastric inflammation is associated with disease risk: antral-predominant gastritis is most closely linked with duodenal ulceration, whereas pangastritis is linked with gastric ulceration and adenocarcinoma. This probably explains why patients with duodenal ulceration rarely develop gastric adenocarcinoma later, despite being colonized by *H. pylori*. Longitudinal analyses of gastric biopsy specimens taken years apart from the same patient show that inflammation may progress stepwise through atrophy, intestinal metaplasia, and dysplasia to carcinoma. Continuous proton pump inhibitor (PPI) therapy—for example, for gastroesophageal reflux disease (GERD)—may speed progression to atrophy when *H. pylori* is present, but it remains unclear whether this situation increases cancer risk.

Most *H. pylori*–colonized persons do not develop clinical sequelae. That some persons develop overt disease whereas others do not is probably due to a combination of bacterial strain differences, host susceptibility to disease, and environmental factors. Several *H. pylori* virulence factors are more common in disease-associated strains. The *cag* PaI is a group of genes including those that encode a secretion system through which a specific protein, CagA, is translocated into epithelial cells. CagA interferes with host cell signaling, causing proliferation and cytoskeletal changes. The secretion system also induces a proinflammatory cytokine response, which results in enhanced inflammation. The CagA protein is highly immunogenic, and patients with peptic ulcer disease or gastric adenocarcinoma are more likely than persons without these conditions to have antibodies to CagA. However, patients with severe reflux esophagitis, the premalignant condition Barrett's esophagus, or esophageal adenocarcinoma are less likely to harbor cag^+ strains than are persons with a normal esophagus. The *H. pylori* vacuolating cytotoxin VacA occurs in several forms that exhibit different levels of toxicity. Strains with the more toxic forms are more commonly isolated from patients with peptic ulcer disease or gastric carcinoma than from persons without these conditions. BabA, an adhesin expressed by only some strains, is associated with increased gastric inflammation and with increased risk of peptic ulceration and gastric adenocarcinoma.

The best-characterized host determinant of disease is the possession of genetic polymorphisms leading to enhanced *H. pylori*–stimulated secretion of the proinflammatory cytokine interleukin 1β. If they are *H. pylori*–positive, individuals with these polymorphisms are at increased risk of hypochlorhydria and gastric adenocarcinoma. Environmental cofactors are also important in pathogenesis. Smoking increases ulcer and cancer risk in *H. pylori*–positive individuals. Diets high in salt and preserved foods increase cancer risk, whereas diets high in antioxidants and vitamin C are protective.

The pathogenesis of duodenal ulceration is becoming clearer. Antral *H. pylori* colonization diminishes the number of somatostatin-producing cells. Since somatostatin inhibits gastrin release, gastrin levels are higher than normal in *H. pylori*–positive persons. Individuals with antral-predominant gastritis (and thus a normally functioning acid-producing gastric corpus) develop increased acid secretion, which induces protective gastric metaplasia in the duodenum; the duodenum becomes colonized by *H. pylori*, inflamed, and then ulcerated. The pathogenesis of gastric ulceration is less well understood. These ulcers usually occur at the junction of antral and corpus-type mucosa, and this region is particularly inflamed. Gastric cancer probably stems from progressive DNA damage and the survival of abnormal epithelial cell clones. The DNA damage is thought to be due principally to reactive oxygen and nitrogen species arising from inflammatory cells and perhaps from other bacteria that survive in the achlorhydric stomachs in which gastric malignancies occur.

CLINICAL MANIFESTATIONS Essentially all *H. pylori*–colonized persons have gastric inflammation, but fewer than 10% of these individuals develop associated illnesses such as peptic ulceration, gastric adenocarcinoma, or gastric lymphoma (Fig. 135-1).

More than 80% of duodenal ulcers and 60% of gastric ulcers are related to *H. pylori* colonization (Chap. 274), most of the remainder being due to aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). The main lines of evidence for an ulcer-promoting role of *H. pylori* are (1) that the presence of the organism is a risk factor for the development of ulcers, (2) that (non-NSAID-induced) ulcers rarely develop in the absence of *H. pylori*, (3) that eradication of *H. pylori* markedly reduces rates of ulcer relapse, and (4) that experimental *H. pylori* infection of gerbils causes gastric ulceration.

Prospective nested case-control studies have shown that *H. pylori* colonization is a risk factor for adenocarcinomas of the distal stomach (Chap. 77). Long-term experimental infection of gerbils also may re-

sult in gastric adenocarcinoma. The presence of *H. pylori* is strongly associated with gastric lymphoma, although this is a rarer condition. Many low-grade gastric B cell lymphomas arising from mucosa-associated lymphoid tissue (MALT) are driven by T cell stimulation, which in turn is driven by *H. pylori* antigen stimulation; *H. pylori* antigen–driven tumors may regress either fully or partially after *H. pylori* eradication.

Many patients have upper gastrointestinal symptoms but normal results in upper gastrointestinal endoscopy (so-called functional or nonulcer dyspepsia; Chap. 274). Because *H. pylori* is common, some of these patients will be positive for the organism. *H. pylori* eradication leads to symptom resolution more commonly than does placebo treatment, but only by a little (<10%). Whether such patients have peptic ulcers in remission at the time of endoscopy or whether a subgroup of patients with true functional dyspepsia respond to *H. pylori* treatment is unclear.

Much interest has focused on a possible protective role for *H. pylori* against GERD (Chap. 273) and adenocarcinoma of the esophagus and gastric cardia (Chap. 77). The main lines of evidence for this role are (1) that there is a temporal relationship between a falling prevalence of *H. pylori* colonization and a rising incidence of these conditions; (2) that in most studies, the prevalence of *H. pylori* colonization (especially with proinflammatory *cagA*$^+$ strains) is significantly lower among patients with these esophageal diseases than among control subjects; and (3) that in some studies, eradication of *H. pylori* leads to the development or worsening of GERD. The mechanism underlying this protective effect appears to be *H. pylori*–induced hypochlorhydria. Since—at the individual level—GERD symptoms may decrease, worsen, or remain unchanged after *H. pylori* treatment, concerns about GERD should not affect treatment decisions where a definite indication exists.

H. pylori has a less-well-established role in other gastric pathologies. *H. pylori* may be one initial precipitant of autoimmune gastritis and pernicious anemia and also may predispose to iron deficiency in some patients through hypochlorhydria and reduced iron absorption. In addition, several extragastrointestinal pathologies have been linked epidemiologically with *H. pylori* colonization, the most notable being ischemic heart disease and cerebrovascular disease. However, the strength of these associations is reduced if confounding factors are considered, and most authorities consider them to be noncausal.

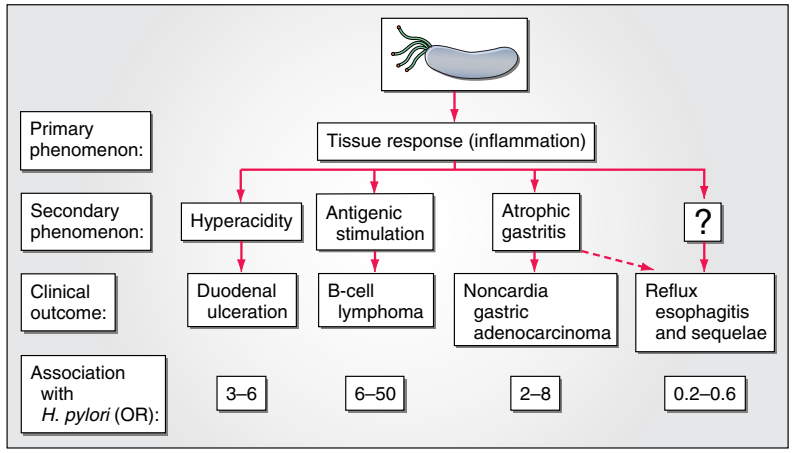

FIGURE 135-1 Schematic of the relationships between colonization with *Helicobacter pylori* and diseases of the upper gastrointestinal tract among persons in developed countries. Essentially all persons colonized with *H. pylori* develop a host response, which is generally termed *chronic gastritis*. The nature of the interaction of the host with the particular bacterial population determines the clinical outcome. *H. pylori* colonization increases the lifetime risk of peptic ulcer disease, noncardia gastric cancer, and B cell non-Hodgkin's gastric lymphoma [odds ratios (ORs) for all, >3]. In contrast, a growing body of evidence indicates that *H. pylori* colonization (especially with *cag*$^+$ strains) protects against adenocarcinoma of the esophagus (and the related gastric cardia) and premalignant lesions such as Barrett's esophagus (OR, <1). While the incidences of peptic ulcer disease (cases not due to nonsteroidal anti-inflammatory drugs) and noncardia gastric cancer are declining in developed countries, the incidence of adenocarcinoma of the esophagus is rapidly increasing. (*Adapted from Blaser 1999, with permission.*)

DIAGNOSIS Tests for *H. pylori* can be divided into two groups: invasive tests, which require upper gastrointestinal endoscopy and are based on the analysis of gastric biopsy specimens, and noninvasive tests (Table 135-1). Endoscopy often is not performed in the initial management of young dyspeptic patients without worrying symptoms but is commonly used in older people to exclude malignancy. If endoscopy is performed, the most convenient biopsy-based test is the biopsy urease test, in which one large or two small antral biopsy specimens are placed into a gel containing urea and an indicator. The presence of *H. pylori* urease elicits a color change, which often occurs within minutes but can require up to 24 h. Histologic examination of biopsy specimens is accurate, provided that a special stain (e.g., a modified Giemsa or silver stain) permitting optimal visualization of *H. pylori* is used. If biopsies from both antrum and corpus are obtained, histologic study yields additional information, including the degree and pattern of inflammation, atrophy, metaplasia, and dysplasia. Microbiologic culture is most specific but may be insensitive because of difficulty with *H. pylori* isolation. Once cultured, the identity of *H. pylori* can be confirmed by its typical appearance on Gram's stain and its positive reactions in oxidase, catalase, and urease tests. Moreover, the organism's antibiotic sensitivities can be determined. The occasional biopsy specimens containing the less common non-*pylori* helicobacters give only weakly positive results in the biopsy urease test. Positive identification of these bacteria requires visualization of the characteristic long, tight spiral bacteria in histologic sections.

Noninvasive *H. pylori* testing is now the norm if gastric cancer does not need to be excluded. The most consistently accurate test is the urea breath test. In this simple test, the patient drinks a labeled urea solution and then blows into a tube. The urea is labeled with either the nonradioactive isotope ^{13}C or a minute dose of the radioactive isotope ^{14}C. If *H. pylori* urease is present, the urea is hydrolyzed and labeled carbon dioxide is detected in breath samples. The stool antigen test is another simple assay that is dependent on the detection of *H. pylori* antigens in stool. It is more convenient and less expensive than the urea breath test but has been slightly less accurate in some

TABLE 135-1 *Tests Commonly Used to Detect Helicobacter pylori*

Test	Advantages	Disadvantages
INVASIVE (BASED ON ENDOSCOPIC BIOPSY)		
Biopsy urease test	Quick, simple	Some commercial tests not fully sensitive before 24 h
Histology	May give additional histologic information	Sensitivity dependent on experience and use of special stains
Culture	Permits determination of antibiotic susceptibility	Sensitivity dependent on experience
NONINVASIVE		
Serology	Inexpensive and convenient	Cannot be used for early follow-up; some commercial kits inaccurate
^{13}C or ^{14}C urea breath test	Inexpensive and simpler than endoscopy; useful for follow-up after treatment	Low-dose irradiation in ^{14}C test
Stool antigen test	Inexpensive and convenient; useful for follow-up after treatment; may be useful in children	New test; role not fully established; appears less accurate than urea breath test

TABLE 135-2 *Recommended Treatment Regimens for Helicobacter pylori*

Regimen, Duration	Drug 1	Drug 2	Drug 3	Drug 4
FIRST-LINE TREATMENT				
Regimen 1: OCA (7 days)[a]	Omeprazole[b] (20 mg bid)	Clarithromycin (500 mg bid)	Amoxicillin (1 g bid)	—
Regimen 2: OCM (7 days)	Omeprazole[b] (20 mg bid)	Clarithromycin (500 mg bid)	Metronidazole (500 mg bid)	—
SECOND-LINE TREATMENT[c]				
Regimen 3: OBTM (14 days)[d]	Omeprazole[b] (20 mg bid)	Bismuth subsalicylate (2 tabs qid)	Tetracycline HCl (500 mg qid)	Metronidazole (500 mg tid)

[a] For first-line therapy, many practitioners prefer Regimen 1 to Regimen 2, as it avoids the use of metronidazole—an important constituent of second-line therapy.
[b] Omeprazole may be replaced with any protein pump inhibitor at an equivalent dosage or, in Regimens 1 and 2, with ranitidine bismuth citrate (400 mg).
[c] An alternative to this second-line therapy is to culture *H. pylori* and to be guided by antibiotic susceptibility data. Patients in whom second-line therapy fails should undergo endoscopy for *H. pylori* culture and antibiotic susceptibility testing.
[d] Data supporting this regimen come mainly from Europe and are based on the use of bismuth subcitrate and metronidazole (400 mg tid).

comparative studies. The urea breath test, the stool antigen test, and biopsy-based tests can all be used to assess the success of treatment. However, because these tests are dependent on *H. pylori* load, their use <4 weeks after treatment may lead to false-negative results. These tests are also unreliable if performed within 4 weeks of intercurrent treatment with antibiotics or bismuth compounds or within 2 weeks of the discontinuation of PPI treatment. In the assessment of treatment success, noninvasive tests are normally preferred; however, after gastric ulceration, endoscopy should be repeated to ensure healing and to exclude gastric carcinoma by further histologic sampling.

The simplest tests for ascertaining *H. pylori* status are serologic assays measuring specific IgG levels in serum by enzyme-linked immunosorbent assay (ELISA) or immunoblot. The best of these tests are as accurate as other diagnostic methods, but many commercial tests, especially rapid office tests, perform poorly. In quantitative tests, a defined drop in antibody titer between matched serum samples taken before and 6 months after treatment (no sooner because of the slow decline in titer) accurately indicates that *H. pylori* has been eradicated. However, serologic tests are not commonly used in this context because of the inconvenient wait and the logistics. Although serology can distinguish between *cag*$^+$ and *cag*$^-$ strains, this technique is not yet commercially available in the United States.

TREATMENT

The most clear-cut indications for treatment are *H. pylori*–related duodenal or gastric ulceration and low-grade gastric B cell lymphoma. *H. pylori* should be eradicated in patients with documented ulcer disease, whether or not the ulcers are currently active, to reduce the likelihood of relapse. Many guidelines now recommend *H. pylori* treatment in uninvestigated simple dyspepsia following noninvasive diagnosis; others also recommend treatment in functional dyspepsia, in case the patient is one of the perhaps 5 to 10% to benefit (beyond placebo effects) from such treatment. People with a strong family history of gastric cancer should be treated for *H. pylori* in the hope that this therapy will reduce their risk. For many reasons, widespread community screening for and treatment of *H. pylori* as primary prophylaxis for gastric cancer and peptic ulcers are not currently recommended. It is unclear whether treatment of *H. pylori* (as opposed to never having acquired the organism) reduces cancer risk, except in certain high-risk populations. Treatment has side effects, which are severe in rare cases. Antibiotic resistance may arise in *H. pylori* or other incidentally carried bacteria. Otherwise healthy people may become anxious, especially if treatment is unsuccessful. Finally, there is a possible risk of provoking or worsening GERD.

Although *H. pylori* is susceptible to a wide range of antibiotics in vitro, monotherapy has been disappointing in vivo, probably because of inadequate antibiotic delivery to the full locus of colonization. Failure of monotherapy has led to the development of multidrug regimens, the most successful of which are triple and quadruple combinations that produce *H. pylori* eradication rates of >90% in many trials and >75% in clinical practice. Current regimens consist of a PPI or ranitidine bismuth citrate and two or three antimicrobial agents given for 7 to 14 days (Table 135-2).

The two most important goals in *H. pylori* eradication are to obtain the patient's close compliance with the dosing regimen and to use drugs to which *H. pylori* has not acquired resistance. Treatment failure following minor lapses in compliance is common and often leads to acquired resistance to metronidazole or clarithromycin. To stress the importance of compliance, written instructions should be given to the patient, and minor side effects of the regimen should be explained. Resistance to metronidazole and clarithromycin is of growing concern. Clarithromycin resistance is less prevalent but, if present, usually results in treatment failure. Metronidazole-resistant strains of *H. pylori* are more common, but infections with these strains may still respond to metronidazole-containing regimens. Assessment of antibiotic susceptibilities before treatment would be optimal but is not usually undertaken. In the absence of susceptibility information, a history of antibiotic use should be obtained, and, even if only distant exposure is identified (e.g., previous metronidazole consumption for giardiasis or trichomoniasis), use of the agent should be avoided if possible. If initial *H. pylori* treatment fails, two strategies are commonly used. One is re-treatment with a quadruple drug regimen (Table 135-2). The second is endoscopy and biopsy culture plus treatment based on documented antibiotic sensitivities. If re-treatment fails, susceptibility testing should always be performed.

Clearance of non-*pylori* gastric helicobacters following the use of bismuth compounds alone or triple-therapy regimens has been described. However, in the absence of trials, it is unclear whether this result represents successful treatment or natural clearance of the bacterium.

PREVENTION Carriage of *H. pylori* has considerable public health significance in developed countries, where it is associated with peptic ulcer disease and gastric adenocarcinoma, and in developing countries, where gastric adenocarcinoma is an even more common cause of cancer death late in life. However, given that *H. pylori* has co-evolved with its human host over millennia, preventing or eliminating colonization on a population basis may have distinct disadvantages. For example, absence of *H. pylori* has been reported to increase the risk of diarrheal diseases and, as has been mentioned, appears to increase the risk of GERD and esophageal adenocarcinoma. If mass prevention were contemplated, vaccination would be the most obvious method, and experimental immunization of animals has given promising results. However, in the United States and other developed countries, rates of *H. pylori* carriage, peptic ulceration, and gastric adenocarcinoma are falling. Thus, prevention of colonization in these countries may be unnecessary or even unwise.

136 INFECTIONS DUE TO *PSEUDOMONAS* SPECIES AND RELATED ORGANISMS

Christopher A. Ohl, Matthew Pollack

Pseudomonas species and phylogenetically related bacteria are ubiquitous, free-living, opportunistic gram-negative pathogens. *Pseudomonas aeruginosa*, the most common human pathogen in this group, is the primary subject of this chapter. Also discussed are *Burkholderia cepacia* (formerly *Pseudomonas cepacia*), *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*), and *Burkholderia pseudomallei* and *Burkholderia mallei* (the causative agents of melioidosis and glanders, respectively).

INFECTIONS DUE TO *P. AERUGINOSA*

MICROBIOLOGY *P. aeruginosa* is a small, nonsporulating, aerobic gram-negative rod belonging to the family Pseudomonadaceae. It is motile by virtue of its single polar flagellum. More than half of all clinical isolates produce the blue-green pigment pyocyanin; this pigment is helpful in the identification of the organism and accounts for the species name *aeruginosa*, which refers to the distinctive color of copper oxide. The organism, which can easily be identified in culture by the clinical laboratory, is differentiated from enteric gram-negative bacilli by its ability to oxidize indophenol and its inability to ferment lactose.

EPIDEMIOLOGY *P. aeruginosa* is widespread in nature, inhabiting soil, water, plants, and animals (including humans). It has a predilection for moist environments. This organism occasionally colonizes the skin, external ear, upper respiratory tract, or large bowel of healthy humans. Rates of carriage are relatively low, however, except among patients who have serious underlying disease, whose host defenses have been naturally or iatrogenically compromised, who have previously received antibiotic therapy, and/or who have been exposed to the hospital environment. Under these circumstances, colonization with *P. aeruginosa* frequently precedes infection, and factors that predispose to the former also increase the likelihood of the latter.

Most *P. aeruginosa* infections are acquired in the hospital, where intensive care units (ICUs) account for higher rates of infection than other hospital units. According to the National Nosocomial Infections Surveillance (NNIS) System, between 1992 and 1999, *P. aeruginosa* was the second most common cause of pneumonia, the fourth most common cause of urinary tract infection, and the sixth most common bloodstream isolate in ICUs. Many potential reservoirs of infection have been identified in the hospital environment, including respiratory equipment, cleaning solutions, disinfectants, sinks, vegetables, flowers, endoscopes, and physiotherapy pools. Most reservoirs are associated with moisture. While some infecting strains of *P. aeruginosa* appear to be endemic within the hospital, others are traced to a common source associated with a specific outbreak or epidemic. Nosocomial outbreaks of *Pseudomonas* infection have been specifically traced to the hands and fingernails of health care workers, and the majority of instances of patient-to-patient transmission in the hospital are thought to occur via this route. Epidemiologic investigation of health care–associated outbreaks is facilitated by the use of molecular techniques such as pulsed-field gel electrophoresis.

PATHOGENESIS The pathogenesis of *Pseudomonas* disease is complex, as is suggested by the clinical diversity of the infections related to this organism and by the multiplicity of putative virulence factors it produces. *P. aeruginosa* rarely causes disease in the healthy host but is highly virulent for persons in whom the normal cutaneous or mucosal barriers have been breached or bypassed, the immunologic defense mechanisms have been compromised, or the protective function of the normal bacterial flora has been disrupted (Table 136-1). The organism's ubiquity, flexible nutritional and metabolic requirements, invasive capacity, toxinogenicity, and innate antibiotic resistance help account for the frequency and success with which it acts as an opportunistic pathogen.

Infections caused by *P. aeruginosa* usually begin with bacterial attachment and superficial colonization of cutaneous or mucosal surfaces and progress to localized bacterial invasion and damage to underlying tissues. The infection may remain anatomically localized or may spread by direct extension to contiguous structures. This process may continue with bloodstream invasion, dissemination, the systemic inflammatory response syndrome (SIRS), multiple-organ dysfunction, and ultimately death. Not only is local infection more likely to occur in immunocompromised hosts (e.g., those with profound neutropenia), it is also more likely to culminate in bloodstream invasion and dissemination in these patients. Both intrinsic and extrinsic virulence factors appear to play roles in the pathogenicity of *P. aeruginosa* (Table 136-2). The organism's 6.3-million base-pair genome has been sequenced in its entirety, and a number of genes with specific regulatory, catabolic, and transport functions have been identified. These findings will undoubtedly increase our understanding of the pathogenicity and virulence of *P. aeruginosa*.

The production and secretion of many of the extracellular virulence factors of *P. aeruginosa* as well as the assembly and maturation of its biofilm are under the regulatory control of a complex cell-to-cell signaling system termed *quorum sensing*. Through lactones and other signal molecules secreted by each individual bacterium, the entire population of *P. aeruginosa* in a biofilm, colonized mucosa, or infected tissue senses its environment, communicates, and discerns its own cell density. This regulatory system may conceivably allow the bacteria to produce extracellular virulence factors in a coordinated manner that depends on cell density and thus may give the pathogen an appreciable advantage over host defense mechanisms.

Some of the exotoxins produced by *P. aeruginosa* (ExoS, ExoT, ExoU, and ExoY) are introduced directly from the bacterial cytosol into the host cell cytoplasm via a complex array of transmembrane proteins that together make up the *type III secretion apparatus*. This

TABLE 136-1 Factors Predisposing to Pseudomonas aeruginosa Infections

DISRUPTION OF CUTANEOUS OR MUCOSAL BARRIERS	
Burn injury	Endotracheal intubation
Cystic fibrosis	Indwelling central venous catheterization
Dermatitis	Urinary bladder catheterization
Penetrating trauma	Injection drug use
Surgery	
IMMUNOSUPPRESSION	
Neutropenia	Extremes of age
Qualitative white blood cell defects	Diabetes mellitus
Hypogammaglobulinemia	Steroid therapy
Defective cell-mediated immunity	Cancer
	AIDS
DISRUPTION OF NORMAL BACTERIAL FLORA	
Broad-spectrum antibiotic therapy	
Exposure to the hospital environment	

TABLE 136-2 *Putative Virulence Factors of Pseudomonas aeruginosa*

Virulence Factor	Function(s)
Pili or fimbriae	Attachment to epithelial cells
Mucoid exopolysaccharide (alginate)	Attachment to epithelial cells, inhibition of mucociliary and opsonophagocytic clearance, biofilm formation
Alkaline protease	Tissue breakdown, proteolysis of immunoglobulin and complement
Elastase	Destruction of elastic tissues, including lamina of blood vessels
Phospholipase C (a hemolysin)	Breakdown of lipids and lecithin, tissue necrosis
Lipopolysaccharide (LPS or endotoxin)	Fever, leukocytosis or leukopenia, hypotension, shock; disseminated intravascular coagulation; adult respiratory distress syndrome; systemic inflammatory response syndrome
Exotoxins	
ExoA	Inhibition of protein synthesis through interference with adenosine diphosphate ribosylation of elongation factor-2
ExoS	Ribosylation of guanosine triphosphate binding proteins; disruption of cellular actin cytoskeleton
ExoT	Disruption of cellular actin cytoskeleton
ExoU	Acute cytotoxicity
ExoY	Increase in intracellular cyclic adenosine monophosphate

system requires direct cell contact and allows the injection of virulence factors from the bacterium into host cells without interference from humoral immune defenses.

CLINICAL MANIFESTATIONS AND DIAGNOSIS ■ Respiratory Tract Infections

Primary pneumonia or *nonbacteremic pneumonia* results from the aspiration of upper respiratory tract secretions and often develops in patients with previous antibiotic use who are exposed to the hospital environment, particularly the ICU. It is a common cause of ventilator-associated pneumonia and is noted especially often in patients with chronic lung disease, congestive heart failure, or AIDS. Community-aquired pneumonia due to *P. aeruginosa* is uncommon among normal hosts. Fever, chills, severe dyspnea, cyanosis, productive cough, apprehension, confusion, and other signs of severe systemic toxicity characterize this acute, often life-threatening infection. Chest roentgenograms typically show bilateral bronchopneumonia with nodular infiltrates and small areas of radiolucency; pleural effusions are common; empyema is relatively uncommon; and lobar consolidation is occasionally seen. Cavitary lesions are unusually common among AIDS patients with *P. aeruginosa* pneumonia. Pathologic lesions include alveolar necrosis, focal hemorrhages, and microabscesses.

Bacteremic pneumonia due to *P. aeruginosa* begins as a respiratory infection. However, unlike primary pneumonia, it is typically associated with neutropenia, subsequent bloodstream invasion, and metastatic spread that produces characteristic lesions in the lungs and other viscera. Alveolar hemorrhage and necrosis are common. The signs and symptoms of this fulminant disease include those described for nonbacteremic pneumonia caused by this organism as well as those associated with gram-negative sepsis. Chest roentgenograms characteristically demonstrate a rapid progression from pulmonary vascular congestion to interstitial edema, then to alveolar edema, and finally to diffuse necrotizing bronchopneumonia with cavity formation. The patient typically dies 3 or 4 days after initial presentation.

Chronic infection of the lower respiratory tract with *P. aeruginosa* is caused almost exclusively by mucoid strains that produce alginate and is prevalent among older children and young adults with cystic fibrosis as well as in some patients with bronchiectasis or AIDS. In patients with cystic fibrosis, mucoid strains invariably colonize and infect patients with increasing prevalence over time and contribute to the acute exacerbations and chronic progression that characterize pulmonary disease in these individuals. Airway obstruction appears to begin with bronchiolitis, which causes mucus plugging and predisposes to *P. aeruginosa* infection. The latter produces more mucus plugging, chronic suppuration, bronchiectasis, atelectasis, and ultimately fibrosis. This process progresses to pulmonary insufficiency, hypoxemia, and alterations in cardiopulmonary dynamics resulting in pulmonary hypertension and cor pulmonale.

Clinical manifestations of lower respiratory tract infections due to *P. aeruginosa* in patients with cystic fibrosis vary with the severity and duration of underlying lung disease, the frequency and intensity of acute episodes, and the presence of co-infecting pathogens such as *B. cepacia* (Chap. 241). Early in the disease, patients may experience recurrent upper respiratory symptoms followed by a lingering cough. Episodes of pneumonia develop later, with persistent cough between acute episodes. Eventually, patients exhibit a chronic productive cough, wheezing, diminished appetite, weight loss, growth retardation, and decreased activity. Acute exacerbations are typically accompanied by low-grade fever and heightened respiratory symptoms. Physical signs include evidence of malnutrition, an increase in anteroposterior diameter, intercostal retractions, cyanosis, inspiratory and expiratory wheezing, rhonchi, moist rales, abdominal distention, and clubbing of the fingers and toes. Laboratory abnormalities include leukocytosis with a left shift and hypoxemia with or without hypercarbia. Tests of pulmonary function demonstrate obstructive and restrictive defects. Chest roentgenograms reveal overaeration, patchy atelectasis, peribronchial fibrosis, and patchy infiltrates associated with pneumonia. In more advanced disease, there may be evidence of severe overaeration, depressed diaphragm, further increased anteroposterior diameter, extensive peribronchial infiltration, generalized bronchiectasis, and cyst formation.

Bacteremia *P. aeruginosa* remains an important cause of life-threatening bloodstream infection in immunocompromised patients, particularly those with hematologic malignancies complicated by neutropenia. Bacteremia is frequently iatrogenic and is usually seen in hospitalized patients with various comorbid conditions (Table 136-1). Bloodstream infection may be primary (with no identifiable source) or secondary to a discrete focus of infection. Common primary sites of infection include the urinary and gastrointestinal tracts, lungs, skin and soft tissues, and intravascular foci, including indwelling central venous catheters.

The clinical features of *P. aeruginosa* bacteremia are similar to those of other forms of bacteremia. Fever, tachypnea, tachycardia, and prostration are common. Disorientation, confusion, or obtundation may be evident. Hypotension can progress to refractory shock. Renal failure, adult respiratory distress syndrome, disseminated intravascular coagulation, and other manifestations of SIRS occur as complications.

Pathognomonic skin lesions termed *ecthyma gangrenosum* (Fig. 136-1) develop in a relatively small minority of patients with *P. aeruginosa* bacteremia. The lesions begin as small hemorrhagic vesicles

FIGURE 136-1 Ecthyma gangrenosum in a neutropenic patient with *Pseudomonas aeruginosa* bacteremia.

surrounded by a rim of erythema and undergo central necrosis with subsequent ulceration. They occur singly or in small numbers on the perineum, buttocks, and extremities; in the axillae; and elsewhere. Bacterial invasion of blood vessels, documented histologically, is the sine qua non of ecthyma lesions. Bacteria are visible on Gram's staining or are recoverable by culture of aspirated material from lesions.

Endocarditis (See also Chap. 109) *P. aeruginosa* infects the native heart valves of intravenous drug users as well as prosthetic heart valves. The source of *P. aeruginosa* strains infecting drug users appears to be standing water contaminating drug paraphernalia. Foreign materials mixed with heroin may cause injury to valve leaflets or mural endocardium, with resulting fibrosis and an increased risk for valve infection. Exposure of the tricuspid valve to both trauma and bacteria apparently accounts for the high incidence of tricuspid involvement in association with intravenous drug use.

The tricuspid, pulmonic, mitral, or aortic valve and the mural endocardium of either atrium may be affected in *P. aeruginosa* endocarditis. Multiple-valve infections are common. Tricuspid or right-sided involvement is often associated with septic pulmonary emboli. Right-sided *P. aeruginosa* endocarditis usually presents subacutely, while the appearance of left-sided disease is likely to be more acute or even fulminant. Fever is virtually invariable, and murmurs are usually detectable at initial presentation or shortly thereafter. Septic pulmonary emboli associated with right-sided disease result in cough, pleuritic chest pain, sputum production, pulmonary infiltration (with or without abscess formation), and pleural effusion. Left-sided infections may present as intractable heart failure or large systemic emboli. Mycotic aneurysms, cerebritis, or brain abscess may occur; septic infarcts are occasionally found in the spleen. Skin and soft tissue manifestations, including Janeway lesions, Osler's nodes, and ecthyma gangrenosum, are relatively uncommon.

The diagnosis of *P. aeruginosa* endocarditis is based on positive blood culture in the absence of an extracardiac source; an indication of valvular dysfunction or vegetation on an echocardiogram; evidence of septic pulmonary lesions on a chest roentgenogram (in right-sided disease); and the actual demonstration of infected heart valves at the time of surgery.

Central Nervous System Infections *P. aeruginosa* infections of the central nervous system include meningitis and brain abscess. These infections follow extension from a contiguous parameningeal structure such as the ear, mastoid, or paranasal sinus; direct inoculation into the subarachnoid space or brain through head trauma, surgery, or diagnostic procedures; or bacteremic spread from infection at a distant site. Like *P. aeruginosa* infections at other anatomical sites, central nervous system infections are documented almost exclusively in patients with compromised local or systemic immune-defense mechanisms. Mortality rates from these infections are high.

The clinical signs of *P. aeruginosa* meningitis, like those of other forms of acute bacterial meningitis, include fever, headache, stiff neck, confusion, and obtundation. The onset of illness may be acute or even fulminant, particularly in bacteremic patients, with a precipitous downhill course, shock, coma, and early death. In nonbacteremic patients, *P. aeruginosa* meningitis or brain abscess may present more insidiously, with a paucity of systemic symptoms. This presentation is especially common in infections resulting from recent neurosurgery, cancer of the head and neck, or direct extension from a parameningeal focus of chronic infection. Occasionally, *P. aeruginosa* meningitis runs a subacute or relapsing course that is thought to be related to the intermittent release of bacteria from a loculated site of infection.

Ear Infections *P. aeruginosa* is often found in the external auditory canal, particularly under moist conditions and in the presence of inflammation or maceration (as in "swimmer's ear"). Moreover, this organism is the predominant pathogen associated with external otitis, a usually benign inflammatory process affecting the external auditory canal. The ear is painful or merely itchy, there is a purulent discharge, and pain is elicited by pulling on the pinna. The external canal appears edematous and is filled with detritus that often prevents visualization of the tympanic membrane.

P. aeruginosa occasionally penetrates the epithelium overlying the floor of the external auditory canal at the junction between bone and cartilage and invades underlying soft tissue. The ensuing invasive process, which involves soft tissue, cartilage, and cortical bone, is typically slow but destructive. Termed *malignant external otitis*, this condition occurs predominantly in elderly diabetic patients but is reported occasionally in infants with other underlying diseases and rarely in elderly nondiabetic patients. Virtually all cases of malignant external otitis are caused by *P. aeruginosa*. From the external ear, the infection advances to the retromandibular area or parotid space and enters the mastoid air cells and temporal bone. Advancing osteomyelitis at the base of the skull often involves the seventh, ninth, tenth, and eleventh cranial nerves. The cavernous sinus can become involved, as can the contralateral petrous apex. The middle ear is commonly spared; meningitis and brain abscess are relatively rare complications.

Otorrhea and severe otalgia are common presenting symptoms of malignant external otitis. Facial-nerve paralysis tends to occur early, while other cranial-nerve palsies appear later. There may be a loss of hearing. Constitutional symptoms such as fever and weight loss are relatively uncommon. Physical examination almost always reveals remarkable tenderness of the pinna and abnormalities of the external auditory canal, including swelling, erythema, purulent discharge, debris, and granulation tissue in the canal wall. The tympanic membrane is often hidden from view and is sometimes perforated. Inflammation may involve the pinna as well as the periauricular, retromandibular, and mastoid areas.

Peripheral leukocytosis is relatively infrequent in malignant external otitis, while the erythrocyte sedimentation rate (ESR) is usually markedly elevated. Cerebrospinal fluid occasionally exhibits pleocytosis and an elevation in the protein level. Computed tomography (CT) or magnetic resonance imaging (MRI) of the mastoid or temporal bone typically reveals bony erosions and new bone formation, while the floor of the skull may have soft tissue densities associated with areas of cellulitis. In addition, technetium 99m bone scans and gallium 67 scans frequently give positive results. Cultures of samples from the external auditory canal and of surgical specimens are almost always positive for *P. aeruginosa*.

Eye Infections (See also Chap. 25) *P. aeruginosa* causes bacterial keratitis or corneal ulcer and endophthalmitis in the human eye. Keratitis due to *P. aeruginosa* may result from even minor corneal injury, which interrupts the integrity of the superficial epithelial surface and permits bacterial access to the underlying stroma. Corneal ulcer may complicate contact lens use, particularly when extended-wear soft contact lenses are involved. Contact lens solutions or the lenses themselves may be the source of the organism, which is probably inoculated into the eye at sites of minor lens-induced corneal damage. Patients who have sustained serious burns, have undergone ocular irradiation or tracheostomy, have been exposed to the intensive care environment, and/or are in a coma are also susceptible to *P. aeruginosa*–associated corneal ulcers. Contaminated eye medications are occasionally implicated in these infections. *P. aeruginosa* keratitis usually starts as a small central ulcer; spreads concentrically to involve a large portion of the cornea, sclera, and underlying stroma; and in some cases progresses to posterior corneal perforation.

The clinical manifestations of *P. aeruginosa* keratitis include a rapidly expanding, necrotic stromal infiltrate in the bed of an epithelial injury; surrounding epithelial edema; an anterior chamber reaction; and mucopurulent discharge adherent to the ulcer's surface. Corneal ulcer due to *P. aeruginosa* may advance rapidly to involve the entire cornea in $\leq$2 days or may evolve subacutely over several days. Systemic symptoms are uncommon. Complications include corneal perforation, anterior chamber involvement, and endophthalmitis.

P. aeruginosa endophthalmitis is typically a rapidly progressive,

sight-threatening condition that demands immediate therapeutic intervention. It may complicate penetrating injuries of the eye, intraocular surgery, hematogenous spread from other sites of *Pseudomonas* infection, or posterior perforation of corneal ulcers. Clinical manifestations may include eye pain, conjunctival hyperemia, chemosis, lid edema, decreased visual acuity, hypopyon, severe anterior uveitis, and signs of possible vitreous involvement. Panophthalmitis may result from this intraocular infection.

Bone and Joint Infections Sternoclavicular pyarthrosis caused by *P. aeruginosa* is often a complication of injection drug use and is rarely associated with *P. aeruginosa* endocarditis. Joint involvement is usually monarticular, with the sternoclavicular joint more often affected than sternochondral joints. Patients present with acute or chronic pain in the anterior chest wall, often associated with fever and restricted movement of the homolateral shoulder. Physical examination reveals tenderness, erythema, and swelling over the affected joint. Leukocytosis is common, and the ESR is almost invariably elevated. Roentgenograms show soft tissue edema, bone demineralization, lytic lesions, and periosteal elevation of the clavicular head, rib, or sternum. Material obtained by arthrocentesis or synovial biopsy yields *P. aeruginosa* in culture.

P. aeruginosa infections of the symphysis pubis are associated with pelvic surgery and injection drug use. The symphysis pubis, like other fibrocartilaginous joints, exhibits a peculiar susceptibility to bloodborne infection with *P. aeruginosa*. Affected patients report pain in the groin, hip, thigh, and/or lower abdomen that is made worse by walking. Fever is variable, and the duration of symptoms before diagnosis ranges from days to months. The ESR is markedly elevated. Roentgenograms or CT scans show irregularities of the pubic margins, separation of the symphysis pubis, and osteomyelitic abnormalities of the pubic rami that may be extensive. Bone scans are usually positive. Needle aspiration or biopsy is necessary to obtain material for culture. A positive culture is particularly important for the discrimination of *P. aeruginosa* infections and other pyogenic infections from osteitis pubis, which is thought to be a noninfectious condition complicating pelvic surgery, childbirth, or trauma.

P. aeruginosa is the most common cause of osteochondritis of the foot following plantar puncture wounds. This infection is seen primarily in children and is usually acquired via the direct inoculation of *P. aeruginosa* that inhabits the moist environment found in the soles of shoes. The organism infects the small joints and bones, including the proximal phalanges, metatarsals, metatarsophalangeal joints, tarsal bones, and calcaneus. On average, local pain and swelling last for several weeks, and systemic symptoms are usually lacking. There may be plantar cellulitis over the involved area or tenderness upon deep palpation. Results of roentgenograms and bone scans are generally positive. Aspiration of the affected joint frequently yields purulent material in which *P. aeruginosa* can be demonstrated by Gram's staining and by culture.

Vertebral osteomyelitis due to *P. aeruginosa* is associated with complicated urinary tract infection, genitourinary instrumentation or surgery, and injection drug use. Vertebral infections that are associated with a urinary tract source most often develop in the elderly and usually affect the lumbosacral spine. Presumably the route of infection in these patients is a shared venous plexus between the pelvis and spine. Drug use–related infections typically occur in younger patients and may affect the cervical or lumbosacral spine. *P. aeruginosa* vertebral osteomyelitis is usually an indolent disease. Accordingly, symptoms may develop weeks or even months before diagnosis. Back or neck pain is generally reported, while fever and systemic symptoms are relatively uncommon. Local tenderness and decreased range of motion of the affected spine are typical. Leukocytosis may be noted, the ESR is almost always markedly elevated, and blood cultures are sometimes positive. Roentgenograms reveal loss of bone density, narrowed intervertebral space, destruction of vertebral end plates, lytic lesions of vertebral bodies, sclerosis, and possible osteophyte formation. MRI or CT is the most sensitive and specific means of defining lesions. Technetium bone scans and gallium scans usually yield positive results but have lower specificity. An etiologic diagnosis requires the culture of material obtained by needle aspiration or biopsy of the affected spine under fluoroscopic guidance; open biopsy is occasionally needed.

P. aeruginosa is one of the most common causative agents in a variety of other, less specific syndromes involving nonhematogenous infections of bones and joints and collectively referred to as *chronic contiguous osteomyelitis*. These infections may result, for example, from compound fractures, contamination associated with open reduction and fixation of closed fractures, sternotomy performed in conjunction with cardiac surgery, contiguous spread from infected ischemic ulcers related to peripheral vascular disease or diabetes mellitus, and cellulitis in general. The chronicity, indolence, and heterogeneity of these infections explain their varied clinical manifestations and the frequent need for complicated long-term management.

Urinary Tract Infections *P. aeruginosa* is one of the most common causes of complicated and nosocomial infections of the urinary tract. These infections may result from urinary tract catheterization, instrumentation, surgery (including renal transplantation), or obstruction; they may arise from persistent foci (e.g., the prostate or stones) and may be chronic or recurrent. The urinary tract may be a target for bloodborne infection in patients with *P. aeruginosa* bacteremia but more often is the source of bacteremia. Chronic *P. aeruginosa* infections of the urinary tract are relatively common among patients with indwelling bladder catheters, altered urinary tract anatomy secondary to diversionary procedures, and paraplegia. Chronic or recurrent urinary tract infection caused by *Pseudomonas* often involves multidrug-resistant (MDR) strains.

The clinical features of urinary tract infections due to *P. aeruginosa* are usually indistinguishable from those of other bacterial infections. However, *P. aeruginosa* infections exhibit a propensity for persistence, chronicity, and recurrence. More unusual forms of urinary tract involvement peculiar to *P. aeruginosa* include (1) ulcerative lesions of the renal pelvis, ureters, and bladder that cause sloughing of vesical membranes in the urine; and (2) ecthyma-like lesions of the renal cortex that are seen in association with *Pseudomonas* sepsis.

Skin and Soft Tissue Infections (See also Chap. 110) As indicated above, *P. aeruginosa* bacteremia may be associated with the disseminated skin lesions of ecthyma gangrenosum (Fig. 136-1). Less common skin manifestations of *P. aeruginosa* sepsis include vesicular or pustular lesions, bullae, subcutaneous nodules, deep abscesses, and cellulitis. Metastatic lesions of the skin or mucous membranes complicate *Pseudomonas* sepsis and occasionally produce massive necrosis or gangrene of the extremities, perineum, face, or oropharynx.

Primary *P. aeruginosa* pyoderma occurs when the skin breaks down secondary to surgery, trauma, burn injury, dermatitis, or ulcers related to peripheral vascular disease or pressure sores. Moist conditions and neutropenia may predispose to this condition. The clinical appearance of primary *P. aeruginosa* pyoderma, which frequently includes hemorrhage and necrosis, resembles that of metastatic *P. aeruginosa* skin lesions. Histologic studies document vascular invasion by bacteria in both diseases. A rare distinguishing feature of *P. aeruginosa* pyoderma is its association with a characteristic fruity odor and an exudate of blue-green hue (due to pyocyanin) that is occasionally noted on dressings or bandages rather than on the wound itself.

P. aeruginosa wound infection complicating extensive third-degree burn injuries typically occurs at least 1 to 2 weeks after the injury and results from colonization of the burn site or burn eschar. Invasion of the subeschar space and underlying dermis, vascular invasion, and systemic spread may occur and are associated with an elevated mortality rate. The development and progression of *P. aeruginosa* burn wound sepsis are facilitated by the injury-associated breakdown of normal skin, selection of antibiotics with inadequate coverage for this pathogen, and burn-related immune defects. Local manifestations include black, dark brown, or violaceous discoloration of the burn es-

char; degeneration of underlying granulation tissue, hemorrhage, and premature eschar separation; edema, hemorrhage, and necrosis of skin adjacent to the burn site; and erythematous nodular lesions in unburned skin. Systemic manifestations include fever or hypothermia and other signs of sepsis, SIRS, or multiple-organ system failure. The diagnosis of *P. aeruginosa* burn sepsis is based on these local and systemic clinical manifestations and on a burn wound biopsy that reveals both $>10^5$ colony-forming units of *P. aeruginosa* per gram of tissue and histologic evidence of bacterial invasion of unburned tissue, vasculitis, or intense inflammation at the burn margin.

P. aeruginosa causes diffuse, pruritic, maculopapular, and vesiculopustular rashes associated with exposure to contaminated hot tubs, spas, whirlpools, and swimming pools. Most cases of *P. aeruginosa* dermatitis have occurred as part of a common-source outbreak. At least two nosocomial common-source outbreaks—one related to a physiotherapy pool—have been reported. Skin rashes may be limited to areas covered by swimsuits or may be more diffuse, sparing only the head and neck. Low-grade fever or other associated symptoms are uncommon. The illness is usually self-limited, and the rash resolves without specific therapy after cessation of exposure. A related benign condition has been reported in children exposed to *P. aeruginosa*–contaminated wading pools. Termed *pseudomonas hot-foot syndrome*, this infection presents with painful nodules on the plantar aspect of the foot.

***P. aeruginosa* Infections in Patients with AIDS** During the 1980s and 1990s, *P. aeruginosa* infections were increasingly associated with AIDS. The vast majority of these infections are currently seen in patients with advanced AIDS, previous opportunistic infections, and CD4+ lymphocyte counts $<100/\mu L$ (often $<50/\mu L$). The specific immunologic factors that lead to *P. aeruginosa* infections in patients with AIDS are not well understood but are thought to result from a loss of mucosal integrity, defects in cellular and humoral immunity, and qualitative leukocyte abnormalities. Notably, the majority of *P. aeruginosa* infections in this population are community-acquired, in contrast to the nosocomial transmission observed for most infections in non-AIDS patients.

Pneumonia accounts for a substantial proportion of *P. aeruginosa* infections in patients with AIDS. In most instances, pneumonia presents as a necrotizing infection of the pulmonary parenchyma, frequently with cavitary lesions, or as a chronic relapsing bronchopulmonary infection reminiscent of the bronchopulmonary disease seen in patients with cystic fibrosis. Also observed are bloodstream infections, including those associated with indwelling central venous catheters, and infections of the paranasal sinuses, skin and soft tissue, and urinary tract. Bacteremia, either primary or secondary to infection at a remote site, is often recurrent, associated with high mortality, and occasionally accompanied by skin manifestations similar to those seen in non-AIDS patients.

Because *P. aeruginosa* infections occur in patients with advanced AIDS, survival after recovery from the initial infection may be limited to a few months. However, with the widespread use of highly active antiretroviral therapy and the resultant increase in CD4+ cell count, the incidence of *P. aeruginosa* infection among patients with AIDS appears to have declined and the natural history of infection to have been modified. For example, a small number of patients with recalcitrant, relapsing *P. aeruginosa* bronchopulmonary infections have reportedly experienced the resolution of infection soon after initiation of intensive antiretroviral therapy. For those patients infected with HIV that has developed antiretroviral resistance, the risk of *Pseudomonas* infection remains elevated.

TREATMENT

Approach to Therapy Table 136-3 lists antimicrobial agents available in the United States that are generally active against *P. aeruginosa*. Table 136-4 outlines suggested antibiotic choices and an approach to therapy for infections at selected sites. The initial antibiotic selection should take into account the local patterns of antimicrobial susceptibility, and the susceptibilities of the isolate from a particular case should guide definitive antibiotic therapy (see below).

In most severe or life-threatening infections due to *P. aeruginosa*, two antipseudomonal antibiotics to which the infecting strain is (or is likely to be) sensitive should be administered together. The putative benefits of this combined therapy, as determined by in vitro studies, are to increase efficacy, to achieve additive or synergistic killing, and to prevent the emergence of antibiotic resistance. Despite widespread acceptance of combination therapy for *P. aeruginosa* infections, there are few clinical data collected since the advent of newer β-lactam antibiotics to document that combination therapy is in fact more efficacious than monotherapy or that it actually forestalls the acquisition of antimicrobial resistance. Nevertheless, combination therapy continues to be recommended—at least as initial treatment—for most fulminant infections, as outlined in Table 136-4.

The appropriate duration of antibiotic therapy for disease caused by *P. aeruginosa* depends on the type, location, and severity of infection. In general, chronic infections associated with extensive tissue injury, disruption of normal anatomy, foreign or prosthetic material, or suboptimal antibiotic accessibility require therapy for weeks or even months rather than days. More acute infections may be treated aggressively but for shorter periods.

P. aeruginosa infections of the lower respiratory tract in cystic fibrosis pose a special challenge because of their long-standing nature (Chap. 241). In general, antibiotic therapy for acute exacerbations results in short-term clinical improvement, while periodic expectant courses of antimicrobial therapy may limit disease progression. The clinical response to antimicrobial therapy may have little relation to the identity and antimicrobial susceptibility of cultured sputum isolates. A more novel approach to antimicrobial treatment—the use of intermittent, cyclical inhaled tobramycin—has been shown to improve pulmonary function, decrease the risk of hospitalization, and reduce the density of *P. aeruginosa* in sputum of older patients with cystic fibrosis. In addition, lung transplantation has been employed with good results in selected cystic fibrosis patients with severe, progressive lower respiratory tract infections due to *P. aeruginosa*.

Antimicrobial Resistance Antibiotic resistance in *P. aeruginosa* is both intrinsic (as reflected by the relative paucity of antibiotics with inherent activity against wild-type strains) and acquired (as defined by high-level resistance to agents that normally would be expected to exhibit antimicrobial activity). Acquired resistance is rapidly increasing among isolates of *P. aeruginosa*, particularly those associated with cystic fibrosis and with ICUs. Escalating resistance among ICU isolates is especially alarming. Data from NNIS and the Intensive Care Antimicrobial Resistance Epidemiology (ICARE) project on the resistance of *P. aeruginosa* between 1998 and 2002 show that the pooled mean figures for resistance to piperacillin, ceftazidime, imipenem, and ciprofloxacin increased from previous years and represented 14.3, 10.5, 13.7, and 28.9% of ICU-associated isolates, respectively. Factors responsible for this increase may include the expanding use of immunosuppressive therapies, the increased severity of illness in hospitalized patients, inadequate infection-control procedures, and growing antibiotic use. Resistant organisms can be transmitted directly to patients from the hospital staff, other patients, or the environment, or they may arise de novo during therapy with any given agent. The emergence of MDR strains has been associated with increases in secondary bacteremia and mortality and has led in some cases to longer hospital stays and increased hospitalization costs. Therapy for resistant *P. aeruginosa* infections should consist of antimicrobial agents selected on the basis of extended susceptibility testing and may involve increased treatment duration as well as surgical drainage or removal of infected tissues. Infections due to strains resistant to all commonly available antimicrobial agents may respond to parenteral or inhaled therapy with the relatively toxic antibiotics polymyxin B and colistin.

TABLE 136-3 *Antimicrobial Agents Active Against Pseudomonas aeruginosa and Available in the United States*

Agent	Dose,[a] Route	Comments
ANTIPSEUDOMONAL PENICILLINS		
Piperacillin Piperacillin/tazobactam Mezlocillin Ticarcillin Ticarcillin/clavulanate	3–4 g q4–6h IV 3.375 g q4h IV 3 g q4h IV 3 g q3–6h IV 3.1 g q4–6h IV	Drugs in class are listed in order of decreasing in vitro activity. Piperacillin/tazobactam or ticarcillin/clavulanate has little more activity against *P. aeruginosa* than piperacillin or ticarcillin alone. Monotherapy should not be used for serious infections.
ANTIPSEUDOMONAL CEPHALOSPORINS		
Ceftazidime[b] Cefoperazone[b] Cefepime	2 g q8–12h IV 2 g q6h IV 2 g q8–12h IV	Use more frequent indicated doses for CNS infections or infections in neutropenic or severely immunocompromised patients. The antipseudomonal activity of cefepime is equivalent to that of ceftazidime, with less potential for β-lactamase induction in gram-negative enteric bacteria.
CARBAPENEMS[b,c]		
Imipenem/cilastatin Meropenem	0.5 g q6h IV 1 g q8h IV	Class is active against strains producing β-lactamases. Imipenem may cause seizures in patients with renal failure (avoid by reducing dose) or CNS infections or lesions. Meropenem is slightly more active in vitro against *P. aeruginosa* than imipenem.
MONOBACTAMS		
Aztreonam	2 g q6–8h IV	Drug can usually be administered to patients with β-lactam hypersensitivity.
AMINOGLYCOSIDES[b]		
Tobramycin Gentamicin Amikacin	MD: 2 mg/kg load, then 1.7 mg/kg q8h IV ODD: 5–7 mg/kg q24h IV MD: Same as tobramycin ODD: Same as tobramycin MD: 7.5 mg/kg load, then 7.5 mg/kg q12h IV ODD: 15 mg/kg q24h IV	Tobramycin has greater in vitro activity against *P. aeruginosa* than gentamicin, but the drugs' clinical efficacies are probably equivalent. Some *P. aeruginosa* isolates that are resistant to tobramycin or gentamicin may be susceptible to amikacin. Except in urinary tract infection, this class should not be used for monotherapy. ODD may reduce adverse effects. Serum levels must be monitored.
FLUOROQUINOLONES[b,d]		
Ciprofloxacin Levofloxacin	0.4 g q12h IV or 0.5–0.75 g bid PO 0.75 g q24h IV or PO	Ciprofloxacin is the most active of the available quinolones against *P. aeruginosa*. Serum levels attained with oral therapy approximate those after IV therapy; thus oral formulations are useful for long-duration therapy in selected patients.
OTHER AGENTS		
Polymyxin B Colistin	0.75–1.25 mg/kg q12h IV 1.5 mg/kg q8h IV	These drugs are reserved for use in multidrug-resistant infections. Nephrotoxicity and neurotoxicity occur. Colistin inhalational therapy consists of 75 mg in 3 mL of normal saline via nebulizer, given twice daily.

[a] Indicated dosages are for the treatment of infections due to *P. aeruginosa* in adults. Doses should be adjusted in renal insufficiency. Higher doses may be required in patients with cystic fibrosis, and lower doses may be adequate for the treatment of uncomplicated urinary tract infections.

[b] Some strains of *P. aeruginosa* may rapidly develop resistance to these agents during therapy.

[c] Ertapenem, an additional drug in this class, has less in vitro activity and should not be used for the treatment of *Pseudomonas* infections.

[d] Trovafloxacin, an additional fluoroquinolone with antipseudomonal activity, has limited usefulness because of its hepatotoxicity. Gatifloxacin and moxifloxacin have in vitro activity against *P. aeruginosa* (albeit less than ciprofloxacin and levofloxacin), but there are no clinical studies to support their use in *Pseudomonas* or nosocomial infections.

Abbreviations: MD, multidose; ODD, once-daily dosing; CNS, central nervous system.

INFECTIONS CAUSED BY OTHER *PSEUDOMONAS* SPECIES AND RELATED BACTERIA

Burkholderia cepacia Like *P. aeruginosa*, *B. cepacia* is primarily an opportunistic pathogen that is implicated in both sporadic endemic infections and occasional nosocomial outbreaks. *B. cepacia* is actually a complex of closely related bacteria, and the species is now divided into nine distinct genomovars based on molecular sequencing and biochemical analysis. Hospital epidemics are most frequently associated with a liquid reservoir or a moist environmental surface. Colonization by this organism precedes infection, and distinction between the two is often difficult. *B. cepacia* has been reported to cause pneumonia, urinary tract infections, meningitis, peritonitis, surgical and burn wound infections, bacteremia, and endocarditis related to injection drug use. In addition, *B. cepacia* has been implicated as a cause of chronic lower respiratory tract infections in patients with chronic granulomatous disease, in patients with sickle cell hemoglobinopathies, and—together with *P. aeruginosa*—in patients with cystic fibrosis. For cystic fibrosis patients, chronic *B. cepacia* respiratory infection (especially that involving genomovar III) is of special concern, as it portends an unusually rapid decline in pulmonary function and a poor clinical prognosis. Moreover, in some patients with cystic fibrosis, *B. cepacia* has been associated with fulminant necrotizing pneumonia, bacteremia, and a rapid downhill course.

TREATMENT

The treatment of *B. cepacia* infections typically is complicated by intrinsic resistance of the organism to several antimicrobial drugs, including many β-lactam agents, the aminoglycosides, colistin, and polymyxin B. Trimethoprim-sulfamethoxazole (TMP-SMX; 15 to 20 mg/kg per day for patients with normal renal function) is preferred for the treatment of *B. cepacia* infections, although acquired resistance to this agent has been reported. Carbapenems, third-generation cephalosporins, fluoroquinolones, minocycline, and chloramphenicol may offer activity against sensitive strains. For infections with MDR strains or those not responding to a single antibiotic, combinations of agents may display in vitro synergy and clinical efficacy. Some cystic fibrosis centers segregate patients infected with *B. cepacia* in an attempt to reduce horizontal transmission to uninfected patients. In addition, many centers consider lung transplantation contraindicated in patients with chronic infection due to genomovar III because of an unacceptably high mortality rate following surgery.

Stenotrophomonas maltophilia A ubiquitous free-living opportunistic bacterium, *S. maltophilia* has emerged as an important pathogen among hospitalized patients, particularly at cancer centers and in ICUs. Most infections are sporadic; however, nosocomial outbreaks of *S. maltophilia* infection have been linked to contaminated respiratory and inhalational equipment and water faucets. As with *P. aeruginosa* and *B. cepacia*, infection can be difficult to discriminate from colonization. Risk factors for either include prolonged hospitalization, malignancy, chemotherapy-induced mucositis and neutropenia, instrumentation (e.g., urinary, peritoneal, and central venous catheterization), and prior administration of broad-spectrum antibiotics. Intrinsic antibiotic resistance of *S. maltophilia*, based on both low outer-membrane permeability and inducible β-lactamases, is at least partly responsible for the emergence of this organism as a nosocomial pathogen under the selective pressure of antibiotic treatment.

TABLE 136-4 *Recommended Antimicrobial Therapy for Selected Infections Due to Pseudomonas aeruginosa*

Anatomical Site or Diagnosis	Preferred Therapy[a,b]	Alternative Therapy[a,b]	Comments
Bacteremia, endocarditis, wound infections, or pneumonia	Antipseudomonal penicillin *plus* aminoglycoside	Antipseudomonal penicillin *plus* ciprofloxacin (IV) *or* Antipseudomonal cephalosporin, aztreonam, or carbapenem *plus* aminoglycoside *or* ciprofloxacin (IV)	Bacteremia due to infection of an indwelling central venous catheter usually necessitates catheter removal. Monotherapy with an antipseudomonal penicillin, cephalosporin, carbapenem, or fluoroquinolone may be acceptable for patients without neutropenia, concomitant *Pseudomonas* pneumonia, septic shock, or life-threatening co-morbidity. Endocarditis: Use highest indicated doses from Table 136-3. MD is preferable to ODD for aminoglycosides. Serum aminoglycoside levels should be 10 times the MBC for the isolate. Valve replacement is often required. Wounds: Debridement is required. Pneumonia: Combination therapy should initially be employed for severe pneumonia if *P. aeruginosa* is highly suspected or confirmed by culture. Repeated or prolonged therapy may be required in patients with AIDS. Inhalational therapy for cystic fibrosis: Give 300 mg of tobramycin inhalation solution (TOBI) q12h via jet nebulizer.
Central nervous system	Ceftazidime *plus or minus* aminoglycoside	Cefepime[c] *or* ciprofloxacin (IV)[c] *or* aztreonam[c] *or* meropenem[c]	Aminoglycosides should be administered intrathecally for central nervous system infections not responding to initial IV therapy. Brain abscesses >2 cm in diameter require drainage.
Bone and joint	Antipseudomonal penicillin *plus* either aminoglycoside or ciprofloxacin	Antipseudomonal cephalosporin *or* aztreonam *or* fluoroquinolone *or* carbapenem	A 4- to 6-week course of therapy is often suggested. Limited data suggest that prolonged therapy with an oral fluoroquinolone may be equivalent to IV administration. Surgical debridement is often required for osteomyelitis that is chronic or associated with trauma, direct inoculation of bone, or extension from adjacent tissues.
Malignant external otitis	Antipseudomonal cephalosporin *or* carbapenem *or* ciprofloxacin (IV or PO)	Antipseudomonal penicillin or cephalosporin *plus* aminoglycoside	Surgical debridement is usually required. At least 4–6 weeks of therapy is suggested. Oral ciprofloxacin can be used with close follow-up for limited disease or after initial IV therapy.
Eye			
Keratitis and corneal ulcer	Tobramycin (14 mg/mL, topical solution[d]) *plus or minus* piperacillin *or* ticarcillin (6–12 mg/mL topical solution[d])	Ciprofloxacin *or* ofloxacin (0.3% topical solution[d])	Fortified aminoglycoside eyedrops require pharmacy preparation. Systemic antibiotics are reserved for severe infections with impending perforation or extension beyond the cornea (see endophthalmitis). If combination therapy is used, the second agent should be administered at least 5 min after the first.
Endophthalmitis	Same as for corneal ulcer above *plus* intravitreal amikacin (0.4 mg in 0.1 mL) *or* ceftazidime (2.25 mg in 0.1 mL)	Same as for corneal ulcer above *plus* intravitreal amikacin (0.4 mg in 0.1 mL) *or* ceftazidime (2.25 mg in 0.1 mL)	Surgical vitrectomy is usually indicated. Addition of systemic therapy with ceftazidime or an antipseudomonal penicillin plus ciprofloxacin or an aminoglycoside and subconjunctival injection of an intravitreal agent may be beneficial.
Urinary tract	Ciprofloxacin (PO or IV)	Aminoglycoside, *or* antipseudomonal penicillin or cephalosporin, *or* carbapenem	Relieve obstructions and remove foreign bodies (e.g., chronic urinary catheters and stones). Monotherapy is usually sufficient.
Dermatitis or folliculitis	None	None	Diffuse folliculitis related to spas, whirlpools, or hot tubs does not require therapy in normal hosts.

[a] Susceptibility testing should be performed on all significant *Pseudomonas* isolates in order to direct definitive therapy. Empirical antibiotic therapy for suspected *Pseudomonas* infections should take into account the institution's antimicrobial susceptibility patterns.
[b] Dosages for individual agents from each antimicrobial class are listed in Table 136-3.
[c] Clinical experience is limited for treatment of this infection with this agent. Addition of a second antipseudomonal agent is advised.
[d] 1 drop q5min X 1 h, then q15–30min for 24–48 h; frequency can then be gradually decreased.
Abbreviations: MD, multidose; ODD, once-daily dosing; MBC, minimal bactericidal concentration.

S. maltophilia has most commonly been associated with pneumonia but also causes bacteremia, urinary tract infection, wound infection, peritonitis, cholangitis, meningitis, and (rarely) endocarditis. Acute *S. maltophilia* pneumonia, an uncommon but devastating disease associated with bacteremia, is usually seen in debilitated patients in ICUs. Bacteremia is most often related to central venous catheter infection, although it may arise secondary to any focal *S. maltophilia* infection.

TREATMENT

TMP-SMX is the drug of choice for the treatment of most *S. maltophilia* infections. Other agents include ticarcillin/clavulanate, minocycline, or doxycycline, either alone or in combination with TMP-SMX. The third-generation cephalosporins cefoperazone and ceftazidime and the fluoroquinolones are occasionally active against *S. maltophilia*, but in vitro susceptibility data may not reflect the clinical efficacy of these agents. The aminoglycosides and carbapenems are almost always inactive. Indwelling catheters or appliances that are associated with infection should be removed.

Melioidosis ■ *ETIOLOGY AND EPIDEMIOLOGY* Infections caused by *B. pseudomallei* (formerly *P. pseudomallei*) constitute a broad spectrum of acute and chronic, local and systemic, clinical and subclinical disease processes collectively called *melioidosis*. *B. pseudomallei* and the infections it causes are found mainly in the tropics and are endemic in Southeast Asia, northern Australia, and—to a lesser extent—southern Asia and southern China. Melioidosis is sometimes seen outside of these regions, however, in immigrants or travelers arriving from endemic areas.

B. pseudomallei is a free-living, small, motile, aerobic gram-negative bacillary saprophyte normally found in soil, ponds, and rice paddies and on produce from endemic areas. It is occasionally a pathogen for animals, but zoonotic transmission to humans is rare. Humans con-

tract the disease during contact with *B. pseudomallei*–contaminated soil or water through exposure of abraded skin, percutaneous inoculation, nasal instillation, inhalation, or possibly ingestion. Unlike *B. cepacia*, *B. pseudomallei* does not cause colonization without infection and is only rarely transmitted from person to person. *B. pseudomallei* is listed as a category B biological agent by the Centers for Disease Control and Prevention (CDC) because of its potential to cause considerable morbidity and mortality if deliberately disseminated as a weapon of mass destruction.

MANIFESTATIONS Melioidosis presents in different forms. The infection may be acute, subacute, or chronic. High rates of seropositivity in endemic areas such as Vietnam, Thailand, and Malaysia suggest that many infections are clinically inapparent. The occasional diagnosis based solely on abnormal routine chest roentgenography represents asymptomatic pneumonitis. Acute pulmonary infections are the most common manifestation of melioidosis and may result from hematogenous spread or originate in the respiratory tract; these infections vary from mild bronchitis to extensive necrotizing pneumonia. Their onset may be sudden or gradual. Fever, rigors, productive cough, and marked tachypnea are common. More chronic pulmonary infections may present as productive cough, hemoptysis, and indolent fever with night sweats mimicking tuberculosis. Chest roentgenograms typically reveal upper-lobe infiltrates, occasionally with thin-walled cavities. Another common manifestation of melioidosis is an acute, localized skin infection with ulceration or abscess that is associated with nodular lymphangitis and regional lymphadenitis. Melioidosis may also present as suppurative parotitis, particularly in children. More rarely, *B. pseudomallei* may cause liver or splenic abscesses, septic arthritis, osteomyelitis, or genitourinary or central nervous system infection. Recrudescent disease arising from inactive sites of infection and perhaps triggered by intercurrent illness or other events may present in an acute or chronic form.

Either acute suppurative infections or pulmonary disease may give rise to hematogenous dissemination and the acute septicemic form of melioidosis. This progression is more likely in chronically debilitated patients, such as those with diabetes mellitus, chronic renal disease, or alcoholism. Septicemic patients may present with severe tachypnea, confusion, headache, pharyngitis, diarrhea, and pustular lesions of the head, trunk, and extremities. The skin may be flushed or cyanotic, signs of meningitis or arthritis may be apparent, the liver and spleen may be enlarged, and muscle tenderness may be striking. Chest roentgenograms show diffuse nodular densities that may expand, coalesce, and finally cavitate. The acute septicemic form of melioidosis usually follows a rapid downhill course, ending in early death. Mortality rates remain high despite optimal therapy.

DIAGNOSIS The diagnosis of melioidosis should be entertained when a febrile patient who has been in an endemic area presents with an acute lower respiratory tract illness, parotitis, lymphadenitis, or unusual skin or subcutaneous lesions or has a chest roentgenogram suggesting tuberculosis in the absence of sputum-associated tubercle bacilli. An etiologic diagnosis is suggested by the microscopic demonstration in exudate material of small, bipolar, irregularly staining, gram-negative rods with a characteristic "safety-pin" appearance and is confirmed by a culture positive for *B. pseudomallei* and/or a fourfold or greater rise in the titer of serum antibody to the organism.

℞ TREATMENT

The mainstay of treatment for melioidosis is antibiotic administration combined with appropriate surgical drainage of abscesses and aggressive support for patients with septicemic forms of the disease. The guidelines for antibiotic therapy are somewhat imprecise. Ceftazidime or carbapenems such as imipenem or meropenem appear to be the agents of choice for clinical disease, including severe infections. TMP-SMX, cefotaxime, and amoxicillin/clavulanate are possible alternatives. Fluoroquinolones are not active against *B. pseudomallei* and have no role in the treatment of melioidosis. Combination therapy with ceftazidime or imipenem plus TMP-SMX may be indicated in severe forms of melioidosis, including septicemia. Unfortunately, the increasing resistance of many strains of *B. pseudomallei* to TMP-SMX, particularly in Southeast Asia, is of concern. Patients with acute pulmonary infections who are treated with either ceftazidime or carbapenems should receive antibiotics until they show definite evidence of clinical improvement (often in 10 to 30 days), at which time they can be switched to oral maintenance or eradication therapy with a combination of chloramphenicol, TMP-SMX, and doxycycline or with the single agent amoxicillin/clavulanate for 12 to 20 weeks. Chronic disease associated with persistently positive sputum cultures and extrapulmonary suppurative disease may require treatment for up to 1 year.

Glanders ■ *ETIOLOGY AND EPIDEMIOLOGY* Glanders is primarily a systemic equine disease that is caused by *B. mallei*. Once widespread, glanders was eradicated from North America in 1938 through the extensive culling of infected or exposed horses. The disease still occurs sporadically, however, in Africa, Asia, and South America. Historically, glanders was occasionally transmitted to humans during close contact with infected horses, mules, or donkeys. *B. mallei* is believed to have been used deliberately as an agent of biological warfare during World War I, an effort resulting in the infection of large numbers of Russian horses and mules. Research on *B. mallei* as an agent of biological warfare may have continued into more recent times, including work to develop an antibiotic-resistant aerosolized form of the bacterium. The first human case of glanders since 1949 was reported in the United States in 2001 and was acquired through laboratory exposure to *B. mallei* during the course of research on defense against agents of biological warfare and terrorism. Like *B. pseudomallei*, *B. mallei* has been classified by the CDC as a category B biological agent.

MANIFESTATIONS Glanders can assume the following forms in humans: acute localized suppurative infection, acute pulmonary infection, acute septicemic infection, and chronic suppurative infection. Disease develops several days or weeks after the inoculation of *B. mallei* into the skin, usually of the hand or arm. A localized skin nodule or suppurative focus is associated with regional lymphadenitis, fever, malaise, and prostration. Mucous membrane infection results in the production of a mucopurulent discharge from the eye, nose, or lips, with the subsequent development of granulomatous ulcers. Inhalation of the organism is accompanied by the typical symptoms and signs of pneumonia. The acute septicemic form of the infection may follow local infection and is characterized by signs of sepsis frequently associated with shock and multiorgan system failure. Evidence of acute *B. mallei* dissemination may include lymphadenopathy, splenomegaly, lung abscesses, lobar consolidation, liver and splenic abscesses, and a diffuse papular or pustular eruption resembling smallpox. Mortality rates from septicemic and acute disseminated disease are high. Chronic suppurative glanders presents as multiple subcutaneous, intramuscular, and visceral abscesses. Any form of glanders could follow aerosolized dissemination of the organism—e.g., in a bioterrorist event.

DIAGNOSIS The diagnosis of glanders may be suggested by the epidemiology and clinical setting of the infection together with evidence of irregularly staining, small, bipolar, gram-negative rods in suppurative exudates. *B. mallei* can be cultured and identified with standard bacteriologic media but may be misidentified as *Pseudomonas fluorescens* or *P. putida* by automated identification systems. Molecular methods, such as 16S rRNA gene sequencing, can be used for rapid identification of *B. mallei* from culture and can discriminate this organism from closely related organisms, including *B. pseudomallei*. A single high titer of serum antibody or a fourfold increase in titer suggests recent infection. A diagnosis of glanders in the absence of close contact with an infected equine should raise suspicion regarding the deliberate, bioterrorism-related dissemination of *B. mallei*.

TREATMENT

Treatment of glanders includes appropriate supportive measures for sepsis and the surgical drainage of abscesses. Optimal antimicrobial therapy for glanders has not been adequately defined because of a lack of human infections in the antibiotic era. Ceftazidime, gentamicin, imipenem, doxycycline, and ciprofloxacin all have in vitro activity against *B. mallei*. A recent laboratory-acquired case of human glanders responded to a combination of imipenem and doxycycline, and experimental glanders in primates responds to a combination of sulfamonomethoxine (not available in the United States) and trimethoprim. It has been suggested that rational therapy for glanders should consist of the same antibiotics recommended for the treatment of melioidosis, with the specific agent chosen on the basis of in vitro susceptibility testing. As in melioidosis, long-term antimicrobial therapy is probably necessary. The antimicrobial susceptibilities of *B. mallei* organisms disseminated in the context of bioterrorism or biowarfare may not be predictable, given the possibility of bioengineered antimicrobial resistance.

Other Species *P. fluorescens* occasionally causes human disease; it is implicated particularly often in infections related to the administration of contaminated (stored) blood products and in pseudoinfections. Additional bacterial species that are associated only rarely with human infections include *P. putida*, *Pseudomonas luteola*, *Pseudomonas stutzeri*, *Pseudomonas alcaligenes*, *Pseudomonas pseudoalcaligenes*, and (all formerly *Pseudomonas* species) *Burkholderia gladioli*, *Burkholderia pickettii*, *Comamonas acidovorans*, *Comamonas testosteroni*, *Brevundimonas diminuta*, and *Brevundimonas vesicularis*.

137 SALMONELLOSIS

Cammie F. Lesser, Samuel I. Miller

Salmonellae constitute a genus of more than 2300 serotypes that are highly adapted for growth in both humans and animals and that cause a wide spectrum of disease. The growth of *S. typhi* and *S. paratyphi* is restricted to human hosts, in whom these organisms cause enteric (typhoid) fever. The remainder of *Salmonella* serotypes, referred to as nontyphoidal *Salmonella*, can colonize the gastrointestinal tracts of a broad range of animals, including mammals, reptiles, birds, and insects. More than 200 of these serotypes are pathogenic to humans, in whom they often cause gastroenteritis and can also be associated with localized infections and/or bacteremia.

ETIOLOGY Salmonellae make up a large genus of gram-negative bacilli within the family Enterobacteriaceae. In 1983, more than 2000 bacterial strains exhibiting a high degree of DNA similarity among their genomes were grouped into one species, *S. choleraesuis*. This species was further divided into seven subgroups based on host range specificity and additional DNA similarity. Almost all the strains pathogenic for humans are in subgroup 1 (*enterica* or *choleraesuis*) except for those causing rare infections [subgroups 3a (*S. arizonae*) and 3b]. The nomenclature of this large species is quite complex. For example, the correct taxonomic name for the organism that causes enteric fever is *Salmonella choleraesuis* ssp. *choleraesuis* (or subgroup 1), serovar *typhi*. A simplified system is commonly used in which the species name that predated the reclassification is accepted. For example, *S. choleraesuis* ssp. *choleraesuis*, serovar *typhi*, is referred to by its common name, *S. typhi*.

The initial identification of *Salmonella* in the clinical microbiology laboratory is based on growth characteristics. Salmonellae, like other Enterobacteriaceae, produce acid on glucose fermentation, reduce nitrates, and do not produce cytochrome oxidase. They are facultatively anaerobic and do not form spores. In addition, all salmonellae except *S. gallinarum-pullorum* are motile by means of peritrichous flagella, and all but *S. typhi* produce gas (H_2S) on sugar fermentation. Notably, only 1% of clinical isolates ferment lactose; a high level of suspicion must be maintained to detect these rare clinical lactose-fermenting isolates.

The genus *Salmonella* can be further divided into serovars based on the detection of three major antigenic determinants: the somatic O antigen [lipopolysaccharide (LPS) cell-wall components], the surface Vi antigen (restricted to *S. typhi* and *S. paratyphi* C), and the flagellar H antigen. In general, clinical laboratories initially divide *Salmonella* into serogroups (A, B, C_1, C_2, D, and E) based on reactivity to somatic O-antigen antisera. These initial groupings provide only limited clinical information since there is a high degree of cross-reactivity. Additional biochemical and serologic tests are needed to identify specific serotypes. Bacteriophage typing, plasmid profile determination, and pulsed-field gel electrophoresis analyses are used to determine whether a specific *Salmonella* strain within a serovar is responsible for an outbreak.

PATHOGENESIS All *Salmonella* infections begin with ingestion of organisms in contaminated food or water. The infectious dose of *Salmonella* varies from 10^3 to 10^6 colony-forming units. This variability probably reflects the ability of salmonellae to resist the low pH of the stomach—a powerful component of host defense. Conditions that decrease stomach acidity (an age of <1 year, antacid ingestion, or achlorhydric disease) or conditions that decrease intestinal integrity (inflammatory bowel disease, history of gastrointestinal surgery, or alteration of the intestinal flora by antibiotic administration) increase susceptibility to *Salmonella* infection.

Once salmonellae reach the small intestines, the bacteria again encounter numerous host defenses, including bile salts, lysozyme, complement, and cationic antimicrobial peptides—all components of the host's innate immune response. The salmonellae next penetrate the mucous layer of the gut and subsequently traverse the intestinal layer through phagocytic microfold (M) cells that reside within Peyer's patches. Salmonellae can also trigger the formation of membrane ruffles in normally nonphagocytic epithelial cells. These ruffles reach out and enclose adherent bacteria within large vesicles by a process referred to as *bacteria-mediated endocytosis* (BME). BME is dependent on the direct delivery of *Salmonella* proteins into the cytoplasm of epithelial cells by a specialized bacterial secretion system (*type III*

secretion). These bacterial proteins mediate alterations in the actin cytoskeleton that are required for *Salmonella* uptake.

After crossing the epithelial layer of the small intestine, *S. typhi* and *S. paratyphi*, which cause enteric (typhoid) fever, are phagocytosed by macrophages. Once internalized, the salmonellae are protected from polymorphonuclear leukocytes (PMNs), the complement system, and the acquired immune response (antibodies). However, these bacteria must survive the antimicrobial environment of the macrophage, which includes the production of reactive oxygen and nitrogen species, antimicrobial peptides, and hydrolytic enzymes. Environmental signals within the macrophage trigger alterations in regulatory systems of the phagocytosed bacteria. The best-characterized regulatory system is PhoP/PhoQ, a two-component regulon that senses changes in bacterial location and alters bacterial protein expression. For example, PhoP/PhoQ triggers the expression of outer-membrane proteins and mediates modifications in LPS so that the bacteria's outer surface can resist microbicidal activities and potentially alter host cell signaling. In addition, salmonellae encode a second type III secretion system that directly delivers bacterial proteins from the phagosome into the macrophage cytoplasm. This secretion system is essential for survival within macrophages.

Once phagocytosed, salmonellae disseminate throughout the body in macrophages via the lymphatics and colonize reticuloendothelial tissues (liver, spleen, lymph nodes, and bone marrow). Patients have relatively few or no signs and symptoms during this initial incubation stage. Signs and symptoms, including fever and abdominal pain, probably result from secretion of cytokines by macrophages when a critical number of organisms have replicated. For example, the development of hepatosplenomegaly is likely to be related to the recruitment of mononuclear cells and the development of a cell-mediated immune response to *S. typhi* colonization. The recruitment of additional mononuclear cells and lymphocytes to Peyer's patches during the several weeks after initial colonization/infection can result in marked enlargement and necrosis of the Peyer's patches.

In contrast to enteric fever, which is characterized by an infiltration of mononuclear cells into the small-bowel mucosa, nontyphoidal *Salmonella* gastroenteritis is characterized by massive PMN infiltration into both the large- and the small-bowel mucosa. This response appears to depend on the induction of interleukin (IL) 8, a strong neutrophil chemotactic factor, which is secreted by intestinal cells. The degranulation and release of toxic substances by neutrophils may result in damage to the intestinal mucosa, causing the inflammatory diarrhea observed with nontyphoidal gastroenteritis.

It is not yet known why *S. typhi* and *S. paratyphi* cause systemic disease and are host restricted, whereas the vast majority of pathogenic *Salmonella* strains cause gastroenteritis in a broad range of hosts. Recently generated genome sequences show that *S. typhi* contains more than 200 pseudogenes, which appear to be functional genes in *S. typhimurium*. These pseudogenes may have been dispensable for *S. typhi* growth in humans.

ENTERIC (TYPHOID) FEVER

Typhoid fever is a systemic disease characterized by fever and abdominal pain caused by dissemination of *S. typhi* or *S. paratyphi*. The disease was initially called *typhoid fever* because of its clinical similarity to typhus. However, in the early 1800s, typhoid fever was clearly defined pathologically as a unique illness on the basis of its association with enlarged Peyer's patches and mesenteric lymph nodes. In 1869, given the anatomical site of infection, the term *enteric fever* was proposed as an alternative designation to distinguish typhoid fever from typhus. However, to this day, the two designations are used interchangeably.

EPIDEMIOLOGY In contrast to other *Salmonella* serotypes, the etiologic agents of enteric fever—*S. typhi* and *S. paratyphi*—have no known hosts other than humans. Thus, enteric fever is transmitted only through close contact with acutely infected individuals or chronic carriers. While direct person-to-person transmission through the fecal-oral route has been documented, it is quite rare. Rather, most cases of disease result from ingestion of contaminated food or water. Health care workers occasionally acquire enteric fever after exposure to infected patients, while laboratory workers can acquire the disease after laboratory accidents.

Over the past four decades, with the advent of improvements in food handling and water/sewage treatment, enteric fever has become a rare occurrence in developed nations. Over the past 10 years, ~400 cases of typhoid fever and even fewer cases of paratyphoid fever have been reported annually in the United States. In contrast, enteric fever continues to be a global health problem, with an estimated 13 to 17 million cases worldwide resulting in ~600,000 deaths per year. Children <1 year of age appear to be most susceptible to initial infection and to the development of severe disease.

Enteric fever is endemic in most developing regions, especially the Indian subcontinent, South and Central America, and Asia, and is related to rapid population growth, increased urbanization, inadequate human waste treatment, limited water supply, and overburdened health care systems. These conditions most likely account for the recent epidemics of typhoid fever in Eastern Europe. Antibiotic resistance among salmonellae is also a rising concern and has been linked to antibiotic use in livestock. Many *S. typhi* strains contain plasmids encoding resistance to chloramphenicol, ampicillin, and trimethoprim—antibiotics that have long been used to treat enteric fever. In addition, resistance to ciprofloxacin, either chromosomally or plasmid encoded, has been observed in Asia (India and Vietnam). Morbidity and mortality are increased in outbreaks associated with antibiotic-resistant strains, presumably because of inadequate or delayed treatment.

The high worldwide prevalence of enteric fever serves as a reservoir for cases in the United States. More than 70% of U.S. cases are related to international travel within 30 days before onset. Only 3% of travelers diagnosed with enteric fever give a history of vaccination against *S. typhi* within the previous 2 years. Of U.S. cases of internationally acquired enteric fever, 80% can be linked to travel in six countries: Mexico (28%), India (25%), the Philippines (10%), Pakistan (8%), El Salvador (5%), and Haiti (4%). While the percentage of cases associated with travel to Mexico is declining, travel to the Indian subcontinent is becoming much riskier, with an incidence 18 times higher than for any other area. The trend toward an increased incidence of multidrug-resistant (MDR) *Salmonella* (see "Treatment," below) in developing countries is reflected by the increase in the proportion of U.S. cases caused by MDR strains from 0.6% in 1985–1989 to 12% in 1990–1994.

Almost 30% of the reported cases of enteric fever in the United States are domestically acquired. Although the majority of these cases (80%) are sporadic, large outbreaks do occur. In 1993, 47 culture-proven and 24 potential cases were linked to contaminated orange juice at a resort in New York. Evaluation of this outbreak led to the identification of a previously unknown chronic carrier. Similarly, evaluation of 25% of the 571 cases of domestically acquired enteric fever reported between 1985 and 1994 led to the identification of previously unknown chronic carriers.

CLINICAL COURSE Enteric fever is a misnomer, in that the hallmark features of this disease—fever and abdominal pain—are variable. While fever is documented at presentation in more than 75% of cases, abdominal pain is reported in only 20 to 40%. Thus, a high index of suspicion for this potentially lethal systemic illness is necessary when a person presents with fever and a history of recent travel to a developing country.

The incubation period for *S. typhi* ranges from 3 to 21 days. This variability is most likely related to the size of the initial inoculum and the health and immune status of the host. The most prominent symptom of this systemic infection is prolonged fever (38.8° to 40.5°C, or 101.8° to 104.9°F). A prodrome of nonspecific symptoms often precedes fever and includes chills, headache, anorexia, cough, weakness,

sore throat, dizziness, and muscle pains. Gastrointestinal symptoms are quite variable. Patients can present with either diarrhea or constipation; diarrhea is more common among patients with AIDS and among children <1 year of age. As stated above, only 20 to 40% of patients present with abdominal pain, although the majority have abdominal tenderness over the course of the disease. In general, the symptoms associated with *S. typhi* are more severe than those associated with *S. paratyphi*.

Early physical findings of enteric fever include rash ("rose spots"), hepatosplenomegaly, epistaxis, and relative bradycardia. Rose spots (Fig. 137-1) make up a faint, salmon-colored, blanching, maculopapular rash located primarily on the trunk and chest. The rash is evident in ~30% of patients at the end of the first week and resolves after 2 to 5 days without leaving a trace. Patients can have two or three crops of lesions, and *Salmonella* can be cultured from punch biopsies of these lesions. The faintness of the rash makes it difficult to detect in dark-skinned patients. On occasion, patients who remain toxic manifest neuropsychiatric symptoms described as a "muttering delirium" or "coma vigil," with picking at bedclothes or imaginary objects.

Late complications, occurring in the third and fourth weeks of infection, are most common in untreated adults and include intestinal perforation and/or gastrointestinal hemorrhage. These complications can develop despite clinical improvement and presumably result from necrosis at the initial site of *Salmonella* infiltration at the Peyer's patches of the small intestine. Both complications are life-threatening and require immediate medical and surgical interventions, with broadened antibiotic coverage for polymicrobial peritonitis (Chap. 112) and treatment of gastrointestinal hemorrhages, including bowel resection.

Rare complications whose incidences are reduced by prompt antibiotic treatment include pancreatitis, hepatic and splenic abscesses, endocarditis, pericarditis, orchitis, hepatitis, meningitis, nephritis, myocarditis, pneumonia, arthritis, osteomyelitis, and parotitis. Despite prompt antibiotic treatment, relapse rates remain at ~10% in immunocompetent hosts.

Approximately 1 to 5% of patients with enteric fever become long-term, asymptomatic, chronic carriers who shed *S. typhi* in either urine or stool for >1 year. The incidence of chronic carriage is higher among women and among persons with biliary abnormalities (e.g., gallstones, carcinoma of the gallbladder) and gastrointestinal malignancies. The anatomical abnormalities associated with these conditions presumably allow prolonged colonization.

DIAGNOSIS Since the clinical presentation of typhoid fever is relatively nondescript, the diagnosis needs to be considered in any febrile traveler returning from a developing country, especially the Indian subcontinent, the Philippines, or Latin America. Other diagnoses that should be considered in this patient population include malaria, hepatitis, bacterial enteritis, dengue fever, rickettsial infections, leptospirosis, amebic liver abscesses, and acute HIV infection (Chap. 108). Other than a positive culture, no specific laboratory test is diagnostic for enteric fever. In 15 to 25% of cases, leukopenia and neutropenia are detectable. In the majority of cases, the white blood cell count is normal despite high fever. However, leukocytosis can develop in typhoid fever (especially in children) during the first 10 days of the illness, or later if the disease course is complicated by intestinal perforation or secondary infection. Other nonspecific laboratory results include moderately elevated values in liver function tests (aminotransferases, alkaline phosphatase, and lactate dehydrogenase). In addition, nonspecific ST and T wave abnormalities can be seen on electrocardiograms.

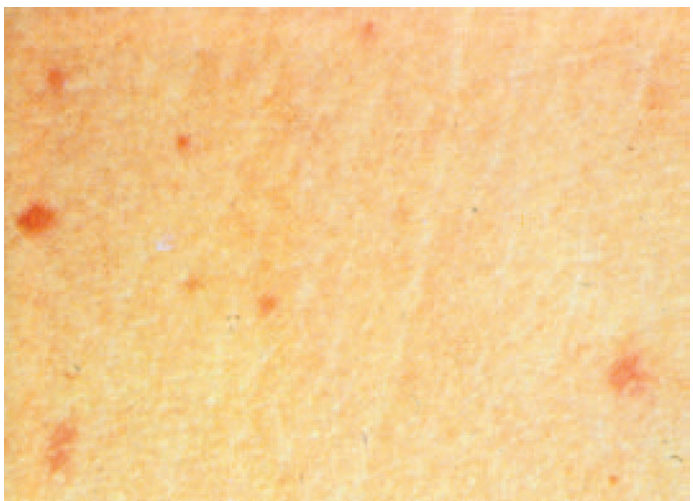

FIGURE 137-1 "Rose spots," the rash of enteric fever due to *S. typhi* or *S. paratyphi*.

The diagnostic "gold standard" is a culture positive for *S. typhi* or *S. paratyphi*. The yield of blood cultures is quite variable: it can be as high as 90% during the first week of infection and decrease to 50% by the third week. A low yield is related to low numbers of *Salmonella* (<15 organisms per milliliter) in infected patients and/or to recent antibiotic treatment. Centrifugation to isolate and culture the buffy coat, which contains abundant blood mononuclear cells associated with the bacteria, decreases time to isolation but does not affect culture sensitivity.

A diagnosis can also be based on positive cultures of stool, urine, rose spots, bone marrow, and gastric or intestinal secretions. Unlike blood cultures, bone marrow cultures remain highly (90%) sensitive despite ≤5 days of antibiotic therapy. Culture of intestinal secretions (best obtained by a noninvasive duodenal string test) can be positive despite a negative bone marrow culture. If blood, bone marrow, and intestinal secretions are all cultured, the yield of a positive culture is >90%. Stool cultures, while negative in 60 to 70% of cases during the first week, can become positive during the third week of infection in untreated patients. Although the majority of patients (90%) clear bacteria from the stool by the eighth week, a small percentage become chronic carriers and continue to have positive stool cultures for at least 1 year.

Several serologic tests, including the classic Widal test for "febrile agglutinins," are available; however, given high rates of false-positivity and false-negativity, these tests are not clinically useful. Polymerase chain reaction and DNA probe assays are being developed.

Rx TREATMENT

In the preantibiotic era, the mortality rate from typhoid fever was as high as 15%. The introduction of treatment with chloramphenicol in 1948 greatly altered the disease course, decreasing mortality to <1% and the duration of fever from 14–28 days to 3–5 days. Chloramphenicol remained the standard treatment for enteric fever until the emergence of plasmid-mediated resistance to this drug in the 1970s. Given the increased mortality associated with resistance to chloramphenicol and the rare chloramphenicol-induced bone marrow toxicity, ampicillin (1 g orally every 6 h) and trimethoprim-sulfamethoxazole (TMP-SMX; one double-strength tablet twice daily) became the mainstays of treatment.

In 1989, MDR *S. typhi* emerged. These bacteria are resistant to chloramphenicol, ampicillin, trimethoprim, streptomycin, sulfonamides, and tetracycline. Like chloramphenicol resistance, resistance to ampicillin and trimethoprim is plasmid-encoded. In 1994, 12% of *S. typhi* isolates in the United States were MDR. Thus either quinolones or third-generation cephalosporins are currently recommended for empirical antibiotic treatment (Table 137-1). Despite efficient in vitro killing of *Salmonella*, first- and second-generation cephalosporins as well as aminoglycosides are ineffective in treating clinical infections.

Quinolones are the only available oral antibiotics for the treatment of MDR *S. typhi* infections. The greatest experience has been gained for ciprofloxacin (500 mg orally twice a day for 10 days). Shorter courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 2 to 3 days) have also been successful. Limited data suggest that treatment with fluoroquinolones is associated with fewer treatment failures

TABLE 137-1 *Antibiotic Therapy Options for Typhoid Fever*

Antibiotic	Dosage
First-line	
Ciprofloxacin	500 mg PO bid for 10 days
Ceftriaxone	1–2 g IV or IM for 10–14 days
Alternative (NARST[a])	
Azithromycin	1 g PO daily for 5 days
Ciprofloxacin	10 mg/kg PO bid for 10 days

[a] Nalidixic acid—resistant *S. typhi*.

and more rapid resolution of symptoms than treatment with β-lactam agents. However, quinolone resistance is emerging. In 1993, an outbreak of nalidixic acid–resistant *S. typhi* (NARST) infections in Vietnam was linked to chromosomal mutations in the gene encoding DNA gyrase (the target of the quinolones). NARST strains have also been isolated in India. Thus, all strains of *S. typhi* must be screened for resistance to nalidixic acid and tested for sensitivity to a clinically appropriate quinolone. Patients infected with NARST strains need to be treated with higher doses of ciprofloxacin (10 mg/kg twice a day for 10 days) or longer courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 7 to 10 days) or with other antibiotics to which the strains are sensitive.

Ceftriaxone (1 to 2 g intravenously or intramuscularly) for 10 to 14 days is equivalent to oral or intravenous chloramphenicol in the treatment of susceptible strains. An alternative agent shown to be effective in an open-label study for the treatment of NARST strains is azithromycin (1 g orally once a day for 5 days or 1 g orally on day 1 followed by 500 mg orally for 6 days).

In cases of severe typhoid fever (fever; an abnormal state of consciousness—i.e., delirium, obtundation, stupor, or coma—or septic shock; and a positive culture for *S. typhi* or *S. paratyphi* A), dexamethasone treatment should be considered. In a single trial in Jakarta in the early 1980s in chloramphenicol-treated patients, treatment with dexamethasone (a single dose of 3 mg/kg followed by eight doses of 1 mg/kg, given every 6 h) decreased the mortality rate from 56% to 10%.

The 1 to 4% of patients who develop chronic carriage of *Salmonella* can be treated for 6 weeks with an appropriate antibiotic. Treatment with oral amoxicillin, TMP-SMX, ciprofloxacin, or norfloxacin has been shown to be ~80% effective in eradicating chronic carriage of susceptible organisms. However, in cases of anatomical abnormality (e.g., biliary or kidney stones), eradication of the infection often cannot be achieved by antibiotic therapy alone and requires surgical correction of the abnormalities.

PREVENTION AND CONTROL Theoretically, it is possible to eliminate salmonellae that cause enteric fever since the bacteria survive only in human hosts and are spread by contaminated food and water. However, given the high prevalence of the disease in developing countries that lack good facilities for sewage disposal and water treatment, this goal is currently unrealistic. Thus, travelers to developing countries should be advised to monitor their food and water intake carefully and to consider vaccination.

Three vaccine alternatives are currently available: (1) a heat-killed, phenol-extracted, whole-cell vaccine (two parenteral doses); (2) Ty21a, an attenuated *S. typhi* vaccine (four oral doses); and (3) ViCPS, consisting of purified Vi polysaccharide from the bacterial capsule (one parenteral dose). In addition, an acetone-killed whole-cell vaccine is available only for use by the U.S. military. The minimal ages for vaccination with the Ty21a, ViCPS, and Vi-rEPA (see below) vaccines are 6 years, 2 years, and 6 months, respectively. A large-scale meta-analysis of vaccine trials comparing the whole-cell vaccine, Ty21a, and ViCPS in populations of endemic areas indicates that, while all three vaccines have similar efficacy for the first year, the 3-year cumulative efficacy of the whole-cell vaccine (73%) exceeds that of both Ty21a (51%) and purified Vi (55%). In addition, the heat-killed whole-cell vaccine maintains its efficacy for 5 years, while Ty21a and ViCPS most likely maintain their efficacy for 4 and 2 years, respectively. However, the whole-cell vaccine is associated with a much higher incidence of side effects than the other two vaccines: 16% of whole-cell vaccine recipients develop fever and 10% miss a day of work or school, while only 1 to 2% of persons receiving the alternative vaccines have any fever. A fourth vaccine, Vi-rEPA, has been developed. This vaccine consists of Vi polysaccharide bound to a nontoxic recombinant protein that is identical to *Pseudomonas aeruginosa* exotoxin A; two parenteral doses are given. Coupling of the Vi polysaccharide to exotoxin A results in impressive T cell responses. In a trial in 2- to 5-year-old children, the vaccine provided 90% efficacy and was very well tolerated, with no serious adverse reactions. Trials of this vaccine in adults and infants are under way.

Although data on typhoid vaccines in travelers are limited, some evidence suggests that efficacy may be substantially lower than that for populations in endemic areas. The Centers for Disease Control and Prevention (CDC) currently recommends vaccination for persons traveling to developing countries who will have prolonged exposure to contaminated food and water or close contact with indigenous populations in rural areas. The only recommendations for domestic vaccination include people who have intimate or household contact with a chronic carrier or laboratory workers who frequently work with *S. typhi*. Given their decreased incidence of side effects and their similar short-term efficacy, the current bias is toward the use of Ty21a or ViCPS for vaccination of travelers.

Enteric fever is a reportable disease in the United States. Individual health departments have their own guidelines for allowing food handlers or health care workers to return to work. The reporting system enables public health departments to track down potential source patients and thus to identify and treat chronic carriers in order to prevent further outbreaks. In addition, since 1 to 4% of patients with *S. typhi* infection become chronic carriers, it is important to monitor patients (especially those employed in child care or food handling) for chronic carriage and to treat this condition if indicated.

NONTYPHOIDAL SALMONELLOSIS

EPIDEMIOLOGY The incidence of nontyphoidal salmonellosis has doubled in the United States over the past two decades. Currently, the CDC estimates that there are 2 million cases annually, with 500 to 2000 deaths. Although more than 200 serovars of *Salmonella* are considered to be human pathogens, the majority of the reported cases in the United States are caused by *S. typhimurium* or *S. enteritidis*. The incidence of salmonellosis is highest during the rainy season in tropical climates and during the warmer months in temperate climates, coinciding with the peak in food-borne outbreaks. Morbidity and mortality associated with salmonellosis are highest among the elderly, infants, and immunocompromised individuals, including those with hemoglobinopathies and those infected with HIV or with pathogens that cause blockade of the reticuloendothelial system (e.g., patients with bartonellosis, malaria, schistosomiasis, or histoplasmosis).

Unlike *S. typhi* and *S. paratyphi*, whose only reservoir is humans, nontyphoidal salmonellosis is acquired from multiple animal reservoirs. The main mode of transmission is from food products contaminated with animal products or waste—most commonly eggs and poultry but also undercooked meat, unpasteurized dairy products, seafood, and fresh produce.

S. enteritidis associated with chicken eggs is emerging as a major cause of food-borne disease. *S. enteritidis* causes infection of the ovaries and upper oviduct tissue of hens, resulting in contamination of the contents of eggs prior to shell deposition. Approximately 1 in 20,000 eggs is thought to be infected with *S. enteritidis*. Between 1974 and 1994, there was a fivefold increase (from 5% to 25%) in the isolation of *S. enteritidis* from eggs in the United States; in 1998, the U.S. Department of Agriculture estimated that 80% of all salmonellosis cases were caused by infected eggs. Eradication of *S. enteritidis* from hens has proved difficult, given that infection is spread to egg-laying

hens both vertically from breeding flocks and horizontally through contact with rodents and manure. Transmission via contaminated eggs can be prevented by cooking of eggs such that the liquid yolk is solidified or through pasteurization of egg products.

Another factor in the increasing incidence of nontyphoidal salmonellosis in developed countries, including the United States, is related to the centralization of food processing and widespread distribution. For example, a 1994 outbreak of ~250,000 cases was linked to a pasteurized ice-cream premix most likely contaminated in tanker trucks that had previously carried unpasteurized eggs. Similar outbreaks have been traced to manufactured foods including pasteurized milk, infant formula, powdered-milk products, paprika-powdered potato chips, and a ready-to-eat savory snack. In addition, large outbreaks have been linked to fresh produce, including alfalfa sprouts, cantaloupe, fresh-squeezed orange juice, and sliced tomatoes, contaminated by manure or water at a single site and then broadly distributed.

A less common source of nontyphoidal *Salmonella* infections is exposure to pets, especially reptiles. Fecal carriage rates in reptiles can be >90%. In the 1970s, 14% of cases of salmonellosis were attributed to small turtles; the U.S. Food and Drug Administration subsequently prohibited the distribution of these pets, with a resultant decline in rates of reptile-associated salmonellosis. However, since 1986, an increase in the popularity of nonbanned reptiles, including iguanas, has been followed by increases in rates of *Salmonella* infections. Other pets, including African hedgehogs, snakes, birds, rodents, baby chicks, ducklings, dogs, and cats, can also serve as potential vectors.

Antibiotic resistance is an increasing phenomenon among nontyphoidal *Salmonella* serovars. In particular, *S. typhimurium* of definitive phage type 104 (DT104)—a serotype resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines—has become prominent in the United Kingdom. This serotype is associated with greater mortality and morbidity than other nontyphoidal *Salmonella* serotypes. Its acquisition is associated with exposure to ill farm animals and to a variety of meat products. The prevalence of *S. typhimurium* DT104 in the United States increased from 0.6% in 1979–1980 to 34% in 1996. Of concern is the isolation in the United Kingdom in 1996 of *S. typhimurium* DT104 strains resistant to ciprofloxacin (14%) or trimethoprim (24%).

Also of concern is the recent increase in ceftriaxone- and fluoroquinolone-resistant nontyphoidal *Salmonella* strains in the United States. The CDC reported that the prevalence of ceftriaxone-resistant strains increased from 0 to 0.5% from 1995 to 1998. Each resistant strain appears to be an independent isolate. The majority of resistant strains have been isolated from children, where the clinical use of fluoroquinolones is limited. The likely source of resistant strains appears to be cattle and chickens treated with ceftiofur, since 2% of *S. typhimurium* strains isolated from these livestock in the United States are also resistant to ceftriaxone. In addition, at least two outbreaks of fluoroquinolone-resistant *S. typhimurium* have been reported in this country. In each instance, the index case presumably originated in the Philippines. Fluoroquinolone-resistant *S. choleraesuis* has also been documented in Taiwan. One outbreak was associated with fluoroquinolone-treated swine; thus the source of these resistant strains also appears to be livestock treated with antibiotics.

CLINICAL MANIFESTATIONS

Gastroenteritis Infection with nontyphoidal *Salmonella* most often results in gastroenteritis indistinguishable from that caused by other bacterial and viral pathogens. Nausea, vomiting, and diarrhea occur 6 to 48 h after the ingestion of contaminated food or water. Patients often experience abdominal cramping and fever (38° to 39°C, or 100.5° to 102.2°F). The diarrhea is usually characterized as loose, nonbloody stools of moderate volume. However, large-volume watery stools, bloody stools, or symptoms of dysentery do not rule out the diagnosis. Rarely, *Salmonella* causes a syndrome of pseudoappendicitis or an illness that mimics inflammatory bowel disease.

Gastroenteritis caused by nontyphoidal *Salmonella* is usually self-limited. Diarrhea resolves within 3 to 7 days and fever within 72 h. Stool cultures remain positive for 4 to 5 weeks after infection and—in rare cases of chronic carriage (<1%)—remain positive for >1 year. Antibiotic treatment usually is not recommended and in some studies has prolonged carriage of *Salmonella*. Neonates, the elderly, and the immunosuppressed (e.g., HIV-infected patients) with nontyphoidal *Salmonella* gastroenteritis are especially susceptible to dehydration and dissemination and may require hospitalization and antibiotic therapy.

Bacteremia and Endovascular Infections Up to 5% of patients with nontyphoidal *Salmonella* gastroenteritis have positive blood cultures, and 5 to 10% of these bacteremic persons develop localized infections. Bacteremia is particularly common and persistent among infants, the elderly, and patients with severe underlying infection or immunosuppression (e.g., transplant recipients, HIV-infected patients). Salmonellae have a propensity for infection of vascular sites; if >50% of three or more blood cultures are positive, an endovascular infection should be suspected. Preexisting valvular heart disease is a strong risk factor for the development of endocarditis, while atherosclerotic plaque, prosthetic grafts, and aortic aneurysms are associated with arteritis. Arteritis should be suspected in elderly patients who have a history of prolonged fever with associated back, chest, or abdominal pain preceded by gastroenteritis. Endocarditis and arteritis are rare (<1% of cases) but are associated with potentially morbid complications. Endocarditis can be complicated by cardiac valve perforation or by ring or septal abscesses, while arteritis can be associated with mycotic aneurysms, ruptured aneurysms, or vertebral osteomyelitis.

Unlike most nontyphoidal *Salmonella* serotypes, *S. choleraesuis* and *S. dublin* are frequently associated with sustained bacteremia and fever, often in the absence of a history of gastroenteritis. Similarly, these serotypes appear to be especially invasive and are often associated with metastatic infection.

Localized Infections

INTRAABDOMINAL INFECTIONS Intraabdominal infections due to nontyphoidal *Salmonella* are rare and usually manifest as hepatic or splenic abscesses or as cholecystitis. Involvement of the pancreas and adrenals and even an infected pheochromocytoma have been reported. Risk factors include anatomical abnormalities of the hepatobiliary system, including gallstones; abdominal malignancy; and sickle cell disease (especially with splenic abscesses). Eradication of the infection often requires surgical correction of anatomical abnormalities and drainage of abscesses.

CENTRAL NERVOUS SYSTEM INFECTIONS *Salmonella* infections of the central nervous system usually manifest as meningitis, although cerebral abscesses have been found. Meningitis is usually seen in neonates (<4 months old) and is associated with severe sequelae, including residual seizures, hydrocephalus, ventriculitis, abscess formation, subdural empyema, and permanent disability (e.g., mental retardation and paralysis).

PULMONARY INFECTIONS Nontyphoidal *Salmonella* pulmonary infections usually present as lobar pneumonia, sometimes complicated by lung abscesses, empyemas, pleural effusions, and bronchopleural fistulas. The majority of cases occur in patients with a preexisting abnormality of lung or pleura, including malignancy. Additional risk factors include sickle cell disease and glucocorticoid use. It is important to determine whether the pulmonary infection is in fact due to *Salmonella* or whether it is a secondary infection.

URINARY AND GENITAL TRACT INFECTIONS Urinary tract infections caused by nontyphoidal salmonellae present as either cystitis or pyelonephritis, usually in association with malignancy, urolithiasis, structural abnormalities, or immunosuppression (HIV infection, renal transplantation). Genital infections due to these bacteria are rare and present as ovarian and testicular abscesses, prostatitis, or epididymitis. Like other focal infections, both genital and urinary tract infections can be complicated by abscess formation.

BONE, JOINT, AND SOFT TISSUE INFECTIONS *Salmonella* osteomyelitis most commonly affects the femur, tibia, humerus, or lumbar vertebrae and

is most often seen in association with sickle cell disease, hemoglobinopathies, or preexisting bone disease (e.g., fractures). Prolonged antibiotic treatment is recommended to decrease the incidence of relapse and chronic osteomyelitis. Septic arthritis occurs in the same patient population as osteomyelitis and usually presents in the knee, hip, or shoulder joints. Reactive arthritis (Reiter's syndrome) can follow *Salmonella* gastroenteritis and is seen most frequently in persons with the HLA-B27 histocompatibility antigen. *Salmonella* can cause rare soft tissue infections, usually at sites of local trauma in immunosuppressed patients.

DIAGNOSIS Nontyphoidal *Salmonella* gastroenteritis is diagnosed when *Salmonella* is cultured from stool. All salmonellae isolated in clinical laboratories should be sent to local public health departments. In cases where there is concern about bacteremia (i.e., those including prolonged or recurrent fever), blood cultures are indicated. Once bacteremia is documented, it is important to determine whether it is high-grade (>50% of three or more blood cultures positive); if so, endovascular infection is possible and further evaluation to identify the source is indicated. In addition, depending on clinical symptoms and on whether metastatic disease is suspected, other body fluids, such as joint fluid or cerebrospinal fluid, should be cultured.

Rx TREATMENT

Antibiotic treatment is not generally recommended for *Salmonella* gastroenteritis. The symptoms are usually self-limited and have not been demonstrated to be altered by short courses of antibiotics. In addition, in case-control and double-blind placebo-controlled trials, antibiotic treatment has been associated with increased rates of relapse and prolonged gastrointestinal carriage. Dehydration secondary to diarrhea should be treated with fluid and electrolyte replacement.

However, preemptive antibiotic treatment should be considered in patients at increased risk for metastatic infection. These patients include neonates (probably up to 3 months of age); persons >50 years old (because of the high risk of atherosclerotic plaque or aneurysm); transplant recipients; and patients with lymphoproliferative disease, HIV infection, prosthetic joints, vascular grafts, significant joint disease, or underlying sickle cell disease. This group should receive a course of oral or intravenous antibiotics lasting for 2 or 3 days or until defervescence in immunologically normal patients. Limited data exist regarding the treatment of highly immunocompromised individuals; however, these individuals may require a longer course of therapy—perhaps 7 to 14 days, depending on the clinical scenario. Rare cases of chronic nontyphoidal *Salmonella* carriage should be treated with a prolonged antibiotic course, as described above for chronic carriage of *S. typhi*.

Focal infections or life-threatening bacteremia with nontyphoidal *Salmonella* should be treated with antibiotics (at the same doses used for enteric fever). Given the increasing prevalence of antibiotic resistance, empirical therapy should include a third-generation cephalosporin or a quinolone. If the bacteremia is low-grade (<50% of blood cultures positive), the patient should be treated for 7 to 14 days. Patients with AIDS and *Salmonella* bacteremia should receive 1 to 2 weeks of intravenous antibiotic therapy followed by 4 weeks of oral therapy with quinolones. Patients who relapse after this regimen should receive long-term suppressive therapy with a quinolone or TMP-SMX, as indicated by bacterial sensitivities.

If the patient has an endovascular infection or endocarditis, treatment for 6 weeks with intravenous β-lactam antibiotics is indicated. Chloramphenicol treatment has been associated with high failure rates and is not recommended. Limited case reports have described the successful treatment of *Salmonella* endovascular infections with quinolones, which may prove an alternative approach in cases caused by sensitive strains. However, concern remains about the development of quinolone resistance during prolonged therapy. Surgical resection of infected aneurysms or other infected endovascular sites is often required. If surgical resection is not possible, lifelong suppressive antibiotic therapy may be indicated. For extraintestinal nonvascular infections, 2 to 4 weeks of antibiotic therapy (depending on the site) are usually recommended. In cases of chronic osteomyelitis, abscesses, and urinary or biliary tract abnormality, surgical interventions may be required in addition to prolonged antibiotic therapy to eradicate infection.

PREVENTION AND CONTROL The incidence of nontyphoidal salmonellosis continues to rise along with rates of emergence of antibiotic-resistant strains. The increased centralization of food production plays a prominent role in the growing incidence, as one oversight can result in rapid, widespread distribution of contaminated food. Thus, it is important to monitor every step of food production, from handling of raw products to preparation of finished foods. In particular, with the increasing prevalence of *S. enteritidis* in egg-laying hens, it is recommended that pasteurized eggs be substituted for bulk-pooled eggs at all nursing homes, hospitals, and commercial food-service establishments. All cases of nontyphoidal salmonellosis should be reported to public health departments, since tracking and monitoring of these cases result in the identification of the sources of local outbreaks and help authorities anticipate large-scale international outbreaks. Lastly, the prudent use of antimicrobial agents in both humans and animals is necessary to minimize the further emergence of antibiotic-resistant strains.

138 SHIGELLOSIS

Gerald T. Keusch, Dennis J. Kopecko

DEFINITION *Shigellosis* is an acute infectious inflammatory colitis due to one of the members of the genus *Shigella*. Although the disease is often referred to as "bacillary dysentery," many patients have only mild watery diarrhea and never develop dysenteric symptoms. Less severe illness predominates in industrialized countries such as the United States, whereas more severe, often fatal dysentery occurs commonly in patients in developing countries.

ETIOLOGIC AGENT Shigellae are small, gram-negative, nonmotile bacilli and are members of the family Enterobacteriaceae and the tribe Escherichieae. They are so closely related to *Escherichia coli* that the two genera cannot be distinguished by DNA hybridization methods. In fact, shigellae are now thought to be differentiated pathogenic *E. coli*. The four *Shigella* species (*S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*) are defined on the basis of somatic O antigens and carbohydrate fermentation patterns. Overall, there are 43 O serotypes of *Shigella*; *S. sonnei* is the only species that exists as a single serotype. Because acquired immunity is serotype-specific, an individual can be infected multiple times by different serotypes. Shigellae are

classically lactose-negative; the exception is *S. sonnei*, which is a late, weak lactose fermenter. All shigellae produce acid but not gas from glucose; the result is a typical acid butt and alkaline slant in triple sugar iron agar without H_2S production. The genus is characterized by its ability to invade intestinal epithelial cells and to cause infection and illness in humans with a very small number of ingested bacteria, from a few hundred to a few thousand organisms.

EPIDEMIOLOGY Worldwide, it is estimated that at least 200 million clinical cases and more than 650,000 deaths due to shigellosis occur annually, primarily in developing countries and especially among children <5 years old. Shigellae are ubiquitous but have no known animal hosts other than higher primates. Poor environmental sanitation and crowding facilitate transmission from person to person. For example, a major outbreak took place in the makeshift camps for refugees fleeing the Rwandan civil war in 1994, with thousands of cases and high mortality.

The Centers for Disease Control and Prevention (CDC) maintain a national *Shigella* surveillance system based on data collected by state public health laboratories. In 2001, 10,598 isolates (primarily *S. sonnei*) were reported to the CDC, representing an apparent 45% decrease from 1991; this figure translates to an isolation rate in 2001 of 3.8/100,000 population—down from 6/100,000 a decade earlier. As in the past, the young were most susceptible, with one-fourth of isolates obtained from children <5 years old and another one-fourth from persons 5 to 19 years old. However, the reporting system seriously underestimates the number of infections occurring in the United States, both because some individuals are not sick enough to seek care and because no culture is performed in some instances when care is sought. Thus, the CDC-estimated number of *Shigella* infections in the United States approaches half a million per year. Rates are similar among males and females except among women aged 20 to 39; in this group, the rate is almost twice that among males, presumably because of greater contact with young children, especially those in day care. Cases are detected most commonly in counties with a relatively high proportion of low-income minority-group residents, including African Americans, Hispanics, and Native Americans; rates are especially high in poor urban communities, in day-care centers, and among retarded children in custodial care. Incidence rates in communities bordering Mexico are 228% higher than those in nonborder states; even so, they are several hundred times lower than those recorded among young children in many developing countries.

Since the discovery of the genus *Shigella* in 1896, major unexplained global shifts in the prevalence of its four species have been noted. Until World War I, *S. dysenteriae* type 1 was the predominant isolate, frequently causing devastating epidemics with high mortality until it was replaced by *S. flexneri*. Since World War II, *S. flexneri* has been steadily replaced by *S. sonnei* in industrialized countries. Since 1969, epidemic *S. dysenteriae* type 1 has reappeared in Latin America, in the Indian subcontinent and elsewhere in Asia, and in sub-Saharan Africa and has been associated with relatively high mortality rates due to multidrug resistance and inadequate diagnosis and case management. In contrast, *S. boydii*, the fourth species, has remained largely confined to the Indian subcontinent. The reasons for these epidemiologic trends are not clear. *Shigella* is highly host-adapted and is a natural pathogen only of humans and higher primates. It is transmitted from feces to the mouth, generally via direct person-to-person contact, although intermediate vectors such as food, water, flies, and fomites can be involved. In the United States, imported herbs and salads have recently caused multistate outbreaks. *Shigella* infection can also be transmitted during participation in recreational water sports in poorly chlorinated pools or lakes fecally contaminated by infected infants and young children and can spread rapidly among confined populations in close contact—for example, in day-care centers, in institutions for the mentally retarded, on cruise ships, or on military bases. Moreover, *Shigella* is transmitted by anal-oral sexual practices among gay men; although these infections were previously caused primarily by *S. flexneri*, *S. sonnei* now accounts for two-thirds of isolates. Similar trends are reported from Canada, Australia, and New Zealand. Rates of *Shigella* infection and recurrent disease among HIV-infected individuals greatly exceed those in the HIV-uninfected population (Chap. 173).

Shigellosis is associated with a high rate of secondary household transmission. As many as 40% of children and 20% of adults who are household contacts of a case (generally a preschool child) develop *Shigella* infection. The infection is often symptomatic in children but asymptomatic in adults, presumably because of acquired immunity in adults. In contrast, epidemic disease due to newly introduced strains affects all ages, with severe and fatal cases occurring primarily in the very young and the very old. Prolonged asymptomatic carriage of *Shigella* in humans is uncommon; unless there is underlying malnutrition, the organisms are generally cleared rapidly. However, veterinary reports suggest that long-term asymptomatic carriage of *Shigella* by nonhuman primates is not uncommon.

PATHOGENESIS AND PATHOLOGY Shigellae enter the host via the mouth. Because they are genetically equipped to survive low pH, they readily pass the gastric acid barrier. An essential step in pathogenesis is invasion of the colonic mucosa and cell-to-cell spread of infection. It was originally thought that shigellae invade the host across the absorptive epithelial cells. However, the luminal surface of colonic cells appears to be resistant to invasion. More recent experimental studies show that *Shigella* uptake occurs primarily through the antigen-sampling M cells, resulting in initial limited penetration of the lamina propria, where the organisms encounter and are ingested by resident macrophages. Shigellae multiply within and trigger apoptosis of the infected macrophage, but not before initiating the production of the proinflammatory cytokine interleukin (IL) 1β. Viable shigellae released from dead macrophages then invade the basolateral surface of the colonic epithelium, spread from cell to cell via a novel host actin-based propulsion mechanism, and provoke the synthesis of IL-8 from the epithelium. IL-8 is a chemokine that induces the migration of polymorphonuclear neutrophils (PMNs) through the epithelial cell layer into the intestinal lumen; the tight junctions are damaged as the PMNs traverse the mucosa, and this damage allows further *Shigella* invasion and exacerbates inflammation. The consequences are mucosal ulcerations and characteristic dysenteric small-volume stools consisting of mucus, cellular debris, neutrophil exudates, and blood. The host inflammatory response is essential to disease pathogenesis, and its blockade by any number of interventions interrupts the cascade from invasion to illness.

After attaching to the colonic epithelium, shigellae induce their own uptake via a host endocytic mechanism (i.e., a phagocytosis-like process) in which the bacteria are initially engulfed within plasma membrane–enclosed endosomes. Subsequently, the bacteria dissolve the endosomal vacuole and are released into the nutrient-rich cytoplasm—a step that is essential for their intracellular replication. This intracellular existence also provides the organism with a means to evade extracellular host defenses, to move within the cell to the plasma membrane, and to spread directly from cell to cell via protrusions it creates at the interface between adjacent cells.

Many of the microbial virulence features as well as the host cell biologic responses occurring during pathogenesis have been defined during the past decade, and this information has led to the following understanding of this complex process: Virulence requires the function of multiple genes and regulatory elements encoded both on the chromosome and on a large (180- to 210-kilobase pair) plasmid present in all virulent shigellae as well as in enteroinvasive *E. coli* (EIEC, which causes a *Shigella*-like disease). Some of these gene products convey acid resistance, some mediate the endocytic cell invasion process, others underlie the subsequent escape from the endosomal vacuole, and still others underlie the movement of the organism to the plasma membrane, leading to cell-to-cell transfer. The plasmid-borne invasion genes encode a type III bacterial secretion system that, upon contact with the host cell, injects invasion effectors into that cell via needle-like microbial structures. These effectors cause an actin-dependent rearrangement of the local plasma membrane, which engulfs the attached bacterium into a plasma membrane–bound endosome.

Shigellae lack flagella and are nonmotile. To move within the cell, they have evolved a novel mechanism involving the formation of a growing tail of polymerized host actin created by the microbial protein IcsA (an ATPase) localized to one pole of the bacterium. Actin polymerization and cross-linking at one end of the bacterium propel it randomly through the cytosol. Some organisms reach the plasma membrane, where they form protrusions into the adjacent cell. When these protrusions are pinched off and the resulting double host-cell membrane surrounding the organism is lysed, the bacterium lies within the cytoplasm of the newly invaded cell, and the process is repeated. Inactivation of IcsA by host phosphorylases may serve as a molecular host-defense mechanism to modulate virulence by limiting microbial spread. Another important host protein essential for cell-to-cell spread is the cadherin L-CAM. Mutations in L-CAM alter the long finger-like protrusions induced by shigellae at the plasma membrane and impair their subsequent fusion with the adjacent cell. Once a single *Shigella* organism has invaded a host epithelial cell, the entire process of bacterial escape from the endosome into the host cell's cytoplasm, multiplication, and cell-to-cell spread can take place without exposure of the bacterium to the extracellular milieu and host immune defenses. Invaded host epithelial cells ultimately die.

Another property of apparent importance in the virulence of *S. dysenteriae* type 1 (which causes the most clinically severe form of shigellosis) is the ability to produce Shiga toxin, a protein encoded by the iron-regulated chromosomal gene *stx*. Related members of this toxin family are produced by some strains of *E. coli*, including serotype O157:H7. Such strains, designated Shiga toxin–producing *E. coli* (STEC), cause hemorrhagic colitis and hemolytic-uremic syndrome (HUS). Shiga toxins are composed of two distinct peptide subunits, each with highly conserved active regions. The first, located on the larger A subunit, is an *N*-glycosidase that hydrolyzes adenine from specific sites of ribosomal RNA of the mammalian 60S ribosomal subunit, irreversibly inhibiting protein synthesis. The second conserved region is a binding site on the B subunit that recognizes the receptor glycolipid Gb3 on host cells. Receptor specificity is determined by a terminal galactose α1→4-galactose disaccharide. Wild-type toxigenic *S. dysenteriae* causes more severe illness than does an isogenic toxin-negative mutant in an experimental monkey model. The related Shiga toxins all target endothelial cells and appear to play a role in the pathogenesis of the microangiopathic complications associated with toxin-producing shigellae and *E. coli*: HUS and thrombotic thrombocytopenic purpura (TTP). Two other *Shigella* enterotoxins, ShET-1 and -2, have been described; the former is restricted almost exclusively to *S. flexneri* 2a, whereas the latter is distributed more widely (e.g., in the physiologically similar EIEC). These two enterotoxins, encoded by chromosomal and plasmid-encoded genes, respectively, alter electrolyte transport by gut segments in vitro and cause net fluid secretion in ligated rabbit ileal loops in vivo. Although both toxins induce antibody in infected humans, their role (if any) in the pathogenesis of the watery-diarrhea phase of shigellosis remains uncertain.

The characteristic pathology of human bacillary dysentery is extensive ulceration of the epithelial surface of the colonic mucosa, with an exudate consisting of desquamated colonic cells, PMNs, and erythrocytes that may resemble a pseudomembrane in severely affected areas. Marked mucus depletion and increased mitotic activity are evident in the crypt regions and presumably reflect a response to the loss of surface colonic cells. The lamina propria is edematous and hemorrhagic and is infiltrated by neutrophils and plasma cells. There is also swelling of capillary and venular endothelial cells, with margination of neutrophils. At the ultrastructural level, intraepithelial-cell bacteria can be seen within endosomes as well as free in the cytoplasm. Histologic examination of colon from dysenteric humans shows an alteration of mucosal endothelial cells similar to that induced by endotoxin (lipopolysaccharide, LPS). Shiga toxin also targets endothelial cells, especially when toxin receptor expression is upregulated by exposure to LPS or proinflammatory cytokines. Circulating LPS is detectable in human shigellosis and is present in blood at especially high levels in *S. dysenteriae* type 1 infection, even without detectable bacteremia. Variation in the lipid A component of LPS is related to virulence—an observation that further suggests the importance of LPS in pathogenesis. One likely mechanism involves the ability of LPS to induce cytokine gene transcription and the strong association of cytokine secretion and inflammation. However, bacterial invasion of the colonic mucosa itself activates the transcription factor NF-κB, which is involved in regulation of cytokine synthesis. Cytokine-producing cells are present in the colonic mucosa of patients infected with *S. dysenteriae* or *S. flexneri* and in their stools as well. In fact, the number of cells producing IL-1, IL-6, interferon γ, and transforming growth factor β is directly related to the severity of inflammation. These inflammatory processes persist longer in children than in adults; this difference may reflect the lesser efficacy of the immune responses of the young in clearing the offending pathogen. Resolution of disease symptoms probably involves clearance of the organisms by both nonspecific immune defenses (i.e., PMNs and accelerated intestinal cell turnover) and specific immune defenses, with down-modulation of inflammation and repair of damaged mucosa.

Epidemiologic evidence indicates that protective immunity develops and is serotype-specific (i.e., LPS-related). Despite much effort, the precise nature of this immunity has not been elucidated. Common surface outer-membrane proteins involved in invasion elicit serum antibodies that, although cross-reactive among *Shigella* species and serotypes, do not seem to be protective. The serotype-specific determinants are likely to be the somatic antigens, as serum antibody to LPS predicts resistance to infection and evidence exists for IgA-mediated mucosal responses to LPS during convalescence from shigellosis.

CLINICAL MANIFESTATIONS Shigellosis in the United States, due primarily to *S. sonnei*, is typically a pediatric ambulatory disease, presenting as a self-limited nonbloody but inflammatory watery diarrhea containing many neutrophils. The clinical spectrum of shigellosis was clearly shown in an experiment in which adult volunteers ingested 10,000 virulent *S. flexneri* type 2a organisms. Approximately one-fourth of the volunteers never became ill. However, over the first 24 to 48 h, one-fourth developed transient fever, another one-fourth had fever and self-limited watery diarrhea, and the remaining one-fourth had fever and watery diarrhea that progressed to bloody diarrhea and dysentery. In young children in particular, body temperature can rise rapidly to 40° to 41°C, sometimes resulting in generalized seizures; however, they rarely recur or result in serious sequelae. Fever is part of a cytokine-mediated response to infection that includes anorexia and muscle catabolism initiating negative nitrogen balance; additional energy is consumed in raising body temperature. This response is of significance in patients who are already poorly nourished, sometimes precipitating severe protein-energy malnutrition that can lead to later death. Dysentery is a syndrome characterized by frequent passage (usually 10 to 30 times per day) of small-volume stools consisting of blood, mucus, and pus; this diarrhea is accompanied by severe abdominal cramps and tenesmus—the painful straining with stooling that may lead to rectal prolapse (especially in young children, in whom the ligamentous support of the rectum is still poorly developed). Severe dysentery most likely involves infection due to *S. dysenteriae* type 1, occurs less commonly with *S. flexneri*, and is least likely with *S. sonnei* or *S. boydii*. Patients with mild disease generally recover without specific therapy in a few days to a week. Severe shigellosis can progress to toxic dilatation and colonic perforation, either of which may be fatal. In developing countries, shigellosis almost doubles the risk of persistent diarrhea; the mortality rate increases by tenfold when persistent *Shigella* diarrhea develops.

Endoscopy shows the mucosa to be hemorrhagic, with mucous discharge and focal ulcerations and sometimes an overlying exudate resembling a pseudomembrane. The majority of lesions are in the distal colon, with progressively fewer in the more proximal segments of large bowel. Mild dehydration is common among patients with watery diarrhea; severe dehydration is very rare. With extensive colonic involvement, protein-losing enteropathy can occur and can have impor-

tant adverse nutritional consequences, especially for already poorly nourished children. The majority of extraintestinal complications of shigellosis arise in patients in developing countries and are related both to the prevalence of infections caused by *S. dysenteriae* type 1 and *S. flexneri* and to the poor nutritional state of the hosts. For example, bacteremia, thought to occur relatively infrequently among patients with shigellosis in the United States, develops in up to 8% of patients hospitalized for shigellosis in Dacca, Bangladesh. The causative *Shigella* species is isolated from half of these patients, while other Enterobacteriaceae are found in the remainder. Bacteremia is associated with higher-than-usual mortality and is more common among infants (<1 year old) and among persons with protein-energy malnutrition. Persistent and clinically severe *Shigella* bacteremia has been encountered in the United States only in patients with AIDS (Chap. 173).

HUS may occur with *S. dysenteriae* type 1 infection. In the United States, STEC strains (such as *E. coli* O157:H7) producing high levels of Shiga-family toxins are the most likely causes of HUS. Manifestations of HUS usually develop toward the end of the first week of shigellosis, when dysentery is already resolving. Oliguria and a marked drop in hematocrit (by as much as 10% within 24 h) are the first signs and may progress to anuria with renal failure and to severe anemia with congestive heart failure, respectively. Even with advanced therapy, 5 to 10% of patients with HUS die of the acute illness. In addition, renal damage progresses slowly over several decades in survivors, some of whom will develop significant renal failure and require long-term dialysis or renal transplantation for survival. Leukemoid reactions, with leukocyte counts of $<50{,}000/\mu L$, usually accompany HUS; thrombocytopenia, with 30,000 to 100,000 platelets/μL, is common and in adults can lead to TTP, which is part of the spectrum of the toxin-mediated microangiopathy. Profound hyponatremia and severe hypoglycemia are also encountered, especially in developing countries, and may underlie central nervous system abnormalities such as seizures and altered consciousness. *S. flexneri* is associated with a rare toxic encephalopathy that is manifested by bizarre posturing and lethal cerebral edema.

Reactive arthritis is a less common extraintestinal manifestation that is usually associated with *S. flexneri* strains. In patients expressing histocompatibility antigen HLA-B27, the full triad of Reiter's syndrome sometimes develops weeks to months after diarrheal illness (Chap. 305). Pneumonia, meningitis, vaginitis (in prepubertal girls), keratoconjunctivitis, and "rose spot" rashes are rare events.

DIAGNOSIS AND LABORATORY FINDINGS Shigellosis is the principal bacterial cause of dysentery and should be considered whenever a patient presents with bloody diarrhea. However, in the United States, because *S. sonnei* is the most common infecting *Shigella* species, most patients present with fever and nonbloody watery diarrhea that are indistinguishable from the signs caused by other bacterial or viral agents of mild to moderate diarrhea. In this country, many patients with bloody diarrhea have STEC or *Campylobacter jejuni* identified as the cause. The specific diagnosis is based on culture of *Shigella* from the stool; sensitive and specific diagnostic methods based on the polymerase chain reaction have been developed but are not yet widely available. A commercial enzyme immunoassay to detect Shiga-family toxins in stool can identify most patients infected with *S. dysenteriae* type 1 (rare in the United States) or STEC within 3 h. The yield of *Shigella* in culture is increased if the patient has fecal leukocytes or bloody diarrhea. The organism is very labile and must be transferred quickly to plates or holding media (such as buffered glycerol saline) if it is to be isolated. Stool samples are preferable to swabs; when the latter are used, a rectal sample should be obtained. More than one differential selective medium should be used for culture—i.e., MacConkey and one other medium, such as Hektoen enteric or xylose-lysine-deoxycholate. Stool cultures to diagnose nonbloody watery diarrhea have a very low yield of positives and are not considered to be cost-effective in the United States.

Serologic tests can be performed, since antibodies to somatic antigens develop early in the acute phase of disease. However, the reagents for such tests generally are not available, even in the United States, and serologic assessments are usually used only for epidemiologic studies.

The differential diagnosis includes inflammatory colitis due to other microbial agents: STEC, EIEC, *C. jejuni*, *Salmonella enteritidis*, *Yersinia enterocolitica*, *Clostridium difficile*, and the protozoan *Entamoeba histolytica*. Ulcerative colitis and Crohn's colitis are among the "noninfectious" conditions that should be considered (Chap. 276). All these infections except that due to *E. histolytica* are associated with the presence of large numbers of fecal leukocytes. Amebiasis can be diagnosed by the detection of erythrophagocytic trophozoites in the stool or by immunoassay (Chap. 194).

Other laboratory studies are nonspecific and may disclose neutrophilic leukocytosis, anemia due to blood loss with hemorrhagic diarrhea, prerenal azotemia, or (if watery diarrhea has been pronounced) hyperchloremic acidosis. Laboratory findings in shigellosis complicated by HUS are discussed above.

TREATMENT

The mild to moderate dehydration in shigellosis is readily corrected with oral rehydration solutions (Chap. 140). The role of antibiotic therapy depends on the bacterial species involved and the severity of disease. Since *S. sonnei* infection is usually self-limited, culture results generally do not become available until the patient is better and there is little clinical need for further therapy. The use of antibiotics in severe cases with bloody diarrhea or dysentery reduces the duration of illness and can shorten the carriage state. Resistance to sulfonamides, streptomycin, chloramphenicol, and tetracyclines is almost universal, and many shigellae are now resistant to ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX) as well. Knowledge of the pattern of resistance in a given population, which can change with time, is essential. In the United States, multiresistant strains are most likely to be acquired during travel abroad; therefore, for domestically acquired infection, either ampicillin or TMP-SMX remains the drug of choice unless resistance is known to be prevalent in particular communities (Table 138-1). Amoxicillin should not be substituted for ampicillin; it is ineffective because it is too well absorbed proximally and does not reach bacteria in the colonic lumen. Similarly, nonabsorbable antibiotics are ineffective because they do not reach the mucosal bacterial population. Short courses of treatment (1 or 3 days) or even single doses of a fluoroquinolone such as ciprofloxacin or the macrolide azithromycin have been employed with success. In developing countries, where resistance to ampicillin and TMP-SMX is commonplace, the drug of choice for the treatment of multiresistant *S. dysenteriae* type 1 infections is nalidixic acid; however, resistance to the latter agent is increasing in prevalence with its increasing use. The fluoroquinolones (e.g., ciprofloxacin, ofloxacin) are highly effective against all strains (Chap. 118) but are currently too costly for use in the developing world and are not yet approved for use in children <17 years old in the United States; these drugs have caused cartilage damage in young rodents during toxicity tests, although there is no evidence for a similar effect at therapeutic doses in humans. Alternative drugs shown to be effective include oral pivamdinocillin (amdinocillin, pivoxil, pivmecillinam; still not available in the United States), azithromycin, and intravenous ceftriaxone (50 mg/kg per day for 5 days). In small-scale clinical trials, 2 to 5 days of cefixime treatment resulted in the resolution of clinical symptoms due to *S. sonnei*, but the relapse rate was 20 to 24%. (Cefixime is not currently available in the United States.) Single doses of ceftriaxone may be effective, but more clinical data are needed. No antibiotic treatment is recommended for the convalescent carrier state, which usually lasts no more than a few weeks—i.e., for a much shorter period than is seen with nontyphoidal *Salmonella* or *Salmonella typhi*. Patients with AIDS can develop chronic carriage of *Shigella* and may be subject to relapsing infection with bacteremia (Chap. 173). This cycle can be interrupted by several weeks of treatment with a quinolone.

The role of antimotility agents such as atropine sulfate and di-

TABLE 138-1 *Options for Oral Antibiotic Treatment of Shigellosis*

Drug	Dose/Duration: Children	Dose/Duration: Adults	Daily Cost ($US)[a]	Comments
UNITED STATES				
Ampicillin	100 mg/kg q6h × 5 d	500 mg q6h × 5 d	$0.12/kg, liquid form $0.88, capsule form	Resistance varies with locale and is very common when infection is acquired abroad. Diarrhea is a frequent side effect.
Trimethoprim-sulfamethoxazole	10/50 mg/kg bid × 3–5 d	160/800 mg (1 DS tablet) bid × 3–5 d	$0.26/kg, liquid form $0.64, tablet form	Resistance varies with locale and is very common when infection is acquired abroad.
Ciprofloxacin	15 mg/kg q12h × 3–5 d; 500 mg max/dose	500 mg bid × 3 d	$0.17/kg, liquid form $10.80, tablet form	Resistance rates are low. Regimen is not licensed for use in children <17 years old, but there is no evidence of toxicity.
Azithromycin	12 mg/kg on day 1 (max, 500 mg), 6 mg/kg on days 2–5 (max, 250 mg/d)	1 g (single dose)	$0.37/kg day 1 (liquid) $27.00, adult tablet form	Single-dose regimen for adults is attractive but has not been tested in children.
Cefixime[b]	8 mg/kg (max, 400 mg) once daily × 5 d	400 mg/d × 5 d	$0.30/kg, liquid form $8.80, adult tablet form	Efficacy differs in different studies. Some studies show bacteriologic relapse rates of 20–24%.
DEVELOPING COUNTRIES				
Naladixic acid	55 mg/kg, divided into daily dose × 5 d	1 g qid × 5 d	$0.20/kg, children $16.00/d, adults	This is not an FDA-approved indication for either children or adults. Prices are likely to be lower in developing countries.

[a] Redbook 2003 average wholesale prices; for comparison only, as actual cost to pharmacies and charges to patients vary greatly.

[b] Cefixime is not currently available in the United States.

Note: DS, double strength; FDA; U.S. Food and Drug Adminstration.

phenoxylate (Lomotil) and loperamide (Imodium) in the early phases of shigellosis is controversial. Loperamide, in particular, may reduce diarrhea volume and in one study was highly effective in combination with antimicrobial therapy. However, antimotility drugs are suspected of enhancing the severity of disease by delaying excretion of organisms and facilitating further invasion of the mucosa, potentially increasing the likelihood of complicating toxic megacolon. Therefore, they are contraindicated in infants and young children. In adults, these agents are contraindicated for use in the dysenteric phase of disease.

Unique therapies are also being tested. Hyperimmune bovine colostrum containing high titers of antibody to *S. dysenteriae* type 1 LPS did not alter the clinical course of disease when coadministered with an effective antibiotic. An energy-dense diet did not improve the outcome of acute shigellosis in malnourished children but appeared to hasten the resolution of rectal prolapse. An interesting experimental approach is the use of engineered avirulent bacteria hyperexpressing Shiga toxin receptors to bind and prevent the biologic effects of the toxin.

Treatment of complications of shigellosis often differs in developed and developing countries. For example, antibiotic-unresponsive toxic megacolon, with or without perforation, is often managed by colectomy and ileostomy in the United States. Surgery is less often employed in developing countries because of a lack of surgical services or difficulties in ileostomy management; instead, management concentrates on antibiotic administration and conservative fluid and electrolyte support. HUS often requires dialysis; however, in developing countries, the threshold for dialysis may be higher than in the United States because azotemia is slow to develop and the risk of significant hyperkalemia is often diminished by a preexisting deficiency in total-body potassium due to malnutrition and wasting of lean body mass. The management of hyponatremia, usually caused by inappropriate secretion of antidiuretic hormone (vasopressin), is governed by the severity of the condition and the symptomatic state of the patient, as outlined in Chap. 41. Infusion of glucose can reverse clinical manifestations caused by hypoglycemia, and responses can be monitored by finger-stick blood glucose tests if no biochemistry laboratory is available. In developing countries, optimal nutritional management is needed to correct deficiencies due to underlying malnutrition as well as the superimposed catabolic stress and protein-losing enteropathy of shigellosis. Nutritional support should begin during the acute illness and is required for months thereafter (Chap. 63).

PREVENTION There are no licensed vaccines against *Shigella*, although considerable effort is being directed toward the development of a safe and effective vaccine. Direct-contact transmission of shigellosis can be prevented by appropriate environmental and personal hygiene. Hand washing with soap and water when caring for infected infants, handling diapers, or preparing food is effective, and efficacy can be enhanced by the use of a triclosan antibacterial soap. Safe water supplies and sanitary latrines or toilets significantly reduce the primary and secondary transmission of *Shigella* infection. In highly endemic developing countries, infants are protected during the period of exclusive breast-feeding, which should be encouraged wherever HIV transmission via breast-feeding is not a consideration. Any measures that reduce the burden of malnutrition also reduce the burden of shigellosis in the population. Stool precautions should be instituted for hospitalized infected patients to ensure safe disposal of infected excreta and linens, and hospital personnel must wash and disinfect their hands and medical instruments (such as stethoscopes) after each contact with an infected patient. In the United States, cohorting of asymptomatic infected children, use of antibiotics to reduce infectiousness, and scrupulous attention to hygiene are usually successful in nosocomial outbreaks. Children in day care must be kept at home while clinically ill and ideally should have one negative stool culture before returning to the day-care facility. Likewise, food handlers who develop shigellosis should be culture-negative before returning to work. Antibiotic treatment is not indicated for the asymptomatic carrier state.

139 INFECTIONS DUE TO *CAMPYLOBACTER* AND RELATED SPECIES

Martin J. Blaser

DEFINITION Bacteria of the genus *Campylobacter* and of the related genera *Arcobacter* and *Helicobacter* (Chap. 135) cause a variety of inflammatory conditions. Although acute diarrheal illnesses are most common, these organisms may cause infections in virtually all parts of the body, especially in compromised hosts, and these infections may have late nonsuppurative sequelae. The designation *Campylobacter* comes from the Greek for "curved rod" and refers to the organism's vibrio-like morphology.

ETIOLOGY Campylobacters are motile, non-spore-forming, curved gram-negative rods. Originally known as *Vibrio fetus*, these bacilli were reclassified as a new genus in 1973, after it was recognized that they were quite dissimilar to other vibrios. Since then, >15 species have been identified. These species are currently divided into three genera: *Campylobacter*, *Arcobacter*, and *Helicobacter*. Not all of the species are pathogens of humans. The human pathogens can be divided into two major groups: those that primarily cause diarrheal disease and those that cause extraintestinal infection. The principal diarrheal pathogen is *C. jejuni*, which accounts for 80 to 90% of all cases of recognized illness due to campylobacters. Other organisms that cause diarrheal disease include *C. coli*, *C. upsaliensis*, *C. lari*, and *C. fetus*. The major species causing extraintestinal illnesses is *C. fetus*; however, any of the diarrheal agents may cause systemic or localized infection as well. Neither aerobes nor strict anaerobes, these microaerophilic organisms are adapted for survival in the gastrointestinal mucous layer. This chapter will focus on *C. jejuni* and *C. fetus* as the major pathogens and prototypes for their groups; the key features of infection are listed by species (excluding *C. jejuni*, described in detail in the text below) in Table 139-1.

EPIDEMIOLOGY Campylobacters are found in the gastrointestinal tract of many animals used for food (including poultry, cattle, sheep, and swine) and of many household pets (including birds, dogs, and cats). These microorganisms usually do not cause illness in their animal hosts. In most cases, campylobacters are transmitted to humans in raw or undercooked food products or through direct contact with infected animals. In the United States and other developed countries, ingestion of contaminated poultry that has not been sufficiently cooked is the most common means of acquiring infection (50 to 70% of cases). Other modes of transmission include ingestion of raw (unpasteurized) milk or untreated water, contact with infected household pets, travel to developing countries (campylobacters being among the causes of traveler's diarrhea; Chap. 113), oral-anal sexual contact, and (occasionally) contact with an index case who is incontinent of stool.

Campylobacter infections are common. Several studies indicate that, in the United States, diarrheal disease due to campylobacters is more common than that due to *Salmonella* and *Shigella* combined. Infections occur throughout the year, but their incidence peaks during summer and early autumn. Persons of all ages are affected; however, attack rates for *C. jejuni* are highest among young children and young adults, while those for *C. fetus* are highest at the extremes of age. Systemic infections due to *C. fetus* (and to other *Campylobacter* and related species) are most common in compromised hosts. Persons at increased risk include those with AIDS, hypogammaglobulinemia, neoplasia, liver disease, diabetes mellitus, and generalized atherosclerosis as well as neonates and pregnant women. However, apparently healthy nonpregnant persons occasionally develop transient *Campylobacter* bacteremia as part of a gastrointestinal illness.

In developing countries, *C. jejuni* infections are hyperendemic, with the highest rates among children <2 years old. Infection rates fall with age, as does the illness-to-infection ratio; these observations suggest that frequent exposure to *C. jejuni* leads to the acquisition of immunity.

PATHOLOGY AND PATHOGENESIS Many *C. jejuni* infections are subclinical, especially in hosts in developing countries who have had multiple prior infections and thus are partially immune. Most illnesses occur within 2 to 4 days (range, 1 to 7 days) of exposure to the organism in food or water. The sites of tissue injury include the jejunum, ileum, and colon. Biopsies show an acute nonspecific inflammatory reaction, with neutrophils, monocytes, and eosinophils in the lamina propria, as

TABLE 139-1 Clinical Features Associated with Infection Due to "Atypical" Campylobacter and Related Species Implicated as Causes of Human Illness

Species	Common Clinical Features	Less Common Clinical Features	Additional Information
Campylobacter coli	Fever, diarrhea, abdominal pain	Bacteremia[a]	Clinically indistinguishable from *C. jejuni*
Campylobacter fetus	Bacteremia,[a] sepsis, meningitis, vascular infections	Diarrhea, relapsing fevers	Not usually isolated from media containing cephalothin or incubated at 42°C
Campylobacter upsaliensis	Watery diarrhea, low-grade fever, abdominal pain	Bacteremia, abscesses	Difficult to isolate because of cephalothin susceptibility
Campylobacter lari	Abdominal pain, diarrhea	Colitis, appendicitis	Seagulls frequently colonized; organism often transmitted to humans via contaminated water
Campylobacter hyointestinalis	Watery or bloody diarrhea, vomiting, abdominal pain	Bacteremia	Causes proliferative enteritis in swine
Helicobacter fennelliae	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones
Helicobacter cinaedi	Chronic mild diarrhea, abdominal cramps, proctitis	Bacteremia[a]	Best treated with fluoroquinolones; identified in healthy hamsters
Campylobacter jejuni subspecies *doylei*	Diarrhea	Chronic gastritis, bacteremia[b]	Uncertain role as human pathogen
Arcobacter cryaerophila	Diarrhea	Bacteremia	Cultured under aerobic conditions
Arcobacter butzleri	Fever, diarrhea, abdominal pain, nausea	Bacteremia, appendicitis	Cultured under aerobic conditions; enzootic in nonhuman primates
Campylobacter sputorum	Pulmonary, perianal, groin, and axillary abscesses	Bacteremia	Three clinically relevant biovars: *C. sputorum* subspecies *sputorum*, *C. sputorum* subspecies *bubulus*, and *Campylobacter mucosalis*

well as damage to the epithelium, including loss of mucus, glandular degeneration, and crypt abscesses. Biopsy findings may be consistent with Crohn's disease or ulcerative colitis, but these "idiopathic" chronic inflammatory diseases should not be diagnosed unless infectious colitis, *specifically including* that due to infection with *Campylobacter* species and related organisms, has been ruled out.

The high frequency of *C. jejuni* infections and their severity and recurrence among hypogammaglobulinemic patients suggest that antibodies are important in protective immunity. The pathogenesis of infection is uncertain. Both the motility of the strain and its capacity to adhere to host tissues appear to favor disease, but classic enterotoxins and cytotoxins (although described and including cytolethal distending toxin, or CLDT) appear not to play any substantial role in tissue injury or disease production. The organisms have been visualized in the epithelium, albeit in low numbers. The documentation of a significant tissue response and occasionally of *C. jejuni* bacteremia further suggests that tissue invasion is clinically significant.

The pathogenesis of *C. fetus* infections is better defined. Virtually all clinical isolates of *C. fetus* possess a proteinaceous capsule-like structure (an S-layer) that renders the organism resistant to complement-mediated killing and opsonization. As a result, *C. fetus* can cause bacteremia and can seed sites beyond the intestinal tract. The ability of the organism to switch the S-layer proteins expressed, a phenomenon that results in antigenic variability, may contribute to the chronicity and high rate of recurrence of these infections in compromised hosts.

CLINICAL MANIFESTATIONS OF *C. JEJUNI* AND *C. FETUS* INFECTIONS The clinical features of infections due to all of the *Campylobacter* and related species causing enteric disease appear to be highly similar. There is often a prodrome, with fever, headache, myalgia, and/or malaise, 12 to 48 h before the onset of diarrheal symptoms. The most common signs and symptoms of the intestinal phase are diarrhea, abdominal pain, and fever. The degree of diarrhea varies from several loose stools to grossly bloody stools; most patients presenting for medical attention have 10 or more bowel movements on the worst day of illness. Abdominal pain usually consists of cramping and may be the most prominent symptom. Pain is usually generalized but may become localized; *C. jejuni* infection may cause pseudoappendicitis. Fever may be the only initial manifestation of *C. jejuni* infection, a situation mimicking the early stages of typhoid fever. Febrile young children may develop convulsions. *Campylobacter* enteritis is generally self-limited; however, symptoms persist for >1 week in 10 to 20% of patients seeking medical attention, and relapses occur in 5 to 10% of untreated patients.

C. fetus may cause a diarrheal illness similar to that due to *C. jejuni*, especially in normal hosts, or may cause either intermittent diarrhea or nonspecific abdominal pain without localizing signs. Sequelae are uncommon, and outcome is benign. *C. fetus* may also cause a prolonged relapsing systemic illness (with fever, chills, and myalgias) that has no obvious primary source; this manifestation is especially common in compromised hosts. Secondary seeding of an organ (e.g., meninges, brain, bone, urinary tract, or soft tissue) complicates the course, which may be fulminant. *C. fetus* infections have a tropism for vascular sites: endocarditis, mycotic aneurysm, and septic thrombophlebitis may all occur. Infection during pregnancy often leads to fetal death. *H. cinaedi* causes recurrent cellulitis with fever and bacteremia in immunocompromised hosts.

COMPLICATIONS Except in the case of infection with *C. fetus*, bacteremia is uncommon, developing most often in immunocompromised hosts and at the extremes of age. Three patterns of extraintestinal infection have been noted: (1) transient bacteremia in a normal host with enteritis (benign course, no specific treatment needed); (2) sustained bacteremia or focal infection in a normal host (bacteremia originating from enteritis, with patients responding well to antimicrobial therapy); and (3) sustained bacteremia or focal infection in a compromised host. Enteritis may not be clinically apparent. Antimicrobial therapy, possibly prolonged, is necessary for suppression or cure of the infection.

Campylobacter infections in patients with AIDS or hypogammaglobulinemia may be severe, persistent, and extraintestinal; relapse after cessation of therapy is common. Hypogammaglobulinemic patients may also develop osteomyelitis and an erysipelas-like rash.

Local suppurative complications of infection include cholecystitis, pancreatitis, and cystitis; distant complications include meningitis, endocarditis, arthritis, peritonitis, cellulitis, and septic abortion. All are rare. Hepatitis, interstitial nephritis, and the hemolytic-uremic syndrome occasionally complicate acute infection. Reactive arthritis and other rheumatologic complaints may develop several weeks after infection, especially in persons with the HLA-B27 phenotype. Guillain-Barré syndrome follows *Campylobacter* infections uncommonly (i.e., in 1 of every 1000 to 2000 cases). For certain *C. jejuni* serotypes, such as O19, Guillain-Barré syndrome may occur once following 100 or 200 cases. Because of their high incidence, it is now estimated that *Campylobacter* infections may trigger 20 to 40% of all cases of Guillain-Barré syndrome.

DIAGNOSIS In patients with *Campylobacter* enteritis, peripheral leukocyte counts reflect the severity of the inflammatory process. However, stools from nearly all *Campylobacter*-infected patients presenting for medical attention in the United States contain leukocytes or erythrocytes. Fecal smears should be treated with Gram's or Wright's stain and examined in all suspected cases. When the diagnosis of *Campylobacter* enteritis is suspected on the basis of findings indicating inflammatory diarrhea (fever, fecal leukocytes), clinicians can ask the laboratory to attempt the visualization of organisms with characteristic vibrioid morphology by direct microscopic examination of stools with Gram's staining or to use phase-contrast or dark-field microscopy to identify the organisms' characteristic "darting" motility. Confirmation of the diagnosis of *Campylobacter* infection is based on identification of an isolate from cultures of stool, blood, or another site. *Campylobacter*-specific media should be used to culture stools from all patients with inflammatory or bloody diarrhea. Since all *Campylobacter* species are fastidious, they will not be isolated unless selective media or other selective techniques are used. Not all media are equally useful for isolation of the broad array of campylobacters; therefore, failure to isolate campylobacters from stool does not entirely rule out their presence. The detection of the organisms in stool almost always implies infection; there is a brief period of postconvalescent fecal carriage and no commensalism in humans. In contrast, *C. sputorum* and related organisms found in the oral cavity are commensals with rare pathogenic significance.

DIFFERENTIAL DIAGNOSIS The symptoms of *Campylobacter* enteritis are not sufficiently unusual to distinguish this illness from that due to *Salmonella*, *Shigella*, or *Yersinia*, among other pathogens. The combination of fever and fecal leukocytes or erythrocytes is indicative of inflammatory diarrhea, and definitive diagnosis is based on culture or demonstration of the characteristic organisms on stained fecal smears. Similarly, extraintestinal *Campylobacter* illness is diagnosed by culture. Infection due to *Campylobacter* should be suspected in the setting of septic abortion and that due to *C. fetus* specifically in the setting of septic thrombophlebitis. It is important to reiterate that the presentation of *Campylobacter* enteritis may mimic that of ulcerative colitis or Crohn's disease, that *Campylobacter* enteritis is much more common than either of the latter (especially among young adults), and that biopsy may not be able to distinguish among these entities. Thus a diagnosis of inflammatory bowel disease should not be made until *Campylobacter* infection has been ruled out, especially in persons with a history of foreign travel, significant animal contact, immunodeficiency, or exposure incurring a high risk of transmission.

TREATMENT

Fluid and electrolyte replacement is central to the treatment of diarrheal illnesses (Chap. 113). Even among patients presenting for medical attention with *Campylobacter* enteritis, fewer than half will clearly benefit from specific antimicrobial therapy. Indications for such therapy include high fever, bloody diarrhea, severe diarrhea, persistence

for >1 week, and worsening of symptoms. A 5- to 7-day course of erythromycin (250 mg orally four times daily or—for children—30 to 50 mg/kg per day, in divided doses) is the regimen of choice. Although no relevant clinical trials have been conducted, the in vitro susceptibility of *Campylobacter* species to macrolides such as clarithromycin and azithromycin suggests that these antibiotics would also be useful therapeutic agents. An alternative regimen for adults is ciprofloxacin (500 mg orally twice daily) or another fluoroquinolone for 5 to 7 days, but resistance to this class of agents is increasing. Other alternatives include tetracycline and furazolidone. Use of antimotility agents, which may prolong the duration of symptoms and has been associated with toxic megacolon and with death, is not recommended.

For systemic infections, treatment with gentamicin (1.7 mg/kg intravenously every 8 h after a loading dose of 2 mg/kg), imipenem (500 mg intravenously every 6 h), or chloramphenicol (50 mg/kg intravenously each day in three or four divided doses) should be started empirically, but susceptibility testing should then be performed. Ciprofloxacin and amoxicillin/clavulanate are alternative agents for susceptible strains. In the absence of immunocompromise or endovascular infections, therapy should be administered for 14 days. For immunocompromised patients with systemic infections due to *C. fetus* and for patients with endovascular infections, prolonged therapy (for up to 4 weeks) is usually necessary.

PROGNOSIS Nearly all patients recover fully from *Campylobacter* enteritis, either spontaneously or after antimicrobial therapy. Volume depletion likely contributes to the few deaths that are reported. As stated above, occasional patients develop reactive arthritis or Guillain-Barré syndrome. Systemic infection with *C. fetus* is much more often fatal than that due to related species; this higher mortality reflects in part the population affected. Prognosis is dependent on the rapidity with which appropriate therapy is begun. Otherwise healthy hosts usually survive *C. fetus* infections without sequelae. Compromised hosts often have recurrent infections.

140 CHOLERA AND OTHER VIBRIOSES

Matthew K. Waldor, Gerald T. Keusch

Members of the genus *Vibrio* cause a number of important infectious syndromes. Classic among them is cholera, a devastating diarrheal disease caused by *V. cholerae* that has been responsible for seven global pandemics and much suffering over the past two centuries. Epidemic cholera remains a significant public health concern in the developing world today. Other vibrioses have also been described, including syndromes of diarrhea, soft tissue infection, or primary sepsis caused by additional named species in the genus *Vibrio*.

All members of the genus are highly motile, facultatively anaerobic, curved gram-negative rods with one or more flagella. Except for *V. cholerae* and *V. mimicus*, all vibrios are halophilic (i.e., require salt for growth). In nature, vibrios most commonly reside in tidal rivers and bays under conditions of moderate salinity. They proliferate in the summer months when water temperatures exceed 20°C. As might be expected, the illnesses they cause also increase in frequency during the warm months.

CHOLERA

DEFINITION Cholera is an acute diarrheal disease that can, in a matter of hours, result in profound, rapidly progressive dehydration and death. Accordingly, cholera gravis (the severe form of cholera) is a much-feared disease, particularly in its epidemic presentation. Fortunately, prompt aggressive fluid repletion and supportive care can obviate the high mortality that cholera has historically wrought. While the term *cholera* has occasionally been applied to any severely dehydrating secretory diarrheal illness, whether infectious in etiology or not, it has generally referred to disease caused by *V. cholerae* serogroup O1. In 1992, however, a new serogroup (O139) that causes epidemic cholera emerged on the Indian subcontinent and has since killed thousands of people.

MICROBIOLOGY AND EPIDEMIOLOGY The species *V. cholerae* comprises a host of organisms classified on the basis of the carbohydrate determinants of their lipopolysaccharide (LPS) O antigens. Some 200 serogroups have now been recognized. They are divided into those that agglutinate in antisera to the O1 group antigen (*V. cholerae* O1) and those that do not (non-O1 *V. cholerae*). Although some non-O1 *V. cholerae* serogroups have occasionally caused sporadic outbreaks of diarrhea, serogroup O1 was, until the emergence of serogroup O139, the exclusive cause of epidemic cholera.

Two biotypes of *V. cholerae* O1, *classical* and *El Tor*, are distinguished. Each biotype is further subdivided into two serotypes, termed *Inaba* and *Ogawa*.

The natural habitat of *V. cholerae* is coastal salt water and brackish estuaries, where the organism lives in close relation to plankton and where it may survive in a viable but nonculturable form. Humans become infected incidentally but, once infected, can act as vehicles for spread. Ingestion of water contaminated by human feces is the most common means of acquisition of *V. cholerae*. Consumption of contaminated food can also contribute to spread. There is no known animal reservoir. While the infectious dose is relatively high, it is markedly reduced in hypochlorhydric persons, in those using antacids, and when gastric acidity is buffered by a meal. Cholera is predominantly a pediatric disease in endemic areas, but it affects adults and children equally when newly introduced into a population. In endemic areas, the disease is more common in the summer and fall months. While this seasonality has not been explained fully, it may be due to environmental conditions that affect the multiplication of vibrios or to seasonal alterations in human behavior that affect contact with water. In endemic areas, children <2 years of age are less likely to develop severe cholera than are older children, perhaps because of passive immunity acquired from breast milk. For unexplained reasons, susceptibility to cholera is significantly influenced by ABO blood group status; those with type O blood are at greatest risk, while those with type AB are at least risk.

Cholera is native to the Ganges delta in the Indian subcontinent. Since 1817, seven global pandemics have occurred. The current (seventh) pandemic—the first due to the El Tor biotype—began in Indonesia in 1961 and spread throughout Asia as *V. cholerae* El Tor displaced the endemic classical strain in many areas. In the early 1970s, El Tor cholera exploded in Africa, causing major epidemics before becoming a persistent endemic problem. Its recent history in Africa has been punctuated by severe outbreaks, often fed by the chaos of war and genocide. Such was the case in the camps for Rwandan refugees set up in 1994 around Goma, Zaire. Tens of thousands of cases occurred and mortality was high. In 1995, the occurrence of hundreds of cases in Romania and the Black Sea states of the former Soviet Union demonstrated the potential of this organism to cause epidemics whenever public health measures break down.

Since 1973, sporadic endemic infections due to vibrios related to the seventh-pandemic strain have been recognized along the U.S. Gulf Coast of Louisiana and Texas. These infections are typically associated with the consumption of contaminated, locally harvested shellfish. Occasionally, cases in U.S. locations remote from the Gulf Coast have been linked to shipped-in Gulf Coast seafood.

It was not until 1991 that the current cholera pandemic reached Latin America. Beginning along the Peruvian coast in January 1991, the disease spread in an explosive epidemic to virtually all of South and Central America and to Mexico (Fig. 140-1). About 400,000 cases were reported in the first year of the outbreak, and >1 million had been reported by the end of 1994. While the cumulative mortality rate has been <1%, the mortality rate approached 30% in the communities first affected, where a lack of familiarity with the disease led initially to the deployment of ineffective treatment. Intensive education of health care providers and of the community at large has enhanced awareness of the disease and its appropriate management and has greatly diminished mortality. As it did in Africa two decades earlier, the epidemic El Tor strain proved capable of establishing itself in inland waters rather than in its classic niche of coastal salt waters; the organism has already become endemic in many of the Latin American countries into which it was recently introduced. Cases linked to the Latin American epidemic have occurred (via importation of contaminated seafood) in the United States. Although secondary spread of this strain has not taken place in the United States, these events underscore the need for vigilance among health care professionals, even in locations remote from an epidemic.

In October 1992, a large-scale outbreak of clinical cholera occurred in southeastern India. The etiologic agent proved to be a novel strain of *V. cholerae* belonging neither to the O1 serogroup that typically causes epidemic cholera nor to any of the 137 other serogroups known at the time. This strain spread rapidly up and down the coast of the Bay of Bengal, reaching Bangladesh in December 1992. There alone, it caused more than 100,000 cases of cholera in the first 3 months of 1993. It subsequently spread across the Indian subcontinent and to neighboring countries, affecting Pakistan, Nepal, western China, Thailand, and Malaysia by the end of 1994 (Fig. 140-2). The organism has since been designated *V. cholerae* O139 Bengal in recognition of its novel O antigen and its geographic origin. The clinical manifestations and epidemiologic features of the disease caused by *V. cholerae* O139

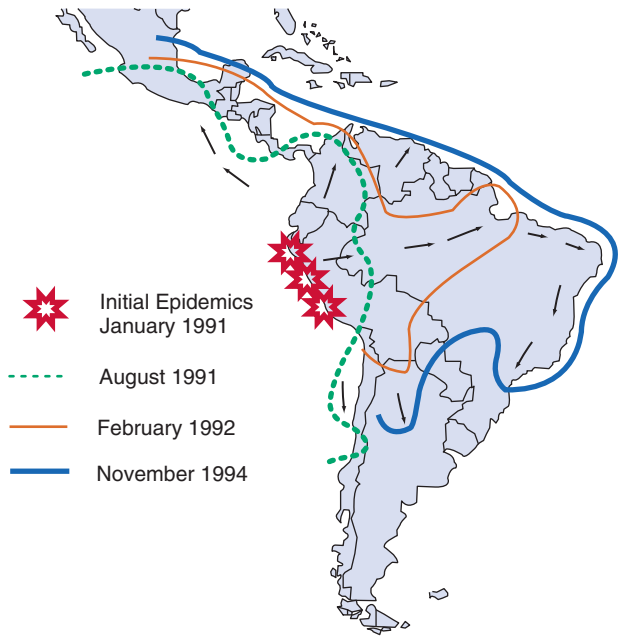

FIGURE 140-1 Spread of *Vibrio cholerae* O1 in the Americas, 1991–1994. *(Courtesy of Dr. Robert V. Tauxe, Centers for Disease Control and Prevention, Atlanta.)*

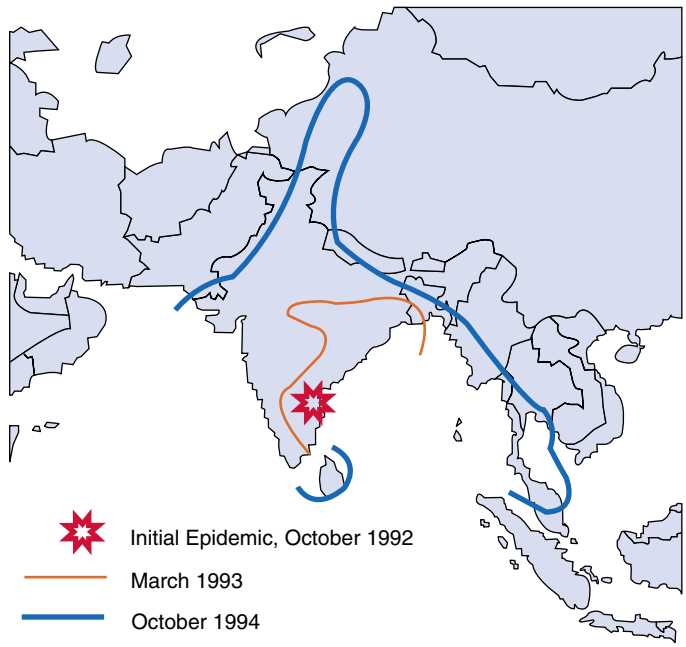

FIGURE 140-2 Spread of *Vibrio cholerae* O139 in the Indian subcontinent and elsewhere in Asia, 1992–1994. *(Courtesy of Dr. Robert V. Tauxe, Centers for Disease Control and Prevention, Atlanta.)*

Bengal are indistinguishable from those of O1 cholera. Immunity to the latter, however, is not protective against the former. Because naturally acquired immunity to *V. cholerae* O1 does not cross-protect against *V. cholerae* O139 Bengal, vaccines being developed against the former are unlikely to be effective against the latter.

Some authorities believed that the emergence of *V. cholerae* O139 signaled the beginning of the eighth global cholera pandemic. Indeed, just as O1 El Tor replaced the classical biotype that preceded it, O139 Bengal in 1993 rapidly replaced O1 El Tor as the most common environmental isolate and the predominant cause of clinical cholera in the areas in which it had appeared. However, by the beginning of 1994, O1 El Tor resumed its dominance in Bangladesh. Currently, in most regions of Southest Asia, O1 *V. cholerae* remains dominant; in others, O139 periodically reemerges.

PATHOGENESIS In the final analysis, cholera is a toxin-mediated disease. Its characteristic watery diarrhea is due to the action of cholera toxin (CT), a potent protein enterotoxin elaborated by the organism following its colonization of the small intestine. For *V. cholerae* to colonize the small intestine and produce CT, it must first recognize, contend with, and traverse several hostile environments. The first of these is the acidic milieu of the stomach. To elude the bactericidal effects of gastric acidity, *V. cholerae* relies, at least in part, on a relatively large inoculum size (compared to that needed for colonization by *Shigella*, for instance). The organism must next traverse the mucous layer lining the small bowel. *V. cholerae* chemotaxis and motility and a variety of proteases may allow the organism to traverse this gel covering the intestinal epithelium. Adherence to the intestinal epithelium is believed to be mediated by the toxin-coregulated pilus (TCP), so named because its synthesis is regulated in parallel with that of CT. CT, TCP, and several other virulence factors are coordinately regulated by the *toxR* gene product. The ToxR protein modulates the expression of virulence genes in response to environmental signals via a cascade of regulatory proteins. Additional regulatory processes, including the density of the bacterial population (in a phenomenon known as *quorum sensing*), control the virulence of *V. cholerae*.

Once established in the human small bowel, the organism produces CT, which consists of a monomeric enzymatic moiety (the A subunit) and a pentameric binding moiety (the B subunit). The B pentamer binds to G_{M1} ganglioside, a glycolipid on the surface of epithelial cells that serves as the toxin receptor and makes possible the delivery of

the A subunit to its cytosolic target. The activated A subunit (A_1) irreversibly transfers ADP-ribose from nicotinamide adenine dinucleotide to its specific target protein, the GTP-binding regulatory component of adenylate cyclase in intestinal epithelial cells. The ADP-ribosylated G protein upregulates the activity of adenylate cyclase; the result is the intracellular accumulation of high levels of cyclic AMP. In intestinal epithelial cells, cyclic AMP inhibits the absorptive sodium transport system in villus cells and activates the secretory chloride transport system in crypt cells, and these events lead to the accumulation of sodium chloride in the intestinal lumen. Since water moves passively to maintain osmolality, isotonic fluid accumulates in the lumen. When the volume of that fluid exceeds the capacity of the rest of the gut to resorb it, watery diarrhea results. Unless the wasted fluid and electrolytes are adequately replaced, shock (due to profound dehydration) and acidosis (due to loss of bicarbonate) follow. Although perturbation of the adenylate cyclase pathway is the primary mechanism by which CT causes excess fluid secretion, it is not the only one. Increasing evidence indicates that CT also enhances intestinal secretion via prostaglandins and/or neural histamine receptors.

The genes encoding CT (*ctxAB*) are part of the genome of a bacteriophage designated CTXΦ. The receptor for this phage on the *V. cholerae* surface is the essential *V. cholerae* intestinal colonization factor TCP. After the infection of TCP+ *ctxAB*− *V. cholerae* cells, the CTXΦ genome stably integrates at a specific site on the *V. cholerae* chromosome. Since *ctxAB* is part of a mobile genetic element (CTXΦ), horizontal transfer of this bacteriophage may account for the emergence of new toxigenic *V. cholerae* serogroups. Many of the other genes important for *V. cholerae* pathogenicity, including the genes encoding the biosynthesis of TCP, those encoding accessory colonization factors, and those regulating virulence gene expression, are clustered together in the *V. cholerae* pathogenicity island. Similar clustering of virulence genes is found in other bacterial pathogens. It is believed that pathogenicity islands are acquired by horizontal gene transfer.

V. cholerae O139 Bengal is closely related to the O1 El Tor strains of the seventh pandemic and seems to have arisen from them by horizontal gene transfer. It shares the virulence attributes and general pathogenic mechanisms of O1 vibrios. *V. cholerae* O139 Bengal is in fact virtually identical to the seventh-pandemic strains of *V. cholerae* O1 El Tor except for two important differences: production of the novel O139 LPS and of an immunologically related O-antigen polysaccharide capsule. The ability to produce the O139 LPS is due to a replacement of a 22-kb DNA segment encoding O1 antigen biosynthesis with a 35-kb segment containing the genes encoding O139 LPS and capsule biosynthesis. Encapsulation is not a feature of O1 strains and may explain the resistance of O139 strains to human serum in vitro as well as the occasional development of O139 bacteremia.

CLINICAL MANIFESTATIONS After a 24- to 48-h incubation period, cholera begins with the sudden onset of painless watery diarrhea that may quickly become voluminous and is often followed shortly by vomiting. In severe cases, stool volume can exceed 250 mL/kg in the first 24 h. If fluids and electrolytes are not replaced, hypovolemic shock and death ensue. Fever is usually absent. Muscle cramps due to electrolyte disturbances are common. The stool has a characteristic appearance: a nonbilious, gray, slightly cloudy fluid with flecks of mucus, no blood, and a somewhat sweet, inoffensive odor. It has been called "rice-water" stool because of its resemblance to the water in which rice has been washed. Clinical symptoms parallel volume contraction: At losses of 3 to 5% of normal body weight, thirst develops; at 5 to 8%, postural hypotension, weakness, tachycardia, and decreased skin turgor are documented; and at >10%, oliguria, weak or absent pulses, sunken eyes (and, in infants, sunken fontanelles), wrinkled ("washerwoman") skin, somnolence, and coma are characteristic. Complications derive exclusively from the effects of volume and electrolyte depletion and include renal failure due to acute tubular necrosis. Thus, if the patient is adequately treated with fluid and electrolytes, complications are averted and the process is self-limited, resolving in a few days.

Laboratory data usually reveal an elevated hematocrit (due to hemoconcentration) in nonanemic patients; mild neutrophilic leukocytosis; elevated levels of blood urea nitrogen and creatinine consistent with prerenal azotemia; normal sodium, potassium, and chloride levels; a markedly reduced bicarbonate level (<15 mmol/L); and an elevated anion gap (due to increases in serum lactate, protein, and phosphate). Arterial pH is usually low (about 7.2).

DIAGNOSIS The clinical suspicion of cholera can be confirmed by the identification of *V. cholerae* in stool; however, the organism must be specifically sought. With experience, it can be detected directly by dark-field microscopy on a wet mount of fresh stool, and its serotype can be discerned by immobilization with Inaba- or Ogawa-specific antiserum. Laboratory isolation of the organism requires the use of a selective medium. The best of these is thiosulfate–citrate–bile salts–sucrose (TCBS) agar, on which the organism grows as a flat yellow colony. If a delay in sample processing is expected, Carey-Blair transport medium and/or alkaline-peptone water-enrichment medium should be inoculated as well. In endemic areas there is little need for biochemical confirmation and characterization, although these tasks may be worthwhile in places where *V. cholerae* is an uncommon isolate. Standard microbiologic biochemical testing for Enterobacteriaceae will suffice for identification of *V. cholerae*. All vibrios are oxidase-positive.

The yield of stool cultures for the diagnosis of *V. cholerae* infection declines late in the course of the illness or when effective antibacterial therapy is initiated. Although not generally performed in clinical laboratories, measurement of serum vibriocidal antibody titers can be used to confirm the diagnosis in non-cholera-endemic regions of the world. Monoclonal antibody–based diagnostic kits and methods based on the polymerase chain reaction and on DNA probes have also been developed for detection of *V. cholerae* O1 and O139.

Rx TREATMENT

Cholera is simple to treat; only the rapid and adequate replacement of fluids, electrolytes, and base is required. The mortality rate for appropriately treated disease is usually <1%. However, analysis of a large outbreak of cholera among airline travelers from an endemic country to the United States revealed frequent misdiagnoses by U.S. health professionals and poor appreciation on their part of the principles of management. It has been proved conclusively that fluid may be given orally. This approach takes advantage of the hexose-Na^+ cotransport mechanism to move Na^+ across the gut mucosa together with an actively transported molecule such as glucose. Since Na^+ losses in the stool are high, a fluid containing Na^+ at 90 mmol/L has been recommended by the World Health Organization (WHO) (Table 140-1). This amount of Na^+ is higher than that needed to treat diarrhea due to most other causes. The solution is safe, even for infants, if its intake is alternated with the consumption of sodium-free fluids such as breast milk or water. For the sake of simplicity, WHO advises routine use of

TABLE 140-1 *Composition of World Health Organization Oral Rehydration Solution (ORS)*[a,b]

Constituent	Concentration, mmol/L
Na^+	90
K^+	20
Cl^-	80
Citrate[c]	10
Glucose	110

[a] Contains (per package, to be added to 1 L of drinking water): NaCl, 3.5 g; $Na_3C_6H_5O_7 \cdot 2H_2O$, 2.9 g; KCl, 1.5 g; and glucose, 20 g.

[b] If prepackaged ORS is unavailable, a simple homemade alternative can be prepared by combining 5 g NaCl (about 1 level teaspoon) with either 50 g precooked rice cereal or 40 g sucrose in 1 L of drinking water. In that case, potassium must be supplied separately (e.g., in orange juice or coconut water).

[c] 10 mmol citrate per liter, which supplies 30 mmol HCO_3/L.

this single solution for diarrheal disease rather than attempts to choose among multiple formulations according to etiology.

Cereal-based formulations are receiving increased attention as alternative oral rehydration solutions. Because of their lower osmolarity, they may reduce stool output. A mixture with a lower sugar and salt content has also been evaluated in cholera patients, with favorable results. However, concerns have been raised over the safety of its use—in particular, whether it could cause significant hyponatremia in patients with moderate or severe diarrhea. Because commercial oral rehydration solutions also contain concentrations of glucose and sodium lower than those of the WHO formulation, they should not yet be used routinely to treat cholera.

For initial management of severely dehydrated patients, intravenous fluid replacement is preferable, if available. Because profound acidosis (pH $<$ 7.2) is common in this group, Ringer's lactate is the best choice among commercial products (Table 140-2). It must be used with additional potassium supplements, preferably given by mouth. The total fluid deficit in severely dehydrated patients ($\geq$10% of body weight) can be replaced safely within the first 4 h of therapy, half within the first hour. Thereafter, oral therapy can usually be initiated, with the goal of maintaining fluid intake equal to fluid output. However, patients with continued large-volume diarrhea may require prolonged intravenous treatment to keep up with gastrointestinal fluid losses. Severe hypokalemia can develop but will respond to potassium given either intravenously or orally. In the absence of adequate staff to monitor the patient's progress, the oral route of rehydration and potassium replacement is safer than the intravenous route.

Although not necessary for cure, the use of an antibiotic to which the organism is susceptible will diminish the duration and volume of fluid loss and will hasten clearance of the organism from the stool. Single-dose tetracycline (2 g) or doxycycline (300 mg) is effective in adults but is not recommended for children $<$8 years of age because of possible deposition in bone and developing teeth. Emerging drug resistance is an ever-present concern. For adults with cholera in areas where tetracycline resistance is prevalent, ciprofloxacin—either in a single dose (30 mg/kg, not to exceed a total dose of 1 g) or in a short course (15 mg/kg twice daily for 3 days, not to exceed a total daily dose of 1 g)—or erythromycin (a total of 40 mg/kg daily in three divided doses for 3 days) is a clinically effective substitute. Both drugs are highly effective in reducing total stool output, and each is significantly better than trimethoprim-sulfamethoxazole. Because of the high cost of quinolones, WHO recommends erythromycin as the first alternative to tetracycline. For children, furazolidone has been the recommended agent and trimethoprim-sulfamethoxazole the second choice. Because of cost and/or toxicity issues related to the other drugs, erythromycin is a good choice for pediatric cholera.

CONTROL In outbreaks, efforts should first be made to identify case contacts and to treat incubating carriers. Next, epidemiologic studies should be undertaken to establish the modes of transmission in order to define the best strategy to interrupt them. Both the establishment of rehydration centers and instruction in rehydration techniques are essential to the reduction of mortality.

TABLE 140-2 *Electrolyte Composition of Cholera Stool and of Intravenous Rehydration Solution*

	Concentration, mmol/L			
Substance	Na^+	K^+	Cl^-	Base
Stool				
Adult	135	15	90	30
Child	100	25	90	30
Ringer's lactate	130	4[a]	109	28

[a] Potassium supplements, preferably administered by mouth, are required to replace the usual potassium losses from stool.

PREVENTION Provision of safe water and facilities for sanitary disposal of feces, improved nutrition, and attention to food preparation and storage in the household could significantly reduce the incidence of cholera. Much effort has been devoted to the development of an effective cholera vaccine over the past two decades, with a particular focus on oral vaccine strains. Traditional killed cholera vaccine given intramuscularly provides little protection to nonimmune subjects and predictably causes adverse effects, including pain at the injection site, malaise, and fever. The vaccine's limited efficacy is at least partially due to its failure to induce a local immune response at the intestinal mucosal surface.

Two types of oral cholera vaccines are under development. The first is a killed whole-cell (WC) vaccine. Two formulations of the killed WC vaccine have been prepared: one that also contains the nontoxic B subunit of CT (WC/BS) and one composed solely of killed bacteria. In field trials in Bangladesh, both of the killed vaccines were compared with placebo and conferred ~50% protection over a 3-year evaluation period. The protective efficacy of WC/BS was superior to that of WC during the initial 8 months of follow-up (69 versus 41%) but equivalent or inferior thereafter. Immunity was relatively sustained in persons vaccinated at an age of $>$5 years but was not well sustained in younger vaccinees. The WC/BS vaccine is now available in Europe but not in the United States.

The second approach is that of a live attenuated vaccine strain developed, for example, by the isolation or creation of mutants lacking the genes encoding CT. Strain CVD 103-HgR, an oral live cholera vaccine licensed for immunization of travelers in Europe, is derived from a classical biotype strain of *V. cholerae* and contains a deletion of the CT A subunit gene. This strain has been extensively tested in volunteers; although it is poorly excreted in the stool of human vaccinees, a single dose produces a significant increase in the titer of vibriocidal antibody in ~75% of recipients, including children between the ages of 2 and 4 years, with almost no side effects. Unfortunately, in a large field trial in Indonesian children, this vaccine failed to induce protection against clinical cholera. Other live attenuated vaccine candidate strains have been prepared from El Tor and O139 *V. cholerae* and are now undergoing clinical trials. Because of the minimal efficacy of existing parenteral vaccines, cholera immunization is recommended for U.S. travelers only if it is mandated by the countries they plan to visit.

OTHER *VIBRIO* SPECIES

The genus *Vibrio* includes several human pathogens that do not cause clinical cholera. Abundant in coastal waters throughout the world, noncholera vibrios can reach high concentrations in the tissues of filter-feeding mollusks. As a result, human infection commonly follows the ingestion of seawater or of raw or undercooked shellfish (Table 140-3). Most noncholera vibrios can be cultured on blood or MacConkey agar, which contains enough salt to support the growth of these halophilic species. In the microbiology laboratory, the species of noncholera vibrios are distinguished by standard biochemical tests. The most important of these organisms are *V. parahaemolyticus* and *V. vulnificus*.

The two major types of syndromes for which these species are responsible are gastrointestinal illness (due to *V. parahaemolyticus*, non-O1 *V. cholerae*, *V. mimicus*, *V. fluvialis*, *V. hollisae*, and *V. furnissii*) and soft tissue infections (due to *V. vulnificus*, *V. alginolyticus*, and *V. damsela*). *V. vulnificus* is also a cause of primary sepsis in some compromised individuals. *V. parahaemolyticus* causes rare cases of wound infection and otitis and very rare cases of sepsis.

SPECIES ASSOCIATED PRIMARILY WITH GASTROINTESTINAL ILLNESS ■ *V. parahaemolyticus* Widespread in marine environments, *V. parahaemolyticus* grows in saline concentrations up to 8 to 10%. This species was originally implicated in enteritis in Japan in 1953, accounting for 24% of reported cases in one study—a rate that presumably was due to the common practice of eating raw seafood in that country. *V. parahaemolyticus* has since been identified as a significant intestinal path-

ogen in many regions of the world. In the United States, common-source outbreaks of diarrhea caused by this organism have been linked to the consumption of undercooked or improperly handled seafood or of other foods contaminated by seawater. Since the mid-1990s, the incidence of *V. parahaemolyticus* infections has increased in several countries, including the United States. Serotypes O3:K6, O4:K68, and O1:K-untypable, which are genetically related to one another, account for this increase. The enteropathogenicity of *V. parahaemolyticus* is closely linked to its ability to cause hemolysis on Wagatsuma agar (i.e., the *Kanagawa phenomenon*). The genome sequence of *V. parahaemolyticus* contains a pathogenicity island—a cluster of likely virulence-associated genes. Although the mechanism by which the organism causes diarrhea remains unclear, it should be considered a possible etiologic agent in all cases of diarrhea that can be linked epidemiologically to seafood consumption or to the sea itself.

TABLE 140-3 *Features of Selected Noncholera Vibrioses*

Organism	Vehicle or Activity	Host at Risk	Syndrome
V. parahaemolyticus	Shellfish, seawater	Normal	Gastroenteritis
	Seawater	Normal	Wound infection
Non-O1 *V. cholerae*	Shellfish, travel	Normal	Gastroenteritis
	Seawater	Normal	Wound infection, otitis media
V. vulnificus	Shellfish	Immunosuppressed[a]	Sepsis, secondary cellulitis
	Seawater	Normal	Wound infection, cellulitis
V. alginolyticus	Seawater	Normal	Wound infection, cellulitis, otitis
	Seawater	Burned, other immunosuppressed	Sepsis

[a] Especially with liver disease or hemochromatosis.
Source: Table 161-3 in *Harrison's Principles of Internal Medicine*, 14th edition.

Infections with *V. parahaemolyticus* can result in two distinct gastrointestinal presentations. The more common of the two presentations (including nearly all cases in North America) is characterized by watery diarrhea, usually occurring in conjunction with abdominal cramps, nausea, and vomiting and accompanied in ~25% of cases by fever and chills. After an incubation period of 4 h to 4 days, symptoms develop and persist for a median of 3 days. Dysentery, the less common presentation, is characterized by severe abdominal cramps, nausea, vomiting, and bloody or mucoid stools. This syndrome is reported from India and Bangladesh.

Most cases of *V. parahaemolyticus*–associated gastrointestinal illness, regardless of the presentation, are self-limited and require neither antimicrobial treatment nor hospitalization. Deaths are extremely rare. Severe infections are associated with underlying diseases, including diabetes, preexisting liver disease, iron-overload states, or immunosuppression. The occasional severe case should be treated with fluid replacement and antibiotics, as described above for cholera.

Non-O1 *V. cholerae* The heterogeneous non-O1 *V. cholerae* organisms cannot be distinguished from *V. cholerae* O1 by routine biochemical tests but do not agglutinate in O1 antiserum. Non-O1 strains have caused several well-studied food-borne outbreaks of gastroenteritis and have also been responsible for sporadic cases of otitis media, wound infection, and bacteremia. Like other vibrios, non-O1 *V. cholerae* organisms are widely distributed in marine environments. In most instances, recognized cases in the United States have been associated with the consumption of raw oysters or with recent travel, typically to Mexico. The broad clinical spectrum of diarrheal illness caused by these organisms is probably due to the group's heterogeneous virulence attributes. *V. cholerae* O139 Bengal, although technically a non-O1 *vibrio*, is not grouped with these pathogens because it can cause epidemic cholera.

In the United States, about half of all non-O1 *V. cholerae* isolates are from stool samples. The typical incubation period for gastroenteritis due to these organisms is <2 days, and the illness lasts for ~2 to 7 days. Patients' stools may be copious and watery or may be partly formed, less voluminous, and bloody or mucoid. Diarrhea can result in severe dehydration. Many cases include abdominal cramps, nausea, vomiting, and fever. Like those with cholera, patients who are seriously dehydrated should receive oral or intravenous fluids; the value of antibiotics is not clear.

Extraintestinal infections due to non-O1 *V. cholerae* commonly follow occupational or recreational exposure to seawater. Around 10% of non-O1 *V. cholerae* isolates come from cases of wound infection, 10% from cases of otitis media, and 20% from cases of bacteremia (which is particularly likely to develop in patients with liver disease). Extraintestinal infections should be treated with antibiotics. Information to guide agent selection and dosing is limited, but most strains are sensitive in vitro to tetracycline, ciprofloxacin, and third-generation cephalosporins.

SPECIES ASSOCIATED PRIMARILY WITH SOFT TISSUE INFECTION OR BACTEREMIA
(See also Chap. 110) ■ ***V. vulnificus*** *V. vulnificus* is the most common cause of severe *Vibrio* infections in the United States. Like most vibrios, this organism proliferates in the warm summer months and requires a saline environment for growth. In this country, infections in humans typically occur in coastal states between May and October and most commonly affect men >40 years of age. *V. vulnificus* has been linked unequivocally to two distinct syndromes: primary sepsis, which usually occurs in patients with underlying liver disease, and primary wound infection, which generally affects people without underlying disease. Some authors have suggested that *V. vulnificus* also causes gastroenteritis independent of other clinical manifestations. *V. vulnificus* is endowed with a number of virulence attributes, including a capsule that confers resistance to phagocytosis and to the bactericidal activity of human serum as well as a cytolysin. Measured as the 50% lethal dose in mice, the organism's virulence is considerably increased under conditions of iron overload; this observation is consistent with the propensity of *V. vulnificus* to infect patients who have hemochromatosis.

Primary sepsis most often develops in patients who have cirrhosis or hemochromatosis. However, *V. vulnificus* bacteremia can also affect individuals who have hematopoietic disorders or chronic renal insufficiency, those who are using immunosuppressive medications or alcohol, or (in rare instances) those who have no known underlying disease. After a median incubation period of 16 h, the patient develops malaise, chills, fever (mean temperature, 39.8°C), and prostration. One-third of patients develop hypotension, which is often apparent at admission. Cutaneous manifestations develop in most cases (usually within 36 h of onset) and characteristically involve the extremities (the lower more often than the upper). In a common sequence, erythematous patches are followed by ecchymoses, vesicles, and bullae. In fact, sepsis and bullous skin lesions suggest the diagnosis in appropriate settings. Necrosis and sloughing may also be evident. Laboratory studies reveal leukopenia more often than leukocytosis, thrombocytopenia, or elevated levels of fibrin split products. *V. vulnificus* can be cultured from blood or cutaneous lesions. The mortality rate approaches 50%, with most deaths due to uncontrolled sepsis. Accordingly, prompt treatment is critical and should include empirical antibiotic administration, aggressive debridement, and general supportive care. *V. vulnificus* is sensitive in vitro to a number of antibiotics, including tetracycline, fluoroquinolones, and third-generation cephalosporins. Data from animal models suggest that either a fluoroquinolone or the combination of minocycline and cefotaxime should be used in the treatment of *V. vulnificus* septicemia.

V. vulnificus can infect either a fresh or an old wound that comes into contact with seawater; the patient may or may not have underlying disease. After a short incubation period (4 h to 4 days; mean, 12 h), the disease begins with swelling, erythema, and (in many cases) intense pain around the wound. These signs and symptoms are followed by cellulitis, which spreads rapidly and is sometimes accompanied by

vesicular, bullous, or necrotic lesions. Metastatic events are uncommon. Most patients have a fever (median temperature, 38.9°C) and leukocytosis. *V. vulnificus* can be cultured from skin lesions and occasionally from the blood. Prompt antibiotic therapy and debridement are usually curative.

V. alginolyticus First identified as a pathogen of humans in 1973, *V. alginolyticus* occasionally causes eye, ear, and wound infections. This species is the most salt-tolerant of the vibrios and can grow in salt concentrations of >10%. Most clinical isolates come from superinfected wounds that presumably become contaminated at the beach. Although severity varies, *V. alginolyticus* infection tends not to be serious and generally responds well to antibiotic therapy and drainage. A few cases of otitis externa, otitis media, and conjunctivitis due to this pathogen have been described. Tetracycline treatment usually results in cure. *V. alginolyticus* is a rare cause of bacteremia in immunocompromised hosts.

ACKNOWLEDGMENT

The authors gratefully acknowledge the valuable contributions of Dr. Robert Deresiewicz, a coauthor of this chapter for the 14th edition of Harrison's.

141 BRUCELLOSIS

Michael J. Corbel, Nicholas J. Beeching

DEFINITION Brucellosis is a bacterial zoonosis transmitted directly or indirectly to humans from infected animals, predominantly domesticated ruminants and swine. The disease is known colloquially as *undulant fever* because of its remittent character. Its distribution is worldwide apart from the few countries where it has been eradicated from the animal reservoir (see "Epidemiology," below). Although brucellosis commonly presents as an acute febrile illness, its clinical manifestations can be quite varied, and definitive signs to indicate the diagnosis can be lacking. Thus the clinical diagnosis must usually be supported by the results of bacteriologic and/or serologic tests.

ETIOLOGIC AGENT Human brucellosis is caused by strains of *Brucella*, a bacterial genus considered on genetic grounds to comprise a single species, *Brucella melitensis*, with a number of biologic variants that exhibit particular host preferences. For the sake of convenience, the traditional classification into nomen species is still in general use; this scheme, which closely follows the epidemiologic patterns of the infection, recognizes *B. melitensis*, which is the commonest cause of symptomatic disease in humans and for which the main sources are sheep, goats, and camels; *B. abortus*, which is usually acquired from cattle or buffalo: *B. suis*, which is generally acquired from swine except for one variant enzootic in reindeer and caribou and another enzootic in rodents; and *B. canis*, which is most often acquired from dogs. *B. ovis*, which causes reproductive disease in sheep, and *B. neotomae*, which is specific for desert rodents, have not been clearly implicated in human disease. Other brucellae have been isolated from marine mammals and probably correspond to at least three distinctive nomen species. At least one case of laboratory-acquired human disease due to these marine types has been described, and apparent cases of natural infection have been reported.

All brucellae are small, gram-negative, unencapsulated, nonsporulating rods or coccobacilli. They grow aerobically on peptone-based media incubated at 37°C; the growth of some types is enhanced by supplementary CO_2. In vivo, brucellae behave as facultative intracellular parasites. The organisms are sensitive to sunlight, ionizing radiation, and moderate heat; they are killed by boiling and pasteurization but are resistant to freezing and drying. Their resistance to drying renders brucellae stable in aerosol form and facilitates airborne transmission. Brucellae can survive for up to 2 months in soft cheeses made from goat or sheep milk; for at least 6 weeks in dry soil contaminated with infected urine, vaginal discharge, or placental or fetal tissues; and for at least 6 months in damp soil or liquid manure kept under cool, dark conditions. The bacteria are easily killed by a wide range of common disinfectants used under optimal conditions but are likely to be much more resistant at low temperatures or in the presence of heavy organic contamination.

EPIDEMIOLOGY Brucellosis is a zoonosis whose occurrence is closely related to its prevalence in domesticated animals. The true global prevalence of human brucellosis is unknown because of the imprecision of diagnosis and the inadequacy of reporting and surveillance systems in many countries. Even in developed countries, the true incidence may be 10 to 20 times higher than the reported figures. Bovine brucellosis has been the subject of control programs in many parts of the world and has been eradicated from the cattle populations of Australia, New Zealand, Bulgaria, Canada, Cyprus, Great Britain (including the Channel Islands), Japan, Luxembourg, Romania, the Scandinavian countries, Switzerland, and the Czech and Slovak Republics. Its incidence in cattle has been reduced to a low level in the United States and most Western European countries, with a varied picture in other parts of the world. There is evidence of some resurgence of brucellosis in cattle in Eastern Europe following economic changes in recent years. Efforts to eradicate *B. melitensis* infection from sheep and goat populations have been much less successful. These efforts have relied heavily on vaccination programs, which have tended to fluctuate with changing economic and political conditions. In some countries, such as Israel, *B. melitensis* has caused serious outbreaks in cattle. Brucellosis still represents a major public health problem in Mediterranean countries; in western, central, and southern Asia; and in parts of Africa and South and Central America.

Human brucellosis is usually associated with occupational or domestic exposure to infected animals or their products. Farmers, shepherds, goatherds, veterinarians, and workers in slaughterhouses and meat-processing plants in endemic areas are occupationally exposed to infection. Family members (including children) of individuals involved in animal husbandry may also be at risk, although it is often difficult to differentiate food-borne infection from environmental contamination under these circumstances. Laboratory workers involved in handling cultures or infected samples are also at risk. Travelers and urban dwellers usually acquire the infection through consumption of contaminated foods. In countries that have eradicated the disease, new cases are most often acquired abroad. Dairy products, especially soft cheeses, unpasteurized milk, and ice cream, are the most frequently implicated sources; raw meat and bone marrow may be sources of infection under exceptional circumstances. Infection resulting from contact with cosmetic products containing infected fetal materials has been recorded. Person-to-person transmission is extremely rare, as is transfer of infection by blood or tissue donation. Although brucellosis is a chronic intracellular infection, there is no evidence for increased prevalence or severity among individuals with HIV infection or other forms of immune deficiency or immune suppression.

Brucellosis may be acquired by ingestion or inhalation or through mucosal or percutaneous exposure. *B. melitensis* and *B. suis* are known to have been developed as biological weapons by several countries and could be exploited as weapons of bioterrorism (Chap. 205). This possibility should be borne in mind in the event of sudden unexplained outbreaks.

IMMUNITY AND PATHOGENESIS The mechanisms of protective immunity against human brucellosis are presumed to be similar to those documented in laboratory animals. Exposure to infection generates both humoral and cell-mediated immune responses. Although antibodies promote clearance of extracellular brucellae by bactericidal action and through the facilitation of phagocytosis by polymorphonuclear phagocytes, the antibody response cannot eradicate the infection. Organisms taken up by macrophages and other cell types can establish persistent intracellular infections. Early in the course of infection, cytokines such as interleukin (IL) 12 promote production of interferon γ, which drives T_H1-type responses and stimulates macrophage activation. Activated macrophages can kill intracellular brucellae (probably mainly through the production of reactive oxygen intermediates) and can clear the infection. Tumor necrosis factor α (TNF-α) is produced early in the immune response and stimulates cytotoxic lymphocytes, which can achieve partial clearance; however, the ability of virulent *Brucella* cells to suppress the TNF-α response may explain its limited role in protection. Inflammatory cytokines, including IL-6 and IL-10, downregulate the protective response. As in other types of intracellular infection, it is assumed that initial replication of brucellae takes place within cells of the lymph nodes draining the point of entry. Subsequent hematogenous spread may result in chronic localizing infection at almost any site, although the reticuloendothelial system, musculoskeletal tissues, and the genitourinary system are most frequently involved. Both acute and chronic inflammatory responses develop in brucellosis, and the local tissue response may include granuloma formation, with or without necrosis and caseation. Abscesses may also develop, especially in chronic localized infection.

The determinants of pathogenicity of *Brucella* have not been fully characterized, and the mechanisms underlying the manifestations of brucellosis are incompletely understood. The survival strategy of the organism is centered on processes that enable it to persist within monocytic cells. The smooth *Brucella* lipopolysaccharide, which has an unusual O-chain composition, possesses endotoxin activity and plays a key role in pyrogenicity and in resistance to phagocytosis and serum killing in the nonimmune host. Specific exotoxins have not been isolated, but a type IV secretion system responsible for secreting proteins that regulate intracellular survival and trafficking has been identified. This system is activated by low pH, and brucellae produce acid-stable proteins that facilitate survival in phagosomes and depress activation of the oxidative burst. Macrophage apoptosis and phagosome-lysosome fusion are also suppressed. Virulent brucellae are resistant to defensins and produce a Cu-Zn superoxide dismutase that enhances resistance to reactive oxygen intermediates.

CLINICAL FEATURES Brucellosis almost invariably causes fever, which may be associated with profuse sweats, especially at night. In endemic areas, brucellosis may be difficult to distinguish from the many other causes of fever. However, two features were recognized in the nineteenth century to distinguish brucellosis from other tropical fevers, such as typhoid and malaria: (1) Left untreated, the fever of brucellosis shows an undulating pattern that persists for weeks before the commencement of an afebrile period that may be followed by relapse, and (2) the fever of brucellosis is associated with musculoskeletal symptoms and signs in about one-half of all patients.

The clinical syndromes caused by the different nomen species are similar, although *B. melitensis* tends to be associated with a more acute and aggressive presentation and *B. suis* with focal abscess induction. *B. abortus* infections may be more insidious in onset and more likely to become chronic.

The incubation period varies from 1 week to several months, and the onset of fever and other symptoms may be abrupt or insidious. In addition to fever and sweats, patients become increasingly apathetic and fatigued; lose appetite and weight; and have nonspecific myalgia, headache, and chills. Overall, the presentations of brucellosis often fit into one of three patterns: febrile illness that resembles typhoid but is less severe; fever and acute monarthritis, typically of hip or knee, in a young child; or long-lasting fever, misery, and low-back pain or hip pain in an older man. In an endemic area (e.g., much of the Middle East), a patient with fever and difficulty walking into the clinic would be regarded as having brucellosis until it was proved otherwise.

Diagnostic clues in the patient's history include travel to an endemic area, employment in a diagnostic microbiology laboratory, consumption of unpasteurized milk products (including soft cheeses), contact with animals, and—in an endemic setting—a history of similar illness in the family (documented in almost 50% of cases).

Focal features are present in the majority of patients. The most common is musculoskeletal pain and physical findings in the peripheral and axial skeleton (~40% of cases). Osteomyelitis more commonly involves the lumbar and lower thoracic vertebrae than the cervical and high thoracic spine. Individual joints that are most commonly affected by septic arthritis are the knee, hip, sacroiliac, shoulder, and sternoclavicular joints, and the pattern may be one of either monarthritis or polyarthritis. Osteomyelitis may also accompany septic arthritis.

In addition to the usual causes of vertebral osteomyelitis or septic arthritis, the most important differential diagnosis is tuberculosis. This point has an impact on the therapeutic approach as well as on the prognosis, given that several antimicrobial agents used to treat brucellosis are also used to treat tuberculosis. Septic arthritis in brucellosis progresses slowly, starting with small pericapsular erosions. In the vertebrae, anterior erosions of the superior end plate are typically the first features to become evident, with eventual involvement and sclerosis of the whole vertebra. Anterior osteophytes eventually develop, but vertebral destruction or impingement on the spinal cord is rare and usually suggests tuberculosis (Table 141-1).

Other systems may be involved in a manner that resembles typhoid. About one-quarter of patients have a dry cough, usually with few changes visible on the chest x-ray, although pneumonia, empyema, intrathoracic adenopathy, or lung abscess can occur. One-quarter of patients have hepatosplenomegaly, and 10 to 20% have significant lymphadenopathy; the differential diagnosis includes glandular fever–like illness such as that caused by Epstein-Barr virus, *Toxoplasma*, and cytomegalovirus; HIV infection; or tuberculosis. Up to 10% of men have acute epididymoorchitis, which must be distinguished from that due to mumps or surgical problems such as torsion. Prostatitis, inflammation of the seminal vesicles, salpingitis, and pyelonephritis all occur. There is an increased incidence of fetal loss among infected pregnant women, although teratogenicity has not been described and

TABLE 141-1 *Radiology of the Spine: Differentiation of Brucellosis from Tuberculosis*

	Brucellosis	*Tuberculosis*
Site	Lumbar and others	Dorsolumbar
Vertebrae	Multiple or contiguous	Contiguous
Diskitis	Late	Early
Body	Intact until late	Morphology lost early
Canal compression	Rare	Common
Epiphysitis	Anterosuperior	General: upper, lower disk region, central, subperiosteal
Osteophyte	Anterolateral	Unusual
Deformity	Wedging uncommon	Anterior wedge, gibbus
Recovery	Sclerosis, whole body	Variable
Paravertebral abscess	Small, well-localized	Common and discrete loss, transverse process
Psoas abscess	Rare	More likely

the tendency to cause abortions is much less pronounced in humans than in farm animals.

Neurologic involvement is common, with depression and lethargy whose severity may not be fully appreciated by either the patient or the physician until after treatment. A small proportion of patients develop lymphocytic meningoencephalitis that mimics neurotuberculosis or noninfectious conditions and that may be complicated by intracerebral abscess, a variety of cranial nerve deficits, and ruptured mycotic aneurysms.

Endocarditis occurs in ~1% of cases, most often affecting the aortic valve (natural or prosthetic). Any site in the body may be involved in metastatic abscess formation or inflammation; the female breast and the thyroid gland are affected particularly often. Nonspecific maculopapular rashes and other skin manifestations are uncommon and are rarely noticed by the patient even if they are present.

DIAGNOSIS Because the clinical picture of brucellosis is not distinctive, the diagnosis must be based on a history of potential exposure, a presentation consistent with the disease, and supporting laboratory findings. Routine biochemical assays are usually within normal limits, although serum levels of hepatic enzymes and bilirubin may be elevated. Peripheral leukocyte counts are usually normal or low, with relative lymphocytosis. Mild anemia may be documented. Thrombocytopenia and disseminated intravascular coagulation with raised levels of fibrinogen degradation products can develop. The erythrocyte sedimentation rate and C-reactive protein levels are often normal but may be raised.

In body fluids such as cerebrospinal fluid (CSF) or joint fluid, lymphocytosis and low glucose levels are the norm. Elevated CSF levels of adenosine deaminase cannot be used to distinguish tubercular meningitis, as they may also be found in brucellosis. Biopsied samples of tissues such as lymph node or liver may show noncaseating granulomas (Fig. 141-1) without acid/alcohol-fast bacilli. The radiologic features of bony disease develop late in brucellosis and are much more subtle than those of tuberculosis or septic arthritis of other etiologies, with less bone and joint destruction. Isotope scanning is more sensitive than plain x-ray and continues to give positive results long after successful treatment.

Isolation of brucellae from blood, CSF, bone marrow, or joint fluid or from a tissue aspirate or biopsy sample is definitive, and attempts at isolation are usually successful in 50 to 70% of cases. Duplicate cultures (in air and 10% CO_2, respectively) should be incubated for up to 6 weeks. Concentration and lysis of buffy coat cells before culture may increase the isolation rate. Cultures in modern nonradiometric or similar signaling systems (e.g., BACTEC) usually become positive within 7 to 10 days but should be maintained for at least 3 weeks before the results are declared negative.

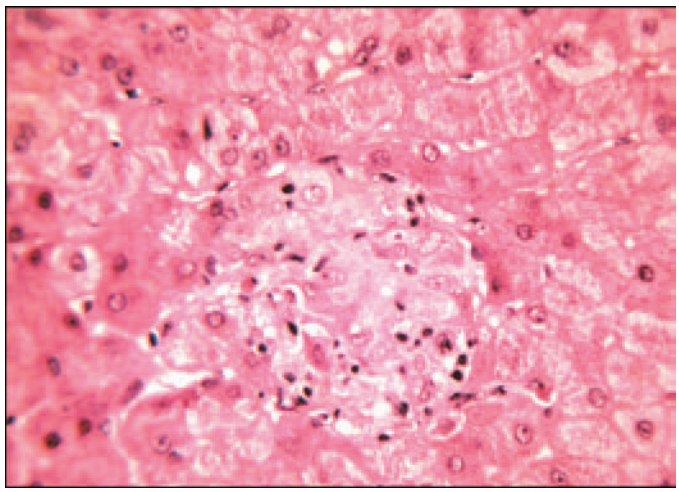

FIGURE 141-1 Liver biopsy specimen from a patient with brucellosis shows a noncaseating granuloma. *[From Mandell's Atlas of Infectious Diseases, Vol II, in DL Stevens (ed): Skin, Soft Tissue, Bone and Joint Infections, Fig. 5-9; with permission.]*

Nucleic acid amplification techniques are not yet widely available for the diagnosis of human brucellosis, and no single standardized procedure has been adopted. The peripheral blood–based polymerase chain reaction (PCR) has enormous potential to detect bacteremia, to predict relapse, and to exclude "chronic brucellosis" (see "Prognosis and Follow-Up," below); PCR is probably more sensitive and is certainly quicker than blood culture, and it does not carry the attendant biohazard risk posed by culture. Primers for the spacer region between the genes encoding the 16S and 23S ribosomal RNAs (*rrs–rrl*), outer-membrane protein Omp2, insertion sequence IS711, or protein BCSP31 are sensitive and specific. Blood or other tissues are the most suitable samples for PCR testing.

Serologic examination often provides the only positive laboratory findings in brucellosis. In acute infection, IgM antibodies appear early and are followed by IgG and IgA antibodies. All these antibodies are active in agglutination tests, whether performed by tube, plate, or microagglutination methods. The majority of patients have detectable agglutinins at this stage. As the disease progresses, IgM levels decline, and the avidity and subclass distribution of IgG and IgA change. The result is reduced or undetectable agglutinin titers. However, the antibodies are detectable by alternative tests, including the complement fixation test, Coombs' antiglobulin test, and enzyme-linked immunosorbent assay. There is no clear cutoff value for a diagnostic titer. Rather, serologic results must be interpreted in the context of exposure history and clinical presentation. In endemic areas or in settings of potential occupational exposure, agglutinin titers of ≥1:320 to 1:640 are considered diagnostic; in nonendemic areas, a titer of ≥1:160 is considered significant. Repetition of tests after 2 to 4 weeks may demonstrate a rising titer.

In most centers, the standard agglutination test (SAT) is still the mainstay of serologic diagnosis, although some investigators rely on the rose bengal test, which has not been fully validated for human diagnostic use. Dipstick assays for anti-*Brucella* IgM are useful for the diagnosis of acute infection but are less sensitive for infection with symptoms of several months' duration. In an endemic setting, >90% of patients with acute bacteremia have SAT titers of at least 1:320.

Antibody to the *Brucella* lipopolysaccharide O chain—the dominant antigen—is detected by all the conventional tests that employ smooth *B. abortus* cells as antigen. Since *B. abortus* cross-reacts with *B. melitensis* and *B. suis*, there is no advantage in replicating the tests with these antigens. Cross-reactions also occur with the O chains of some other gram-negative bacteria, including *Escherichia coli* O157, *Francisella tularensis*, *Salmonella enterica* group N, *Stenotrophomonas maltophilia*, and *Vibrio cholerae*. Cross-reactions do not occur with the cell-surface antigens of rough *Brucella* strains such as *B. canis* or *B. ovis*; serologic tests for these nomen species must employ an antigen prepared from either one. Most protein antigens are shared by all *Brucella* strains, and some are also common to *Ochrobactrum* species.

TREATMENT

The broad aims of antimicrobial therapy for brucellosis are to treat current infection and relieve its symptoms and to prevent relapse. Focal disease presentations may require surgical intervention (e.g., cardiac valve replacement, abscess drainage, joint replacement) in addition to more prolonged and tailored antibiotic therapy. In addition, tuberculosis must always be excluded, or—to prevent the emergence of resistance—the regimen must be tailored to specifically exclude monotherapy with agents active against tuberculosis (e.g., rifampin) or to include a full antituberculous regimen.

Early experience with streptomycin monotherapy for brucellosis showed that relapse was common; thus dual therapy with streptomycin and tetracyclines became the norm. This is still the most effective combination, but alternatives may be used, with the options depending on local or national policy about the use of rifampin for the treatment of nonmycobacterial infection. Antimicrobial efficacy can usually be predicted by in vitro testing. The efficacy of fluoroquinolone monotherapy has been disappointing, with a high relapse rate, despite the good in vitro activity and white-cell penetration of most agents of this class.

For adults with acute nonfocal brucellosis (duration, <1 month), a 6-week course of therapy incorporating at least two antimicrobial agents is required. Complex or focal disease necessitates ≥3 months of therapy. Adherence to the therapeutic regimen is very important, and poor compliance underlies almost all cases of apparent treatment failure; such failure is rarely due to the emergence of drug resistance, although increasing resistance to trimethoprim-sulfamethoxazole (TMP-SMX) has been reported at one center. There is good retrospective evidence that a 3-week course of two agents is as good as a 6-week course for treatment and prevention of relapse in children, but this point has not yet been proved in prospective studies.

The "gold standard" for the treatment of brucellosis in adults is intramuscular streptomycin (750 mg to 1 g daily for 14 to 21 days) together with doxycycline (100 mg twice daily for 6 weeks). In both clinical trials and observational studies, relapse follows such treatment in 5 to 10% of patients. The usual alternative regimen (and the current World Health Organization recommendation) is rifampin (600 to 900 mg/d) plus doxycycline (100 mg twice daily) for 6 weeks. In trial conditions, the relapse/failure rate is ~10%, but this rate rises to >20% in many nontrial situations, possibly because doxycycline levels are reduced and clearance rates increased by concomitant rifampin administration. Patients who cannot tolerate or receive tetracyclines (children, pregnant women) can be given high-dose TMP-SMX instead (2 or 3 standard-strength tablets twice daily for adults, depending on weight).

Evidence is beginning to accumulate that other aminoglycosides can be substituted for streptomycin—e.g., netilmicin or gentamicin given at a dosage of 5 to 6 mg/kg per day for at least 2 weeks. (Shorter courses have been associated with high failure rates in adults.) A 5- to 7-day course of therapy with gentamicin (and a 3-week course of TMP-SMX) is probably adequate for children with uncomplicated disease. Early experience with fluoroquinolone monotherapy was disappointing, but high-dose ofloxacin (400 mg twice daily) or ciprofloxacin (500 mg twice daily), given for 6 weeks with rifampin, may become accepted as an alternative to the other 6-week regimens for adults.

Significant neurologic disease due to *Brucella* requires prolonged treatment (i.e., for 6 to 12 months), usually with ceftriaxone supplementation of a standard regimen. *Brucella* endocarditis is treated with at least three drugs (an aminoglycoside, a tetracycline, and rifampin), and many experts add ceftriaxone and/or a fluoroquinolone to reduce the need for valve replacement. Treatment is usually given for at least 6 months, and clinical end points for its discontinuation are often difficult to define. Surgery is still required for the majority of cases of infection of prosthetic heart valves and prosthetic joints.

There is no evidence base to guide prophylaxis after exposure to brucellae in the laboratory, inadvertent immunization with live vaccine intended for use in animals, or exposure to deliberately released brucellae. Most authorities recommend the administration of rifampin plus doxycycline for 3 weeks after a low-risk exposure (e.g., a nonspecific laboratory accident) and for 6 weeks after a major exposure to aerosol or injected material.

PROGNOSIS AND FOLLOW-UP Relapse occurs in up to 30% of poorly compliant patients. Thus patients ideally should be followed clinically for up to 2 years to detect relapse, which responds to a prolonged course of the same therapy that was originally used. The general well-being and body weight of the patient are more useful guides than serology to lack of relapse. IgG antibody levels detected by SAT and variants of this test can remain in the diagnostic range for >2 years after successful treatment. Complement fixation titers usually fall to normal within 1 year of cure. Immunity is not solid; patients can be reinfected after repeated exposures. Fewer than 1% of patients die of brucellosis. When the outcome of this infection is fatal, death is usually a consequence of cardiac involvement; more rarely, it results from severe neurologic disease. Despite the low mortality rate, recovery from brucellosis is slow, and the illness in humans can cause prolonged inactivity, with consequent domestic difficulties and economic losses.

The existence of a prolonged chronic brucellosis state after successful treatment remains controversial. Evaluation of patients in whom this state is considered (often those with work-related exposure to brucellae) includes careful exclusion of malingering, nonspecific chronic fatigue syndromes and other causes of excessive sweating, such as alcohol abuse and obesity. In the future, the availability of more sensitive assays to detect *Brucella* antigen or DNA may help to identify patients with ongoing infection.

PREVENTION Vaccines based on live attenuated *Brucella* strains, such as *B. abortus* strain 19BA or 104M, have been used in some countries to protect high-risk populations but have displayed only short-term efficacy and a high incidence of local and systemic side effects (local inflammation, pain, lymphadenopathy, fever, malaise, nausea). Subunit vaccines have been developed but are of uncertain value and cannot be recommended at present. Interest in biodefense has stimulated research in this area (Chap. 205). The mainstay of veterinary prevention is a national commitment to testing and slaughter of infected herds and flocks (with compensation for owners), control of animal movement, and active immunization of animals. These measures are usually sufficient to control human disease as well. In their absence, pasteurization of all milk products before consumption is sufficient to prevent animal-to-human transmission. All cases of *Brucella* infection in animals and humans should be reported to the appropriate public health authorities.

142 TULAREMIA

Richard F. Jacobs

DEFINITION Tularemia is a zoonosis caused by *Francisella tularensis*. Humans of any age, sex, or race are universally susceptible to this systemic infection. Tularemia is primarily a disease of wild animals and persists in contaminated environments, ectoparasites, and animal carriers. Human infection is incidental and usually results from interaction with biting or blood-sucking insects, wild or domestic animals, or the environment. Tularemia is common in Arkansas, Oklahoma, and Missouri, where more than 50% of the cases in the United States occur. An increasing number of cases of tularemia have been reported from the Scandinavian countries, eastern Europe, and Siberia. The illness is characterized by various clinical syndromes, the most common of which consists of an ulcerative lesion at the site of inoculation, with regional lymphadenopathy and lymphadenitis. Systemic manifestations, including pneumonia, typhoidal tularemia, and fever without localizing findings, pose a greater diagnostic challenge.

ETIOLOGY AND EPIDEMIOLOGY With rare exceptions, tularemia is the only disease produced by *F. tularensis*—a small (0.2 μm by 0.2 to 0.7 μm),

gram-negative, pleomorphic, nonmotile, non-spore-forming bacillus. Bipolar staining results in a coccoid appearance. The organism is a thinly encapsulated, nonpiliated strict aerobe that invades host cells. In nature, *F. tularensis* is a hardy organism that persists for weeks or months in mud, water, and decaying animal carcasses. Dozens of biting and blood-sucking insects, especially ticks and tabanid flies, serve as vectors. Ticks and wild rabbits are the source for most of the human cases in the endemic areas of the southeastern and Rocky Mountain states. In Utah, Nevada, and California, tabanid flies are the most common vectors. Animal reservoirs include wild rabbits, squirrels, birds, sheep, beavers, muskrats, and domestic dogs and cats. Humans become infected by various modes, including bites by infected arthropods; handling of infected animal tissues or fluids; direct contact with or ingestion of contaminated water, food, or soil; and inhalation of infected aerosols.

The two main biovars of *F. tularensis*—*tularensis* (type A) and *palearctica* (type B)—are both found in the United States. Type A produces more serious disease in humans; without treatment, the associated fatality rate is ~5%. Type B produces a milder, often subclinical infection that is usually contracted from water or marine mammals. Although all strains appear serologically identical, individual strains may possess varying degrees of virulence. *F. tularensis* does not produce an exotoxin, but an endotoxin similar to that of other gram-negative bacilli has been identified. The progression of illness depends on the organism's virulence, the inoculum size, the portal of entry, and the host's immune status.

Ticks pass the organism to their offspring via a transovarian route. The organism is found in tick feces but not in large quantities in tick salivary glands. In the United States, the disease can be carried by *Dermacentor andersoni* (Rocky Mountain wood tick), *D. variabilis* (American dog tick), *D. occidentalis* (Pacific coast dog tick), and *Amblyomma americanum* (Lone Star tick). *F. tularensis* is transmitted frequently during blood meals taken by embedded ticks following hours of attachment. It is the taking of a blood meal through a fecally contaminated field that transmits the organism. Tularemia is more common among men than among women. Person-to-person transmission is rare or nonexistent. Transmission of the organism by ticks and tabanid flies takes place mainly in the spring and summer. However, continued transmission in the winter months by trapped or hunted animals has been documented. The organism is extremely infectious. Biosafety level 2 is recommended for clinical laboratory work with material whose contamination is suspected, and biosafety level 3 is required for culture of the organism in large quantities. Issues related to the intentional spread of tularemia through ingestion or inhalation are discussed in Chap. 205.

PATHOGENESIS AND PATHOLOGY The most common portal of entry for human infection is through skin or mucous membranes, either directly—through the bite of ticks, other arthropods, or other animals—or via inapparent abrasions. Inhalation or ingestion of *F. tularensis* can also result in infection. Although more than 10^8 organisms are usually required to produce infection via the oral route (oropharyngeal or gastrointestinal tularemia), fewer than 50 organisms will result in infection when injected into the skin (ulceroglandular/glandular tularemia) or inhaled (pneumonia). After inoculation into the skin, the organism multiplies locally; within 2 to 5 days (range, 1 to 10 days), it produces an erythematous, tender, or pruritic papule. The papule rapidly enlarges and forms an ulcer with a black base (chancriform lesion). The bacteria spread to regional lymph nodes, producing lymphadenopathy (buboes), and, with bacteremia, may spread to distant organs.

Tularemia is characterized by mononuclear cell infiltration with pyogranulomatous pathology. The histopathologic findings can be quite similar to those in tuberculosis, although tularemia develops more rapidly. As a facultatively intracellular bacterium, *F. tularensis* can parasitize both phagocytic and nonphagocytic host cells and survive intracellularly for prolonged periods. In the acute phase of infection, the primary organs affected (skin, lymph nodes, liver, and spleen) include areas of focal necrosis, initially surrounded by polymorphonuclear leukocytes (PMNs). Subsequently, granulomas form, with epithelioid cells, lymphocytes, and multinucleated giant cells surrounded by areas of necrosis. These areas may resemble caseation necrosis but later coalesce to form abscesses.

Conjunctival inoculation can result in infection of the eye, with regional lymph node enlargement (preauricular lymphadenopathy, Parinaud's complex). Aerosolization and inhalation or hematogenous spread of organisms can result in pneumonia. In the lung, an inflammatory reaction develops, including foci of alveolar necrosis and cell infiltration (initially polymorphonuclear and later mononuclear) with granulomas. Chest roentgenograms usually reveal bilateral patchy infiltrates rather than large areas of consolidation. Pleural effusions are common and may contain blood. Lymphadenopathy occurs in regions draining infected organs. Therefore, in pulmonary infection, mediastinal adenopathy may be evident, whereas patients with oropharyngeal tularemia develop cervical lymphadenopathy. In gastrointestinal or typhoidal tularemia, mesenteric lymphadenopathy may follow the ingestion of large numbers of organisms. The term *typhoidal tularemia* may be used to describe severe bacteremic disease, irrespective of the mode of transmission or portal of entry. Meningitis has been reported as a primary or secondary manifestation of bacteremia. Patients may also present with fever and no localizing signs.

IMMUNOLOGY Infection with *F. tularensis* stimulates the host to produce antibodies. However, this antibody response probably plays only a minor role in the containment of infection. In contrast, cell-mediated immunity, which develops over 2 to 4 weeks, plays a major role in containment and eradication. Macrophages, once activated, can kill *F. tularensis*. Recovery from infection generally renders the patient resistant to reinfection; this point is not completely understood.

Immunospecific protection against tularemia can be afforded either by natural infection or by vaccination with live attenuated strains of *F. tularensis*. Killed vaccines, on the other hand, induce no protection against virulent *F. tularensis*. After natural infection or vaccination, serum antibodies to surface-exposed carbohydrate antigens predominate, whereas T cell determinants are located on membrane proteins beneath the bacterial capsule. T cell responses are thought to be due to priming by the organism. The anamnestic T cell response to *F. tularensis* seems to involve a multitude of microbial proteins, each with a distinct set of T cell determinants. A predominant role for CD4+ T cells is supported by the results of experiments in mice, which indicated that resistance to infection was restricted at the level of the major histocompatibility complex (MHC) class II determinants. Humans primed to *F. tularensis* (like those primed to *Mycobacterium tuberculosis*) show a T_H1-like response. T cell proliferation is associated with the production of interleukin (IL) 2 and interferon γ but with little or no production of IL-4. Recent evidence indicates that the percentage of $\gamma\delta$ T cells expressing tumor necrosis factor α is decreased during the first 7 to 40 days after infection. This decrease may reflect the modulation of an inflammatory response. Investigations of neutrophils in tularemia suggest that PMNs are needed for defense against primary infection. PMNs may restrict the growth of *F. tularensis* before the organism becomes intracellular.

CLINICAL MANIFESTATIONS Tularemia often starts with a sudden onset of fever, chills, headache, and generalized myalgias and arthralgias (Table 142-1). This onset takes place when the organism penetrates the skin, is ingested, or is inhaled. An incubation period of 2 to 10 days is followed by the formation of an ulcer at the site of penetration, with local inflammation. The ulcer may persist for several months as organisms are transported via the lymphatics to the regional lymph nodes. These nodes enlarge and may become necrotic and suppurative. If the organism enters the bloodstream, widespread dissemination as well as signs and symptoms of endotoxemia may result.

In the United States, most patients with tularemia (75 to 85%) acquire the infection by inoculation of the skin. In adults, the most

TABLE 142-1 *Clinical Presentation of Tularemia*

common localized form is inguinal/femoral lymphadenopathy; in children, it is cervical lymphadenopathy. About 20% of patients develop a generalized maculopapular rash, which occasionally becomes pustular. Erythema nodosum occurs infrequently. The clinical manifestations of tularemia have been divided into various syndromes, which are listed in Table 142-2.

Ulceroglandular/Glandular Tularemia These two forms of tularemia account for ~75 to 85% of cases. The predominant form in children involves cervical or posterior auricular lymphadenopathy and is usually related to tick bites on the head and neck. In adults, the most common form is inguinal/femoral lymphadenopathy resulting from insect and tick exposures on the lower limbs. In cases related to wild game, the usual portal of entry for *F. tularensis* is either an injury sustained while skinning or cleaning an animal carcass or a bite (usually on the hand). Epitrochlear lymphadenopathy/lymphadenitis is common in patients with bite-related injuries.

In ulceroglandular tularemia, the ulcer is erythematous, indurated, and nonhealing, with a punched-out appearance that lasts from 1 to 3 weeks. The papule may begin as an erythematous lesion that is tender or pruritic; it evolves over several days into an ulcer with sharply demarcated edges and a yellow exudate. The ulcer gradually develops a black base, and simultaneously the regional lymph nodes become tender and severely enlarged (Fig. 142-1). The affected lymph nodes may become fluctuant and drain spontaneously, but usually the condition resolves with effective treatment. Late suppuration of lymph nodes has been described in up to 25% of patients with ulceroglandular/glandular tularemia. Examination of material taken from these late fluctuant nodes after successful antimicrobial treatment has revealed sterile necrotic tissue. In 5 to 10% of patients, the skin lesion may be inapparent, with lymphadenopathy plus systemic signs and symptoms the only physical findings (*glandular tularemia*). Conversely, a tick or deerfly bite on the trunk may result in an ulcer without evident lymphadenopathy.

Oculoglandular Tularemia In ~1% of patients, the portal of entry for *F. tularensis* is the conjunctiva. Usually, the organism reaches the conjunctiva through contact with contaminated fingers. The inflamed conjunctiva is painful, with numerous yellowish nodules and pinpoint ulcers. Purulent conjunctivitis with regional lymphadenopathy (preauricular, submandibular, or cervical) is evident. Because of debilitating pain, the patient may seek medical attention before regional lymphadenopathy develops. Painful preauricular lymphadenopathy is unique to tularemia and distinguishes it from cat-scratch disease, tuberculosis, sporotrichosis, and syphilis. Corneal perforation may occur.

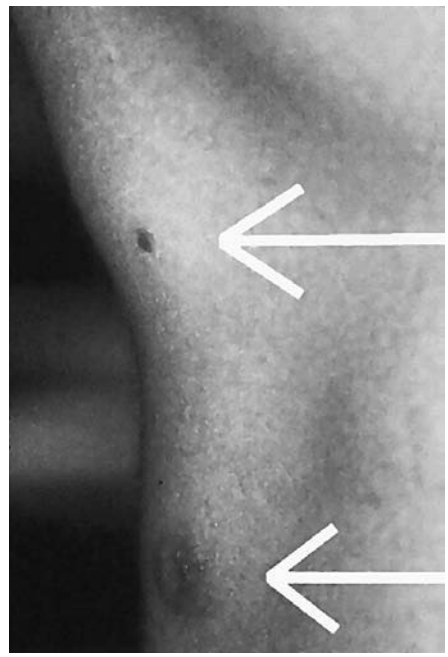

FIGURE 142-1 An ulcerative lesion (*lower arrow*) with adjacent lymphadenitis (*upper arrow*) on the lateral chest wall of a patient with ulceroglandular tularemia.

Oropharyngeal and Gastrointestinal Tularemia Rarely, tularemia follows the ingestion of contaminated undercooked meat, the oral inoculation of *F. tularensis* from the hands in association with the skinning and cleaning of animal carcasses, or the consumption of contaminated food or water. Oral inoculation may result in acute, exudative, or membranous pharyngitis associated with cervical lymphadenopathy or in ulcerative intestinal lesions associated with mesenteric lymphadenopathy, diarrhea, abdominal pain, nausea, vomiting, and gastrointestinal bleeding. Infected tonsils become enlarged and develop a yellowish-white pseudomembrane, which can be confused with that of diphtheria. The clinical severity of gastrointestinal tularemia varies from mild, unexplained, persistent diarrhea with no other symptoms to a fulminant, fatal disease. In fatal cases, the extensive intestinal ulceration found at autopsy suggests an enormous inoculum.

Pulmonary Tularemia Tularemia pneumonia presents as variable parenchymal infiltrates that are unresponsive to treatment with β-lactam antibiotics. Tularemia must be considered in the differential diagnosis of atypical pneumonia in a patient with a history of travel to an endemic area. The disease can result from either inhalation of an infectious aerosol or can spread to the lungs and pleura after bloodstream dissemination. Inhalation-related pneumonia has been described in laboratory workers after exposure to contaminated materials and is associated with a relatively high mortality rate. Exposure to *F. tularensis* in aerosols from live domestic animals or dead wildlife (including birds) has been reported to cause pneumonia. Hematogenous dissemination to the lungs occurs in 10 to 15% of cases of ulceroglandular tularemia and in about half of cases of typhoidal tularemia. Previously, tularemia pneumonia was thought to be a disease of older patients, but as many as 10 to 15% of children with clinical manifestations of tularemia have parenchymal infiltrates detected by chest roentgenography. Patients with pneumonia usually have a nonproductive cough and may have dyspnea or pleuritic chest pain. Roentgenograms of the chest usually reveal bilateral patchy infiltrates (described as ovoid or lobar densities), lobar parenchymal infiltrates, and cavitary lesions. Pleural effusions may have a predominance of mononuclear

[d] Hematologic and reticuloendothelial malignancies.

leukocytes or PMNs and sometimes red blood cells. Empyema may develop. Blood cultures may be positive for *F. tularensis*.

Typhoidal Tularemia The typhoidal presentation is now considered rare in the United States. The source of infection in typhoidal tularemia is usually associated with pharyngeal and/or gastrointestinal inoculation or bacteremic disease. Fever usually develops without apparent skin lesions or lymphadenopathy. Some patients have cervical and mesenteric lymphadenopathy. In the absence of a history of possible contact with a vector, diagnosis can be extremely difficult. Blood cultures may be positive and patients may present with classic sepsis or septic shock in this acute systemic form of the infection. Typhoidal tularemia is usually associated with a huge inoculum or with a preexisting compromising condition. High continuous fevers, signs of endotoxemia, and severe headache are common. The patient may be delirious and may develop prostration and shock. If presumptive antibiotic therapy in culture-negative cases does not include an aminoglycoside, the mortality rate can approach 30%.

Other Manifestations *F. tularensis* infection has been associated with meningitis, pericarditis, hepatitis, peritonitis, endocarditis, osteomyelitis, and sepsis and septic shock with rhabdomyolysis and acute renal failure. In the rare cases of tularemia meningitis, a predominantly lymphocytic response is demonstrated in cerebrospinal fluid.

DIFFERENTIAL DIAGNOSIS When patients in endemic areas present with fever, chronic ulcerative skin lesions, and large tender lymph nodes (Fig. 142-1), a diagnosis of tularemia should be made presumptively, and confirmatory diagnostic testing and appropriate therapy should be undertaken. When the possibility of tularemia is considered in a nonendemic area, an attempt should be made to identify contact with a potential animal vector. The level of suspicion should be especially high in hunters, trappers, game wardens, veterinarians, laboratory workers, and individuals exposed to an insect or another animal vector. However, up to 40% of patients with tularemia have no known history of epidemiologic contact with an animal vector.

The characteristic presentation of ulceroglandular tularemia does not pose a diagnostic problem, but a less classic progression of regional lymphadenopathy or glandular tularemia must be differentiated from other diseases (Table 142-3). The skin lesion of tularemia may resemble those seen in various other diseases but is generally accompanied by more impressive regional lymphadenopathy. In children, the differentiation of tularemia from cat-scratch disease is made more difficult by the chronic papulovesicular lesion associated with *Bartonella henselae* infection (Chap. 144). Oropharyngeal tularemia can resemble and must be differentiated from pharyngitis due to other bacteria or viruses. Tularemia pneumonia may resemble any atypical pneumonia. Typhoidal tularemia may resemble a variety of other infections.

LABORATORY DIAGNOSIS Direct microscopic examination of polychromatically stained tissue smears or clinical specimens reveals *F. tularensis* organisms, singly and in groups, both intra- and extracellularly. Gram's staining of clinical or biopsy material is of little value, as the small, weakly staining organisms cannot be readily distinguished from the background. An indirect fluorescent antibody test with commercially available antisera can be useful, although false-positive results due to *Legionella* spp. have been reported.

The diagnosis of tularemia is most frequently confirmed by serologic testing. In the standard tube agglutination test, a single titer of $\geq$1:160 is interpreted as a presumptive positive result. A fourfold increase in titer between paired serum samples collected 2 to 3 weeks apart is considered diagnostic. False-negative serologic responses are obtained early in infection; up to 30% of patients infected for 3 weeks have sera that test negative. Late in infection, titers into the thousands are common, and titers of 1:20 to 1:80 may persist for years. A microagglutination test that may be as much as 100-fold more sensitive than the standard tube agglutination test has been described and is currently being used in many clinical microbiology laboratories. Enzyme-linked immunosorbent assays have proved useful for the detection of both antibodies and antigens. Analysis of urine for *F. tularensis* antigen has yielded promising results in clinical trials, but facilities for this type of analysis are not widely available. A skin test for delayed hypersensitivity to *F. tularensis* turns positive during the first week of illness and remains positive for years. The skin-test antigen, which is not commercially available, can boost titers of agglutinating antibody.

Culture and isolation of *F. tularensis* are difficult. In one study the organism was isolated in only 10% of more than 1000 human cases, 84% of which were confirmed by serology. The medium of choice is cysteine-glucose-blood agar. *F. tularensis* can be isolated directly from infected ulcer scrapings, lymph-node biopsy specimens, gastric washings, sputum, and blood cultures. Colonies are blue-gray, round, smooth, and slightly mucoid. On media containing blood, a small zone of α hemolysis usually surrounds the colony. Slide agglutination tests or direct fluorescent antibody tests with commercially available antisera can be applied directly to culture suspensions for identification.

The polymerase chain reaction (PCR) has been used to detect *F. tularensis* DNA in multiple clinical specimens. During one outbreak, a multiplex PCR was used to target 16S rRNA and to diagnose ulceroglandular tularemia with DNA extracted from wound swabs; the PCR result was positive in 29 (73%) of 40 serologically confirmed cases. However, this test has not been shown to be more sensitive than direct culture and at present remains a research tool.

TREATMENT

F. tularensis cannot be subjected to standardized antimicrobial susceptibility testing because the organism will not grow on the media used. A wide variety of antibiotics, including all β-lactam antibiotics and the newer cephalosporins, are ineffective for the treatment of this infection. Several studies indicated that third-generation cephalosporins were active against *F. tularensis* in vitro, but clinical case reports suggested a nearly universal failure rate of ceftriaxone in pediatric patients with tularemia. Although in vitro data indicate that imipenem may be active, therapy with imipenem, sulfanilamides, and macrolides is not presently recommended because of the lack of relevant clinical data. Fluoroquinolones have shown promise in terms of their relatively low toxicity and their potential for oral administration. With intracellular activity, fluoroquinolones have been used for successful treatment of tularemia and are candidates for primary or alternative therapy, pending clinical trials. The use of these agents should also be consid-

ered when patients are allergic or intolerant to other treatments. When used, ciprofloxacin should be given for a total of 10 days. Chloramphenicol and tetracycline have been used successfully for treatment of the acute stages of tularemia but have been associated with higher relapse rates (up to 20%) than conventionally used agents. Oral chloramphenicol is no longer available in the United States.

Streptomycin, given intramuscularly at a dose of 7.5 to 10 mg/kg every 12 h, is considered the drug of choice for adults. In severe cases, 15 mg/kg every 12 h may be used for the first 48 to 72 h. Streptomycin is also considered the drug of choice for children; the appropriate dose is 30 to 40 mg/kg daily in two divided doses administered intramuscularly. In children, after a clinical response is demonstrated at 3 to 5 days, the dose can be reduced to 10 to 15 mg/kg daily in two divided doses. Therapy is typically continued for 7 to 10 days; however, in mild to moderate cases of tularemia in which the patient becomes afebrile within the first 48 to 72 h of streptomycin treatment, a 5- to 7-day course has been successful.

Gentamicin, at a dose of 1.7 mg/kg given intravenously or intramuscularly every 8 h, is also effective and may be more readily available. The published experience in adults consists of two reports describing, respectively, nine and eight patients who were treated effectively with gentamicin. The eight patients in one of the reports all had fever before treatment, and all eight became afebrile within 24 to 72 h. In a pediatric study, other symptoms, such as tender lymphadenitis and pharyngitis, also responded within 24 to 72 h of the start of gentamicin therapy.

Virtually all strains of *F. tularensis* are susceptible to streptomycin and gentamicin. In successfully treated patients, defervescence usually occurs within 2 days, but skin lesions and lymph nodes may take 1 to 2 weeks to heal. When therapy is not initiated within the first several days of illness, defervescence may be delayed. Relapses are uncommon with streptomycin or gentamicin therapy. Late lymph-node suppuration, however, occurs in ~40% of children, regardless of the treatment received. These nodes have typically been found to contain sterile necrotic tissue without evidence of active infection. Patients with fluctuant nodes should receive several days of antibiotic therapy before drainage to minimize the risk to hospital personnel. Unlike streptomycin and gentamicin, tobramycin is ineffective in the treatment of tularemia and should not be used.

PROGNOSIS If tularemia goes untreated, symptoms usually last 1 to 4 weeks but may continue for months. The mortality rate from severe untreated infection (including all cases of untreated tularemia pneumonia and typhoidal tularemia) can be as high as 30%. However, the overall mortality rate for untreated tularemia is <8%. Mortality is <1% with appropriate treatment. Poor outcomes are often associated with long delays in diagnosis and treatment. Lifelong immunity usually follows tularemia.

PREVENTION The prevention of tularemia is based on avoidance of exposure to biting and blood-sucking insects, especially ticks and deerflies. An intradermal vaccine made from live attenuated *F. tularensis* is available from the Centers for Disease Control and Prevention. This vaccine is effective in reducing the frequency and severity of infection. Vaccination of high-risk individuals working with large quantities of cultured organisms is recommended. Others who come into contact with the organisms, such as veterinarians, hunters, or game wardens, should consider vaccination, particularly if they live in endemic areas. The avoidance of skinning wild animals, especially rabbits, and the wearing of gloves while handling animal carcasses decrease the risk of transmission. Use of insect repellents and preparations that prevent tick attachment as well as prompt removal of ticks can be helpful. Prophylaxis of tularemia has not proved effective in patients with embedded ticks or insect bites. However, in patients who are known to have been exposed to large quantities of organisms (e.g., in the laboratory) and who have incubating infection with *F. tularensis*, early treatment can prevent the development of significant clinical disease.

143 PLAGUE AND OTHER *YERSINIA* INFECTIONS

David T. Dennis, Grant L. Campbell

PLAGUE

DEFINITION Plague is an acute, febrile, zoonotic disease caused by infection with *Yersinia pestis*. Although human cases are infrequent and are curable with antibiotics, plague is one of the most virulent and potentially lethal bacterial diseases known. The plague bacterium occurs in widely scattered foci in Asia, Africa, and the Americas, where its usual hosts are various wild rodents and human-associated rats. Infection is transmitted to humans typically by flea bite and less commonly by direct contact with infected animal tissues or by airborne droplet. The principal clinical forms of plague are bubonic, septicemic, and pneumonic. Although most cases are now sporadic, occurring singly or in small clusters, the potential for outbreaks and epidemic spread remains. Because of its virulence and transmissibility, *Y. pestis* is considered an important potential agent of biological terrorism that requires special countermeasures to protect the public's health (Chap. 205).

ETIOLOGIC AGENT *Y. pestis* is a gram-negative coccobacillus in the family Enterobacteriaceae. Genomic analysis suggests that it has recently evolved from *Y. pseudotuberculosis*. *Y. pestis* is microaerophilic, nonmotile, nonsporulating, oxidase and urease negative, and biochemically unreactive. The organism is nonfastidious and infective for laboratory rodents. It grows well, if slowly, on routinely used microbiologic media (e.g., sheep blood agar, brain-heart infusion broth, and MacConkey agar). *Y. pestis* can multiply within a wide range of temperatures (−2°C to 45°C) and pH values (5.0 to 9.6), but optimal growth occurs at 28°C and at pH ~7.4. When stained with a polychromatic stain (e.g., Wayson or Giemsa), *Y. pestis* isolated from clinical specimens exhibits a characteristic bipolar appearance, resembling closed safety pins. The bacterium is nonencapsulated but when grown at ≥30°C produces a plasmid-expressed envelope glycoprotein, fraction 1 (F1) antigen—a virulence factor that serves as the principal immunodiagnostic marker of infection.

HISTORIC BACKGROUND Plague's deadly epidemic potential is notorious and well documented. The Justinian pandemic (542 to 767 A.D.) spread from central Africa to the Mediterranean littoral and thence to Asia Minor, causing an estimated 40 million deaths. The second pan-

demic began in central Asia, was carried to Sicily by ship from Constantinople in 1347, and within a few years swept through Europe and the British Isles; successive epidemics of lesser magnitude occurred over the next four centuries. At its height, the second plague pandemic killed as many as a quarter of the affected population and became known as the Black Death. In the third (modern) pandemic, plague appeared in Yunnan, China, in the latter half of the nineteenth century; established itself in Hong Kong in 1894; and spread by ship to Bombay in 1896 and subsequently to major port cities throughout the world, including San Francisco and several other West Coast and Gulf Coast ports in the United States. The plague bacillus was first cultured by Alexandre Yersin in Hong Kong in 1894. In 1898, Paul-Louis Simond, a French scientist sent to investigate epidemic bubonic plague in Bombay, identified the bacillus in the tissues of dead rats and proposed transmission by rat fleas. Waldemar Haffkine, also in Bombay at that time, developed a crude vaccine.

By 1910, plague had circled the globe and was established in rodent populations on all inhabited continents other than Australia. After 1920, however, the spread of plague was largely halted by international regulations that mandated control of rats in harbors and inspection and rat-proofing of ships. Before subsiding, the third pandemic had resulted in an estimated 26 million plague cases and >12 million deaths, the vast majority in India. By 1950, plague outbreaks around the world had become isolated, sporadic, and manageable with modern techniques of surveillance, flea and rat control, and antimicrobial treatment of patients. Plague has nearly disappeared from cities and now occurs mostly in rural and semirural areas, where it is maintained in various rodents and their fleas. In the United States, the last outbreak of urban plague occurred in Los Angeles in 1924 and 1925, and human cases since then have, with very few exceptions, resulted from exposures in rural areas of western states.

Plague remains one of three quarantinable diseases subject to international health regulations (the other two being cholera and yellow fever). The alarm that plague is still able to evoke was highlighted by the public panic and exaggerated official responses to reported outbreaks of bubonic and pneumonic plague in India in 1994. The plague bacillus is considered to have a high potential for use in biological terrorism; the agent is available around the world, has been "weaponized" for airborne delivery, and would be expected to cause a high primary fatality rate as well as secondary spread among an affected population (Chap. 205).

EPIDEMIOLOGY *Y. pestis* is maintained in well-established "silent" enzootic cycles involving relatively resistant wild rodents and their fleas in remote, lightly populated areas of Asia, Africa, and the Americas and in limited rural foci in extreme southeastern Europe near the Caspian Sea. Humans and mammals other than rodents are incidental hosts. Outbreaks (epizootics) of plague in susceptible rodent populations may result in widespread die-offs of these animals, an avid search by their fleas for new hosts, and an increased risk of spread of infection to humans. In the United States, the principal epizootic hosts are various ground squirrels, prairie dogs, and chipmunks; a variety of burrowing rodents act as epizootic hosts in rural areas elsewhere in the world. *Y. pestis* occasionally spills over from wild rodents to rat species that inhabit cultivated fields and adjacent homes, villages, and towns. The organism can then be transported from towns to cities by these highly adaptable rats and their fleas.

Plague in populated areas is most likely to develop when sanitation is poor and rats are numerous—especially the common black or roof rat (*Rattus rattus*), its close relatives, and the larger brown sewer or Norway rat (*R. norvegicus*). The cosmopolitan oriental rat flea *Xenopsylla cheopis* and (in southern Africa and Brazil) the related species *X. brasiliensis* are efficient vectors of the plague bacillus from rat to rat and from rats to humans. *Y. pestis* multiplies to enormous numbers in the foregut (proventriculus) of these fleas, resulting in a bolus of organisms and clotted blood that blocks the passage of subsequent blood meals. This situation occurs only at temperatures of ≤28°C and depends on a single protease expressed by the plasminogen activator (*pla*) gene of a 9.5-kb plasmid of *Y. pestis*. Regurgitation by a "blocked" flea while it feeds facilitates transmission of the plague bacillus to the new host. Except for large outbreaks of pneumonic plague in Manchuria in the early part of the twentieth century, person-to-person respiratory transmission of plague has since occurred only sporadically and has been limited to clusters of close, direct contacts of pneumonic plague patients, such as household members and caregivers.

International health regulations require that national authorities immediately report plague cases to the World Health Organization. From 1987 through 2001, 36,876 human plague cases (mean, 2458 cases per year) and 2847 deaths (mortality, 8%) were reported by 24 countries. In the same 15-year period, the United States reported 125 cases and 12 deaths (mortality, 10%). Cases reported by the United States are confirmed by the plague laboratory of the Centers for Disease Control and Prevention (CDC). Animal plague occurs in 17 contiguous western states, extending from the Great Plains states and eastern Texas to the Pacific Coast; around 80% of human cases in this country now occur in New Mexico, Arizona, and Colorado and around 10% in California. The arid Native American reservations of New Mexico and Arizona are active plague foci, and Native Americans account for a disproportionately high percentage of plague cases in the United States. Although plague is a rural disease in this country, >50% of cases are thought to be caused by peridomestic exposures, especially in the southwestern states, where homes are often situated in natural surroundings that provide a favorable habitat for plague-susceptible animals (such as rock squirrels and wood rats) and their fleas. In the Sierra Nevadas of California and Nevada, epizootic plague in chipmunks and ground squirrels poses a risk to visitors in public parks. Hikers, campers, and hunters in natural areas throughout the western states are at a small but finite risk of exposure to plague, especially in the summer months.

Plague can be transmitted during the skinning and handling of carcasses of wild animals such as rabbits and hares, prairie dogs, wildcats, and coyotes. Such direct inoculation of mammal-adapted organisms expressing the F1 antigen is associated with primary septicemia and high mortality. Pharyngeal plague can result from the ingestion of undercooked contaminated meat, from inhaling respiratory droplets, and perhaps from the manual transfer of infected fluids to the mouth during the handling of infected animal tissues.

Carnivores, including dogs and cats, can become infected with *Y. pestis* by eating infected rodents and possibly by being bitten by infective fleas. Although clinical plague commonly develops in infected cats, it rarely does so in infected dogs. Both dogs and cats may transport infected fleas from rodent-infested areas to the home environment.

From 1947 through 2001, 421 plague cases were reported in the United States. Of the 409 evaluable cases, 349 cases (85%) presented as primary lymphadenitic (bubonic) plague, almost all of them thought to be associated with flea bites; 55 cases (13%) presented as primary septicemic plague, many of them following direct animal exposures; and 8 cases (2%) presented as primary pneumonic plague, 6 resulting from the inhalation of respiratory droplets released by infected cats and 2 from unknown sources. The last case of human-to-human plague transmission in the United States occurred in Los Angeles in 1924.

PATHOGENESIS AND PATHOLOGY *Y. pestis* is highly invasive and pathogenic. The mechanisms by which the organism causes disease are incompletely understood, but both chromosome- and plasmid-encoded gene products as well as altered cell-mediated immune responses are involved. Three plasmids encode for a variety of known or presumed virulence factors; these include the F1 envelope antigen and various *Yersinia* outer-membrane proteins (Yops), which confer bacterial resistance to phagocytosis; the V antigen, which is essential for virulence and immunocompromises the host by suppressing the synthesis of various proinflammatory cytokines (e.g, interferon γ and tumor necrosis factor α); pesticin, which interferes with iron uptake; a protease that

FIGURE 143-1 Plague patient in the southwestern United States with a left axillary bubo and an unusual plague ulcer and eschar at the site of the infective flea bite.

activates plasminogen and degrades serum complement and is thought to enhance dissemination of *Y. pestis* following inoculation of the skin; a coagulase; and a fibrinolysin. A chromosomally encoded lipopolysaccharide endotoxin is important in sepsis, triggering the systemic inflammatory response syndrome and its complications.

Y. pestis organisms inoculated through the skin or mucous membranes are typically carried to regional lymph nodes via lymphatic channels, although direct bloodstream inoculation and dissemination may take place. Mononuclear phagocytes, which can phagocytize *Y. pestis* organisms without destroying them, may play a role in dissemination of the infection to distant sites. Plague can involve almost any organ, and untreated plague generally results in widespread and massive tissue destruction. In the early stages, infected lymph nodes (*buboes*, Fig. 143-1) are characterized by edema and congestion without inflammatory infiltrates or apparent vascular injury. Fully developed buboes contain huge numbers of infectious plague organisms and show distorted or obliterated lymph node architecture with loss of vascular integrity, hemorrhage, necrosis, infiltration of polymorphonuclear neutrophils (PMNs), and extensive serosanguineous effusion. The effusion typically involves perinodal tissues. If several adjacent lymph nodes are involved, a boggy edematous mass can result.

Primary septicemic plague consists of sepsis in the absence of a bubo; secondary septicemic plague is a complication of bubonic or pneumonic plague that occurs when local host defenses are breached. In fatal septicemic plague, multifocal hepatic and splenic necrosis is common. Diffuse interstitial myocarditis with cardiac dilatation is sometimes found. If disseminated intravascular coagulation (DIC) ensues, vascular necrosis may lead to widespread cutaneous, mucosal, and serosal ecchymoses and petechiae. Acral ischemia and resulting gangrene sometimes develop.

Primary plague pneumonia generally begins as a lobular process and then extends by confluence, becoming lobar and then multilobar (Fig. 143-2). Plague organisms are typically most numerous in the alveoli. Secondary plague pneumonia begins more diffusely, with organisms at first most numerous in the interstitium. In advanced cases of both primary and secondary plague pneumonia, affected lung tissue is characterized by edema, hemorrhagic necrosis, and infiltration by neutrophilic leukocytes.

MANIFESTATIONS Plague is characterized by a rapid onset of fever and other systemic manifestations of gram-negative bacterial infection. If it is not quickly and correctly treated, plague can follow a toxic course, resulting in shock, multiple-organ failure, and death. In humans, the three principal forms of plague are bubonic, septicemic, and pneumonic. Bubonic plague, the most common form, is almost always caused by the bite of an infected flea but occasionally results from direct contact with infectious materials. Septicemic and pneumonic plague can be either primary or secondary to metastatic spread. Unusual forms include plague meningitis, endophthalmitis, and lymphadenitis at multiple sites. Primary plague pharyngitis has been documented by culture of organisms from throat swabs and can result from respiratory exposure or ingestion of undercooked flesh of infected animals.

Bubonic Plague Bubonic plague has a usual incubation period of 2 to 6 days. Patients experience chills; fever, with temperatures that rise within hours to ≥38°C; myalgias; arthralgias; headache; and a feeling of weakness. Soon—usually within 24 h—the patient notices tenderness and pain in one or more regional lymph nodes proximal to the site of inoculation of the plague bacillus (Fig. 143-1). Because fleas most often bite the legs, femoral and inguinal nodes are most commonly involved; axillary and cervical nodes are next most commonly affected. Within hours, the enlarging bubo becomes progressively painful and tender, sometimes exquisitely so. The patient usually guards against palpation and limits movement, pressure, and stretch around the bubo. The surrounding tissue often becomes edematous, sometimes markedly so, and the overlying skin may be erythematous, warm, and tense. Inspection of the skin surrounding or distal to the bubo sometimes reveals the site of a flea bite marked by a papule, pustule, or ulcer. The ulcer may be covered by an eschar (Fig. 143-1). A list of lymphadenitic conditions that could be confused with bubonic plague includes *Staphylococcus aureus* and group A β-hemolytic streptococcal infections, cat-scratch disease, tularemia, and—in filariasis endemic areas—acute filarial lymphadenitis. The bubo of plague

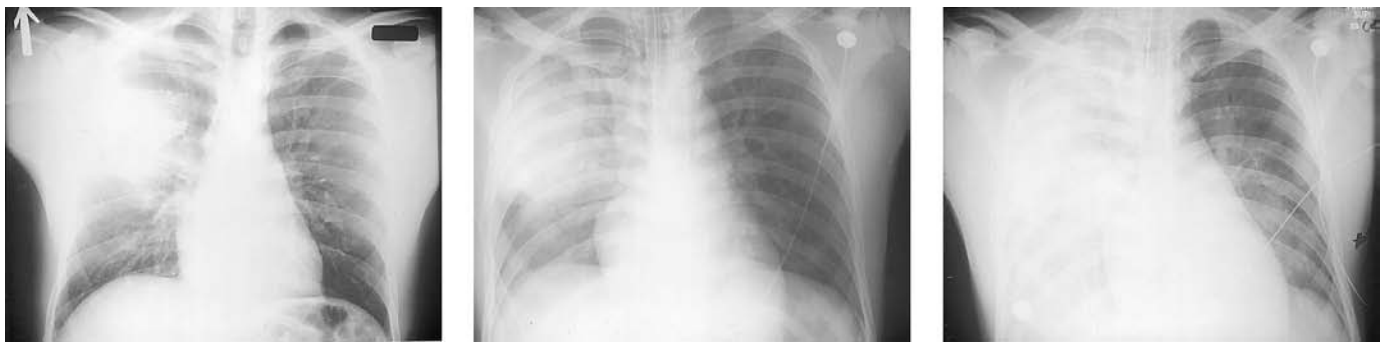

FIGURE 143-2 Sequential chest radiographs of a patient with fatal primary plague pneumonia. *Left*: Upright posteroanterior film taken at admission to hospital emergency department on third day of illness, showing segmental consolidation of right upper lobe. *Center*: Portable anteroposterior film taken 8 h after admission, showing extension of pneumonia to right middle and right lower lobes. *Right*: Portable anteroposterior film taken 13 h after admission (when patient had clinical adult respiratory distress syndrome), showing diffuse infiltration throughout right lung and patchy infiltration of left lower lung. A cavity later developed at the site of initial right-upper-lobe consolidation.

is distinguishable from lymphadenitis of most other causes, however, by its rapid onset, its extreme tenderness, the accompanying signs of toxemia, and the absence of cellulitis or obvious ascending lymphangitis. The pain and swelling of bubonic plague can be confused with a strangulated hernia or trauma.

Treated in the uncomplicated state with an appropriate antibiotic, bubonic plague usually responds quickly, with resolution of fever and alleviation of other systemic manifestations over 2 to 5 days. Buboes often remain enlarged and tender for a week or more after the initiation of treatment and can become fluctuant. Without effective antimicrobial treatment, patients with typical bubonic plague manifest an increasingly toxic state of fever, tachycardia, lethargy leading to prostration, agitation and confusion, and (occasionally) convulsions and delirium. Secondary plague sepsis may result in an alarmingly rapid and refractory cascade of DIC, bleeding, shock, and organ failure. Mild forms of bubonic plague, called *pestis minor*, have been described in South America and other plague endemic areas; in these cases, the patients are ambulatory, are only mildly febrile, and have subacute buboes.

Septicemic Plague Septicemic plague is a progressive, overwhelming gram-negative infection. Primary septicemia develops in the absence of a bubo, and the diagnosis is often not suspected until preliminary blood culture results are reported to be positive by the laboratory. *Y. pestis*, however, can also be cultured from the blood of most bubonic plague patients, and bacteremia should be distinguished from septicemia, in which the patient is desperately ill and requires aggressive care. Septic patients often present with gastrointestinal symptoms of nausea, vomiting, diarrhea, and abdominal pain, which may further confound the correct diagnosis. If not treated early with appropriate antibiotics, septicemic plague can be fulminant and fatal. In the United States in 1947 through 2001, 55 cases of primary septicemic plague with 13 deaths were reported, for a case-fatality rate of 24%. Petechiae, ecchymoses, bleeding from puncture wounds and orifices, and gangrene of acral parts are manifestations of DIC; refractory hypotension, renal shutdown, obtundation, and other signs of shock are preterminal events. Adult respiratory distress syndrome (ARDS), which can occur at any stage of septicemic plague, is sometimes confused with other conditions, such as hantavirus pulmonary syndrome. The differential diagnosis of septicemic plague includes sepsis of other gram-negative bacterial etiology, meningococcemia, and acute severe viral infections such as hantavirus illness.

Pneumonic Plague Of all forms of the disease, pneumonic plague develops most rapidly and is most frequently fatal. The incubation period for primary pneumonic plague is usually 3 to 5 days (range, 1 to 7 days). The onset is most often sudden, with chills, fever, headache, myalgias, weakness, and dizziness. Pulmonary signs, including tachypnea and dyspnea, cough, sputum production, and chest pain, typically arise on the second day of illness and may be accompanied by hemoptysis, increasing respiratory distress, cardiopulmonary insufficiency, and circulatory collapse. In primary plague pneumonia, the sputum is most often watery or mucoid, frothy, and blood-tinged, but it may become frankly bloody. Pulmonary signs in primary pneumonic plague may indicate involvement of a single lobe in the early stage, with rapidly developing segmental consolidation before bronchopneumonic spread to other lobes of the same and opposite lungs (Fig. 143-2). Liquefaction necrosis and cavitation may occur early in areas of consolidation and may or may not leave significant residual scarring.

Secondary plague pneumonia, which occurs in 10 to 15% of bubonic plague cases in the United States, typically manifests first as a diffuse interstitial pneumonitis in which sputum production is scant; since the sputum is more likely to be inspissated and tenacious in character than the sputum found in primary pneumonia, it may be less infectious. In the United States in 1947 through 2001, 46 cases of secondary pneumonic plague and 8 cases of primary pneumonic plague were described, with no known transmission to contacts and an overall case-fatality rate of 41%. Observers in the early twentieth century remarked on the relative lack of auscultatory findings, the usual presence of toxemia, and the frequency of sudden death among patients with pneumonic plague as compared to patients with other bacterial pneumonias.

The differential diagnosis of pneumonic plague includes acute community-acquired pneumonia of another bacterial or a viral etiology, tularemia, coccidioidomycosis, *Pneumocystis* pneumonia, and Q fever.

Plague Meningitis Meningitis is an unusual manifestation of plague. In the United States, there were 17 meningitis cases among the 409 evaluable plague cases reported in 1947 through 2001. All cases of meningitis were complications of bubonic plague, and all but three patients survived. Although meningitis may be a part of the initial presentation of plague, its onset is often delayed and is a manifestation of insufficient treatment. Recent cases in the United States have occurred in association with treatment of bubonic plague with tetracyclines, which are bacteriostatic against *Y. pestis*. Chronic relapsing meningeal plague over periods of weeks or even months was described in the preantibiotic era. The affected patients typically present with fever, headache, meningismus, and neutrophilic pleocytosis.

Plague Pharyngitis Plague pharyngitis presents as fever, sore throat, cervical lymphadenitis, and headache and is often indistinguishable clinically from pharyngitis and tonsillitis of other infectious etiologies, especially streptococcal pharyngitis. Plague pharyngitis can be difficult to distinguish from cervical bubonic plague arising from an infective flea bite on the head and neck region. Caregivers working in endemic areas must be alert to plague in the differential diagnosis of pharyngitis to avoid delayed and/or inappropriate treatment.

LABORATORY FINDINGS AND DIAGNOSIS Since plague is a rare disease in the United States, a high index of clinical suspicion as well as the elicitation of a thorough clinical and epidemiologic history and a careful physical examination are required for timely diagnosis and prompt institution of specific therapy. When the diagnosis of plague is delayed or missed altogether, a high case-fatality rate results; infected travelers who seek medical care after they have left endemic areas (peripatetic plague cases) are at especially high risk. Plague must be considered in the differential diagnosis of acute regional lymphadenitis, sepsis, or acute severe pneumonia in an otherwise-healthy person who has a history of recent travel to or residence in the rural western United States. When the diagnosis of plague is being considered, close communication between clinicians and the diagnostic laboratory and between the diagnostic laboratory and a qualified reference laboratory is essential. Tests for plague are highly reliable when conducted by laboratory personnel experienced with *Y. pestis*, but such expertise is usually limited to selected reference laboratories, including state health department laboratories in some plague-endemic states and the CDC plague laboratory (Fort Collins, Colorado; tel. 970-221-6400).

When plague is suspected, specimens should be collected promptly for laboratory studies, chest roentgenograms should be obtained, and specific antimicrobial therapy should be initiated pending confirmation. Appropriate diagnostic specimens for smear and culture include citrated or heparinized whole blood from all patients with suspected plague; lymph node aspirates from those with suspected buboes; sputum samples, pharyngeal swabs, and tracheal or pulmonary alveolar aspirates from those with suspected pneumonic plague; and cerebrospinal fluid (CSF) from those with suspected plague meningitis. Since early buboes are often exquisitely tender and are seldom fluctuant or necrotic, these lesions usually require aspiration under local anesthesia following the injection of 1 to 2 mL of normal saline (sterile but nonbacteriostatic) into the bubo with a 20- to 22-gauge needle. Typically, aspiration produces a scant amount of serosanguineous fluid. A variety of appropriate culture media (including brain-heart infusion broth, sheep blood agar, and MacConkey agar) should be inoculated with a portion of each specimen. Moreover, for each specimen, at least one smear should be examined immediately with Wayson or Giemsa stain and at least one with Gram's stain; a smear should also be submitted to a reference laboratory for direct fluorescent antibody testing, anti-

gen-capture enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR) analysis, or testing by another rapid detection method (e.g., immunochromatographic hand-held assay). An acute-phase serum specimen should be tested for antibody to *Y. pestis*; whenever possible, a convalescent-phase serum specimen collected 3 to 4 weeks later should also be tested. When a patient dies and plague is suspected, appropriate autopsy tissues for culture, direct fluorescent antibody testing, and immunohistochemical staining include buboes, all solid organs (especially liver, spleen, and lung), and bone marrow. If culture of such specimens is to be attempted, they should be sent to the laboratory either fresh or frozen on dry ice, not in preservatives or fixatives. If necessary, Cary-Blair or a similar medium can be used to transport *Y. pestis*–infected tissues.

Laboratory confirmation of plague depends on the isolation of *Y. pestis* from cultures of body fluids or tissues. Cultures of three blood samples taken over a 45-min period before treatment will usually result in isolation of the bacterium. *Y. pestis* strains are readily distinguished from those of the closely related species *Y. pseudotuberculosis* by differences in biochemical profile, temperature-dependent susceptibility to lysis by a *Y. pestis*–specific bacteriophage, and motility. Automated bacteriologic test systems can be used to assist in the identification of isolates as *Y. pestis*, but *Y. pestis* can be misidentified (e.g., as *Y. pseudotuberculosis*) or overlooked if these systems are improperly programmed.

In the absence of *Y. pestis* isolation, plague cases can be confirmed either by the demonstration of seroconversion (a fourfold or greater titer rise) to *Y. pestis* F1 antigen in passive hemagglutination tests of acute- and convalescent-phase serum specimens or by detection of an antibody titer of >128 in a single serum sample from a patient with a plague-compatible illness who has not received plague vaccine. The specificity of a positive passive-hemagglutination test requires confirmation with the F1 antigen hemagglutination-inhibition test. A few plague patients seroconvert to F1 antigen as early as 5 days after the onset of illness; most seroconvert between 1 and 2 weeks after onset; a few seroconvert >3 weeks after onset; and a few (<5%) fail to seroconvert at all. Early, specific antibiotic treatment may delay seroconversion by several weeks. After seroconversion, positive serologic titers diminish gradually over months to years. ELISAs for IgM and IgG antibodies to *Y. pestis* are replacing hemagglutination tests in some laboratories. Other new test methods include those mentioned above: antigen-capture ELISAs, PCR, and immunochromatographic hand-held assays for rapid identification of *Y. pestis* in aspirates, sputum, and other infected body fluids or tissues. The hand-held assays can be used at the bedside in the remote rural settings where most plague cases occur and could prove important in responding to bioterrorism (Chap. 205).

Patients with plague typically have white blood cell (WBC) counts of 10,000 to 25,000/μL, with a predominance of PMNs and a left shift. Leukemoid reactions with WBC counts as high as 100,000/μL can occur. Modest thrombocytopenia is usually documented, and fibrin-fibrinogen split products are often detected even in patients without frank DIC. Serum levels of aminotransferases and bilirubin may be elevated. In plague pneumonia, stained respiratory secretions usually contain PMNs and characteristic bipolar-staining bacilli. In *Y. pestis* septicemia, visualization of the characteristic bacilli in a routine blood smear or a buffy-coat smear is an uncommon but grave prognostic sign (Fig. 143-3). In patients with plague meningitis, PMN pleocytosis is typical, and the bacilli are usually visible in stained CSF smears.

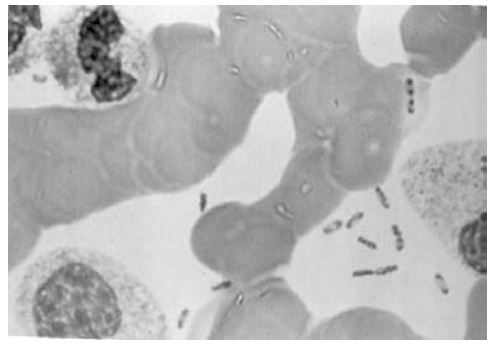

FIGURE 143-3 Peripheral blood smear from a patient with fatal plague septicemia and shock, showing characteristic bipolar-staining *Y. pestis* bacilli (Wright's stain, oil immersion).

Rx TREATMENT

Left untreated, plague is fatal in >50% of cases of bubonic disease and in nearly all cases of septicemic and pneumonic disease. The overall mortality rate for plague cases in the United States since 1950 has been ~14%; deaths are almost always due to delays in seeking treatment, misdiagnosis, delays in the institution of treatment, or incorrect treatment. Rapid diagnosis and appropriate antimicrobial therapy are essential.

Guidelines for the treatment of plague are given in Table 143-1. Although streptomycin is the drug of choice, gentamicin is increasingly used for the treatment of plague in the United States because of its ready availability; it is probably as effective as streptomycin and less toxic, although results of controlled studies in humans have not been published. Alternative antibiotics include the tetracyclines and chloramphenicol; these agents are usually given orally with initial loading doses but may be given intravenously to critically ill patients and to patients unable to tolerate oral medication. Doxycycline is considered the tetracycline of choice. Penicillins, cephalosporins, and macrolides are suboptimal and should not be used. Trimethoprim-sulfamethoxazole (TMP-SMX) has been used successfully to treat bubonic plague but is not considered a first-line agent. Chloramphenicol may be indicated for the treatment of plague meningitis, pleuritis, endophthalmitis, and myocarditis because of its superior tissue penetration; it is used alone or in combination with streptomycin or another first-line agent. In general, antimicrobial treatment should be continued for 7 to 10 days or for at least 3 days after the patient has become afebrile and has made a clinical recovery. Patients initially given intravenous antibiotics may be switched to oral regimens upon clinical improvement. Such improvement is usually evident 2 or 3 days after the start of treatment, even though fever may continue for several days. National bioterrorism-response protocols propose gentamicin, ciprofloxacin, and doxycycline as antimicrobial agents of first choice for treatment and postexposure prophylaxis in the event of an attack using *Y. pestis* (Chap. 205).

Consequences of delayed treatment of plague include DIC, ARDS, and other complications of gram-negative sepsis. Patients with these

TABLE 143-1 *Guidelines for the Treatment of Plague*

Drug	Daily Dosage	Interval, h	Route(s) of Administration
Streptomycin			
Adults	2 g	12	IM
Children	30 mg/kg	12	IM
Gentamicin			
Adults	3–5 mg/kg[a]	8	IM or IV
Children	6.0–7.5 mg/kg	8	IM or IV
Infants/neonates	7.5 mg/kg	8	IM or IV
Tetracycline			
Adults	2 g	6	PO or IV
Children ≥8 y	25–50 mg/kg	6	PO or IV
Doxycycline			
Adults	200 mg	12 or 24	PO or IV
Children ≥8 y	4.4 mg/kg	12 or 24	PO or IV
Chloramphenicol			
Adults	50 mg/kg[b]	6	PO or IV
Children ≥1 y	50 mg/kg[b]	6	PO or IV

[a] Dosage should be reduced to 3 mg/kg daily as soon as clinically indicated.
[b] For meningitis, up to 100 (mg/kg)/d initially.

disorders require intensive monitoring and close physiologic support, as outlined elsewhere (Chaps. 102 and 251). Buboes may require surgical drainage. Abscessed nodes can cause recurrent fever in patients who have apparently recovered; the cause may be occult if intrathoracic or intraabdominal nodes are involved. Although *Y. pestis* is considered to be genetically stable, a multidrug-resistant strain was recently isolated from a plague patient in Madagascar. This strain exhibited resistance (mediated by a transferable plasmid) to principal first-line antibiotics used for treatment and prophylaxis of plague.

PREVENTION AND CONTROL Persons at greatest risk for plague in the United States are individuals who live, work, and participate in outdoor recreational activities in areas of those western states in which plague is enzootic. Surveillance, education, and environmental management are the cornerstones of prevention and control. A network of biologists and public health specialists coordinates these activities through local and state health departments and the CDC. Personal protective measures include the avoidance of areas with known epizootic plague (in which warning signs may be posted) and of sick or dead animals; the use of repellents, insecticides, and protective clothing when at risk of exposure to rodents' fleas; and the wearing of gloves when handling animal carcasses. Short-term antibiotic prophylaxis (Table 143-2) is recommended for persons known to have had close contact with a patient with suspected or confirmed pneumonic plague and occasionally for persons who are unable to avoid an area where a plague outbreak is in progress or who may be caring for patients with plague. Patients in whom respiratory plague is suspected should be managed under isolation, with use of respiratory-droplet precautions until pneumonia has been ruled out or until 48 h of effective antimicrobial therapy has been administered, after which standard infection-control precautions are adequate. Masks are considered to be protective against respiratory transmission of plague and would be expected to be an important tool to prevent secondary plague spread in the event of bioterrorism (Chap. 205).

Rodent food (garbage, pet food) and habitats (brush piles, junk heaps, woodpiles) should be eliminated in domestic, peridomestic, and working environments; buildings and food stores should be rodent-proofed. The control of fleas with insecticides is a key public health measure in situations where epizootic plague activity places humans at high risk; this effort includes dusting and spraying of rodent burrows, rodent runs, and other sites where rodents and their fleas are found. In plague-endemic areas of the western United States, persons should keep their dogs and cats free of fleas and restrained. The decision to control plague by killing rodents should be left to public health authorities, and such a program should be carried out only in conjunction with effective flea control. Killing of rodents has no lasting benefit without environmental sanitation.

TABLE 143-2 *Guidelines for Plague Prophylaxis*

Drug	Daily Dosage	Interval, h	Route of Administration
Tetracycline			
Adults	1–2 g	6 or 12	PO
Children ≥8 y	25–50 mg/kg	6 or 12	PO
Doxycycline			
Adults	100–200 mg	12 or 24	PO

Ciprofloxacin[b]			
Adults	1 g	12	PO
Children	40 mg/kg	12	PO

[a] Trimethoprim component.
[b] Recommended as an alternative to doxycycline in bioterrorism-response plans.

The previously used killed, whole-cell plague vaccine is no longer available in the United States. New and improved vaccines are being evaluated that use recombinant F1 and V antigens to induce protective antibodies. In the United States, the indications for use of these newer vaccines would probably be similar to those for the previously available killed vaccine, which was mostly limited to protecting laboratory personnel who routinely worked with *Y. pestis* and some persons whose vocations brought them into regular contact with wild rodents and their fleas in areas with enzootic or epizootic plague. In addition, a vaccine might be useful in protecting selected persons at risk from biowarfare or bioterrorism.

OTHER *YERSINIA* INFECTIONS

DEFINITION Yersiniosis is an uncommon bacterial zoonosis caused primarily by infection with either of two enteropathogenic *Yersinia* species: *Y. enterocolitica* or *Y. pseudotuberculosis*. Reservoir hosts of these bacteria include swine and other wild and domestic animals, and transmission to humans is predominantly via the oral route. Both sporadic cases and common-source outbreaks occur. The most frequent acute clinical manifestations are (1) enteritis or enterocolitis with self-limited diarrhea (especially with *Y. enterocolitica*) and (2) mesenteric adenitis and terminal ileitis (especially with *Y. pseudotuberculosis*), which can be confused with acute appendicitis. Septicemia and metastatic focal infections are less common. Yersiniosis can be complicated by nonsuppurative, extraintestinal, inflammatory sequelae—e.g., reactive arthritis (Chap. 305) and erythema nodosum (Chap. 17). Other nonplague *Yersinia* species, including *Y. intermedia*, *Y. frederiksenii*, and *Y. kristensenii*, have been associated with enteritis or enterocolitis in humans (particularly immunocompromised adults), but little is known about their pathogenicity, public health importance, or clinical management.

ETIOLOGIC AGENTS *Y. enterocolitica* and *Y. pseudotuberculosis* are pleomorphic gram-negative bacilli in the family Enterobacteriaceae. They can multiply within a wide temperature range (−1°C to 45°C). Pathogenic *Y. enterocolitica* isolates are most commonly identified by biotyping based on biochemical profiles and serotyping according to somatic O and H antigens. Six biotypes and >60 serotypes of *Y. enterocolitica* are recognized. A separate serotyping system for *Y. pseudotuberculosis* (also based on somatic antigens) has distinguished six major serotypes (I through VI) and their subtypes.

EPIDEMIOLOGY ■ ***Yersinia enterocolitica*** *Y. enterocolitica* is distributed worldwide and has been isolated from soil, fresh water, contaminated foodstuffs (e.g., meat, milk, and vegetables), and a wide variety of wild and domestic animals. Many serotypes isolated from environmental sources, however, evidently are not human pathogens. Most human infections have been caused by *Y. enterocolitica* serotypes O:3, O:5,27, O:8, and O:9, which are primarily associated with wild and domestic mammals. The recognized incidence of these infections and their sequelae is highest in Scandinavia and some other northern European countries, but reliable population-based estimates of incidence are unavailable.

All age groups are susceptible to *Y. enterocolitica* infections, but the majority of cases of enterocolitis are in children aged 1 to 4. Moreover, these infections show a modest predilection for males. Mesenteric adenitis and terminal ileitis are most common among older children and young adults. Risk factors for *Y. enterocolitica* septicemia and metastatic focal infections include chronic liver disease, malignancy, diabetes mellitus, immunosuppressive therapy, alcoholism, malnutrition, advanced age, iron overload (see below), and hemolytic anemias (including the thalassemias). The nonsuppurative sequelae of yersiniosis are most common among adults. HLA-B27 is expressed in 70 to 80% of patients who develop reactive arthritis associated with yersiniosis. HLA-B27 is not a risk factor for *Yersinia*-induced erythema nodosum; females with this condition outnumber males by 2 to 1.

Among *Y. enterocolitica* strains isolated from patients in recent decades, serotypes O:3 and O:9 have predominated in Europe, while

serotype O:3 has predominated in Canada, Japan, and the United States. The apparent incidence of *Yersinia*-induced nonsuppurative sequelae reportedly is 10 to 30% in Scandinavia and much lower in most other countries, including the United States.

Common-source outbreaks of *Y. enterocolitica* enteritis have been traced to such vehicles as raw milk, contaminated pasteurized milk, and foods prepared with contaminated fresh water. Because *Y. enterocolitica* commonly colonizes the gastrointestinal tracts of swine, sporadic human cases and outbreaks of yersiniosis have also been associated with the preparation or ingestion of raw pork products (e.g., chitterlings). In some cases of yersiniosis, circumstantial evidence suggests transmission via contact with dogs and cats or their feces. Several nosocomial outbreaks of *Y. enterocolitica* infection have been described; fecal-oral transmission from person to person was suspected. Fecal-oral transmission among family members may also explain occasional secondary cases in households. In a prospective study of 50 children with *Y. enterocolitica* enteritis, fecal excretion of the organism persisted for an average of 27 days (range, 4 to 79 days) after the cessation of symptoms. A chronic carrier state, however, has not been demonstrated. *Y. enterocolitica* is a rare but often lethal cause of transfusion-associated septicemia. The explanation is that blood donors occasionally have transient, occult *Y. enterocolitica* bacteremia and that this organism can slowly multiply to high concentrations in blood refrigerated for at least 10 days.

Yersinia pseudotuberculosis The ecology of *Y. pseudotuberculosis* seems to parallel that of *Y. enterocolitica* closely. *Y. pseudotuberculosis* is also widespread in wild and domestic animals and is isolated from many environmental sources. Human infections with *Y. pseudotuberculosis*, however, appear to be rare. Swine appear to be an important reservoir for pathogenic strains of *Y. pseudotuberculosis*.

PATHOGENESIS AND PATHOLOGY With rare exceptions (e.g., transmission via contaminated blood products or direct cutaneous inoculation), the enteropathogenic yersiniae are thought to enter the host via the oral route. The incubation period averages 5 days (range, 1 to 11 days). Studies of animals have shown that the organisms initially invade the ileal epithelium, then are translocated via M cells into the lamina propria, and finally enter Peyer's patches, where they are able to replicate. They subsequently drain into the mesenteric lymph nodes, which undergo hyperplasia and from which the bacteria can be disseminated. The mesenteric lymph nodes can become intensely swollen and matted and are occasionally detected on physical examination as a tender right-lower-quadrant mass. Intestinal inflammation (most commonly of the distal ileum and less commonly of the ascending colon) develops and may be accompanied by mucosal ulcerations and by the shedding of PMNs and red blood cells into the intestinal lumen. In relatively severe cases, thrombosis of mesenteric blood vessels, intestinal hemorrhage, and necrosis can occur. In patients with enteropathogenic yersinial infections who undergo exploratory laparotomy, the appendix usually is histologically normal or shows only lymphoid hyperplasia, but frank suppuration is sometimes evident.

A plasmid of ~70 kb is essential for virulence of the enteropathogenic yersiniae because it encodes at least six Yops, which confer a variety of pathogenic properties—e.g., cytotoxicity; resistance to phagocytosis by PMNs; and the ability to cause monocyte apoptosis (programmed cell death), to suppress the host's expression of tumor necrosis factor α, and to interfere with platelet aggregation and host complement activation. A chromosomal gene (*inv*) encodes for the surface protein invasin, which is necessary for yersinial invasion of nonphagocytic host cells (e.g., epithelial cells) in vitro and which facilitates the translocation of bacteria across the intestinal epithelium. Both *Y. enterocolitica* and *Y. pseudotuberculosis* can express at least one protein superantigen that selectively stimulates the proliferation of T cells. Many strains of *Y. enterocolitica* produce a heat-stable enterotoxin that is similar to *Escherichia coli* enterotoxin. The cell walls of *Y. enterocolitica* and *Y. pseudotuberculosis* contain a lipopolysaccharide (endotoxin). Some *Yersinia* strains are unable to synthesize bacterial iron chelators called *siderophores*. However, they can exploit host-chelated iron stores and the drug deferoxamine (a siderophore produced by *Streptomyces pilosus*). Therefore, iron overload (e.g., caused by hemodialysis or multiple transfusions) and deferoxamine therapy appear to be independent risk factors for *Y. enterocolitica* bacteremia, especially that involving serotypes O:3 and O:9, and to a lesser degree for *Y. pseudotuberculosis* bacteremia.

Immunogenetic factors and cell-mediated immune responses are clearly involved in the pathogenesis of reactive arthritis following infection with the enteropathogenic yersiniae. As noted above, most patients with *Yersinia*-induced reactive arthritis express HLA-B27. In addition, *Y. pseudotuberculosis* shares at least one cross-reactive epitope with HLA-B27, and *Y. enterocolitica* infection alters the expression of serologic HLA-B27 epitopes on lymphocytes and monocytes. In patients with reactive arthritis following *Y. enterocolitica* infection, yersinial antigens are commonly detectable in synovial fluid cells in the apparent absence of whole organisms. Thus, it is unknown whether the arthritis results from occult bacterial persistence through self-tolerance of HLA-B27 with a failure of cross-reactive immune responses to yersiniae, from an immune response to common antigenic determinants shared by the bacteria and host HLA-B27 (i.e., molecular mimicry), or from other mechanisms. The pathogenesis of *Yersinia*-induced erythema nodosum is obscure.

In some assays, patients with Graves' disease have an increased prevalence of serum antibodies to *Y. enterocolitica*, and the immunoglobulins of patients recovering from *Y. enterocolitica* infections react with the human thyroid-stimulating hormone receptor. However, a link between *Y. enterocolitica* infection and the subsequent development of autoimmune thyroiditis has not been convincingly demonstrated.

MANIFESTATIONS ■ ***Yersinia enterocolitica*** The principal clinical manifestations of *Y. enterocolitica* infection are enteritis, enterocolitis, mesenteric adenitis, and terminal ileitis. Less common manifestations include exudative pharyngitis, septicemia, metastatic focal infections, reactive polyarthritis, and erythema nodosum. When age groups are combined, the most common presentation of *Y. enterocolitica* infection is acute diarrhea from enteritis or enterocolitis. Low-grade fever and cramping abdominal pain occur in most cases, nausea and vomiting in 15 to 40%, hematochezia in up to 30%, and a generalized maculopapular skin rash in a few cases. Diarrhea persists for an average of 2 weeks (range, 1 day to many months), during which the frequency of bowel movements diminishes. Uncommonly, enteritis or enterocolitis can be complicated by severe abdominal pain and high fever. Rare (and sometimes fatal) complications include diffuse inflammation, ulceration, hemorrhage, and necrosis of the small bowel and colon; intestinal perforation; peritonitis; ascending cholangitis; mesenteric vein thrombosis; diverticulitis; toxic megacolon; and ileocecal intussusception.

The syndrome of mesenteric adenitis and terminal ileitis without diarrhea is easily confused with appendicitis. Low-grade fever and right-lower-quadrant pain, tenderness, guarding, and rebound tenderness are common. During six recognized common-source outbreaks in the United States, 10% of 444 patients with symptomatic undiagnosed *Y. enterocolitica* infections underwent laparotomy for suspected appendicitis; surgical incisions became infected with *Y. enterocolitica* in a few of these cases.

Acute pharyngitis and pharyngotonsillitis, with or without cervical adenitis or intestinal illness, are less common but potentially lethal manifestations of *Y. enterocolitica* infection, particularly in adults. *Y. enterocolitica* septicemia generally presents as a severe illness with fever and leukocytosis, often with abdominal pain and jaundice and without localized signs of infection. Metastatic focal *Y. enterocolitica* infections can occur with or without clinically apparent bacteremia and can affect almost any organ system. Examples include abscess formation (e.g., in liver, spleen, kidney, lung, skeletal muscle, lymph node, or cutaneous tissue), osteomyelitis, meningitis, peritonitis, uri-

nary tract infection, pneumonia, empyema, endocarditis, pericarditis, mycotic aneurysm, septic arthritis, suppurative conjunctivitis, panophthalmitis, Parinaud's oculoglandular syndrome, and cutaneous pustules or bullae.

In Scandinavia, the incidence of reactive arthritis following *Y. enterocolitica* infection among adults is estimated to be at least 10%. About 80% of these patients have preceding symptoms such as fever, diarrhea, or abdominal pain. Typically, these symptoms precede the arthritis by 1 week and are of short duration. The most commonly affected joints are the knees and ankles, but other joints can be involved. Typically, multiple (two to eight) joints become involved sequentially and asymmetrically over a period of a few days to 2 weeks, after which no additional joints are affected. Monarticular arthritis occurs less commonly. In two-thirds of cases, the acute arthritis remits spontaneously within 1 to 3 months. Chronic joint disease is documented in a minority of cases. A few HLA-B27-positive patients with *Y. enterocolitica*–induced arthritis have subsequent ankylosing spondylitis, but this development is best explained by the fact that HLA-B27 is a major risk factor for each of these diseases. Mild, self-limited myocarditis accompanies ~10% of cases of *Yersinia*-induced arthritis and can occur independently. Typical manifestations include cardiac murmurs and transient electrocardiographic abnormalities, such as prolongation of the PR interval and nonspecific ST-segment and T-wave changes. The syndrome of *Yersinia*-induced arthritis and carditis can be confused with acute rheumatic fever. In Scandinavia, erythema nodosum occurs in 15 to 20% of patients with yersiniosis, usually within a few days to 3 weeks after the onset of intestinal illness. Lesions typically are located on the lower extremities and resolve within 1 month. Less commonly reported nonsuppurative sequelae of *Y. enterocolitica* infections include reactive uveitis, iritis, conjunctivitis, urethritis, and glomerulonephritis. The complete triad of Reiter's syndrome (arthritis, conjunctivitis, and urethritis) is seen in 5 to 10% of patients with *Yersinia*-induced arthritis.

Yersinia pseudotuberculosis The most common clinical presentation of *Y. pseudotuberculosis* infection is fever and abdominal pain caused by mesenteric adenitis; diarrheal illness is less common than in *Y. enterocolitica* infection. Systemic manifestations, including septicemia, focal infections, reactive arthritis, and erythema nodosum, are generally similar to those associated with *Y. enterocolitica* infection. In addition, *Y. pseudotuberculosis* has been associated with a scarlet fever–like syndrome, acute interstitial nephritis, and hemolytic-uremic syndrome.

LABORATORY FINDINGS AND DIAGNOSIS Results of routine laboratory tests in most patients with yersiniosis are nonspecific. Leukocyte counts are usually normal or slightly elevated, often with a modest left shift. Standard microbiologic methods are sufficient to isolate *Y. enterocolitica* and *Y. pseudotuberculosis* from otherwise-sterile sites, such as blood, CSF, lymph node tissue, and peritoneal fluid, and from abscesses. Isolation of these organisms from feces is impeded by their slow growth and the overgrowth of normal fecal flora on culture media routinely used to select for enteric bacteria. The yield from feces and other grossly contaminated specimens can be increased by the use of *Yersinia*-selective [e.g., cefsulodin-Irgasan-novobiocin (CIN)] agar and by cold enrichment. Because bacteriologic procedures designed to isolate yersiniae from feces are not considered cost-effective, many laboratories undertake them by special request only.

The results of serologic tests can be used to support a diagnosis of yersiniosis. Agglutination tests or ELISAs are used most commonly; immunoblotting has also been used. The existence of multiple serotypes makes routine serologic tests laborious; thus these tests are generally conducted only in research laboratories or large commercial laboratories. Since these tests are experimental and are neither standardized nor well validated, and since some strains of *Yersinia* cross-react with other bacteria (e.g., *Brucella*, *Salmonella*, and *Vibrio*) and with serum from some patients with thyroiditis, results should be interpreted with caution. In typical uncomplicated cases of yersiniosis, agglutinin titers begin to rise within the first week of illness, peak in the second week, and then gradually diminish and return to normal within 3 to 6 months, although agglutinating antibody may remain detectable for several years in some cases. Because an initial serum specimen is often collected a week or more after the onset of illness, when agglutinin titers are already high, it is usually impossible to document a fourfold or greater rise in titer between paired specimens (although a fourfold or greater fall in titer may be found). Immunohistochemical techniques and PCR tests to detect yersinial antigens and DNA, respectively, in clinical specimens are experimental at this time.

In patients with *Yersinia*-induced reactive arthritis, synovial fluid is sterile and the leukocyte count ranges from a few hundred to 60,000/μL, with a majority of PMNs. The erythrocyte sedimentation rate is often >100 mm/h. Rheumatoid factor and antinuclear antibodies are usually absent. The diagnosis of *Yersinia*-induced reactive arthritis or other nonsuppurative inflammatory sequelae can be difficult, especially when triggering infections are asymptomatic or clinically mild or occur several weeks before the diagnosis is attempted. Because the isolation of a pathogenic *Yersinia* strain from feces is the most specific diagnostic test in such cases, it should be attempted. Since culture is of limited sensitivity in this clinical setting, a high index of suspicion and positive results of serologic tests for *Y. enterocolitica* or *Y. pseudotuberculosis* are usually required for diagnosis.

TREATMENT

The effectiveness of antimicrobial agents in the treatment of yersinial enteritis, enterocolitis, mesenteric adenitis, or terminal ileitis has not been established. These conditions are usually self-limited, and their treatment is symptom-based and supportive. In uncomplicated cases, diarrhea should be treated with fluid and electrolyte replacement, with the route of delivery dependent on clinical severity. Enteric precautions are advisable for patients hospitalized with yersinial diarrhea. In general, antimicrobial treatment should be reserved for patients with septicemia, metastatic focal infections, or immunosuppression and enterocolitis. Controlled clinical comparisons of antimicrobial agents in the treatment of severe cases of yersiniosis have not yet been conducted. In such cases, drug selection should ultimately be guided by clinical response and bacterial sensitivity patterns. Clinical isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* are usually susceptible in vitro to aminoglycosides, third-generation cephalosporins, chloramphenicol, quinolones, tetracyclines, and TMP-SMX. In laboratory animals infected with enteropathogenic yersiniae, the fluoroquinolones have exerted the strongest bactericidal effects in vivo; clinical experience with these drugs against these pathogens in humans is promising but limited. Because they produce β-lactamases, isolates typically are resistant to penicillin, ampicillin, carbenicillin, and first-generation and most second-generation cephalosporins. Optimal dosages and durations of therapy have not been established. Mortality from *Y. enterocolitica* septicemia is ~10% despite treatment. Focal extraintestinal infections may require at least 3 weeks of therapy. No role for antimicrobial agents in the management of the nonsuppurative inflammatory manifestations of yersiniosis has been established. Patients with reactive arthritis may benefit from treatment with nonsteroidal anti-inflammatory drugs, intraarticular steroid injections, and physical therapy.

PREVENTION AND CONTROL The importance of safe food-handling and food-preparation practices in the prevention of yersiniosis cannot be overemphasized. Caution is particularly warranted in the case of pork and other animal products. The consumption of raw or undercooked meats, especially pork, should be avoided. Increased efforts to prevent the spread of enteric pathogens in household, pet-care, day-care, and hospital settings and in the food industry would be likely to decrease the incidence of yersiniosis. Current regulations of the U.S. Food and Drug Administration require visual inspection of packed red cell units before transfusion, with the discarding of units in which bacterial contamination is suspected on the basis of darkening (reflecting decreased

oxygen saturation and hemolysis). Since the risk is minimal, more specific measures to further decrease the likelihood of transfusion of *Y. enterocolitica*–contaminated blood products (e.g., limiting the period for which red cells can be stored before transfusion) have not been widely implemented.

Yersiniosis is not routinely reportable to public health authorities in most jurisdictions. However, clinicians who suspect a common-source outbreak (e.g., because they have documented a familial case cluster) or some other public health threat (e.g., because they have found *Y. enterocolitica* bacteremia in a recent blood donor) should consult promptly with local public health officials.

144 *BARTONELLA* INFECTIONS, INCLUDING CAT-SCRATCH DISEASE

Lucy Stuart Tompkins

Bartonella species, including *B. bacilliformis*, *B. henselae*, and *B. quintana*, are tiny gram-negative bacilli that can adhere to and invade mammalian cells, including endothelial cells and erythrocytes. Previously classified as *Rochalimaea* species within the rickettsia group, *Bartonella* species have now been removed from the order Rickettsiales on the grounds that they are not obligate intracellular parasites. These agents cause a wide spectrum of clinical illnesses, including trench fever, cat-scratch disease (CSD), bacillary angiomatosis, peliosis hepatis, endocarditis, Oroya fever, and verruga peruana. The pathologic manifestations of *Bartonella* disease vary with the immune status of the host. Key features of major *Bartonella* infections are summarized in Table 144-1.

OROYA FEVER AND VERRUGA PERUANA

DEFINITION AND ETIOLOGY Oroya fever and verruga peruana are caused by *B. bacilliformis*. Oroya fever is characterized by fever, profound anemia, and—unless antibiotic treatment is given—high mortality. The lesions referred to as verruga peruana may develop during the convalescent phase of Oroya fever or during chronic infection with *B. bacilliformis*. In 1885 Daniel Carrion, a Peruvian medical student, inoculated himself with material from a patient with verruga peruana and subsequently died of Oroya fever, thus proving that a single agent causes both diseases.

EPIDEMIOLOGY Infection with *B. bacilliformis* follows the bite of the sandfly vector *Phlebotomus*, an insect found in the river valleys of the Andes Mountains at altitudes of 600 to 2500 m. Oroya fever develops in nonimmune individuals who are not residents of the endemic region, whereas verruga peruana occurs in persons who apparently have been exposed in the past, including those who have recently had Oroya fever. The infection has not been acquired in the United States.

PATHOLOGY During initial infection in the nonimmune host, *B. bacilliformis* cells adhere to erythrocytes and produce indentations in the cell membrane; the bacteria subsequently enter the erythrocytes and cause persistent deformation of the cytoskeleton. The parasitized erythrocytes are ultimately phagocytosed and destroyed. Although the life span of infected erythrocytes is markedly shortened, not all of this

TABLE 144-1 Bartonella *Infections: Clinical Syndromes, Risk Factors, and Therapy*

Bartonella *Species*	*Clinical Syndrome*	*Risk Factors*	*Therapy*[a]
Bartonella henselae	Cat-scratch disease	Cat scratch or bite	Azithromycin for 5 days (500 mg on day 1, 250 mg on days 2–5); or variable duration of rifampin (300 mg daily or bid), doxycycline (100 mg/d), or ciprofloxacin (500 mg/d)
	Bacillary angiomatosis/ peliosis	Cat scratch or bite	Erythromycin (500 mg qid) or doxycycline (100 mg/d) for 3–6 weeks
	Endocarditis	Cat exposure	If patient is *Bartonella* culture-positive or seropositive: Give azithromycin (250 mg/d) or doxycycline (100 mg/d) for 4–6 months (surgery may be required)
			If *Bartonella* is suspected but unconfirmed: Treat for culture-negative endocarditis with ceftriaxone (2 g/d IV) plus gentamicin for 6–8 weeks[b]
Bartonella quintana	Trench fever	Homelessness; alcoholism; body lice	Doxycycline (100 mg bid) or azithromycin (500 mg/d) for 4–6 weeks
	Bacillary angiomatosis	Homelessness ± body lice; HIV infection	Same as for bacillary angiomatosis due to *B. henselae*
	Endocarditis	Same as for other *B. quintana* infections	Same as for endocarditis due to *B. henselae*
Bartonella bacilliformis	Oroya fever	Lack of immunity; sandfly bite	Chloramphenicol for 10 days (in South America); ampicillin (1 g q6h IV or PO) or cephalexin (500 mg qid PO) for 10–14 days
	Verruga peruana	Previous exposure to *B. bacilliformis*	Rifampin (300 mg bid) or ciprofloxacin (500 mg/d) for 7–10 days

[a] Azithromycin therapy for cat-scratch disease is based on clinical-trial data; all other recommendations are based on case reports or case series.

[b] If culture results confirm *Bartonella* infection, ceftriaxone may be discontinued and therapy with azithromycin or doxycycline given for a prolonged period.

change can be attributed to the mechanical fragility induced by the internalization of bacteria. Decreased bone marrow erythropoiesis also contributes to anemia.

CLINICAL MANIFESTATIONS The onset of symptoms in Oroya fever may be either insidious or abrupt, after an incubation period of ~3 weeks. The subacute presentation may include low-grade fever, malaise, headache, and anorexia. Sudden-onset disease commences with high fever, chills, diaphoresis, headaches, and changes in mental status. These manifestations are followed by the sudden development of profound anemia, which is due to a marked decrease in erythrocyte numbers and is associated with macrocytic changes, poikilocytosis, Howell-Jolly bodies, nucleated erythrocytes, and immature myeloid cells. The leukocyte differential usually shifts to the left, although the total leukocyte count may be normal. The erythrocyte count may fall to extremely low levels. In eosin/thiazine-stained peripheral-blood smears, numerous microorganisms can be seen adhering to most erythrocytes.

During the acute phase, muscle and joint pain and headache may be severe; central nervous system changes include insomnia, delirium, and a decreased level of consciousness. Thrombocytopenic purpura may develop. If the patient survives, a convalescent phase ensues, characterized by the sudden disappearance of bacteria from blood smears, declining fever, and an increase in the erythrocyte count. Although much of the mortality associated with Oroya fever is due to profound anemia and toxicity, secondary bacterial infections (including salmonellosis and other enteric infections, malaria, and tuberculosis) are often an important contributing factor.

After convalescence from acute Oroya fever, nodular dermal eruptions known as *verrugas*, *verruga peruana*, or *Peruvian warts* may develop. These red or purple cutaneous lesions may be either tiny and sessile or large, pedunculated, and nodular. They bear a marked resemblance to the lesions of bacillary angiomatosis and to Kaposi's sarcoma.

DIAGNOSIS During acute infection, bacteria can be cultured from the blood on agar containing rabbit blood, with incubation at 28°C. The hallmark of verruga peruana is the formation of new blood vessels (angiogenesis) at the sites of bacterial replication.

Rx TREATMENT

Oroya fever responds to a variety of antimicrobial agents, including chloramphenicol, tetracyclines, penicillin, and streptomycin. In South America, chloramphenicol is used most often because of its simultaneous efficacy against most *Salmonella* infections (which may develop intercurrently). Ampicillin (1 g every 6 h) has also been used, as has cephalexin (500 mg every 6 h). Verruga peruana may respond similarly; rifampin (300 mg twice a day) and ciprofloxacin (500 mg/d) have also been used. Failure to respond to therapy and relapse are common and require the reinstitution of prolonged therapy.

CAT-SCRATCH DISEASE

DEFINITION AND ETIOLOGY Typical CSD is manifest by painful regional lymphadenopathy persisting for several weeks or months after a cat scratch. Occasionally, infection may disseminate and produce more generalized lymphadenopathy and systemic manifestations, which may be confused with the manifestations of lymphoma. *B. henselae* is the causative agent of CSD. There is no evidence that other *Bartonella* species cause CSD. The role of *Afipia felis* (originally proposed as the agent of CSD) is unclear inasmuch as only a few cases are associated with its isolation. Several reports suggest that *B. clarridgeiae* may cause feline lymphadenopathy.

EPIDEMIOLOGY Acquisition of *B. henselae* has been significantly associated with exposure to young cats infested with fleas (*Ctenocephalides felis*). The finding that a high proportion of cats with fleas have persistent asymptomatic *B. henselae* bacteremia suggests that the domestic cat is the animal reservoir of this microorganism. The flea can serve as a transmitting vector in the cross-infection of cats, but its role in human infection is not clear. Regions of the United States where fleas are endemic have higher rates of CSD. Approximately 60% of cases occur in children.

MICROBIOLOGY *B. henselae* may be isolated from blood and rarely from lymph nodes or other tissues. Co-cultivation with endothelial cell monolayers has been employed to detect growth. Colonies develop after prolonged incubation (1 to 4 weeks) with 5 to 10% CO_2 at 37°C on blood-containing media (rabbit blood is preferred); the colonies pit the agar. Bacterial cells are gram-negative.

CLINICAL MANIFESTATIONS A localized papule, progressing to a pustule that often crusts over, develops 3 to 5 days after a cat scratch. Tender regional lymphadenopathy develops within 1 to 2 weeks after inoculation; by this time, the papule may have healed spontaneously. Scratches are most often sustained on the hands or face, producing epitrochlear, axillary, pectoral, or cervical lymph node involvement. The involved nodes occasionally become suppurative; bacterial superinfection with staphylococci or other cutaneous pathogens may develop. Although most patients do not have fever, systemic symptoms are frequent and include malaise, anorexia, and weight loss. Without treatment, lymphadenopathy persists for weeks or even months and may be confused with lymphatic malignancy. Other manifestations in apparently immunocompetent patients include encephalitis, seizures and coma (especially in children), meningitis, transverse myelitis, granulomatous hepatitis and splenitis, osteomyelitis, and disseminated infection. Conjunctival inoculation may cause Parinaud's oculoglandular syndrome, with conjunctivitis and periauricular lymphadenopathy. *B. henselae* is considered the most common cause of acute neuroretinitis. This condition may present as an acute change in vision associated with a stellate macular lesion; other pathologic changes of the retina may also occur.

PATHOLOGY The histopathologic hallmark of CSD is granulomatous inflammation with stellate necrosis but no evidence of angiogenesis. Infection by *B. henselae* can produce two entirely different pathologic reactions, depending on the immune status of the host: granulomatous inflammation or angiogenesis.

DIAGNOSIS CSD should be suspected if the patient has a history of exposure to cats and develops lymphadenopathy and a skin lesion. The diagnosis can be confirmed by pathologic examination of the involved nodes. Tiny bacilli in clusters can sometimes be seen in biopsy samples stained with Warthin-Starry silver. The CSD skin test, in which lymph node material obtained from patients with CSD serves as an antigen, is no longer used. Specific serologic tests have been developed and produce positive results in 70 to 90% of patients with intact immunity. These tests are commercially available. The identification of *B. henselae* 16S ribosomal RNA genes in biopsy material by polymerase chain reaction (PCR) amplification with specific oligonucleotide primers can also be diagnostically useful; however, these methods are not commercially available. Cultures of lymph nodes, cerebrospinal fluid, or other tissues are rarely positive.

Rx TREATMENT

Although CSD is generally self-limited, tender regional lymphadenopathy and systemic symptoms may be debilitating. Patients with encephalitis or other serious manifestations should be treated with antibiotics. A randomized, double-blind, placebo-controlled trial demonstrated significant clinical benefit of treatment with oral azithromycin for 5 days in cases of typical CSD (regimen for adults weighing >100 lb: one dose of 500 mg on day 1, 250 mg on days 2 through 5). Several reports suggest that aminoglycoside treatment (e.g., intravenous gentamicin at standard doses calculated to result in therapeutic levels) is effective in patients with encephalitis and other systemic infections. On the basis of case reports and case series, the oral agents

that appear to be useful are those that also are most effective for the treatment of bacillary angiomatosis; they include doxycycline (100 mg/d), rifampin (300 mg daily or twice daily), and azithromycin (250 mg/d). Unlike bacillary angiomatosis, CSD may also respond to treatment with ciprofloxacin (500 mg/d). The necessary duration of therapy is variable. Antibiotic treatment of neuroretinitis is followed by partial or complete resolution.

TRENCH FEVER

DEFINITION AND ETIOLOGY Trench fever was first described as a debilitating febrile illness associated with prolonged *B. quintana* bacteremia in soldiers fighting in Europe during World War I. Cases have since occurred throughout the world. In recent years, trench fever has reemerged in the United States and France among urban homeless patients.

EPIDEMIOLOGY Although trench fever was once thought to have disappeared from the United States, recent cases have been diagnosed in homeless persons with alcohol abuse. Similar epidemiologic features have been noted in Marseilles, France. An outbreak of infection occurred in Seattle, Washington, in 1993, and few cases have been documented subsequently. In World War I, *B. quintana* was transmitted from person to person by the human body louse, and recent cases in Seattle and Marseilles have also been associated with lice.

CLINICAL MANIFESTATIONS Trench fever is characterized by the sudden onset of headache, aseptic meningitis, persistent or relapsing fever (which can be high-grade and is commonly paroxysmal), malaise, weight loss, and other nonspecific symptoms. Some patients may have an indolent course with minimal clinical manifestations.The incubation period is 3 to 38 days. Severe musculoskeletal pain is more common among immunocompetent than among immunocompromised patients. Bacteremia can persist for days or weeks, and relapses have followed short courses of antibiotic therapy. Localized findings are uncommon.

DIAGNOSIS The infection is diagnosed by the finding of sustained bacteremia. *B. quintana* grows slowly, and colonies may develop on rabbit blood agar after 1 to 4 weeks of incubation under conditions of increased CO_2. The infection may also be detected serologically, although these tests are not standardized.

℞ TREATMENT

A prolonged course (4 to 6 weeks) of antimicrobial therapy may be required. Agents that can cross the mammalian cell membrane are most effective, including doxycycline (100 mg by mouth twice daily), erythromycin (2 g/d), or azithromycin (500 mg/d). Data on the efficacy of these agents come from a limited number of case reports.

BACILLARY ANGIOMATOSIS

DEFINITION AND ETIOLOGY Bacillary angiomatosis was initially described as a condition occurring primarily in patients with AIDS and characterized by vascular cutaneous lesions resembling verruga peruana and Kaposi's sarcoma. The disease can disseminate to involve virtually any organ system, including the liver (peliosis hepatis). Immunocompromised individuals, especially those infected with HIV, are at particularly high risk for bacillary angiomatosis, although in rare instances the patient is not obviously immunosuppressed. Both *B. henselae* and *B. quintana* produce bacillary angiomatosis in persons with immunodeficiency.

EPIDEMIOLOGY A case-control study revealed that *B. henselae* and *B. quintana* differ significantly in terms of epidemiologic risk factors. All cases of *B. henselae* infection were associated with exposure to cats and their fleas and occurred sporadically, whereas the cases of *B. quintana* bacillary angiomatosis occurred in clusters and were associated with low socioeconomic status, homelessness, and exposure to body lice. Direct transmission of *B. henselae* from cats to their owners, presumably through cutaneous trauma, was supported by the matching DNA fingerprint patterns of isolates from the two sources.

PATHOGENESIS AND PATHOLOGY Bacillary angiomatosis is characterized by a lobular proliferation of new blood vessels (angiogenesis) and a neutrophilic inflammatory response to myriad bacilli located within collagen-rich microscopic and macroscopic nodules. The organisms can be visualized with Warthin-Starry silver stain. The endothelial cells lining the vascular spaces have a typical epithelioid appearance, and the lesions may resemble Kaposi's sarcoma histopathologically, although the characteristic spindle cell of the latter disease is usually absent. The bacterial and eukaryotic host factors that elicit the pathologic response are unknown.

CLINICAL MANIFESTATIONS The skin lesions of bacillary angiomatosis (also called *epithelioid angiomatosis*) are vascular nodules, papules, or tumors that range from tiny lesions resembling cherry angiomas or pyogenic granulomas to large, pedunculated, exophytic masses (Fig. 144-1). Characteristically, the lesions are red or purple, resembling Kaposi's sarcoma; they may be surrounded by an epithelial collarette, may be located anywhere on the skin, and may involve mucous membranes. The overlying epidermis may be focally ulcerated, and the underlying bone may be invaded and destroyed.

Dissemination of *B. henselae* infection occurs primarily in patients with cellular immune defects. Clinical manifestations accompanying dissemination are often nonspecific and include persistent fever, abdominal pain, weight loss, and malaise. Although the liver, spleen, bone marrow, and lymph nodes are primarily affected, HIV-infected patients may also develop central nervous system abnormalities (including psychiatric disorders and brain lesions), which are responsive to antibiotic therapy. Skin lesions usually are not evident in disseminated infection. Involvement of the liver or spleen may produce bacillary peliosis hepatis. Patients with the latter condition may report localized pain on palpation of the abdomen. Nodular lesions of variable size can be demonstrated by computed tomography or magnetic resonance imaging, with or without contrast agents. As these lesions are associated with neovascularization, percutaneous biopsy may lead to hemorrhage.

In a case-control study of bacillary angiomatosis (see "Epidemiology" above), only *B. henselae* was associated with hepatosplenic disease (peliosis hepatis) and displayed a predilection for lymph nodes. *B. quintana*, in contrast, was associated with osseous and subcutaneous infection.

DIAGNOSIS The diagnosis of bacillary angiomatosis is based primarily on the typical histopathologic findings of angiomas in association with clumps of tiny bacilli revealed by Warthin-Starry silver stain. Infection can also be established by blood cultures performed with a lysis-centrifugation system or by identification of specific DNA sequences. Bacilli picked from new colonies growing on blood agar but not subcultured may not stain, even with acridine orange; they stain weakly with

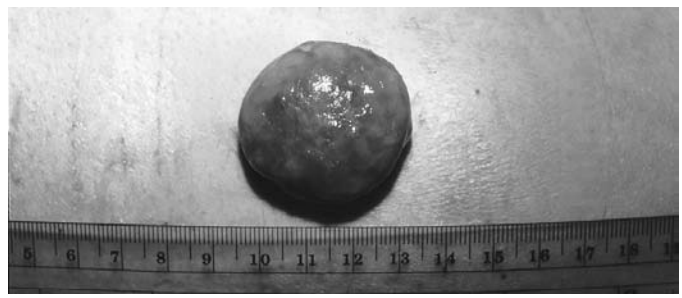

FIGURE 144-1 Characteristic skin lesion of bacillary angiomatosis in an HIV-positive young woman. This large, pedunculated tumor exhibits the typical angiomatous appearance. The patient was treated with oral erythromycin, with nearly complete resolution of the lesion; however, on discontinuation of antibiotic therapy after a 4-week course, the lesion recurred.

safranin. Identification of *B. henselae* and *B. quintana* is based primarily on cellular fatty-acid analysis and PCR-based restriction fragment length polymorphism analysis. Definitive identification of *Bartonella* species depends on DNA sequence analysis of 16S ribosomal RNA genes. The sensitivity and specificity of serologic tests have not been determined.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of cutaneous bacillary angiomatosis includes Kaposi's sarcoma, angiomas, and pyogenic granulomas. These conditions can be distinguished by histopathologic examination of biopsied material. AIDS patients may have both Kaposi's sarcoma lesions and bacillary angiomatosis lesions simultaneously; thus biopsy is essential to differentiate the two.

℞ TREATMENT

Cutaneous lesions have been treated with a wide variety of antimicrobial drugs, including macrolides, tetracyclines, and antituberculous agents; *B. henselae* is susceptible to most antibiotics in vitro. Erythromycin (2 g/d), given orally for 3 weeks, is usually effective, as are newer macrolides; however, relapse may require prolonged therapy (3 weeks to 2 months) with an antibiotic that reaches an intracellular compartment, such as a macrolide or doxycycline (100 mg/d). Patients with peliosis hepatis should be treated with intravenous antibiotics, and those with disseminated disease or bacteremia should be treated with a prolonged course of a systemic antibiotic. In a case-control study of bacillary angiomatosis, treatment with a macrolide was associated with a therapeutic response and sterile tissue samples and may have been protective, whereas treatment with trimethoprim-sulfamethoxazole, ciprofloxacin, penicillins, or cephalosporins had no protective effect. Cutaneous lesions may or may not regress spontaneously, perhaps depending on the status of the host's immunity. The safety of ciprofloxacin in pregnant or lactating women has not been established. No antimicrobial agent has been studied prospectively, and information on efficacy comes only from case reports.

OTHER *BARTONELLA* INFECTIONS, INCLUDING CULTURE-NEGATIVE ENDOCARDITIS

The application of molecular methods to the detection of microorganisms that are difficult to cultivate in the laboratory has revealed new *Bartonella* species and has established *Bartonella* species as a cause of endocarditis cases previously classified as being of unknown etiology. *B. quintana* is the *Bartonella* species most frequently isolated from patients with endocarditis. Two other species, *B. elizabethae* and *B. clarridgeiae*, as well as *B. henselae* have also been identified as agents of subacute and chronic endocarditis.

The diagnosis of *Bartonella* endocarditis is confirmed by blood cultures. A presumptive diagnosis can be made on the basis of epidemiologic history and by serology. Infection may elicit antibodies that cross-react with *Chlamydia pneumoniae*, and *Coxiella burnetii* infection (Q fever) elicits antibodies that cross-react with *B. quintana*.

In culture-positive or seropositive endocarditis, initial treatment with azithromycin (250 mg/d) or doxycycline (100 mg/d) for 4 to 6 months is recommended. A third-generation cephalosporin or an aminoglycoside may be added for the initial 2 to 3 weeks of therapy. If *Bartonella* infection is suspected but not yet confirmed, therapy for culture-negative endocarditis with ceftriaxone (2 g/d by the intravenous route) plus an aminoglycoside for 6 to 8 weeks is recommended. If culture results prove positive, ceftriaxone administration may be discontinued and treatment with a macrolide (azithromycin) or doxycycline given for a prolonged period.

145 DONOVANOSIS

Gavin Hart

Donovanosis is a chronic, progressively destructive bacterial infection of the genital region that is generally regarded as sexually transmitted. The disease has been known by many other names, the most common of which are granuloma inguinale and granuloma venereum.

ETIOLOGY Donovanosis is caused by *Calymmatobacterium granulomatis*, an intracellular, gram-negative, pleomorphic, encapsulated (when mature) bacterium measuring 1.5 by 0.7 μm. *C. granulomatis* shares many morphologic and serologic characteristics and >99% homology at the nucleotide level with *Klebsiella* species that are pathogenic to humans. Polymerase chain reaction (PCR) amplification of the *phoE* gene shows it to be closely related to that in *Klebsiella pneumoniae*, *K. rhinoscleromatis*, and *K. ozaenae*. Electron microscopy shows typical gram-negative morphology and a large capsule but no flagella. Filiform or vesicular protrusions occur on a corrugated cell wall.

EPIDEMIOLOGY Donovanosis is endemic among Aborigines in central Australia as well as in Papua New Guinea, southeastern India, southern Africa, and the Caribbean and adjacent areas of South America. In the first half of the twentieth century, the disease was endemic in parts of the United States (with an estimated 5000 to 10,000 cases in 1947); small epidemics still occur in this country and in other developed countries. The decline in the United States to fewer than 20 reported cases annually in the past decade has probably resulted from lower transmission rates due to earlier presentation for increasingly effective antibiotic therapy. Over 70% of cases involve persons 20 to 40 years of age. The infection is predominantly sexually transmitted, but extragenital skin lesions can follow transmission from concurrent genital lesions via the fingers or through other nonsexual contact, and autoinoculation may produce new lesions from contact with adjacent skin ("kissing" lesions). Infants born to infected mothers have acquired infection at birth.

The classification of donovanosis as a sexually transmitted disease (STD) has been disputed because of cases in young children and occasionally in sexually inactive individuals, transmission by direct body contact and via inanimate intermediaries, and the low and variable prevalence of donovanosis among sexual partners (0.4 to 52%). The dominance of sexual transmission is suggested by the combined factors of lesions predominantly affecting the genitalia, the highest prevalence among persons in age and socioeconomic groups that are most

FIGURE 145-1 Multiple granulomatous lesions of the penis in a patient with donovanosis.

often affected by STDs, and the predictable occurrence of disease in visitors to areas of endemicity following sexual exposure.

CLINICAL MANIFESTATIONS The incubation period is usually 1 to 4 weeks but may extend to 1 year. Skin lesions have been detected in infants 6 weeks to 6 months after birth. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, granulomatous, sharply defined, usually painless lesions (Fig. 145-1). These lesions, which bleed readily on contact, slowly enlarge. The genitalia are involved in 90% of cases, the inguinal region in 10%, and the anal region in 5 to 10%. Genital swelling, particularly of the labia, is a common feature and occasionally progresses to pseudoelephantiasis. Phimosis and paraphimosis are common local complications, and progressive erosion of affected tissues may completely destroy the penis or other organs. Less common clinical variants include a hypertrophic form (cauliflower- or wartlike lesions), a necrotic form (destructive lesions with foul-smelling exudate, often resembling amebiasis), and a sclerotic or cicatricial form, which has a dry base with extensive scar tissue.

Extragenital lesions occur in at least 6% of cases. Oral donovanosis, the most common extragenital manifestation, presents as pain or bleeding in the mouth, lesions on the lips, or extensive swelling of the gums and palate. Donovanosis may affect most bones, and sometimes many bones are affected at the same time; the tibia is involved in over 50% of such cases. Bony lesions are associated with constitutional symptoms (weight loss, fever, night sweats, and malaise) and are usually found in women. More than 50% of women with donovanosis have primary lesions on the cervix. Prompt pelvic examinations and early diagnosis are likely to substantially decrease the morbidity and mortality (likely outcomes in misdiagnosed spinal lesions) associated with extragenital donovanosis in women.

DIAGNOSIS ■ Laboratory Diagnosis The preferred diagnostic method involves demonstration of typical intracellular Donovan bodies within large mononuclear cells visualized in smears prepared from lesions or biopsy specimens. With typical beefy lesions, a small piece of tissue is removed with forceps and scalpel, and a crush impression of the deep surface is made on a glass slide. The smear is air-dried, heat-fixed, and stained with Giemsa, Leishman's, or Wright's stain. For dry, flat, or necrotic lesions, a punch-biopsy specimen should be obtained from the advancing edge. This specimen can be used to prepare a smear or embedded for histologic examination (with a silver stain). Histologic examination shows epithelial proliferation, often simulating neoplasia, with a heavy inflammatory infiltrate of plasma cells, some neutrophils, and few if any lymphocytes. The large mononuclear cells are 25 to 90 μm in diameter, with a vesicular or pyknotic nucleus. Up to 20 intracytoplasmic vacuoles contain pleomorphic Donovan bodies in either young unencapsulated forms (which often resemble closed safety pins) or mature encapsulated forms. *C. granulomatis* has never been grown on artificial solid media but has been cultured in chicken embryonic yolk sacs, on human monocytes, and on human epithelial (HEp-2) cells. A diagnostic PCR test has been developed and incorporated into a colorimetric detection system for *C. granulomatis*. A serologic test, based on indirect immunofluorescence, is more useful in confirming the diagnosis in cases with long-standing lesions than in early disease.

TABLE 145-1 *Differential Diagnosis of Donovanosis*

Disease (Chapter)	Distinguishing Features
Secondary syphilis: condylomata lata (153)	White or pale moist plaques in anogenital region (as opposed to bright red donovanosis lesions); lesions subside within 1 week of treatment with benzathine penicillin, 2.4 mU (whereas donovanosis lesions remain unchanged)
Squamous cell carcinoma (73)	Histologic appearance
Penile amebiasis (194)	Microscopic identification of *Entamoeba histolytica*
Chancroid: pseudogranuloma inguinale (130)	Culture of *Haemophilus ducreyi*
Tuberculosis (150)	Histologic features of bony lesions
Actinomycosis (147)	Microscopic identification of sulfur granules
Rhinoscleroma (134)	Histologic features
Leishmaniasis (196)	Histologic features
Histoplasmosis (183)	Histologic features

Differential Diagnosis The differential diagnosis of donovanosis is summarized in Table 145-1. Syphilis and donovanosis frequently coexist because syphilis is usually highly prevalent in areas where donovanosis is endemic; thus positive syphilis serology does not exclude a diagnosis of donovanosis. Genital ulcers are a risk factor for HIV acquisition in developing countries, and patients with donovanosis should be tested for HIV infection.

℞ TREATMENT

Table 145-2 shows the most effective regimens for treating donovanosis. Doxycycline offers the advantage of convenient administration and has been widely used in developed countries, but azithromycin is increasingly being used as first-choice therapy. Extensive lesions have been cured with oral azithromycin at a dosage of 500 mg/d, but the more convenient dose of 1 g weekly is also effective. Although chlor-

TABLE 145-2 *The Most Effective Antibiotic Regimens for Treatment of Donovanosis*[a]

Antibiotic	Oral Dosage
Azithromycin	1 g weekly or 500 mg/d
Erythromycin	500 mg qid
Tetracycline	500 mg qid
Doxycycline	100 mg bid
Trimethoprim-sulfamethoxazole	1 double-strength tablet[b] bid
Chloramphenicol	500 mg tid

[a] Patients should be examined weekly, and therapy should be continued until lesions have healed (3 to 5 weeks, except in severe cases).
[b] 160 mg/800 mg.

amphenicol is the drug of choice in some developing countries, it is unlikely to be acceptable in developed countries because of bone marrow toxicity. Penicillin is not effective for treating donovanosis. Patients should be examined weekly, and therapy should be continued until lesions have healed (3 to 5 weeks, except in severe cases). If antibiotic therapy is stopped earlier, lesions often continue to heal, but the relapse rate is higher. If the lesions are unchanged after 2 weeks of treatment, an alternative antibiotic regimen should be used.

The treatment regimens listed in Table 145-2 are usually adequate in HIV-infected patients without immunosuppression, but an increasing failure rate has been reported in immunosuppressed patients, for whom daily administration of azithromycin is recommended if other regimens fail to elicit a response.

Section 7 Miscellaneous Bacterial Infections

146 NOCARDIOSIS

Gregory A. Filice

Nocardiosis refers to disease associated with members of the genus *Nocardia*. Of several distinctive syndromes associated with these bacteria, pneumonia and disseminated disease are most common. Others include cellulitis, lymphocutaneous syndrome, actinomycetoma, and keratitis.

MICROBIOLOGY Nocardiae are saprophytic aerobic actinomycetes that are common worldwide in soil, where they contribute to decay of organic matter. Nocardial taxonomy is complex and incompletely understood. Seven species have been clearly associated with human disease: *N. asteroides*, *N. brasiliensis*, *N. otitidis-caviarum* (formerly *N. caviae*), *N. farcinica*, *N. nova*, *N. transvalensis*, and *N. pseudobrasiliensis*. In addition, two newly described species have been associated with disease in humans: *N. abscessus* from soft-tissue abscesses and *N. africana* from respiratory secretions of patients in the Sudan with pneumonia.

N. asteroides is the species most commonly associated with invasive disease. *N. farcinica* disease is less common, but this species is more virulent and prone to dissemination. *N. pseudobrasiliensis* is most often associated with invasive disease, and *N. brasiliensis* is usually associated with disease limited to the skin. *N. transvalensis* is generally associated with pulmonary or systemic disease in immunosuppressed persons or with *actinomycetoma*, an indolent, slowly progressive disease of skin and underlying tissues with nodular swellings and draining sinuses.

EPIDEMIOLOGY Approximately 1000 cases of nocardial infection are diagnosed annually in the United States, 85% of them pulmonary and/or systemic. The disease is more common among adults than among children and among males than among females. Nearly all cases are sporadic, but outbreaks have been associated with contamination of the hospital environment, solutions, or drug injection equipment. Person-to-person spread is not well documented. There is no known seasonality.

The risk of pulmonary or disseminated disease is greater than usual among persons with deficient cell-mediated immunity, especially that associated with lymphoma, transplantation, glucocorticoid therapy, or AIDS. In AIDS, nocardiosis usually affects persons with <250 CD4+ lymphocytes/μL. Nocardiosis has also been associated with pulmonary alveolar proteinosis, tuberculosis and other mycobacterial diseases, chronic granulomatous disease, and interleukin 12 deficiency.

N. brasiliensis, *N. asteroides*, *N. otitidis-caviarum*, and *N. transvalensis* are associated with actinomycetoma. Cases occur mainly in tropical and subtropical regions, especially those of Mexico, Central and South America, Africa, and India. The most important risk factor is frequent contact with soil or vegetable matter.

PATHOLOGY AND PATHOGENESIS Pneumonia and disseminated disease are both thought to follow inhalation of fragmented bacterial mycelia. The characteristic histologic feature of nocardiosis is an abscess with extensive neutrophil infiltration and prominent necrosis. Granulation tissue usually surrounds the lesions, but extensive fibrosis or encapsulation is uncommon. Actinomycetoma is characterized by suppurative inflammation with sinus tract formation. Granules—microcolonies composed of dense masses of bacterial filaments extending radially from a central core—are occasionally observed in histologic preparations. They are frequently found in discharges from lesions of actinomycetoma but almost never from lesions in other forms of nocardiosis. Infrequently, nocardiae and other indolent pathogens, including fungi or mycobacteria, are isolated from the same patient.

Nocardiae have evolved a number of properties that enable them to survive within phagocytes, including neutralization of oxidants, prevention of phagosome-lysosome fusion, and prevention of phagosome acidification. Neutrophils phagocytose the organisms and limit their growth but do not kill them efficiently. Cell-mediated immunity is important for definitive control and elimination of nocardiae.

CLINICAL MANIFESTATIONS ■ Respiratory Tract Disease Pneumonia is by far the most common respiratory tract nocardial disease. Nocardial pneumonia is typically subacute; symptoms have usually been present for days or weeks at presentation. The onset is more acute in some immunosuppressed patients. Cough is prominent and produces small amounts of thick, purulent sputum that is not malodorous. Fever, anorexia, weight loss, and malaise are common; dyspnea, pleuritic pain, and hemoptysis are less common. Remissions and exacerbations over several weeks are frequent.

Roentgenographic patterns vary, but some are highly suggestive of nocardial pneumonia. Infiltrates vary in size and are typically of at least moderate density. Single or multiple nodules are common, sometimes suggesting tumor metastases (Fig. 146-1). Infiltrates and nodules tend to cavitate. Empyema is present in one-third of cases.

Nocardiosis may spread directly from the lungs to adjacent tissues. Pericarditis, mediastinitis, and the superior vena cava syndrome have all been reported. Nocardial laryngitis, tracheitis, and bronchitis are much less common than pneumonia. In the major airways, disease often presents as a nodular or granulomatous mass. A few cases of sinusitis have been reported.

Nocardiae are sometimes isolated from respiratory secretions of patients without apparent nocardial disease. Most of these patients have chronic pulmonary disease with abnormal airways or parenchyma and do not necessarily require treatment for nocardiosis (see "Diagnosis," below).

Extrapulmonary Disease In half of all cases of pulmonary nocardiosis, disease appears outside the lungs. In one-fifth of cases of disseminated disease, lung disease is not apparent. The most common site of dissemination is the brain. Other common sites include the skin and sup-

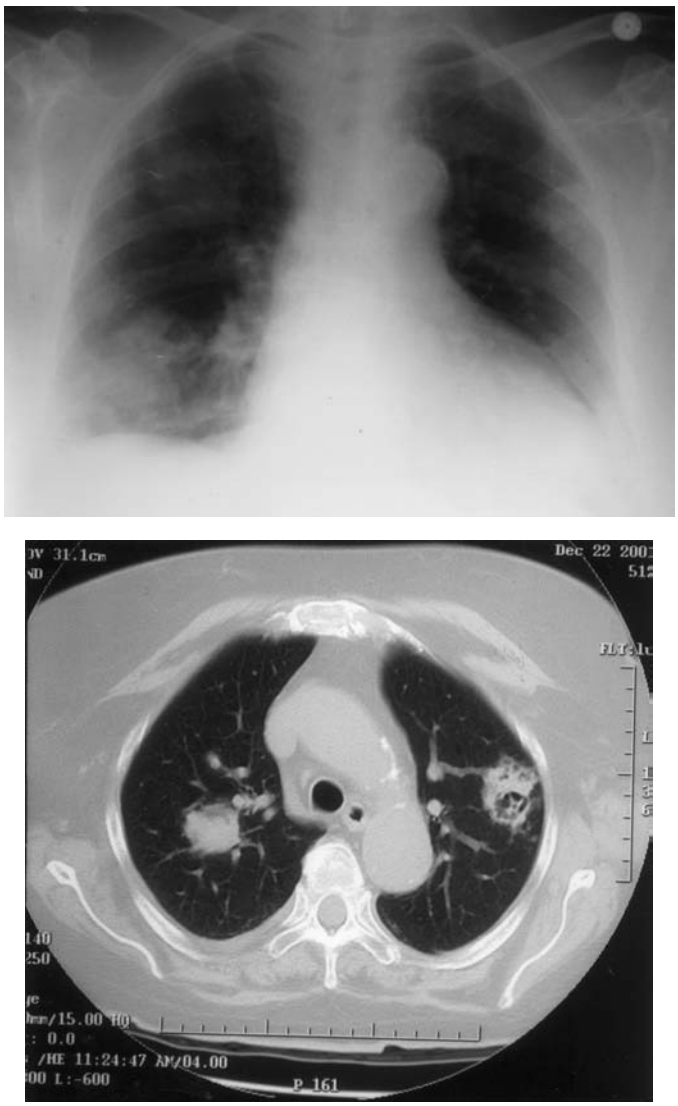

FIGURE 146-1 Nocardial pneumonia. *Top*: Three large nodules with apparent cavitation are apparent on the anterior-posterior chest roentgenograph. *Bottom*: A computed tomographic scan of the same patient confirms the presence of bilateral nodules and cavitation in the nodule in the left midlung field.

porting structures, kidneys, bone, and muscle, but almost any organ can be involved. Peritonitis has been reported. Nocardiae have been recovered from blood in a few cases of pneumonia or disseminated disease. Nocardial endocarditis occurs rarely and can affect either native or prosthetic valves. A few cases of nocardial bacteremia associated with infected central venous catheters have been reported.

The typical manifestation of extrapulmonary dissemination is a subacute abscess. A minority of abscesses outside the lungs or central nervous system (CNS) form fistulae and discharge small amounts of pus.

In CNS infections, brain abscesses are usually supratentorial, are often multiloculated, and may be single or multiple (Fig. 146-2). Brain abscesses tend to burrow into the ventricles or extend out into the subarachnoid space. The symptoms and signs are somewhat more indolent than those of other types of bacterial brain abscess. Meningitis is uncommon and is usually due to spread from a nearby brain abscess. Nocardiae are not easily recovered from cerebrospinal fluid (CSF).

Disease Following Transcutaneous Inoculation Disease following transcutaneous nocardial inoculation usually takes one of three forms: cellulitis, lymphocutaneous syndrome, or actinomycetoma.

Cellulitis generally begins 1 to 3 weeks after a recognized breach of the skin, often with soil contamination. Subacute cellulitis with pain, swelling, erythema, and warmth develops over days to weeks. The lesions are usually firm and nonfluctuant. Disease may progress to involve underlying muscle, tendon, bones, or joints. Dissemination is rare. *N. asteroides* is common in colder climates, while *N. brasiliensis* predominates in warmer climates.

Lymphocutaneous disease usually begins with a pyodermatous lesion at the site of inoculation, with central ulceration and purulent or honey-colored drainage. Subcutaneous nodules often appear along lymphatics that drain the primary lesion. The lymphangitic form closely resembles lymphocutaneous sporotrichosis (Chap. 190). Most cases of the lymphocutaneous syndrome are associated with *N. brasiliensis*.

Actinomycetoma usually begins with a nodular swelling, sometimes at a site of local trauma. Lesions typically develop on the feet or hands but may involve the posterior part of the neck, the upper back, the head, and other sites. The nodule eventually breaks down and a fistula appears, which is then accompanied by others. The fistulas tend to come and go, with new ones forming as old ones disappear. The discharge is serous or purulent, may be bloody, and often contains 0.1- to 2-mm white granules consisting of masses of mycelia. The lesions spread slowly along fascial planes to involve adjacent areas of skin, subcutaneous tissue, and bone. Over months or years, there may be extensive deformation of the affected part. Lesions involving soft tissues are only mildly painful; those affecting bones or joints are more so. Systemic symptoms are absent or minimal. Infection rarely disseminates from actinomycetoma, and lesions on the hands and feet usually cause only local disability. Lesions on the head, neck, and trunk can invade locally to involve deep organs and result in severe disability or death.

Keratitis *Nocardia* species, usually *N. asteroides*, are uncommon causes of subacute keratitis. The infection usually follows eye trauma. Nocardial infection of lacrimal glands has been reported. Endophthalmitis and other diseases involving deeper eye structures are usually manifestations of dissemination.

DIAGNOSIS The first step in diagnosis is examination of sputum or pus for crooked, branching, beaded, gram-positive filaments 1 μm wide and up to 50 μm long. Most nocardiae are acid-fast in direct smears if a weak acid is used for decolorization (e.g., in the modified Kinyoun, Ziehl-Neelsen, and Fite-Faraco methods). The organisms often take up silver stains. Nocardiae grow relatively slowly; colonies may take

TABLE 146-1 *Treatment for Nocardiosis*

Disease	Duration	Drugs (Daily Dose)[a]
Pulmonary or systemic		Systemic therapy
Intact host defenses	6–12 mo	Oral
Deficient host defenses	12 mo[b]	1. Sulfonamides (6–8 g) or combination of trimethoprim (10–20 mg/kg) and sulfamethoxazole (50–100 mg/kg)
CNS disease	12 mo[c]	2. Minocycline (200–400 mg)
Cellulitis, lymphocutaneous syndrome	2 mo	Parenteral
Osteomyelitis, arthritis, laryngitis, sinusitis	4 mo	1. Amikacin (10–15 mg/kg)
Actinomycetoma	6–12 mo after clinical cure	2. Cefotaxime (6 g), ceftizoxime (6 g), ceftriaxone (2 g), imipenem (2 g)
Keratitis	Topical: Until apparent cure	1. Sulfonamide drops 2. Amikacin drops
	Systemic: Until 2–4 mo after apparent cure	Drugs for systemic therapy as listed above

[a] For each category, choices are numbered in order of preference.
[b] In some patients with AIDS or chronic granulomatous disease, therapy for pulmonary or systemic disease must be continued indefinitely.
[c] If all apparent CNS disease has been excised, the duration of therapy may be reduced to 6 months.

up to 2 weeks to appear and may not develop their characteristic appearance for up to 4 weeks. Several blood culture systems support nocardial growth. Yield is enhanced when blood cultures are incubated aerobically for up to 4 weeks and when blind subcultures are performed. Nocardial growth is so different from that of more common pathogens that the laboratory should be alerted when nocardiosis is suspected to maximize the likelihood of isolation. Since nocardiae are among the few aerobic microorganisms that use paraffin as a carbon source, paraffin baiting can be used to isolate the organisms from mixed cultures.

In cases of pneumonia, sputum smears are often negative. Unless the diagnosis can be made in these cases by sampling lesions in other, more accessible sites, bronchoscopy or lung aspiration is usually necessary. Transtracheal aspiration should be avoided, as it frequently leads to nocardial cellulitis in tissues around the puncture wound.

In patients with nocardial pneumonia, a careful history should be obtained and a thorough physical examination performed to evaluate the possibility of dissemination. Suggestive symptoms or signs should be pursued with further diagnostic tests. Computed tomography or magnetic resonance imaging of the head, with and without contrast material, should be undertaken if signs or symptoms suggest brain involvement. Some authorities recommend brain imaging in all cases of pulmonary or disseminated disease.

When clinically indicated, CSF or urine should be concentrated and then cultured. In actinomycetoma cases, granules should be sought in the discharge. Suspect particles should be washed in saline, examined microscopically, and cultured.

Isolation of nocardiae from sputum or blood occasionally represents colonization, transient infection, or contamination. In typical cases of respiratory tract colonization, Gram-stained specimens are negative and cultures are only intermittently positive. A positive sputum culture in an immunosuppressed patient usually reflects disease. When nocardiae are isolated from an immunocompetent patient without apparent nocardial disease, the patient should be observed carefully without treatment. A patient with a host-defense defect that increases the risk of nocardiosis should usually receive antimicrobial treatment.

Nocardia spp. are difficult to differentiate from one another with standard biochemical tests, and isolates from patients with systemic or severe disease should be sent to a reference laboratory for definitive identification and antimicrobial susceptibility testing. Susceptibility results, which help differentiate species, are of less certain clinical value but sometimes guide therapy in difficult cases.

Several presumptive diagnostic tests for nocardial infection have been studied, including tests for antibodies, nocardial metabolites, and nocardial DNA. None is ready for clinical use at this time.

TREATMENT

Sulfonamides are the drugs of choice for nocardiosis (Table 146-1). Initially, 6 to 8 g/d of sulfadiazine or sulfisoxazole in four divided doses should be used. After disease is controlled, 4 g/d can be used to complete therapy. In difficult cases, sulfonamide levels should be measured and dosages adjusted to keep serum levels between 100 and 150 μg/mL. The combination of sulfamethoxazole (SMX) and trimethoprim (TMP) is probably equivalent to sulfonamides; some authorities believe that the combination may in fact be more effective, but it also poses a modestly greater risk of hematologic toxicity. At the outset, 10 to 20 mg of TMP per kg and 50 to 100 mg of SMX per kg should be given each day in two divided doses. Later, the daily doses can be decreased to as little as 5 mg/kg and 25 mg/kg, respectively. In persons with sulfonamide allergies, desensitization usually allows continuation of therapy with these effective and inexpensive drugs.

Minocycline is the best-established alternative oral drug and should be given in doses of 100 to 200 mg twice a day. Other tetracyclines are usually ineffective. *N. nova* infections can be treated with erythromycin (500 to 750 mg four times a day) and/or ampicillin (1 g four times a day), but other *Nocardia* species are often resistant to both drugs. Amoxicillin (500 mg) combined with clavulanic acid (125 mg), given three times a day, has been effective in a few cases but should be avoided in cases due to *N. nova*, in which clavulanate induces β-lactamase production. Ofloxacin (400 mg twice a day) and clarithromycin (500 mg twice a day) have each been successful in a few cases. Linezolid is active in vitro against most *Nocardia* isolates, but there is little clinical experience with this drug as nocardiosis therapy.

Amikacin, the best-established parenteral drug, is given in doses of 5 to 7.5 mg/kg every 12 h. Serum levels should be monitored during prolonged therapy in patients with diminished renal function and in the elderly. Newer β-lactam antibiotics, including cefotaxime, ceftizoxime, ceftriaxone, and imipenem, are usually effective. These agents may be less effective in some cases caused by *N. farcinica*.

In vitro, strains of *N. farcinica* differ from most in that they are usually resistant to cephalosporins and in one-fifth of cases are resistant to imipenem. *N. pseudobrasiliensis* strains often exhibit resistance to minocycline or amoxicillin/clavulanic acid and susceptibility to ciprofloxacin or clarithromycin. *N. transvalensis* displays increased resistance to many antimicrobial agents, including amikacin, tobramycin, cefotaxime, ceftriaxone, and amoxicillin/clavulanic acid. *N. nova* isolates appear to be susceptible to ampicillin and erythromycin in vitro but also produce β-lactamase constitutively or in the presence of a β-lactam.

Use of SMX and TMP in high-risk populations to prevent *Pneumocystis carinii* disease or urinary tract infections appears to reduce the risk of nocardiosis as well. However, the incidence of nocardiosis is infrequent enough that prophylaxis of this disease is not recommended.

In patients with nocardiosis who need immunosuppressive therapy for an underlying disease or prevention of transplant rejection, such therapy should be continued. In many cases, two or more antimicrobial agents have been used to treat nocardiosis, often in combinations including drugs that are usually effective by themselves, like a sulfonamide or minocycline. Whether such combination therapy is better than monotherapy is not known, and it certainly increases the risk of toxicity.

Surgical management of nocardial disease is similar to that of other bacterial diseases. Brain abscesses should be aspirated, drained, or excised if the diagnosis is unclear, if an abscess is large and accessible,

or if an abscess fails to respond to chemotherapy. Brain abscesses that are small or inaccessible should be treated medically; in these cases, clinical improvement should be noticeable within 1 to 2 weeks. Brain imaging should be repeated to document the resolution of lesions, although abatement on images often lags behind clinical improvement.

Antimicrobial therapy usually suffices for nocardial actinomycetoma. In deep or extensive cases, drainage or excision of heavily involved tissue may facilitate healing, but structure and function should be preserved whenever possible.

Nocardial infections tend to relapse (particularly in patients with chronic granulomatous disease), and long courses of antimicrobial therapy are necessary. If disease is unusually extensive, if the patient is immunosuppressed, or if the response to therapy is slow, the recommendations in Table 146-1 should be exceeded.

The mortality rate for pulmonary or disseminated nocardiosis outside the CNS should be <5%. CNS disease carries a higher mortality rate. Patients should be followed carefully for at least 6 months after therapy has ended. Any child with nocardiosis and no known cause of immunosuppression should undergo tests to determine the adequacy of the phagocytic respiratory burst.

147 ACTINOMYCOSIS

Thomas A. Russo

Actinomycosis is an indolent, slowly progressive infection caused by anaerobic or microaerophilic bacteria, primarily of the genus *Actinomyces*, that colonize the mouth, colon, and vagina. Mucosal disruption may lead to infection at virtually any site in the body. In vivo growth of actinomycetes usually results in the formation of characteristic clumps called *grains* or *sulfur granules*. The clinical presentations of actinomycosis are myriad. Common in the preantibiotic era, actinomycosis has diminished in incidence, as has its timely recognition. Actinomycosis has been called "the most misdiagnosed disease," and it has been said that "no disease is so often missed by experienced clinicians." Thus this entity remains a diagnostic challenge. Three clinical presentations that should prompt consideration of this unique infection are (1) the combination of chronicity, progression across tissue boundaries, and mass-like features (mimicking malignancy, with which it is often confused); (2) the development of a sinus tract, which may spontaneously resolve and recur; and (3) a refractory or relapsing infection after a short course of therapy, since cure of established actinomycosis requires prolonged treatment. An awareness of the full spectrum of the disease will expedite its diagnosis and treatment and will minimize the unnecessary surgical interventions, morbidity, and mortality that are reported all too often.

ETIOLOGIC AGENTS Actinomycosis is most commonly caused by *A. israelii*. *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. meyeri*, *A. gerencseriae*, and *Propionibacterium propionicum* are established but less common causes of the disease. Most if not all actinomycotic infections are polymicrobial. *Actinobacillus actinomycetemcomitans*, *Eikenella corrodens*, Enterobacteriaceae, and species of *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, and *Streptococcus* are commonly isolated with actinomycetes in various combinations, depending on the site of infection. The contribution of these other species to the pathogenesis of actinomycosis is uncertain.

Comparative 16S rRNA gene sequencing has led to the identification of *A. europaeus*, *A. neuii*, *A. radingae*, *A. graevenitzii*, *A. turicensis*, and *A. funkei* in clinical specimens. Increasing data suggest that these species may also cause actinomycosis.

EPIDEMIOLOGY Actinomycosis occurs throughout life, with a peak incidence in the middle decades. Males have a threefold higher incidence of infection than females, possibly because of poorer dental hygiene and/or more frequent trauma. Likely contributing factors to the decrease in the incidence of actinomycosis since the preantibiotic era include improved dental hygiene and the initiation of antimicrobial treatment early on—before the full development of the disease. Individuals who do not seek or have access to health care are undoubtedly at higher risk.

PATHOGENESIS AND PATHOLOGY The etiologic agents of actinomycosis are members of the normal oral flora and are often cultured from the bronchi, the gastrointestinal tract, and the female genital tract. The critical step in the development of actinomycosis is disruption of the mucosal barrier. Local infection may consequently ensue. Once established, actinomycosis spreads contiguously in a slow progressive manner, ignoring tissue planes. Although acute inflammation may initially develop at the site of infection, the hallmark of actinomycosis is the characteristic chronic, indolent phase. This stage is manifested by lesions that usually appear as single or multiple indurations. Central necrosis consisting of neutrophils and sulfur granules develops and is virtually diagnostic of this disease. The fibrotic walls of the mass are typically described as "wooden." The responsible bacterial and/or host factors have not yet been identified. Over time, sinus tracts to the skin, adjacent organs, or bone may develop. In rare instances, distant hematogenous seeding may occur. As mentioned above, these unique features of actinomycosis mimic malignancy, with which it is often confused.

Foreign bodies appear to facilitate infection. This association most frequently involves intrauterine contraceptive devices (IUCDs). In addition, an increasing number of reports have described an association of actinomycosis with HIV infection, transplantation, and radio- or chemotherapy. Ulcerative mucosal infections (e.g., by herpes simplex virus or cytomegalovirus) and abnormalities in host defenses may facilitate the development of actinomycosis in the latter settings.

CLINICAL MANIFESTATIONS ■ Oral-Cervicofacial Disease Actinomycosis occurs most frequently at an oral, cervical, or facial site, usually as a soft tissue swelling, abscess, or mass lesion that is often mistaken for a neoplasm. The angle of the jaw is generally involved, but a diagnosis of actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck (Chap. 27). Otitis, sinusitis, and canaliculitis can also develop. Pain, fever, and leukocytosis are variably reported. Contiguous extension to the cranium, cervical spine, or thorax is a potential sequela.

Thoracic Disease Thoracic actinomycosis usually follows an indolent progressive course, with involvement of the pulmonary parenchyma and/or the pleural space. Chest pain, fever, and weight loss are common. A cough, when present, is variably productive. The usual radiographic appearance is either a mass lesion or pneumonia. On computed tomography (CT), central areas of low attenuation and ringlike rim

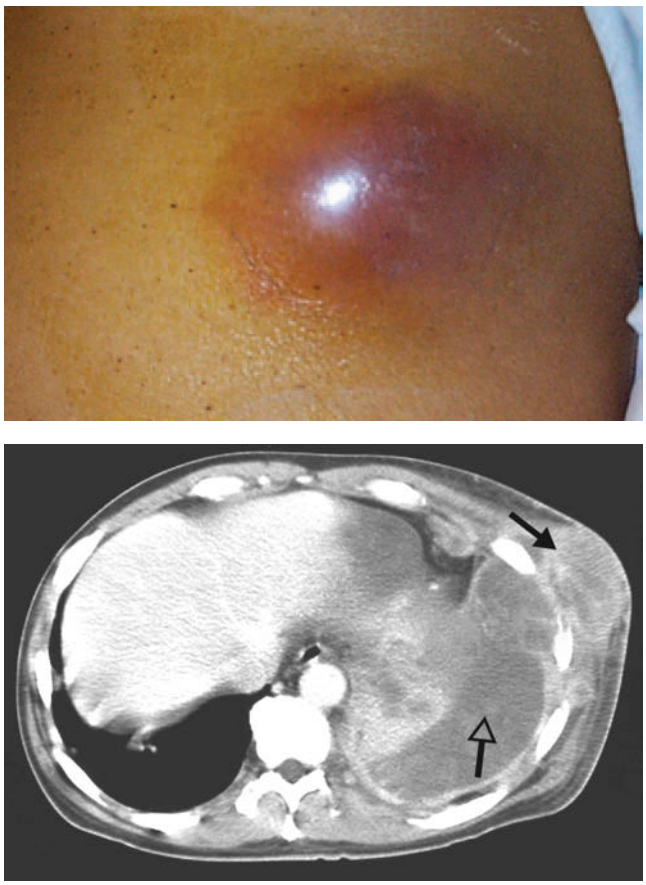

FIGURE 147-1 Thoracic actinomycosis. *Top*: A chest wall mass from extension of pulmonary infection. *Bottom*: Pulmonary infection is complicated by empyema (*open arrow*) and extension to the chest wall (*closed arrow*). (*Courtesy of Dr. C. B. Hsiao, Division of Infectious Diseases, Department of Medicine, State University of New York at Buffalo.*)

enhancement may be seen. Cavitary disease or hilar adenopathy may develop. More than 50% of cases include pleural thickening, effusion, or empyema (Fig. 147-1). Rarely, pulmonary nodules or endobronchial lesions occur. Pulmonary lesions suggestive of actinomycosis may cross fissures or pleura; may involve the mediastinum, contiguous bone, or chest wall; or may be associated with a sinus tract. In the absence of these findings, thoracic actinomycosis is usually mistaken for a neoplasm or for pneumonia due to more usual causes.

Mediastinal infection is uncommon, usually arising from thoracic extension but rarely resulting from perforation of the esophagus, from trauma, or from head and neck or abdominal disease. The structures within the mediastinum and the heart can be involved in various combinations; consequently, the possible presentations are diverse. Primary endocarditis and isolated disease of the breast have been described.

Abdominal Disease Abdominal actinomycosis poses a great diagnostic challenge. Months or years usually pass from the inciting event (e.g., appendicitis, diverticulitis, peptic ulcer disease, foreign-body perforation, bowel surgery, or ascension from IUCD-associated pelvic disease) to clinical recognition. Because of the flow of peritoneal fluid and/or the direct extension of primary disease, virtually any abdominal organ, region, or space can be involved. The disease usually presents as an abscess, a mass, or a mixed lesion that is often fixed to underlying tissue and mistaken for a tumor. On CT, enhancement is most often heterogeneous and adjacent bowel is thickened. Sinus tracts to the abdominal wall, to the perianal region, or between the bowel and other organs may develop and mimic inflammatory bowel disease. Recurrent disease or a wound or fistula that fails to heal suggests actinomycosis.

Hepatic infection usually presents as single or multiple abscesses or masses. Isolated disease presumably develops via hematogenous seeding from cryptic foci. Presently available imaging and percutaneous techniques have resulted in improved diagnosis and treatment.

All levels of the urogenital tract can be infected. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess. Bladder involvement, usually due to extension of pelvic disease, may result in ureteral obstruction or fistulas to bowel, skin, or uterus. *Actinomyces* can be detected in urine with use of appropriate stains and cultures.

Pelvic Disease Actinomycotic involvement of the pelvis occurs most commonly in association with an IUCD. Pelvic symptoms when an IUCD is in place or has recently been removed should prompt consideration of actinomycosis. Although the risk has not yet been quantified, it appears to be small. The disease rarely develops when the IUCD has been in place for <1 year, but the risk increases with time. Actinomycosis can also present months after the removal of the device. Symptoms are typically indolent; fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge are the most common. The earliest stage of disease—often endometritis—commonly progresses to pelvic masses or a tuboovarian abscess (Fig. 147-2). Unfortunately, because the diagnosis is often delayed, a "frozen pelvis" mimicking malignancy or endometriosis can develop by the time of recognition.

An unresolved issue is whether screening of cervical or endometrial specimens for *Actinomyces*-like organisms (ALOs) can predict or prevent IUCD-associated disease. Although the risk appears to be small, the consequences of infection are significant. Therefore, until more quantitative data become available, it would appear prudent to remove the IUCD in the presence of symptoms that cannot be accounted for, regardless of whether ALOs or immunofluorescence-positive organisms are detected, and—if advanced disease is excluded—to initiate a 14-day course of empirical treatment for possible early pelvic actinomycosis. The detection of ALOs or immunofluorescence-positive organisms in the absence of symptoms warrants education of the patient and close follow-up but not removal of the IUCD unless an equally suitable means of contraception can be agreed upon.

Central Nervous System Disease Actinomycosis of the central nervous system is rare. Single or multiple brain abscesses are most common. An abscess usually appears on CT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Meningitis, epidural or subdural space infection, and cavernous sinus syndrome have also been described.

FIGURE 147-2 Computed tomogram showing pelvic actinomycosis associated with an intrauterine contraceptive device. The device is encased by endometrial fibrosis (*solid arrow*); also visible are paraendometrial fibrosis (*open triangular arrowhead*) and an area of suppuration (*open arrow*).

Musculoskeletal and Soft Tissue Infection Actinomycotic infection of the bone is usually due to adjacent soft-tissue infection but may be associated with trauma (e.g., fracture of the mandible) or hematogenous spread. Because of slow disease progression, new bone formation and bone destruction are seen concomitantly. Infection of an extremity is uncommon and is usually a result of trauma. Skin, subcutaneous tissue, muscle, and bone (with periostitis or acute or chronic osteomyelitis) are involved alone or in various combinations. Cutaneous sinus tracts frequently develop.

Disseminated Disease Hematogenous dissemination of disease from any location rarely results in multiple-organ involvement. The lungs and liver are most commonly affected, with the presentation of multiple nodules mimicking disseminated malignancy. The clinical presentation may be surprisingly indolent given the extent of disease.

DIAGNOSIS The diagnosis of actinomycosis is rarely considered. All too often, the first mention of actinomycosis is by the pathologist after extensive surgery has been performed. Since medical therapy alone is often sufficient for cure, the challenge for the clinician is to consider the possibility of actinomycosis in time to diagnose it in the least invasive fashion and to avoid unnecessary surgery. The clinical and radiographic presentations that suggest actinomycosis have been discussed above. Aspirations and biopsies (with or without CT or ultrasound guidance) are being used successfully to obtain clinical material for diagnosis, although surgery may be required. The diagnosis is most commonly made by microscopic identification of sulfur granules (an in vivo matrix of bacteria, calcium phosphate, and host material) in pus or tissues. Occasionally these granules can be grossly identified from draining sinus tracts or pus. Although sulfur granules are a defining characteristic of actinomycosis, granules are also found in mycetoma (Chaps. 146 and 190) and botryomycosis (a chronic suppurative bacterial infection of soft tissue or, in rare cases, visceral tissue that produces clumps of bacteria resembling granules); however, these entities can easily be differentiated from actinomycosis with appropriate histopathologic and microbiologic studies. Microbiologic identification of actinomycetes is often precluded by the administration of prior antimicrobial therapy or the failure to perform appropriate microbiologic cultures. For optimal yield, the avoidance of even a single dose of antibiotics is mandatory. Primary isolation usually requires 5 to 7 days but may take as long as 2 to 4 weeks. Immunofluorescence testing for *A. israelii*, *A. naeslundii*, and *P. propionicum* (available through the Centers for Disease Control and Prevention in Atlanta) is a useful diagnostic alternative. Although 16S rRNA gene amplification and sequencing would be predicted to have increased diagnostic sensitivity, this method apparently has not been used so far. Because these organisms are components of the normal oral and genital-tract flora, their identification in the absence of sulfur granules in sputum, bronchial washings, and cervicovaginal secretions is of little significance.

TREATMENT

Decisions about treatment are based on the collective clinical experience of the past 50 years. Actinomycosis must be treated with high doses of antimicrobials for a prolonged period. The need for this intensive treatment is presumably due to difficulty encountered by antimicrobial agents in penetrating the thick-walled masses that commonly occur in this infection and/or the sulfur granules themselves. Although therapy needs to be individualized, the intravenous administration of 18 to 24 million units of penicillin daily for 2 to 6 weeks, followed by oral therapy with penicillin or amoxicillin for 6 to 12 months, is a reasonable guideline for serious infections. Less extensive disease, particularly that involving the oral-cervicofacial region, may require less intensive therapy. If therapy is extended beyond the point of resolution of measurable disease, the risk of relapse—a clinical hallmark of this infection—will be minimized; CT and magnetic resonance imaging (MRI) are generally the most sensitive and objective techniques by which to accomplish this goal. A similar approach is reasonable for immunocompromised patients, although refractory disease has been described in HIV-infected individuals. Suitable alternative antimicrobial agents and those deemed unreliable are listed in Table 147-1. Although the role played by "companion" microbes in actinomycosis is unclear, many isolates are pathogens in their own right, and a regimen covering these organisms during the initial treatment course is reasonable.

Combined medical-surgical therapy is still advocated by some authorities. However, an increasing body of literature now supports an initial attempt at cure with medical therapy alone, even in extensive disease. CT and MRI should be used to monitor the response to therapy. In most cases, either surgery can be avoided or a less extensive procedure can be used. This approach is particularly valuable in sparing critical organs, such as the bladder or the reproductive organs in women of child-bearing age. For a well-defined abscess, percutaneous drainage in combination with medical therapy is a reasonable approach. When a critical location is involved (e.g., the epidural space, the central nervous system) or when suitable medical therapy fails, surgical intervention may be appropriate.

TABLE 147-1 *Appropriate and Inappropriate Antibiotic Therapy for Actinomycosis*[a]

Category	*Agent*
Agents for which there is extensive successful clinical experience[b]	Penicillin: 18–24 mU/d IV q4h, 1–2 g/d PO q6h Amoxicillin: 1.5 g/d PO q8h Erythromycin: 2–4 g/d IV q6h, 1–2 g/d PO q6h Tetracycline: 1–2 g/d PO q6h Doxycycline: 200 mg/d IV or PO q12–24 h Minocycline: 200 mg/d IV or PO q12h Clindamycin: 2.7 g/d IV q8h, 1.2–1.8 g/d PO q6–8h
Agents for which there is anecdotal successful clinical experience	Ceftriaxone Ceftizoxime Imipenem Ciprofloxacin
Agents that should be avoided	Metronidazole Aminoglycosides Oxacillin Dicloxacillin Cephalexin

[a] Additional coverage for concomitant "companion" bacteria may be required.
[b] Controlled evaluations have not been performed. Dosing regimens require individualization according to the site and extent of infection. As a general rule, parenteral administration of the maximal antimicrobial dose for 2 to 6 weeks followed by oral therapy, for a total duration of 6 to 12 months, is required for most infections.

148 INFECTIONS DUE TO MIXED ANAEROBIC ORGANISMS

Dennis L. Kasper

DEFINITIONS *Anaerobic bacteria* are organisms that require reduced oxygen tension for growth, failing to grow on the surface of solid media in 10% CO_2 in air. (In contrast, *microaerophilic bacteria* can grow in an atmosphere of 10% CO_2 in air or under anaerobic or aerobic conditions, although they grow best in the presence of only a small amount of atmospheric oxygen, and *facultative bacteria* can grow in the presence or absence of air.) This chapter describes infections caused by nonsporulating anaerobic bacteria. In general, anaerobes associated with human infections are relatively aerotolerant. They can survive for as long as 72 h in the presence of oxygen, although generally they will not multiply in this environment. A far smaller number of pathogenic anaerobic bacteria (which are also part of the normal flora) die after brief contact with oxygen, even in low concentrations.

The nonsporulating anaerobic bacteria exist as components of the normal flora on the mucosal surfaces of humans and animals. The major reservoirs of these bacteria are the mouth, lower gastrointestinal tract, skin, and female genital tract. Among the constituents of the oral flora, anaerobes are the predominant commensal organisms, ranging in concentration from 10^9/mL in saliva to 10^{12}/mL in gingival scrapings. In the oral cavity, the ratio of anaerobic to aerobic bacteria ranges from 1:1 on the surface of a tooth to 1000:1 in the gingival crevice. Anaerobic bacteria are not found in appreciable numbers in the normal upper intestine until the distal ileum. In the colon, the proportion of anaerobes increases significantly, as does the overall bacterial count. For example, in the colon there are 10^{11} to 10^{12} organisms per gram of stool, with an anaerobe-to-aerobe ratio of ~1000:1. In the female genital tract, there are ~10^9 organisms per milliliter of secretions, with an anaerobe-to-aerobe ratio of ~10:1.

It is becoming clear that anaerobes play a key role in maintaining the balance between the host and its colonizing organisms. Hundreds of species of anaerobic bacteria have been identified as part of the normal flora of humans. Identification of as many as 500 different anaerobic species in fecal specimens reflects the diversity of the anaerobic flora. Despite the complex array of bacteria in the normal flora, relatively few species are isolated commonly from human infection. Anaerobic infections occur when the harmonious relationship between the host and the bacteria is disrupted. Any site in the body is susceptible to infection with these indigenous organisms when a mucosal barrier or the skin is compromised by surgery, trauma, tumor, or ischemia or necrosis, all of which can reduce local tissue redox potentials. Because the sites that are colonized by anaerobes contain many species of bacteria, disruption of anatomical barriers allows the penetration of many organisms, resulting in mixed infections involving multiple species of anaerobes combined with facultative or microaerophilic organisms. Such mixed infections are seen in the head and neck (chronic sinusitis, chronic otitis media, Ludwig's angina, and periodontal abscesses). Brain abscesses and subdural empyema are the most common anaerobic infections of the central nervous system. Anaerobes are responsible for pleuropulmonary diseases such as aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema. These organisms also play an important role in various intraabdominal infections, such as peritonitis and intraabdominal and liver abscesses (Chap. 112). They are isolated frequently in female genital tract infections, such as salpingitis, pelvic peritonitis, tuboovarian abscess, vulvovaginal abscess, septic abortion, and endometritis (Chap. 115). Anaerobic bacteria are also found often in infections of the skin, soft tissues, and bones and in bacteremia.

ETIOLOGY The taxonomic classification of anaerobes is a rapidly evolving field, with frequent changes in nomenclature based on newly discovered relationships among bacterial species. The major anaerobic gram-positive cocci that produce disease are *Peptostreptococcus* spp. The major species of this genus that are involved in infections are *Peptostreptococcus micros*, *P. magnus*, *P. asaccharolyticus*, *P. anaerobius*, and *P. prevotii*. Clostridia (Chap. 126) are gram-positive rods that are isolated from wounds, abscesses, sites of abdominal infection, and blood. The principal anaerobic gram-negative bacilli found in human infections are the *Bacteroides fragilis* group as well as *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp. Other members of the Bacteroidaceae family include *Bilophila wadsworthia*, an organism that has been isolated from infected sites and has been reported to cause serious infections, including bacteremia, necrotizing fasciitis, and abscesses; this organism is frequently resistant to several antimicrobial agents, including imipenem, cefoxitin, and other β-lactam drugs. Gram-positive anaerobic non-spore-forming bacilli are uncommon as etiologic agents of human infection. *Propionibacterium acnes*, a rare cause of foreign-body infections, is one of the few nonclostridial gram-positive rods associated with infections.

The *B. fragilis* group contains the anaerobic pathogens most frequently isolated from clinical infections. Members of this group are part of the normal bowel flora; they include several distinct species, such as *B. fragilis*, *B. thetaiotaomicron*, *B. distasonis*, *B. vulgatus*, *B. uniformis*, and *B. ovatus*. Of this group, *B. fragilis* is the most important clinical isolate. However, *B. fragilis* is isolated from the normal fecal flora in lower numbers than some of the other *Bacteroides* spp.

A second major group of phenotypically similar organisms is part of the indigenous oral flora. Thus these organisms are found at infected sites that can be seeded with oral microflora. Many of these species are pigment-producing bacteria previously classified as *Bacteroides melaninogenicus*. The nomenclature of this group has changed so that two distinct genera, *Prevotella* and *Porphyromonas*, are now recognized; these genera comprise several pathogenic species, including *Porphyromonas gingivalis*, *Porphyromonas asaccharolytica*, and *Prevotella oralis*. *Porphyromonas* and *Prevotella* spp. cause localized infections that can spread contiguously.

In female genital tract infections, organisms normally colonizing the vagina, such as *Prevotella bivia* and *Prevotella disiens*, are the most frequent isolates, although *B. fragilis* is not uncommon. The *Fusobacterium* species *Fusobacterium necrophorum*, *F. nucleatum*, and *F. varium*, which reside primarily in the oral cavity and the gastrointestinal tract, are also isolated from clinical infections, including necrotizing pneumonia and abscesses.

Infections caused by anaerobic bacteria most frequently are due to more than one organism. These polymicrobial infections may be caused by one or several anaerobic species or by a combination of anaerobic organisms and microaerophilic or facultative bacteria acting synergistically.

APPROACH TO THE PATIENT

The physician must consider several points when approaching the patient with presumptive infection due to anaerobic bacteria.

1. Most of the organisms colonizing mucosal sites are harmless commensals; very few cause disease.
2. For anaerobes to cause tissue infection, they must spread beyond the normal mucosal barriers.
3. Conditions favoring the propagation of these bacteria, particularly a lowered oxidation-reduction potential, are necessary. These conditions exist at sites of trauma, tissue destruction, compromised vascular supply, and complications of preexisting infection, which produce necrosis.
4. There is a complex array of infecting flora. For example, as many as 12 different types of organisms can be isolated from a suppurative site.
5. Anaerobic organisms tend to be found in abscess cavities or in necrotic tissue. The failure of an abscess to yield organisms on routine culture is a clue that the abscess is likely to contain

anaerobic bacteria. Often smears of this "sterile pus" are found to be teeming with bacteria when Gram's stain is applied. Malodorous pus suggests anaerobic infection. Although some facultative organisms, such as *Staphylococcus aureus*, are also capable of causing abscesses, abscesses in organs or deeper body tissues should call to mind anaerobic infection.

6. Gas is found in many anaerobic infections of deep tissues.
7. Some species (the best example being the *B. fragilis* group) require specific therapy. However, many synergistic infections can be cured with antibiotics directed at some but not all of the organisms involved. Antibiotic therapy, combined with debridement and drainage, disrupts the interdependent relationship among the bacteria, and some species that are resistant to the antibiotic do not survive without the coinfecting organisms.
8. Manifestations of disseminated intravascular coagulation are unusual in patients with purely anaerobic infection.

EPIDEMIOLOGY Difficulties in the performance of appropriate cultures, contamination of cultures by aerobic bacteria or components of the normal flora, and the lack of readily available, reliable culture techniques have made it impossible to obtain accurate incidence or prevalence data. However, anaerobic infections are encountered frequently in hospitals with active surgical, trauma, and obstetric and gynecologic services. In some centers, anaerobic bacteria, particularly *B. fragilis*, account for ~4% of positive blood cultures.

PATHOGENESIS Anaerobic bacterial infections usually occur when an anatomical barrier becomes disrupted and constituents of the local flora enter a site that was previously sterile. Because of the specific growth requirements of anaerobic organisms and their presence as commensals on mucosal surfaces, conditions must arise that allow these organisms to penetrate mucosal barriers and enter tissue with a lowered oxidation-reduction potential. Therefore, tissue ischemia, trauma, surgery, perforated viscus, shock, and aspiration provide environments conducive to the proliferation of anaerobes. In the case of a perforated viscus, hundreds of species of anaerobic bacteria are spilled into the peritoneal cavity, but many of these organisms are unable to survive because the highly vascularized tissue provides a sufficiently high redox potential. The entry of oxygen into the environment results in the selection of the more aerotolerant anaerobic organisms.

The ability of an organism to adhere to host tissues is important to the establishment of infection. Some oral species adhere to crevicular epithelium in the oral cavity. *Prevotella melaninogenica* actually attaches to other microorganisms; *P. gingivalis* is a common isolate in periodontal disease. These organisms have fimbriae that facilitate attachment. Some unencapsulated *Bacteroides* strains appear to be piliated, a characteristic that may account for their ability to adhere.

The most extensively studied virulence factor of the nonsporulating anaerobes is the polysaccharide capsule of *B. fragilis*. This polysaccharide possesses distinct biologic properties, such as the ability (owing to a unique zwitterionic motif of charged sugars) to promote abscess formation. Intraabdominal abscess induction is related to the capacity of the polysaccharide to stimulate the release of cytokines and chemokines—in particular interleukin (IL) 8, IL-17, and tumor necrosis factor (TNF) α—from resident peritoneal cells. The release of cytokines and chemokines results in the chemotaxis of polymorphonuclear neutrophils (PMNs) into the peritoneum, where they adhere to mesothelial cells induced by TNF-α to upregulate their expression of intercellular adhesion molecule 1 (ICAM-1). PMNs adherent to ICAM-1-expressing cells probably represent the nidus for an abscess. Prophylactic or therapeutic administration of the polysaccharide or a zwitterionic mimetic to experimental animals confers protection against abscess induction following challenge with intestinal microorganisms capable of inducing abscesses. This protection is mediated by T cells controlling cytokine release; IL-10 appears to be the cytokine primarily responsible for downregulating the tissue response of abscess formation. Although abscesses constitute a host response that localizes and contains infecting bacteria, abscess formation in patients with sepsis often results in severe and chronic illness that requires surgical drainage in combination with antimicrobial therapy.

Anaerobic bacteria produce a number of exoproteins that are capable of enhancing the organisms' virulence. The collagenase produced by *P. gingivalis* may enhance tissue destruction. An enterotoxin has been identified in *B. fragilis* strains associated with diarrheal disease in animals and young children. This 20-kDa zinc-dependent metalloprotease reversibly alters the morphology of the tight junctional complexes of intestinal epithelial cells. Both *B. fragilis* and *P. melaninogenica* possess lipopolysaccharides (endotoxins) that are less biologically potent than endotoxins associated with aerobic gram-negative bacteria. This relative biologic inactivity may account for the lower frequency of disseminated intravascular coagulation and purpura in *Bacteroides* bacteremia than in facultative and aerobic gram-negative bacillary bacteremia.

CLINICAL MANIFESTATIONS ■ Anaerobic Infections of the Mouth, Head, and Neck (See also Chap. 27) Infections of the mouth can arise from either the supragingival or the subgingival dental plaque. Supragingival plaque formation begins with the adherence of gram-positive bacteria to the tooth surface. This form of plaque is influenced by salivary and dietary components, oral hygiene, and local host factors. Once the supragingival plaque is established, the acquisition of pathogenic bacteria and an increase in the amount of plaque are responsible for the ultimate development of gingivitis. Early bacteriologic changes in the supragingival plaque initiate an inflammatory response in the gingiva, including edema, swelling, and increased gingival fluid, and cause the development of caries and endodontic (pulp) infections. In addition, these changes contribute to the subsequent pathogenic alteration in the subgingival plaque that arises from poor or inadequate oral hygiene.

Subgingival plaque is associated with periodontal disease and disseminated infection arising from the oral cavity. Bacteria that colonize the subgingival area are primarily anaerobic. The black-pigmented gram-negative anaerobic bacilli (principally *P. gingivalis*, *P. asaccharolytica*, and *P. melaninogenica*) are the most important. Infections in this area are frequently mixed and involve both anaerobic and aerobic bacteria. After establishment of local infection either in root canals or in the periodontal area, infection may extend into the mandible, causing osteomyelitis of the maxillary sinuses, or to local tissues in the submandibular or submental spaces, depending on which teeth are involved. Periodontitis may also result in spreading infection that can involve adjacent bone or soft tissues.

NECROTIZING ULCERATIVE GINGIVITIS Gingivitis may become a necrotizing infection (trench mouth, Vincent's stomatitis). The onset of disease is usually sudden and is associated with tender bleeding gums, foul breath, and a bad taste. The gingival mucosa, especially the papillae between the teeth, becomes ulcerated and may be covered by a gray exudate, which is removable with gentle pressure. Patients may become systemically ill, developing fever, cervical lymphadenopathy, and leukocytosis. Occasionally, ulcerative gingivitis can spread to the buccal mucosa, the teeth, and the mandible or maxilla, resulting in widespread destruction of bone and soft tissue. This infection is termed *acute necrotizing ulcerative mucositis* (cancrum oris, noma). It destroys tissue rapidly, causing the teeth to fall out and large areas of bone—or even the whole mandible—to be sloughed. A strong putrid odor is frequently detected, although the lesions are not painful. The gangrenous lesions eventually heal, leaving large disfiguring defects. This infection most commonly follows a debilitating illness or affects severely malnourished children. It has been known to complicate leukemia or to develop in individuals with a genetic deficiency of catalase.

ACUTE NECROTIZING INFECTIONS OF THE PHARYNX These infections usually occur in association with ulcerative gingivitis. Symptoms include an extremely sore throat, foul breath, and a bad taste accompanied by fever and a sensation of choking. Examination of the pharynx demonstrates that the tonsillar pillars are swollen, red, ulcerated, and covered with

a grayish membrane that peels easily. Lymphadenopathy and leukocytosis are common. The disease may last for only a few days or, if not treated, may persist for weeks. Lesions begin unilaterally but may spread to the other side of the pharynx or the larynx. Aspiration of the infected material by the patient can result in lung abscesses. Soft tissue infection of the oral-facial area may or may not be odontogenic. Ludwig's angina, a periodontal infection usually arising from the tissues surrounding the third molar, may produce submandibular soft tissue infection that results in marked local swelling of tissues, with pain, trismus, and superior and posterior displacement of the tongue. Submandibular swelling of the neck can impair swallowing and cause respiratory obstruction. In some cases, tracheotomy may be lifesaving.

FASCIAL INFECTIONS These infections arise from the spread of organisms originating in the upper airways to potential spaces formed by the fascial planes of the head and neck. Perimandibular space infection most commonly involves the submandibular, peritonsillar, and parapharyngeal spaces. Peritonsillar abscesses occur in association with pharyngitis. Complicated dental infections spread to the submandibular and buccal spaces. Entry of organisms by either portal can result in parapharyngeal space infections. Although there are few well-documented reports on the microbiology of these syndromes, anaerobes from the oral flora have been implicated in many cases. Fascial infections associated with *S. aureus* or *Streptococcus pyogenes* may arise from boils or impetigo, whereas anaerobes are associated with space infections either occurring spontaneously or arising from diseases of the mucous membranes or from dental manipulations.

SINUSITIS AND OTITIS The role of anaerobic bacteria in acute sinusitis may be underestimated because of improper collection of specimens. In a study of chronic sinusitis, anaerobic bacteria were found in 52% of specimens collected during external frontoethmoidotomy or radical antrotomy. However, antibiotic therapy against anaerobes alone is not usually curative. Anaerobic bacteria are much more easily implicated in chronic suppurative otitis media than in acute otitis media. Purulent exudate from chronically draining ears has been found to contain anaerobes, particularly *Bacteroides* spp., in up to 50% of cases. *B. fragilis* has been isolated from up to 28% of patients with chronic otitis media.

COMPLICATIONS OF ANAEROBIC HEAD AND NECK INFECTIONS Contiguous craniad spread of these infections may result in osteomyelitis of the skull or mandible or in intracranial infections such as brain abscess and subdural empyema. Caudad spread can produce mediastinitis or pleuropulmonary infection. Hematogenous complications may also result from anaerobic infections of the head and neck. Bacteremia, which occasionally is polymicrobial, can lead to endocarditis or other distant infections. Lemierre syndrome, which has been uncommon in the antimicrobial era, is an acute oropharyngeal infection with secondary septic thrombophlebitis of the internal jugular vein and frequent metastatic infections (see also "Bone and Joint Infections," below). *F. necrophorum* is the usual cause. This infection typically begins with pharyngitis, which is followed by local invasion in the lateral pharyngeal space with resultant internal jugular vein thrombophlebitis. The most common site for metastatic infection is the lungs. A typical clinical triad seen in recent series is pharyngitis, a tender/swollen neck, and noncavitating pulmonary infiltrates.

Central Nervous System Infections Brain abscesses are frequently associated with anaerobic bacteria (Chap. 360). If optimal bacteriologic techniques are employed, as many as 85% of brain abscesses yield anaerobic bacteria—most often anaerobic gram-positive cocci (especially peptostreptococci), which are followed in frequency by *Fusobacterium* and *Bacteroides* spp. Facultative or microaerophilic streptococci and coliforms are often are part of a mixed infecting flora in brain abscesses.

Pleuropulmonary Infections Anaerobic pleuropulmonary infections result from the aspiration of oropharyngeal contents, often in the context of an altered state of consciousness or an absent gag reflex. Four clinical syndromes are associated with anaerobic pleuropulmonary infection produced by aspiration: simple aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema.

ASPIRATION PNEUMONITIS Aspiration pneumonitis must be distinguished from two other clinical syndromes associated with aspiration that are not of bacterial etiology. One syndrome results from aspiration of solids, usually food. Obstruction of major airways typically results in atelectasis and moderate nonspecific inflammation. Therapy consists of removal of the foreign body.

The second aspiration syndrome is more easily confused with bacterial aspiration. *Mendelson's syndrome* results from regurgitation of stomach contents and aspiration of chemical material, usually gastric juices. Pulmonary inflammation—including the destruction of the alveolar lining, with transudation of fluid into the alveolar space—occurs with remarkable rapidity. Typically this syndrome develops within hours, often following anesthesia when the gag reflex is depressed. The patient becomes tachypneic, hypoxic, and febrile. The leukocyte count may rise, and the chest x-ray may evolve suddenly from normal to a complete bilateral "whiteout" within 8 to 24 h. Sputum production is minimal. The pulmonary signs and symptoms can resolve quickly with symptom-based therapy or can culminate in respiratory failure, with the subsequent development of bacterial superinfection over a period of days. Antibiotic therapy is not indicated unless bacterial infection supervenes. The signs of bacterial infection include sputum production, persistent fever, leukocytosis, and clinical evidence of sepsis.

In contrast to these syndromes, bacterial aspiration pneumonia develops more slowly. It is seen in patients who are hospitalized and have a depressed gag reflex, impaired swallowing, or a tracheal or nasogastric tube; elderly patients; or those with transiently impaired consciousness in the wake of seizures, cerebrovascular accidents, or alcoholic blackouts. Patients who enter the hospital with this syndrome typically have been ill for several days and generally report low-grade fever, malaise, and sputum production. Usually the history reveals factors predisposing to aspiration, such as alcohol overdose or residence in a nursing home. Sputum characteristically is not malodorous unless the process has been underway for at least a week. A mixed bacterial flora with many PMNs is evident on Gram's staining of sputum. The most commonly encountered anaerobes in sputum in these infections are pigmented and nonpigmented *Prevotella* spp., *F. nucleatum*, *Peptostreptococcus* spp., and *Bacteroides* spp. Cultures are reliable only if contamination with the normal oral flora is avoided—that is, if specimens are obtained by open lung biopsy. In general, this procedure is not indicated in the evaluation of these patients. Chest x-rays show consolidation in dependent pulmonary segments: in the basilar segments of the lower lobes if the patient has aspirated while upright and in either the posterior segment of the upper lobe (usually on the right side) or the superior segment of the lower lobe if the patient has aspirated while supine. The organisms isolated from the lungs reflect the pharyngeal flora; *P. melaninogenica*, *Fusobacterium* spp., and anaerobic cocci are the most common isolates. The patient who aspirates in the hospital may also have a mixed infection involving enteric gram-negative rods.

NECROTIZING PNEUMONITIS This form of anaerobic pneumonitis is characterized by numerous small abscesses that spread to involve several pulmonary segments. The process can be indolent or fulminating. This syndrome is less common than either aspiration pneumonia or lung abscess and includes features of both types of infection.

ANAEROBIC LUNG ABSCESSES These abscesses result from subacute anaerobic pulmonary infection. The clinical syndrome typically involves a history of constitutional symptoms, including malaise, weight loss, fever, chills, and foul-smelling sputum, perhaps over a period of weeks (Chap. 239). Patients who develop lung abscesses characteristically have dental infection and periodontitis, but lung abscesses in edentu-

lous patients have been reported. Abscess cavities may be single or multiple and generally occur in dependent pulmonary segments (Fig. 148-1). Anaerobic abscesses must be distinguished from those associated with tuberculosis, neoplasia, and other conditions. Oral anaerobes predominate, although *B. fragilis* is isolated in up to 10% of cases. *S. aureus* may be found as well.

EMPYEMA Empyema is a manifestation of long-standing anaerobic pulmonary infection. The clinical presentation, which includes the presence of foul-smelling sputum, resembles that of other anaerobic pulmonary infections. Patients may report pleuritic chest pain and marked chest-wall tenderness.

Empyema may be masked by overlying pneumonitis and should be considered especially in cases of persistent fever despite antibiotic therapy. Diligent physical examination and the use of ultrasound to localize a loculated empyema are important diagnostic tools. The collection of a foul-smelling exudate by thoracentesis is typical. Cultures of infected pleural fluid yield an average of 3.5 anaerobes and 0.6 facultative or aerobic bacterial species. Drainage is required. Defervescence, a return to a feeling of well-being, and resolution of the process may require several months.

Extension from a subdiaphragmatic infection may also result in anaerobic empyema. Septic pulmonary emboli may originate from intraabdominal or female genital tract infections and can produce anaerobic pneumonia.

Intraabdominal Infections Enterotoxigenic *B. fragilis* has been associated with watery diarrhea in a small number of young children and adults. In case-control studies of children with undiagnosed diarrheal disease, enterotoxigenic *B. fragilis* was isolated from significantly more children with diarrhea than children in the control group. This organism may play a role in a small proportion of childhood diarrhea cases. Neutropenic enterocolitis (typhlitis) has been associated with anaerobic infection of the cecum but—in the setting of neutropenia (Chap. 72)—may involve the entire bowel. Patients usually present with fever; abdominal pain, tenderness, and distention; and watery diarrhea. The bowel wall is edematous with hemorrhage and necrosis. The primary pathogen is thought by some authorities to be *Clostridium septicum*, but other clostridia and mixed anaerobic infections have also been implicated. More than 50% of patients developing early clinical signs can benefit from antibiotic therapy and bowel rest. Surgery is sometimes required to remove gangrenous bowel. →***See Chap. 112 for a complete discussion of intraabdominal infections.***

Pelvic Infections The vagina of a healthy woman is one of the major reservoirs of anaerobic and aerobic bacteria. In the normal flora of the female genital tract, anaerobes outnumber aerobes by a ratio of ~10:1 and include anaerobic gram-positive cocci and *Bacteroides* spp. Anaerobes are isolated from most women with genital tract infections that are not caused by a sexually transmitted pathogen. The major anaerobic pathogens are *B. fragilis*, *P. bivia*, *P. disiens*, *P. melaninogenica*, anaerobic cocci, and *Clostridium* spp. Anaerobes are frequently encountered in tuboovarian abscess, septic abortion, pelvic abscess, endometritis, and postoperative wound infection, particularly following hysterectomy. Although these infections are often of mixed etiology, involving both anaerobes and coliforms, pure anaerobic infections without coliform or other facultative bacterial species occur more often in pelvic than in intraabdominal sites and are characterized by drainage of foul-smelling pus or blood from the uterus, generalized uterine or local pelvic tenderness, and continued fever and chills. Suppurative thrombophlebitis of the pelvic veins may complicate the infections and lead to repeated episodes of septic pulmonary emboli.

FIGURE 148-1 Chest radiograph of right-lower-lobe lung abscess in a 60-year-old alcoholic. *[From GL Mandell (ed): Atlas of Infectious Diseases, Vol VI. Philadelphia, Current Medicine Inc, Churchill Livingstone, 1996; with permission.]*

Anaerobic bacteria have been thought to be contributing factors in the etiology of bacterial vaginosis. This syndrome of unknown etiology is characterized by a profuse malodorous discharge and an increase in the number of bacteria in the vagina, including *Gardnerella vaginalis*, *Prevotella* spp., *Mobiluncus* spp., peptostreptococci, and genital mycoplasmas. Anaerobic bacteria are thought to play a role in the etiology of pelvic inflammatory disease (Chap. 115), and several investigations have shown an association between bacterial vaginosis and the development of pelvic inflammatory disease.

Pelvic infections due to *Actinomyces* spp. have been associated with use of intrauterine devices (Chap. 147).

Skin and Soft Tissue Infections Injury to skin, bone, or soft tissue by trauma, ischemia, or surgery creates a suitable environment for anaerobic infections. These infections are most frequently found in sites prone to contamination with feces or with upper airway secretions—for example, wounds associated with intestinal surgery, decubitus ulcers, or human bites. Anaerobic bacteria can be isolated in cases of crepitant cellulitis, synergistic cellulitis, or gangrene and necrotizing fasciitis (Chaps. 110 and 126). Moreover, these organisms have been isolated from cutaneous abscesses, rectal abscesses, and axillary sweat gland infections (hidradenitis suppurativa). Anaerobes are frequently cultured from foot ulcers in diabetic patients.

These soft tissue or skin infections are usually polymicrobial. A mean of 4.8 bacterial species are isolated, with an anaerobe-to-aerobe ratio of ~3:2. The most frequently isolated organisms include *Bacteroides* spp., peptostreptococci, enterococci, clostridia, and *Proteus* spp. The involvement of anaerobes in these types of infections is associated with a higher frequency of fever, foul-smelling lesions, gas in the tissues, and visible foot ulcer.

Anaerobic bacterial *synergistic gangrene* (*Meleney's gangrene*) is characterized by exquisite pain, redness, and swelling followed by induration. Erythema surrounds a central zone of necrosis. A granulating ulcer forms at the original center as necrosis and erythema extend outward. Symptoms are limited to pain; fever is not typical. These infections usually involve a combination of *Peptostreptococcus* spp. and *S. aureus*; the usual site of infection is an abdominal surgical wound or the area surrounding an ulcer on an extremity. Treatment includes surgical removal of necrotic tissue and antimicrobial administration.

Necrotizing fasciitis, a rapidly spreading destructive disease of the fascia, is usually attributed to group A streptococci (Chap. 121) but can also be a mixed infection involving anaerobes and aerobes. The most frequently isolated anaerobes in these infections are *Peptostreptococcus* and *Bacteroides* spp. Gas may be found in the tissues. Similarly, myonecrosis can be associated with mixed anaerobic infection. *Fournier's gangrene* consists of cellulitis involving the scrotum, perineum, and anterior abdominal wall, with mixed anaerobic organisms spreading along deep external fascial planes and causing extensive loss of skin.

Bone and Joint Infections Although actinomycosis (Chap. 147) accounts on a worldwide basis for most anaerobic infections in bone, organisms including peptostreptococci or microaerophilic cocci, *Bacteroides* spp., *Fusobacterium* spp., and *Clostridium* spp. can also be found. These infections frequently arise adjacent to soft tissue infections. Hematogenous seeding of bone is uncommon. *Prevotella* and *Porphyromonas* spp. are detected in infections involving the maxilla and

mandible, whereas *Clostridium* spp. have been reported as anaerobic pathogens in cases of osteomyelitis of the long bones following fracture or trauma. Fusobacteria have been isolated in pure culture from sites of osteomyelitis adjacent to the perinasal sinuses. Peptostreptococci and microaerophilic cocci have been reported as significant pathogens in infections involving the skull, mastoid, and prosthetic implants placed in bone. In patients with osteomyelitis (Chap. 111), the most reliable culture specimen is a bone biopsy sample free of normal uninfected skin and subcutaneous tissue. In patients with anaerobic osteomyelitis, a mixed flora is frequently isolated from a bone biopsy specimen.

In cases of anaerobic septic arthritis, the most common isolates are *Fusobacterium* spp. Most of the patients involved have uncontrolled peritonsillar infections progressing to septic cervical venous thrombophlebitis (Lemierre syndrome) and resulting in hematogenous dissemination with a predilection for the joints. Unlike anaerobic osteomyelitis, anaerobic pyoarthritis in most cases is not polymicrobial and may be acquired hematogenously. Anaerobes are important pathogens in infections involving prosthetic joints; in these infections, the causative organisms (such as *Peptostreptococcus* spp. and *P. acnes*) are part of the normal skin flora.

Bacteremia Transient bacteremia is a well-known event in healthy people whose anatomical mucosal barriers have been injured (e.g., during dental extractions or dental scaling). These bacteremic episodes, which are often due to anaerobes, have no pathologic consequences. However, anaerobic bacteria are found in cultures of blood from clinically ill patients when proper culture techniques are used. *B. fragilis* is the single most common anaerobic isolate from the bloodstream.

In recent years, the rate of isolation of anaerobic bacteria from blood cultures has been decreasing. Studies from the 1970s and early 1980s found that 10 to 15% of positive blood cultures yielded anaerobes, while more recent surveys have found rates as low as 4%. The cause of this change is unknown but may be related to the administration of antibiotic prophylaxis before intestinal surgery, the earlier recognition of localized infections, and the empirical use of broad-spectrum antibiotics for presumed infection.

Once the organism has been identified, both the portal of bloodstream entry and the underlying problem that probably led to seeding of the bloodstream can often be deduced from an understanding of the organism's normal site of residence. For example, mixed anaerobic bacteremia including *B. fragilis* usually implies colonic pathology with mucosal disruption from neoplasia, diverticulitis, or some other inflammatory lesion. The initial manifestations are determined by the portal of entry and reflect the localized condition. When bloodstream invasion occurs, patients can become extremely ill, with rigors and hectic fevers ranging up to 40.6°C (105°F). The clinical picture may be quite similar to that seen in sepsis involving aerobic gram-negative bacilli. Although other complications of anaerobic bacteremia, such as septic thrombophlebitis and septic shock, have been reported, the incidence of these complications in association with anaerobic bacteremia is low. Anaerobic bacteremia is potentially fatal and requires rapid diagnosis and appropriate therapy. Mortality appears to increase with the age of the patient (with reported rates of >66% among patients >60 years old), with the isolation of multiple species from the bloodstream, and with the failure to surgically remove a focus of infection.

Endocarditis and Pericarditis (See also Chap. 109) Endocarditis due to anaerobes is uncommon. However, anaerobic streptococci, which are often classified incorrectly, are responsible for this disease more frequently than is generally appreciated. Gram-negative anaerobes are unusual causes of endocarditis. Signs and symptoms of anaerobic endocarditis are similar to those of endocarditis due to facultative organisms. The mortality rate for anaerobic endocarditis has been reported at 21 to 43%.

Anaerobes, particularly *B. fragilis* and *Peptostreptococcus* spp., are uncommonly found in infected pericardial fluids. Anaerobic pericarditis is associated with a mortality rate of >50%.

DIAGNOSIS There are three critical steps in the diagnosis of anaerobic infection: (1) proper specimen collection; (2) rapid transport of the specimens to the microbiology laboratory, preferably in anaerobic transport media; and (3) proper handling of the specimens by the laboratory. Specimens must be collected by meticulous sampling of infected sites, with avoidance of contamination by the normal flora. When such contamination is likely, the specimen is unacceptable. Examples of specimens unacceptable for anaerobic culture include sputum collected by expectoration or nasal tracheal suction, bronchoscopy specimens, samples collected directly through the vaginal vault, urine collected by voiding, and feces. Specimens that can be cultured for anaerobes include blood, pleural fluid, transtracheal aspirates, pus obtained by direct aspiration from an abscess cavity, fluid obtained by culdocentesis, suprapubic bladder aspirates, cerebrospinal fluid, and lung puncture specimens.

Because even brief exposure to oxygen may kill some anaerobic organisms and result in failure to isolate them in the laboratory, air must be expelled from the syringe used to aspirate the abscess cavity, and the needle must be capped with a sterile rubber stopper. Proper precautions should be used in the handling of contaminated needles. Specimens can be injected into transport bottles containing a reduced medium or taken immediately in syringes to the laboratory for direct culture on anaerobic media. In general, swabs should not be used. If a swab must be used, it should be placed in a reduced semisolid carrying medium before transport to the laboratory. Delays in transport may lead to a failure to isolate anaerobes due to exposure to oxygen or overgrowth of facultative organisms, which may eliminate or obscure any anaerobes that are present. All clinical specimens from suspected anaerobic infections should be Gram-stained and examined for organisms with characteristic morphology. It is not unusual for organisms to be observed on Gram's staining but not isolated in culture. If purulent materials are found to be sterile or organisms are seen on Gram's staining but do not grow in the culture, the involvement of anaerobes should be suspected.

Because of the time and difficulty involved in the isolation of anaerobic bacteria, diagnosis of anaerobic infections must frequently be based on presumptive evidence. Certain sites (such as avascular necrotic tissues) with lowered oxidation-reduction potential favor the diagnosis of an anaerobic infection. When infections occur in proximity to mucosal surfaces normally harboring an anaerobic flora, such as the gastrointestinal tract, female genital tract, or oropharynx, anaerobes should be considered as potential etiologic agents. A foul odor is often indicative of anaerobes, which produce certain organic acids as they proliferate in necrotic tissue. Although these odors are nearly pathognomonic for anaerobic infection, the absence of odor does not exclude an anaerobic etiology. Because anaerobes often coexist with other bacteria to cause mixed or synergistic infection, Gram's staining of exudate frequently reveals numerous pleomorphic cocci and bacilli suggestive of anaerobes. Sometimes these organisms have morphologic characteristics associated with specific species.

The presence of gas in tissues is highly suggestive, but not diagnostic, of anaerobic infection. When cultures of obviously infected sites yield no growth, streptococci only, or a single aerobic species (such as *Escherichia coli*) and Gram's staining reveals a mixed flora, the implication is that the anaerobic microorganisms failed to grow because of inadequate transport and/or culture techniques. Failure of a patient to respond to antibiotics that are not active against anaerobes (e.g., aminoglycosides and—in some circumstances—penicillin, cephalosporins, or tetracyclines) suggests anaerobic infection.

TREATMENT

Successful therapy for anaerobic infections requires the administration of a combination of appropriate antibiotics, surgical resection, debridement of devitalized tissues, and drainage. Perforations must be closed promptly, closed spaces drained, tissue compartments decompressed,

and an adequate blood supply established. Abscess cavities should be drained as soon as fluctuation or localization occurs. Surgery was formerly required to establish drainage; however, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound now allow diagnostic radiologists to drain many abscess sites percutaneously.

Antibiotic Therapy and Resistance Decisions about the treatment of anaerobic infections with antibiotics are usually based on known resistance patterns in certain species, on the likelihood of encountering a given species in the case at hand, and on Gram's stain findings. Antibiotics active against *Bacteroides* spp., penicillin-resistant *Prevotella* and *Porphyromonas* spp., and *Fusobacterium* spp. can be grouped into four categories on the basis of their predicted activity against anaerobes (Table 148-1). (Nearly all the drugs listed have toxic side effects, which are described in detail in Chap. 118.) In many infections, anaerobes are mixed with coliforms and other facultative organisms. The best therapeutic regimens, therefore, are usually those active against both aerobic and anaerobic bacteria. The choice of empirical antibiotics for the anaerobes in mixed infections can nearly always be made reliably, since patterns of antimicrobial susceptibility are usually predictable (Chap. 118 and Table 148-1).

TABLE 148-1 *Antimicrobial Therapy for Infections Involving Commonly Encountered Anaerobic Gram-Negative Rods*

Category 1 (<2% Resistance)	Category 2 (<15% Resistance)	Category 3 (Variable Resistance)	Category 4 (Resistance)
Imipenem	Cefoxitin	Penicillin	Aminoglycosides
Meropenem	Clindamycin	Cephalosporins	Quinolones[b]
Metronidazole[a]	High-dose antipseudomonal penicillins	Tetracycline	Monobactams
Ampicillin/sulbactam		Vancomycin	
Ticarcillin/clavulanic acid		Erythromycin	
Piperacillin/tazobactam			
Chloramphenicol[c]			

[a] Usually needs to be given in combination with aerobic bacterial coverage. For infections originating below the diaphragm, aerobic gram-negative coverage is essential. For infections from an oral source, aerobic gram-positive coverage is added. Metronidazole also is not active against *Actinomyces*, *Propionibacterium*, or other gram-positive non-spore-forming bacilli (e.g., *Eubacterium*, *Bifidobacterium*) and is unreliable against peptostreptococci.

[b] Moxifloxacin appears to have in vitro activity against many anaerobes.

[c] Chloramphenicol is probably not as effective as other category 1 antimicrobials in treating anaerobic infections.

Antibiotic susceptibility testing of anaerobic bacteria has been difficult and controversial. Owing to the slow growth rate of many anaerobes, the lack of standardized testing methods and of clinically relevant standards for resistance, and the generally good results obtained with empirical therapy, there has been limited interest in testing these organisms for antibiotic susceptibility. However, a recent study found mortality rates of 45 and 16% among antibiotic-treated patients with *Bacteroides* blood isolates deemed resistant and sensitive, respectively, to the agent used. These figures suggest that in vitro susceptibility testing should be performed for *Bacteroides* isolates from hospitalized patients with bacteremia and that the results of this testing should guide treatment.

Clinically important *Bacteroides* spp. are essentially all resistant to penicillin, and penicillin resistance rates among *Porphyromonas*, *Prevotella*, and *Fusobacterium* spp. are increasing rapidly. Failures of therapy are common when documented *Bacteroides* (especially *B. fragilis*) infection is treated with penicillin or first-generation cephalosporins. The number of antimicrobial agents effective against *Bacteroides* spp. has expanded, and there are currently several useful choices (Table 148-1). In general, cure rates of >80% can be attained in patients with *Bacteroides* infection by means of appropriate antimicrobial therapy and drainage.

Resistance to metronidazole has been reported only rarely in *Bacteroides* spp. This well-tolerated drug, which reaches significant levels in serum and can also be found at high concentrations in abscess cavities, should be considered first-line therapy against *Bacteroides* infection. However, if metronidazole is used to treat mixed anaerobic and aerobic infections, it is imperative that other appropriate antibiotics be used in conjunction. Metronidazole is inactive against aerobic and facultative bacteria, *Actinomyces* spp., and *Propionibacterium* spp. The sensitivity of peptostreptococci to metronidazole is unpredictable, and penicillin remains the drug of choice.

If a patient fails to respond to one of the category 1 or category 2 drugs (Table 148-1), consideration should be given to alternative therapy and to determination of the resistance patterns among *Bacteroides* isolates. Although in vitro resistance of *Bacteroides* spp. to chloramphenicol has not been reported, this drug may not be as effective as other category 1 drugs. Ampicillin/sulbactam, ticarcillin/clavulanic acid, piperacillin/tazobactam, imipenem, and meropenem have been effective in the treatment of *B. fragilis* infection. Some newer quinolones, such as moxifloxacin, appear to be highly active in vitro against certain anaerobes, including *B. fragilis*, but not against all members of the *B. fragilis* group; consideration of their use must await appropriate clinical trials.

Treatment of Infections at Specific Sites In clinical situations, specific regimens must be tailored to the initial site of infection. The duration of therapy also depends on the infection site; the reader is referred to specific chapters on sites of infection for recommendations.

β-Lactamase production has been reported in anaerobic strains that are usually isolated from infections originating above the diaphragm. Up to 60% of clinical isolates classified as *Prevotella* or *Porphyromonas* spp., non-*B. fragilis* species of *Bacteroides*, or *Fusobacterium* spp. reportedly produce β-lactamase. The clinical significance of resistance in these organisms has been suggested by studies showing clindamycin to be superior to penicillin (which for many years was considered the therapeutic "gold standard") for the treatment of lung abscesses. Presumably, the success of clindamycin is attributable to a broader spectrum of activity against oral anaerobes; thus, a combination of penicillin and metronidazole or another antibiotic combination that is active against both oral anaerobes and aerobes is likely to be as effective as clindamycin. Bronchoscopy in lung abscess is indicated only to rule out airway obstruction and does not enhance drainage; in any event, it should be delayed until the antimicrobial regimen has begun to affect the disease process so that the procedure does not spread the infection. Surgery is almost never indicated because of the danger of spilling the abscess contents into the lungs.

Although many oral anaerobic infections and most cases of anaerobic pneumonia still respond to penicillin therapy, some infections due to oral organisms fail to respond to this drug, and in these cases the use of a drug that is effective against penicillin-resistant anaerobes is recommended (Table 148-1). Life-threatening infections involving the anaerobic flora of the mouth, such as space infections of the head and neck, should be treated empirically as if penicillin-resistant anaerobes are involved. Less serious infections involving the oral microflora can be treated with penicillin alone; metronidazole can be added (or clindamycin can be substituted) if the patient responds poorly to penicillin therapy. Combinations of antibiotics used to treat mixed infections of oral origin must include drugs active against the gram-positive aerobic flora of the mouth.

Chloramphenicol has been used successfully against anaerobic central nervous system infections at doses of 30 to 60 mg/kg per day, with the exact dose depending on the severity of illness. However, penicillin G and metronidazole also cross the blood-brain barrier and are bactericidal for many anaerobic organisms (Chap. 360).

Anaerobic infections arising below the diaphragm (e.g., colonic and intraabdominal infections) must be treated specifically with agents active against *Bacteroides* spp. (Table 148-1). In intraabdominal sepsis (Chap. 112), the use of antibiotics effective against penicillin-resistant anaerobes has clearly reduced the incidence of postoperative infections and serious infectious complications. Specifically, a drug from cate-

TABLE 148-2 Doses and Schedules for Treatment of Serious Infections Due to Commonly Encountered Anaerobic Gram-Negative Rods

First-Line Therapy	Dose	Schedule[a]
Metronidazole[b]	500 mg	q6h
Ticarcillin/clavulanic acid	3.1 g	q4h
Piperacillin/tazobactam	3.375 g	q6h
Imipenem	0.5 g	q6h
Meropenem	1.0 g	q8h

[a] See disease-specific chapters for recommendations on duration of therapy.
[b] Should generally be used in conjunction with drugs active against aerobic or facultative organisms.
Note: All drugs are given by the intravenous route.

gory 1 (Table 148-1) must be included for broad-spectrum coverage. Recommended doses for commonly used category 1 drugs are given in Table 148-2. Therapy for intraabdominal sepsis must also include drugs active against the gram-negative aerobic flora of the bowel. If the involvement of gram-positive bacteria such as enterococci is suspected, either ampicillin or vancomycin should be added.

Cases of anaerobic osteomyelitis in which a mixed flora is isolated from a bone biopsy specimen should be treated with a regimen that covers all the isolates. When an anaerobic organism is recognized as a major or sole pathogen infecting a joint, the duration of treatment should be similar to that used for arthritis caused by aerobic bacteria (Chap. 314). Therapy includes the management of underlying disease states, the administration of appropriate antimicrobial agents, temporary joint immobilization, percutaneous drainage of effusions, and (usually) the removal of infected prostheses or internal fixation devices. Surgical drainage and debridement procedures such as sequestrectomy are essential for the removal of necrotic tissue that can sustain anaerobic infections.

The outcome of anaerobic bacteremia is significantly better in patients either initially given or switched to appropriate therapy based on known antibiotic susceptibilities.

Failure of Therapy Anaerobic infections that fail to respond to treatment or that relapse should be reassessed. Consideration should be given to additional surgical drainage or debridement. Superinfections with resistant gram-negative facultative or aerobic bacteria should be ruled out. The possibility of drug resistance must be entertained; if resistance is involved, repeated cultures may yield the pathogenic organism.

Supportive Measures Other supportive measures in the management of anaerobic infections include careful attention to fluid and electrolyte balance (since extensive local edema may lead to hypoalbuminemia), hemodynamic support for septic shock, immobilization of infected extremities, maintenance of adequate nutrition during chronic infections by parenteral hyperalimentation, relief of pain, and anticoagulation with heparin for thrombophlebitis. For patients with severe anaerobic infections of soft tissues, hyperbaric oxygen therapy is advocated by some experts, but its value has not been proven in controlled trials.

Section 8 Mycobacterial Diseases

149 ANTIMYCOBACTERIAL AGENTS

Richard J. Wallace, Jr., David E. Griffith

The physician is greatly challenged to provide optimal therapy for mycobacterial illnesses because of the increase in both drug-susceptible and multidrug-resistant tuberculosis; the increasing number of pathogenic nontuberculous mycobacteria (NTM); drug-related toxicities and drug-drug interactions (especially in patients who have AIDS, with their complex antiretroviral drug regimens); and the plethora of new antibiotics with antimycobacterial potential. This chapter reviews the therapeutic agents used for treatment of tuberculosis, leprosy (Hansen's disease), and diseases caused by NTM, including *Mycobacterium avium-intracellulare* (MAI), *M. kansasii*, the rapidly growing mycobacteria, and *M. marinum*. The use of antimycobacterial agents in patients with renal or hepatic disease and in pregnant women is summarized in Table 149-1. The effects of antimycobacterial agents on the levels, activity, and toxicity of other commonly used drugs are summarized in Table 149-2.

TUBERCULOSIS

Drugs used to treat tuberculosis have been classified into first-line and second-line agents. *First-line essential* antituberculous agents are the most effective and are a necessary component of any short-course therapeutic regimen. The three drugs in this category are rifampin, isoniazid, and pyrazinamide. The *first-line supplemental* agents, which are highly effective and infrequently toxic, include ethambutol and streptomycin. Favorable experience in patients with tuberculosis resistant to first-line essential drugs suggests that rifabutin and the fluoroquinolones ciprofloxacin and levofloxacin are important additions to multidrug antituberculous regimens; thus these agents have now been added to the list of first-line supplemental drugs. *Second-line* antituberculous drugs are clinically much less effective than first-line agents and elicit severe reactions much more frequently. These drugs are rarely used in therapy and then only by caregivers experienced with their use. The older agents include para-aminosalicylic acid (PAS), ethionamide, cycloserine, amikacin, and capreomycin. *Newer* antituberculous drugs, which have not yet been placed in the above categories, include rifapentine and the 8-methoxyfluoroquinolones gatifloxacin and moxifloxacin.

FIRST-LINE ESSENTIAL ANTITUBERCULOUS DRUGS ■ Rifampin Rifampin, a semisynthetic derivative of *Streptomyces mediterranei*, is considered the most important and potent antituberculous agent. It is also active against a wide spectrum of other organisms, including some gram-positive and gram-negative bacteria, *Legionella* spp., *M. kansasii*, and *M. marinum*.

MECHANISM OF ACTION Rifampin has both intracellular and extracellular bactericidal activity. It blocks RNA synthesis by specifically binding and inhibiting DNA-dependent RNA polymerase. Susceptible strains

TABLE 149-1 *Use of Antimycobacterial Agents in Patients with Renal or Hepatic Disease and in Pregnant Women*

Agent	Use in Indicated Circumstances			
		Renal Disease: Creatinine Clearance Rate		
	Severe Hepatic Disease	>30 mL/min	≤30 mL/min	Pregnancy[a]
Azithromycin	No change	No change	?Decrease dose	No evidence of risk (B)

[c] Use in pregnancy is recommended by international organizations outside the United States.

of *M. tuberculosis* as well as *M. kansasii* and *M. marinum* are inhibited by ≤1 μg/mL.

PHARMACOLOGY Rifampin is a fat-soluble complex macrocyclic antibiotic that is absorbed readily after either oral or intravenous administration. Serum levels of 10 to 20 μg/mL follow a standard adult oral dose of 600 mg. Rifampin distributes well throughout most body tissues, including inflamed meninges. The fact that rifampin turns body fluids (urine, saliva, sputum, tears) a red-orange color makes it simple and inexpensive to check on patients' compliance with therapy. Rifampin is excreted primarily through the bile and the enterohepatic circulation, while 30 to 40% of a dose is excreted via the kidneys. The drug is administered either twice weekly or daily at a dose of 600 mg for adults (10 mg/kg) and 10 to 20 mg/kg for children. As mentioned above, rifampin is also available for intravenous administration.

TABLE 149-2 *Effects of Major Antimycobacterial Agents on Levels/Activity/Toxicity of Other Commonly Used Drugs*[a]

Rifampin/rifabutin[b]
- Acetaminophen (↓)
- Antiarrhythmics (↓)
- Anticonvulsants (↓)
- Azole antifungals (↓)
- Barbiturates (↓)
- β Blockers (↓)
- Calcium channel blockers (↓)
- Chloramphenicol (↓)
- Clarithromycin (↓)
- Cyclosporine (↓)
- Dapsone (↓)
- Delavirdine (↓)
- Diazepam (↓)
- Digoxin (↓)
- Doxycycline (↓)
- Fluoroquinolones (↓)

- Carbamazepine (↑)
- Digoxin (↑)
- Rifabutin (↑)
- Ritonavir (↓)
- Terfenadine (↑)
- Zidovudine (↓)

[a] The following antimycobacterial agents have no or minimal effects on other drugs: amikacin, azithromycin, capreomycin, ethambutol, streptomycin, pyrazinamide.
[b] Rifabutin, which induces the cytochrome P450 system, has the same effects (↓) as rifampin but to a lesser degree. All drugs whose half-life is decreased by rifampin induction of hepatic microsomal enzymes may be subject to the same effect when coadministered with rifabutin; however, this point has not yet been studied.
[c] NNRTIs, nonnucleoside reverse transcriptase inhibitors.

ADVERSE EFFECTS (Table 149-3) Rifampin is generally well tolerated; the most common adverse event is gastrointestinal upset. Patients with chronic liver disease, especially those with alcoholism and the elderly, appear to be at unusually high risk for the most serious adverse drug reaction: hepatitis. Other adverse effects of rifampin include rash (0.8%), hemolytic anemia (<1%), thrombocytopenia, and immunosuppression of unknown clinical importance. Rifampin is a potent inducer of the hepatic microsomal enzymes and thereby decreases the half-life of a number of drugs, including digoxin, warfarin, prednisone, cyclosporine, methadone, oral contraceptives, clarithromycin, the HIV protease inhibitors, the HIV nonnucleoside reverse transcriptase inhibitors, and quinidine (Table 149-2). The dose of rifampin generally does not require reduction in patients with renal failure, especially those receiving intermittent rifampin administration (Table 149-1).

RESISTANCE Resistance to rifampin results from spontaneous point mutations that alter the β subunit of the RNA polymerase (*rpoB*) gene. Studies have shown that 96% of rifampin-resistant strains have a missense mutation within a 91-bp central core region of the gene. Rifampin-resistant strains of *M. leprae* have similar mutations that alter a single serine residue (Ser-425) in the same core region of the *rpoB* gene.

Isoniazid After rifampin, isoniazid is considered the best antituberculous drug currently available. Isoniazid should be included in all tuberculosis treatment regimens unless the organism is resistant. Isoniazid is inexpensive, readily synthesized, available worldwide, highly selective for mycobacteria, and well tolerated, with only 5% of patients exhibiting adverse effects.

MECHANISM OF ACTION Isoniazid is the hydrazide of isonicotinic acid, a small, water-soluble molecule that easily penetrates the cell. Its mechanism of action involves inhibition of mycolic acid cell-wall synthesis via oxygen-dependent pathways such as the catalase-peroxidase reaction. Isoniazid is bacteriostatic against resting bacilli and bactericidal against rapidly multiplying organisms, both extracellularly and intracellularly. The minimal inhibitory concentrations (MICs) of isoniazid for wild-type (untreated) strains of *M. tuberculosis* are <0.1 μg/mL, while those for *M. kansasii* are usually 0.5 to 2.0 μg/mL. The MICs of this drug for other NTM are often higher.

PHARMACOLOGY Both oral and intramuscular preparations of isoniazid are readily absorbed. The standard adult daily oral dose of 300 mg produces peak serum levels of 3 to 5 μg/mL. Isoniazid diffuses well throughout the body and reaches therapeutic concentrations in serum, cerebrospinal fluid (CSF), and infected tissue, including caseous granulomas. Isoniazid is metabolized in the liver via acetylation and hydrolysis; its metabolites are excreted into the urine. The rate of acetylation is genetically controlled. The recommended daily dose for the treatment of tuberculosis in the United States is 5 mg/kg for adults and 10 to 20 mg/kg for children, with a maximal daily dose of 300 mg for both groups. (Tuberculosis organizations outside the United States have recommended 5 mg/kg daily for both groups.) For inter-

TABLE 149-3 *Monitoring Side Effects of Common Antituberculous Drugs*

Drug	Side Effect	Management
Rifampin	Rash	Observe patient/stop drug if significant
	Liver dysfunction	Monitor AST/limit alcohol consumption/monitor for hepatitis symptoms
	Flulike syndrome	Administer at least twice weekly/limit dose to 10 mg/kg (adults)
	Red-orange urine	Reassure patient
	Drug interactions	Consider monitoring levels of other drugs affected by rifampin, especially with contraceptives, anticoagulants, and digoxin/avoid use with protease inhibitors
	Fever, chills	Stop drug
Isoniazid	Hepatitis	Monitor AST/limit alcohol consumption/monitor for hepatitis symptoms/educate patient/stop drug at first symptoms of hepatitis (nausea, vomiting, anorexia, flulike syndrome)
	Peripheral neuritis	Administer vitamin B_6
	Optic neuritis	Administer vitamin B_6/stop drug
	Seizures	Administer vitamin B_6
Pyrazinamide	Hepatitis	Monitor AST/limit daily dosage to 15–30 mg/kg/discontinue with signs or symptoms of hepatitis
	Hyperuricemia	Monitor uric acid level only in cases of gout or renal failure
Ethambutol	Optic neuritis	Use 25 mg/kg daily only for first 2 months (except in drug-resistant tuberculosis), then use lower daily dose (15 mg/kg) when possible/monitor visual acuity (eye chart) and red-green color vision (Ishihara Color Book) at baseline and with any visual complaint/educate patient/stop drug at first change in vision, get ophthalmologic evaluation
Streptomycin, amikacin, capreomycin	Ototoxicity, renal toxicity	Limit dose and duration of therapy as much as possible/avoid daily therapy in patients >50 years old/monitor BUN and serum creatinine levels and possibly conduct audiometry before and as needed during therapy/question patient regularly about tinnitus, dizziness, vertigo, and decreased hearing/measure serum drug levels if possible/educate patient/stop drug at first development of adverse effect (usually tinnitus)

Note: AST, aspartate aminotransferase; BUN, blood urea nitrogen.

mittent therapy (usually directly observed), a maximal dose of 900 mg twice or thrice weekly is used. Even in moderate to severe renal failure, the adult dose rarely needs to be reduced below 200 mg/d. Although not approved by the Food and Drug Administration (FDA), intravenous isoniazid can be given in an urgent situation.

ADVERSE EFFECTS (Table 149-3) The two most important adverse effects of isoniazid therapy are hepatotoxicity and peripheral neuropathy. Other adverse reactions are either rare or less significant and include rash (2%), fever (1.2%), anemia, acne, arthritic symptoms, a systemic lupus erythematosus–like syndrome, optic atrophy, seizures, and psychiatric symptoms. Isoniazid-associated hepatitis is idiosyncratic and increases in incidence with age, daily alcohol consumption, concomitant rifampin administration, and HIV infection as well as in women who are pregnant or in the immediate (3 months) postpartum period. Appropriate clinical monitoring of patients receiving isoniazid includes at least monthly questioning about hepatitis-related symptoms and filling of prescriptions for no more than 1 month's worth of medication. Clinical monitoring is essential for all patients since discontinuation of the drug at the onset of hepatitis symptoms reduces the risk of progression to fatal hepatitis. The Centers for Disease Control and Prevention (CDC) and the American Thoracic Society (ATS) recommend that serum concentrations of aspartate aminotransferase (AST) or alanine aminotransferase (ALT) be determined at baseline in patients with liver disorders or HIV infection, in women who are pregnant or in the immediate postpartum period (3 months), in persons with a history of liver disease (e.g., hepatitis B or C, alcoholic hepatitis, or cirrhosis), in persons who use alcohol regularly, and in other individuals at risk for chronic liver disease who are receiving isoniazid for treatment of latent tuberculosis. Baseline testing is no longer routinely indicated in persons >35 years of age. Routine laboratory monitoring during isoniazid treatment is indicated for patients whose baseline liver function tests yield abnormal results and for persons at risk for hepatic disease, including the groups just mentioned. Measurement of the ALT or AST level is certainly mandatory whenever a patient notices the onset of symptoms suggestive of isoniazid-associated hepatitis (e.g., fever, anorexia, nausea, vomiting, and/or a flulike syndrome including fever and myalgias), and treatment should be discontinued until the relationship between therapy and symptoms is ascertained. Several studies have demonstrated that many patients with isoniazid intolerance can be desensitized. The CDC/ATS recommends that discontinuation of isoniazid be strongly considered whenever an asymptomatic elevation of the AST or ALT level exceeds 150 to 200 IU (three to five times the upper limit of normal) in high-risk patients whose baseline values were normal. In one study, only 11 (0.1%) of 11,141 patients had hepatotoxic reactions to isoniazid during preventive treatment.

Peripheral neuritis associated with isoniazid is uncommon and probably relates to interference with pyridoxine (vitamin B_6) metabolism. The risk of isoniazid-related neurotoxicity is greatest for patients with preexisting disorders that also pose a risk of neuropathy, such as diabetes, alcohol abuse, or malnutrition. In these patients, the prophylactic administration of 25 to 50 mg of pyridoxine daily should be considered.

RESISTANCE Isoniazid-resistant mutants of *M. tuberculosis* occur spontaneously at a rate of 1 in 10^5 to 10^6 organisms. The molecular sites of isoniazid resistance have been detailed. Most isoniazid-resistant strains have amino acid changes in either the catalase-peroxidase gene (*katG*) or the promoter of a two-gene locus known as *inhA*. Missense mutations or deletion of *katG* is also associated with reduced catalase and peroxidase activity. Rates of primary isoniazid resistance in untreated patients are much higher in many foreign-born populations than in populations born in the United States.

Pyrazinamide A derivative of nicotinic acid, pyrazinamide is an important bactericidal drug used in short-course therapy for tuberculosis.

MECHANISM OF ACTION Pyrazinamide is similar to isoniazid in its narrow spectrum of antibacterial activity, which essentially includes only *M. tuberculosis*. The drug is bactericidal to slowly metabolizing organisms located within the acidic environment of the phagocyte or caseous granuloma; it is active only at a pH of <6.0. Pyrazinamide is considered a prodrug and is converted by the tubercle bacillus to the active form pyrazinoic acid. The target for this compound is thought to be a fatty acid synthase gene (*fasI*). Susceptible strains of *M. tuberculosis* are inhibited by 20 μg/mL.

PHARMACOLOGY Pyrazinamide is well absorbed after oral administration, with a plasma concentration range of 20 to 60 μg/mL 1 to 2 h after oral ingestion of the currently recommended adult daily dose of 15 to 30 mg/kg (maximum, 2 g/d). The drug is well distributed throughout the body. Levels in CSF are excellent, reaching 50 to 100% of levels

in serum. The serum half-life of the drug is 9 to 11 h. Pyrazinamide is metabolized by at least two major pathways and one minor pathway in the liver; its several metabolites include pyrazinoic acid, 5-hydroxypyrazinamide, and 5-hydroxypyrazinoic acid. Pyrazinamide is not available in a parenteral formulation.

ADVERSE EFFECTS (Table 149-3) At the high dosages used in the past, hepatotoxicity was a prominent complication of pyrazinamide therapy. However, at the currently recommended dosages, the frequency of hepatotoxicity is no higher than that for concomitant isoniazid and rifampin therapy. Although pyrazinamide is recommended by international tuberculosis organizations for routine use in pregnancy, it is not recommended in the United States because of inadequate teratogenicity data (Table 149-1). The combination of rifampin/pyrazinamide once recommended for treatment of latent tuberculosis has recently been shown to have an unacceptably high rate of hepatitis. Hyperuricemia is a common adverse effect of pyrazinamide therapy; the incidence is probably reduced by concurrent rifampin therapy. Clinical gout is seen only rarely. Polyarthralgias are encountered fairly commonly but are not related to the hyperuricemia.

RESISTANCE Resistance to pyrazinamide is associated with loss of pyrazinamidase activity such that pyrazinamide is no longer converted to pyrazinoic acid. More than 90% of isolates with MICs of >100 μg/mL have mutations in the *pncA* gene, which encodes for pyrazinamidase. All strains of *M. bovis* are naturally resistant to pyrazinamide and have a point substitution within the *pncA* gene.

FIRST-LINE SUPPLEMENTAL DRUGS ■ Ethambutol A derivative of ethylenediamine, ethambutol is a water-soluble compound that is active only against mycobacteria. Susceptible species include *M. tuberculosis*, *M. marinum*, *M. kansasii*, and MAI. Among first-line drugs, ethambutol is the least potent against *M. tuberculosis*. It is used most often with rifampin for treatment of tuberculosis in patients who cannot tolerate isoniazid or who are thought or known to be infected with isoniazid-resistant organisms.

MECHANISM OF ACTION Ethambutol at standard doses is bacteriostatic against *M. tuberculosis*. Its primary mechanism of action appears to be inhibition of an arabinosyltransferase that mediates the polymerization of arabinose into arabinogalactan within the cell wall.

PHARMACOLOGY After oral administration, 75 to 80% of a dose of ethambutol is absorbed from the gastrointestinal tract. Peak serum levels of 2 to 4 μg/mL are achieved 2 to 4 h after the standard adult daily dose of 15 mg/kg. The drug's distribution throughout the body is adequate except in the CSF, where it reaches only low levels. However, ethambutol can reach CSF levels up to 50% as high as peak plasma levels when administered at a daily dosage of 25 mg/kg (which may be given in one daily dose) for the first 2 months, with subsequent reduction to 15 mg/kg. In cases of drug-resistant tuberculosis or where re-treatment is necessary, the higher dose may be given for the duration. For intermittent therapy, the dosage is 50 mg/kg twice weekly or 30 mg/kg thrice weekly. The dosage must be lowered for patients with renal insufficiency (a creatinine clearance rate of <50 mL/min) to prevent drug accumulation and toxicity.

ADVERSE EFFECTS (Table 149-3) Ethambutol is usually well tolerated. Retrobulbar optic neuritis is the most serious adverse effect; axial or central neuritis—the only form reported in patients taking doses of <30 mg/kg—involves the papillomacular bundle of fibers and results in reduced visual acuity, central scotoma, and loss of ability to see green. Symptoms of ocular toxicity typically develop several months after initiation of therapy, but rapid-onset optic neuritis has been reported. The risk of optic neuritis depends on the dose and duration of therapy: this reaction develops in 5% of patients receiving a daily dose of 25 mg/kg but in fewer than 1% of patients given a daily dose of 15 mg/kg. Patients taking the lower dose should be tested at baseline and whenever there is a subjective visual change for visual acuity and red-green color discrimination. Patients taking the higher dose should be tested at baseline, monthly thereafter, and whenever there is subjective visual change. Intermittent (three times weekly) administration of ethambutol at 25 mg/kg per dose appears to be better tolerated than daily administration of 15 mg/kg, especially in elderly populations being treated for *M. avium* complex infection. Optic neuritis with associated visual loss is usually reversible, but recovery may take >6 months.

Other adverse effects of ethambutol are infrequent. Hyperuricemia occurs but is usually asymptomatic. Peripheral sensory neuropathy occurs in rare instances. Optic neuritis is rare at the low dose in children; however, the use of ethambutol in very young children is problematic because visual complications are difficult to monitor.

RESISTANCE Ethambutol resistance in *M. tuberculosis* most commonly relates to missense mutations in the *embB* gene that encodes for arabinosyltransferase. Such mutations have been found in 70% of resistant strains and involve amino acid replacements at position 306 or 406 in ~90% of cases. Species of NTM that are intrinsically resistant to ethambutol have variant amino acids in this region of the gene, while susceptible species have the same amino acid sequences as *M. tuberculosis*.

Streptomycin An aminoglycoside isolated from *Streptomyces griseus*, streptomycin is available for intramuscular and intravenous administration only. In the United States, it is the least-used first-line supplemental drug for tuberculosis because of its toxicity, the difficulty in obtaining adequate CSF levels, and the inconvenience of parenteral administration. In developing countries, however, streptomycin is frequently used because of its low cost. The drug is active against untreated strains of *M. tuberculosis*, *M. kansasii*, and *M. marinum* and against some strains of the *M. avium* complex at achievable serum levels.

MECHANISM OF ACTION Streptomycin inhibits protein synthesis by disruption of ribosomal function.

PHARMACOLOGY Serum levels of streptomycin peak at 25 to 40 μg/mL after a 1.0-g dose. Streptomycin is bactericidal for rapidly dividing extracellular mycobacteria but is ineffective in the acidic environment within the macrophage. It diffuses poorly into the meninges and, in patients with meningitis, reaches CSF levels that are only 20% of serum levels.

The usual adult dose of streptomycin for a 70-kg patient is 0.5 to 1.0 g (10 to 15 mg/kg) given intramuscularly daily or five times per week; the pediatric dose is 20 to 40 mg/kg daily, with a maximum of 1 g/d. Because streptomycin is eliminated almost exclusively by the kidneys, the dosage must be lowered and the frequency of administration reduced (to only two or three times per week) in most patients >50 years of age and in any patient with renal impairment (Table 149-1) or reduced body weight. Although this approach is not approved by the FDA, streptomycin can be given intravenously.

ADVERSE EFFECTS (Table 149-3) Adverse reactions to streptomycin therapy occur in 10 to 20% of recipients. Ototoxicity and renal toxicity are the most common and the most serious. Renal toxicity, usually manifested as nonoliguric renal failure, is less common with streptomycin than with other frequently used aminoglycosides, such as gentamicin. Ototoxicity involves both hearing loss and vestibular dysfunction. The latter is more common and includes loss of balance, vertigo, and tinnitus. Patients receiving streptomycin must be monitored carefully for these adverse effects. Less serious reactions include perioral paresthesia, eosinophilia, rash, and drug fever.

RESISTANCE Spontaneous resistance to streptomycin occurs in 1 in 10^5 to 10^7 organisms. In two-thirds of streptomycin-resistant strains of *M. tuberculosis*, mutations have been identified in one of two targets: a 16S rRNA gene (*rrs*) or the gene encoding ribosomal protein S12 (*rpsL*). Both targets are believed to be involved in streptomycin ribosomal binding. No mutational change has been identified in the other one-third of resistant isolates. Strains of *M. tuberculosis* resistant to streptomycin are not cross-resistant to capreomycin or amikacin.

SECOND-LINE ANTITUBERCULOUS DRUGS Second-line and/or newer antituberculosis agents are used either when tuberculosis is drug resistant or when first-line supplemental drugs are not available. The more important second-line drugs are discussed below in their general (descending) order of usefulness.

Quinolones A surprisingly large number of fluorinated quinolones are being developed and studied as inhibitors of mycobacteria. Their mode of action presumably is the prevention of DNA synthesis through the inhibition of DNA gyrase. Ofloxacin, levofloxacin, ciprofloxacin, gatifloxacin, and moxifloxacin are active against many mycobacteria, including *M. tuberculosis*, *M. leprae*, *M. marinum*, *M. kansasii*, and *M. fortuitum*. These drugs are well absorbed orally, reach high serum levels, and distribute well to body tissues and fluids. While not approved for antituberculous therapy in the United States, ofloxacin—used in combination with isoniazid and rifampin for the treatment of pulmonary tuberculosis—has been as active and safe as ethambutol in initial trials. Adverse effects are relatively uncommon, occurring in 0.5 to 10% of cases and consisting mostly of benign reactions such as gastrointestinal intolerance, rashes, dizziness, and headache. However, more serious adverse effects are being reported and include confusion, seizures, interstitial nephritis, skin vasculitis, and acute renal failure. The quinolones are rapidly becoming some of the most important and effective drugs for the treatment of tuberculosis resistant to first-line essential drugs. Some experts would classify the quinolones as first-line supplemental agents. The quinolones can also be administered intravenously.

Mycobacterial resistance to the fluoroquinolones develops rapidly. Its molecular basis is complex; only some strains exhibit missense mutations in the A subunit (*gyrA* gene) of DNA gyrase. Fluoroquinolone-resistant tuberculosis is a source of growing concern. Antituberculous therapy with quinolones should be reserved for patients with multidrug resistance and for those who cannot tolerate first-line drugs.

Capreomycin Capreomycin, a complex cyclic polypeptide antibiotic derived from *Streptomyces capreolus*, is similar to streptomycin in terms of dosing, mechanism of action, pharmacology, and toxicity. It is administered only by the intramuscular route in doses of 10 to 15 mg/kg daily or five times per week (maximal daily dose, 1 g), with peak blood levels of 20 to 40 μg/mL. After 2 to 4 months, the dosage should be reduced to 1 g two or three times a week. Cross-resistance to kanamycin and amikacin—but not to streptomycin—is common. After streptomycin, capreomycin is the injectable drug of choice for tuberculosis.

Rifabutin Rifabutin, a semisynthetic rifamycin spiropiperidyl derivative, shares many characteristics with rifampin, including its activity against *M. tuberculosis*. Rifabutin is also active against some strains of rifampin-resistant *M. tuberculosis* and is more active than rifampin against the *M. avium* complex and other NTM. To date, rifabutin has been most useful in the prophylaxis of disseminated MAI infection and in the treatment of drug-resistant tuberculosis. Because it seems to exhibit more antituberculous activity than rifampin in vitro and in animals, its possible clinical advantages over rifampin are being evaluated. In a multinational trial in which either rifampin (600 mg/d) or rifabutin (150 mg/d) was administered in combination with isoniazid plus a 2-month regimen of pyrazinamide and ethambutol, the two rifamycins were equally effective and well tolerated in the treatment of newly diagnosed pulmonary tuberculosis. Rifabutin is recommended in place of rifampin for the treatment of HIV-positive individuals who are also taking a protease inhibitor because its effect on these agents is less pronounced (Table 149-2).

MECHANISM OF ACTION In *Escherichia coli* and *Bacillus subtilis*, rifabutin inhibits DNA-dependent RNA polymerase in the same manner as rifampin. Its mode of action against mycobacteria is believed to be the same.

PHARMACOLOGY The pharmacology of rifabutin is dramatically different from that of rifampin. Rifabutin is readily absorbed after a single oral dose of 300 mg and reaches peak serum levels (0.35 μg/mL) in 2 to 4 h. This lipophilic drug distributes best to tissues: tissue levels are 5 to 10 times higher than plasma levels. CSF concentrations are 30 to 70% of plasma levels in HIV-infected patients who have meningitis. The drug's slow clearance via hepatic metabolism and renal excretion results in a mean serum half-life of 45 h, which is much longer than the 3- to 5-h half-life of rifampin. Clarithromycin (but not azithromycin) and fluconazole appear to block the hepatic metabolism of rifabutin, with consequent increases in serum levels. When rifabutin is administered orally with food, its rate of absorption is slowed but the extent of absorption is unchanged. Adjustment of dosage is usually unnecessary in elderly patients and in patients with reduced hepatic or renal function (Table 149-1).

ADVERSE EFFECTS The majority of rifabutin's adverse effects are dose related and occur most frequently in patients receiving >300 mg/d. Discontinuation of therapy because of adverse drug reactions is reported in 16% of patients receiving rifabutin as opposed to 8% of those receiving a placebo. The most common symptoms are gastrointestinal; other reactions include rash, headache, asthenia, chest pain, myalgia, and insomnia. Like those taking rifampin, most patients taking rifabutin have discolored (orange to tan) urine and other body fluids. Less common adverse reactions include fever, chills, a flulike syndrome, hepatitis, *Clostridium difficile*–associated diarrhea, a diffuse polymyalgia syndrome, and a yellow skin discoloration ("pseudojaundice"). After a rifabutin dose of 450 or 600 mg in combination with clarithromycin, anterior uveitis is reported in up to 40% of patients; also common at these high doses are hyperpigmentation and the polymyalgia/arthralgia syndrome. All of these conditions are reversible when treatment is discontinued. Laboratory abnormalities include neutropenia, leukopenia, thrombocytopenia, and increased levels of liver enzymes.

Rifabutin induces the hepatic cytochrome P450 enzymes but does so much less strongly than rifampin. Drugs whose metabolism is enhanced by rifabutin include anticoagulants, quinidine, oral contraceptives, sulfonylureas, analgesics, dapsone, narcotics, glucocorticoids, clarithromycin, zidovudine, protease inhibitors, nonnucleoside reverse transcriptase inhibitors, and cardiac glycosides.

RESISTANCE Resistance to rifabutin is attributable to the same mechanism as that to rifampin—i.e., mutations involving the *rpoB* gene. However, of the 14 mutant *rpoB* alleles that confer resistance to rifampin, only 9 confer high-level resistance to rifabutin, while the remaining 5 result in only small changes in rifabutin MICs, which remain at $\leq$0.5 μg/mL. The MIC of rifabutin for susceptible strains of *M. tuberculosis* is low (<0.06 μg/mL), and the drug is considered clinically active against partially resistant strains that are inhibited by plasma levels of $\leq$0.5 μg/mL. Thus rifabutin inhibits about one-quarter of rifampin-resistant strains of *M. tuberculosis*.

Amikacin This well-known aminoglycoside is bactericidal to extracellular organisms. Amikacin is active against *M. tuberculosis* and several of the nontuberculous species, including the rapidly growing mycobacteria, *M. kansasii*, *M. leprae*, and the *M. avium* complex. The usual adult dosage is 7 to 10 mg/kg intramuscularly or intravenously three to five times per week (generally no more than 500 to 750 mg/d). Resistance relates to a single A $\rightarrow$ G base-pair change at position 1408 in the 16S ribosomal RNA gene.

Ethionamide Like isoniazid and pyrazinamide, ethionamide is a derivative of isonicotinic acid. This agent is bacteriostatic against metabolizing *M. tuberculosis* and some NTM. It is most useful in the treatment of multidrug-resistant tuberculosis. However, its use is severely limited by its toxicity and frequent side effects, which include intense gastrointestinal intolerance (anorexia, vomiting, and dysgeusia), serious neurologic reactions, reversible hepatitis (5% of cases), hypersensitivity reactions, and hypothyroidism. Ethionamide is well

absorbed orally and is widely distributed throughout the body at sites including the CSF.

Para-Aminosalicylic Acid PAS as a calcium or sodium salt inhibits the growth of *M. tuberculosis* by impairing folate synthesis. It is rarely indicated for the treatment of tuberculosis because of its low level of antituberculous activity and its high level of gastrointestinal toxicity (manifesting as nausea, vomiting, and diarrhea). Enteric-coated PAS granules (4 g every 8 h) may be better tolerated than other formulations and produce higher therapeutic blood levels. PAS is well absorbed after oral administration but reaches only low concentrations in the CSF. The drug has a short half-life (1 h), and 80% of the dose is excreted in the urine.

Cycloserine Cycloserine (D-4-amino-3-isoxazolidinone) is produced by *Streptomyces orchidaceus* and is active against a broad spectrum of bacteria, including *M. tuberculosis*. Cycloserine is well absorbed after oral administration and is widely distributed throughout body fluids, including the CSF. Serious side effects limit the use of this drug and include psychosis (with suicide in some cases), seizures, peripheral neuropathy, headaches, somnolence, and allergic reactions. Cycloserine should not be given to patients with epilepsy, active alcohol abuse, severe renal insufficiency, or a history of depression or psychosis.

NEWER ANTITUBERCULOUS DRUGS A number of drugs are being evaluated for their antituberculous activity. This group includes rifapentine, the newer 8-methoxyfluoroquinolones gatifloxacin and moxifloxacin, clarithromycin, linezolid and other oxazolidinones, and rifamycins not yet approved by the FDA, such as KRM-1648 (benzoxazinorifamycin).

Rifapentine A semisynthetic cyclopentyl rifamycin antibiotic, rifapentine has received accelerated approval from the FDA for the treatment of tuberculosis. It is the first new drug approved for tuberculosis in the United States in 25 years. While similar to rifampin, rifapentine is lipophilic and longer acting—characteristics that enhance patient compliance; the drug can be administered at a dose of 600 mg once or twice weekly. It is active against *M. tuberculosis* but has undergone only minimal testing against NTM. Rifapentine has not yet been approved for the treatment of patients with HIV disease because rifapentine/rifampin monoresistance frequently develops in HIV-positive patients receiving isoniazid plus once-weekly rifapentine. Like rifampin, rifapentine is active against many nonmycobacterial organisms, including *Haemophilus influenzae*, *Bordetella pertussis*, *Bordetella parapertussis*, *Brucella* spp., *Legionella* spp., *Neisseria* spp., streptococci, and staphylococci.

In a randomized comparative study, 672 Chinese patients received isoniazid plus either rifapentine or rifampin. The isoniazid/rifapentine group had a higher relapse rate than the isoniazid/rifampin group (10% vs 5%). Nevertheless, this disadvantage was considered acceptable in light of the lower rate of adverse effects and the less frequent administration for isoniazid/rifapentine.

MECHANISM OF ACTION Rifapentine exerts its bactericidal effect by inhibiting DNA-dependent RNA polymerase in susceptible bacteria. The MICs of rifapentine for rifampin-susceptible strains of *M. tuberculosis* range from 0.03 to 0.12 μg/mL.

PHARMACOLOGY Food enhances the oral absorption of rifapentine, whereas antacids impair its absorption. After oral administration with food, this drug reaches peak serum concentrations in 5 to 6 h and achieves a steady state in 10 days. The half-life of rifapentine and its active metabolite 25-desacetyl rifapentine is ~13 h. The administered dose is excreted via the liver (70%). Oral clearance is more rapid in males than in females (2.51 vs 1.69 L/h), but the clinical significance of this difference is unknown.

ADVERSE EFFECTS Rifapentine demonstrates an adverse-event pattern similar to that of rifampin. Both drugs are frequently associated with hyperuricemia when administered with pyrazinamide and with elevated hepatocellular enzyme levels in 3 to 4% of patients when administered with other antituberculous agents. Liver enzyme levels should be monitored in patients receiving rifapentine who already have elevated liver enzyme concentrations or known liver disease. Like rifampin, rifapentine causes an orange-red discoloration of body fluids, including urine, saliva, and tears, and stains contact lenses.

Rifapentine induces the hepatic cytochrome P450 enzymes CYP3A4 and 2C8/9. Current induction studies suggest that its potential for drug-drug interaction may be less than that of rifampin but greater than that of rifabutin. Other drugs potentially affected by concomitant administration of rifapentine are listed in Table 149-2.

Rifapentine is in category C for use in pregnancy (Table 149-1) because of its teratogenesis in rats and rabbits. There are insufficient data concerning use of this drug in pregnant and breast-feeding patients.

RESISTANCE Strains of *M. tuberculosis* resistant to rifapentine, rifampin, and rifabutin all involve spontaneous point mutations in the *rpoB* gene. All strains resistant to rifampin are also resistant to rifapentine.

LEPROSY (HANSEN'S DISEASE)

Therapy for leprosy remains difficult, especially in developing countries. Obstacles include the long courses of drug therapy required, the high cost and low availability of most drugs, the frequency of adverse drug reactions, the difficulty of determining a treatment endpoint, and (given that *M. leprae* still cannot be grown in vitro) the difficulty of conducting susceptibility testing. While many drugs are active against *M. leprae*, efficacy in the treatment of leprosy has been established only for dapsone, rifampin, clofazimine, and ethionamide. Initiation of multidrug treatment has reduced the problem of acquired drug resistance seen previously with dapsone monotherapy.

Rifampin Rifampin is considered the most active agent for the treatment of leprosy. Its worldwide use is limited only by its cost. This drug is highly bactericidal against *M. leprae* and reduces the number of viable bacilli in patients' tissues faster than any other available agent. Rifampin must be combined with other antileprosy drugs to forestall resistance. For cost reasons, the drug dose of 600 mg is given once a month (supervised) outside the United States, but it is given daily in the United States. For details on pharmacology, adverse events, and resistance, see relevant sections under "Tuberculosis." Allergic interstitial nephritis is a rare but significant complication of rifampin use in Hansen's disease.

Dapsone Dapsone (4,4′-diaminodiphenylsulfone) inhibits bacterial folic acid synthesis. It is now considered the second most active drug (after rifampin) in the treatment of Hansen's disease because of its ready availability, low cost, and low toxicity and the susceptibility of untreated strains of *M. leprae* to low concentrations.

PHARMACOLOGY Dapsone is well absorbed orally and distributes well throughout the body. The usual daily dosage is 100 mg for adults and 0.9 to 1.4 mg/kg for children. Plasma concentrations peak within 1 to 3 h. The median elimination half-life is 22 h. Dapsone is cleared by acetylation in the liver, with genetic variation similar to that documented for the acetylation of isoniazid. The drug is 70% bound to plasma protein. Usual daily doses produce serum concentrations of 10 to 15 μg/mL, which far exceed the MIC for *M. leprae* (0.01 to 0.001 μg/mL).

ADVERSE EFFECTS Hemolysis and methemoglobinemia are common untoward reactions to dapsone. Patients should be screened for glucose-6-phosphate dehydrogenase deficiency to prevent serious drug-induced hemolysis. However, most patients tolerate dapsone therapy well with adequate clinical and laboratory supervision. Other side effects include gastrointestinal intolerance, headache, pruritus, peripheral neuropathies, nephrotic syndrome, fever, and rash. In lepromatous and borderline lepromatous leprosy, erythema nodosum leprosum (ENL) may occur. ENL and other reactions of leprosy may be difficult

to distinguish from drug reactions and the infectious mononucleosis–like syndrome due to dapsone.

Clofazimine A phenazine iminoquinone dye, clofazimine is weakly bactericidal against *M. leprae*. It is useful in treating dapsone-resistant leprosy and may lessen the severity of ENL. Clofazimine's mode of action is not well understood, but the drug may inhibit DNA binding. It is absorbed orally and distributed to the fatty tissues and the reticuloendothelial system. Its serum half-life is ~60 to 70 days; only a small proportion of the dose is excreted daily into the urine or bile. Bactericidal activity is very slow and is evident for ~50 days after administration. The usual adult dosage is 50 to 100 mg/d, 100 mg three times a week, or (for treatment of ENL) 300 mg/d. Untoward effects include skin discoloration and, less commonly, gastrointestinal intolerance. Clofazimine was reported to be responsible for a case of cardiotoxicity induced via ventricular arrhythmia. Even though clofazimine-resistant disease has been reported only rarely when this agent is used alone, it should be used with other effective antibiotics. Clofazimine is active in vitro against some NTM species, including MAI, *M. kansasii*, *M. simiae*, and *M. abscessus*.

Ethionamide While ethionamide (250 mg/d) has not been approved by the FDA for the treatment of leprosy, it is sometimes used in the United States in combination with rifampin (600 mg/d) to treat dapsone-resistant leprosy in patients who cannot accept the skin-pigmentation effect of clofazimine. Because resistance to ethionamide develops quickly when the drug is used alone, it must be used with other effective agents. Patients should be monitored closely for hepatotoxicity when taking ethionamide (especially in combination with rifampin), and treatment should be discontinued if the patient's ALT levels exceed 2.5 times the normal value. Prothionamide, a congener of ethionamide that is not available in the United States, has pharmacologic properties similar to those of ethionamide and is widely used throughout the world.

Other Agents A number of other drugs exhibit significant activity against *M. leprae*, but clinical experience with these agents is lacking. Thalidomide is now approved by the FDA for treatment of ENL. This drug is sedating and extremely teratogenic and should *never* be taken by anyone who is or may become pregnant. Physicians wishing to prescribe thalidomide must register with the System for Thalidomide Education and Prescription Safety (S.T.E.P.S) at 1-888-423-5436 (Celgene Corporation); the sole exceptions to this registration requirement are physicians at Hansen's disease clinics that are receiving medication support from the national Hansen's disease program. It is noteworthy that ENL may be a presenting feature of Hansen's disease *before* treatment. It is not considered an adverse drug reaction but may be confused with drug reactional states.

The newer macrolide antibiotics (particularly clarithromycin), minocycline (a long-acting tetracycline), and a number of fluoroquinolones (including ofloxacin, sparfloxacin, and pefloxacin) have shown promising bactericidal activity against *M. leprae*. Ofloxacin and minocycline are being investigated with rifampin in short-course regimens for lepromatous disease. All of these newer leprosy drugs have low toxicity profiles, modes of action different from those of the established agents, and bactericidal activity against *M. leprae*. However, their levels of bactericidal activity are lower than that of rifampin.

NONTUBERCULOUS MYCOBACTERIA

Although less pathogenic than *M. tuberculosis*, NTM can cause pulmonary, skin, bone, joint, lymph node, and soft tissue infection as well as disseminated disease in immunocompromised hosts, including patients with AIDS. MAI and *M. kansasii* are the two most common causes of NTM pulmonary infection. Up to 40% of AIDS patients with CD4+ cell counts of $<50/\mu L$ develop disseminated disease due to *M. avium* unless they are receiving specific *M. avium* prophylaxis.

Clarithromycin Clarithromycin (6-*O*-methylerythromycin) is a newer macrolide that is similar to erythromycin in its mechanism of action. It is well absorbed with or without meals and elicits little gastrointestinal intolerance at low doses. Clarithromycin distributes well into body tissues and fluids and is highly concentrated in macrophages. The drug is metabolized in the liver, with ~30% of a given dose excreted in the urine. The dosage should be reduced if the creatinine clearance rate is ≤30 mL/min. Like erythromycin, clarithromycin binds with plasma proteins (65 to 70%) and can raise the levels of drugs such as theophylline and carbamazepine. Serum levels of clarithromycin are reduced by rifampin and, to a lesser degree, by rifabutin; clarithromycin increases serum levels of rifabutin and some antihistamines (e.g., terfenadine), thus potentially increasing their toxicity. Clarithromycin and (probably) azithromycin are the most active agents for the treatment of MAI infections; one of these drugs is considered an essential component of any regimen for this purpose. However, because of the risk of mutational drug resistance, clarithromycin should be given in combination with other agents, such as ethambutol and rifampin or rifabutin. The drug is also highly active against almost all other NTM, including *M. marinum*, *M. kansasii*, *M. haemophilum*, *M. genavense*, *M. xenopi*, *M. abscessus*, *M. chelonae*, and most isolates of *M. fortuitum*. Standard antimycobacterial doses have been 500 mg twice daily or, in the case of MAI pulmonary disease, three times weekly. The more common side effects of high doses include nausea, vomiting, and (occasionally) abnormal liver function tests. A bitter taste is common even with routine doses. Most gastrointestinal side effects can be minimized by reducing the dose. Clarithromycin is teratogenic in laboratory animals and is in category C for use in pregnancy (Table 149-1). Resistance results from point mutations involving adenine at positions 2058 or 2059 in the 23S ribosomal RNA gene macrolide binding site. Mutational resistance occurs in 1 in 10^8 to 10^9 organisms and develops with monotherapy, especially for all slowly growing species and the rapid growers *M. chelonae* and *M. abscessus*, which have only a single copy of the ribosomal genes.

Azithromycin Azithromycin is a macrolide that belongs to the family of azalides. This drug reaches much lower serum levels than clarithromycin (usually ≤0.5 μg/mL), but its high tissue and macrophage concentrations and longer half-life suggest the feasibility of intermittent therapy. Azithromycin is involved in few drug interactions since it does not affect the cytochrome P450 system. The usual doses are 250 to 500 mg three times weekly (MAI therapy) or 1200 mg once a week (prophylaxis for disseminated *M. avium*). No alteration in dose is required in renal failure. The most common side effects are gastrointestinal symptoms and reversible hearing loss. Azithromycin appears to be less active than clarithromycin for both pulmonary and disseminated MAI disease. Resistance to azithromycin develops by the same mechanism as that to clarithromycin, with cross-resistance between the two macrolides.

Therapy for Specific NTM Infections ■ *MAI* Therapy for MAI lung disease in the adult usually involves the administration of clarithromycin (500 mg morning and night), ethambutol (25 mg/kg), and rifampin (600 mg) on a Monday-Wednesday-Friday schedule. Therapy is generally continued until cultures have been negative for 12 months.

For disseminated disease in AIDS, daily administration of one of the newer macrolides (clarithromycin or azithromycin) and ethambutol (15 mg/kg) is considered an essential component of any treatment regimen, with rifabutin (300 mg) a commonly used third drug. Other alternative drugs include streptomycin and amikacin. Clofazimine appears to increase mortality and should be avoided. For prophylaxis of disseminated MAI disease, rifabutin (300 mg/d), clarithromycin (500 mg twice daily), and azithromycin (1200 mg once weekly) have all been demonstrated to be effective in controlled or comparative clinical trials. Once-weekly azithromycin is the drug most often used.

MYCOBACTERIUM KANSASII *M. kansasii* is usually susceptible to most antituberculous drugs except for pyrazinamide. Current ATS recommendations for the treatment of *M. kansasii* pulmonary disease are 18 to 24 months of daily isoniazid (300 mg), rifampin (600 mg), and etham-

butol (15 mg/kg). In patients taking protease inhibitors, rifabutin (150 mg/d) or clarithromycin (500 mg twice daily) should be substituted for rifampin. The potential advantages of the highly active rifabutin and the newer macrolides in immunocompetent patients have not been studied.

RAPIDLY GROWING MYCOBACTERIA The *M. fortuitum* group, *M. abscessus*, and *M. chelonae* account for more than 80% of cases of clinical disease due to rapidly growing mycobacteria. These organisms are resistant to antituberculous agents other than amikacin but are variably susceptible to several traditional antibiotics Clarithromycin has dramatically changed the approach to therapy for infection with these organisms, as it inhibits all rapidly growing mycobacteria (except for 20% of *M. fortuitum* strains and most *M. smegmatis* strains) at concentrations of $\leq$4 μg/mL. Other drugs with good activity include amikacin (which inhibits 80 to 100% of strains), cefoxitin (80% of *M. abscessus* and *M. fortuitum* strains), doxycycline (50% of *M. fortuitum* strains), imipenem (100% of *M. fortuitum* strains, 70% of *M. chelonae* strains, and 70% of *M. abscessus* strains), the fluorinated quinolones (100% of *M. fortuitum* strains), sulfonamides (90% of *M. fortuitum* strains), and linezolid (>90% of isolates of *M. chelonae* and *M. fortuitum*).

MYCOBACTERIUM MARINUM *M. marinum*, a cause of posttraumatic localized skin infection, is typically susceptible to minocycline, rifampin, ethambutol, clarithromycin, and trimethoprim-sulfamethoxazole and is resistant to isoniazid.

MYCOBACTERIUM HAEMOPHILUM Infection due to *M. haemophilum* occurs most commonly as disseminated cutaneous disease in immunocompromised patients with or without AIDS. Isolates typically show in vitro resistance to most drugs but may be susceptible to rifampin, rifabutin, quinolones, and clarithromycin.

MYCOBACTERIUM XENOPI In the United States, *M. xenopi* is best known as a cause of nosocomial pseudoinfections associated with contamination of the hospital's hot-water system. Drug therapy for *M. xenopi* infection is difficult. *M. xenopi* is often resistant to first-line antituberculous agents but susceptible to the newer macrolides, quinolones, streptomycin, and ethionamide. Patients usually respond to multidrug regimens that include clarithromycin, but relapses are common.

MYCOBACTERIUM GENAVENSE *M. genavense* is a fastidious organism that grows only in liquid media, such as BACTEC 12B or 13A, after prolonged incubation. This organism almost exclusively infects AIDS patients, causing disseminated disease and being isolated from blood, bone marrow, liver, lymph node, spleen, and intestinal cultures. The in vitro susceptibility profile of *M. genavense* has not been well established. Some isolates are susceptible to amikacin, clarithromycin, ofloxacin, rifampin, and rifabutin. Isolates generally respond to macrolide-containing regimens similar to those used for disseminated *M. avium* infection.

MYCOBACTERIUM SIMIAE *M. simiae* is a cause of chronic lung disease, especially in Texas and other southwestern states. It is highly drug resistant, and no satisfactory treatment regimen has yet been established.

150 TUBERCULOSIS

Mario C. Raviglione, Richard J. O'Brien

DEFINITION Tuberculosis, one of the oldest diseases known to affect humans, is caused by bacteria belonging to the *Mycobacterium tuberculosis* complex. The disease usually affects the lungs, although in up to one-third of cases other organs are involved. If properly treated, tuberculosis caused by drug-susceptible strains is curable in virtually all cases. If untreated, the disease may be fatal within 5 years in more than half of cases. Transmission usually takes place through the airborne spread of droplet nuclei produced by patients with infectious pulmonary tuberculosis.

ETIOLOGIC AGENT Mycobacteria belong to the family Mycobacteriaceae and the order Actinomycetales. Of the pathogenic species belonging to the *M. tuberculosis* complex, the most frequent and important agent of human disease is *M. tuberculosis*. The complex includes *M. bovis* (the bovine tubercle bacillus, once an important cause of tuberculosis transmitted by unpasteurized milk and currently the cause of a small percentage of cases in developing countries), *M. africanum* (isolated from cases in West, Central, and East Africa), *M. microti* (the "vole" bacillus, a less virulent and rarely encountered organism), and *M. canettii* (a very rare isolate in African cases).

M. tuberculosis is a rod-shaped, non-spore-forming, thin aerobic bacterium measuring 0.5 μm by 3 μm. Mycobacteria, including *M. tuberculosis*, are often neutral on Gram's staining. However, once stained, the bacilli cannot be decolorized by acid alcohol, a characteristic justifying their classification as acid-fast bacilli (AFB; Fig. 150-1). Acid fastness is due mainly to the organisms' high content of mycolic acids, long-chain cross-linked fatty acids, and other cell-wall lipids. Microorganisms other than mycobacteria that display some acid fastness include species of *Nocardia* and *Rhodococcus*, *Legionella micdadei*, and the protozoa *Isospora* and *Cryptosporidium*. In the mycobacterial cell wall, lipids (e.g., mycolic acids) are linked to underlying arabinogalactan and peptidoglycan. This structure confers very low permeability of the cell wall, thus reducing effectiveness of most antibiotics. Another molecule in the mycobacterial cell wall, lipoarabinomannan, is involved in the pathogen-host interaction and facilitates the survival of *M. tuberculosis* within macrophages. The several proteins characteristic of *M. tuberculosis* include those in purified protein derivative (PPD) tuberculin, a precipitate of non-species-specific molecules obtained from filtrates of heat-sterilized, concentrated broth cultures. The complete genome sequence of *M. tuberculosis* comprises ~4000 genes and has a high guanine-plus-cytosine content. A large proportion of genes are devoted to the production of enzymes involved in cell wall metabolism.

EPIDEMIOLOGY More than 3.8 million new cases of tuberculosis—all forms (pulmonary and extrapulmonary), 90% of them from developing countries—were reported to the World Health Organization (WHO) in 2001. However, because of a low level of case detection and incomplete notifications, reported cases represent only a fraction of the total. It is estimated that 8.5 million new cases of tuberculosis occurred worldwide in 2001, 95% of them in developing countries of Asia (5 million), Africa (2 million), the Middle East (0.6 million), and Latin

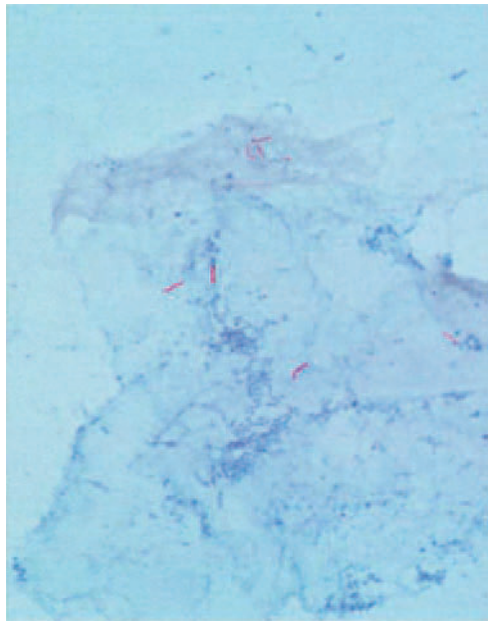

FIGURE 150-1 Acid-fast bacillus (AFB) smear showing *M. tuberculosis* bacilli. (*Courtesy of the CDC, Atlanta.*)

America (0.4 million). It is also estimated that 1.8 million deaths from tuberculosis occurred in 2000, 98% of them in developing countries. Estimates of tuberculosis incidence rates (per 100,000 population) and numbers of tuberculosis-related deaths in 2001 are depicted in Fig. 150-2 and Fig. 150-3, respectively.

After an increase in the late 1980s, numbers of cases have declined during the past few years in several industrialized countries, including the United States. The increases in the 1980s were largely related to immigration from countries with a high prevalence of tuberculosis; infection with HIV; social problems, such as poverty, homelessness, and drug abuse; and dismantling of tuberculosis services. In the United States, with the implementation of stronger control programs, the decrease resumed in 1993. In 2002, 15,075 cases of tuberculosis (5.2 cases per 100,000 population) were reported to the U.S. Centers for Disease Control and Prevention (CDC)—a 43% decrease from the 1992 peak.

In the United States, tuberculosis is uncommon among young adults of European descent, who have only rarely been exposed to *M. tuberculosis* infection during recent decades. In contrast, because of a high risk in the past, the prevalence of *M. tuberculosis* infection is relatively high among elderly Caucasians, who remain at increased risk of developing active tuberculosis. Tuberculosis in the United States is also a disease of young adult members of the HIV-infected, immigrant, and disadvantaged/marginalized populations. Similarly, in Europe, tuberculosis has reemerged as an important public health problem, mainly as a result of cases among immigrants from high-prevalence countries.

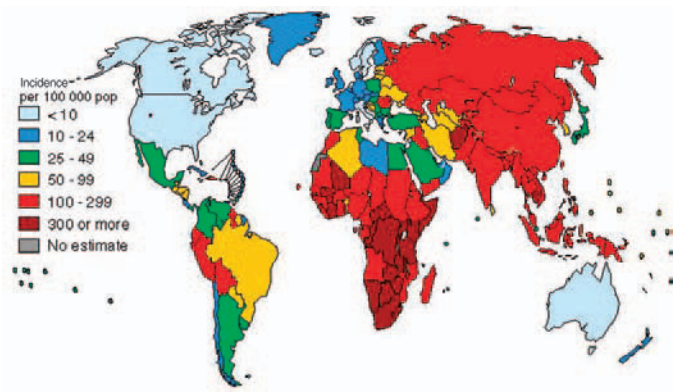

FIGURE 150-2 Map of the world showing the estimated tuberculosis incidence rates (per 100,000 population) in 2001. The designations employed and the presentation of material on this map do not imply the expression of any opinion whatsoever on the part of the WHO concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. White lines on maps represent approximate border lines for which there may not yet be full agreement. (*Courtesy of the Stop TB Department, WHO.*)

Recent tuberculosis trends in developing countries indicate a stable situation, with almost no decline. There are two exceptions. First, in sub-Saharan Africa, the spread of the HIV epidemic has resulted in doubling or tripling of the number of reported cases of tuberculosis during the past 15 years. Second, in countries of the former Soviet Union and in Romania, numbers of cases have increased by two- or threefold in the past 10 years, largely as the result of deterioration in socioeconomic conditions and the health care infrastructure.

From Exposure to Infection *M. tuberculosis* is most commonly transmitted from a patient with infectious pulmonary tuberculosis to other persons by droplet nuclei, which are aerosolized by coughing, sneezing, or speaking. The tiny droplets dry rapidly; the smallest (<10 μm in diameter) may remain suspended in the air for several hours and may gain direct access to the terminal air passages when inhaled. There may be as many as 3000 infectious nuclei per cough. Other routes of transmission of tubercle bacilli, such as through the skin or the placenta, are uncommon and of no epidemiologic significance.

The probability of contact with a case of tuberculosis, the intimacy and duration of that contact, the degree of infectiousness of the case, and the shared environment of the contact are all important determinants of transmission. Several studies of close contacts have clearly demonstrated that tuberculosis patients whose sputum contains AFB visible by microscopy play the greatest role in the spread of infection. These patients often have cavitary pulmonary disease or tuberculosis of the respiratory tract (endobronchial or laryngeal tuberculosis) and

produce sputa containing as many as 10^5 AFB/mL. Patients with sputum smear–negative/culture-positive tuberculosis are less infectious, and those with culture-negative pulmonary disease and extrapulmonary tuberculosis are essentially noninfectious. The frequent absence of cavities among HIV-infected patients may reduce their infectiousness. Crowding in poorly ventilated rooms is one of the most important factors in the transmission of tubercle bacilli, since it increases the intensity of contact with a case.

In short, the risk of acquiring *M. tuberculosis* infection is determined mainly by exogenous factors. Because of delays in seeking care and in diagnosis, it is estimated that up to 20 contacts may be infected by each AFB-positive case before detection in high-prevalence settings.

From Infection to Disease Unlike the risk of acquiring infection with *M. tuberculosis*, the risk of developing disease after being infected depends largely on endogenous factors, such as the individual's innate susceptibility to disease and level of function of cell-mediated immunity. Clinical illness directly following infection is classified as *primary tuberculosis* and is common among children up to 4 years of age. Although this form may be severe and disseminated, it is usually not transmissible. When infection is acquired later in life, the chance is greater that the immune system will contain it, at least temporarily. The majority of infected individuals who ultimately develop tuberculosis do so within the first year or two after infection. Dormant bacilli, however, may persist for years before reactivating to produce *secondary* (or *postprimary*) *tuberculosis*, which is often infectious. Overall, it is estimated that ~10% of persons infected in their youth will eventually develop active tuberculosis. This risk, however, is greatly increased among HIV-infected persons. Reinfection of a previously infected individual, which is common in areas with high rates of tuberculosis transmission, may also favor the development of disease. Molecular typing and comparison of strains of *M. tuberculosis* have suggested that up to one-third of cases of active tuberculosis in U.S. inner-city communities are due to recent transmission rather than to reactivation of latent infection.

Age is an important determinant of the risk of disease after infection. Among infected persons, the incidence of tuberculosis is highest during late adolescence and early adulthood; the reasons are unclear. The incidence among women peaks at 25 to 34 years of age. In this age group rates among women are usually higher than those among men, while at older ages the opposite is true. The risk may increase in the elderly, possibly because of waning immunity and comorbidity.

A variety of diseases and conditions favor the development of active tuberculosis (Table 150-1). The most potent risk factor for tuberculosis among infected individuals is clearly HIV co-infection, which suppresses cellular immunity. The risk that latent *M. tuberculosis* infection will proceed to active disease is directly related to the patient's degree of immunosuppression. In a study of HIV-infected, PPD-positive persons, this risk varied from 2.6 to 13.3 cases per 100 person-years and depended upon the CD4+ cell count.

TABLE 150-1 *Risk Factors for Active Tuberculosis among Persons Who Have Been Infected with Tubercle Bacilli*

Factor	Relative Risk/Odds[a]
Recent infection (<1 year)	12.9
Fibrotic lesions (spontaneously healed)	2–20
Comorbidity	
HIV infection	100
Silicosis	30
Chronic renal failure/hemodialysis	10–25
Diabetes	2–4
Intravenous drug use	10–30
Immunosuppressive treatment	10
Gastrectomy	2–5
Jejunoileal bypass	30–60
Posttransplantation period (renal, cardiac)	20–70
Malnutrition and severe underweight	2

[a] Old infection = 1.

NATURAL HISTORY OF DISEASE Studies conducted in various countries before the advent of chemotherapy showed that untreated tuberculosis is often fatal. About one-third of patients died within 1 year after diagnosis, and one-half died within 5 years. Five-year mortality among sputum smear–positive cases was 65%. Of the survivors at 5 years, ~60% had undergone spontaneous remission, while the remainder were still excreting tubercle bacilli.

With effective, timely, and proper chemotherapy, patients have a very high chance of being cured. However, improper use of antituberculosis drugs, while reducing mortality, may also result in large numbers of chronic infectious cases, often with drug-resistant bacilli.

PATHOGENESIS AND IMMUNITY The interaction of *M. tuberculosis* with the human host begins when droplet nuclei containing microorganisms from infectious patients are inhaled. While the majority of inhaled bacilli are trapped in the upper airways and expelled by ciliated mucosal cells, a fraction (usually <10%) reach the alveoli. There, nonspecifically activated alveolar macrophages ingest the bacilli. Invasion of macrophages by mycobacteria may result in part from association of C2a with the bacterial cell wall followed by C3b opsonization of the bacteria and recognition by the macrophages. The balance between the bactericidal activity of the macrophage and the number and virulence of the bacilli (with virulence partially linked to the bacterium's lipid-rich cell wall and to its glycolipid capsule, both of which confer resistance to complement and free radicals of the phagocyte) determines the events following phagocytosis.

Several genes thought to confer virulence to *M. tuberculosis* have been identified; *katG* encodes for catalase, an enzyme protective against oxidative stress; *rpoV* is the main sigma factor initiating transcription of several genes. Defects in these two genes result in loss of virulence. The *erp* gene, encoding a protein required for multiplication, also contributes to virulence. Outbreaks of tuberculosis in Tennessee and Kentucky in 1994 through 1996 exemplify how infection with virulent strains can result in enhanced transmission with high rates of disease. Strains of the Beijing/W genotype family have been identified in outbreak conditions in a variety of settings worldwide and have been associated with high mortality and drug resistance.

Several observations suggest that genetic factors play a key role in innate nonimmune resistance to infection with *M. tuberculosis*. The existence of this resistance is suggested by the differing degrees of susceptibility to tuberculosis in different populations. In mice, a gene called *Nramp1* (natural resistance–associated macrophage protein 1) has a regulatory role in resistance/susceptibility to mycobacteria. The human homologue NRAMP1, cloned to chromosome 2q, may have a role in determining susceptibility to tuberculosis, as is suggested by a study among West Africans.

In the initial stage of host-bacterium interaction, either the host's macrophages contain bacillary multiplication by producing proteolytic enzymes and cytokines or the bacilli begin to multiply. If the bacilli multiply, their growth quickly kills the macrophages, which lyse. Nonactivated monocytes attracted from the bloodstream to the site by various chemotactic factors ingest the bacilli released from the lysed macrophages. These initial stages of infection are usually asymptomatic.

About 2 to 4 weeks after infection, two additional host responses to *M. tuberculosis* develop: a tissue-damaging response and a macrophage-activating response. The *tissue-damaging response* is the result of a delayed-type hypersensitivity (DTH) reaction to various bacillary antigens; it destroys nonactivated macrophages that contain multiplying bacilli. The *macrophage-activating response* is a cell-mediated phenomenon resulting in the activation of macrophages that are capable of killing and digesting tubercle bacilli. Although both of these responses can inhibit mycobacterial growth, it is the balance between the two that determines the form of tuberculosis that will develop subsequently.

With the development of specific immunity and the accumulation

of large numbers of activated macrophages at the site of the primary lesion, granulomatous lesions (tubercles) are formed. These lesions consist of lymphocytes and activated macrophages, such as epithelioid cells and giant cells. Initially, the newly developed tissue-damaging response is the only event capable of limiting mycobacterial growth within macrophages. This response, mediated by various bacterial products, not only destroys macrophages but also produces early solid necrosis in the center of the tubercle. Although *M. tuberculosis* can survive, its growth is inhibited within this necrotic environment by low oxygen tension and low pH. At this point, some lesions may heal by fibrosis and calcification, while others undergo further evolution.

Cell-mediated immunity is critical at this early stage. In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate T lymphocytes to release a variety of lymphokines. These activated cells aggregate around the lesion's center and effectively neutralize tubercle bacilli without causing further tissue destruction. In the central part of the lesion, the necrotic material resembles soft cheese (*caseous necrosis*)—a phenomenon that may also be observed in other conditions, such as neoplasms. Even when healing takes place, viable bacilli may remain dormant within macrophages or in the necrotic material for years or even throughout the patient's lifetime. These "healed" lesions in the lung parenchyma and hilar lymph nodes may later undergo calcification.

In a minority of cases, the macrophage-activating response is weak, and mycobacterial growth can be inhibited only by intensified DTH reactions, which lead to tissue destruction. The lesion tends to enlarge further, and the surrounding tissue is progressively damaged. At the center of the lesion, the caseous material liquefies. Bronchial walls as well as blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing large numbers of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply well and spread into the airways and the environment through expectorated sputum.

In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they disseminate widely to many organs and tissues. The resulting lesions may undergo the same evolution as those in the lungs, although most tend to heal. In young children with poor natural immunity, hematogenous dissemination may result in fatal miliary tuberculosis or tuberculous meningitis.

Cell-mediated immunity confers partial protection against *M. tuberculosis*, while humoral immunity has no defined role in protection. Two types of cells are essential: macrophages, which directly phagocytize tubercle bacilli, and T cells (mainly CD4+ lymphocytes), which induce protection through the production of lymphokines, especially interferon γ (IFN-γ).

After infection with *M. tuberculosis*, alveolar macrophages secrete a number of cytokines: interleukin (IL) 1 contributes to fever; IL-6 contributes to hyperglobulinemia; and tumor necrosis factor α (TNF-α) contributes to the killing of mycobacteria, the formation of granulomas, and a number of systemic effects, such as fever and weight loss. Macrophages are also critical in processing and presenting antigens to T lymphocytes; the result is a proliferation of CD4+ lymphocytes, which are crucial to the host's defense against *M. tuberculosis*. Qualitative and quantitative defects of CD4+ T cells explain the inability of HIV-infected individuals to contain mycobacterial proliferation. Reactive CD4+ lymphocytes produce cytokines of the T_H1 pattern and participate in MHC class II–restricted killing of cells infected with *M. tuberculosis*. T_H1 CD4+ cells produce IFN-γ and IL-2 and promote cell-mediated immunity. T_H2 cells produce IL-4, IL-5, and IL-10 and promote humoral immunity. The interplay of these various cytokines and their cross-regulation determine the host's response. The role of cytokines in promoting intracellular killing of mycobacteria has not been entirely elucidated. IFN-γ may induce release of nitric oxide, and TNF-α also seems to be important. Observations in transgenic knockout mice suggest that other T cell subsets (especially CD8+ cells) restricted by alternative antigen-presenting molecules containing a β_2-microglobulin subunit may play an important role. Lipids have been involved in mycobacterial recognition by the innate immune system, and lipoproteins have been proven to trigger potent signals through Toll-like receptors. Finally, a recently described subset of T cells capable of recognizing lipid elements of the bacillus presented by CD1 molecules may be implicated in protection.

M. tuberculosis possesses various protein antigens. Some are present in the cytoplasm and cell wall; others are secreted. That the latter are more important in eliciting a T lymphocyte response is suggested by experiments documenting the appearance of protective immunity in animals after immunization with live, protein-secreting mycobacteria. Among the antigens with a potential protective role are the 30-kDa (or 85B) and the ESAT-6 antigens. Protective immunity is probably the result of reactivity to a large number of different mycobacterial antigens.

Coincident with the appearance of immunity, DTH to *M. tuberculosis* develops. This reactivity is the basis of the PPD skin test, which is used primarily for the detection of *M. tuberculosis* infection in persons without symptoms. The cellular mechanisms responsible for PPD reactivity are related mainly to previously sensitized CD4+ lymphocytes, which are attracted to the skin-test site. There, they proliferate and produce cytokines.

While DTH is associated with protective immunity (PPD-positive persons being less susceptible to a new *M. tuberculosis* infection than PPD-negative persons), it by no means guarantees protection against reactivation. In fact, severe cases of active tuberculosis are often accompanied by strongly positive skin-test reactions.

CLINICAL MANIFESTATIONS Tuberculosis is classified as pulmonary or extrapulmonary. Before the recognition of HIV infection, >80% of all cases of tuberculosis were limited to the lungs. However, up to two-thirds of HIV-infected patients with tuberculosis may have both pulmonary and extrapulmonary disease or extrapulmonary disease alone.

Pulmonary Tuberculosis Pulmonary tuberculosis can be categorized as primary or postprimary (secondary).

PRIMARY DISEASE Primary pulmonary tuberculosis results from an initial infection with tubercle bacilli. In areas of high tuberculosis prevalence, this form of disease is often seen in children and is frequently localized to the middle and lower lung zones. The lesion forming after infection is usually peripheral and accompanied by hilar or paratracheal lymphadenopathy, which may not be detectable on chest radiography. In the majority of cases, the lesion heals spontaneously and may later be evident as a small calcified nodule (*Ghon lesion*).

In children and in persons with impaired immunity (e.g., those with malnutrition or HIV infection), primary pulmonary tuberculosis may progress rapidly to clinical illness. The initial lesion increases in size and can evolve in different ways. Pleural effusion, a frequent finding, results from the penetration of bacilli into the pleural space from an adjacent subpleural focus. In severe cases, the primary site rapidly enlarges, its central portion undergoes necrosis, and acute cavitation develops (progressive primary tuberculosis). Tuberculosis in young children is almost invariably accompanied by hilar or mediastinal lymphadenopathy due to the spread of bacilli from the lung parenchyma through lymphatic vessels. Enlarged lymph nodes may compress bronchi, causing obstruction and subsequent segmental or lobar collapse. Partial obstruction may cause obstructive emphysema, and bronchiectasis may also develop. Hematogenous dissemination, which is common and is often asymptomatic, may result in the most severe manifestations of primary *M. tuberculosis* infection. Bacilli reach the bloodstream from the pulmonary lesion or the lymph nodes and disseminate into various organs, where they may produce granulomatous lesions. Although healing frequently takes place, immunocompromised persons (e.g., patients with HIV infection) may develop miliary tuberculosis and/or tuberculous meningitis.

POSTPRIMARY DISEASE Also called adult-type, reactivation, or secondary tuberculosis, postprimary disease results from endogenous reactivation of latent infection and is usually localized to the apical and posterior segments of the upper lobes, where the high oxygen concentration favors mycobacterial growth. In addition, the superior segments of the lower lobes are frequently involved. The extent of lung parenchymal involvement varies greatly, from small infiltrates to extensive cavitary disease. With cavity formation, liquefied necrotic contents are ultimately discharged into the airways, resulting in satellite lesions within the lungs that may in turn undergo cavitation (Fig. 150-4). Massive involvement of pulmonary segments or lobes, with coalescence of lesions, produces tuberculous pneumonia. While up to one-third of untreated patients reportedly succumb to severe pulmonary tuberculosis within a few weeks or months after onset, others undergo a process of spontaneous remission or proceed along a chronic, progressively debilitating course ("consumption"). Under these circumstances, some pulmonary lesions become fibrotic and may later calcify, but cavities persist in other parts of the lungs. Individuals with such chronic disease continue to discharge tubercle bacilli into the environment. Most patients respond to treatment, with defervescence, decreasing cough, weight gain, and a general improvement in well-being within several weeks.

Early in the course of disease, symptoms and signs are often nonspecific and insidious, consisting mainly of fever and night sweats, weight loss, anorexia, general malaise, and weakness. However, in the majority of cases, cough eventually develops—often initially nonproductive and subsequently accompanied by the production of purulent sputum. Blood streaking of the sputum is frequently documented. Massive hemoptysis may ensue as a consequence of the erosion of a fully patent vessel located in the wall of a cavity. Hemoptysis, however, may also result from rupture of a dilated vessel in a cavity (*Rasmussen's aneurysm*) or from aspergilloma formation in an old cavity. Pleuritic chest pain sometimes develops in patients with subpleural parenchymal lesions but can also result from muscle strain due to persistent coughing. Extensive disease may produce dyspnea and (occasionally) adult respiratory distress syndrome (ARDS).

Physical findings are of limited use in pulmonary tuberculosis. Many patients have no abnormalities detectable by chest examination, while others have detectable rales in the involved areas during inspiration, especially after coughing. Occasionally, rhonchi due to partial bronchial obstruction and classic amphoric breath sounds in areas with large cavities may be heard. Systemic features include fever (often low-grade and intermittent) and wasting. In some cases, pallor and finger clubbing develop. The most common hematologic findings are mild anemia and leukocytosis. Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has also been reported.

FIGURE 150-4 Chest radiograph showing bilateral upper-lobe infiltrates and cavities in a patient with active tuberculosis. (*Courtesy of L. Richeldi, G. Ferrera, and L. M. Fabbri, University of Modena and Reggio Emilia, Italy.*)

Extrapulmonary Tuberculosis In order of frequency, the extrapulmonary sites most commonly involved in tuberculosis are the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, peritoneum, and pericardium. However, virtually all organ systems may be affected. As a result of hematogenous dissemination in HIV-infected individuals, extrapulmonary tuberculosis is seen more commonly today than in the past.

LYMPH-NODE TUBERCULOSIS (TUBERCULOUS LYMPHADENITIS) The most common presentation of extrapulmonary tuberculosis (documented in >25% of cases), lymph-node disease is particularly frequent among HIV-infected patients. In the United States, children and women (particularly non-Caucasians) also seem to be especially susceptible. Once caused mainly by *M. bovis*, tuberculous lymphadenitis is today due largely to *M. tuberculosis*. Lymph-node tuberculosis presents as painless swelling of the lymph nodes, most commonly at cervical and supraclavicular sites (a condition often referred to as *scrofula*). Lymph nodes are usually discrete in early disease but may be inflamed and have a fistulous tract draining caseous material. Systemic symptoms are usually limited to HIV-infected patients, and concomitant lung disease may or may not be present. The diagnosis is established by fine-needle aspiration or surgical biopsy. AFB are seen in up to 50% of cases, cultures are positive in 70 to 80%, and histologic examination shows granulomatous lesions. Among HIV-infected patients, granulomas are usually not seen. Differential diagnosis includes a variety of infectious conditions as well as neoplastic diseases such as lymphomas or metastatic carcinomas.

PLEURAL TUBERCULOSIS Involvement of the pleura is common in primary tuberculosis and results from penetration by tubercle bacilli into the pleural space. Depending on the extent of reactivity, the effusion may be small, remain unnoticed, and resolve spontaneously or may be sufficiently large to cause symptoms such as fever, pleuritic chest pain, and dyspnea. Physical findings are those of pleural effusion: dullness to percussion and absence of breath sounds. A chest radiograph reveals the effusion and, in no more than one-third of cases, also shows a parenchymal lesion. Thoracentesis is required to ascertain the nature of the effusion. The fluid is straw colored and at times hemorrhagic; it is an exudate with a protein concentration >50% of that in serum, a normal to low glucose concentration, a pH that is generally <7.2, and detectable white blood cells (usually 500 to 2500/μL). Neutrophils may predominate in the early stage, while mononuclear cells are the typical finding later. Mesothelial cells are generally rare or absent. AFB are very rarely seen on direct smear, but cultures may be positive for *M. tuberculosis* in up to one-third of cases. Needle biopsy of the pleura is often required for diagnosis and reveals granulomas and/or yields a positive culture in up to 70% of cases. This form of pleural tuberculosis responds well to chemotherapy and may resolve spontaneously. The usefulness of glucocorticoids is debatable.

Tuberculous empyema is a less common complication of pulmonary tuberculosis. It is usually the result of the rupture of a cavity, with delivery of a large number of organisms into the pleural space, or of a bronchopleural fistula from a pulmonary lesion. A chest radiograph may show pyopneumothorax with an air-fluid level. The effusion is purulent and thick and contains large numbers of lymphocytes. An acid-fast smear of pleural fluid is often found to be positive when examined by microscopy, as is culture of the pleural fluid. Surgical drainage is usually required as an adjunct to chemotherapy. Tuberculous empyema may result in severe pleural fibrosis and restrictive lung disease.

TUBERCULOSIS OF THE UPPER AIRWAYS Nearly always a complication of advanced cavitary pulmonary tuberculosis, tuberculosis of the upper airways may involve the larynx, pharynx, and epiglottis. Symptoms include hoarseness and dysphagia in addition to chronic productive cough. Findings depend on the site of involvement, and ulcerations may be seen on laryngoscopy. Acid-fast smear of the sputum is often positive, but biopsy may be necessary in some cases to establish the diagnosis. Cancer may have similar features but is usually painless.

GENITOURINARY TUBERCULOSIS Genitourinary tuberculosis accounts for ~15% of all extrapulmonary cases, may involve any portion of the genitourinary tract, and is usually due to hematogenous seeding following primary infection. Local symptoms predominate. Urinary frequency, dysuria, hematuria, and flank pain are common presentations. However, patients may be asymptomatic and the disease discovered only after severe destructive lesions of the kidneys have developed. Urinalysis gives abnormal results in 90% of cases, revealing pyuria and hematuria. The documentation of culture-negative pyuria in acidic urine raises the suspicion of tuberculosis. An intravenous pyelogram helps in diagnosis. Calcifications and ureteral strictures are suggestive findings. Culture of three morning urine specimens yields a definitive diagnosis in nearly 90% of cases. Severe ureteral strictures may lead to hydronephrosis and renal damage.

Genital tuberculosis is diagnosed more commonly in female than in male patients. In female patients, it affects the fallopian tubes and the endometrium and may cause infertility, pelvic pain, and menstrual abnormalities. Diagnosis requires biopsy or culture of specimens obtained by dilatation and curettage. In male patients, tuberculosis preferentially affects the epididymis, producing a slightly tender mass that may drain externally through a fistulous tract; orchitis and prostatitis may also develop. In almost half of cases of genitourinary tuberculosis, urinary tract disease is also present. Genitourinary tuberculosis responds well to chemotherapy.

SKELETAL TUBERCULOSIS In the United States, tuberculosis of the bones and joints is responsible for ~10% of extrapulmonary cases. In bone and joint disease, pathogenesis is related to reactivation of hematogenous foci or to spread from adjacent paravertebral lymph nodes. Weight-bearing joints (spine, hips, and knees—in that order) are affected most commonly. Spinal tuberculosis (Pott's disease or tuberculous spondylitis; Fig. 150-5) often involves two or more adjacent vertebral bodies. While the upper thoracic spine is the most common site of spinal tuberculosis in children, the lower thoracic and upper lumbar vertebrae are usually affected in adults. From the anterior superior or inferior angle of the vertebral body, the lesion reaches the adjacent body, also destroying the intervertebral disk. With advanced disease, collapse of vertebral bodies results in kyphosis (*gibbus*). A paravertebral "cold" abscess may also form. In the upper spine, this abscess may track to the chest wall as a mass; in the lower spine, it may reach the inguinal ligaments or present as a psoas abscess. Computed tomography (CT) or magnetic resonance imaging (MRI) reveals the characteristic lesion and suggests its etiology, although the differential diagnosis includes other infections and tumors. Aspiration of the abscess or bone biopsy confirms the tuberculous etiology, as cultures are usually positive and histologic findings highly typical. A catastrophic complication of Pott's disease is paraplegia, which is usually due to an abscess or a lesion compressing the spinal cord. Paraparesis due to a large abscess is a medical emergency and requires abscess drainage. Tuberculosis of the hip joints causes pain and limping; tuberculosis of the knee produces pain and swelling and sometimes follows trauma. If the disease goes unrecognized, the joints may be destroyed. Skeletal tuberculosis responds to chemotherapy, but severe cases may require surgery.

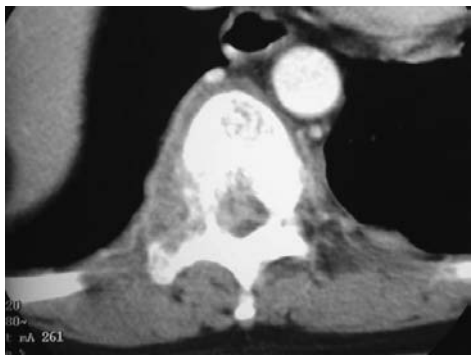

FIGURE 150-5 Computed tomography scan demonstrating destruction of the right pedicle of T10 due to Pott's disease. The patient, a 70-year-old Asian woman, presented with back pain and weight loss and had biopsy-proven tuberculosis. (*Courtesy of Charles L. Daley, M.D., University of California, San Francisco.*)

TUBERCULOUS MENINGITIS AND TUBERCULOMA Tuberculosis of the central nervous system accounts for ~5% of extrapulmonary cases. It is seen most often in young children but also develops in adults, especially those who are infected with HIV. Tuberculous meningitis results from the hematogenous spread of primary or postprimary pulmonary disease or from the rupture of a subependymal tubercle into the subarachnoid space. In more than half of cases, evidence of old pulmonary lesions or a miliary pattern is found on chest radiography. The disease may present subtly as headache and mental changes or acutely as confusion, lethargy, altered sensorium, and neck rigidity. Typically, the disease evolves over 1 or 2 weeks, a course longer than that of bacterial meningitis. Paresis of cranial nerves (ocular nerves in particular) is a frequent finding, and the involvement of cerebral arteries may produce focal ischemia. Hydrocephalus is common. Lumbar puncture is the cornerstone of diagnosis. In general, examination of the cerebrospinal fluid (CSF) reveals a high leukocyte count (usually with a predominance of lymphocytes but often with a predominance of neutrophils in the early stage), a protein content of 1 to 8 g/L (100 to 800 mg/dL), and a low glucose concentration; however, any of these three parameters can be within the normal range. AFB are seen on direct smear of CSF sediment in only 20% of cases, but repeated lumbar punctures increase the yield. Culture of CSF is diagnostic in up to 80% of cases. Imaging studies (CT and MRI) may show hydrocephalus and abnormal enhancement of basal cisterns or ependyma. If unrecognized, tuberculous meningitis is uniformly fatal. This disease responds to chemotherapy; however, neurologic sequelae are documented in 25% of treated cases, in most of which the diagnosis has been delayed. Clinical trials have demonstrated that patients treated with adjunctive glucocorticoids experience a significantly faster resolution of CSF abnormalities and elevated CSF pressure. Adjunctive glucocorticoids (e.g., dexamethasone, up to 12 mg/d for 4 to 6 weeks) enhance the chances of survival and reduce the frequency of neurologic sequelae.

Tuberculoma, an uncommon manifestation of tuberculosis, presents as one or more space-occupying lesions and usually causes seizures and focal signs. CT or MRI reveals contrast-enhanced ring lesions, but biopsy is necessary to establish the diagnosis.

GASTROINTESTINAL TUBERCULOSIS Any portion of the gastrointestinal tract may be affected by tuberculosis. Various pathogenetic mechanisms are involved: swallowing of sputum with direct seeding, hematogenous spread, or (although rare today) ingestion of milk from cows affected by bovine tuberculosis. The terminal ileum and the cecum are the sites most commonly involved. Abdominal pain (at times similar to that associated with appendicitis), diarrhea, obstruction, hematochezia, and a palpable mass in the abdomen are common findings at presentation. Fever, weight loss, and night sweats are also frequent. With intestinal-wall involvement, ulcerations and fistulae may simulate Crohn's disease. Anal fistulae should prompt an evaluation for rectal tuberculosis. As surgery is required in most cases, the diagnosis can be established by histologic examination and culture of specimens obtained intraoperatively.

Tuberculous peritonitis follows either the direct spread of tubercle bacilli from ruptured lymph nodes and intraabdominal organs or hematogenous seeding. Nonspecific abdominal pain, fever, and ascites

should raise the suspicion of tuberculous peritonitis. The coexistence of cirrhosis (Chap. 288) in patients with tuberculous peritonitis complicates the diagnosis. In tuberculous peritonitis, paracentesis reveals an exudative fluid with a high protein content and leukocytosis that is usually lymphocytic (although neutrophils occasionally predominate). The yield of direct smear and culture is relatively low; culture of a large volume of ascitic fluid can increase the yield, but peritoneal biopsy is often needed to establish the diagnosis.

PERICARDIAL TUBERCULOSIS (TUBERCULOUS PERICARDITIS) Due to direct progression of a primary focus within the pericardium, to reactivation of a latent focus, or to rupture of an adjacent lymph node, pericardial tuberculosis has often been a disease of the elderly in countries with low tuberculosis prevalence but also develops frequently in HIV-infected patients. Case-fatality rates are as high as 40% in some series. The onset may be subacute, although an acute presentation, with fever, dull retrosternal pain, and a friction rub, is possible. An effusion eventually develops in many cases; cardiovascular symptoms and signs of cardiac tamponade may ultimately appear (Chap. 222). In the presence of effusion detected on chest radiography, tuberculosis must be suspected if the patient belongs to a high-risk population (HIV-infected, originating in a high-prevalence country), if there is evidence of previous tuberculosis or disease in other organs, or if echocardiography shows thick strands crossing the pericardial space. Diagnosis can be facilitated by pericardiocentesis under echocardiographic guidance. The pericardial fluid must be submitted for biochemical, cytologic, and microbiologic study. The effusion is exudative in nature, with a high count of leukocytes (predominantly mononuclear cells). Hemorrhagic effusion is frequent. Culture of the fluid reveals *M. tuberculosis* in ~30% of cases, while biopsy has a higher yield. High levels of adenosine deaminase and IFN-γ may also suggest a tubercular etiology. Without treatment, pericardial tuberculosis is usually fatal. Even with treatment, complications may develop, including chronic constrictive pericarditis with thickening of the pericardium, fibrosis, and sometimes calcification, which may be visible on a chest radiograph. A course of glucocorticoid treatment (e.g., prednisone, 20 to 60 mg/d for up to 6 weeks) is useful in the management of acute disease, reducing effusion, facilitating hemodynamic recovery, and thus decreasing mortality. Progression to chronic constrictive pericarditis, however, seems unaffected by such therapy.

MILIARY OR DISSEMINATED TUBERCULOSIS Miliary tuberculosis is due to hematogenous spread of tubercle bacilli. Although in children it is often the consequence of a recent primary infection, in adults it may be due to either recent infection or reactivation of old disseminated foci. Lesions are usually yellowish granulomas 1 to 2 mm in diameter that resemble millet seeds (thus the term *miliary*, coined by nineteenth-century pathologists).

Clinical manifestations are nonspecific and protean, depending on the predominant site of involvement. Fever, night sweats, anorexia, weakness, and weight loss are presenting symptoms in the majority of cases. At times, patients have a cough and other respiratory symptoms due to pulmonary involvement as well as abdominal symptoms. Physical findings include hepatomegaly, splenomegaly, and lymphadenopathy. Eye examination may reveal choroidal tubercles, which are pathognomonic of miliary tuberculosis, in up to 30% of cases. Meningismus occurs in <10% of cases.

A high index of suspicion is required for the diagnosis of miliary tuberculosis. Frequently, chest radiography reveals a miliary reticulonodular pattern (more easily seen on underpenetrated film), although no radiographic abnormality may be evident early in the course and among HIV-infected patients. Other radiologic findings include large infiltrates, interstitial infiltrates (especially in HIV-infected patients), and pleural effusion. A sputum smear is negative in 80% of cases. Various hematologic abnormalities may be seen, including anemia with leukopenia, neutrophilic leukocytosis and leukemoid reactions, and polycythemia. Disseminated intravascular coagulation has been reported. Elevation of alkaline phosphatase levels and other abnormal values in liver function tests are detected in patients with severe hepatic involvement. The PPD test may be negative in up to half of cases, but reactivity may be restored during chemotherapy. Bronchoalveolar lavage and transbronchial biopsy are more likely to permit bacteriologic confirmation, and granulomas are evident in liver or bone-marrow biopsy specimens from many patients. If it goes unrecognized, miliary tuberculosis is lethal; with proper treatment, however, it is amenable to cure.

A rare presentation seen in the elderly is *cryptic miliary tuberculosis*, which has a chronic course characterized by mild intermittent fever, anemia, and—ultimately—meningeal involvement preceding death. An acute septicemic form, *nonreactive miliary tuberculosis*, occurs very rarely and is due to massive hematogenous dissemination of tubercle bacilli. Pancytopenia is common in this form of disease, which is rapidly fatal. At postmortem examination, multiple necrotic but nongranulomatous ("nonreactive") lesions are detected.

LESS COMMON EXTRAPULMONARY FORMS Tuberculosis may cause chorioretinitis, uveitis, panophthalmitis, and painful hypersensitivity-related phlyctenular conjunctivitis. Tuberculous otitis is rare and presents as hearing loss, otorrhea, and tympanic membrane perforation. In the nasopharynx, tuberculosis may simulate Wegener's granulomatosis. Cutaneous manifestations of tuberculosis include primary infection due to direct inoculation, abscesses and chronic ulcers, scrofuloderma, lupus vulgaris, miliary lesions, and erythema nodosum. Adrenal tuberculosis is a manifestation of advanced disease presenting as signs of adrenal insufficiency. Finally, congenital tuberculosis results from transplacental spread of tubercle bacilli to the fetus or from ingestion of contaminated amniotic fluid. This rare disease affects the liver, spleen, lymph nodes, and various other organs.

HIV-Associated Tuberculosis (See also Chap. 173) Tuberculosis is an important opportunistic disease among HIV-infected persons worldwide. In some African countries, the rate of HIV infection among tuberculosis patients may reach 70 to 80% in certain urban settings. A person with skin test–documented *M. tuberculosis* infection who acquires HIV infection has a 3 to 15% annual risk of developing active tuberculosis.

Tuberculosis can appear at any stage of HIV infection, and its presentation varies with the stage. When cell-mediated immunity is only partially compromised, pulmonary tuberculosis presents as a typical pattern (Fig. 150-4) of upper lobe infiltrates and cavitation, without significant lymphadenopathy or pleural effusion. In late stages of HIV infection, a primary tuberculosis–like pattern, with diffuse interstitial or miliary infiltrates, little or no cavitation, and intrathoracic lymphadenopathy, is more common. Overall, sputum smears may be positive less frequently among tuberculosis patients with HIV infection than among those without; thus the diagnosis of tuberculosis may be unusually difficult, especially in view of the variety of HIV-related pulmonary conditions mimicking tuberculosis.

Extrapulmonary tuberculosis is common among HIV-infected patients. In various series, extrapulmonary tuberculosis—alone or in association with pulmonary disease—has been documented in 40 to 60% of all cases in HIV co-infected individuals. The most common forms are lymphatic, disseminated, pleural, and pericardial. Mycobacteremia and meningitis are also frequent, particularly in advanced HIV disease.

The diagnosis of tuberculosis in HIV-infected patients may be difficult not only because of the increased frequency of sputum-smear negativity (up to 40% in culture-proven pulmonary cases) but also because of atypical radiographic findings, a lack of classic granuloma formation in the late stages, and negative results in PPD skin tests. Delays in treatment may prove fatal.

Recommendations for the prevention and treatment of tuberculosis in HIV-infected individuals are provided below.

DIAGNOSIS The key to the diagnosis of tuberculosis is a high index of suspicion. Diagnosis is not difficult with a high-risk patient—e.g., a homeless alcoholic who presents with typical symptoms and a classic chest radiograph showing upper lobe infiltrates with cavities (Fig.

150-4). On the other hand, the diagnosis can easily be missed in an elderly nursing-home resident or a teenager with a focal infiltrate.

Often, the diagnosis is first entertained when the chest radiograph of a patient being evaluated for respiratory symptoms is abnormal. If the patient has no complicating medical conditions that favor immunosuppression, the chest radiograph may show the typical picture of upper lobe infiltrates with cavitation (Fig. 150-4). The longer the delay between the onset of symptoms and the diagnosis, the more likely is the finding of cavitary disease. In contrast, immunosuppressed patients, including those with HIV infection, may have "atypical" findings on chest radiography—e.g., lower-zone infiltrates without cavity formation.

AFB Microscopy A presumptive diagnosis is commonly based on the finding of AFB on microscopic examination of a diagnostic specimen such as a smear of expectorated sputum or of tissue (for example, a lymph node biopsy). Most modern laboratories processing large numbers of diagnostic specimens use auramine-rhodamine staining and fluorescence microscopy. The more traditional method—light microscopy of specimens stained with Kinyoun or Ziehl-Neelsen basic fuchsin dyes—is satisfactory, although more time-consuming. For patients with suspected pulmonary tuberculosis, three sputum specimens, preferably collected early in the morning, should be submitted to the laboratory for AFB smear and mycobacteriology culture. If tissue is obtained, it is critical that the portion of the specimen intended for culture not be put in formaldehyde. The use of AFB microscopy on urine or gastric lavage fluid is limited by the presence of mycobacterial commensals, which can cause false-positive results.

Mycobacterial Culture Definitive diagnosis depends on the isolation and identification of *M. tuberculosis* from a diagnostic specimen—in most cases, a sputum specimen obtained from a patient with a productive cough. Specimens may be inoculated onto egg- or agar-based medium (e.g., Löwenstein-Jensen or Middlebrook 7H10) and incubated at 37°C under 5% CO_2. Because most species of mycobacteria, including *M. tuberculosis*, grow slowly, 4 to 8 weeks may be required before growth is detected. Although *M. tuberculosis* may be presumptively identified on the basis of growth time and colony pigmentation and morphology, a variety of biochemical tests have traditionally been used to speciate mycobacterial isolates. In today's laboratories, the use of liquid media for isolation and speciation by nucleic acid probes or high-pressure liquid chromatography of mycolic acids has replaced the traditional methods of isolation on solid media and identification by biochemical tests. These new methods have decreased the time required for bacteriologic confirmation to 2 to 3 weeks.

Nucleic Acid Amplification Several test systems based on amplification of mycobacterial nucleic acid are available. These systems permit the diagnosis of tuberculosis in as little as several hours. However, their applicability is limited by low sensitivity (lower than culture, but higher than AFB smear microscopy) and high cost. At present, these tests are most useful for the rapid confirmation of tuberculosis in persons with AFB-positive sputa. However, they may also have utility for the diagnosis of AFB-negative pulmonary and extrapulmonary tuberculosis in selected patients.

Drug Susceptibility Testing In general, the initial isolate of *M. tuberculosis* should be tested for susceptibility to isoniazid, rifampin, and ethambutol. In addition, expanded susceptibility testing is mandatory when resistance to one or more of these drugs is found or the patient either fails to respond to initial therapy or has a relapse after the completion of treatment (see below). Susceptibility testing may be conducted directly (with the clinical specimen) or indirectly (with mycobacterial cultures) on solid or liquid medium. Results are obtained most rapidly by direct susceptibility testing on liquid medium, with an average reporting time of 3 weeks. With indirect testing on solid medium, results may not be available for ≥8 weeks. Molecular methods for the rapid identification of drug resistance are becoming available. One of the most promising uses polymerase chain reaction (PCR) to detect mutations in the *rpoB* gene associated with resistance to rifampin.

Radiographic Procedures As noted above, the initial suspicion of pulmonary tuberculosis is often based on abnormal chest radiographic findings in a patient with respiratory symptoms. Although the "classic" picture is that of upper lobe disease with infiltrates and cavities (Fig. 150-4), virtually any radiographic pattern—from a normal film or a solitary pulmonary nodule to diffuse alveolar infiltrates in a patient with ARDS—may be seen. In the era of AIDS, no radiographic pattern can be considered pathognomonic.

PPD Skin Testing and Diagnosis of Latent Tuberculosis Infection In 1891, Robert Koch discovered components of *M. tuberculosis* in a concentrated liquid culture medium. Subsequently named "old tuberculin" (OT), this material was initially believed to be useful in the treatment of tuberculosis (although this idea was later disproved). It soon became clear that OT was capable of eliciting a skin reaction when injected subcutaneously into patients with tuberculosis. In 1932, Seibert and Munday purified this product by ammonium sulfate precipitation. The result was an active protein fraction known as *tuberculin PPD*. However, the complexity and diversity of the constituents of PPD rendered its standardization difficult. PPD-S, developed by Seibert and Glenn in 1941, was chosen as the international standard. Later, the WHO and UNICEF sponsored large-scale production of a master batch of PPD, termed *RT23*, and made it available for general use. The greatest limitation of PPD is its lack of mycobacterial species specificity, a property that is due to the large number of proteins in this product that are highly conserved in the various species of mycobacteria.

Skin testing with PPD is most widely used in screening for *M. tuberculosis* infection (see below). The test is of limited value in the diagnosis of active tuberculosis because of its low sensitivity and specificity. False-negative reactions are common in immunosuppressed patients and in those with overwhelming tuberculosis. Positive reactions are obtained when patients have been infected with *M. tuberculosis* but do not have active disease and when persons have been sensitized by nontuberculous mycobacteria (Chap. 152) or bacille Calmette-Guérin (BCG) vaccination. Although BCG vaccine is not used in the United States for tuberculosis prevention, many immigrants will have received it. In the absence of a history of BCG vaccination, a positive skin test may provide additional support for the diagnosis of tuberculosis in culture-negative cases.

Because results of anergy testing in HIV-infected populations do not seem useful to clinicians making decisions about preventive therapy, anergy testing based on other DTH antigens is no longer recommended as a routine component of tuberculosis screening among HIV-infected persons. However, some experts support the use of anergy testing to help guide individual decisions regarding preventive therapy, and some recommend that PPD skin testing be performed for patients previously classified as anergic if evidence indicates that these patients' immune systems have responded to therapy with antiretroviral drugs.

Cytokine Release Assays A commercially available whole-blood cytokine assay, the QuantiFERON-TB test (Cellestis Ltd), has been approved by the U.S. Food and Drug Administration (FDA) as an aid in the diagnosis of latent tuberculosis infection. The test requires overnight incubation of a peripheral-blood sample with PPD and control antigens followed by measurement of IFN-γ released by sensitized lymphocytes in an enzyme-linked immunosorbent assay (ELISA). A multicenter study conducted by the CDC indicated good agreement between this assay and the PPD skin test, although the assay's ability to predict the development of active tuberculosis is not known. At present, the QuantiFERON-TB test is recommended for screening for latent tuberculosis infection in populations at low to moderate risk of tuberculosis. Studies are under way to assess the performance of this test in contact investigations, persons with suspected tuberculosis disease, HIV-infected persons, and children. The test's performance will probably be enhanced by the use of antigens such as ESAT-6 and CPF-

10 that are present in *M. tuberculosis* but absent from BCG strains and most nontuberculous mycobacteria.

Additional Diagnostic Procedures Other diagnostic tests may be used when pulmonary tuberculosis is suspected. Sputum induction by ultrasonic nebulization of hypertonic saline may be useful for patients unable to produce a sputum specimen spontaneously. Frequently, patients with radiographic abnormalities that are consistent with other diagnoses (e.g., bronchogenic carcinoma) undergo fiberoptic bronchoscopy with bronchial brushings or transbronchial biopsy of the lesion. Bronchoalveolar lavage of a lung segment containing an abnormality may also be performed. In all cases, it is essential that specimens be submitted for AFB smear and mycobacterial culture. For the diagnosis of primary pulmonary tuberculosis in children, who often do not expectorate sputum, specimens from early-morning gastric lavage may yield positive cultures.

Invasive diagnostic procedures are indicated for patients with suspected extrapulmonary tuberculosis. In addition to specimens of involved sites (e.g., CSF for tuberculous meningitis, pleural fluid and biopsy samples for pleural disease), bone marrow and liver biopsy and culture have a good diagnostic yield in disseminated (miliary) tuberculosis, particularly in HIV-infected patients, who also have a high frequency of positive blood cultures.

In some cases, cultures will be negative, but a clinical diagnosis of tuberculosis will be supported by consistent epidemiologic evidence (e.g., a history of close contact with an infectious patient), a positive PPD skin test, and a compatible clinical and radiographic response to treatment. In the United States and other industrialized countries with low rates of tuberculosis, some patients with limited abnormalities on chest radiographs and sputum positive for AFB are infected with organisms of the *M. avium* complex or *M. kansasii* (Chap. 152). Factors favoring the diagnosis of nontuberculous mycobacterial disease over tuberculosis include an absence of risk factors for tuberculosis, a negative PPD skin test, and underlying chronic obstructive pulmonary disease.

Patients with HIV-associated tuberculosis pose several diagnostic problems, as noted above in the description of clinical manifestations. Moreover, HIV-infected patients with sputum culture–positive and AFB-positive tuberculosis may present with a normal chest radiograph. With the advent of highly active antiretroviral therapy (HAART), the occurrence of disseminated *M. avium* complex disease that can be confused with tuberculosis has become much less common.

Adjunctive Diagnostic Tests A number of methods have been evaluated as adjuncts to standard laboratory diagnosis. The most thoroughly investigated is serologic diagnosis based on detection of antibody to a variety of mycobacterial antigens. However, tests with most of the target antigens have a low predictive value when used in a population with a low probability of disease. Tests aimed at detection of mycobacterial antigen by serologic methods have generally been insufficiently sensitive to be useful.

TREATMENT

The two aims of tuberculosis treatment are to interrupt tuberculosis transmission by rendering patients noninfectious and to prevent morbidity and mortality by curing patients with tuberculosis disease. Chemotherapy for tuberculosis became possible with the discovery of streptomycin in the mid-1940s. Randomized clinical trials clearly indicated that the administration of streptomycin to patients with chronic tuberculosis reduced mortality and led to cure in the majority of cases. However, monotherapy with streptomycin was frequently associated with the development of resistance to this drug and the attendant failure of treatment. With the discovery of para-aminosalicylic acid (PAS) and isoniazid, it became axiomatic that cure of tuberculosis required the concomitant administration of at least two agents to which the organism was susceptible. Furthermore, early clinical trials demonstrated that a long period of treatment—i.e., 12 to 24 months—was required to prevent the recurrence of tuberculosis.

The introduction of rifampin in the early 1970s heralded the era of effective short-course chemotherapy, with a treatment duration of <12 months. The discovery that pyrazinamide, which was first used in the 1950s, augmented the potency of isoniazid/rifampin regimens led to the use of a 6-month course of this triple-drug regimen as standard therapy.

DRUGS Four major drugs are considered the first-line agents for the treatment of tuberculosis: isoniazid, rifampin, pyrazinamide, and ethambutol (Table 150-2). These drugs are well absorbed after oral administration, with peak serum levels at 2 to 4 h and nearly complete elimination within 24 h. These agents are recommended on the basis of their bactericidal activity (ability to rapidly reduce the number of viable organisms and render patients noninfectious), their sterilizing activity (ability to kill all bacilli and thus sterilize the affected organ, measured in terms of the ability to prevent relapses), and their low rate of induction of drug resistance. Rifapentine and rifabutin, two drugs related to rifampin, are also available in the United States and are useful for selected patients. →***For a detailed discussion of the drugs used for the treatment of tuberculosis, see Chap. 149.***

Because of a lower degree of efficacy and a higher degree of intolerability and toxicity, a number of second-line drugs are generally used only for the treatment of patients with tuberculosis resistant to first-line drugs. Included in this group are the injectable drugs streptomycin (formerly a first-line agent), kanamycin, amikacin, and capreomycin and the oral agents ethionamide, cycloserine, and PAS. Recently, fluoroquinolone antibiotics have become the most commonly used second-line drugs. Of available agents, ofloxacin is the most widely used, but levofloxacin, gatifloxacin, and moxifloxacin are the most active. Other drugs of doubtful efficacy that have been used in the treatment of patients with resistance to most of the first- and second-line agents include clofazimine, amithiozone (thiacetazone, still used in less wealthy countries but not marketed in North America or Europe), amoxicillin/clavulanic acid, and linezolid.

REGIMENS Short-course regimens are divided into an initial, or bactericidal, phase and a continuation, or sterilizing, phase. During the initial phase, the majority of the tubercle bacilli are killed, symptoms resolve, and the patient becomes noninfectious. The continuation phase is required to eliminate persisting mycobacteria and prevent relapse.

The treatment regimen of choice for virtually all forms of tuberculosis in both adults and children consists of a 2-month initial phase of isoniazid, rifampin, pyrazinamide, and ethambutol followed by a 4-month continuation phase of isoniazid and rifampin (Table 150-3). Treatment may be given daily throughout the course or intermittently (either three times weekly throughout the course or twice weekly following an initial phase of daily therapy). A continuation phase of once-weekly rifapentine and isoniazid is equally effective for HIV-

TABLE 150-2 *Recommended Dosage for Initial Treatment of Tuberculosis in Adults*[a]

Drug	Dosage	
	Daily Dose	Thrice-Weekly Dose[b]
Isoniazid	5 mg/kg, max 300 mg	15 mg/kg, max 900 mg
Rifampin	10 mg/kg, max 600 mg	10 mg/kg, max 600 mg
Pyrazinamide	20–25 mg/kg, max 2 g	30–40 mg/kg, max 3 g
Ethambutol[c]	15–20 mg/kg	25–30 mg/kg

[a] Dosages for children are similar, except that some authorities recommend higher doses of isoniazid (10–15 mg/kg daily; 20–30 mg/kg intermittent) and rifampin (10–20 mg/kg).

[b] Dosages for twice-weekly administration are the same for isoniazid and rifampin but are higher for pyrazinamide (50 mg/kg, with a maximum of 4 g/d) and ethambutol (40–50 mg/d).

[c] In certain settings, streptomycin (15 mg/kg daily, with a maximum dose of 1 g; or 25–30 mg/kg thrice weekly, with a maximum dose of 1.5 g) can replace ethambutol in the initial phase of treatment. However, streptomycin is no longer considered a first-line drug by the ATS, the IDSA, or the CDC.

TABLE 150-3 *Recommended Antituberculosis Treatment Regimens*

Indication	Initial Phase		Continuation Phase	
	Duration, Months	Drugs	Duration, Months	Drugs
New smear- or culture-positive cases	2	HRZE[a,b]	4	HR[a,c,d]
New culture-negative cases	2	HRZE[a]	2	HR[a]
Pregnancy	2	HRE[e]	7	HR
Failure and relapse[f]	—	—	—	—
Resistance (or intolerance) to H	Throughout (6)	RZE[g]		
Resistance to H + R	Throughout (18–24)	ZEQ + S (or another injectable agent[h])		
Resistance to all first-line drugs	Throughout (24)	1 injectable agent[h] + 3 of these 4: ethionamide, cycloserine, Q, PAS		
Standardized re-treatment (susceptibility testing unavailable)	3	HRZES[i]	5	HRE
Drug intolerance to R	Throughout (12)[j]	HZE		
Drug intolerance to Z	2	HRE	7	HR

[a] All drugs can be given daily or intermittently (three times weekly throughout or twice weekly after 2 to 8 weeks of daily therapy during the initial phase).
[b] Streptomycin can be used in place of ethambutol but is no longer considered to be a first-line drug by ATS/IDSA/CDC.
[c] The continuation phase should be extended to 7 months for patients with cavitary pulmonary tuberculosis who remain sputum culture–positive after the initial phase of treatment.
[d] HIV-negative patients with noncavitary pulmonary tuberculosis who have negative sputum AFB smears after the initial phase of treatment can be given once-weekly rifapentine/isoniazid in the continuation phase.
[e] The 6-month regimen with pyrazinamide can probably be used safely during pregnancy and is recommended by the WHO and the International Union Against Tuberculosis and Lung Disease. If pyrazinamide is not included in the initial treatment regimen, the minimum duration of therapy is 9 months.
[f] Regimen is tailored according to the results of drug susceptibility tests.
[g] A fluoroquinolone (Q) may strengthen the regimen for patients with extensive disease.
[h] Amikacin, kanamycin, or capreomycin. All these agents should be discontinued after 2 to 6 months, depending upon tolerance and response.
[i] Streptomycin should be discontinued after 2 months. This regimen is less effective for patients in whom treatment has failed, who have an increased probability of rifampin-resistant disease. In such cases, the re-treatment regimen might include second-line drugs chosen in light of the likely pattern of drug resistance.
[j] Streptomycin for the initial 2 months or a fluoroquinolone might strengthen the regimen for patients with extensive disease.
Note: H, isoniazid; R, rifampin; Z, pyrazinamide; E, ethambutol; S, streptomycin; Q, a quinolone antibiotic; PAS, para-aminosalicylic acid.

seronegative patients with noncavitary pulmonary tuberculosis who have negative sputum cultures at 2 months. Intermittent treatment is especially useful for patients whose therapy is being directly observed (see below). Patients with cavitary pulmonary tuberculosis and delayed sputum-culture conversion (i.e., those who remain culture-positive at 2 months) should have their treatment extended by 3 months, for a total course of 9 months. For patients with sputum culture–negative pulmonary tuberculosis, the duration of treatment may be reduced to a total of 4 months. To prevent isoniazid-related neuropathy, pyridoxine (10 to 25 mg/d) should be added to the regimen given to persons at high risk of vitamin B6 deficiency (e.g., alcoholics; malnourished persons; pregnant and lactating women; and patients with conditions such as chronic renal failure, diabetes, and HIV infection or AIDS, which are also associated with neuropathy). A full course of therapy (completion of treatment) is defined more accurately by the total number of doses taken than by the length of treatment. Specific recommendations on the required numbers of doses for each of the various treatment regimens have been published jointly by the American Thoracic Society (ATS), the Infectious Diseases Society of America (IDSA), and the CDC.

Lack of adherence to treatment is recognized worldwide as the most important impediment to cure. Moreover, the tubercle bacilli infecting patients who do not adhere to the prescribed regimen are likely to become drug resistant. Both patient- and provider-related factors may affect compliance. Patient-related factors include a lack of belief that the illness is significant and/or that treatment will have a beneficial effect; the existence of concomitant medical conditions (notably substance abuse); lack of social support; and poverty, with attendant joblessness and homelessness. Provider-related factors that may promote compliance include the education and encouragement of patients, the offering of convenient clinic hours, and the provision of incentives and enablers such as meals and bus tokens.

In addition to specific measures addressing noncompliance, two other strategic approaches are used: direct observation of treatment and provision of fixed-drug-combination (FDC) products. Because it is difficult to predict which patients will adhere to the recommended treatment, all patients should have their therapy directly supervised, especially during the initial phase. In the United States, personnel to supervise therapy are usually available through tuberculosis control programs of local public health departments. Supervision increases the proportion of patients completing treatment and greatly lessens the chances of relapse and acquired drug resistance. FDC products (e.g., isoniazid/rifampin, isoniazid/rifampin/pyrazinamide, and isoniazid/rifampin/pyrazinamide/ethambutol) are available (except, in the United States, for the four-drug FDC) and strongly recommended as a means of minimizing the likelihood of prescription error and of the development of drug resistance as the result of monotherapy. In some formulations of these combination products, the bioavailability of rifampin has been found to be substandard. In North America and Europe, regulatory authorities ensure that combination products are of good quality; however, this type of quality assurance cannot be assumed to take place in less affluent countries. Alternative regimens for patients who exhibit drug intolerance or adverse reactions are listed in Table 150-3. However, severe side effects prompting discontinuation of any of the first-line drugs and use of these alternative regimens are uncommon.

MONITORING TREATMENT RESPONSE AND DRUG TOXICITY Bacteriologic evaluation is the preferred method of monitoring the response to treatment for tuberculosis. Patients with pulmonary disease should have their sputum examined monthly until cultures become negative. With the recommended regimen, >80% of patients will have negative sputum cultures at the end of the second month of treatment. By the end of the third month, virtually all patients should be culture-negative. In some patients, especially those with extensive cavitary disease and large numbers of organisms, AFB smear conversion may follow culture conversion. This phenomenon is presumably due to the expectoration and microscopic visualization of dead bacilli. As noted above, patients with cavitary disease who do not achieve sputum culture conversion by 2 months require extended treatment. When a patient's sputum cultures remain positive at ≥3 months, treatment failure and drug resistance should be suspected (see below). A sputum specimen should be collected by the end of treatment to document cure. If mycobacterial cultures are not practical, then monitoring by AFB smear examination should be undertaken at 2, 5, and 6 months. Smears positive after 5 months are indicative of treatment failure.

Bacteriologic monitoring of patients with extrapulmonary tuberculosis is more difficult and often is not feasible. In these cases, the response to treatment must be assessed clinically.

Monitoring of the response to treatment during chemotherapy by serial chest radiographs is not recommended, as radiographic changes may lag behind bacteriologic response and are not highly sensitive. After the completion of treatment, neither sputum examination nor chest radiography is recommended for follow-up purposes. However, a chest radiograph may be obtained at the end of treatment and used for comparative purposes should the patient develop symptoms of recurrent tuberculosis months or years later. Patients should be instructed

to report promptly for medical assessment should they develop any such symptoms.

During treatment, patients should be monitored for drug toxicity (Table 149-3). The most common adverse reaction of significance is hepatitis. Patients should be carefully educated about the signs and symptoms of drug-induced hepatitis (e.g., dark urine, loss of appetite) and should be instructed to discontinue treatment promptly and see their health care provider should these symptoms occur. Although biochemical monitoring is not routinely recommended, all adult patients should undergo baseline assessment of liver function (e.g., measurement of serum levels of hepatic aminotransferases and serum bilirubin). Older patients, those with concomitant diseases, those with a history of hepatic disease, and those using alcohol daily should be monitored especially closely (i.e., monthly), with repeated measurements of aminotransferases, during the initial phase of treatment. Up to 20% of patients have small increases in aspartate aminotransferase (up to three times the upper limit of normal) that are accompanied by no symptoms and are of no consequence. For patients with symptomatic hepatitis and those with marked (five- to sixfold) elevations in serum levels of aspartate aminotransferase, treatment should be stopped and drugs reintroduced one at a time after liver function has returned to normal.

Hypersensitivity reactions usually require the discontinuation of all drugs and rechallenge to determine which agent is the culprit. Because of the variety of regimens available, it is usually not necessary—although it is possible—to desensitize patients. Hyperuricemia and arthralgia caused by pyrazinamide can usually be managed by the administration of acetylsalicylic acid; however, pyrazinamide treatment should be stopped if the patient develops gouty arthritis. Individuals who develop autoimmune thrombocytopenia secondary to rifampin therapy should not receive the drug thereafter. Similarly, the occurrence of optic neuritis with ethambutol is an indication for permanent discontinuation of this drug. Other common manifestations of drug intolerance, such as pruritus and gastrointestinal upset, can generally be managed without the interruption of therapy.

TREATMENT FAILURE AND RELAPSE As stated above, treatment failure should be suspected when a patient's sputum cultures remain positive after 3 months or when AFB smears remain positive after 5 months. In the management of such patients, it is imperative that the current isolate be tested for susceptibility to first- and second-line agents. When the results of susceptibility testing are expected to become available within a few weeks, changes in the regimen can be postponed until that time. However, if the patient's clinical condition is deteriorating, an earlier change in regimen may be indicated. A cardinal rule in the latter situation is always to add more than one drug at a time to a failing regimen: at least two and preferably three drugs that have never been used and to which the bacilli are likely to be susceptible should be added. The patient may continue to take isoniazid and rifampin along with these new agents pending the results of susceptibility tests.

The mycobacterial strains infecting patients who experience a relapse after apparently successful treatment are less likely to have acquired drug resistance (see below) than are strains from patients in whom treatment has failed. However, if the regimen administered initially does not contain rifampin (and thus is not a short-course regimen), the probability of isoniazid resistance is high. Acquired resistance is uncommon among strains from patients who relapse after completing a short-course regimen. However, it is prudent to begin the treatment of all relapses with all five first-line drugs pending the results of susceptibility testing. In less affluent countries and other settings where facilities for culture and drug susceptibility testing are not available, a standard regimen should be used in all instances of relapse and treatment failure (Table 150-3).

HIV-ASSOCIATED TUBERCULOSIS In general, the standard treatment regimens are equally efficacious in HIV-negative and HIV-positive patients. However, adverse drug effects may be more pronounced in HIV-infected patients. Since these effects may include serious or even fatal skin reactions to amithiozone (thiacetazone), this drug, which has been used in place of ethambutol in developing countries, is no longer recommended by WHO.

There are three important considerations relevant to tuberculosis treatment in HIV-infected patients: an increased frequency of paradoxical reactions, drug interactions between HAART and rifamycins, and development of rifampin monoresistance with widely spaced intermittent treatment. Exacerbations in symptoms, signs, and laboratory or radiographic manifestations of tuberculosis—termed *paradoxical reactions*—have been associated with the administration of HAART regimens. The presumed pathogenesis of paradoxical reactions is an immune response to antigens released as bacilli are killed by effective chemotherapy. In patients in whom HAART has recently been started, paradoxical reactions may be due to improving immune function. The first priority in the management of a possible paradoxical reaction is to ensure that the clinical syndrome does not represent a failure of tuberculosis treatment or the development of another infection. Mild paradoxical reactions can be managed with symptom-based treatment. Glucocorticoids have been used for more severe reactions, although this practice has not been formally evaluated in clinical trials.

Most HIV-infected tuberculosis patients are candidates for HAART, although the optimal timing for antiretroviral treatment is not known. Rifampin, a potent inducer of enzymes of the cytochrome P450 system, lowers serum levels of many HIV protease inhibitors and some nonnucleoside reverse transcriptase inhibitors, essential drugs used in HAART regimens. In such cases, rifabutin, which has much less enzyme-inducing activity, has been recommended in place of rifampin. However, dose adjustments for rifabutin and/or the antiretroviral drugs may be necessary. Because recommendations are frequently updated, consultation of the CDC website is advised (www.cdc.gov/nchstp/tb).

Several clinical trials of HIV-associated tuberculosis have found that patients with advanced immunosuppression (CD4+ cell counts of <100) are prone to treatment failure and relapse with rifampin-resistant organisms when treated with "highly intermittent" (i.e., once- or twice-weekly) rifamycin-containing regimens. Consequently, it is recommended that these patients receive daily or thrice-weekly therapy for the entire course.

DRUG-RESISTANT TUBERCULOSIS Strains of *M. tuberculosis* resistant to individual drugs arise by spontaneous point mutations in the mycobacterial genome, which occur at low but predictable rates. Because there is no cross-resistance among the commonly used drugs, the probability that a strain will be resistant to two drugs is the product of the probabilities of resistance to each drug and thus is low. The development of drug-resistant tuberculosis is invariably the result of monotherapy—i.e., the failure of the health care provider to prescribe at least two drugs to which tubercle bacilli are susceptible or of the patient to take properly prescribed therapy.

Drug-resistant tuberculosis may be either primary or acquired. Primary drug resistance is that in a strain infecting a patient who has not previously been treated. Acquired resistance develops during treatment with an inappropriate regimen. In North America and Europe, rates of primary resistance are generally low, and isoniazid resistance is most common. In the United States, while primary isoniazid resistance was stable at about 7 to 8% between 1993 and 2002, the rate of primary multidrug-resistant (MDR) tuberculosis declined from 2.5% to 1%. Resistance rates are higher among foreign-born and HIV-infected patients. Worldwide, MDR tuberculosis is a serious problem in some regions, especially in the former Soviet Union and parts of Asia. As noted above, drug-resistant tuberculosis can be prevented by adherence to the principles of sound therapy: the inclusion of at least two bactericidal drugs to which the organism is susceptible and the verification that patients complete the prescribed course.

Although the 6-month regimen described in Table 150-3 is generally effective for patients with initial isoniazid-resistant disease, it is

prudent to include ethambutol and pyrazinamide for the full 6 months. In such cases, isoniazid probably does not contribute to a successful outcome and should be omitted. MDR tuberculosis is more difficult to manage than is disease caused by a drug-susceptible organism, especially because resistance to other first-line drugs as well as to isoniazid and rifampin is common. For strains resistant to isoniazid and rifampin, combinations of a fluoroquinolone, ethambutol, pyrazinamide, and streptomycin (or, for those resistant to streptomycin as well, another injectable agent such as amikacin), given for 18 to 24 months and for at least 9 months after sputum culture conversion, may be effective. For patients with bacilli resistant to all of the first-line agents, cure may be attained with a combination of four second-line drugs, including one injectable agent (Table 150-3). The optimal duration of treatment in this situation is not known; however, a duration of 24 months is recommended. For patients with localized disease and sufficient pulmonary reserve, lobectomy or pneumonectomy may be helpful. Because the management of patients with MDR tuberculosis is complicated by both social and medical factors, care of these patients should be restricted to specialists and tuberculosis control programs.

SPECIAL CLINICAL SITUATIONS Although comparative clinical trials of treatment for extrapulmonary tuberculosis are limited, the available evidence indicates that most forms of disease can be treated with the 6-month regimen recommended for patients with pulmonary disease. The American Academy of Pediatrics recommends that children with bone and joint tuberculosis, tuberculous meningitis, or miliary tuberculosis receive 9 to 12 months of treatment.

Treatment for tuberculosis may be complicated by underlying medical problems that require special consideration (Table 149-1). As a rule, patients with chronic renal failure should not receive aminoglycosides and should receive ethambutol only if serum levels can be monitored. Isoniazid, rifampin, and pyrazinamide may be given in the usual doses in cases of mild to moderate renal failure, but the dosages of isoniazid and pyrazinamide should be reduced for all patients with severe renal failure except those undergoing hemodialysis. Patients with hepatic disease pose a special problem because of the hepatotoxicity of isoniazid, rifampin, and pyrazinamide. Patients with severe hepatic disease may be treated with ethambutol and streptomycin and, if required, with isoniazid and rifampin under close supervision. The use of pyrazinamide by patients with liver failure should be avoided. Silicotuberculosis necessitates the extension of therapy by at least 2 months. The regimen of choice for pregnant women (Tables 149-1 and 150-3) is 9 months of treatment with isoniazid and rifampin supplemented by ethambutol for the first 2 months. When required, pyrazinamide may be given, although there are no data concerning its safety in pregnancy. Streptomycin is contraindicated because it is known to cause eighth-cranial-nerve damage in the fetus. Treatment for tuberculosis is not a contraindication to breast feeding; most of the drugs administered will be present in small quantities in breast milk, albeit at concentrations far too low to provide any therapeutic or prophylactic benefit to the child.

PREVENTION By far the best way to prevent tuberculosis is to diagnose infectious cases rapidly and administer appropriate treatment until cure. Additional strategies include BCG vaccination and treatment of persons with latent tuberculosis infection who are at high risk of developing active disease.

BCG Vaccination BCG was derived from an attenuated strain of *M. bovis* and was first administered to humans in 1921. Many BCG vaccines are available worldwide; all are derived from the original strain, but the vaccines vary in efficacy. In fact, estimates of efficacy from randomized, placebo-controlled trials have ranged from 80% to nil. A similar range of efficacy was found in recent observational studies (case-control, historic cohort, and cross-sectional) in areas where infants are vaccinated at birth. These studies also found higher rates of efficacy in the protection of infants and young children from relatively serious forms of tuberculosis, such as tuberculous meningitis and miliary tuberculosis.

BCG vaccine is safe and rarely causes serious complications. The local tissue response begins 2 to 3 weeks after vaccination, with scar formation and healing within 3 months. Side effects—most commonly, ulceration at the vaccination site and regional lymphadenitis—occur in 1 to 10% of vaccinated persons. Some vaccine strains have caused osteomyelitis in ~1 case per million doses administered. Disseminated BCG infection and death have occurred in 1 to 10 cases per 10 million doses administered, although this problem is restricted almost exclusively to persons with impaired immunity, such as children with severe combined immunodeficiency syndrome or adults with HIV infection. BCG vaccination induces PPD reactivity, which tends to wane with time. The presence or size of PPD skin-test reactions after vaccination does not predict the degree of protection afforded.

BCG vaccine is recommended for routine use at birth in countries with high tuberculosis prevalence. However, because of the low risk of transmission of tuberculosis in the United States and the unreliable protection afforded by BCG, the vaccine has never been recommended for general use in the United States. The CDC has recommended that HIV-infected adults and children not receive BCG vaccine, although the WHO has recommended that asymptomatic HIV-infected children residing in tuberculosis-endemic areas receive BCG.

Treatment of Latent Tuberculosis Infection A major component of tuberculosis control in the United States is the treatment of selected persons with latent tuberculosis infection to prevent active disease. This intervention (formerly called preventive chemotherapy or chemoprophylaxis) is based on the results of a large number of randomized, placebo-controlled clinical trials demonstrating that a 6- to 12-month course of isoniazid reduces the risk of active tuberculosis in infected people by ≥90%. Analysis of available data indicates that the optimal duration of treatment is 9 to 10 months. In the absence of reinfection, the protective effect is believed to be lifelong. Clinical trials have also shown that isoniazid reduces rates of tuberculosis among PPD-positive persons with HIV infection. Studies in HIV-infected patients have demonstrated the effectiveness of shorter courses of rifampin-based treatment.

In most cases, candidates for treatment of latent tuberculosis (Table 150-4) are identified by PPD skin testing of persons in defined high-risk groups. For skin testing, 5 tuberculin units of polysorbate-stabilized PPD should be injected intradermally into the volar surface of the forearm (Mantoux method). Multipuncture tests, which may be useful for screening large populations, are not recommended for this purpose; any positive reaction to a multipuncture test must be confirmed by Mantoux testing. Reactions are read at 48 to 72 h as the transverse diameter in millimeters of induration; the diameter of erythema is not considered. In some persons, PPD reactivity wanes with time but can be recalled by a second skin test administered ≥1 week after the first (i.e., two-step testing). For persons undergoing periodic

TABLE 150-4 *Tuberculin Reaction Size, Treatment of Latent Tuberculosis Infection*

Risk Group	Tuberculin Reaction Size, mm
HIV-infected persons or persons receiving immunosuppressive therapy	≥5
Close contacts of tuberculosis patients	≥5[a]
Persons with fibrotic lesions on chest radiography	≥5
Recently infected persons (≤2 years)	≥10
Persons with high-risk medical conditions[b]	≥10
Low-risk persons[c]	≥15

[a] Tuberculin-negative contacts, especially children, should receive prophylaxis for 2 to 3 months after contact ends and should then be retested with PPD. Those whose results remain negative should discontinue prophylaxis. HIV-infected contacts should receive a full course of treatment regardless of PPD results.

[b] Includes diabetes mellitus, some hematologic and reticuloendothelial diseases, injection drug use (with HIV seronegativity), end-stage renal disease, and clinical situations associated with rapid weight loss.

[c] Decision to treat should be based on individual risk/benefit considerations.

PPD skin testing, such as health care workers and individuals admitted to long-term-care institutions, initial two-step testing may preclude subsequent misclassification of persons with boosted reactions as PPD converters.

The cutoff for a positive skin test (and thus for treatment) is related both to the probability that the reaction represents true infection and to the likelihood that the individual, if truly infected, will develop tuberculosis (Table 150-4). Thus positive reactions for close contacts of infectious cases, persons with HIV infection, persons receiving drugs that suppress the immune system, and previously untreated persons whose chest radiograph is consistent with healed tuberculosis are defined as an area of induration ≥5 mm in diameter. A 10-mm cutoff is used to define positive reactions in most other at-risk persons. For persons with a very low risk of developing tuberculosis if infected, a cutoff of 15 mm is used. Treatment should be considered for persons from tuberculosis-endemic countries who have a history of BCG vaccination.

Some PPD-negative individuals are also candidates for treatment. Infants and children who have come into contact with infectious cases should be treated and should have a repeat skin test 2 or 3 months after contact ends. Those whose test results remain negative should discontinue treatment. HIV-infected persons who have been exposed to an infectious tuberculosis patient should receive treatment regardless of the PPD test result.

TABLE 150-5 *Revised Drug Regimens for Treatment of Latent Tuberculosis Infection (LTBI) in Adults*

Drug	Interval and Duration	Comments[a]	Rating[b] (Evidence[c]) HIV-Negative	Rating[b] (Evidence[c]) HIV-Infected
Isoniazid	Daily for 9 months[d,e]	In HIV-infected persons, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors, protease inhibitors, or nonnucleoside reverse transcriptase inhibitors (NNRTIs).	A (II)	A (II)
	Twice weekly for 9 months[d,e]	Directly observed therapy (DOT) must be used with twice-weekly dosing.	B (II)	B (II)
	Daily for 6 months[e]	Regimen is not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children.	B (I)	C (I)
	Twice weekly for 6 months[e]	DOT must be used with twice-weekly dosing.	B (II)	C (I)
Rifampin[f]	Daily for 4 months	Regimen is used for contacts of patients with isoniazid-resistant, rifampin-susceptible tuberculosis. In HIV-infected persons, most protease inhibitors and delavirdine should not be administered concurrently with rifampin. Rifabutin, with appropriate dose adjustments, can be used with protease inhibitors (saquinavir should be augmented with ritonavir) and NNRTIs (except delavirdine). Clinicians should consult web-based updates for the latest specific recommendations.	B (II)	B (III)
Rifampin plus pyrazinamide (RZ)	Daily for 2 months	Regimen generally should not be offered for treatment of LTBI in either HIV-infected or HIV-negative persons.	D (II)	D (II)
	Twice weekly for 2–3 months		D (III)	D (III)

[a] Interactions with HIV-related drugs are updated frequently and are available at http://www.aidsinfo.nih.gov/guidelines.

[b] Strength of the recommendation: A. Both strong evidence of efficacy and substantial clinical benefit support recommendation for use. Should always be offered. B. Moderate evidence for efficacy or strong evidence for efficacy, but only limited clinical benefit, supports recommendation for use. Should generally be offered. C. Evidence for efficacy is insufficient to support a recommendation for or against use, or evidence for efficacy might not outweigh adverse consequences (e.g., drug toxicity, drug interactions) or cost of the treatment or alternative approaches. Optional. D. Moderate evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should generally not be offered. E. Good evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should never be offered.

[c] Quality of evidence supporting the recommendation: I. Evidence from at least one properly randomized controlled trial. II. Evidence from at least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), from multiple time-series studies, or from dramatic results in uncontrolled experiments. III. Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.

[d] Recommended regimen for persons aged <18 years.

[e] Recommended regimen for pregnant women.

[f] The substitution of rifapentine for rifampin is not recommended because rifapentine's safety and effectiveness have not been established for patients with LTBI.

Source: Adapted from CDC: Targeted tuberculin testing and treatment of latent tuberculosis infection. MMWR 49(RR-6), 2000

Isoniazid is administered at a daily dose of 5 mg/kg (up to 300 mg/d) for 9 months (Table 150-5). On the basis of cost-benefit analyses, a 6-month period of treatment has been recommended in the past and may be considered for HIV-negative adults with normal chest radiographs when financial considerations are important. When supervised treatment is desirable and feasible, isoniazid may be given at a dose of 15 mg/kg (up to 900 mg) twice weekly. An alternative regimen for adults is 4 months of daily rifampin. A previously recommended regimen of 2 months of rifampin and pyrazinamide has been associated with serious and fatal hepatotoxicity and is now generally not recommended for use. The rifampin regimen should be considered for persons who are likely to have been infected with an isoniazid-resistant strain.

Isoniazid should not be given to persons with active liver disease. All persons at increased risk of hepatotoxicity (e.g., those abusing alcohol daily and those with a history of liver disease) should undergo baseline and then monthly assessment of liver function. All patients should be carefully educated about hepatitis and instructed to discontinue use of the drug immediately should any symptoms develop. Moreover, patients should be seen and questioned monthly during therapy about adverse reactions and should be given no more than 1 month's supply of drug at each visit.

It may be more difficult to ensure compliance when treating persons with latent infection than when treating those with active tuberculosis. If family members of active cases are being treated, compliance and monitoring may be easier. When feasible, twice-weekly supervised therapy may increase the likelihood of completion. As in active cases, the provision of incentives may also be helpful.

BASICS OF CONTROL The highest priority in any tuberculosis control program is the prompt detection of cases and the provision of short-course chemotherapy to all tuberculosis patients under proper case-management conditions, including directly observed therapy, with emphasis on the cure of sputum smear–positive cases. In addition, in low-prevalence countries with adequate resources, screening of high-risk groups (such as immigrants from high-prevalence countries and HIV-seropositive persons) is recommended. Identification of active cases of tuberculosis should be followed by treatment. PPD-positive high-risk persons should be treated for latent infection. Contact investigation is an important component of efficient tuberculosis control. In the United States, a great deal of attention has been given to the transmission of tuberculosis (particularly in association with HIV infection) in institutional settings such as hospitals, homeless shelters, and prisons. Measures to limit such transmission include respiratory isolation of persons with suspected tuberculosis until they are proven to be noninfectious (i.e., by sputum AFB smear negativity), proper ventilation in rooms of patients with infectious tuberculosis, use of ultraviolet lights in areas of increased risk of tuberculosis transmission, and

periodic screening of personnel who may come into contact with known or unsuspected cases of tuberculosis. In the past, radiographic surveys, especially those conducted with portable equipment and miniature films, were advocated for case finding. Today, however, the prevalence of tuberculosis in industrialized countries is sufficiently low that "mass miniature radiography" is not cost-effective.

In high-prevalence countries, tuberculosis control programs should be based on the following key elements defining the DOTS strategy promoted by the WHO: (1) political commitment by the government to sustained tuberculosis control; (2) case detection through microscopic examination of sputum from patients who present to health care facilities with cough of >2 to 3 weeks' duration; (3) administration of standard short-course chemotherapy to all sputum smear–positive patients under proper case-management conditions, including direct observation of drug ingestion; (4) establishment and maintenance of a system of regular drug supply; and (5) establishment and maintenance of an effective surveillance and monitoring system that allows assessment of treatment outcomes (e.g., cure, completion of treatment without bacteriologic proof of cure, death, treatment failure, and default) in all cases registered and notified.

151 LEPROSY (HANSEN'S DISEASE)

Robert H. Gelber

Leprosy, first described in ancient Indian texts from the sixth century B.C., is a nonfatal, chronic infectious disease caused by *Mycobacterium leprae*, whose clinical manifestations are largely confined to the skin, peripheral nervous system, upper respiratory tract, eyes, and testes. The unique tropism of *M. leprae* for peripheral nerves (from large nerve trunks to microscopic dermal nerves) and certain immunologically mediated reactional states are the major causes of morbidity in leprosy. The propensity of the disease, when untreated, to result in characteristic deformities and the recognition in most cultures that the disease is communicable from person to person have resulted historically in a profound social stigma. Today, with early diagnosis and the institution of appropriate and effective antimicrobial therapy, patients can lead productive lives in the community, and deformities and other visible manifestations can largely be prevented.

ETIOLOGY *M. leprae* is an obligate intracellular bacillus (0.3 to 1 μm wide and 1 to 8 μm long) that is acid-fast, indistinguishable microscopically from other mycobacteria, and ideally detected in tissue sections by a modified Fite stain. Strain variability was recently discovered in this organism. *M. leprae* produces no known toxins and is well adapted to penetrate and reside within macrophages, yet it may survive outside the body for months. In untreated patients, only ~1% of *M. leprae* organisms are viable. The morphologic index (MI), a measure of the number of acid-fast bacilli (AFB) in skin scrapings that stain uniformly bright, correlates with viability. The bacteriologic index (BI), a logarithmic-scaled measure of the density of *M. leprae* in the dermis, may be as high as 4+ to 6+ in untreated patients, falling by one unit per year during effective therapy; the rate of fall is independent of the relative potency of effective antimicrobial therapy. A rising MI or BI suggests relapse and perhaps—if the patient is being treated—drug resistance; the latter possibility can be confirmed or excluded in the mouse model.

As a result of reductive evolution, almost half of the *M. leprae* genome contains nonfunctional genes; only 1605 genes encode for proteins. In contrast, *M. tuberculosis* uses 91% of its genome to encode for 4000 proteins. Among the lost genes in *M. leprae* are those for catabolic and respiratory pathways; transport systems; purine, methionine, and glutamine synthesis; and nitrogen regulation. The genome of *M. leprae* provides a metabolic rationale for its obligate intracellular existence and reliance on host biochemical support, a template for targets of drug development, and ultimately a pathway to cultivation. The recent finding of strain variability among *M. leprae* isolates provides a powerful tool with which to address anew the organism's epidemiology and pathobiology. The bacterium's complex cell wall has a peptidoglycan backbone, which is linked to arabinogalactan and mycolic acids. Lipoarabinomannan is a key component of the cell membrane, and the outer capsule contains large amounts of an *M. leprae*–specific phenolic glycolipid (PGL-1), which is detected in serologic tests.

Among the mycobacteria, *M. leprae* is unique in exhibiting dopa oxidase activity and an acid-fastness that is pyridine-extractable. Although it was the first bacterium to be etiologically associated with human disease, *M. leprae* remains one of the few bacterial species that still has not been cultivated on artificial medium or tissue culture. The multiplication of *M. leprae* in mouse footpads (albeit limited, with a doubling time of ~2 weeks) has provided a means to evaluate antimicrobial agents, monitor clinical trials, and screen vaccines. *M. leprae* grows best in cooler tissues (the skin, peripheral nerves, anterior chamber of the eye, upper respiratory tract, and testes), sparing warmer areas of the skin (the axilla, groin, scalp, and midline of the back).

EPIDEMIOLOGY ■ Demographics Leprosy is almost exclusively a disease of the developing world, affecting areas of Asia, Africa, Latin America, and the Pacific. While Africa has the highest disease prevalence, Asia has the most cases. More than 80% of the world's cases occur in a few countries: India, China, Myanmar, Indonesia, Brazil, Nigeria, Madagascar, and Nepal. Within endemic locales, the distribution of leprosy is quite uneven, with areas of high prevalence bordering on areas with little or no disease. In Brazil the majority of cases occur in the Amazon basin and two western states, while in Mexico leprosy is mostly confined to the Pacific coast. Except as imported cases, leprosy is largely absent from the United States, Canada, and northwestern Europe. In the United States, ~4000 persons have leprosy and 100 to 200 new cases are reported annually, most of them in California, Texas, New York, and Hawaii among immigrants from Mexico, Southeast Asia, the Philippines, and the Caribbean.

The global prevalence of leprosy is difficult to assess, given that many of the locales with high prevalence lack a significant medical or public health infrastructure. Estimates range from 0.6 to 8 million affected individuals. The lower estimate includes only persons who have not completed chemotherapy, excluding those who may be phys-

ically or psychologically damaged from leprosy and who may yet relapse or develop immune-mediated reactions; the higher figure includes patients whose infections probably are already cured and many who have no leprosy-related deformity or disability. Although the figures on the worldwide prevalence of leprosy are debatable, it is generally agreed that the annual incidence of new cases is rising (529,000 estimated new cases in 1995 and 719,000 in 2001, with 60% of the latter number from India alone).

Leprosy is associated with poverty and rural residence. It appears not to be associated with AIDS, perhaps because of leprosy's long incubation period. Most people appear to be naturally immune to leprosy and do not develop disease manifestations following exposure. The time of peak onset is in the second and third decades of life. The most severe polar form of leprosy is twice as common among men as among women and is rarely encountered in children. The frequency of the polar forms of leprosy in different countries varies widely and may in part be genetically determined; certain HLA associations are known for both polar forms of leprosy (see below). In India and Africa, 90% of cases are tuberculoid; in Southeast Asia, 50% are tuberculoid and 50% lepromatous; and in Mexico, 90% are lepromatous. (For definitions of disease types, see Table 151-1 and "Clinical, Histologic, and Immunologic Spectrum," below).

Transmission The route of transmission of leprosy remains uncertain and may be multiple; nasal droplet infection, contact with infected soil, and even insect vectors have been considered the prime candidates. Aerosolized *M. leprae* can cause infection in immunosuppressed mice, and a sneeze from an untreated lepromatous patient may contain $>10^{10}$ AFB. Furthermore, both IgA antibody to *M. leprae* and genes of *M. leprae*—demonstrable by polymerase chain reaction (PCR)—have been found in the nose of individuals without signs of leprosy from endemic areas and in 19% of occupational contacts of lepromatous patients.

Several lines of evidence implicate soil transmission of leprosy: (1) in endemic countries such as India, leprosy is primarily a rural and not an urban disease; (2) *M. leprae* products have been demonstrated to be resident in soil in endemic locales; and (3) direct dermal inoculation (e.g., during tattooing) may transmit *M. leprae*, and common sites of leprosy in children are the buttocks and thighs, suggesting that microinoculation of infected soil may transmit the disease.

Evidence for insect vectors of leprosy includes the demonstration that bedbugs and mosquitoes in the vicinity of leprosaria regularly harbor *M. leprae* and that experimentally infected mosquitoes can transmit infection to mice. Skin-to-skin contact is generally not considered an important route of transmission.

In endemic countries, ~50% of leprosy patients have a history of intimate contact with an infected person (often a household member), while, for unknown reasons, leprosy patients in nonendemic locales can identify such contact only 10% of the time. Moreover, household contact with an infected lepromatous case carries an eventual risk of disease acquisition of ~10% in endemic areas as opposed to only 1% in nonendemic locales. Contact with a tuberculoid case carries a very low risk. Physicians and nurses caring for leprosy patients and the coworkers of these patients are not at risk for leprosy.

M. leprae causes disease primarily in humans. However, in Texas and Louisiana, 15% of nine-banded armadillos are infected, and armadillo contact occasionally results in human disease; armadillos develop a disseminated infection following intravenous inoculation of live *M. leprae*.

CLINICAL, HISTOLOGIC, AND IMMUNOLOGIC SPECTRUM The incubation period prior to manifestation of clinical disease can vary between 2 and 40 years, although it is generally 5 to 7 years in duration. Leprosy presents as a spectrum of clinical manifestations that have bacteriologic, pathologic, and immunologic counterparts. The spectrum from polar tuberculoid (TT) to borderline tuberculoid (BT) to mid-borderline (BB, which is rarely encountered) to borderline lepromatous (BL) to polar lepromatous (LL) disease is associated with an evolution from asymmetric localized macules and plaques to nodular and indurated symmetric generalized skin manifestations, an increasing bacterial

TABLE 151-1 *Clinical, Bacteriologic, Pathologic, and Immunologic Spectrum of Leprosy*

Clinical and Histologic Features	Tuberculoid (TT) Leprosy	Borderline Tuberculoid (BT) Leprosy	Mid-Borderline (BB) Leprosy	Borderline Lepromatous (BL) Leprosy	Lepromatous (LL) Leprosy
Skin Lesions	Up to 3 in number; sharply defined asymmetric macules or plaques with tendency toward central clearing, elevated borders	Smaller or larger than in TT; potentially more numerous than in TT; usually annular lesions with sharp margination on exterior and interior borders; borders not as elevated as in TT	Dimorphic lesions intermediate between BT and BL	LL-type lesions; ill-defined plaques with an occasional sharp margin; few or many in number, shiny appearance	Symmetric, poorly marginated, multiple infiltrated nodules and plaques or diffuse infiltration; xanthoma-like or dermatofibroma papules; leonine facies and eyebrow alopecia
Nerve lesions	Skin lesions anesthetic early; nerve near lesions sometimes enlarged	Skin lesions anesthetic early; nerve trunk palsies asymmetric; nerve abscesses most common in BT	Anesthetic skin lesions; nerve trunk palsies	Skin lesions usually hypoesthetic, may be anesthetic; nerve trunk palsies common and frequently symmetric	Hypesthesia a late sign; nerve palsies variable; acral, distal, symmetric anesthesia common
Acid-fast bacilli (BI)	3	0–1+	3–4+	4–5+	4–6+
Lymphocytes	3+	2+	1+	1+	0–1+
Macrophage differentiation	Epithelioid	Epithelioid	Epithelioid	Usually undifferentiated; epithelioid foci sometimes present; may show foamy change	Foamy change the rule; may be undifferentiated in early lesions
Langhans' giant cells	1–3+	2+	—	—	—
Lepromin skin test	+++	+++	—	—	—
Lymphocyte transformation test	95%	40%	10%	1–2%	1–2%
CD4+/CD8+ T-cell ratio in lesions	1.35	1.11	NT	0.48	0.50
M. leprae PGL-1 antibodies	1+ (60%+)	2+	2+	3+	3+ (95%+)

Abbreviations: BI, bacteriologic index; PGL-1, phenolic glycolipid 1.

load, and loss of *M. leprae*–specific cellular immunity (Table 151-1). Distinguishing dermatopathologic characteristics include the number of lymphocytes, giant cells, and AFB as well as the nature of epithelioid cell differentiation. Where a patient presents on the clinical spectrum largely determines prognosis, complications, reactional states, and the intensity of antimicrobial therapy required.

Tuberculoid Leprosy At the less severe end of the spectrum is tuberculoid leprosy, which encompasses TT and BT disease. In general, these forms of leprosy result in symptoms confined to the skin and peripheral nerves. The skin lesions of tuberculoid leprosy consist of one or a few hypopigmented macules or plaques that are sharply demarcated and hypesthetic, often have erythematous or raised borders, and are devoid of the normal skin organs (sweat glands and hair follicles) and thus are dry, scaly, and anhidrotic. AFB are generally absent or few in number. Tuberculoid leprosy patients may have asymmetric enlargement of one or a few peripheral nerves. Indeed, leprosy and certain rare hereditary neuropathies are the only human diseases associated with peripheral-nerve enlargement. Although any peripheral nerve may be enlarged (including small digital and supraclavicular nerves), those most commonly affected are the ulnar, posterior auricular, peroneal, and posterior tibial nerves, with associated hypesthesia and myopathy. TT leprosy is the most common form of the disease encountered in India and Africa but is virtually absent in Southeast Asia, where BT leprosy is frequent.

In tuberculoid leprosy, T cells breach the perineurium, and destruction of Schwann cells and axons may be evident, resulting in fibrosis of the epineurium, replacement of the endoneurium with epithelial granulomas, and occasionally caseous necrosis. Such invasion and destruction of nerves in the dermis by T cells are pathognomonic for leprosy.

Circulating lymphocytes from patients with tuberculoid leprosy readily recognize *M. leprae* and its constituent proteins, and patients have positive lepromin skin tests (see "Diagnosis," below). In tuberculoid leprosy tissue, there is a 2:1 predominance of helper CD4+ over CD8+ T lymphocytes. Tuberculoid tissues are rich in the mRNAs of the proinflammatory T_H1 family of cytokines: interleukin (IL) 2, interferon γ (IFN-γ), and IL-12; in contrast, IL-4, IL-5, and IL-10 mRNAs are scarce.

Lepromatous Leprosy Lepromatous leprosy patients present with symmetrically distributed skin nodules, raised plaques, or diffuse dermal infiltration, which, when on the face, results in leonine facies. Late manifestations include loss of eyebrows (initially the lateral margins only; Fig. 151-1) and eyelashes, pendulous earlobes, and dry scaling skin, particularly on the feet. In LL leprosy, bacilli are numerous in the skin (as many as 10^9/g), where they are often found in large clumps (*globi*), and in peripheral nerves, where they initially invade Schwann cells, resulting in foamy degenerative myelination and axonal degeneration and later in Wallerian degeneration. In addition, bacilli are plentiful in circulating blood and in all organ systems except the lungs and the central nervous system. Nevertheless, patients are afebrile, and there is no evidence of major organ system dysfunction. Almost exclusively found in western Mexico and the Caribbean is a form of lepromatous leprosy without visible skin lesions but with diffuse dermal infiltration and a demonstrably thickened dermis, termed *diffuse lepromatosis*. In lepromatous leprosy, nerve enlargement and damage tend to be symmetric, result from actual bacillary invasion, and are more insidious but ultimately more extensive than in tuberculoid leprosy. Patients with LL leprosy have acral, distal, symmetric peripheral neuropathy and a tendency toward symmetric nerve-trunk enlargement. They may also have signs and symptoms related to involvement of the upper respiratory tract, the anterior chamber of the eye, and the testes.

In untreated LL patients, lymphocytes regularly fail to recognize either *M. leprae* or its protein constituents, and lepromin skin tests are negative (see "Diagnosis," below). This loss of protective cellular immunity appears to be antigen-specific, as patients are not unusually susceptible to opportunistic infections, cancer, or AIDS and maintain delayed-type hypersensitivity to *Candida*, *Trichophyton*, mumps, tetanus toxoid, and even purified protein derivative of tuberculin. At times, *M. leprae*–specific anergy is reversible with effective chemotherapy. In LL tissues, there is a 2:1 ratio of CD8+ to CD4+ T lymphocytes. LL tissues demonstrate a T_H2 cytokine profile, being rich in mRNAs for IL-4, IL-5, and IL-10 and poor in those for IL-2, IFN-γ, and IL-12. It appears that cytokines mediate a protective tissue response in leprosy, as injection of IFN-γ or IL-2 into lepromatous lesions causes a loss of AFB and histopathologic conversion toward a tuberculoid pattern. Macrophages of lepromatous leprosy patients appear to be functionally intact; circulating monocytes exhibit normal microbicidal function and responsiveness to IFN-γ.

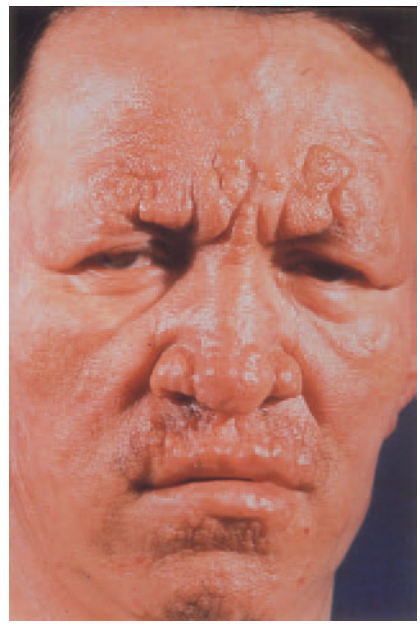

FIGURE 151-1 A patient with features of polar lepromatous leprosy: multiple nodular skin lesions, particularly of the forehead, and loss of eyebrows.

Reactional States Lepra reactions comprise several common immunologically mediated inflammatory states that cause considerable morbidity. Some of these reactions precede diagnosis and the institution of effective antimicrobial therapy. Indeed, these reactions may precipitate presentation for medical attention and diagnosis; others occur after the initiation of appropriate chemotherapy. In the latter circumstances, patients often lose confidence in conventional therapy, perceiving that their leprosy is worsening. Only by warning patients of the potential for these reactions and describing their manifestations can physicians treating leprosy patients ensure continued credibility.

TYPE 1 LEPRA REACTIONS (DOWNGRADING AND REVERSAL REACTIONS) These reactions occur in almost half of patients with borderline forms of leprosy but not in patients with polar disease. Manifestations include classic signs of inflammation within previously involved macules, papules, and plaques and, on occasion, the appearance of new skin lesions, neuritis, and (less commonly) fever—generally low-grade. The nerve trunk most commonly involved in this process is the ulnar nerve at the elbow, which may be painful and exquisitely tender. If patients with affected nerves are not treated promptly with glucocorticoids (see below), irreversible nerve damage may result in as little as 24 h. The most dramatic manifestation is footdrop, which occurs when the peroneal nerve is involved.

When type 1 lepra reactions precede the initiation of appropriate antimicrobial therapy, they are termed *downgrading reactions*, and the case becomes histologically more lepromatous; when they occur after the initiation of therapy, they are termed *reversal reactions*, and the case becomes more tuberculoid. Reversal reactions often occur in the first months or years after the initiation of therapy but may also develop several years thereafter.

Edema is the most characteristic microscopic feature of type 1 lepra

lesions, whose diagnosis is primarily clinical. Reversal reactions are typified by a T_H1 cytokine profile, with an influx of CD4+ helper cells and increased levels of IFN-γ and IL-2. In addition, type 1 reactions are associated with large numbers of T cells bearing γ/∂ receptors—a unique feature of leprosy.

TYPE 2 LEPRA REACTIONS (ERYTHEMA NODOSUM LEPROTICUM, ENL) ENL occurs exclusively in patients near the lepromatous end of the leprosy spectrum (BL-LL), affecting nearly 50% of this group. Although ENL may precede leprosy diagnosis and initiation of therapy—sometimes, in fact, prompting the diagnosis—in 90% of cases it follows the institution of chemotherapy, generally within 2 years. The most common features of ENL are crops of painful erythematous papules that resolve spontaneously in a few days to a week but may recur; malaise; and fever that can be profound. However, patients may also experience symptoms of neuritis, lymphadenitis, uveitis, orchitis, and glomerulonephritis and may develop anemia, leukocytosis, and abnormal liver function tests, particularly increased aminotransferase levels. Individual patients may have either a single bout of ENL or chronic recurrent manifestations. Bouts may be either mild or severe and generalized; in rare instances, ENL results in death.

Skin biopsy of ENL papules reveals vasculitis or panniculitis, sometimes with many lymphocytes but characteristically with polymorphonuclear leukocytes as well.

Elevated levels of circulating tumor necrosis factor (TNF) have been demonstrated in ENL; thus, TNF may play a central role in the pathobiology of this syndrome. ENL is thought to be a consequence of immune complex deposition, given its T_H2 cytokine profile and its high levels of IL-6 and IL-8. However, in ENL tissue, the presence of HLA Dr framework antigen of epidermal cells—considered a marker for a delayed-type hypersensitivity response—and evidence for higher levels of IL-2 and IFN-γ than are usually seen in polar lepromatous disease suggest an alternative mechanism.

LUCIO'S PHENOMENON This unusual reaction is seen exclusively in patients from the Caribbean and Mexico who have the diffuse lepromatosis form of lepromatous leprosy, most often those who are untreated. Patients with this reaction develop recurrent crops of large, sharply marginated, ulcerative lesions—particularly on the lower extremities—that may be generalized and, when so, are frequently fatal as a result of secondary infection and consequent septic bacteremia. Histologically, the lesions are characterized by ischemic necrosis of the epidermis and superficial dermis, heavy parasitism of endothelial cells with AFB, and endothelial proliferation and thrombus formation in the larger vessels of the deeper dermis. Like ENL, the Lucio phenomenon is probably mediated by the immune complex.

Complications ■ *THE EXTREMITIES* Complications of the extremities in leprosy patients are primarily a consequence of neuropathy leading to insensitivity and myopathy. Insensitivity affects fine touch, pain, and heat receptors but generally spares position and vibration appreciation. The most commonly affected nerve trunk is the ulnar nerve at the elbow, whose involvement results in clawing of the fourth and fifth fingers, loss of dorsal interosseous musculature in the affected hand, and loss of sensation in these distributions. Median nerve involvement in leprosy impairs thumb opposition and grasp, while radial nerve dysfunction, though rare in leprosy, leads to wristdrop. Tendon transfers can restore hand function but should not be performed until 6 months after the initiation of antimicrobial therapy and the conclusion of episodes of acute neuritis.

Plantar ulceration, particularly at the metatarsal heads, is probably the most frequent complication of leprous neuropathy. Therapy requires careful debridement; administration of appropriate antibiotics; avoidance of weight-bearing until ulcerations are healed, with slowly progressive ambulation thereafter; and wearing of specialized shoes to prevent recurrence.

Footdrop as a result of peroneal nerve palsy should be treated with a simple nonmetallic brace within the shoe or surgical correction attained by tendon transfers. Although uncommon, Charcot's joints, particularly of the foot and ankle, may result from leprosy.

The loss of distal digits in leprosy is a consequence of insensitivity, trauma, secondary infection, and—in lepromatous patients—a poorly understood and sometimes profound osteolytic process. Conscientious protection of the extremities during cooking and work and the early institution of therapy have substantially reduced the frequency and severity of distal digit loss in recent times.

THE NOSE In lepromatous leprosy, bacillary invasion of the nasal mucosa can result in chronic nasal congestion and epistaxis. Saline nose drops may relieve these symptoms. Long-untreated LL leprosy may further result in destruction of the nasal cartilage, with consequent saddle-nose deformity or anosmia (more common in the preantibiotic era than at present). Nasal reconstructive procedures can ameliorate significant cosmetic defects.

THE EYE Owing to cranial nerve palsies, lagophthalmus and corneal insensitivity may complicate leprosy, resulting in trauma, secondary infection, and (without treatment) corneal ulcerations and opacities. For patients with these conditions, eyedrops during the day and ointments at night provide some protection from such consequences. Furthermore, in LL leprosy, the anterior chamber of the eye is invaded by bacilli, and ENL may result in uveitis, with consequent cataracts and glaucoma. Thus leprosy is a major cause of blindness in the developing world. Slit-lamp evaluation of LL patients often reveals "corneal beading," representing globi of *M. leprae*.

THE TESTES *M. leprae* invades the testes, while ENL may cause orchitis. Thus males with lepromatous leprosy often manifest mild to severe testicular dysfunction, with an elevation of luteinizing and follicle-stimulating hormones, decreased testosterone, and aspermia or hypospermia in 85% of LL patients but in only 25% of BL patients. LL patients may become impotent and infertile. Impotence is sometimes responsive to testosterone replacement.

AMYLOIDOSIS Secondary amyloidosis is a complication of LL leprosy and ENL that is encountered infrequently in the antibiotic era. This complication may result in abnormalities of hepatic and particularly renal function.

NERVE ABSCESSES Patients with various forms of leprosy, but particularly those with the BT form, may develop abscesses of nerves (most commonly the ulnar) with an adjacent cellulitic appearance of the skin. In such conditions, the affected nerve is swollen and exquisitely tender. Although glucocorticoids may reduce signs of inflammation, rapid surgical decompression is necessary to prevent irreversible sequelae.

DIAGNOSIS Leprosy most commonly presents with both characteristic skin lesions and skin histopathology. Thus the disease should be suspected when a patient from an endemic area has suggestive skin lesions or peripheral neuropathy; the diagnosis should be confirmed by histopathology. In tuberculoid leprosy, lesional areas—preferably the advancing edge—must be biopsied because normal-appearing skin does not have pathologic features. In lepromatous leprosy, nodules, plaques, and indurated areas are optimal biopsy sites, but biopsies of normal-appearing skin are also generally diagnostic. Lepromatous leprosy is associated with diffuse hyperglobulinemia, which may result in false-positive serologic tests (e.g., VDRL, RA, ANA) and therefore may cause diagnostic confusion. On occasion, tuberculoid lesions may not (1) appear typical, (2) be hypesthetic, and (3) contain granulomas but only nonspecific lymphocytic infiltrates. In such instances, two of these three characteristics are considered sufficient for a diagnosis. It is preferable to overdiagnose leprosy rather than to allow a patient to remain untreated.

IgM antibodies to PGL-1are found in 95% of untreated lepromatous leprosy patients; the titer decreases with effective therapy. However, in tuberculoid leprosy—the form of disease most often associated with diagnostic uncertainty owing to the absence or paucity of AFB—patients have significant antibodies to PGL-1 only 60% of the time; moreover, in endemic locales, exposed individuals without

clinical leprosy may harbor antibodies to PGL-1. Thus PGL-1 serology is of little diagnostic utility in tuberculoid leprosy. Heat-killed *M. leprae* (lepromin) has been used as a skin test reagent. It generally elicits a reaction in tuberculoid leprosy patients, may do so in individuals without leprosy, and gives negative results in lepromatous leprosy patients; consequently, it is likewise of little diagnostic value. Unfortunately, PCR of the skin for *M. leprae*, although positive in LL and BL leprosy, yields negative results in 50% of tuberculoid leprosy cases, again offering little diagnostic assistance.

Included in the differential diagnosis of lesions that resemble leprosy are sarcoidosis, leishmaniasis, lupus vulgaris, lymphoma, syphilis, yaws, granuloma annulare, and various other disorders causing hypopigmentation. Sarcoidosis may result in perineural inflammation, but actual granuloma formation within dermal nerves is pathognomonic for leprosy. In lepromatous leprosy, sputum specimens may be loaded with AFB—a finding that can be inappropriately interpreted as representing pulmonary tuberculosis.

TREATMENT

Antimicrobial Therapy ■ *ACTIVE AGENTS* Established agents used to treat leprosy include dapsone (50 to 100 mg/d), clofazimine (50 to 100 mg/d, 100 mg three times weekly, or 300 mg monthly), and rifampin (600 mg daily or monthly). Of these drugs, only rifampin is bactericidal. The sulfones (folate antagonists), the foremost of which is dapsone, were the first antimicrobials found to be effective for the treatment of leprosy and are still the mainstay of therapy. With sulfone treatment, skin lesions resolve and numbers of viable bacilli in the skin are reduced. Although primarily bacteriostatic, dapsone monotherapy results in only a 2.5% resistance-related relapse rate; after ≥18 years of therapy and subsequent discontinuation, only another 10% of patients relapse, developing new, usually asymptomatic, shiny, "histoid" nodules. Dapsone is generally safe and inexpensive. Individuals with glucose-6-phosphate dehydrogenase deficiency who are treated with dapsone may develop severe hemolysis; those without this deficiency also have reduced red cell survival and a hemoglobin decrease averaging 1 g/dL. Dapsone's usefulness is limited occasionally by allergic dermatitis and rarely by the sulfone syndrome (including high fever, anemia, exfoliative dermatitis, and a mononucleosis-type blood picture). It must be remembered that rifampin induces microsomal enzymes, necessitating increased doses of medications such as glucocorticoids and oral birth control regimens. Clofazimine is often cosmetically unacceptable to light-skinned leprosy patients because it causes a red-black skin discoloration that accumulates, particularly in lesional areas, and makes the patient's diagnosis obvious to members of the community.

Other antimicrobial agents active against *M. leprae* in animal models and at the usual daily doses used in clinical trials include ethionamide/prothionamide; the aminoglycosides streptomycin, kanamycin, and amikacin (but not gentamicin or tobramycin); minocycline; clarithromycin; and several fluoroquinolones, particularly ofloxacin. Next to rifampin, minocycline, clarithromycin, and ofloxacin appear to be most bactericidal for *M. leprae*, but these drugs have not been used extensively in leprosy control programs. Most recently, rifapentine and moxifloxacin have been found to be especially potent against *M. leprae*.

CHOICE OF REGIMENS Antimicrobial therapy for leprosy must be individualized, depending on the clinical/pathologic form of the disease encountered. Tuberculoid leprosy, which is associated with a low bacterial burden and a protective cellular immune response, is the easier form to treat and can be reliably cured with a finite course of chemotherapy. In contrast, lepromatous leprosy may have a higher bacillary load than any other human bacterial disease, and the absence of a salutary T cell repertoire requires prolonged or even lifelong chemotherapy. Hence, careful classification of disease prior to therapy is important. In developed countries, clinical experience with leprosy classification is limited; fortunately, however, the resources needed for skin biopsy are highly accessible and pathologic interpretation is readily available. In developing countries, clinical expertise is greater but is now waning substantially as the care of leprosy patients is integrated into general health services. In addition, access to dermatopathology services is often limited. In such instances, skin smears may prove useful, but in many locales access to the resources needed for their preparation and interpretation may also be unavailable. Use of skin smears is no longer encouraged by the World Health Organization (WHO) and is often replaced by mere counting of lesions, which, together with the lack of histopathology, may negatively affect decisions about chemotherapy, increase the potential for reactions, and worsen the ultimate prognosis.

A reasoned approach to the treatment of leprosy is confounded by these and several other issues:

1. Even without therapy, TT leprosy may heal spontaneously, and prolonged dapsone monotherapy (even for LL leprosy) is generally curative in 80% of cases.
2. In tuberculoid disease, there are often no bacilli found in the skin prior to therapy, and thus there is no objective measure of therapeutic success. Furthermore, despite adequate treatment, TT and particularly BT lesions often resolve little or incompletely, while relapse and late type 1 lepra reactions can be difficult to distinguish.
3. LL leprosy patients commonly harbor viable persistent *M. leprae* organisms after prolonged intensive therapy; the propensity of these organisms to initiate clinical relapse is unclear. Because relapse in LL patients after discontinuation of rifampin-containing regimens usually begins only after 7 to 10 years, follow-up over the very long term is necessary to assess ultimate clinical outcomes.
4. Even though primary dapsone resistance is exceedingly rare and multidrug therapy is generally recommended (at least for lepromatous leprosy), there is a paucity of information from experimental animals and clinical trials on the optimal combination of antimicrobials, dosing schedule, or duration of therapy.

In 1982, the WHO made recommendations for "the chemotherapy of leprosy for control programs." These recommendations came on the heels of the demonstration of the relative success of long-term dapsone monotherapy and in the context of concerns about dapsone resistance. Other complicating considerations included the limited resources available for leprosy care in the very areas where it is most prevalent and the frustration and discouragement of patients and program managers with the previous requirement for lifelong therapy for many leprosy patients. The WHO delineated for the first time a finite duration of therapy for all forms of leprosy and—given the prohibitive cost of daily rifampin treatment in developing countries—encouraged the monthly administration of this agent as part of a multidrug regimen.

Over the ensuing years, these WHO recommendations have been broadly implemented, and the duration of therapy required, particularly for lepromatous leprosy, has been progressively shortened. For treatment purposes, the WHO classifies patients as paucibacillary and multibacillary. Previously, patients without demonstrable AFB in the dermis were classified as paucibacillary and those with AFB as multibacillary. Currently, owing to the perceived unreliability of skin smears in the field, patients are classified as multibacillary if they have six or more skin lesions and as paucibacillary if they have fewer. The WHO recommends that paucibacillary adults be treated with 100 mg of dapsone daily and 600 mg of rifampin monthly (supervised) for 6 months (Table 151-2). For patients with single-lesion paucibacillary leprosy, the WHO recommends as an alternative a single dose of rifampin (600 mg), ofloxacin (400 mg), and minocycline (100 mg). Multibacillary adults should be treated with 100 mg of dapsone plus 50 mg of clofazimine daily (unsupervised) and with 600 mg of rifampin plus 300 mg of clofazimine monthly (supervised). Originally, the WHO recommended that lepromatous patients be treated for 2 years or until smears became negative (generally in ~5 years); subsequently,

TABLE 151-2 *Antimicrobial Regimens Recommended for the Treatment of Leprosy in Adults*

Form of Leprosy	More Intensive Regimen	WHO Recommended Regimen (1982)
Tuberculoid (paucibacillary)	Dapsone (100 mg/d) for 5 years	Dapsone (100 mg/d, unsupervised) *plus* rifampin (600 mg/month, supervised) for 6 months
Lepromatous (multibacillary)	Rifampin (600 mg/d) for 3 years *plus* dapsone (100 mg/d) indefinitely	Dapsone (100 mg/d) *plus* clofazimine (50 mg/d), unsupervised; *and* rifampin (600 mg) *plus* clofazimine (300 mg) monthly (supervised) for 1–2 years

Note: See text for discussion and comparison of WHO recommendations and more intensive approach as well as alternative WHO regimen for single-lesion paucibacillary leprosy.

the acceptable course was reduced to 1 year—a change that remains especially controversial in the absence of supporting clinical trials.

Several factors have caused many authorities to question the WHO recommendations and to favor a more intensive approach. Among these factors are—for multibacillary patients—a high (double-digit) relapse rate in three locales (reaching 20 to 40% in one locale, with the rate directly related to the initial bacterial burden) and—for paucibacillary patients—demonstrable lesional activity for years in fully half of patients after the completion of therapy. The more intensive approach (Table 151-2) calls for tuberculoid leprosy to be treated with dapsone (100 mg/d) for 5 years and for lepromatous leprosy to be treated with rifampin (600 mg/d) for 3 years and with dapsone (100 mg/d) throughout life.

On effective antimicrobial therapy, new skin lesions and signs and symptoms of peripheral neuropathy cease appearing. Nodules and plaques of lepromatous leprosy noticeably flatten in 1 to 2 months and resolve in 1 year or a few years, while tuberculoid skin lesions may disappear, improve, or remain relatively unchanged. Although the peripheral neuropathy of leprosy may improve somewhat in the first few months of therapy, rarely is it significantly ameliorated by treatment.

Therapy for Reactions ■ *TYPE 1* Type 1 lepra reactions are best treated with glucocorticoids (e.g., prednisone, initially at doses of 40 to 60 mg/d). As the inflammation subsides, the glucocorticoid dose can be tapered, but steroid therapy must be continued for at least 3 months lest recurrence supervene. Because of the myriad toxicities of prolonged glucocorticoid therapy, the indications for its initiation are strictly limited to lesions whose intense inflammation poses a threat of ulceration; lesions at cosmetically important sites, such as the face; and cases in which neuritis is present. Mild to moderate lepra reactions that do not meet these criteria should be tolerated and glucocorticoid treatment withheld. Thalidomide is ineffective against type 1 lepra reactions; clofazimine (200 to 300 mg/d) is of questionable benefit but in any event is far less efficacious than glucocorticoids.

TYPE 2 Treatment of ENL must be individualized. If ENL is mild (i.e., without fever or other organ involvement, with occasional crops of only a few skin papules), it may be treated with antipyretics alone. However, in cases with many skin lesions, fever, malaise, and other tissue involvement, brief courses (1 to 2 weeks) of glucocorticoids (initially 40 to 60 mg/d) are often effective. With or without therapy, individual inflamed papules last for >1 week. Successful therapy is defined by the cessation of skin lesion development and the disappearance of other systemic signs and symptoms. If, despite two courses of glucocorticoid therapy, ENL appears to be recurring and persisting, treatment with thalidomide (100 to 300 mg nightly) should be initiated, with the dose depending on the initial severity of the reaction. Because even a single dose of thalidomide administered early in pregnancy may result in severe birth defects, including phocomelia, the use of this drug in the United States for the treatment of fertile female patients is tightly regulated and requires informed consent, prior pregnancy testing, and maintenance of birth control measures. Although the mechanism of thalidomide's dramatic action against ENL is not entirely clear, the drug's efficacy is probably attributable to its reduction of TNF levels and IgM synthesis and its slowing of polymorphonuclear leukocyte migration. After the reaction is controlled, lower doses of thalidomide (50 to 200 mg nightly) are effective in preventing relapses of ENL. Clofazimine in high doses (300 mg nightly) has some efficacy against ENL, but its use permits only a modest reduction of the glucocorticoid dose necessary for ENL control.

LUCIO'S PHENOMENON Neither glucocorticoids nor thalidomide is effective against this syndrome. Optimal wound care and therapy for bacteremia are indicated. Ulcers tend to be chronic and heal poorly. In severe cases, exchange transfusion may prove useful.

PREVENTION AND CONTROL Vaccination at birth with bacille Calmette-Guérin (BCG) has proved variably effective in preventing leprosy: the results have ranged from total inefficacy to 80% efficacy. The addition of heat-killed *M. leprae* to BCG does not increase vaccine efficacy. Because whole mycobacteria contain large amounts of lipids and carbohydrates that have proven in vitro to be immunosuppressive for lymphocytes and macrophages, *M. leprae* proteins may prove to be superior vaccines. Data from a mouse model support this possibility.

Chemoprophylaxis with dapsone may reduce the number of cases of tuberculoid leprosy but not of lepromatous leprosy and hence is not recommended, even for household contacts. Because leprosy transmission appears to require close prolonged household contact, hospitalized patients need not be isolated.

In 1992, the WHO—on the basis of that organization's treatment recommendations—launched a landmark campaign to eliminate leprosy as a public health problem by the year 2000 (goal, <1 case per 10,000 population). The campaign mobilized and energized nongovernmental organizations and national health services to treat leprosy with multiple drugs and to clean up outdated registries; in these respects, the effort has proven hugely successful, with >6 million patients completing therapy. However, the target of leprosy elimination has not yet been reached. In fact, the success of the WHO campaign in reducing the number of cases worldwide has been largely attributable to the redefinition of what constitutes a case of leprosy: Formerly calculated by disease prevalence, the case count is now limited to those not yet treated with multiple drugs. In each of the 23 countries with the largest number of leprosy cases, the annual incidence of leprosy is stable or actually rising. Furthermore, after the completion of therapy, when a patient is no longer considered to represent a "case," half of all patients continue to manifest disease activity for years; relapse rates (at least for multibacillary patients) are unacceptably high; disabilities and deformities go unchecked; and the social stigma of the disease persists.

During most of the twentieth century, nongovernmental organizations, particularly Christian missionaries, provided a medical infrastructure devoted to the care and treatment of leprosy patients—the envy of those with other medical priorities in the developing world. With the public perception that leprosy is near eradication, resources for patient care are rapidly being diverted, and the burden of patient care is being transferred to nonexistent or overloaded national health services and to health workers who lack the tools and skills needed for disease diagnosis, classification, and nuanced therapy (particularly in cases of reactional neuritis). Thus the prerequisites for a salutary outcome are increasingly unmet.

152 NONTUBERCULOUS MYCOBACTERIA

C. Fordham von Reyn

The designation *nontuberculous mycobacteria* (NTM) encompasses the mycobacterial species other than organisms of the *Mycobacterium tuberculosis* complex and *M. leprae*. The NTM are distributed widely in the environment, are typically acquired from environmental sources, and therefore are also referred to as *environmental mycobacteria*. Most species are less virulent for humans than is *M. tuberculosis*. Thus symptomatic infections are often associated with local or generalized defects in host defenses. Because isolation of an NTM species from a clinical specimen may represent true infection, colonization, or environmental contamination, strict criteria are required to assess the clinical significance of a positive culture. Although the >90 species of NTM have been associated with a wide variety of infections, most NTM infections are due to a relatively limited number of species that cause characteristic patterns of disease (Table 152-1).

MICROBIOLOGY Similar to *M. tuberculosis*, NTM organisms resist decolorization after staining and are referred to as *acid-fast bacilli* (AFB). NTM have conventionally been characterized by the time required for clinical specimens to yield visible growth on solid media. Rapidly growing NTM species, such as *M. abscessus*, *M. fortuitum*, and *M. chelonae*, appear within 7 days. These organisms grow on standard microbiologic media and thus may be reported even when the clinician has not explicitly requested cultures for mycobacteria. Slow-growing species, in contrast, often take 2 to 3 weeks to grow on solid media and require special mycobacterial media such as Lowenstein-Jensen or Middlebrook. Accordingly, slow-growing NTM species are usually isolated only when the clinician specifically requests cultures for mycobacteria. Representative species include *M. avium*, *M. kansasii*, *M. ulcerans*, and *M. marinum*. Automated broth culture systems are now used in many laboratories and may permit isolation of slow-growing NTM organisms within 10 to 14 days, thus tending to blur species distinctions based on growth rate.

Further classification based on colony pigmentation (Runyon classification) has been replaced by the use of DNA probes for identification of common species such as *M. avium*, *M. intracellulare*, *M. gordonae* (which is rarely pathogenic), and *M. kansasii*. Less common species may be identified rapidly on the basis of fatty acid composition or DNA sequencing. Molecular strain typing ("fingerprinting") based on analysis of polymorphisms among large restriction fragments can be used to determine whether two or more isolates are genotypically—and, by implication, epidemiologically—related. This technique has been useful for identifying common-source outbreaks of infection or contamination.

Antibiotic susceptibility testing should be performed for rapidly growing NTM species. However, susceptibility testing of slow-growing species is of limited value: testing methods are not well standardized, and the relevance of the results to outcome is uncertain since patients are usually treated with multiple-drug regimens. Testing of *M. avium* or *M. kansasii* for susceptibility to specific drugs may be useful in certain situations (see below).

DISTRIBUTION NTM have a waxy, hydrophobic, triple-layered cell wall that renders them unusually resistant to physical conditions and chemical agents (including disinfectants such as chlorine at concentrations used in drinking water). These organisms can make use of a wide variety of carbon and nitrogen sources and can survive in nutrient-poor environments. Thus they are widely distributed in water, biofilms, and soil as well as in numerous animal species. Optimal growth temperatures vary and may influence distribution. For example, *M. avium* and *M. intracellulare* are often isolated from potable hot-water sources, whereas *M. marinum* is found in the cooler water of fish tanks. Most species of NTM are obligate aerobes and grow best at acid pH. Soil and natural water samples from most regions of the world contain numerous species of NTM, which are as common in northern regions (e.g., Finland) as they are in more temperate areas (e.g., the southern United States).

EPIDEMIOLOGY Asymptomatic infections with NTM are common in humans and are probably acquired most often from childhood contact with soil, water, and possibly animals. Studies with skin tests derived from NTM indicate that 30 to 40% of adults in the northern and southern United States have had prior unrecognized or asymptomatic infection with NTM—most often with organisms of the *M. avium* complex (MAC). Since latent infection is not a recognized characteristic of NTM, most symptomatic infections are thought to represent recent exposure. Molecular methods have identified clusters of infections and pseudoinfections associated with potable water as well as with clinical procedures such as endoscopy and surgery. Environmental exposures are assumed to cause most symptomatic infections; however, this point has been difficult to document by molecular methods, presumably because there are many potential exposures (some of which are sporadic) and because a specific NTM species may be present only transiently or in low numbers in any given source.

TABLE 152-1 Main Species of NTM and Patterns of Disease

Species	Growth on Solid Media	Environmental Reservoir	Patterns of Disease[a]			
			Cutaneous	Pulmonary	Disseminated	Other
M. avium	Slow	Hot water systems, natural water, soil	−	++	+++	Lymphadenitis
M. intracellulare	Slow	Hot water systems, natural water, soil	−	+++	+	Lymphadenitis
M. kansasii	Slow	Potable and natural water	−	+++	++	−
M. abscessus, *M. chelonae*, *M. fortuitum*	Rapid	Potable and natural water, soil	++	+	−	Sporotrichoid spread
M. marinum	Slow	Fish tanks, salt water	++	−	−	Sporotrichoid spread
M. ulcerans	Slow	Natural water	++	−	−	"Buruli ulcer," osteomyelitis

[a] Symbols indicate relative prevalence among NTM infections of the indicated species and pattern of disease: +++, most common; ++, common; +, reported but uncommon; −, rare or not reported.

PATHOGENESIS NTM may be acquired through cutaneous, respiratory, gastrointestinal, or (rarely) parenteral exposure. Organisms are ingested by host macrophages and may survive within these cells to replicate and cause symptomatic infection. Disease manifestations in immunocompetent hosts are due to host cellular immune responses and the formation of granulomas. Intracellular killing of mycobacteria, with ultimate control of infection, requires the action of cellular immune mechanisms including proliferation of CD4+ T lymphocytes and elaboration of interferon γ (IFN-γ) and interleukin 12. Deficiencies in CD4+ T cell function due to HIV infection and inherited deficiencies in the production of or response to IFN-γ are associated with disseminated NTM infection (Chap. 173).

There is no convincing evidence that NTM can establish latent infection with subsequent clinical reactivation—a pattern characteristic of *M. tuberculosis*. Asymptomatic infection with NTM in a healthy host may induce beneficial immunity; persons with skin-test reactivity to NTM antigens (e.g., *M. intracellulare*) are at decreased risk for the subsequent development of tuberculosis. Likewise, immunization with bacille Calmette-Guérin (BCG) from *M. bovis* provides protection against childhood cervical adenitis due to NTM.

CLINICAL SYNDROMES ■ Cutaneous Disease NTM can cause a variety of cutaneous disease syndromes when directly inoculated from an environmental source into an area of open or diseased skin or into a surgical wound. *M. abscessus*, *M. fortuitum*, *M. chelonae*, *M. marinum*, and *M. ulcerans* are the most commonly involved species. Cutaneous disease may be nodular or ulcerating, sometimes with reddish-blue discoloration and typically with minimal drainage. Lesions may be single, or the infection may spread proximally up the lymphatics, producing additional nodules (sporotrichoid spread). In compromised hosts, disseminated lesions may appear as a result of bacteremic spread. Clinical suspicion of NTM infection is based on chronicity, the absence of bacterial growth on routine culture, and the failure to respond to standard antibacterial therapy. Biopsies often reveal granuloma formation, and acid-fast stains may be positive.

Pulmonary Disease NTM species cause chronic progressive pulmonary infection both in normal hosts and in those with underlying pulmonary disease. The clinical features may resemble slowly progressive pulmonary tuberculosis, which is often the initial diagnosis in patients with positive AFB smears. Among patients born in the United States, pulmonary disease due to acid-fast organisms is more likely to be due to NTM than to *M. tuberculosis*.

The diagnosis of pulmonary NTM infection is complicated by the variability in clinical and radiologic manifestations, the frequent presence of significant prior pulmonary disease, and the fact that isolation of NTM from the sputum may represent harmless colonization of the lower respiratory tract. The diagnosis should be based on specific, validated criteria that emphasize a compatible clinical syndrome, characteristic findings on computed tomography (CT), and repeated isolation of NTM from the sputum or growth of NTM from a lung biopsy (Table 152-2).

In normal hosts, infection may result in the onset of chronic cough, dyspnea, and fatigue; fever is unusual. Pathologic and radiologic manifestations of NTM pulmonary infection include the formation of solitary or multiple nodules, chronic pneumonitis, bronchiectasis, cavity formation, or a combination of these features. In some patients with NTM pulmonary disease, CT shows the characteristic formation of small cylindrical bronchiectasis and multiple small (<5-mm) nodules and fibrosis. Patients with these findings and negative results of routine sputum cultures for mycobacteria should have bronchoscopy and transbronchial biopsy performed in an attempt to identify granulomas and acid-fast organisms. In patients with chronic pulmonary disease, the superimposition of infection with NTM may not be associated with easily recognizable changes in symptoms or radiologic features.

MAC organisms (especially *M. intracellulare*) are the most common cause of pulmonary disease due to NTM in developed countries; next in frequency are *M. kansasii* (United States, Europe, South Africa), *M. abscessus* (United States), *M. xenopi* (Europe, Canada), and *M. malmoense* (United Kingdom, northern Europe). However, isolation of NTM from the sputum must be considered in the context of clinical manifestations. For example, NTM (most prominently MAC organisms, less commonly *M. abscessus*) can be cultured from 13% of cystic fibrosis patients in the United States (Chap. 241); however, not all of these patients appear to have invasive NTM disease. Although invasive disease is particularly strongly suspected when the same NTM species is isolated on multiple occasions from a patient with lung disease, even persistent organisms may represent colonization or slowly progressive disease apparent only on long-term follow-up. Additional laboratory tests (e.g., immunologic assessments) are of no value in the diagnosis.

TABLE 152-2 *Criteria for the Diagnosis of Pulmonary Disease Due to NTM*[a]

Category	Requirement
Clinical	Compatible symptoms (e.g., fever, cough), *and* deterioration in clinical status (if underlying lung disease present), *and* reasonable exclusion of other disease
Radiologic	Chest radiograph: Infiltrates with or without nodules, either persistent (≥2 months) or progressive; *or* cavitation; *or* multiple nodules alone High-resolution CT: Multiple small nodules; *or* multifocal bronchiectasis, with or without small nodules
Bacteriologic	Sputum/bronchial wash: At least 3 positive cultures in 1 year Bronchial wash only: At least 1 positive culture with moderate growth or positive AFB smear Lung biopsy: Positive culture

[a] Diagnosis requires clinical criteria plus one radiologic criterion and one bacteriologic criterion.

Abbreviations: AFB, acid-fast bacilli; CT, computed tomography.

Source: Adapted from RJ Wallace et al: Am Rev Respir Crit Care Med 156:S1, 1997.

Although treatment should be considered in patients who meet clinical, radiologic, and microbiologic criteria for disease (Table 152-2), several other factors require consideration. For example, species such as *M. kansasii* are usually pathogenic, and a single isolate may be significant, while species such as *M. gordonae* are rarely pathogenic, even when isolated repeatedly. In addition, in some patients with true invasive disease, infection may progress so slowly that it is unlikely to have much impact on longevity determined by such factors as age or comorbid illness. Since therapy for NTM requires prolonged administration of multiple drugs and is associated with significant side effects, the decision to institute treatment in patients with noncavitary disease who do not have clearly progressive pulmonary disease should be made with careful deliberation after a period of clinical and radiologic follow-up.

Disseminated Disease Patients with impaired cellular immunity—most notably, patients with advanced HIV disease (Chap. 173)—are susceptible to disseminated disease due to NTM. Other conditions that predispose patients to this syndrome include treatment with glucocorticoids or other immunosuppressive agents (e.g., for organ transplantation), lymphoma and leukemia (especially hairy cell leukemia), and heritable disorders of IFN-γ production and function. *M. avium* and *M. kansasii* are the species most commonly isolated in disseminated disease, but numerous other organisms (e.g., *M. genavense*, *M. haemophilum*) have also been recovered.

Patients with disseminated infection present with fever, weight loss, and fatigue and sometimes with hepatosplenomegaly or lymphadenopathy. Chest radiographs are typically normal in infection with *M. avium* (although they may show a miliary pattern) but are usually abnormal in that with *M. kansasii*. Laboratory studies may demonstrate anemia and an elevated level of alkaline phosphatase in serum. Disseminated disease is characterized by the widespread presence of foamy macrophages with AFB, which may be demonstrated

in biopsy samples of bone marrow, intestine, or liver. Granulomas are typically absent in patients with impaired cellular immunity. In most cases, the diagnosis can be established by one or two sets of mycobacterial blood cultures, which will be positive for the etiologic mycobacteria in 2 to 3 weeks. Treatment requires long-term administration of a multiple-drug antimycobacterial regimen and attempts to ameliorate the defect in cellular immunity (e.g., institution of antiretroviral therapy, discontinuation of glucocorticoid administration).

Other Disease NTM species have been associated with disease at numerous other anatomical locations, including ocular infections, mastoiditis, sinusitis, mastitis, catheter site infections, endocarditis, meningitis, peritonitis, appendicitis, pericarditis, pyelonephritis, prostatitis, tenosynovitis, bursitis, septic arthritis, osteomyelitis, and lymphadenitis (especially in children). Accumulating data support an association between infection with *M. avium* subspecies *paratuberculosis* and Crohn's disease.

ORGANISMS

***M. AVIUM COMPLEX* ■ Pulmonary Disease** MAC organisms (*M. avium*, *M. intracellulare*, and genetically related unnamed species) are more common than *M. tuberculosis* as a cause of mycobacterial pulmonary disease among persons born in the United States. Epidemiologic data support a marked increase in the incidence of MAC infection over the past two to three decades. Two patterns of MAC disease are recognized: a primary form in apparently healthy nonsmokers and a secondary form in patients with preexisting pulmonary disease (Table 152-3). The description of subtle defects in cellular immune responses and body morphotype in patients with primary disease raises the possibility of an as-yet-undefined immune defect predisposing to MAC infection. Patients with secondary disease include those with chronic obstructive pulmonary disease, prior tuberculosis, cystic fibrosis, or pulmonary alveolar proteinosis. The sources of infection have not been identified.

CLINICAL FEATURES AND DIAGNOSIS Symptoms and diagnostic studies are described above (see "Clinical Syndromes"). CT identifies characteristic cylindrical bronchiectasis with nodule formation, documents the extent of disease, and establishes a baseline for possible treatment. Standard diagnostic criteria should be applied (Table 152-2), and antibiotic susceptibility testing should be reserved for patients with prolonged prior macrolide exposure and for those in whom treatment fails.

℞ TREATMENT

Treatment should be initiated in most patients with cavitary disease and those with documented progression of a pulmonary process who meet diagnostic criteria for NTM infection. A period of observation prior to consideration of treatment may be useful when there is no evidence of an otherwise-explainable progressive pulmonary process and when the patient's age or underlying disease is likely to be the critical determinant of survival over the next few years.

Recommended treatment for pulmonary disease includes daily ethambutol and rifabutin plus a macrolide (either daily clarithromycin or thrice-weekly azithromycin; Table 152-4). Concomitant streptomycin therapy for the first 2 months should be considered in patients with extensive or cavitary disease. As many as 30% of patients treated with standard drugs and doses are unable to tolerate therapy, generally because of gastrointestinal side effects. Rifabutin appears to have the highest rate of side effects. Thus, doses often need to be reduced or drugs eliminated or replaced with alternatives. A fluoroquinolone may be considered as a substitute drug, although clinical data on this option are limited.

For patients with positive sputum cultures who receive a macrolide-containing regimen, treatment should be continued for at least 12 months after cultures revert to negative—typically for ≥18 months. The duration of therapy with other regimens may need to be extended to 24 months. In some cases, cough and radiographic findings may improve after several months; in others, treatment may serve only to prevent the progression of disease. Approximately 20% of patients experience treatment failure or relapse; some apparent treatment failures may actually represent reinfection. Surgical resection is an option for patients with localized disease who are intolerant or unresponsive to multiple-drug therapy; however, this approach is associated with postoperative complications in as many as 20% of patients and should be undertaken only by surgeons who have considerable experience with this intervention.

Disseminated Disease Disseminated MAC disease occurs principally among patients with advanced HIV disease who live in developed countries but are not receiving antiretroviral therapy. Almost all cases occur at CD4+ T cell counts of $<100/\mu L$, and the risk is ~20% per year for untreated patients with CD4+ T cell counts of $<50/\mu L$. The risk of disease is essentially eliminated for patients given highly active antiretroviral therapy (HAART) who have an increase in CD4+ T cell count to $>100/\mu L$ for 3 months. Most cases are due to *M. avium*, and molecular studies indicate that as many as 25% of disseminated infections involve more than one strain. Strains causing bacteremia differ genetically from those typically isolated from respiratory sources or the environment. Molecular techniques have documented nosocomial acquisition from potable hot water and have demonstrated common genotypes among isolates from humans and those from peat used in potting soil. Epidemiologic studies have demonstrated an increased risk associated with consumption of untreated spring water and of raw or partially cooked fish or shellfish and a decreased risk associated with showering. Overall, sources of acquisition appear to be diverse and exposure is probably unavoidable; at this time, no specific behavioral changes are recommended for at-risk patients.

CLINICAL FEATURES AND DIAGNOSIS Disseminated *M. avium* infection in AIDS is associated with fever, weakness, and weight loss and usually presents as a wasting syndrome in patients who are not receiving HAART or chemoprophylaxis for *M. avium* (Chap. 173). Untreated disease shortens the survival period of patients with advanced AIDS by 4 to 5 months. Laboratory findings may include anemia, hypoalbuminemia, and elevated serum levels of alkaline phosphatase and lactate dehydrogenase. HIV-infected patients with prior disseminated MAC infection or unrecognized or subclinical MAC infection may experience an immune reconstitution syndrome when they start to receive HAART (Chap. 173). This syndrome presents 1 to 12 weeks after the institution of HAART and manifests as localized (or generalized) culture-positive lymphadenitis with negative blood cultures for *M. avium*.

℞ TREATMENT

Disseminated *M. avium* disease requires treatment with the combination of clarithromycin and ethambutol, with or without rifabutin (Table

TABLE 152-3 *Typical Features of Primary and Secondary Pulmonary Disease Due to the M. avium Complex*

Feature	Primary	Secondary
Age	>50 years	30–70 (mean, 60) years
Sex	F > M	M > F
Underlying disease	None definitively identified; subtle defect in cellular immunity postulated	Chronic obstructive pulmonary disease, cystic fibrosis, prior tuberculosis, alveolar proteinosis
Clinical features	Early disease may be limited to cylindrical bronchiectasis, <5-mm nodules, and midzone involvement on chest radiography	Infiltrates, <5-mm nodules, cavities

152-4), along with HAART for HIV. Antimycobacterial treatment should be continued for at least 12 months and until the CD4+ T cell count has been >100/μL for at least 6 months. The immune reconstitution syndrome should be treated with initiation or continuation of the same antimycobacterial regimen.

PREVENTION Chemoprophylaxis is highly effective for the prevention of disseminated *M. avium* infection in AIDS. Weekly azithromycin administration should be instituted when the CD4+ T cell count is <50/μL or when a patient with HIV infection has had an AIDS-defining opportunistic infection (e.g., *Pneumocystis* infection). Chemoprophylaxis may be discontinued when the CD4+ T cell count has been >100/μL for >6 months.

***M. KANSASII* ■ Pulmonary Disease** Pulmonary disease due to *M. kansasii* has been reported from many areas of the world, including North America, Europe, and South Africa. In the United States, *M. kansasii* is the second most common cause of lung disease due to NTM and is distributed largely in central and southern states and California. The average age of onset is 60 years, and most patients have predisposing factors, such as chronic obstructive pulmonary disease, carcinoma of the lung, silicosis, or prior tuberculosis. However, pulmonary infection sometimes occurs in persons without predisposing disease and has also been associated with poverty. Disease may sometimes wax and wane over many years; this pattern is assumed to represent chronic infection rather than reactivation. Localized pulmonary infection has been described in South African miners with early HIV infection and preserved CD4+ T cell counts. The source of infection has not been identified, although *M. kansasii* has been isolated from both potable and natural water sources.

CLINICAL FEATURES AND DIAGNOSIS *M. kansasii* is the most pathogenic nontuberculous mycobacterial species affecting the lung, and the clinical features of *M. kansasii* disease resemble those of tuberculosis. Most cases include cough and sputum production; 30% include frank hemoptysis. Systemic signs and symptoms, including fever, night sweats, and weight loss, are reported by as many as 50% of patients. However, symptoms may be subtle or absent in patients with underlying malignancy. Chest radiographs show cavitation in 50% of patients, pleural scarring in 40%, and infiltrates in 30%; abnormalities are most prominent in the apices. Clinical and radiographic effects progress in the absence of treatment.

Sputum samples should be obtained for AFB staining and mycobacterial culture. The isolation of *M. kansasii* sometimes represents colonization; the diagnostic criteria in Table 152-2 are useful when multiple sputum samples can be obtained. However, the growth of *M. kansasii* from even a single sputum culture should be considered to have potential clinical significance, especially in HIV-positive patients. Testing of *M. kansasii* isolates for susceptibility to rifampin is recommended.

Rx TREATMENT

For susceptible strains of *M. kansasii*, rifampin is the foundation of a multiple-drug regimen. The recommended regimen consists of daily rifampin (600 mg), isoniazid (300 mg), and ethambutol (25 mg/kg for the initial 2 months, 15 mg/kg subsequently) for at least 18 months. Sputum cultures almost always become negative by 4 months; patients with delayed conversion should be treated for at least 12 months after the last positive culture. Resistance to rifampin may develop, in which case clarithromycin or azithromycin may be substituted.

Disseminated Disease Disseminated *M. kansasii* disease occurs principally among patients with advanced AIDS and CD4+ T cell counts of <100/μL. It has also been reported in patients with leukemia, lymphoma, or solid-organ transplantation.

CLINICAL FEATURES AND DIAGNOSIS Symptoms are similar to those reported for disseminated MAC infection, although cough is more common with disseminated *M. kansasii* infection and chest radiographs often demonstrate alveolar or interstitial infiltrates or cavities. An immune reconstitution syndrome may occur after the institution of HAART in HIV-infected patients and manifests as cervical or mediastinal lymphadenitis (Chap. 173).

The diagnosis is established by the isolation of *M. kansasii* from a normally sterile parenchymal site or from blood. In one series of cases, concurrent disseminated infection with a second NTM species (most often *M. avium*), was found in one-third of patients. The isolation of *M. kansasii* from sputum from a patient with advanced HIV disease suggests possible disseminated infection and is an indication for mycobacterial blood culture.

TABLE 152-4 *Regimens for Prevention and Treatment of Disease Due to the M. avium Complex*

Category	Regimen	Indication and Duration
Pulmonary disease treatment	Clarithromycin 500 mg bid (or azithromycin 600 mg 3 times/week), ethambutol 15 mg/kg/d, and rifabutin 150–300 mg/d; consider adding streptomycin 500–1000 mg 2 or 3 times/week for first 2 months	Treat for 18 months or until 12 months after conversion of sputum culture.
Disseminated disease		
Treatment	Clarithromycin 500 mg PO bid (or azithromycin 500 mg/d[a]) plus ethambutol 15 mg/kg per day[b]	Treat when MAC blood culture is positive or MAC organism is isolated from ordinarily sterile site. Continue with secondary prevention.
Primary prevention	Azithromycin 1200 mg PO weekly[a] or clarithromycin 500 mg PO bid	Treat when CD4+ T cell count is <50/μL. Discontinue if CD4+ T cell count exceeds 100/μL for >3 months during HAART.
Secondary prevention	Clarithromycin 500 mg PO bid (or azithromycin 500 mg/d[a]) plus ethambutol 15 mg/kg per day[b]	Discontinue if disease resolves with >12 months of MAC therapy and CD4+ T cell count exceeds 100/μL for >6 months during HAART.

[a] Azithromycin is preferred to clarithromycin in pregnancy.
[b] Concomitant rifabutin (150–300 mg/d) may protect against the development of clarithromycin resistance and improve survival but can cause interactions with antiretroviral therapy.
Abbreviations: HAART, highly active antiretroviral therapy.

Rx TREATMENT

Antimycobacterial treatment of disseminated *M. kansasii* disease is the same as that for pulmonary disease due to this organism. Patients with AIDS who are receiving HAART should have rifabutin (150 mg/d) or clarithromycin (500 mg twice daily) substituted for rifampin because of drug interactions. Untreated disease is associated with shortened survival, and the response to treatment is good in patients who do not have rapidly progressive HIV infection. HIV-positive patients who experience clearing of systemic symptoms and have positive cultures with sustained recovery of the CD4+ T cell count can probably have treatment discontinued (as described above for *M. avium* infection), although there are no clinical data on this point. Azithromycin prophylaxis for disseminated *M. avium* infection may also be effective in preventing disseminated *M. kansasii* infection.

M. ABSCESSUS, M. CHELONAE,* AND *M. FORTUITUM Three rapidly growing NTM species are prominent in reports of human infection and colonization: *M. abscessus*, *M. chelonae*, and *M. fortuitum*. These organisms are acquired from water, soil, or nosocomial sources. The most common clinical manifestation of infection is disseminated cutaneous

disease in patients who have defects in cellular immunity or are receiving glucocorticoid therapy. Normal hosts develop localized cutaneous infection in surgical or traumatic wounds, from contaminated injections, or after body piercing. Cutaneous lesions are cellulitic or nodular; are typically erythematous, indurated, and tender; and may progress to ulceration and purulent drainage. Proximal sporotrichoid spread has also been reported. Pulmonary infections (usually due to *M. abscessus*) are the next most common manifestation and occur principally in patients with underlying lung disease, such as cystic fibrosis.

The rapidly growing NTM species may be isolated from clinical specimens submitted for routine microbiologic testing. However, reliable evaluation requires inoculation onto special mycobacterial media and an extended incubation period. Because rapidly growing NTM species are also common laboratory contaminants, numerous false alarms in the form of pseudoepidemics have been reported.

TREATMENT

Treatment varies with the patient group and with the species of rapidly growing NTM. Susceptibility tests should be performed and used to guide antibiotic selection. All three species are usually susceptible to clarithromycin and amikacin; *M. abscessus* and *M. fortuitum* are also susceptible to cefoxitin. Other agents that may be active include imipenem, doxycycline, and fluoroquinolones. Patients with localized cutaneous disease may respond to a single active agent (e.g., clarithromycin, 500 mg twice daily by mouth for ≥2 weeks). Up to 6 months of therapy may be optimal for bacteremic or disseminated cutaneous disease, and a second agent should be added on the basis of susceptibility tests. Pulmonary disease is especially difficult to treat since prolonged therapy is required and the most active drugs require parenteral administration. Current recommendations are to administer intravenous amikacin (5 to 7.5 mg/kg every 12 h) and cefoxitin (3 g every 6 h) with oral clarithromycin (500 mg twice daily) and to continue treatment for 6 to 12 months. Surgery can be considered for localized disease.

M. MARINUM *M. marinum* is widely distributed in water and causes chronic cutaneous infection when an open cutaneous lesion is exposed to a colonized water source. Most infections are due to hand or upper-extremity exposure to fish tanks, and some are due to shellfish or marine exposures. Swimming pools are no longer a common source of infection because of current chlorination standards. *M. marinum* grows optimally at 30°C—a lower temperature than is optimal for most pathogenic mycobacteria. After a median incubation period of 21 days (≥30 days in 35% of cases), a granulomatous or ulcerating skin lesion develops at the site of entry with subsequent sporotrichoid spread in many cases. In some patients, especially those with serious underlying disease and those receiving immunosuppressive therapy, infection may extend to deeper structures, producing tenosynovitis or osteomyelitis. The diagnosis is established by mycobacterial culture of a biopsied lesion or by demonstration of granulomas or AFB in a biopsy sample from a patient with a compatible exposure history.

TREATMENT

Treatment consists of the combination of clarithromycin and ethambutol, with administration continuing for 1 to 2 months after resolution of lesions—typically 3 to 4 months in total. Surgical debridement may be necessary in extensive or deep disease; however, in contrast to pyogenic infections, routine incision and drainage are not helpful. Persons with occupational or avocational exposure to fish tanks or salt water should wear waterproof gloves to prevent infection of open cutaneous lesions.

M. ULCERANS *M. ulcerans* causes cutaneous infection ("Buruli ulcer") in endemic regions of Central and West Africa, Central and South America, Malaysia, Indonesia, Papua New Guinea, and Australia. The organism is closely related to *M. marinum*, has a similar temperature for optimal growth, and has been isolated from natural bodies of water. Most cases of human infection occur on the bare arms or legs of children or young adults living near rivers, lakes, or swamps. Transmission is thought to result from minor trauma or the bite of an aquatic insect. The initial lesion is a small painless nodule that progresses to a deep ulcer. The ulcer expands, resulting in sloughing of skin and subcutaneous tissue; osteomyelitis may also occur. Stellate scarring and deforming contractures may result from extensive necrosis.

Biopsy analyses demonstrate extracellular AFB in early lesions, with a limited inflammatory reaction. Tissue destruction extends beyond the area of demonstrable bacterial infection and has been attributed to a unique mycobacterial toxin, mycolactone.

TREATMENT

Antimicrobial therapy has not yet been shown to be beneficial, although rifampin, dapsone, clarithromycin, streptomycin, and amikacin display in vitro activity against *M. ulcerans*. Surgical treatment is primary and may require skin grafting. Immunization with BCG reduces the risk of disease by ~50%.

OTHER NTM SPECIES Numerous other NTM species have been associated with human disease, although they may represent contaminants in clinical specimens. Species and sites of possible infection include *M. celatum* (lung, lymph nodes), *M. genavense* (disseminated), *M. gordonae* (skin, contaminant), *M. haemophilum* (skin, disseminated), *M. malmoense* (lung), *M. simiae* (lung, disseminated), *M. scrofulaceum* (lymphadenitis), *M. szulgai* (skin, lung), and *M. xenopi* (lung, disseminated).

153 SYPHILIS

Sheila A. Lukehart

DEFINITION Syphilis, a chronic systemic infection caused by *Treponema pallidum* subspecies *pallidum*, is usually sexually transmitted and is characterized by episodes of active disease interrupted by periods of latency. After an incubation period averaging 2 to 6 weeks, a primary lesion appears, often associated with regional lymphadenopathy. A secondary bacteremic stage, associated with generalized mucocutaneous lesions and generalized lymphadenopathy, is followed by a latent period of subclinical infection lasting many years. In about one-third of untreated cases, the tertiary stage is characterized by progressive destructive mucocutaneous, musculoskeletal, or parenchymal lesions; aortitis; or symptomatic central nervous system (CNS) disease.

ETIOLOGY The Spirochaetales include three genera that are pathogenic for humans and for a variety of other animals: *Leptospira*, which causes human leptospirosis (Chap. 155); *Borrelia*, which causes relapsing fever and Lyme disease (Chaps. 156 and 157); and *Treponema*, which causes the diseases known as treponematoses (see also Chap. 154). The genus *Treponema* includes *T. pallidum* subspecies *pallidum*, which causes venereal syphilis; *T. pallidum* subspecies *pertenue*, which causes yaws; *T. pallidum* subspecies *endemicum*, which causes endemic syphilis or bejel; and *T. carateum*, which causes pinta. Until recently, the subspecies were distinguished primarily by the clinical syndromes they produce. Researchers have now identified molecular signatures that can differentiate *T. pallidum* subspecies *pallidum* from the other pathogenic *T. pallidum* subspecies by culture-independent, polymerase chain reaction (PCR)–based methods. Other *Treponema* species found in the human mouth, genital mucosa, and gastrointestinal tract have no proven pathogenic role in human disease. These spirochetes can be confused with *T. pallidum* on dark-field examination.

T. pallidum subspecies *pallidum* (hereafter referred to in this chapter simply as *T. pallidum*), a thin delicate organism with 6 to 14 spirals and tapered ends, measures 6 to 15 μm in total length and 0.2 μm in width. The cytoplasm is surrounded by a trilaminar cytoplasmic membrane, which in turn is surrounded by a delicate peptidoglycan layer providing some structural rigidity. This layer is surrounded by a lipid-rich outer membrane that contains relatively few integral membrane proteins. Endoflagella wind around the cell body in the periplasmic space and appear to be responsible for motility.

The sequencing of the genome of *T. pallidum* has yielded information about the organism's metabolic capabilities. *T. pallidum* lacks the genes required to synthesize enzyme cofactors, fatty acids, and nucleotides de novo. In addition, it lacks genes encoding the enzymes of the Krebs cycle and oxidative phosphorylation. To compensate, the organism contains numerous genes predicted to code for transporters of amino acids, carbohydrates, and cations. In addition, the genome analyses and other studies have revealed the existence of a 12-member gene family (called *tpr*) that bears similarities to variable outer-membrane antigens of other spirochetes. One member, TprK, has discrete variable (V) regions that are targets of the humoral immune response. Data suggest that sequence variation occurs in TprK during infection and that this variation is a mechanism for immune invasion.

The only known natural host for *T. pallidum* is the human. *T. pallidum* can infect many mammals, but only humans, higher apes, and a few laboratory animals regularly develop syphilitic lesions. Virulent strains of *T. pallidum* are grown and maintained in rabbits, as none of the pathogenic treponemes has been successfully cultured.

EPIDEMIOLOGY Nearly all cases of syphilis are acquired by sexual contact with infectious lesions (i.e., the chancre, mucous patch, skin rash, or condyloma latum). Less common modes of transmission include nonsexual personal contact, infection in utero, and blood transfusion.

The total number of cases of syphilis reported annually in the United States declined from 575,593 in 1943 to a low of 31,575 in 2000—a 95% decrease. This downward trend was interrupted by an epidemic peaking in 1990. Surveillance of the number of new cases of infectious syphilis—a better indicator of disease activity—has revealed four cycles of 7 to 10 years, each with a rapid rise and fall in incidence (with peaks in 1965, 1975, 1982, and 1990). From 1990 to 2000, the number of reported cases of infectious syphilis declined by >88%. In 1997, however, the number of cases of early syphilis began to rise in Seattle, Washington, marking the beginning of a trend that, by 2000, included Los Angeles and San Francisco. Infectious syphilis rates have also begun to rise in the southern region of the United States.

The populations at highest risk for acquiring syphilis have changed. Between 1977 and 1982, approximately half of all patients with early syphilis in the United States were homosexual or bisexual men. The epidemic of syphilis that peaked in 1990 predominantly involved African-American heterosexual men and women and occurred largely in urban areas, where infectious syphilis has been correlated significantly with the exchange of sex for crack cocaine. Since 1996, syphilis rates have declined steadily among African Americans but remain higher than those for other racial/ethnic groups. Foci of syphilis still exist in a small number of counties in the southern United States, and rates are still increasing there. The current outbreak of syphilis in large cities on the West Coast of the United States is focused in men who have sex with men; a high proportion of the individuals in this group who have syphilis are also infected with HIV.

The incidence of congenital syphilis roughly parallels that of infectious syphilis in females. The number of reported cases of congenital syphilis in infants ≤1 year of age was lowest (107 cases) in 1978, when infectious syphilis was most prevalent among homosexual and bisexual men. The dramatic increase in the incidence of primary and secondary syphilis among women from 1986 to 1990 resulted in a proportionate increase in the number of infants born with congenital syphilis—to 4424 infants in 1991. The incidence of early syphilis among women has declined since 1991, as has the number of reported cases of congenital syphilis in infants (with 529 cases in 2000). It is important to note that the case definition for congenital syphilis was broadened in 1989 and now includes all live or stillborn infants delivered to women with untreated or inadequately treated syphilis at delivery.

Approximately one of every two individuals named as sexual contacts of persons with infectious syphilis becomes infected. Many sexual contacts will already have developed manifestations of syphilis when they are first seen, and ~30% of apparently uninfected contacts who are examined within 30 days of exposure actually have incubating infection and will later develop infectious syphilis if not treated. Thus, the identification and "epidemiologic" treatment of all recently exposed sexual contacts constitute an important aspect of syphilis control. Also important is the identification of infected persons by serologic testing of pregnant women, persons admitted to hospitals, military inductees, and persons undergoing examination in physicians' offices. Still controversial are laws and regulations requiring routine premarital serologic testing for syphilis, where—though national data are not available—the yield is undoubtedly lower.

NATURAL COURSE AND PATHOGENESIS OF UNTREATED SYPHILIS *T. pallidum* rapidly penetrates intact mucous membranes or microscopic abrasions in skin and within a few hours enters the lymphatics and blood to produce systemic infection and metastatic foci long before the appearance of a primary lesion. Blood from a patient with incubating or early syphilis is infectious. The generation time of *T. pallidum* during

early active disease in vivo is estimated to be 30 to 33 h, and the incubation period of syphilis is inversely proportional to the number of organisms inoculated. The concentration of treponemes generally reaches at least 10^7/g of tissue before the appearance of a clinical lesion. On the basis of intradermal injection of graded doses of *T. pallidum* into eight volunteers, the 50% infectious dose was calculated to be 57 organisms. The median incubation period in humans (~21 days) suggests an average inoculum of 500 to 1000 infectious organisms for naturally acquired disease. The incubation period (from inoculation until the primary lesion becomes discernible) rarely exceeds 6 weeks. Subcurative therapy during the incubation period may delay the onset of the primary lesion, but it is not certain that such treatment reduces the probability that symptomatic disease will ultimately develop.

The primary lesion appears at the site of inoculation, usually persists for 4 to 6 weeks, and then heals spontaneously. Histopathologic examination of primary lesions shows perivascular infiltration, chiefly by lymphocytes (including CD8+ and CD4+ cells), plasma cells, and macrophages, with capillary endothelial proliferation and subsequent obliteration of small blood vessels. The cellular infiltration displays a T_H1-type cytokine profile consistent with the activation of macrophages. At this time *T. pallidum* is demonstrable in the chancre in spaces between epithelial cells; within invaginations or phagosomes of epithelial cells, fibroblasts, plasma cells, and the endothelial cells of small capillaries; within lymphatic channels; and in the regional lymph nodes. Phagocytosis of organisms by activated macrophages ultimately causes their destruction, which results in spontaneous resolution of the chancre.

The generalized parenchymal, constitutional, and mucocutaneous manifestations of secondary syphilis usually appear about 6 to 8 weeks after healing of the chancre, although 15% of patients with secondary syphilis still have persisting or healing chancres. In other patients, secondary lesions may appear several months after the chancre has healed, and some patients may enter the latent stage without ever recognizing secondary lesions. The histopathologic features of secondary maculopapular skin lesions are hyperkeratosis of the epidermis; capillary proliferation with endothelial swelling in the superficial corium; and dermal papillae with transmigration of polymorphonuclear leukocytes and, in the deeper corium, perivascular infiltration by CD8+ lymphocytes, CD4+ lymphocytes and macrophages, and plasma cells. Treponemes are found in many tissues, including the aqueous humor of the eye and the cerebrospinal fluid (CSF). Invasion of the CNS by *T. pallidum* occurs during the first weeks or months of infection, and CSF abnormalities are detected in as many as 40% of patients during the secondary stage. Clinical hepatitis and immune complex–induced membranous glomerulonephritis are relatively rare but recognized manifestations of secondary syphilis; liver function tests may yield abnormal results in up to a quarter of patients with early syphilis. Generalized nontender lymphadenopathy is noted in 85% of patients with secondary syphilis. The paradoxical appearance of secondary manifestations despite high titers of antibody (including immobilizing antibody) to *T. pallidum* is unexplained but may result from changes in expression of surface antigens. Secondary lesions subside within 2 to 6 weeks, and the infection enters the latent stage, which is detectable only by serologic testing. In the preantibiotic era, up to 25% of untreated patients experienced at least one generalized or localized mucocutaneous relapse, usually during the first year; therefore, identification and examination of sexual contacts are most important for patients with syphilis of <1 year's duration. Recurrent generalized rash is now rare.

In the preantibiotic era, about one-third of patients with untreated latent syphilis developed clinically apparent tertiary disease; today, in industrialized countries, specific treatment and coincidental therapy for early and latent syphilis have all but eliminated tertiary disease except for sporadic cases of neurosyphilis in persons infected with HIV. In the past, the most common type of tertiary disease was the gumma, a usually benign granulomatous lesion. Today, gummas are very uncommon. Cardiovascular syphilis, now also rare, is caused by obliterative small-vessel endarteritis, usually involving the vasa vasorum of the ascending aorta and resulting in aneurysm. Asymptomatic CNS involvement is demonstrable in up to 25% of patients with late latent syphilis. The factors that contribute to the development and progression of tertiary disease are unknown.

The course of untreated syphilis was studied retrospectively in a group of nearly 2000 patients with primary or secondary disease diagnosed clinically (the Oslo Study, 1891–1951) and was assessed prospectively in 431 African-American men with seropositive latent syphilis of ≥3 years' duration (the notorious Tuskegee Study, 1932–1972). In the Oslo Study, 24% of patients developed relapsing secondary lesions within 4 years, and 28% eventually developed one or more manifestations of tertiary syphilis. Cardiovascular syphilis, including aortitis, was detected in 10% of patients, none of whom had been infected before age 15; 7% of patients developed symptomatic neurosyphilis, and 16% developed benign tertiary syphilis (gummas of the skin, mucous membranes, and skeleton). Syphilis was the primary cause of death in 15% of men and 8% of women. Cardiovascular syphilis was documented in 35% of men and 22% of women who eventually came to autopsy. In general, serious late complications were nearly twice as common among men as among women.

The Tuskegee Study showed that the death rate among untreated African-American men with syphilis (25 to 50 years old) was 17% higher than that among uninfected subjects and that 30% of all deaths were attributable to cardiovascular or CNS syphilis. By far the most important factor in increased mortality was cardiovascular syphilis. Anatomic evidence of aortitis was found in 40 to 60% of autopsied subjects with syphilis (vs. 15% of control subjects), whereas CNS syphilis was found in only 4%. Rates of hypertension were also higher among the infected subjects. The ethical issues eventually raised by this study, begun in the preantibiotic era but continuing into the early 1970s, had a major influence on the development of current guidelines for human medical experimentation, and the history of the study may still contribute to a reluctance of some African Americans to participate as subjects in clinical research.

These two studies both showed that about one-third of patients with untreated syphilis develop clinical or pathologic evidence of tertiary syphilis, that about one-fourth die as a direct result of tertiary syphilis, and that there is additional excess mortality not directly attributable to tertiary syphilis.

MANIFESTATIONS ■ Primary Syphilis The typical primary chancre usually begins as a single painless papule that rapidly becomes eroded and usually becomes indurated, with a characteristic cartilaginous consistency on palpation of the edge and base of the ulcer. In heterosexual men the chancre is usually located on the penis (Fig. 153-1), whereas in homosexual men it is often found in the anal canal or rectum, in the mouth, or on the external genitalia. In women, common primary

FIGURE 153-1 Primary syphilis with a firm, nontender chancre.

FIGURE 153-2 Secondary syphilis demonstrating the papulosquamous truncal eruption.

sites are the cervix and labia. Consequently, primary syphilis goes unrecognized in women and homosexual men more often than in heterosexual men. Multiple primary lesions may be more common among men with concurrent HIV infection.

Atypical primary lesions are common. The clinical appearance depends on the number of treponemes inoculated and on the immunologic status of the patient. A large inoculum produces a dark-field-positive ulcerative lesion in nonimmune volunteers but may produce a small dark-field-negative papule, an asymptomatic but seropositive latent infection, or no response at all in individuals with a history of syphilis. A small inoculum may produce only a papular lesion, even in nonimmune individuals. Therefore, syphilis should be considered even in the evaluation of trivial or atypical dark-field-negative genital lesions. The genital lesions that most commonly must be differentiated from those of primary syphilis include those caused by herpes simplex virus infection (Chap. 163), chancroid (Chap. 130), traumatic injury, and donovanosis (Chap. 145). *Primary genital herpes* may produce inguinal adenopathy, but the nodes are tender and the lesions consist of multiple painful vesicles, which later ulcerate and are often accompanied by systemic symptoms, including fever. *Recurrent genital herpes* typically begins with a unilateral cluster of painful vesicles, usually without associated adenopathy. *Chancroid* produces painful, superficial, exudative, nonindurated ulcers, more often multiple than in syphilis (see Fig. 130-2); adenopathy is common, can be either unilateral or bilateral, is tender, and may be suppurative. Donovanosis, which is rare in the United States and Europe, is usually seen as a granulomatous ulcer that, although painless, is friable.

Regional lymphadenopathy usually accompanies the primary syphilitic lesion, appearing within 1 week of the onset of the lesion. The nodes are firm, nonsuppurative, and painless. Inguinal lymphadenopathy is bilateral and may occur with anal as well as with external genital chancres. The chancre generally heals within 4 to 6 weeks (range, 2 to 12 weeks), but lymphadenopathy may persist for months.

FIGURE 153-3 Secondary syphilis commonly affects the palms and soles with scaling, firm, red-brown papules.

FIGURE 153-4 Condylomata lata are moist, somewhat verrucous intertriginous plaques seen in secondary syphilis.

Secondary Syphilis The protean manifestations of the secondary stage usually include localized or diffuse symmetric mucocutaneous lesions and generalized nontender lymphadenopathy. The healing primary chancre is still present in 15% of cases, and the stages may overlap more frequently in persons with concurrent HIV infection than in those without this co-infection. The skin rash consists of macular, papular, papulosquamous, and occasionally pustular syphilides; often more than one form is present simultaneously. The eruption may be very subtle. Approximately 25% of patients with a discernible rash of secondary syphilis may be unaware that they have dermatologic manifestations. Initial lesions are bilaterally symmetric, pale red or pink, nonpruritic, discrete, round macules that measure 5 to 10 mm in diameter and are distributed on the trunk and proximal extremities. After several days or weeks, red papular lesions 3 to 10 mm in diameter also appear (Fig. 153-2). These lesions, which may progress to necrotic lesions (resembling pustules) in association with increasing endarteritis and perivascular mononuclear infiltration, are distributed widely, frequently involve the palms and soles (Fig. 153-3), and may occur on the face and scalp. Tiny papular *follicular syphilides* involving hair follicles may result in patchy alopecia, with loss of scalp hair, eyebrows, or beard in up to 5% of cases.

In warm, moist, intertriginous body areas, including the perianal area, vulva, scrotum, inner thighs, axillae, and skin under pendulous breasts, papules can enlarge and become eroded to produce broad, moist, pink or gray-white, highly infectious lesions called *condylomata lata* (Fig. 153-4); these lesions develop in 10% of patients with secondary syphilis. Superficial mucosal erosions, called *mucous patches*, occur in 10 to 15% of patients and may involve the lips, oral mucosa, tongue (Fig. 153-5), palate, pharynx, vulva and vagina, glans penis, or inner prepuce. The typical mucous patch is a painless silver-gray erosion surrounded by a red periphery. During relapses of secondary syphilis, condylomata lata are particularly common, and skin lesions tend to be asymmetrically distributed and more infiltrated, resembling skin lesions of late syphilis. These characteristics may reflect increasing cellular immunity.

Constitutional symptoms that may accompany or precede secondary syphilis include sore throat (15 to 30%), fever (5 to 8%), weight loss (2 to 20%), malaise (25%), anorexia (2 to 10%), headache (10%), and meningismus (5%). *Acute meningitis* occurs in only 1 to 2% of cases, but numbers of cells and levels of protein in CSF are increased

FIGURE 153-5 Mucous patches on the tongue of a patient with secondary syphilis. (*Courtesy of Ron Roddy.*)

in ≥30% of cases. *T. pallidum* has been recovered from CSF during primary and secondary syphilis in 30% of cases; this finding is often but not always associated with other CSF abnormalities.

Less common complications of secondary syphilis include hepatitis, nephropathy, gastrointestinal involvement (hypertrophic gastritis, patchy proctitis, ulcerative colitis, or a rectosigmoid mass), arthritis, and periostitis. Ocular findings that suggest secondary syphilis include otherwise-unexplained pupillary abnormalities, optic neuritis, and a retinitis pigmentosa syndrome as well as the classic iritis (especially granulomatous iritis) or uveitis. The diagnosis of secondary syphilis is often considered in such patients only after they fail to respond to steroid therapy. Anterior uveitis has been reported in 5 to 10% of patients with secondary syphilis, and *T. pallidum* has been demonstrated in the aqueous humor from such patients. Hepatic involvement is common in syphilis; although it is usually asymptomatic, at least 25% of patients may have abnormal liver function tests. Frank *syphilitic hepatitis* is distinguished by an unusually high serum level of alkaline phosphatase and by a nonspecific histologic appearance that is unlike that of viral hepatitis and includes moderate inflammation with polymorphonuclear leukocytes and lymphocytes, some hepatocellular damage, and no cholestasis. *Renal involvement* produces proteinuria associated with an acute nephrotic syndrome (or rarely with hemorrhagic glomerulonephritis) and is characterized by subepithelial electron-dense deposits and glomerular immune complexes—findings suggesting immune-complex glomerulonephritis. Like those of primary syphilis, the manifestations of the secondary stage resolve spontaneously, usually within 1 to 6 months.

Latent Syphilis Positive serologic tests for syphilis, together with a normal CSF examination and the absence of clinical manifestations of syphilis, indicate a diagnosis of latent syphilis. The diagnosis is often suspected on the basis of a history of primary or secondary lesions, a history of exposure to syphilis, or the delivery of an infant with congenital syphilis. A previous negative serologic test or a history of lesions or exposure may help establish the duration of latent infection, which is an important factor in the selection of appropriate therapy. *Early latent* syphilis encompasses the first year after infection, whereas *late latent* syphilis (beginning ≥1 year after infection in the untreated patient) is associated with relative immunity to infectious relapse. *T. pallidum* may still seed the bloodstream intermittently during the latent stage, and pregnant women with latent syphilis may infect the fetus in utero. Moreover, syphilis has been transmitted through the transfusion of blood from patients with latent syphilis of many years' duration. It was previously thought that untreated late latent syphilis had three possible outcomes: (1) it could persist throughout the lifetime of the infected individual; (2) it could end in the development of late syphilis; or (3) it could end with the spontaneous cure of infection, with reversion of serologic tests to negative. It is now apparent, however, that the more sensitive treponemal antibody tests rarely, if ever, become negative without treatment. About 70% of untreated patients with latent syphilis never develop clinically evident late syphilis, but the occurrence of spontaneous cure is in doubt.

Involvement of the Central Nervous System Traditionally, neurosyphilis has been considered to be a late manifestation of syphilis, but this view is inaccurate. CNS syphilis represents a continuum encompassing early invasion (usually within the first weeks or months of infection), months to years of asymptomatic involvement, and, in some cases, development of early or late neurologic manifestations.

ASYMPTOMATIC NEUROSYPHILIS The diagnosis of asymptomatic neurosyphilis is made in patients who lack neurologic symptoms and signs but who have CSF abnormalities including mononuclear pleocytosis, increased protein concentrations, or a reactive Venereal Disease Research Laboratory (VDRL) slide test. Such abnormalities are found in up to one-quarter of patients with untreated latent syphilis, and these are the patients who are known to be at risk for neurologic complications. In primary and secondary syphilis, such abnormalities may be found in up to 40% of untreated patients, and *T. pallidum* can be isolated from CSF of 30% of patients even in the absence of other CSF abnormalities. Although the therapeutic implications of these findings in early syphilis are uncertain, it seems appropriate to conclude that even patients with early syphilis who have such findings do indeed have asymptomatic neurosyphilis and should be treated for neurosyphilis. In patients with untreated asymptomatic neurosyphilis, the overall cumulative probability of progression to clinical neurosyphilis is about 20% in the first 10 years but increases with time; the likelihood is highest among patients with the greatest degree of pleocytosis or protein elevation. Patients with untreated latent syphilis and normal CSF probably run no risk of subsequent neurosyphilis. In one study, neurosyphilis was associated with a rapid plasma reagin (RPR) titer of ≥1:32, regardless of clinical stage or HIV infection status.

SYMPTOMATIC NEUROSYPHILIS Although mixed features are common, the major clinical categories of symptomatic neurosyphilis include meningeal, meningovascular, and parenchymatous syphilis. The last category includes general paresis and tabes dorsalis. The onset of symptoms usually comes <1 year after infection for meningeal syphilis, at 5 to 10 years for meningovascular syphilis, at 20 years for general paresis, and at 25 to 30 years for tabes dorsalis. However, symptomatic neurosyphilis, particularly in the antibiotic era, often presents not as a classic picture but rather as mixed and subtle or incomplete syndromes.

Meningeal syphilis may involve either the brain or the spinal cord, and patients may present with headache, nausea, vomiting, neck stiffness, cranial nerve involvement, seizures, and changes in mental status. This condition may be concurrent with or may follow the secondary stage. Patients presenting with uveitis or iritis frequently have meningeal syphilis. *Meningovascular syphilis* reflects diffuse inflammation of the pia and arachnoid together with evidence of focal or widespread arterial involvement of small, medium, or large vessels. The most common presentation is a stroke syndrome involving the middle cerebral artery of a relatively young adult; however, unlike the usual thrombotic or embolic stroke syndrome of sudden onset, meningovascular syphilis often becomes manifest after a subacute encephalitic prodrome (with headaches, vertigo, insomnia, and psychological abnormalities), which is followed by a gradually progressive vascular syndrome.

The manifestations of *general paresis* reflect widespread late parenchymal damage and include abnormalities corresponding to the mnemonic *paresis: p*ersonality, *a*ffect, *r*eflexes (hyperactive), *e*ye (e.g., Argyll Robertson pupils), *s*ensorium (illusions, delusions, hallucinations), *i*ntellect (a decrease in recent memory and in the capacity for orientation, calculations, judgment, and insight), and *s*peech. *Tabes*

dorsalis is also a late manifestation of syphilis that presents as symptoms and signs of demyelination of the posterior columns, dorsal roots, and dorsal root ganglia. Symptoms include ataxic wide-based gait and footslap; paresthesia; bladder disturbances; impotence; areflexia; and loss of position, deep pain, and temperature sensations. Trophic joint degeneration (Charcot's joints) and perforating ulceration of the feet can result from loss of pain sensation. The small, irregular Argyll Robertson pupil, a feature of both tabes dorsalis and paresis, reacts to accommodation but not to light. *Optic atrophy* also occurs frequently in association with tabes.

Other Manifestations of Late Syphilis The slowly progressive inflammatory disease leading to tertiary manifestations begins early during the pathogenesis of syphilis, although these manifestations may not become clinically apparent for years. Early syphilitic aortitis becomes evident soon after secondary lesions subside, and treponemes that trigger the development of gummas may have seeded the tissue years earlier.

CARDIOVASCULAR SYPHILIS Cardiovascular manifestations are attributable to endarteritis obliterans of the vasa vasorum, which provide the blood supply to large vessels. This condition results in uncomplicated aortitis, aortic regurgitation, saccular aneurysm, or coronary ostial stenosis, with symptoms usually appearing 10 to 40 years after infection. In the preantibiotic era, symptomatic cardiovascular complications developed in ~10% of persons with late untreated syphilis, although syphilitic aortitis was demonstrated at autopsy in about one-half of African-American men with untreated syphilis.

Linear calcification of the ascending aorta on chest x-ray films suggests asymptomatic syphilitic aortitis, as arteriosclerosis seldom produces this sign. Syphilitic aneurysms—usually saccular, occasionally fusiform—do not lead to dissection. Only 1 in 10 aortic aneurysms of syphilitic origin involves the abdominal aorta.

LATE BENIGN SYPHILIS (GUMMA) Gummas may be multiple or diffuse but are usually solitary lesions that range from microscopic in size to several centimeters in diameter. Histologic examination shows a granulomatous inflammation with a central area of necrosis. Although rarely demonstrated microscopically, *T. pallidum* has reportedly been recovered from these lesions. The most commonly involved sites include the skin and skeletal system, the mouth and upper respiratory tract, the larynx, the liver, and the stomach; however, any organ may be involved. Gummas of the skin produce painless and indurated nodular, papulosquamous, or ulcerative lesions that are usually indolent. These lesions may resemble those of many other chronic granulomatous conditions, including tuberculosis and sarcoidosis, leprosy, and deep fungal infections. Skeletal gummas most frequently involve the long bones of the legs, although any bone may be affected. Radiographic abnormalities with advanced gummas of bone include periostitis or destructive or sclerosing osteitis. Upper respiratory gummas can lead to perforation of the nasal septum or palate.

Because the histologic changes may be suggestive but are nonspecific, the diagnosis of late benign syphilis is confirmed by serologic testing and by therapeutic trial. Treatment with penicillin results in rapid healing of active gummatous lesions.

Congenital Syphilis Transmission of *T. pallidum* from a syphilitic woman to her fetus across the placenta may occur at any stage of pregnancy, but the lesions of congenital syphilis generally have their onset after the fourth month of gestation, when fetal immunologic competence begins to develop. This timing suggests that the pathogenesis of congenital syphilis depends on the immune response of the host rather than on a direct toxic effect of *T. pallidum*. The risk of infection of the fetus during untreated early maternal syphilis is estimated to be 75 to 95%, decreasing to about 35% for maternal syphilis of >2 years' duration. Adequate treatment of the mother before the 16th week of pregnancy should prevent fetal damage. Untreated maternal infection may result in a rate of fetal loss of up to 40% (with stillbirth more common than abortion because of the late onset of fetal pathology), prematurity, neonatal death, or nonfatal congenital syphilis. Among infants born alive, only fulminant congenital syphilis is clinically apparent at birth, and these babies have a very poor prognosis. The most common clinical problem is the healthy-appearing baby born to a mother with a positive serologic test. Routine serologic testing in early pregnancy is considered cost-effective in virtually all populations, even in areas with a low prenatal prevalence of syphilis. Where the prevalence of syphilis is high or when the patient is at high risk, serologic testing should be repeated in the third trimester and at delivery.

The manifestations of congenital syphilis can be divided into three types according to their timing: (1) early manifestations, which appear within the first 2 years of life (often between 2 and 10 weeks of age), are infectious and resemble the manifestations of severe secondary syphilis in the adult; (2) late manifestations, which appear after 2 years and are noninfectious; and (3) residual stigmata. The earliest sign of congenital syphilis is usually rhinitis, or "snuffles" (23%), which is soon followed by other mucocutaneous lesions (35 to 41%). These may include bullae (syphilitic pemphigus), vesicles, superficial desquamation, petechiae, and (later) papulosquamous lesions, mucous patches, and condylomata lata. The most common early manifestations are bone changes (61%), including osteochondritis, osteitis, and periostitis. Hepatosplenomegaly (50%), lymphadenopathy (32%), anemia (34%), jaundice (30%), thrombocytopenia, and leukocytosis are common. *T. pallidum* can be isolated, by rabbit inoculation, from the CSF of 22% of infected neonates without prior antibiotic exposure.

Neonatal congenital syphilis must be differentiated from other generalized congenital infections, including rubella, cytomegalovirus or herpes simplex virus infection, and toxoplasmosis, as well as from erythroblastosis fetalis. Neonatal death is usually due to pulmonary hemorrhage, secondary bacterial infection, or severe hepatitis.

Late congenital syphilis is that which remains untreated after 2 years of age. In 60% of cases, the infection remains subclinical; the clinical spectrum in the remainder of cases differs in certain respects from that of acquired late syphilis in the adult. For example, cardiovascular syphilis rarely develops in late congenital syphilis, whereas interstitial keratitis is much more common and occurs between the ages of 5 and 25. Other manifestations include eighth-nerve deafness and recurrent arthropathy. Bilateral knee effusions are known as *Clutton's joints*. Asymptomatic neurosyphilis is present in about one-third of untreated patients, and clinical neurosyphilis occurs in one-quarter of untreated individuals >6 years old. Gummatous periostitis occurs between the ages of 5 and 20 and, as in nonvenereal endemic syphilis, tends to cause destructive lesions of the palate and nasal septum.

Characteristic stigmata include *Hutchinson's teeth*—centrally notched, widely spaced, peg-shaped upper central incisors—and "mulberry" molars—sixth-year molars with multiple, poorly developed cusps. The abnormal facies of patients with congenital syphilis include frontal bossing, saddle nose, and poorly developed maxillae. Saber shins, characterized by anterior tibial bowing, are rare. *Rhagades* are linear scars at the angles of the mouth and nose that are caused by secondary bacterial infection of the early facial eruption.

LABORATORY EXAMINATIONS ■ Demonstration of the Organism *T. pallidum* cannot be detected by culture; therefore, other tests are necessary. Dark-field microscopic examination of lesion exudate is useful in evaluating moist cutaneous lesions, such as the chancre of primary syphilis or the condylomata lata of secondary syphilis. The identification of a single characteristic motile organism by a trained observer is sufficient for diagnosis. Examination of oral lesions and anal ulcers by this method is not recommended, as it is difficult to differentiate *T. pallidum* from other spirochetes that may be present.

Most syphilis is diagnosed in settings where dark-field microscopy is not available. The direct fluorescent antibody *T. pallidum* (DFA-TP) test, an alternative available at central laboratories, uses fluorescein-conjugated polyclonal antitreponemal antibody for the detection of *T. pallidum* in fixed smears prepared from suspect lesions. More

sensitive PCR tests have been developed but are available only in research laboratories.

T. pallidum can be found in tissue with appropriate silver stains, although these results should be interpreted with caution because artifacts resembling *T. pallidum* are often seen. Treponemes can be demonstrated more reliably in tissue by immunofluorescence or immunohistochemical methods using specific monoclonal or polyclonal antibodies to *T. pallidum*.

Serologic Tests for Syphilis There are two types of serologic test for syphilis: nontreponemal and treponemal. Both types of test are reactive in persons with any treponemal infection, including yaws, pinta, and endemic syphilis.

The nontreponemal tests measure IgG and IgM directed against a cardiolipin-lecithin-cholesterol antigen complex. The most widely used nontreponemal antibody tests for syphilis are the RPR test, which can be automated (ART), and the VDRL slide test. The RPR test is easier to perform and uses unheated serum; it is the test of choice for rapid serologic diagnosis in a clinic or office setting. The VDRL test, however, remains the standard for use with CSF.

The RPR and VDRL tests are equally sensitive and may be used for initial screening or for quantitation of serum antibody. The titer reflects the activity of the disease. Titers rise during the evolution of early syphilis; VDRL titers usually reach 1:32 or higher in secondary syphilis. A persistent fall by two dilutions (fourfold) or more after treatment of early syphilis provides essential evidence of an adequate response to therapy. VDRL titers do not correspond directly to RPR titers, and sequential quantitative testing (as for response to therapy) must employ a single test.

Two standard treponemal tests are used for confirmation of reactive nontreponemal results: the fluorescent treponemal antibody–absorbed (FTA-ABS) test and the agglutination assays for antibodies to *T. pallidum*. The microhemagglutination assay for *T. pallidum* (MHA-TP) has been replaced by the Serodia TP-PA test (Fujirebio, Tokyo), which is more sensitive for primary syphilis. The *T. pallidum* hemagglutination test (TPHA) is widely used in Europe but is not available in the United States. Both the agglutination assays and the FTA-ABS test are very specific and, when used for confirmation of positive nontreponemal tests, have a very high positive predictive value for the diagnosis of syphilis. However, even these tests give false-positive results at rates as high as 1 to 2% when used for the screening of normal populations. New enzyme-linked immunosorbent assays have also been approved as confirmatory tests.

The relative sensitivities of the VDRL and RPR tests, the FTA-ABS test, and the TP-PA test in the various stages of untreated syphilis are shown in Table 153-1. The nontreponemal tests may be nonreactive in very early primary syphilis, and the detection of antibody can be maximized by the performance of a treponemal test. All treponemal and nontreponemal tests are reactive during secondary syphilis, and a nonreactive result virtually excludes syphilis in a patient with otherwise-compatible mucocutaneous lesions. (Fewer than 1% of patients with secondary syphilis have a VDRL test that is nonreactive or weakly reactive with undiluted serum but is positive at higher serum dilutions—the *prozone phenomenon*.) Although the nontreponemal tests will become nonreactive or will be reactive at lower titers after therapy for early syphilis, the treponemal tests often remain reactive after therapy and therefore are not helpful in determining the infection status of persons with past syphilis. Treatment of early primary syphilis may result in seroreversion in treponemal tests.

For practical purposes, most clinicians need to be familiar with the three uses of serologic tests for syphilis: (1) testing of large numbers of sera for screening or diagnostic purposes (e.g., the RPR or VDRL test), (2) quantitative measurement of antibody titer to assess the clinical activity of syphilis or to monitor the response to therapy (e.g., the RPR or VDRL test), and (3) confirmation of the diagnosis of syphilis in a patient with a positive nontreponemal antibody test or with a suspected clinical diagnosis of syphilis (e.g., the FTA-ABS test or the Serodia TP-PA test).

TABLE 153-1 *Sensitivity of Serodiagnostic Tests in Untreated Syphilis*

Test[a]	Mean Percentage Positive (Range) at Indicated Stage of Disease[b]			
	Primary	Secondary	Latent	Tertiary
VDRL, RPR	78 (74–87)	100	95 (88–100)	71 (37–94)
FTA-ABS	84 (70–100)	100	100	96
TP-PA[c]	89	100	100	NA

[a] The specificity for each of these tests is 94 to 99%.
[b] In CDC studies.
[c] Limited numbers of sera have been evaluated by TP-PA.
Source: Modified from SA Larsen et al: Clin Microbiol Rev 8:1, 1995; and V Pope et al: J Clin Microbiol 38:2543, 2000.

For measurement of IgM in neonates in whom congenital syphilis is suspected, the syphilis Captia-M test (Trinity Biotech, Jamestown, NY) and the 19S IgM FTA-ABS test are available.

False-Positive Serologic Tests for Syphilis Because the antigen used in nontreponemal tests is found in other tissues, the tests may be reactive in persons without treponemal infection, although rarely do titers exceed 1:8 in such patients. In a population selected for screening because of clinical suspicion, history of exposure, or increased risk for sexually transmitted infections, fewer than 1% of reactive tests are falsely positive. The modern VDRL and RPR tests are 97 to 99% specific, and false-positive reactions are now limited largely to those conditions listed in Table 153-2. False positivity is common among persons with autoimmune disorders. The prevalence of false-positive nontreponemal tests increases with advancing age; 10% of people >70 years of age have false-positive reactions. In the patient with a false-positive nontreponemal test, syphilis is excluded by a nonreactive treponemal test.

Evaluation for Neurosyphilis Involvement of the CNS is detected by examination of CSF for pleocytosis (>5 white blood cells/mm^3), increased protein concentration (>45 mg/dL), or VDRL reactivity. CSF abnormalities can be demonstrated in up to 40% of cases of primary or secondary syphilis and in 25% of cases of latent syphilis. In older asymptomatic seropositive individuals, the yield of lumbar puncture is relatively low. *T. pallidum* has been recovered by CSF inoculation into rabbits from up to 30% of patients with primary or secondary syphilis but rarely from those with latent syphilis. The demonstration of *T. pallidum* in CSF is often associated with other CSF abnormalities; however, organisms can be recovered from patients with otherwise-normal CSF. Before the advent of penicillin, the risk of developing clinical neurosyphilis was roughly proportional to the intensity of CSF changes. CSF examination is recommended by the Centers for Disease Control and Prevention (CDC) in the evaluation of any sero-

TABLE 153-2 *Causes of False-Positive Reactions in Nontreponemal Serologic Tests for Syphilis*

Cause	Rate of False-Positive Reactions, %[a]
ACUTE FALSE-POSITIVE REACTION (<6 MONTHS)	
Recent viral illness or immunization	1–2
Genital herpes	4
Human immunodeficiency virus infection	1–4
Malaria	11
Parenteral drug use	20–25
CHRONIC FALSE-POSITIVE REACTION (≥6 MONTHS)	
Aging	9–11
Autoimmune disorders	1–20
Systemic lupus erythematosus	11–20
Rheumatoid arthritis	5
Parenteral drug use	20–25

[a] Data were collected from a variety of published reports.

positive patient with neurologic signs and symptoms, patients with other late syphilis, cases of suspected treatment failure, and HIV-infected patients with untreated syphilis of unknown duration or of >1 year's duration. The possibility of asymptomatic neurosyphilis in some patients with early disease is not addressed by these recommendations. Because standard therapy with penicillin G benzathine (benzathine benzylpenicillin) for early syphilis fails to result in treponemicidal drug levels in the CSF, some experts also advise lumbar puncture in early syphilis, particularly in patients with HIV infection or with nontreponemal test titers of ≥1:32.

The CSF VDRL test is highly specific but is insensitive and may be nonreactive even in cases of progressive symptomatic neurosyphilis. The degree of sensitivity is highest in meningovascular syphilis and paresis and is lower in asymptomatic neurosyphilis and tabes dorsalis. The unabsorbed FTA test on CSF is reactive far more often than the CSF VDRL test in all stages of syphilis, but FTA reactivity may reflect passive transfer of serum antibody into the CSF. A nonreactive CSF FTA test, however, may be used to rule out neurosyphilis.

TABLE 153-3 *Recommendations for the Treatment of Syphilis*[a]

Stage of Syphilis	Patients without Penicillin Allergy	Patients with Confirmed Penicillin Allergy
Primary, secondary, or early latent	Penicillin G benzathine (single dose of 2.4 mU IM)	Tetracycline hydrochloride (500 mg PO qid) or doxycycline (100 mg PO bid) for 2 weeks
Late latent (or latent of uncertain duration), cardiovascular, or benign tertiary	Lumbar puncture CSF normal: Penicillin G benzathine (2.4 mU IM weekly for 3 weeks) CSF abnormal: Treat as neurosyphilis	Lumbar puncture CSF normal and patient not infected with HIV: Tetracycline hydrochloride (500 mg PO qid) or doxycycline (100 mg PO bid) for 4 weeks CSF normal and patient infected with HIV: Densensitization and treatment with penicillin if compliance cannot be ensured CSF abnormal: Treat as neurosyphilis
Neurosyphilis (asymptomatic or symptomatic)	Aqueous penicillin G (18–24 mU/d IV, given as 3–4 mU q4h or continuous infusion) for 10–14 days *or* Aqueous penicillin G procaine (2.4 mU/d IM) plus oral probenecid (500 mg qid), both for 10–14 days	Desensitization and treatment with penicillin
Syphilis in pregnancy	According to stage	Desensitization and treatment with penicillin

[a] See text for full discussion of syphilis therapy in HIV-infected individuals.
Abbreviation: mU, million units.
Source: These recommendations are based on those issued by the Centers for Disease Control and Prevention in 2002.

Evaluation for Syphilis in Patients Infected with HIV Because persons at highest risk for syphilis (inner-city populations, homosexually active men, and people in many developing countries) are also at increased risk for HIV infection, these two infections frequently coexist. There is evidence that syphilis and other genital-ulcer diseases may be important risk factors for the acquisition and transmission of HIV infection.

The manifestations of syphilis may be altered in patients with concurrent HIV infection, and multiple cases of neurologic relapse after standard therapy have been reported in HIV-infected patients. *T. pallidum* has been isolated from the CSF of several patients after therapy for early syphilis with penicillin G benzathine. A multicenter U.S. study of early syphilis found similar clinical responses to therapy in persons with and without concurrent HIV infection, although the study lacked sufficient statistical power to exclude an effect of HIV and 41% of subjects were lost to follow-up. Serologically defined treatment failure was more common among HIV-infected patients than among those without this co-infection. This investigation confirmed the high rate of CNS invasion in early syphilis and the persistence of *T. pallidum* after standard therapy: 11 of 43 HIV-infected patients and 21 of 88 HIV-uninfected patients had *T. pallidum* detectable in CSF before therapy; 7 of the 35 patients who underwent lumbar puncture after therapy (some HIV-infected and others uninfected) still had *T. pallidum* detectable in CSF.

There is no clear evidence that the sensitivity of serologic tests for syphilis differs in HIV-infected versus HIV-uninfected patients. Rates of decline of serologic titers appear to be slower in HIV-infected individuals. The clinical significance of this observation is unclear.

Persons with newly diagnosed HIV infection should be tested for syphilis; conversely, all patients with newly diagnosed syphilis should be tested for HIV infection. Some authorities, persuaded by reports of the persistence of *T. pallidum* in the CSF of HIV-infected persons after standard penicillin benzathine therapy for early syphilis, recommend examination of CSF for evidence of neurosyphilis for all co-infected patients, regardless of the clinical stage of syphilis, with treatment for neurosyphilis if CSF abnormalities are found or if CSF examination is not performed. Others do not recommend routine CSF examination for HIV-co-infected patients with early syphilis and believe that standard therapy is sufficient. Serologic testing after treatment is important for all patients with syphilis, particularly those also infected with HIV.

TREATMENT

Treatment of Acquired Syphilis The CDC's 2002 guidelines for the treatment of syphilis are summarized in Table 153-3 and are discussed below. Penicillin G is the drug of choice for all stages of syphilis. *T. pallidum* is killed by very low concentrations of penicillin G, although a long period of exposure to penicillin is required because of the unusually slow rate of multiplication of the organism. The efficacy of penicillin against syphilis remains undiminished after 50 years of use. Other antibiotics effective in syphilis include the tetracyclines, erythromycin, and the cephalosporins. Aminoglycosides and spectinomycin inhibit *T. pallidum* only in very large doses, and the sulfonamides and the quinolones are inactive. Azithromycin shows significant promise as an effective oral agent against *T. pallidum*.

Serum levels of penicillin G of ≥0.03 μg/mL for at least 7 days are considered necessary for the cure of early syphilis. Recurrence rates for a given regimen increase as infection progresses from incubating to seronegative primary to seropositive primary to secondary to late syphilis. Therefore, it is probable, but unproven, that a longer duration of therapy is required to effect cure as the infection progresses.

PATIENTS WITH EARLY SYPHILIS AND THEIR CONTACTS Preventive (abortive, "epidemiologic") treatment is recommended for seronegative individuals without signs of syphilis who have been exposed to infectious syphilis within the previous 3 months. Before treatment is given, every effort should be made to establish a diagnosis by examination and serologic testing. *The regimens recommended for prevention are the same as those recommended for early syphilis.*

Penicillin G benzathine is the most widely used agent for the treat-

ment of early syphilis, although it is more painful on injection than penicillin G procaine. A single dose of 2.4 million units cures more than 95% of cases of primary syphilis. Because the drug's efficacy in secondary syphilis may be slightly lower, some physicians administer a second dose of 2.4 million units 1 week after the initial dose at this stage of disease. Clinical relapse can follow treatment with penicillin G benzathine in patients with both HIV infection and early syphilis. Because the risk of neurorelapse may be higher in HIV-infected patients, examination of CSF from HIV-seropositive individuals with syphilis of any stage is recommended by some experts; therapy appropriate for neurosyphilis should be given if there is any evidence of CNS syphilis.

For penicillin-allergic patients with early syphilis, a 2-week course of therapy with doxycycline or tetracycline is recommended. These regimens appear to be effective, although no well-controlled studies have been performed and poor compliance may be problematic. Limited studies suggest that ceftriaxone (1 g/d, given intramuscularly or intravenously, for 8 to 10 days) and azithromycin (a single oral dose of 2 g) may be effective against early syphilis. These nonpenicillin regimens have not been evaluated in HIV-infected individuals and should be used with caution.

LATE LATENT AND LATE SYPHILIS If CSF abnormalities are found, the patient should be treated for neurosyphilis. The recommended treatment for late latent syphilis with normal CSF, for cardiovascular syphilis, and for late benign syphilis (gumma) is penicillin G benzathine, 2.4 million units intramuscularly once a week for 3 successive weeks (7.2 million units total). Doxycycline or tetracycline (given for 4 weeks) offers an untested alternative for penicillin-allergic patients with latent or late syphilis and normal CSF. Penicillin-allergic HIV-infected persons with late latent or late syphilis should be desensitized and treated with penicillin if compliance and follow-up cannot be ensured. The clinical response to treatment for benign tertiary syphilis is usually impressive; however, responses to therapy for cardiovascular syphilis are not dramatic because aortic aneurysm and aortic regurgitation cannot be reversed by antibiotic treatment.

NEUROSYPHILIS Penicillin G benzathine, given in total doses of up to 7.2 million units to adults, or 50,000 units/kg to infants, does not produce detectable concentrations of penicillin G in CSF, and asymptomatic neurosyphilis may relapse in patients treated with 2.4 million units; the risk may be higher in HIV-infected patients. Therefore, the use of penicillin G benzathine alone for the treatment of neurosyphilis is not recommended. On the other hand, administration of intravenous penicillin G in recommended doses is thought to ensure treponemicidal concentrations of penicillin G in CSF. The clinical response to penicillin therapy for meningeal syphilis is dramatic, but the response to treatment for parenchymal neurosyphilis is variable. In general, treatment of neurosyphilis with existing damage may produce no clinical change but may arrest disease progression.

Several recent publications have reported neurologic relapse after high-dose intravenous penicillin therapy for neurosyphilis in HIV-infected patients. No alternative therapies have been explored, but careful follow-up is essential, and re-treatment is warranted in such patients.

No data support the use of antibiotics other than penicillin G for the treatment of neurosyphilis; however, some of the third-generation cephalosporins and azithromycin may deserve further evaluation. In patients with penicillin allergy demonstrated by skin testing, desensitization and treatment with penicillin is the recommended course.

MANAGEMENT OF SYPHILIS IN PREGNANCY Every pregnant woman should undergo a nontreponemal test at her first prenatal visit, and women at high risk of exposure should have a repeat test in the third trimester and at delivery. In the untreated pregnant patient with presumed syphilis, expeditious evaluation and initiation of treatment appropriate to the stage of the disease are essential. Patients should be warned of the risk of a Jarisch-Herxheimer reaction, which may be associated with mild premature contractions but rarely results in premature delivery.

Penicillin is the only recommended therapy for syphilis in pregnancy. If the patient has a well-documented penicillin allergy, desensitization and penicillin therapy should be undertaken according to the CDC's 2002 treatment guidelines. After treatment, a quantitative nontreponemal test should be repeated monthly throughout pregnancy. Treated women whose titers rise by fourfold or who do not show a fourfold decrease in titer over a 3-month period should be re-treated.

Evaluation and Management of Congenital Syphilis Newborn infants of mothers with reactive serologic tests may themselves have reactive tests, whether or not they have become infected, because of transplacental transfer of maternal IgG antibody. Rising or persistent titers indicate infection, and the infant should be treated. Neonatal IgM antibody can be detected in cord or neonatal serum with the syphilis Captia-M or 19S IgM FTA-ABS test; its detection indicates active infection. For asymptomatic infants born to women treated adequately with penicillin during pregnancy, monthly quantitative nontreponemal tests may be performed to monitor for appropriate declines in titer.

An infant should be treated at birth if the seropositive mother has received penicillin therapy in the third trimester, inadequate penicillin treatment, or therapy with a drug other than penicillin; if her treatment status is unknown; or if the infant may be difficult to follow. It is unwise to require proof of diagnosis before treatment in such cases. The CSF should be examined to obtain baseline values before treatment. Penicillin is the only recommended drug for syphilis in infants. The penicillin dosage used for the treatment of the patient with late congenital syphilis is calculated in the same way as for the infant, until dosage based on weight reaches that used for adult neurosyphilis. Specific recommendations for the treatment of infants are included in the CDC's 2002 guidelines.

Jarisch-Herxheimer Reaction A dramatic though usually mild reaction consisting of fever (average temperature elevation, 1.5°C), chills, myalgias, headache, tachycardia, increased respiratory rate, increased circulating neutrophil count, and vasodilation with mild hypotension may follow the initiation of treatment for syphilis. This reaction occurs in ~50% of patients with primary syphilis, 90% of those with secondary syphilis, and 25% of those with early latent syphilis, and defervescence takes place within 12 to 24 h. The reaction is more delayed in neurosyphilis, with fever peaking after 12 to 14 h. In patients with secondary syphilis, erythema and edema of the mucocutaneous lesions may increase. Patients should be warned to expect such symptoms, which can be managed with symptom-based treatment. Steroid and other anti-inflammatory therapy is not required for this mild transient reaction.

Follow-Up Evaluation of Responses to Therapy The response of syphilis to treatment should be determined by monitoring of the quantitative VDRL or RPR titer (Table 153-4). More frequent serologic examination is recommended for patients concurrently infected with HIV. Because the FTA-ABS and agglutination tests remain positive in most patients treated for seropositive syphilis, these tests are not useful in following the response to therapy. After successful treatment of seropositive first-episode primary or secondary syphilis, the VDRL titer progressively declines, becoming negative by 12 months in 40 to 75% of seropositive primary cases and in 20 to 40% of secondary cases. Patients with a history of syphilis have less rapid declines in titer and are less likely to become VDRL- or RPR-negative. Re-treatment should be considered if serologic responses are not adequate or if clinical signs persist or recur. Every effort should be made to differentiate treatment failure from reinfection, and the CSF should be examined. Patients in whom treatment failure is suspected, especially those with abnormal CSF, should be treated for neurosyphilis. If the patient remains seropositive but asymptomatic after such re-treatment, no further therapy is necessary. Patients treated for late latent syphilis frequently have low initial VDRL or RPR titers and may not have a fourfold drop after therapy with penicillin; about half of these patients remain seropositive (with low titers) for years after therapy. Re-treat-

TABLE 153-4 *Recommended Follow-Up Evaluation after Therapy for Syphilis*

Stage of Syphilis	Tests to Perform	When to Perform	Re-Treatment[a] Considered If:
Primary or secondary	Quantitative RPR or VDRL[b]	HIV-uninfected: 6 and 12 months HIV-infected: 3, 6, 9, and 12 months	1. Titer increases by fourfold *or* 2. Titer fails to decline by fourfold or test fails to become nonreactive by 6 months *or* 3. Clinical signs persist or recur
Latent or late	Quantitative RPR or VDRL[b]	6, 12, and 24 months	1. Titer increases by fourfold *or* 2. Initial titer of ≥1:32 fails to decline by fourfold by 6 months *or* 3. New clinical signs develop
Neurosyphilis (asymptomatic or symptomatic)	1. If CSF pleocytosis was documented initially, repeat CSF exam. 2. Monitor decline in CSF protein and CSF-VDRL. (Note: Rate of decline may be slow.) 3. Quantitative RPR or VDRL[b]	1. Every 6 months until CSF cell count is normal 2. Until normal 3. At 6, 12, 18, and 24 months	1. CSF cell count has not decreased at 6 months *or* 2. CSF is not normal after 2 years

[a] Try to distinguish between reinfection and treatment failure. If evidence of treatment failure exists, perform CSF examination. If CSF is normal, treat as for late latent syphilis (Table 153-3). If CSF is abnormal, treat as for neurosyphilis (Table 153-3).

[b] VDRL and RPR titers cannot be compared; use the same test for each follow-up sample.

ment is not warranted unless the titer rises or signs and symptoms of syphilis appear.

The activity of neurosyphilis correlates best with CSF pleocytosis, and this measure provides the most sensitive index of response to treatment. An elevated CSF cell count falls to normal in 3 to 12 months in adequately treated HIV-uninfected patients. The persistence of mild pleocytosis in HIV-infected patients may be due to the presence of HIV in CSF; this scenario may be difficult to distinguish from treatment failure. Elevated levels of CSF protein fall more slowly, and the CSF VDRL titer declines gradually over a period of several years.

IMMUNITY TO AND PREVENTION OF SYPHILIS The rate of development of acquired resistance to *T. pallidum* after natural or experimental infection is related to the size of the antigenic stimulus, which depends on both the size of the infecting inoculum and the duration of infection before treatment. The role of serum antibody in conferring immunity to syphilis remains undefined, although antibodies have been implicated in strain-specific immunity. Cellular immunity is considered to be of major importance in immunity and in the healing of early lesions. The cellular infiltration, predominantly T lymphocytes and macrophages, produces a T_H1 cytokine milieu consistent with the clearance of organisms by activated macrophages. Specific antibody enhances phagocytosis and is required for macrophage-mediated killing of *T. pallidum*. Recent unpublished studies indicate that sequence variation of TprK occurs during *T. pallidum* infection. This observation suggests a role for antigenic variation in the persistence of infection and in susceptibility to reinfection with another strain.

154 ENDEMIC TREPONEMATOSES

Sheila A. Lukehart

The endemic, or nonvenereal, treponematoses are bacterial infections that are caused by close relatives of *Treponema pallidum* subspecies *pallidum*, the etiologic agent of venereal syphilis (Chap. 153). Yaws, pinta, and endemic syphilis are distinguished from venereal syphilis by mode of transmission, age of acquisition, geographic distribution, and clinical features. These infections are limited primarily to rural areas of developing nations and are seen in the United States and Europe only in recent immigrants from endemic regions. Much of our "knowledge" about the endemic treponematoses is based upon impressions and observations of health care workers who have visited endemic areas; virtually no well-designed studies of the natural history, diagnosis, or treatment of these infections have been conducted. The treponemal infections are compared and contrasted in Table 154-1.

EPIDEMIOLOGY The endemic treponematoses are chronic diseases acquired during childhood and, like syphilis, can cause severe late manifestations years after initial infection. These infections were very common in Africa, Asia, and South America when the World Health Organization (WHO) and UNICEF embarked on a highly successful mass eradication campaign. From 1952 to 1969, it is estimated that over 160 million people were examined for treponemal infections and over 50 million cases, contacts, and latent infections were treated. This categorical program is one of WHO's outstanding successes in that the prevalence of active yaws was reduced from >20% to <1% in many rural areas and endemic syphilis was eradicated in Bosnia. In the decades since the eradication programs, lack of focused surveillance and diversion of resources to other pressing needs have resulted in a resurgence of these infections in some regions, particularly in Africa. The estimated geographic distribution of the endemic treponematoses in the 1990s is shown in Fig. 154-1. In the early 1980s, WHO sponsored a series of regional meetings on the endemic treponematoses, and areas of resurgent yaws morbidity were identified in West Africa (Ivory Coast, Ghana, Togo, Benin) and extending into the Central African Republic and rural Democratic Republic of Congo (formerly Zaire). The prevalence of endemic syphilis is estimated to be >10% in some regions of Mali, Niger, Burkina Faso, and Senegal. In Asia and the western Pacific, yaws is still prevalent in Indonesia,

TABLE 154-1 *Comparison of the Treponemes and Associated Diseases*

Feature	Venereal Syphilis	Yaws	Endemic Syphilis	Pinta
Organism	*T. pallidum* subspecies *pallidum*	*T. pallidum* subspecies *pertenue*	*T. pallidum* subspecies *endemicum*	*T. carateum*
Mode of transmission	Sexual, transplacental	Skin-to-skin	Household contacts: mouth-to-mouth or via shared drinking/eating utensils	Skin-to-skin
Usual age of acquisition	Adulthood	Early childhood	Early childhood	Late childhood
Primary lesion	Cutaneous ulcer (chancre)	Papilloma, often ulcerative	Rarely seen	Nonulcerating papule with satellites, pruritic
Location	Genital, oral, anal	Extremities	Oral	Extremities, face
Secondary lesions	Mucocutaneous lesions; condylomata lata	Cutaneous papulosquamous lesions; osteoperiostitis	Florid mucocutaneous lesions (mucous patch, split papule, condyloma latum); osteoperiostitis	Pintides, pigmented, pruritic
Infectious relapses	~25%	Common	Unknown	None
Late complications	Gummas, cardiovascular and CNS involvement[a]	Destructive gummas of skin, bone, cartilage	Destructive gummas of skin, bone, cartilage	Nondestructive, dyschromic, achromic macules

[a] CNS involvement in the endemic treponematoses has been postulated by some investigators (see text).

Papua New Guinea, and the Solomon Islands; cases have also been identified in Laos and Kampuchea. In the Americas, foci of yaws persist in Haiti and other Caribbean islands, Peru, Colombia, Ecuador, Brazil, Guyana, and Surinam. Pinta is limited to Central America and northern South America, where it is found rarely and only in remote villages. No accurate prevalence data are available for any of the endemic treponematoses because of a lack of active surveillance for these diseases. WHO estimates that there are 2.6 million cases overall, of which 460,000 are infectious.

MICROBIOLOGY The etiologic agents of the endemic treponematoses are *T. pallidum* subspecies *pertenue* (yaws), *T. pallidum* subspecies *endemicum* (endemic syphilis), and *T. carateum* (pinta). These little-studied organisms are morphologically identical to *T. pallidum* subspecies *pallidum*, and no antigenic differences among the pathogenic treponemes have been identified to date. A controversy has existed about whether the treponematoses are caused by different organisms or by the same organism, with clinical manifestations and routes of transmission defined by the climate of the region and the culture of the population. Three of the four organisms have been placed in the same species because of their genetic similarity; the fourth (*T. carateum*) remains a separate species simply because no organisms have been available for genetic studies. However, a molecular signature has been defined that can be used to differentiate *T. pallidum* subspecies *pallidum* from the nonvenereal subspecies of *T. pallidum*, and unpublished studies have identified a number of distinct differences in the *tpr* gene family between venereal and nonvenereal treponemes. Whether these differences are related to the different clinical courses has not yet been determined.

CLINICAL FEATURES All of the treponemal infections are characterized by defined disease stages, with a localized primary lesion, disseminated secondary lesions, periods of latency, and possible late lesions. Primary and secondary stages are more frequently overlapping in yaws and endemic syphilis, and the late manifestations of pinta are very mild relative to the destructive lesions of the other treponematoses. The current preference is to divide the clinical course of the endemic treponematoses into "early" and "late" stages.

The major clinical features differing between venereal syphilis and the nonvenereal infections are the apparent lack of congenital transmission and the lack of central nervous system (CNS) involvement in the nonvenereal infections. It is not known whether these distinctions are accurate. Because of the high degree of genetic relatedness among the organisms, there is little biologic reason to think that *T. pallidum* subspecies *endemicum* and *T. pallidum* subspecies *pertenue* would be unable to cross the blood-brain barrier or to invade the placenta. These organisms obviously can disseminate from the site of primary infection to other tissues, and they can persist for decades. In this respect, they are like *T. pallidum* subspecies *pallidum*. The lack of recognized congenital infection may be due to the fact that the nonvenereal treponematoses are usually acquired during childhood. By the time an infected girl becomes sexually mature, she would be at low risk for

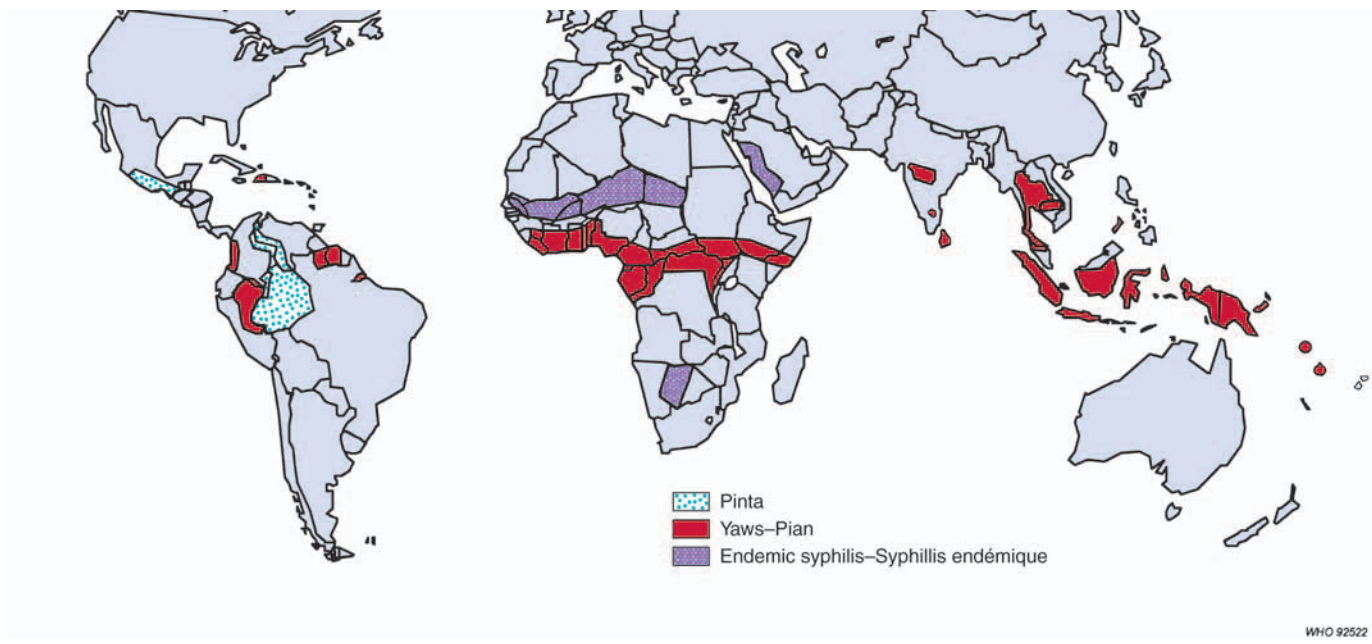

FIGURE 154-1 Geographic distribution of endemic treponematoses in the 1990s. *(Courtesy of the World Health Organization.)*

transplacental transmission. Neurologic involvement may not have been recognized in nonvenereal treponemal infection because of the lack of trained medical personnel in endemic regions, the lag of years to decades between acquisition of infection and possible CNS manifestations, or a low rate of symptomatic CNS disease.

Some published evidence supports congenital transmission as well as cardiovascular, ophthalmologic, and CNS involvement in yaws. Although the case is strong, particularly for CNS involvement, most studies that have shown a relatively high incidence (average, 24.9%) of cerebrospinal fluid (CSF) abnormalities in patients with yaws were not controlled for other possible causes of CSF abnormalities, did not include treponeme-specific tests, or did not follow patients for resolution of abnormalities after antitreponemal therapy. Thus, while no firm conclusions can be drawn about the invasion of the CNS and placenta by the non-*pallidum* treponemes, it may be erroneous to accept unquestioningly the frequently repeated belief that these organisms fail to cause such manifestations.

Yaws Also known as *pian*, *framboesia*, or *bouba*, yaws is a chronic infection that is usually acquired in childhood and is caused by *T. pallidum* subspecies *pertenue*. The disease is characterized by the development of one or several primary lesions (called the "mother yaw"), followed by the appearance of multiple disseminated skin lesions. The early lesions may persist for many months, are infectious, and usually recur several times within the early years of infection. Late manifestations are destructive and can involve skin, bone, and joints.

The infection is transmitted by direct contact with infectious lesions, and transmission may be enhanced by disruption of the skin by insect bites or abrasions. Children with open lesions and without covering clothing are most likely to transmit infection during play or group sleeping. After an average incubation period estimated at 3 to 4 weeks, the first lesion begins as a papule, usually on an extremity, and then enlarges (particularly during moist warm weather) to become papillomatous or "raspberry-like" (thus the name "framboesia") (Fig. 154-2). Regional lymphadenopathy develops, and the lesion usually heals within 6 months; dissemination is thought to occur during the early weeks and months of infection. A generalized secondary eruption, accompanied by generalized lymphadenopathy, appears either concurrent with or following the primary lesion, may take several forms (macular, papular, or papillomatous), and may become secondarily infected with other bacteria. Painful papillomatous lesions on the soles of the feet result in a painful crablike gait ("crab yaws"), and periostitis may result in nocturnal bone pain and polydactylitis. All early skin lesions are infectious, and cutaneous relapses are common during the first 5 years. Late yaws is recognized in ~10% of untreated patients and is manifested by gummas of the skin and long bone, hyperkeratoses of the palms and soles, osteitis and periostitis, and hydrarthrosis. The late gummatous lesions are characteristically very destructive and extensive. Destruction of the nose, maxilla, palate, and pharynx is termed *gangosa* and is similar to the destructive lesions seen in leprosy and leishmaniasis.

Endemic Syphilis Endemic syphilis, also called *bejel*, *siti*, *dichuchwa*, *njovera*, or *skerljevo*, is a chronic infection caused by *T. pallidum* subspecies *endemicum*. Like other endemic treponematoses, endemic syphilis is chronic and is acquired in childhood. The early lesions are primarily localized to the mucocutaneous and mucosal surfaces, and the infection may be transmitted by direct contact, by kissing, or by sharing drinking and eating utensils. A role for insects in transmission has been suggested but is unproved. The initial lesion, usually an intraoral papule (Fig. 154-2), often goes unrecognized and is followed by mucous patches on the oral mucosa and mucocutaneous lesions resembling the condylomata lata of secondary syphilis. This eruption may last for months or even years, and treponemes can readily be demonstrated in early lesions. Periostitis and regional lymphadenopathy are common. After a variable period of latency, late manifestations may appear, including osseous and cutaneous gummas. Destructive gummas, osteitis, and gangosa are more common in endemic syphilis than in late yaws. Gummas of the nipples develop in women who have previously had endemic syphilis and who breast-feed infants with oral lesions. Thus, it appears that the late lesion may result from repeated exposure of a sensitized host.

Pinta Pinta (also called *mal del pinto*, *carate*, *azul*, or *purupuru*) is the most benign of the treponemal infections and is caused by *T. carateum*. This disease has three stages that are characterized by marked changes in skin color (Fig. 154-2), but it does not appear to cause destructive lesions or to involve other tissues. Transmission occurs by direct contact, usually during late childhood. The initial papule is most often located on the extremities or face and is pruritic. After one to many months of infection, numerous disseminated secondary lesions (*pintides*) appear. These lesions are initially red but become deeply pigmented, ultimately turning a dark slate blue. The secondary lesions are infectious and highly pruritic and may persist for years. Late pigmented lesions are called *dyschromic macules* and contain treponemes. Over time, most pigmented lesions show varying degrees of depigmentation, becoming brown and eventually white and giving the skin a mottled appearance. White achromic lesions are characteristic of the late stage.

DIAGNOSIS Diagnosis of the endemic treponematoses is based upon clinical manifestations and, when available, dark-field microscopy and serologic testing. The same tests that are used for venereal syphilis (Chap. 153) become reactive during all treponemal infections, and there is no serologic test that can discriminate among the different infections. The nonvenereal treponemal infections should be considered in the evaluation of a reactive syphilis serology in any person who has emigrated from an endemic area.

TREATMENT

The recommended therapy for patients and their contacts is benzathine penicillin at a dose of 1.2 million units intramuscularly; the dose for children <10 years of age is 600,000 units. There have been no controlled studies to show that the recommended lower dose (which is half the dose recommended for patients and contacts in early venereal syphilis) is effective in stopping relapse or progression to late disease. Definitive evidence of resistance to penicillin is lacking. However, because failure to heal existing lesions and frequent relapse following treatment for yaws have been described in Papua New Guinea, some health workers have suggested doubling the recommended dose of benzathine penicillin. Limited data suggest the efficacy of tetracycline for the treatment of yaws, but no such data exist for other endemic treponematoses. Solely on the basis of experience with venereal syphilis, it is thought that doxycycline, tetracycline, and erythromycin (at doses appropriate for syphilis; Chap. 153) are therapeutic alternatives for patients allergic to penicillin. A Jarisch-Herxheimer reaction (Chap. 153) may follow treatment of endemic treponematoses. Nontreponemal serologic titers [in the Venereal Disease Research Laboratory (VDRL) slide test or the rapid plasma reagin (RPR) test] usually decline after effective therapy, but patients may not become seronegative.

CONTROL The endemic treponematoses can be controlled with inexpensive therapy. However, remote locations of affected populations can limit the availability of medical care. Although the mass treatment programs of three decades ago were widely successful, time has shown that sustained control requires vigilance in regular screening and in the investigation of outbreaks—luxuries that are often impossible in countries with more pressing medical needs. There is concern that, as HIV spreads throughout developing countries, it may markedly affect the manifestations and transmission of the endemic treponematoses.

155 LEPTOSPIROSIS

Peter Speelman

Leptospirosis is an emerging infectious disease, as illustrated by recent large outbreaks in Asia, Central and South America, and the United States. The disease is caused by pathogenic leptospires and characterized by a broad spectrum of clinical manifestations, varying from inapparent infection to fulminant, fatal disease. In its mild form, leptospirosis may present as an influenza-like illness with headache and myalgias. Severe leptospirosis, characterized by jaundice, renal dysfunction, and hemorrhagic diathesis, is referred to as *Weil's syndrome*.

ETIOLOGIC AGENTS Leptospires are spirochetes belonging to the order Spirochaetales and the family Leptospiraceae. Traditionally, the genus *Leptospira* comprised two species: the pathogenic *L. interrogans* and the free-living *L. biflexa*. Although 16 genomospecies of pathogenic leptospires are now recognized on the basis of their DNA relatedness, it is more practical clinically and epidemiologically to use a classification based on serologic differences. The pathogenic leptospires are divided into serovars according to their antigenic composition. More than 200 serovars make up the 25 serogroups.

Leptospires are coiled, thin, highly motile organisms with hooked ends and two periplasmic flagella that permit burrowing into tissue (Fig. 155-1). These organisms are 6 to 20 μm long and ~0.1 μm wide; they stain poorly but can be seen microscopically by dark-field examination and after silver impregnation staining. Leptospires require special media and conditions for growth; it may take weeks for cultures to become positive.

EPIDEMIOLOGY Leptospirosis is an important zoonosis with a worldwide distribution that affects at least 160 mammalian species. Rodents, especially rats, are the most important reservoir, although other wild mammals as well as domestic and farm animals may also harbor these microorganisms. Leptospires establish a symbiotic relationship with their host and can persist in the renal tubules for years. Some serovars are generally associated with particular animals—e.g., icterohaemorrhagiae/copenhageni with rats, grippotyphosa with voles, hardjo with cattle, canicola with dogs, and pomona with pigs—but may occur in other animals as well.

Transmission of leptospires may follow direct contact with urine, blood, or tissue from an infected animal or exposure to a contaminated environment; human-to-human transmission is rare. Since leptospires are excreted in the urine and can survive in water for many months, water is an important vehicle in their transmission. Epidemics of leptospirosis may result from exposure to flood waters contaminated by urine from infected animals, as has been reported from Nicaragua. Leptospirosis occurs most commonly in the tropics because the climate as well as the sometimes poor hygienic conditions favor the pathogen's survival. In many developing countries, leptospirosis is an underestimated problem. Reliable data on morbidity and mortality from leptospirosis have gradually started to appear. In 1999, more than 500,000 cases were reported from China, with case-fatality rates ranging from 0.9 to 7.9%. In Brazil, more than 28,000 cases were reported in the same year.

Humans are not commonly infected with leptospires. However, in the United States, the 40 to 120 cases reported annually to the Centers for Disease Control and Prevention (CDC) surely represent a significant underestimation of the total number. Certain occupational groups

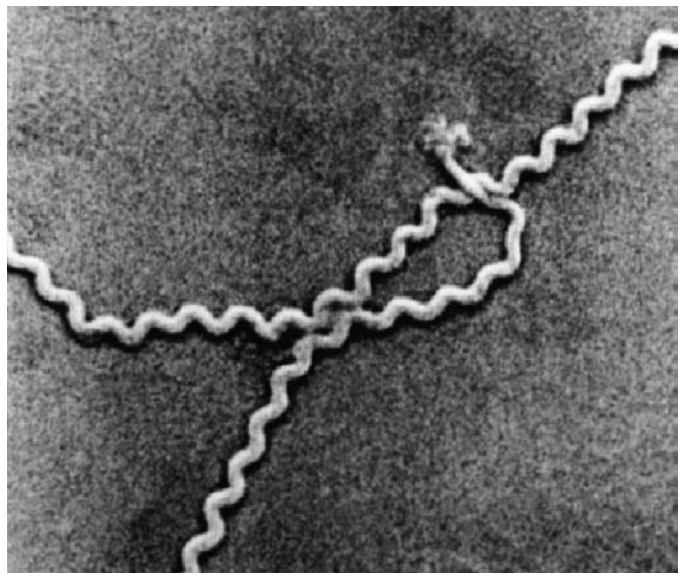

FIGURE 155-1 Scanning electron micrograph of leptospires.

are at especially high risk; included are veterinarians, agricultural workers, sewage workers, slaughterhouse employees, and workers in the fishing industry. Such individuals may acquire leptospirosis through direct exposure to or contact with contaminated water and soil. Leptospirosis has also been recognized in deteriorating inner cities where rat populations are expanding. One report described leptospirosis in urban residents of Baltimore who were sporadically exposed to rat urine.

Recreational exposure and domestic-animal contact are also prominent sources of leptospirosis. Recreational water activities, such as canoeing, windsurfing, swimming, and waterskiing, place persons at risk for leptospirosis. In 1998, a large outbreak occurred among athletes and community residents after a triathlon in Illinois. Among athletes, the ingestion of one or more swallows of lake water was a prominent risk factor for illness. Heavy rains that preceded the triathlon, with consequent agricultural runoff, are likely to have increased the level of leptospiral contamination in the lake water.

Sometimes leptospirosis is acquired during travel abroad. In a study in the Netherlands, 14% of patients with confirmed leptospirosis had acquired the infection while traveling in tropical countries, mostly in Southeast Asia. Transmission via laboratory accidents has been reported but is rare. Leptospirosis develops occasionally after unanticipated immersion in contaminated water (e.g., in an automobile accident) and rarely after an animal bite. Most cases occur in men, with a peak incidence during the summer and fall in Western countries and during the rainy season in the tropics.

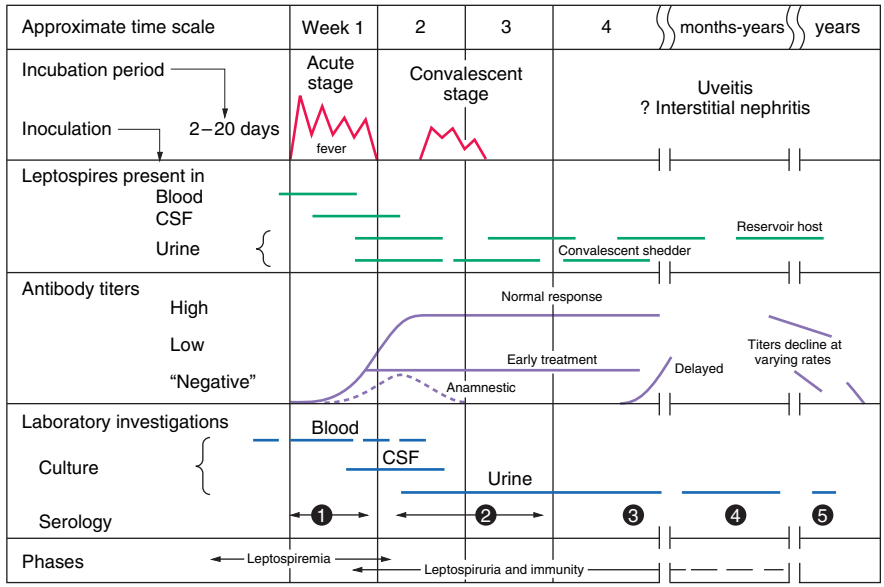

FIGURE 155-2 Biphasic nature of leptospirosis and relevant investigations at different stages of disease. Specimens 1 and 2 for serology are acute-phase serum samples; specimen 3 is a convalescent-phase serum sample that may facilitate detection of a delayed immune response; and specimens 4 and 5 are follow-up serum samples that can provide epidemiologic information, such as the presumptive infecting serogroup. [*Reprinted as adapted by Levett (from Turner LH: Leptospirosis. BMJ 1:231, 1969) with permission from the American Society for Microbiology and the BMJ Publishing Group.*]

PATHOGENESIS The pathogenesis of leptospirosis is incompletely understood. Leptospires may enter the host through abrasions in the skin or through intact mucous membranes, especially the conjunctiva and the lining of the oro- and nasopharynx. Drinking of contaminated water may introduce leptospires through the mouth, throat, or esophagus. After entry of the organisms, leptospiremia develops, with subsequent spread to all organs. Multiplication takes place in blood and in tissues, and leptospires can be isolated from blood and cerebrospinal fluid (CSF) during the first 4 to 10 days of illness. CSF examination during this period documents pleocytosis in the majority of instances, but only a minority of patients develop symptoms and signs of meningitis at this point. All forms of leptospires can damage the wall of small blood vessels; this damage leads to vasculitis with leakage and extravasation of cells, including hemorrhages. The most important known pathogenic properties of leptospires are adhesion to cell surfaces and cellular toxicity.

Vasculitis is responsible for the most important manifestations of the disease. Although leptospires mainly infect the kidneys and liver, any organ may be affected. In the kidney, leptospires migrate to the interstitium, renal tubules, and tubular lumen, causing interstitial nephritis and tubular necrosis. Hypovolemia due to dehydration or altered capillary permeability may contribute to the development of renal failure. In the liver, centrilobular necrosis with proliferation of Kupffer cells may be found. However, severe hepatocellular necrosis is not a feature of leptospirosis. Pulmonary involvement is the result of hemorrhage and not of inflammation. Invasion of skeletal muscle by leptospires results in swelling, vacuolation of the myofibrils, and focal necrosis. In severe leptospirosis, vasculitis may ultimately impair the microcirculation and increase capillary permeability, resulting in fluid leakage and hypovolemia.

When antibodies are formed, leptospires are eliminated from all sites in the host except the eye, the proximal renal tubules, and perhaps the brain, where they may persist for weeks or months. The persistence of leptospires in the aqueous humor occasionally causes chronic or recurrent uveitis. The systemic immune response is effective in eliminating the organism but may also produce symptomatic inflammatory reactions. A rise in antibody titer coincides with the development of meningitis; this association suggests that an immunologic mechanism is responsible.

After the start of antimicrobial treatment for leptospirosis, a Jarisch-Herxheimer reaction similar to that seen in other spirochetal diseases may develop. Although frequently described in older publications, this reaction seems to be a rare event in leptospirosis and is certainly less frequent in this infection than in other spirochetal diseases.

CLINICAL MANIFESTATIONS (Fig. 155-2) It is important to try to obtain a history of exposure to contaminated materials. Serologic evidence of past inapparent infection is found in 15 to 40% of persons who have been exposed but have not become ill. In symptomatic cases of leptospirosis, clinical manifestations vary from mild to serious or even fatal. More than 90% of symptomatic persons have the relatively mild and usually anicteric form of leptospirosis, with or without meningitis. Severe leptospirosis with profound jaundice (Weil's syndrome) develops in 5 to 10% of infected individuals. The idea that distinct clinical syndromes are associated with specific serogroups has been refuted.

The incubation period is usually 1 to 2 weeks but ranges from 2 to 20 days (Fig. 155-2). Typically, an acute leptospiremic phase is followed by an immune leptospiruric phase. The distinction between the first and second phases is not always clear, and milder cases do not always include the second phase.

Anicteric Leptospirosis Leptospirosis may present as an acute influenza-like illness, with fever, chills, severe headache, nausea, vomiting, and myalgias. Muscle pain, which especially affects the calves, back, and abdomen, is an important feature of leptospiral infection. Less common features include sore throat and rash. The patient usually has an intense headache (frontal or retroorbital) and sometimes develops photophobia. Mental confusion may be evident. Pulmonary involvement, manifested in most cases by cough and chest pain and in a few cases by hemoptysis, is not uncommon.

The most common finding on physical examination is fever with conjunctival suffusion. Less common findings include muscle tender-

ness, lymphadenopathy, pharyngeal injection, rash, hepatomegaly, and splenomegaly. The rash may be macular, maculopapular, erythematous, urticarial, or hemorrhagic. Mild jaundice may be present.

Most patients become asymptomatic within 1 week. After an interval of 1 to 3 days, the illness recurs in a number of cases. The start of this second (immune) phase coincides with the development of antibodies. Symptoms are more variable than during the first (leptospiremic) phase. Usually the symptoms last for only a few days, but occasionally they persist for weeks. Often the fever is less pronounced and the myalgias are less severe than in the leptospiremic phase. An important event during the immune phase is the development of aseptic meningitis. Although no more than 15% of all patients have symptoms and signs of meningitis, many patients have CSF pleocytosis. Meningeal symptoms usually disappear within a few days but may persist for weeks. Similarly, pleocytosis generally disappears within 2 weeks but occasionally persists for months. Aseptic meningitis is more common among children than among adults. Iritis, iridocyclitis, and chorioretinitis—late complications that may persist for years—can become apparent as early as the third week but often present several months after the initial illness. One epidemic of uveitis among patients with leptospirosis has been reported. Mortality in anicteric leptospirosis is almost nil, although death as a result of pulmonary hemorrhage occurred in 2.4% of cases in a Chinese outbreak.

Severe Leptospirosis (Weil's Syndrome) Weil's syndrome, the most severe form of leptospirosis, is characterized by jaundice, renal dysfunction, hemorrhagic diathesis, and a mortality rate ranging from 5 to 15%. In Europe, this syndrome is frequently but not exclusively associated with infection due to serovar icterohaemorrhagiae/copenhageni. The onset of illness is no different from that of less severe leptospirosis; however, after 4 to 9 days, jaundice as well as renal and vascular dysfunction generally develop. Although some degree of defervescence may be noted after the first week of illness, a biphasic disease pattern like that seen in anicteric leptospirosis is lacking. The jaundice of Weil's syndrome, which can be profound and give an orange cast to the skin, is usually not associated with severe hepatic necrosis. Death is rarely due to liver failure. Hepatomegaly and tenderness in the right upper quadrant are usually detected. Splenomegaly is found in 20% of cases.

Renal failure may develop, often during the second week of illness. Hypovolemia and decreased renal perfusion contribute to the development of acute tubular necrosis with oliguria or anuria. Dialysis is sometimes required, although a fair number of cases can be managed without dialysis. Renal function may be completely regained.

Pulmonary involvement occurs frequently; in some clusters of cases, it is a major manifestation, resulting in cough, dyspnea, chest pain, and blood-stained sputum and sometimes in hemoptysis or even respiratory failure. Hemorrhagic manifestations are seen in Weil's syndrome: epistaxis, petechiae, purpura, and ecchymoses are found commonly, while severe gastrointestinal bleeding and adrenal or subarachnoid hemorrhage are detected rarely.

Rhabdomyolysis, hemolysis, myocarditis, pericarditis, congestive heart failure, cardiogenic shock, adult respiratory distress syndrome, necrotizing pancreatitis, and multiorgan failure have all been described during severe leptospirosis.

LABORATORY AND RADIOLOGIC FINDINGS (Fig. 155-2) The kidneys are invariably involved in leptospirosis. Related findings range from urinary sediment changes (leukocytes, erythrocytes, and hyaline or granular casts) and mild proteinuria in anicteric leptospirosis to renal failure and azotemia in severe disease.

The erythrocyte sedimentation rate is usually elevated. In anicteric leptospirosis, peripheral leukocyte counts range from 3000 to 26,000/μL, with a left shift; in Weil's syndrome, leukocytosis is often marked. Mild thrombocytopenia occurs in up to 50% of patients and is associated with renal failure.

In contrast to patients with acute viral hepatitis, those with leptospirosis typically have elevated serum levels of bilirubin and alkaline phosphatase as well as mild increases (up to 200 U/L) in serum levels of aminotransferases. In Weil's syndrome, the prothrombin time may be prolonged but can be corrected with vitamin K. Levels of creatine phosphokinase, which are elevated in up to 50% of patients with leptospirosis during the first week of illness, may help to differentiate this infection from viral hepatitis.

When a meningeal reaction develops, polymorphonuclear leukocytes predominate initially and the number of mononuclear cells increases later. The protein concentration in the CSF may be elevated; CSF glucose levels are normal.

In severe leptospirosis, pulmonary radiographic abnormalities are more common than would be expected on the basis of physical examination. These abnormalities most frequently develop 3 to 9 days after the onset of illness. The most common radiographic finding is a patchy alveolar pattern that corresponds to scattered alveolar hemorrhage. Radiographic abnormalities most often affect the lower lobes in the periphery of the lung fields.

DIAGNOSIS (Fig. 155-2) A definite diagnosis of leptospirosis is based either on isolation of the organism from the patient or on seroconversion or a rise in antibody titer in the microscopic agglutination test (MAT). In the United States, the MAT is performed only at the CDC. In cases with strong clinical evidence of infection, a single antibody titer of 1:400 to 1:800 (depending on whether the case occurs in a low- or high-endemic area) in the MAT is required. Preferably, a fourfold or greater rise in titer is detected between acute- and convalescent-phase serum specimens. Antibodies generally do not reach detectable levels until the second week of illness. The antibody response can be affected by early treatment.

The MAT, which uses a battery of live leptospiral strains, and the enzyme-linked immunosorbent assay (ELISA), which uses a broadly reacting antigen, are the standard serologic procedures. These tests usually are available only in specialized laboratories and are used for determination of the antibody titer and for tentative identification of the serogroup—and in some cases the serovar—involved (thus the importance of using antigens representative of the serovars prevalent in the particular geographic area). Since cross-reactions occur frequently, however, it is often impossible to identify the infecting serogroup or serovar. Serologic testing cannot be used as the basis for a decision about whether to start treatment.

In addition to the MAT and the ELISA, various other tests with diagnostic value have been developed. Some tests, such as an indirect hemagglutination test and a microcapsule agglutination test, are commercially available. A recent advance is the development of rapid serologic assays that apply lateral flow, latex agglutination, or ELISA methodology with reasonable sensitivity and specificity. These methods do not require culture or MAT facilities. However, in endemic areas, pooled serum samples from the local population are required as positive and negative controls. Polymerase chain reaction (PCR) techniques have been developed but so far have not found widespread use outside research and reference laboratories.

Leptospires can be isolated from blood and/or CSF during the first 10 days of illness and from urine for several weeks beginning at around 1 week. Cultures most often become positive after 2 to 4 weeks, with a range of 1 week to 4 months. Sometimes urine cultures remain positive for months or years after the start of illness. For isolation of leptospires from body fluids or tissues, Ellinghausen-McCullough-Johnson-Harris (EMJH) medium is useful; other possibilities are Fletcher medium and Korthof medium. Specimens can be mailed to a reference laboratory for culture, since leptospires remain viable in anticoagulated blood (heparin, EDTA, or citrate) for up to 11 days. Isolation of leptospires is important since it is the only way the infecting serovar can be correctly identified. Dark-field examination of blood or urine frequently results in misdiagnosis and should not be used.

DIFFERENTIAL DIAGNOSIS Leptospirosis should be differentiated from other febrile illnesses associated with headache and muscle pain, such

as dengue, malaria, enteric fever, viral hepatitis, *Hantavirus* infections, and rickettsial diseases. In light of the strong similarity in epidemiology and clinical presentation between leptospirosis and *Hantavirus* infections and given the reported occurrence of dual infections, it is advisable to conduct serologic testing for *Hantavirus* in cases of suspected leptospirosis. When patients have a flulike disease with disproportionately severe myalgia or aseptic meningitis, a diagnosis of leptospirosis should be considered.

TREATMENT

The effectiveness of antimicrobial therapy for the mild febrile form of leptospirosis is controversial, but such treatment is indicated for more severe forms. Treatment should be initiated as early as possible; nevertheless, contrary to previous reports, treatment started after the first 4 days of illness is effective.

For severe cases of leptospirosis, intravenous administration of penicillin G, amoxicillin, ampicillin, or erythromycin is recommended (Table 155-1). In milder cases, oral treatment with tetracycline, doxycycline, ampicillin, or amoxicillin should be considered. Although several other antibiotics, including newer cephalosporins, are highly active against leptospires in vitro, no clinical experience has yet been gained with these drugs.

In rare cases, a Jarisch-Herxheimer reaction develops within hours after the start of antimicrobial therapy (see "Pathogenesis" above). Although so far the only effective mode of management is supportive, the role of antibodies to tumor necrosis factor in the treatment of this reaction deserves further study. A beneficial effect of the use of such antibodies for the modulation of the reaction has been demonstrated in patients with louse-borne relapsing fever. Patients with severe leptospirosis and renal failure may require dialysis. Those with Weil's syndrome may need transfusions of whole blood and/or platelets. Intensive care may be necessary.

PROGNOSIS Most patients with leptospirosis recover. Mortality is highest among patients who are elderly and those who have Weil's syndrome. Leptospirosis during pregnancy is associated with high fetal mortality. Long-term follow-up of patients with renal failure and hepatic dysfunction has documented good recovery of renal and hepatic function.

PREVENTION Individuals who may be exposed to leptospires through their occupations or their involvement in recreational water activities should be informed about the risks. Measures for controlling leptospirosis include avoidance of exposure to urine and tissues from infected animals, vaccination of animals, and rodent control. The animal vaccine used in a given area should contain the serovars known to be present in that area. Unfortunately, some vaccinated animals still excrete leptospires in their urine. Vaccination of humans against a specific serovar prevalent in an area has been undertaken in some European and Asian countries and has proved effective. Although a large-scale trial of vaccine in humans has been reported from Cuba, no conclusions can be drawn about efficacy and adverse reactions because of insufficient details on study design. Chemoprophylaxis with doxycycline (200 mg once a week) has appeared to be efficacious to some extent but is indicated only in rare instances of sustained short-term exposure (Table 155-1).

TABLE 155-1 *Treatment and Chemoprophylaxis of Leptospirosis*

Purpose of Drug Administration	*Regimen*
Treatment	
Mild leptospirosis	Doxycycline, 100 mg orally bid *or* Ampicillin, 500–750 mg orally qid *or* Amoxicillin, 500 mg orally qid
Moderate/severe leptospirosis	Penicillin G, 1.5 million units IV qid *or* Ampicillin, 1 g IV qid *or* Amoxicillin, 1 g IV qid *or* Erythromycin, 500 mg IV qid
Chemoprophylaxis	Doxycycline, 200 mg orally once a week

Note: All regimens used for treatment are administered for 7 days.

156 RELAPSING FEVER

David T. Dennis, Edward B. Hayes

DEFINITION The term *relapsing fever* describes two distinct diseases. *Tick-borne (endemic)* relapsing fever (TBRF) is a zoonosis that is transmitted principally from rodents to humans by the bite of various soft ticks. *Louse-borne* (*epidemic*) relapsing fever (LBRF) is a disease of humans that is transmitted from one person to another by the body louse. Both are characterized by recurrent acute episodes of spirochetemia and fever alternating with spontaneous spirochetal clearance and apyrexia.

ETIOLOGY Relapsing fever is caused by infection with spirochetal gram-negative bacteria of the genus *Borrelia* (family Spirochaetaceae). The borreliae are helical in shape and average 0.2 to 0.5 μm in width and 5 to 20 μm in length. They comprise an outer membrane, an intermediate peptidoglycan layer, and an inner cytoplasmic membrane, which encloses the protoplasmic cylinder. A variable number of periplasmic flagella are situated beneath the outer membrane. Relapsing-fever borreliae are slow-growing and microaerophilic; they grow best at 30° to 35°C in Barbour-Stoenner-Kelly (BSK II) medium.

B. recurrentis is the only species that causes LBRF. Most of the several species of *Borrelia* that cause TBRF are named after the species of *Ornithodoros* tick responsible for their transmission. In North America, *B. hermsii* and *B. turicatae* cause almost all cases of TBRF; *B. duttoni* is the most common cause of TBRF in sub-Saharan Africa, an area of high endemicity. Borreliae are unique among bacteria in having a genome composed of a linear chromosome and a series of linear and circular plasmids. The sequences of both the flagellin and the 16S ribosomal RNA genes are homogeneous among LBRF strains; in contrast, there is considerable heterogeneity of these genes between Old World and New World TBRF strains. A unique process of DNA rearrangement within *vmp* genes located on linear plasmids results in extensive variation in the expression of the surface antigens in relapsing-fever borreliae. These *vmp* genes encode variable major proteins (VMPs) found on the spirochete's outer-membrane surface. The antigenic variation generated by sequential expression of previously silent *vmp* genes allows the borreliae to intermittently escape the im-

mune response of the host and results in the febrile relapses that are characteristic of infection with these organisms.

EPIDEMIOLOGY ■ Louse-Borne Relapsing Fever Body lice (*Pediculus humanus* var. *corporis*) become infected with *B. recurrentis* by feeding on spirochetemic humans, the only reservoirs of infection. In lice, *B. recurrentis* spirochetes are found almost exclusively in the hemolymph; humans acquire infection when infected body lice are crushed and their fluids contaminate mucous membranes or breaks in the skin (such as abrasions caused by scratching of pruritic louse bites). Spirochetes are *not* transmitted directly by the bite of a louse (anterior station transmission) or by inoculation of louse feces (posterior station transmission). Lice have a life span of only a few weeks, feed at frequent intervals, and survive only a few days off the human host. Head lice do not appear to be vectors of LBRF.

LBRF has severely affected military and civilian populations disrupted by war and other disasters. In the nineteenth century, the disease was common among slum dwellers, prisoners, and others living in impoverished, overcrowded, and unhygienic conditions. In the first half of the twentieth century, during periods of war and famine, both LBRF and louse-borne typhus were epidemic in eastern Europe, the Balkans, and the former Soviet Union. The global distribution and incidence of LBRF were substantially reduced following improvements in standards of living, sanitation, and hygiene; LBRF is now an important disease only in northeastern Africa, especially the highlands of Ethiopia, where an estimated 10,000 cases occur annually. In Ethiopia, the disease affects mostly homeless men crowded together in unhygienic circumstances, especially during the cool rainy season, when washing and changing clothing is more difficult. LBRF has repeatedly spilled out of Ethiopia into populations of displaced persons in neighboring Somalia and Sudan. During the Second World War, the spread of LBRF from Ethiopia and the Sudan to western Africa was pandemic.

Short-term visitors to endemic areas (e.g., tourists) are at almost no risk of LBRF, but persons who have close contact with LBRF populations (such as relief workers) can acquire the disease from lice, accidental needle sticks, or other direct contact with contaminated blood.

Tick-Borne Relapsing Fever Argasid ticks of the genus *Ornithodoros* transmit TBRF through their saliva and excreta when they feed on humans. As a rule, the ticks become infected with TBRF borreliae as part of a zoonotic cycle when they feed on spirochetemic rodents and lagomorphs; the exception to this rule is *O. moubata*, a tick species that acquires *B. duttoni* by feeding on infected humans. Ticks transmit TBRF borreliae vertically from one stage to the next; in some species, infection is transmitted transovarially over several generations. Soft ticks are hardy and can survive for 10 years with only an occasional blood meal. These ticks feed painlessly, relatively quickly (for 20 to 45 min), and usually at night while hosts are sleeping. Thus patients with TBRF are often unaware of tick exposures.

TBRF borreliae are widely distributed throughout the world. Human infection with these organisms is generally underrecognized and underreported. TBRF is most highly endemic in sub-Saharan Africa but is also found in countries of the Mediterranean littoral, Middle Eastern states, southern Russia, the Indian subcontinent, Central Asia, and China and at low frequency in North, Central, and South America. The disease typically occurs sporadically or in small—often familial—clusters. Infected soft ticks may cause repeated infections among persons living or sleeping in the same dwelling. In sub-Saharan Africa, *O. moubata*, the vector of *B. duttoni*, infests native huts and rest houses, hiding in crevices of floors and walls during the day and emerging at night to feed on sleeping inhabitants.

In the United States, TBRF disease occurs west of the Mississippi River, especially in forested mountainous areas of far western states, where *B. hermsii* is the causative agent. Less commonly, persons are infected with *B. turicatae* following exposures in tick-infested caves in semidesert areas of the Southwest. On average, ~35 cases of TBRF are reported annually in the United States. *B. hermsii* infections most often occur during spring and summer months among persons sleeping in rustic mountain cabins and vacation homes and occasionally in permanent residences and in outdoor settings. Infections of humans are sometimes precipitated by the disappearance of rodents (e.g., as a result of epizootic plague) that nest in foundations, wall spaces, and attics and that serve as the usual maintenance hosts for *O. hermsii* ticks. Outbreaks caused by *B. hermsii* have taken place among persons staying in cabins along the north rim of the Grand Canyon and in the mountains of California, Idaho, and Colorado. In North America, most recent cases have been reported from Washington, California, Colorado, Idaho, Oregon, and British Columbia.

PATHOGENESIS AND PATHOLOGY In humans, relapsing-fever borreliae pass through the skin or mucous membranes, multiply in the blood, and circulate in great numbers during febrile periods. The organisms have also been found in the liver, spleen, bone marrow, and central nervous system and may be sequestered at these sites during periods of remission. The disease tends to be more severe when spirochete density in the blood is high. Even though the pathophysiologic manifestations of the disease resemble responses to endotoxin, and although plasma from some patients with relapsing fever coagulates *Limulus* amebocyte lysates, borreliae and other spirochetes have not been shown to express a true lipopolysaccharide (endotoxin) molecule. Infection with *B. recurrentis* has been shown, however, to activate protein mediators of inflammation, such as Hageman factor (factor XII), prekallikrein, and proteins of the complement system; furthermore, a spirochetal heat-stable pyrogenic factor stimulates mononuclear phagocytes to express increased amounts of leukocyte pyrogen and thromboplastin.

The treatment of relapsing fever with antibiotics may provoke a Jarisch-Herxheimer reaction (see "Treatment," below). In patients with LBRF, this reaction has been associated with a release of various cytokines into the plasma, including interleukin 6, interleukin 8, C-reactive protein, and large amounts of tumor necrosis factor a (TNF-α). Pretreatment of LBRF patients with antibody to TNF-α suppressed Jarisch-Herxheimer reactions following penicillin treatment and reduced the plasma concentrations of certain other cytokines.

Death due to TBRF is rare. In contrast, fatality rates of 20% have been recorded during outbreaks of LBRF in malnourished and stressed populations. Relapsing fever in pregnancy can result in abortion, stillbirth, and fatal neonatal infections. Autopsies of patients with relapsing fever most often reveal hepatosplenomegaly and variable edema and swelling of other organs, including brain, lungs, and kidneys. On microscopic examination, the spleen is congested and contains multiple microabscesses composed of mononuclear cells that replace the white pulp, the myocardium displays diffuse histiocytic inflammation and interstitial edema, and the liver has areas of midzonal necrosis. Petechial hemorrhages are commonly evident over the surfaces of the meninges, pleura, heart, spleen, liver, kidneys, and mesentery. Subcapsular and parenchymal hemorrhagic infarcts of the spleen, heart, liver, and brain are sometimes grossly visible.

CLINICAL MANIFESTATIONS The clinical manifestations of LBRF and TBRF are similar. The common signs and symptoms of TBRF, as documented in North America, are listed in Table 156-1. The mean incubation period is 7 days (range, 2 to 18 days), and the onset of illness is sudden, with fever, headache, shaking chills, sweats, myalgias, and arthralgias. The arthralgia of relapsing fever can be severe, involving small and large joints, but there is no evidence of arthritis. Dizziness, nausea, and vomiting are common. Sleep may be difficult and is sometimes accompanied by disturbing dreams. The patient is coherent but withdrawn, thirsty, and uninterested in food and other outside stimuli. The fever is high from the first, with temperature usually reaching ≥40°C (≥104°F) and then becoming irregular in pattern. High fever is sometimes accompanied by delirium. Patients are usually

tachycardic and mildly tachypneic and become prostrate as the disease progresses. Some patients have meningismus. The conjunctivae are often injected, and photophobia is common. The sclerae may become icteric, particularly in the later stages of illness. The mucous membranes may be dry, and patients are often dehydrated. Scattered petechiae develop on the trunk, extremities, and mucous membranes in one-third or more of patients with LBRF but in a smaller proportion of patients with TBRF. A nonproductive cough is common, but chest sounds are usually normal; pleuritic pain and an accompanying pleuritic rub are sometimes noted. Cardiac findings are compatible with a high-output state; tachycardia and summation gallop are common. Tender enlargement of the spleen and liver frequently occurs in the acute phase of illness.

Epistaxis and blood-tinged sputum are common complications, and gastrointestinal and central nervous system hemorrhage can occur. Because of this coagulopathy, one LBRF outbreak in southern Sudan was thought to be viral hemorrhagic fever. Other complications of variable incidence include iridocyclitis, optic neuritis, lymphocytic meningitis, coma, isolated cranial-nerve palsy, pneumonitis, myocarditis, and rupture of the spleen. Life-threatening complications are unusual in otherwise healthy persons given supportive care, especially if the illness is diagnosed and treated early. Children generally have a milder course of illness than adults.

Without treatment, symptoms intensify over a 2- to 7-day period (average, 5 days in LBRF and 3 days in TBRF), ending in a spontaneous crisis that coincides with the disappearance of spirochetes from the circulation. The crisis comprises two phases over several hours: a *chill phase*, characterized by rigors, rising temperature, and hypermetabolism, and a *flush phase* of falling temperature, diaphoresis, and a decreased effective circulating blood volume. The pathophysiologic events associated with this crisis are magnified when precipitated by antibiotic treatment and are indistinguishable from the Jarisch-Herxheimer reaction of treated syphilis (see "Treatment," below). The crisis is followed by a period of exhaustion, sleep, and an uneventful recovery. Orthostatic hypotension is typical in the early recovery phase. Not uncommonly, in the first week of convalescence, the patient experiences 1 or 2 days of mild fever unassociated with detectable spirochetemia. In untreated patients, spirochetemia and symptoms may recur after a period of several days or weeks (average interval to first relapse, 9 days in LBRF and 7 days in TBRF). Only one or two relapses characteristically occur in untreated patients with LBRF, whereas as many as 10 (average, three) can occur in untreated patients with TBRF. In most cases, the illness becomes shorter and milder and the afebrile intervals longer with each relapse. Because of the great antigenic variation among *Borrelia* strains, infection confers only partial immunity, and repeated infections of the same individual have been recorded.

Diseases that should be considered in the differential diagnosis of relapsing fever or that may complicate relapsing fever include typhus fever, typhoid fever, nontyphoid salmonellosis, malaria, dengue and other arboviral illnesses, tuberculosis, leptospirosis, and viral hemorrhagic fevers. In the United States, the geographic distribution of Colorado tick fever (Chap. 180) overlaps that of TBRF, and the two diseases have similar manifestations early in their courses.

LABORATORY FINDINGS AND DIAGNOSIS The diagnosis of relapsing fever is confirmed most easily by the detection of spirochetes in blood, bone marrow aspirates, or cerebrospinal fluid. Motile spirochetes can be seen when specimens are examined by dark-field microscopy. Fixed organisms are clearly visible in Wright-, Giemsa-, or acridine orange–stained preparations of thin or dehemoglobinized thick smears of peripheral blood or buffy-coat preparations (Fig. 156-1). Organisms are most numerous in specimens taken during periods of high temperature preceding the crisis; smears of peripheral blood are positive in ≥70% of patients with LBRF and in a lower percentage of patients with TBRF. In reference laboratories, relapsing-fever spirochetes are cultured from blood by the inoculation of BSK II medium or by the intraperitoneal inoculation of immature laboratory mice. Serum antibodies to *Borrelia* can be detected by enzyme immunoassays, indirect fluorescent antibody (IFA) assay, and western immunoblotting using whole-cell sonicates as antigen; however, these tests are unstandardized and subject to insensitivity and cross-reactivity with other spirochetal agents, including *B. burgdorferi* (the agent of Lyme disease) and *Treponema pallidum*. A recently developed western immunoblot test employing species-specific recombinant glycerophosphodiester phosphodiesterase (GlpQ) as antigen has been shown to be more sensitive and specific than the whole-cell sonicate IFA or enzyme-linked immunosorbent assay (ELISA) tests.

Other laboratory findings in relapsing fever are nonspecific. The leukocyte count is normal or moderately elevated, with an unremarkable cell differential. Serum bilirubin levels are generally only slightly elevated. Thrombocytopenia commonly occurs in relapsing-fever patients during the acute phase of the illness; platelet counts rebound during early convalescence. Prothrombin and partial thromboplastin times are often moderately prolonged during acute illness, as are standardized bleeding times. Fibrinogen concentrations in the blood are normal, and fibrinolysis is mild or absent. Results of the Rumpel-

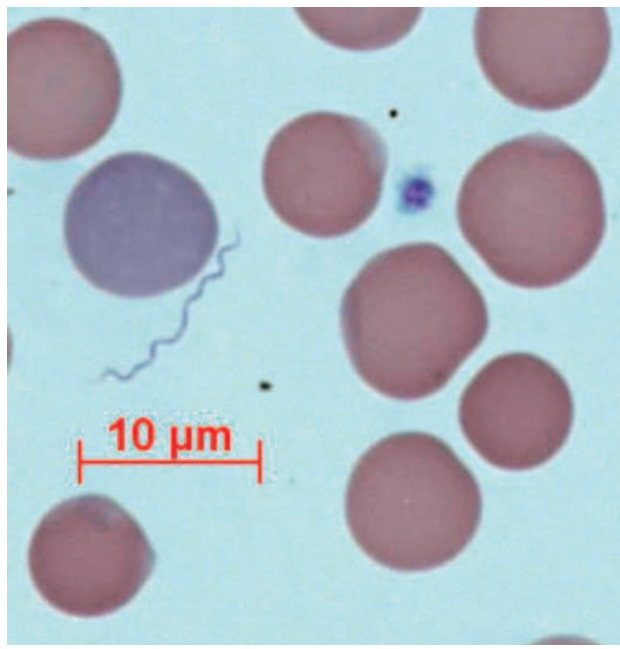

FIGURE 156-1 Photomicrograph of tick-borne relapsing fever spirochete (*B. hermsii*) in a Wright-Giemsa-stained peripheral blood film.

Leede tourniquet test for capillary fragility are negative, despite the presence of petechiae.

TREATMENT

Relapsing-fever borreliae are exquisitely sensitive to antibiotics. Treatment with doxycycline (or another tetracycline), erythromycin, or chloramphenicol produces rapid clearance of spirochetes and a remission of symptoms (Table 156-2). The response to a single dose of penicillin may be delayed and incomplete. Although a single dose of doxycycline (or another tetracycline), erythromycin, or chloramphenicol is highly effective in the treatment of LBRF, less is known about the efficacy of single-dose treatment of TBRF. Empirical treatment of TBRF for 7 days is therefore recommended to reduce the risk of persisting or relapsing borreliosis. For children <8 years of age and for pregnant women, erythromycin or penicillin may be preferred, given the potential adverse effects of tetracyclines.

Treatment of LBRF with a rapidly acting antibiotic regularly precipitates a Jarisch-Herxheimer-like reaction within 1 to 4 h of the first dose. This reaction, which occurs in more than 50% of treated TBRF patients in North America, tends to be more severe when the patient has LBRF rather than TBRF and when high numbers of spirochetes are circulating in the bloodstream. In the chill phase of the reaction, rigors and rising fever are accompanied by an increasing metabolic rate, alveolar hyperventilation, high cardiac output, increasing peripheral vascular resistance, and decreased pulmonary arterial pressure. The body temperature commonly rises to ≥41°C (≥105.8°F). This high fever is accompanied often by agitation and confusion and sometimes by delirium. Fever can be partially controlled by the use of a cooling blanket and ice packs and by sponging of the patient with tepid water and alcohol. The chill phase terminates after 10 to 30 min, giving way to a flush phase characterized by a fall in body temperature, drenching sweats, and sometimes (more commonly in LBRF) a potentially dangerous fall in systemic arterial pressure and rise in pulmonary arterial pressure. Although cardiac output is maintained at high levels, the effective circulating blood volume decreases as peripheral vascular resistance falls. Vital signs must be monitored carefully during this period of the reaction, which usually lasts ≤8 h. Clinical and electrocardiographic evidence of myocarditis and myocardial dysfunction includes a prolonged QT_c interval, a third heart sound (S_3), elevated central venous pressure, arterial hypotension, and rare pulmonary congestion. The use of delayed-release intramuscular penicillin may prolong or delay the clearance of spirochetes and thereby attenuate the accompanying Jarisch-Herxheimer reaction, but this response is not predictable; furthermore, single-dose penicillin treatment sometimes results in relapse of spirochetemia and symptoms. Glucocorticoids and nonsteroidal anti-inflammatory agents do not prevent or significantly modify the cardiopulmonary disturbances of the Jarisch-Herxheimer reaction, although hydrocortisone and acetaminophen given at the same time as antibiotics reduce peak body temperature. Although pretreatment with antibody to TNF-α may moderate the Jarisch-Herxheimer reaction in treated patients with LBRF, its use in LBRF is impractical and its use in TBRF (whose treatment is associated with a relatively mild Jarisch-Herxheimer reaction) is not warranted. Close monitoring of fluid balance, arterial and venous pressures, and myocardial function is advised in supportive management of the Jarisch-Herxheimer reaction in patients with LBRF.

The management of patients with relapsing fever–induced myocardial dysfunction requires caution in the administration of intravenous fluids and, in some cases, use of short-term inotropic therapy. The inability of heparin to control bleeding in LBRF suggests that disseminated intravascular coagulation is not important in its causation. Vitamin K and other soluble vitamins are sometimes given to counter dietary deficiencies in patients with LBRF. Because postural hypotension is often pronounced during the acute phase of relapsing fever and in the early stage of recovery, patients should be assisted when arising from bed.

Untreated LBRF has a high case-fatality rate, especially among persons in otherwise poor health, such as those in famine-affected populations. The fatality rate among treated persons is usually <5%. In general, TBRF is a milder disease than LBRF: the spontaneous crisis and the Jarisch-Herxheimer reactions are less pronounced and the case-fatality rates are lower for TBRF than for LBRF.

TABLE 156-2 *Antibiotic Treatment of Louse-Borne and Tick-Borne Relapsing Fever in Adults*

Medication	Louse-Borne Relapsing Fever (Single Dose)	Tick-Borne Relapsing Fever (7-Day Schedule)
Oral		
Erythromycin	500 mg	500 mg q6h
Tetracycline	500 mg	500 mg q6h
Doxycycline	100 mg	100 mg q12h
Chloramphenicol	500 mg	500 mg q6h
Parenteral[a]		
Erythromycin	500 mg	500 mg q6h
Tetracycline	250 mg	250 mg q6h
Doxycycline	100 mg	100 mg q12h
Chloramphenicol	500 mg	500 mg q6h
Penicillin G (procaine)	600,000 IU	600,000 IU daily

[a]For tick-borne relapsing fever, parenteral therapy is used only until oral treatment is tolerated.

PREVENTION AND CONTROL LBRF can be prevented by addressing socioeconomic circumstances that promote louse infestation (crowding, poverty, homelessness), by applying hygienic practices that reduce numbers of body lice (washing clothes, drying clothes in direct sunlight, changing clothes at frequent intervals), and by using acaricides. Spread of infection can be controlled by early case detection and treatment of infected persons and close contacts. Historically, outbreaks of LBRF have been controlled by mass delousing. In situations like those in refugee camps, individuals, their clothes, and their bedding should be deloused with appropriate acaricides, such as 0.5% permethrin dust. Impregnation of clothing with liquid permethrin, a residual acaricide, can provide long-term protection against infestation. In outbreaks of fever that involve louse-infested populations, empirical single-dose treatment with doxycycline will be effective against typhus as well as LBRF. *B. recurrentis* has a fragile life cycle and is eradicable.

TBRF can be prevented by the avoidance of rodent- and tick-infested dwellings and infested natural sites. Limiting rodent access to the foundations and attics of homes and vacation cabins and eliminating harborage for rodents in and around these dwellings reduce the potential for tick exposure. Rodents and rodent nests should be removed from infested buildings and their surroundings. Tick harborages of infested buildings or other circumscribed sites, such as rodent burrows and nests in hollow logs surrounding dwellings and in rodent-infested caves, can be chemically treated by pest-control specialists using various acaricides, such as carbaryl, diazinon, chlorpyrifos, pyrethrins, and malathion. Persons who enter tick-infested sites can protect themselves by wearing clothing that denies ticks access to the skin, by applying repellents to exposed skin and to clothing, and by applying an acaricide containing permethrin to clothing. Reporting of suspected cases of relapsing fever to public health authorities is important so that an epidemiologic investigation and control measures can be initiated promptly. Prompt diagnosis and treatment of relapsing fever in pregnant women is important in avoiding the potentially severe consequences of fetal or neonatal infection acquired in utero.

157 LYME BORRELIOSIS

Allen C. Steere

DEFINITION Lyme borreliosis is caused by a spirochete, *Borrelia burgdorferi*, *sensu lato*, that is transmitted by ticks of the *Ixodes ricinus* complex. The infection usually begins with a characteristic expanding skin lesion, erythema migrans (EM; stage 1, localized infection). After several days or weeks, the spirochete may spread hematogenously to many different sites (stage 2, disseminated infection). Possible manifestations of disseminated infection include secondary annular skin lesions, meningitis, cranial or peripheral neuritis, carditis, atrioventricular nodal block, or migratory musculoskeletal pain. Months to years later (usually after periods of latent infection), intermittent or chronic arthritis, chronic encephalopathy or polyneuropathy, or acrodermatitis may develop (stage 3, persistent infection). Most patients experience early symptoms of the illness during the summer, but the infection may not become symptomatic until it progresses to stage 2 or 3. Despite regional variations, the basic stages of the illness are similar worldwide.

Lyme disease was recognized as a separate entity in 1976 because of geographic clustering of children in Lyme, Connecticut, who were thought to have juvenile rheumatoid arthritis. The rural setting of the case clusters and the identification of EM as a feature of the illness suggested that the disorder was transmitted by an arthropod. It became apparent that Lyme disease was a multisystem illness that affected primarily the skin, nervous system, heart, and joints. Epidemiologic studies of patients with EM implicated certain *Ixodes* ticks as vectors of the disease. Early in the twentieth century, EM had been described in Europe and attributed to *I. ricinus* tick bites. In 1982, a previously unrecognized spirochete, now called *Borrelia burgdorferi*, was recovered from *Ixodes scapularis* ticks and then from patients with Lyme disease. The entity is now called Lyme disease or Lyme borreliosis.

ETIOLOGIC AGENT *B. burgdorferi*, the causative agent of Lyme disease, is a fastidious, microaerophilic bacterium. The spirochete's genome is quite small (~1.5 Mb) and consists of a highly unusual linear chromosome of 950 kb as well as 9 linear and 12 circular plasmids. *B. burgdorferi* contains many immunogenic proteins, including a number of differentially expressed lipoproteins, most of which are encoded by plasmid DNA. To date, three groups of pathogenic *B. burgdorferi* organisms, together referred to as *B. burgdorferi sensu lato*, have been identified. All North American strains have belonged to the first group, *B. burgdorferi sensu stricto*. Although all three of the identified groups have been found in Europe, most isolates there have been strains of group 2 (*B. garinii*) or group 3 (*B. afzelii*), and only the latter two groups have been found in Asia. These differences may well account for the clinical variations in the disease in different geographic regions.

EPIDEMIOLOGY Lyme borreliosis in all locations is transmitted by ticks of the *I. ricinus* complex: *I. scapularis* (also called *I. dammini*), *I. pacificus*, *I. ricinus*, and *I. persulcatus*. *I. scapularis* is the principal vector in the northeastern United States from Maine to Maryland and in the midwestern states of Wisconsin and Minnesota. *I. pacificus* is the vector in the western states of California and Oregon. The disease is acquired throughout Europe (from Great Britain to Scandinavia to European Russia), where *I. ricinus* is the vector, and in Asian Russia, China, and Japan, where *I. persulcatus* is the vector. These ticks may transmit other diseases as well. In the United States, *I. scapularis* also transmits babesiosis and human anaplasmosis; in Europe and Asia, *I. ricinus* and *I. persulcatus* also transmit tick-borne encephalitis.

Ticks of the *I. ricinus* complex have larval, nymphal, and adult stages; they require a blood meal at each stage. The risk of infection in a given area depends largely on the density of these ticks as well as their feeding habits and animal hosts, which have evolved differently in different locations. For *I. scapularis* in the northeast, the white-footed mouse is the preferred host of the immature larval and nymphal ticks. It is critical that both of the tick's immature stages feed on the same host, because the life cycle of the spirochete depends on horizontal transmission: in early summer from infected nymphs to mice and in late summer from infected mice to larvae, which then molt to become the infected nymphs that will begin the cycle again the following year. It is the tiny nymphal tick that is primarily responsible for transmission of the disease to humans during the early summer months. White-tailed deer, which are not involved in the life cycle of the spirochete, are the preferred host for the adult stage of *I. scapularis* and seem to be critical to the tick's survival.

Lyme disease is now the most common vector-borne infection in the United States. Since surveillance was begun by the Centers for Disease Control and Prevention (CDC) in 1982, the number of cases has increased dramatically. More than 15,000 new cases are now reported each summer. In Europe, Lyme borreliosis is widely established in forested areas; there, the highest reported frequencies of the disease are in the middle of the continent and in Scandinavia. Cases have occurred in persons who reside in endemic suburban, wooded, or rural areas and in persons who visit, hike, camp, or hunt in these areas.

PATHOGENESIS To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments: the tick and the mammalian host. The spirochete expresses outer-surface proteins A and B (OspA and OspB) in the midgut of the tick, whereas OspC is upregulated as the organism travels to the tick's salivary gland and thence to the mammalian host. The tick must usually be attached for at least 24 h for transmission of *B. burgdorferi*.

After injection into the human skin, *B. burgdorferi* may migrate outward, producing EM, and may spread hematogenously to other organs. A number of mechanisms may aid in spirochetal dissemination. For example, the sequences of OspC vary considerably among strains, and only a few groups of sequences are associated with disseminated disease. Spread through the skin and other tissue matrices may be facilitated by the binding of human plasminogen and its activators to the surface of the spirochete. During its dissemination and homing to specific sites, the organism attaches to certain host integrins, matrix glycosaminoglycans, and extracellular matrix proteins. For example, *Borrelia* decorin-binding proteins A and B bind decorin, a glycosaminoglycan on collagen fibrils; this binding may explain why the organism is commonly aligned with collagen fibrils in the extracellular matrix in the heart, nervous system, or joints. The only known virulence factors of *B. burgdorferi* are surface proteins that allow the spirochete to attach to mammalian cells.

Inflammatory innate immune responses are critical in the control of early disseminated infection. Spirochetal lipoproteins, which bind to the CD14 molecule and toll-like receptor 2 on macrophages, are potent activators of the innate immune response, leading to the production of macrophage-derived inflammatory cytokines. After the first several weeks of infection, T cells, which are part of the adaptive immune response, generally exhibit heightened responsiveness to *B.*

burgdorferi antigens, and evidence of B-cell hyperactivity is found, including elevated total serum IgM levels, cryoprecipitates, and circulating immune complexes. Titers of specific IgM antibody to *B. burgdorferi* peak between the third and sixth week after disease onset. The specific IgG response develops gradually over months, with response to an increasing array of at least 12 spirochetal polypeptides and maximal expansion during the period of arthritis. Histologic examination of all affected tissues reveals an infiltration of lymphocytes, macrophages, and plasma cells with some degree of vascular damage (including mild vasculitis or hypervascular occlusion), suggesting that the spirochete may have been present in or around blood vessels.

Despite the innate and adaptive immune responses, *B. burgdorferi* may sometimes survive in certain sites. The ability of the spirochete to downregulate the expression of surface-exposed protein antigens is one important mechanism of immune evasion. In addition, during disseminated infection, a surface-exposed lipoprotein called VlsE undergoes extensive antigenic variation. However, the organism does not have mechanisms that help to protect it from antibiotic therapy. For example, *B. burgdorferi* has only been seen extracellularly in affected tissues; it has not been shown to "hide out" in intracellular locations, thereby evading antibiotic exposure.

CLINICAL MANIFESTATIONS ■ Early Infection: Stage 1 (Localized Infection) After an incubation period of 3 to 32 days, EM, which occurs at the site of the tick bite, usually begins as a red macule or papule that expands slowly to form a large annular lesion. As the lesion increases in size, it often develops a bright red outer border and partial central clearing. Because of the small size of ixodid ticks, most patients do not remember the preceding tick bite. The center of the lesion sometimes becomes intensely erythematous and indurated, vesicular, or necrotic. In other instances, the expanding lesion remains an even, intense red; several red rings are found within an outside ring; or the central area turns blue before the lesion clears. Although EM can be located anywhere, the thigh, groin, and axilla are particularly common sites. The lesion is warm but not often painful. Approximately 20% of patients do not exhibit this characteristic skin manifestation. In Europe, EM is often an indolent localized infection of the skin; in contrast, in the United States, this lesion is associated with more intense inflammation and signs that often suggest dissemination of the spirochete.

Early Infection: Stage 2 (Disseminated Infection) In cases in the United States, *B. burgdorferi* often spreads hematogenously to many sites within days or weeks after the onset of EM. In these cases, patients may develop secondary annular skin lesions similar in appearance to the initial lesion. Skin involvement is commonly accompanied by severe headache, mild stiffness of the neck, fever, chills, migratory musculoskeletal pain, arthralgias, and profound malaise and fatigue. Less common manifestations include generalized lymphadenopathy or splenomegaly, hepatitis, sore throat, nonproductive cough, conjunctivitis, iritis, or testicular swelling. Except for fatigue and lethargy, which are often constant, the early signs and symptoms of Lyme disease are typically intermittent and changing. Even in untreated patients, the early symptoms usually become less severe or disappear within several weeks. In ~15% of patients, the infection presents with these nonspecific systemic symptoms.

Symptoms suggestive of meningeal irritation may develop early in Lyme disease when EM is present but usually are not associated with cerebrospinal fluid (CSF) pleocytosis or an objective neurologic deficit. After several weeks or months, ~15% of untreated patients develop frank neurologic abnormalities, including meningitis, subtle encephalitic signs, cranial neuritis (including bilateral facial palsy), motor or sensory radiculoneuropathy, mononeuritis multiplex, cerebellar ataxia, or myelitis—alone or in various combinations. In the United States, the usual pattern consists of fluctuating symptoms of meningitis accompanied by facial palsy and peripheral radiculoneuropathy. Lymphocytic pleocytosis (~100 cells per μL) is found in CSF, often along with elevated protein levels and normal or slightly low glucose concentrations. In Europe and Asia, the first neurologic sign is characteristically radicular pain, which is followed by the development of CSF pleocytosis (called meningopolyneuritis or *Bannwarth's syndrome*), but meningeal or encephalitic signs are frequently absent. In children, the optic nerve may be affected because of inflammation or increased intracranial pressure, which may lead to blindness. These early neurologic abnormalities usually resolve completely within months, but in rare cases, chronic neurologic disease may occur later.

Within several weeks after the onset of illness, ~8% of patients develop cardiac involvement. The most common abnormality is a fluctuating degree of atrioventricular block (first-degree, Wenckebach, or complete heart block). Some patients have more diffuse cardiac involvement, including electrocardiographic changes indicative of acute myopericarditis, left ventricular dysfunction evident on radionuclide scans, or (in rare cases) cardiomegaly or pancarditis. Cardiac involvement usually lasts for only a few weeks but may recur. Chronic cardiomyopathy caused by *B. burgdorferi* has been reported in Europe.

During this stage, musculoskeletal pain is common. The typical pattern consists of migratory pain in joints, tendons, bursae, muscles, or bones (usually without joint swelling) lasting for hours or days and affecting one or two locations at a time.

Late Infection: Stage 3 (Persistent Infection) Months after the onset of infection, ~60% of patients in the United States who have received no antibiotic treatment develop frank arthritis. The typical pattern comprises intermittent attacks of oligoarticular arthritis in large joints (especially the knees), lasting for weeks to months in a given joint. Small joints and periarticular sites also may be affected, primarily during early attacks. The number of patients who continue to have recurrent attacks decreases each year. However, in a small percentage of cases, involvement of large joints—usually one or both knees—becomes chronic and may lead to erosion of cartilage and bone. These patients have a higher frequency of the class II major histocompatibility complex alleles associated with rheumatoid arthritis, particularly HLA-DRBI*0401 or *0101 alleles, than patients with brief Lyme arthritis. Moreover, they may have persistent arthritis for months or even several years after the apparent eradication of spirochetes from the joints with antibiotic therapy. In these genetically susceptible individuals, it has been postulated that autoimmunity may develop within the proinflammatory milieu of the joints because of molecular mimicry between a dominant T-cell epitope of OspA and a similar sequence in a human protein.

White cell counts in joint fluid range from 500 to 110,000/μL (average, 25,000/μL); most of these cells are polymorphonuclear leukocytes. Tests for rheumatoid factor or antinuclear antibodies usually give negative results. Examination of synovial biopsy samples reveals fibrin deposits, villous hypertrophy, vascular proliferation, microangiopathic lesions, and a heavy infiltration of lymphocytes and plasma cells.

Although less common, chronic neurologic involvement may also become apparent months or years after the onset of infection, sometimes following long periods of latent infection. The most common form of chronic central nervous system involvement is subtle encephalopathy affecting memory, mood, or sleep and often accompanied by axonal polyneuropathy manifested as either distal paresthesia or spinal radicular pain. Patients with encephalopathy frequently have evidence of memory impairment in neuropsychological tests and abnormal results in CSF analyses. In cases with polyneuropathy, electromyography generally shows extensive abnormalities of proximal and distal nerve segments. Encephalomyelitis or leukoencephalitis, a rare manifestation of Lyme borreliosis associated primarily with *B. garinii* infection in Europe, is a severe neurologic disorder that may include spastic paraparesis, upper motor-neuron bladder dysfunction, and lesions in the periventricular white matter. The prolonged course of chronic neuroborreliosis following periods of latent infection is reminiscent of tertiary neurosyphilis.

Acrodermatitis chronica atrophicans, the late skin manifestation of the disorder, has been associated primarily with *B. afzelii* infection in Europe and Asia. It has been observed mostly in elderly women. The skin lesions, which are usually found on the acral surface of an arm or leg, begin insidiously with reddish-violaceous discoloration; they become sclerotic or atrophic over a period of years.

DIAGNOSIS The culture of *B. burgdorferi* in Barbour-Stoenner-Kelly (BSK) medium permits definitive diagnosis, but this complex method has been used only in research studies. Moreover, with a few exceptions, positive cultures have been obtained only early in the illness—primarily from biopsy samples of EM skin lesions, less often from plasma samples, and occasionally from CSF samples. Later in the infection, polymerase chain reaction (PCR) is greatly superior to culture for the detection of *B. burgdorferi* DNA in joint fluid, and this has been the major use for PCR testing in Lyme disease. In one study, *B. burgdorferi* DNA was detected by PCR in synovial fluid samples from 75 (85%) of 88 patients and in none of 64 control samples. However, the sensitivity of PCR determinations in CSF from patients with neuroborreliosis has been much lower. There seems to be little if any role for PCR in the detection of *B. burgdorferi* DNA in blood or urine samples. Moreover, this procedure, which must be carefully controlled to prevent contamination, is not routinely available.

Because of the problems associated with direct detection of *B. burgdorferi*, Lyme disease is usually diagnosed by the recognition of a characteristic clinical picture with serologic confirmation. Although serologic testing may yield negative results during the first several weeks of infection, most patients have a positive antibody response to *B. burgdorferi* after that time. The limitation of serologic tests is that they do not clearly distinguish between active and inactive infection. Patients with previous Lyme disease—particularly in cases progressing to late stages—often remain seropositive for years, even after adequate antibiotic treatment. In addition, about 10% of patients are seropositive because of asymptomatic infection. If these individuals subsequently develop another illness, the positive serologic test for Lyme disease may cause diagnostic confusion. Conversely, in rare instances, patients who receive inadequate antibiotic therapy during the first several weeks of infection may subsequently develop subtle joint or neurologic symptoms but are seronegative. The important point is that seronegative Lyme disease is usually a mild, attenuated illness that responds well to standard courses of antibiotic therapy. According to an algorithm published by the American College of Physicians (Table 157-1), serologic testing for Lyme disease is recommended only for patients with at least an intermediate pretest probability of Lyme disease, such as those with oligoarticular arthritis. It should not be used as a screening procedure in patients with pain or fatigue syndromes. In such patients, the probability of a false-positive serologic result is higher than that of a true-positive result.

For serologic analysis of Lyme disease in the United States, the CDC recommends a two-step approach in which samples are first tested by enzyme-linked immunosorbent assay (ELISA) and equivocal or positive results are then tested by western blotting. During the first month of infection, both IgM and IgG responses to the spirochete should be determined, preferably in both acute- and convalescent-phase serum samples. Approximately 20 to 30% of patients have a positive response detectable in acute-phase samples, whereas about 70 to 80% have a positive response during convalescence (2 to 4 weeks later). After 1 month of infection, by which time most patients with active Lyme disease have disseminated infection, the sensitivity and specificity of the IgG response to the spirochete are both very high—in the range of 95% to 99%—as determined by the two-test approach of ELISA and western blot. At this point and thereafter, a single test (that for IgG) is usually sufficient. In persons with illness of >1 month's duration, a positive IgM test result alone is likely to be false-positive and therefore should not be used to support the diagnosis. According to current criteria adopted by the CDC, an IgM western blot is considered positive if two of the following three bands are present: 23, 39, and 41 kDa. However, the combination of the 23- and 41-kDa bands may still represent a false-positive result. An IgG blot is considered positive if 5 of the following 10 bands are present: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa. In European cases, there is less expansion of the antibody response, and no single set of criteria for the interpretation of immunoblots results in high levels of sensitivity and specificity in all countries.

Several second-generation tests that use recombinant spirochetal proteins or synthetic peptides have shown promising results. For example, an IgG ELISA employing a 26-mer peptide from invariant region 6 (IR_6) of the VlsE lipoprotein has a sensitivity and a specificity similar to those achieved with the IgM and IgG two-test approach using sonicated whole spirochetes. However, the IR_6 ELISA has a limitation similar to that affecting standard serology, in that a positive test result does not distinguish clearly between active and past infection. The IR_6 ELISA may be of value with regard to European as well as American strains of the spirochete.

DIFFERENTIAL DIAGNOSIS Classic EM is a slowly expanding erythema, often with partial central clearing. If the lesion expands little, it may represent the red papule of an uninfected tick bite. If the lesion expands rapidly, it may represent cellulitis (e.g., streptococcal cellulitis) or an allergic reaction, perhaps to tick saliva. Patients with secondary annular lesions may be thought to have erythema multiforme, but neither the development of blistering mucosal lesions nor the involvement of the palms or soles is a feature of *B. burgdorferi* infection. In the southeastern United States, an EM-like skin lesion, sometimes with mild systemic symptoms, may be associated with *Amblyomma americanum* tick bites, but the cause of this illness has not yet been identified.

In the United States, *I. scapularis* ticks may transmit not only *B. burgdorferi* but also *Babesia microti*, a red blood cell parasite (Chap. 195), or *Anaplasma phagocytophila*, the agent of human anaplasmosis (formerly called the agent of human granulocytotropic ehrlichiosis; Chap. 158). Although babesiosis and anaplasmosis are most often asymptomatic, infection with any of these three agents may cause nonspecific systemic symptoms, and coinfected patients may have more severe or persistent symptoms than patients infected with a single agent. Standard blood counts may yield clues regarding the presence of coinfection. Anaplasmosis may cause leukopenia or thrombocytopenia, and babesiosis may cause thrombocytopenia or (in severe cases) hemolytic anemia. However, IgM serologic responses may confuse the diagnosis. For example, *A. phagocytophila* may elicit a positive IgM response to *B. burgdorferi*. The frequency of coinfection in different studies has been variable. In one prospective study, 4% of patients with EM had evidence of coinfection.

Facial palsy caused by *B. burgdorferi*, which occurs in the early disseminated phase of the infection (often in July, August, or September), is usually recognized by its association with EM. However, facial palsy without EM may be the presenting manifestation of Lyme disease. In such cases, both the IgM and IgG responses to the spirochete are usually positive. The most common infectious agents that cause

TABLE 157-1 *Algorithm for Testing for and Treating Lyme Disease*

Pretest Probability	Example	Recommendation
High	Patients with erythema migrans	Empirical antibiotic treatment without serologic testing
Intermediate	Patients with oligoarticular arthritis	Serologic testing and antibiotic treatment if test results are positive
Low	Patients with nonspecific symptoms (myalgias, arthralgias, fatigue)	Neither serologic testing nor antibiotic treatment

Source: Adapted from the recommendations of the American College of Physicians (G Nichol et al: Ann Intern Med 128:37, 1998, with permission).

facial palsy are herpes simplex virus type 1 (Bell's palsy; Chap. 163) and varicella-zoster virus (Ramsay-Hunt syndrome; Chap. 164).

Later in the infection, oligoarticular Lyme arthritis most resembles reactive arthritis in an adult or the pauciarticular form of juvenile rheumatoid arthritis in a child. Patients with Lyme arthritis usually have the highest IgG antibody responses seen in the infection, with reactivity to many spirochetal proteins.

The most common problem in diagnosis is to mistake Lyme disease for chronic fatigue syndrome (Chap. 370) or fibromyalgia (Chap. 315). This difficulty is compounded by the fact that a small percentage of patients do in fact develop these chronic pain or fatigue syndromes in association with or soon after Lyme disease. Compared with Lyme disease, chronic fatigue syndrome or fibromyalgia tends to produce more generalized and disabling symptoms, including marked fatigue, severe headache, diffuse musculoskeletal pain, multiple symmetric tender points in characteristic locations, pain and stiffness in many joints, diffuse dysesthesia, difficulty with concentration, and sleep disturbances. Patients with chronic fatigue syndrome or fibromyalgia lack evidence of joint inflammation; they have normal results in neurologic tests; and they usually have a greater degree of anxiety and depression than patients with chronic neuroborreliosis.

TREATMENT

As outlined in the algorithm in Fig. 157-1, the various manifestations of Lyme disease can usually be treated successfully with orally administered antibiotics; the exceptions are objective neurologic abnormalities and third-degree atrioventricular heart block, which seem to require intravenous therapy. For early Lyme disease, doxycycline is effective in men and in nonpregnant women. An advantage of this regimen is that it is also effective against *A. phagocytophila*, which is transmitted by the same tick that transmits the Lyme disease agent. Amoxicillin, cefuroxime axetil, and erythromycin or its congeners are second-, third-, and fourth-choice alternatives, respectively. In children, amoxicillin is effective (not more than 2 g/d); in cases of penicillin allergy, cefuroxime axetil or erythromycin may be used. In contrast to second- or third-generation cephalosporin antibiotics, first-generation cephalosporins, such as cephalexin, are not effective. For patients with infection localized to the skin, a 14-day course of therapy is generally sufficient; in contrast, for patients with disseminated infection, a 21-day course is recommended. Approximately 15% of patients experience a Jarisch-Herxheimer-like reaction during the first 24 h of therapy. In multicenter studies, more than 90% of patients whose early Lyme disease was treated with these regimens had satisfactory outcomes. Although some patients reported symptoms after treatment, objective evidence of persistent infection or relapse was rare, and retreatment was usually unnecessary.

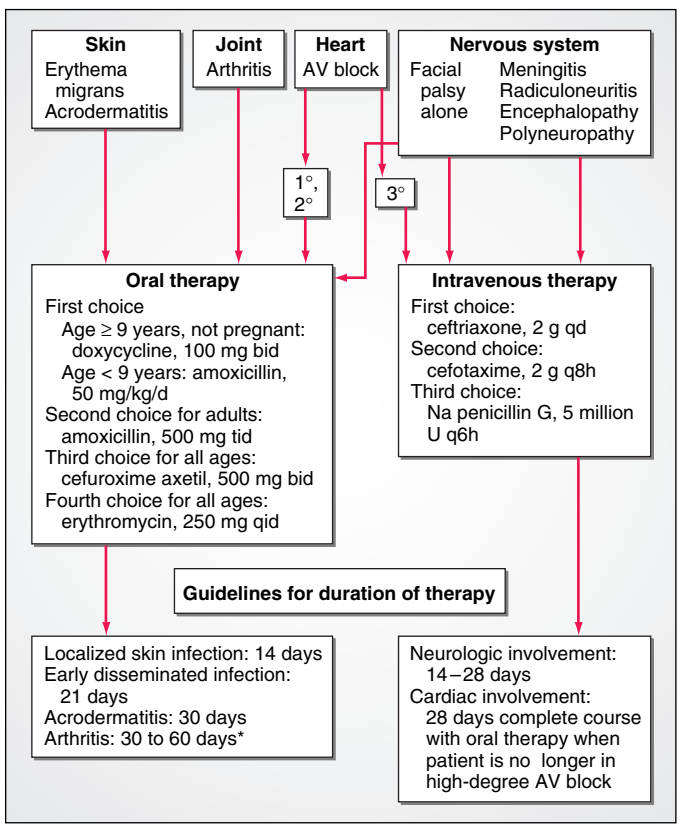

FIGURE 157-1 Algorithm for the treatment of the various acute or chronic manifestations of Lyme borreliosis. AV, atrioventricular. *For Lyme arthritis, intravenous ceftriaxone, 2 g given once a day for 14 to 28 days, is also effective and may elicit a response more quickly than oral therapy; however, compared with oral treatment, this regimen is less convenient to administer, has more side effects, and is more expensive.

One of these oral antibiotic regimens, when given for 30 to 60 days, or intravenous ceftriaxone, given for 14 to 28 days, is effective for the treatment of Lyme arthritis. Oral therapy is easier to administer, is associated with fewer side effects, and is considerably less expensive. However, the response to oral therapy may be slower than that to intravenous therapy, and some patients given oral therapy have subsequently developed overt neuroborreliosis, which may require intravenous therapy for a successful outcome. In the small percentage of patients with arthritis in whom arthritic symptoms persist for months or even years after the apparent eradication of spirochetes from the joints with antimicrobial therapy, treatment with anti-inflammatory agents or synovectomy may be successful.

For objective neurologic abnormalities (with the possible exception of facial palsy alone), parenteral antibiotic therapy seems to be necessary. Intravenous ceftriaxone, given for 14 to 28 days, is most commonly used for this purpose, but intravenous cefotaxime or intravenous penicillin G for the same duration may also be effective. In patients with high-degree atrioventricular block or a PR interval of >0.3 s, intravenous therapy for at least part of the course and cardiac monitoring are recommended, but the insertion of a permanent pacemaker is not necessary.

It is unclear how and whether asymptomatic infection should be treated, but patients with such infection are often given a course of oral antibiotics. Because maternal-fetal transmission of *B. burgdorferi* seems to occur rarely, if at all, standard therapy for the manifestations of the illness is recommended for pregnant women. Long-term persistence of *B. burgdorferi* has not been documented in any large series of patients after treatment with currently recommended regimens. Therefore, there is no indication for multiple, repeated antibiotic courses in the treatment of Lyme disease.

After appropriately treated Lyme disease, a small percentage of patients continue to have subjective symptoms, primarily musculoskeletal pain, neurocognitive difficulties, or fatigue. This so-called chronic Lyme disease or post–Lyme disease syndrome is a disabling condition that is similar to chronic fatigue syndrome or fibromyalgia. In a large study, one group of patients with post–Lyme disease syndrome received intravenous ceftriaxone for 30 days followed by oral doxycycline for 60 days, while another group received intravenous and oral placebo preparations for the same durations. No significant differences were found between groups in the numbers of patients reporting that their symptoms had improved, become worse, or stayed the same. Such patients are best treated for the relief of symptoms rather than with prolonged courses of antibiotics.

The risk of infection with *B. burgdorferi* after a recognized tick bite is so low that antibiotic prophylaxis is not routinely indicated. However, if an attached, engorged *I. scapularis* nymph is found or if follow-up is anticipated to be difficult, a single 200-mg dose of doxycycline, which effectively prevents Lyme disease when given within 72 h after the tick bite, may be administered.

PROGNOSIS The response to treatment is best early in the disease. Later treatment of Lyme borreliosis is still effective, but the period of con-

valescence may be longer. Eventually, most patients recover with minimal or no residual deficits.

REINFECTION Reinfection may occur after EM when patients are treated with antimicrobial agents. In such cases, the immune response is not adequate to provide protection from subsequent infection. However, patients who develop an expanded immune response to the spirochete over a period of months (such as those with Lyme arthritis) have protective immunity for a period of years and do not acquire the infection again.

PREVENTION Protective measures for the prevention of Lyme disease may include the avoidance of tick-infested areas, the use of repellents and acaricides, tick checks, and modification of landscapes in or near residential areas. Although a vaccine for Lyme disease used to be available, the manufacturer has discontinued its production. Therefore, no vaccine is now commercially available for the prevention of this infection.

Section 10 Diseases Caused by Rickettsia, Mycoplasma, and Chlamydia

158 RICKETTSIAL DISEASES

David H. Walker, Didier Raoult, J. Stephen Dumler, Thomas Marrie

The rickettsiae make up a family of gram-negative coccobacilli and short bacilli that grow strictly in eukaryotic cells. Characteristics of these organisms include their obligately intracellular location and persistence. The pathogenic rickettsiae move through mammalian reservoirs; they are transmitted by insect or tick vectors. Except for louse-borne typhus, humans are incidental hosts. Among rickettsiae, *Coxiella burnetii* (the agent of Q fever) is notorious for its ability to survive for an extended period outside of the reservoir or vector and for its extreme infectiousness: inhalation of a single microorganism can cause pneumonia. Clinical infections with rickettsiae can be classified into five general groups: (1) tick-, louse-, flea-, and gamasid mite–borne, spotted fever group (SFG) and typhus group rickettsial diseases; (2) chigger-borne scrub typhus; (3) tick-borne ehrlichioses and anaplasmosis; (4) neorickettsiosis (sennetsu fever); and (5) Q fever. The rickettsiae that cause spotted fevers, typhus, and scrub typhus are listed along with their vectors, geographic ranges, and associated diseases in Table 158-1.

TICK-, MITE-, AND FLEA-BORNE SPOTTED FEVERS

ROCKY MOUNTAIN SPOTTED FEVER Rocky Mountain spotted fever (RMSF), the most severe of the rickettsial diseases, is caused by *Rickettsia rickettsii*. This organism possesses two major immunodominant surface-exposed proteins, OmpA and OmpB, which have species-specific conformational epitopes. OmpA functions as an adhesin for the host cell; OmpB, the most abundant outer-membrane protein, shares genetic sequences and limited antigens with typhus group rickettsiae. This small (0.3 μm by 1.0 μm) bacillus has a gram-negative cell wall

TABLE 158-1 Features of Selected Rickettsial Infections

Disease	Organism	Vector(s)	Geographic Range	Incubation Period	Duration
Rocky Mountain spotted fever	*Rickettsia rickettsii*	*Dermacentor andersoni* *D. variabilis* *Amblyomma cajennense* *Rhipicephalus sanguineus*	United States United States Central/South America Mexico	2–14 days	10–20 days
Mediterranean spotted fever[a]	*R. conorii*	*R. sanguineus*	Southern Europe, Africa, Middle East, Central Asia	5–7 days	7–14 days
African tick-bite fever	*R. africae*	*A. hebraeum*, *A. variegatum*	Sub-Saharan Africa, West Indies	4–10 days	?
Rickettsialpox[a]	*R. akari*	*Liponyssoides sanguineus*	United States, Ukraine, Croatia	10–17 days	3–11 days
Cat-flea typhus	*R. felis*	*Ctenocephalides felis*	North and South America, Europe	8–16 days	8–16 days
Epidemic typhus	*R. prowazekii*	*Pediculus humanus corporis*	Worldwide	7–14 days	10–18 days
Brill-Zinsser disease	*R. prowazekii*	—[b]	Worldwide	Years	7–11 days
Murine typhus	*R. typhi*	*Xenopsylla cheopis*	Worldwide	8–16 days	8–16 days
Scrub typhus[a]	*Orientia tsutsugamushi*	*Leptotrombidium deliense*	Asia, Australia, New Guinea, Pacific Islands	6–21 days	6–21 days

[a] Eschar is usually present at the bite site.

[b] Brill-Zinsser disease represents a recrudescence of latent epidemic typhus.

structure; its lipopolysaccharide shares antigens mainly within the SFG and is not endotoxic in the quantities found in human infections.

Discovered in the American West in the late nineteenth century, RMSF is at present documented in 48 states (with the highest prevalences in the south-central and southeastern states) as well as in Canada, Mexico, Costa Rica, Panama, Colombia, Argentina, and Brazil. It is transmitted by *Dermacentor variabilis*, the American dog tick, in the eastern two-thirds of the United States and in California; by *D. andersoni*, the Rocky Mountain wood tick, in the western United States; by *Rhipicephalus sanguineus* in Mexico; and by *Amblyomma cajennense* in Central and South America. Maintained principally by transovarian transmission from one generation of ticks to the next, *R. rickettsii* can be acquired by uninfected ticks through the ingestion of a blood meal from rickettsemic small mammals.

Humans become infected during the active season of the vector tick species. In northern areas, cases occur mainly in the spring; in warmer southern states, most cases occur from May to September, although some cases are reported in the winter. Although 4% of *D. variabilis* ticks contain rickettsiae, the vast majority of these are nonpathogenic species such as *R. montanensis* and *R. bellii*. The likelihood of an individual tick's containing *R. rickettsii* is remote. From 1971 to 2001, the reported incidence of RMSF was in the range of 0.16 to 0.50 cases per 100,000 population in the United States. In 2001, 0.20 persons per 100,000 in the United States developed RMSF. This rate is probably an underestimate, since the diagnosis is difficult and reporting incomplete. The 5- to 9-year-old age group has the highest incidence. The mortality rate was 20 to 25% in the preantibiotic era and now remains at ~3 to 5% because of delayed diagnosis and treatment. The case-fatality ratio increases with each decade of life above age 20.

Pathogenesis *R. rickettsii* organisms are inoculated into the dermis along with secretions of the tick's salivary glands after ≥6 h of feeding. Rickettsiae spread lymphohematogenously throughout the body, attach via OmpA to the endothelial cell membrane, and induce their own engulfment. Once intracellularly located, they escape rapidly from the phagosome, replicate in the cytosol by binary fission, and spread from cell to cell, propelled by polar polymerization of the host cell's actin. The result is numerous foci of contiguous infected endothelial cells that are extensive enough to manifest clinically after a dose-dependent incubation period of ~1 week (range, 2 to 14 days). *R. rickettsii* is more invasive than other rickettsiae, routinely spreading to infect vascular smooth-muscle cells. Despite frequent statements to the contrary, occlusive thrombosis and ischemic necrosis are not the fundamental pathologic basis for tissue and organ injury in RMSF. Instead, increased vascular permeability, with resulting edema, hypovolemia, and ischemia, is responsible. Indeed, immunohistologic studies of severely infected humans and animals have demonstrated numerous zones of infected endothelium, only a small proportion of which contain thrombi. The thrombi are usually located to one side of the lumen, which is not occluded. These hemostatic plugs appear to be an appropriate host response rather than a pathogenic process. Consumption of platelets results in thrombocytopenia in 32 to 52% of patients, but disseminated intravascular coagulation with hypofibrinogenemia is rare. Activation of platelets, generation of thrombin, and activation of the fibrinolytic system all appear to be homeostatic physiologic responses to endothelial injury.

Clinical Manifestations The incubation period averages 7 days. Early in the illness, when medical attention usually is first sought, RMSF is difficult to distinguish from many self-limiting viral illnesses. Fever, headache, malaise, myalgia, nausea, vomiting, and anorexia are the most frequent symptoms during the first 3 days. The patient becomes progressively more ill as vascular infection and injury advance. In one large series, only one-third of patients were diagnosed with presumptive RMSF early in the clinical course and treated appropriately as outpatients. In the tertiary care setting, RMSF is all too often recognized only when its late severe manifestations, developing at the end of the first week or during the second week of illness in patients without appropriate treatment, prompt admission to the intensive care unit.

The progressive nature of the infection is clearly manifested in the skin. Rash is evident in only 14% of patients on the first day of illness and in only 49% during the first 3 days. Macules (1 to 5 mm) appear first on the wrists and ankles and then on the remainder of the extremities and the trunk. Later, more severe vascular damage results in frank hemorrhage at the center of the maculopapule, a petechia that does not disappear upon compression (Fig. 158-1). This sequence of events is sometimes delayed or aborted by effective treatment. In fact, rash appears on day 6 or later in 20% of cases and does not appear at all in 9 to 16% of cases, including some with severe visceral lesions that result in death. Petechiae occur in 41 to 59% of cases, appearing on or after day 6 in 74% of cases that include a rash. Involvement of the palms and soles, often considered diagnostically important, usually occurs relatively late in the course (after day 5 in 43% of cases) and does not occur at all in 18 to 64% of cases.

The microcirculation, both systemic and pulmonary, is the target of intracellular rickettsial infection, and the clinical manifestations reflect the ensuing vascular changes. Widespread increased vascular permeability results in edema, decreased plasma volume, hypoalbuminemia, reduced serum oncotic pressure, and prerenal azotemia. Hypotension occurs in 17% of cases. Extensive infection of the pulmonary microcirculation is associated with noncardiogenic pulmonary edema. Cardiac involvement is most frequently manifested as dysrhythmia, which is detected in 7 to 16% of cases. Pulmonary involvement, often a major factor in fatal cases, is observed in 17% of cases, of which 12% are considered to represent severe respiratory disease and 8% require mechanical ventilation.

Central nervous system (CNS) involvement is the other important

FIGURE 158-1 *Top*: Petechial lesions of Rocky Mountain spotted fever on the lower legs and soles of a young, otherwise-healthy patient. *Bottom*: Close-up of lesions from the same patient. (*Photos courtesy of Dr. Lindsey Baden.*)

determinant of the outcome of RMSF. Encephalitis, presenting as confusion or lethargy, is apparent in 26 to 28% of cases. Progressively severe encephalitis manifests as stupor or delirium in 21 to 26% of cases, as ataxia in 18%, as coma in 9 to 10%, and as seizures in 8%. Cranial nerve palsy, hearing loss, severe vertigo, nystagmus, dysarthria, aphasia, unilateral corticospinal signs, ankle clonus, extensor toe signs, hyperreflexia, spasticity, fasciculations, athetosis, neurogenic bladder, hemiplegia, paraplegia, and complete paralysis have been reported. Meningoencephalitis results in cerebrospinal fluid (CSF) pleocytosis in 34 to 38% of cases; usually there are 10 to 100 cells per microliter with a mononuclear predominance, but occasionally there are more than 100 cells per microliter and a polymorphonuclear predominance. The CSF protein concentration is increased in 30 to 35% of cases, but the CSF glucose concentration is usually normal.

Renal failure, which occurs in more severely ill patients, is often reversible with rehydration. However, in the most severe cases, shock results in acute tubular necrosis–induced renal failure, which often requires hemodialysis.

Hepatic injury is manifested in 38% of cases as mildly or moderately increased serum aminotransferase concentrations and is due to focal death of individual hepatocytes, but hepatic failure does not occur. Jaundice is recognized in 8 to 9% of cases and an elevated serum bilirubin concentration in 18 to 30%. Marked hyperbilirubinemia occasionally occurs, probably as a consequence of both hemolysis and hepatocytic injury.

Bleeding is a potentially life-threatening effect of severe vascular damage. Anemia develops in 30% of cases and is severe enough to require red blood cell transfusions in 11%. Blood is detected in the stools or vomitus of 10% of patients, and death has followed massive upper gastrointestinal hemorrhage.

Other characteristic clinical laboratory findings include a normal white blood cell count with increased numbers of immature myeloid cells, increased plasma levels of proteins of the acute-phase response (C-reactive protein, fibrinogen, ferritin, and others), and hyponatremia (in 56% of cases) due to the appropriate secretion of antidiuretic hormone in response to the hypovolemic state. Skeletal muscle injury, clinically manifested as myositis, has been documented in several individual cases by the detection of marked elevations in serum creatine kinase or of histopathologic evidence of vascular injury in skeletal muscle and multifocal rhabdomyonecrosis. Ocular involvement includes conjunctivitis in 30% of cases and retinal vein engorgement, flame hemorrhages, arterial occlusion, and papilledema with normal CSF pressure in some instances.

In untreated cases, death usually occurs 8 to 15 days after the onset of illness. A rare presentation, fulminant RMSF, is fatal within 5 days after onset. This fulminant presentation has been associated with RMSF in black males who have a glucose-6-phosphate dehydrogenase (G6PD) deficiency and is thought to be related to an undefined effect of hemolysis on the rickettsial infection. Although survivors of RMSF usually appear to return to their previous state of health, permanent sequelae, including neurologic deficits and amputation of gangrenous extremities, may follow severe illness.

Diagnosis The diagnosis of RMSF during the acute stage is more difficult than is generally appreciated. Clinical and epidemiologic considerations are more important than laboratory features early in the illness. The most important epidemiologic factor is a history of exposure within the 12 days preceding disease onset to a potentially tick-infested environment during a season of possible tick activity. However, only 60% of patients actually recall being bitten by a tick during the incubation period.

The differential diagnosis for early clinical manifestations of RMSF (fever, headache, and myalgia without a rash) includes influenza, enteroviral infection, infectious mononucleosis, viral hepatitis, leptospirosis, typhoid fever, gram-negative or gram-positive bacterial sepsis, human monocytotropic or granulocytotropic ehrlichiosis or anaplasmosis, murine typhus, sylvatic flying-squirrel typhus, and rickettsialpox. Enterocolitis may be suggested by nausea, vomiting, and abdominal pain; prominence of abdominal tenderness has resulted in exploratory laparotomy. CNS involvement may masquerade as bacterial and viral meningoencephalitis, with seizures, coma, neurologic signs, and CSF abnormalities. Cough, pulmonary signs, and chest roentgenographic opacities may lead to a diagnostic consideration of bronchitis or pneumonia.

At presentation during the first 3 days of illness, only 3% of patients exhibit the classic triad of fever, rash, and history of tick exposure. When a rash appears, a diagnosis of RMSF should certainly be considered. However, many illnesses considered in the differential diagnosis may also be associated with a rash, including rubeola, rubella, meningococcemia, disseminated gonococcal infection, secondary syphilis, toxic shock syndrome, drug hypersensitivity, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, Kawasaki syndrome, and immune complex vasculitis. Conversely, any person in an endemic area with a provisional diagnosis of one of the above illnesses may have RMSF.

The most common serologic test for confirmation of the diagnosis is the indirect immunofluorescence assay. Between 7 and 10 days after onset, a diagnostic titer of $\geq$1:64 is usually detectable. Latex agglutination and a solid-state enzyme immunoassay are also available commercially. Latex agglutination usually yields a diagnostic titer of $\geq$1:128 at 7 to 9 days after onset. The sensitivity and specificity of the indirect immunofluorescence assay are 94 to 100% and 100%, respectively, and the latex agglutination test has a sensitivity of 71 to 94% and a specificity of 96 to 99%. The performance of the solid-state immunoassay has not been reported. It is important to understand that serologic tests for RMSF are usually negative at the time of presentation for medical care and that treatment should not be delayed while a positive serologic result is awaited.

The only diagnostic test that is useful during the acute illness is immunohistologic examination (immunofluorescence or immunoenzyme staining) of a cutaneous biopsy of a rash lesion for *R. rickettsii*. Examination of a 3-mm punch biopsy of such a lesion is 70% sensitive and 100% specific. Polymerase chain reaction (PCR) amplification and detection of *R. rickettsii* DNA in peripheral blood is a relatively insensitive approach except in the preterminal state; rickettsiae are present in large quantities in heavily infected foci of endothelial cells but in relatively low quantities in the circulation. Cultivation of rickettsiae in cell culture is technically feasible but is seldom undertaken because of biohazard and technologic concerns.

Rx TREATMENT

The drug of choice for the treatment of both children and adults with RMSF is doxycycline, except when the patient is pregnant or allergic to the drug. Because of the severity of RMSF, immediate empirical administration of doxycycline should be strongly considered in any patient with a consistent clinical presentation in the appropriate epidemiologic setting. Doxycycline is administered orally (or, in the presence of coma or vomiting, intravenously) at 200 mg/d in two divided doses. Patients who are allergic to doxycycline or in whom this drug is contraindicated should receive chloramphenicol (50 to 75 mg/kg daily in four divided oral doses, for 7 days); the complete blood count should be monitored during chloramphenicol treatment. For children with suspected RMSF infection, up to five courses of doxycycline may be administered with minimal risk of dental staining. Other regimens include oral tetracycline (25 to 50 mg/kg per day) in four divided doses. The antirickettsial drug should be administered until the patient has been afebrile and improving clinically for 2 or 3 days. β-Lactam antibiotics, erythromycin, and aminoglycosides have no role in the treatment of RMSF, and sulfa-containing drugs are likely to exacerbate this infection. There is not enough clinical experience to comment on the use of fluoroquinolones in this setting. The most seriously ill patients are managed in intensive care units, with careful administration of fluids to achieve optimal tissue perfusion without precipitating non-

TABLE 158-2 *Laboratory Diagnosis and Treatment of Selected Rickettsial Diseases*

Disease	Laboratory Diagnosis	Treatment
Mediterranean spotted fever, Japanese spotted fever, Queensland tick typhus, Flinders Island spotted fever, African tick-bite fever	Isolation of rickettsiae by shell-vial culture; serology, IFA (IgM, ≥1:64; or IgG, ≥1:128); skin biopsy immunohistochemical detection of rickettsiae; PCR amplification of DNA from tissue specimens	Doxycycline (100 mg bid PO for 1–5 days) *or* Ciprofloxacin (750 mg bid PO for 5 days) *or* Chloramphenicol (500 mg qid PO for 7–10 days) *or* (in pregnancy) Josamycin[a] (3 g/d PO for 5 days)
Rickettsialpox	IFA: seroconversion to a titer of ≥1:64 or a single titer of ≥1:128; cross-adsorption to eliminate antibodies to shared antigens necessary for a specific diagnosis of the spotted fever rickettsial species; skin biopsy immunohistochemistry	Doxycycline (100 mg bid PO for 1–5 days) *or* Ciprofloxacin (750 mg bid PO for 5 days) *or* Chloramphenicol (500 mg qid PO for 7–10 days) *or* (in pregnancy) Josamycin[a] (3 g/d PO for 5 days)
Endemic (murine) typhus	IFA: fourfold rise to a titer of ≥1:64 or a single titer of ≥1:128; immunohistology: skin biopsy; PCR amplification of *R. typhi* or *R. felis* DNA from blood; dot ELISA and immunoperoxidase methods also available	Doxycycline (100 mg bid PO for 7–15 days) *or* Chloramphenicol (500 mg qid PO for 7–15 days)
Epidemic typhus	IFA: titer of ≥1:128; necessary to use clinical and epidemiologic data to distinguish among louse-borne epidemic typhus, flying-squirrel typhus, and Brill-Zinsser disease	Doxycycline (200 mg PO as a single dose or until patient is afebrile for 24 h)
Scrub typhus	IFA: titer of ≥1:200; PCR amplification of *O. tsutsugamushi* DNA from blood of febrile patients	Doxycycline[b] (100 mg bid PO for 7–15 days) *or* Chloramphenicol (500 mg qid PO for 7–15 days *or* (for children) Chloramphenicol (150 mg/kg per day for 5 days)

[a] Not approved by the U.S. Food and Drug Administration.
[b] Azithromycin is more effective than doxycycline in vitro against both doxycycline-susceptible and doxycycline-resistant strains of *O. tsutsugamushi*.

cardiogenic pulmonary edema. In some severely ill patients, hypoxemia requires intubation and mechanical ventilation; oliguric or anuric acute renal failure requires hemodialysis; seizures necessitate the use of antiseizure medication; anemia or severe hemorrhage necessitates transfusions of packed red blood cells; and bleeding with severe thrombocytopenia requires platelet transfusions. Heparin is not a useful component of treatment, and there is no evidence that glucocorticoids, although frequently administered, affect outcome.

Prevention Avoidance of tick bites is the only available preventive approach. Protective clothing and tick repellents, which could reduce the risk, are seldom actually used. After possible tick exposure, it is wise to inspect the body once or twice a day and remove ticks before they can inoculate rickettsiae.

MEDITERRANEAN SPOTTED FEVER (BOUTONNEUSE FEVER) AND OTHER TICK-BORNE SPOTTED FEVERS The etiologic agent of Mediterranean spotted fever, *R. conorii*, is prevalent in southern Europe (below the 45th parallel), all of Africa, and southwestern and south-central Asia. The tick vector and reservoir is *R. sanguineus*, the brown dog tick. The name of this disease varies with the region in which it occurs; examples include Kenya tick typhus, Indian tick typhus, Israeli spotted fever, and Astrakhan spotted fever. Whatever the designation, the disease is characterized by a high fever, rash, and—in most geographic locales—an inoculation eschar (*tâche noire*) at the site of the tick bite. A severe form of the disease, associated with a 50% mortality rate, has been observed in patients with diabetes, alcoholism, or heart failure.

African tick-bite fever, which is caused by *R. africae* and has been recognized since the beginning of the twentieth century, was first documented in the modern era in Zimbabwe in 1992. The disease occurs in rural areas and follows bites by ticks of cattle and wild animals. *R. africae* is prevalent in *Amblyomma hebraeum* and *A. variegatum* ticks, which readily feed on humans. Cases occur throughout sub-Saharan Africa and in the Caribbean islands. The average incubation period is 7 days (range, 4 to 10 days). The illness is mild and consists of headache, fever, eschar at the tick bite site, and regional lymphadenopathy. *Amblyomma* ticks often feed in groups, and several ticks may be found on one patient, with the subsequent development of multiple eschars. Rash is frequently lacking or transient and may be vesicular. African tick-bite fever is the most prevalent rickettsiosis worldwide, and—because of tourism in sub-Saharan Africa—is the most frequently occurring imported rickettsiosis in Europe and North America.

Rickettsia japonica causes *Japanese spotted fever*. Patients present with fever, cutaneous eruption, and an inoculation eschar. A similar disease in northern Asia is caused by *R. sibirica*. In Australia, two spotted fevers have been described. *Queensland tick typhus* is due to *R. australis* and is transmitted by *Ixodes holocyclus*. The skin rash in this disease is usually maculopapular but is sometimes vesicular, and there is an inoculation eschar. *Flinders Island spotted fever*, observed also on nearby Tasmania, is due to *R. honei*. In Europe, patients infected with *R. slovaca* after a *Dermacentor* tick bite manifest an eschar and regional lymphadenopathy.

Diagnosis The diagnosis of these tick-borne spotted fevers is based on clinical and epidemiologic findings and is confirmed by cell-culture isolation of rickettsiae, by PCR of skin biopsies (a method not available in most laboratories), or by serology. The serologic identification of infection with a specific species requires cross-adsorption (Table 158-2). In an endemic area, patients presenting with fever, rash, and/or a skin lesion consisting of a black necrotic area or a crust surrounded by erythema should be considered to have one of these rickettsial spotted fevers.

Rx TREATMENT

See Table 158-2.

RICKETTSIALPOX Rickettsialpox was first described in 1946 by a general practitioner in New York City and soon afterwards was shown to be caused by a distinct species, *R. akari*. This organism was isolated from mice and their mites (*Liponyssoides sanguineus*), which maintain the organisms by transovarian transmission. *R. akari* shares lipopolysaccharide antigens with other members of the SFG.

Epidemiology More than 100 cases of rickettsialpox were diagnosed annually in the northeastern United States in the late 1940s and the 1950s, and outbreaks occurred in the Ukraine in the 1950s. However, few cases are diagnosed currently. Recently, a culture-confirmed case of rickettsialpox was documented in southern Europe; this case was initially misdiagnosed as Mediterranean spotted fever on the basis of the development of serum antibodies cross-reactive with *R. conorii*. Investigation of eschars suspected to represent bioterrorism-associated cutaneous anthrax has resulted in the diagnosis of cases of rickettsialpox in the United States and has revealed that its occurrence is more widespread than was previously realized. Rickettsialpox is recognized principally in New York City, but cases have also been reported in North Carolina, Virginia, Maryland, Arizona, Utah, and Ohio.

Clinical Manifestations A papule forms at the site of the mite bite. This lesion develops a central vesicle that becomes a 1- to 2.5-cm painless black crusted eschar surrounded by an erythematous halo (Fig. 158-2). Enlargement of the lymph nodes draining the region of the eschar suggests initial lymphogenous spread. After an incubation period of 10 to 17 days, during which the eschar and regional lymphadenopathy frequently go unnoticed, the onset of illness is marked by malaise, chills, fever, headache, and myalgia. A macular rash appears 2 to 6 days after onset and evolves sequentially into papules, vesicles, and crusts that heal without scarring (Fig. 158-3). In some cases the rash remains macular or maculopapular. Some patients suffer nausea, vomiting, abdominal pain, cough, conjunctivitis, or photophobia. Untreated rickettsialpox is not fatal, with fever lasting 6 to 10 days.

Diagnosis and Treatment See Table 158-2.

CAT FLEA–ASSOCIATED RICKETTSIOSIS An emerging rickettsiosis caused by *R. felis* has been documented in North and South America and Europe. Transmitted and maintained transovarially in the geographically widespread cat flea *Ctenocephalides felis*, the infection has been described as moderately severe, with fever, rash, headache, and CNS and gastrointestinal signs. However, the clinical spectrum and frequency of the various clinical manifestations have yet to be determined.

FLEA- AND LOUSE-BORNE TYPHUS GROUP RICKETTSIOSES

ENDEMIC MURINE TYPHUS (FLEA-BORNE) Murine typhus was postulated to be a distinct disease, with rats as the reservoir and fleas as the vector, by Maxcy in 1926. Dyer isolated the etiologic agent, *R. typhi*, from rats and fleas in 1931. By the end of World War II, murine typhus was known to be a global disease.

Epidemiology *R. typhi* is maintained in mammalian host/flea cycles, with rats (*Rattus rattus* and *R. norvegicus*) and the Oriental rat flea (*Xenopsylla cheopis*) as the classic zoonotic niche. Fleas acquire *R. typhi* from rickettsemic rats and carry the organism throughout the rest of their life span. Nonimmune rats and humans are infected when rickettsia-laden flea feces are "scratched" into pruritic bite lesions; less frequently, the flea bite itself transmits the organisms. Yet another possible route of transmission is the inhalation of aerosolized flea feces. Infected rats appear healthy, although they are rickettsemic for ~2 weeks.

Currently, <100 cases of endemic typhus are reported annually in the United States. These cases occur mainly in southern Texas and southern California, where the classic rat/flea cycle is absent and an opossum/cat flea (*C. felis*) cycle is prominent. Cases of endemic typhus occur year-round, mainly in warm (often coastal) areas. This infection has also been reported from Greece, Spain, and Indonesia. The prevalence peaks from April through June in southern Texas and during the warm months of summer and early fall in other geographic locations. Patients seldom recall a flea bite or exposure to fleas, although exposure to animals such as cats, opossums, raccoons, skunks, and rats is reported by nearly 40% of those who are questioned.

FIGURE 158-2 Eschar at the site of the mite bite in a patient with rickettsialpox. (*Reprinted from A Krusell et al: Emerg Infect Dis 8:727, 2002. Photo obtained by Dr. Kenneth Kaye.*)

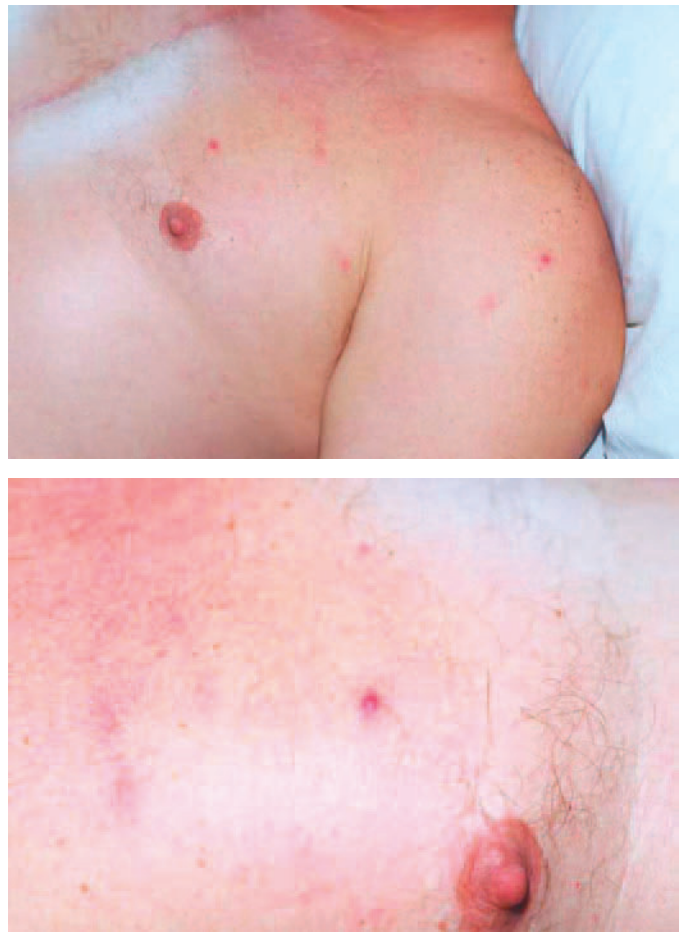

FIGURE 158-3 *Top*: Papulovesicular lesions on the trunk of the patient with rickettsialpox shown in Fig. 158-2. *Bottom*: Close-up of lesions from the same patient. (*Reprinted from A Krusell et al: Emerg Infect Dis 8:727, 2002. Photos obtained by Dr. Kenneth Kaye.*)

Clinical Manifestations The incubation period of experimental murine typhus in volunteers averages 11 days, with a range of 8 to 16 days. Close observation during this period reveals prodromal symptoms of headache, myalgia, arthralgia, nausea, and malaise developing 1 to 3 days before the abrupt onset of chills and fever. Nearly all patients experience nausea and vomiting early in the illness.

The duration of untreated illness averages 12 days, with a range of 9 to 18 days. Rash is present in only 13% of patients at the time of presentation for medical care (usually ~4 days after onset of symptoms), appearing an average of 2 days later in half of the remaining patients and never appearing in the other half. The initial macular rash is often detected by careful inspection of the axilla or the inner surface of the arm. Subsequently, the rash becomes maculopapular, involving the trunk more often than the extremities; it is seldom petechial and rarely involves the face, palms, or soles. A rash is detected in only 20% of patients with dark brown or black skin.

Pulmonary involvement is frequently prominent in murine typhus; 35% of patients have a hacking, nonproductive cough, and 23% of patients who undergo chest radiography have pulmonary densities due to interstitial pneumonia, pulmonary edema, and pleural effusions. Bibasilar rales are the most common pulmonary sign. Less common clinical symptoms and signs include abdominal pain, confusion, stupor, seizures, ataxia, coma, and jaundice. Clinical laboratory studies fre-

quently reveal anemia and leukopenia early in the course, leukocytosis late in the course, thrombocytopenia, hyponatremia, hypoalbuminemia, mildly increased serum levels of hepatic aminotransferases, and prerenal azotemia. Complications may include respiratory failure requiring intubation and mechanical ventilation, hematemesis, cerebral hemorrhage, and hemolysis (in patients with G6PD deficiency and some hemoglobinopathies). The illness is severe enough to necessitate the admission of 10% of hospitalized patients to an intensive care unit. Greater severity is generally associated with old age, underlying disease, and treatment with a sulfonamide drug; the case-fatality rate is 1%. In a study of children with murine typhus, 50% suffered only nocturnal fevers, feeling well enough for active daytime play.

Diagnosis and Treatment See Table 158-2.

EPIDEMIC TYPHUS (LOUSE-BORNE) Epidemic typhus due to infection with *R. prowazekii* is transmitted by the human body louse (*Pediculus humanus corporis*), which lives on clothes and is found in poor hygienic conditions (especially in jails, where the disease it causes is called *jail fever*) and usually in cold areas. Lice acquire *R. prowazekii* when they ingest a blood meal from a rickettsemic patient. The rickettsiae multiply in the midgut epithelial cells of the louse and spill over into the louse feces. The infected louse defecates during its blood meal, and the patient autoinoculates the organisms by scratching. The fact that the louse abandons dead hosts and patients with high fever (>40°C) improves its efficiency as a vector. Since the louse does not pass *R. prowazekii* to its offspring, the disease is usually spread from person to person by the louse-borne route. Lice die within 1 to 2 weeks after infection, turning red because of intestinal perforation just prior to death—hence the name *red louse disease*. This epidemic form of typhus is related to poverty, cold weather, war, and disasters and is currently prevalent in mountainous areas of Africa, South America, and Asia. A large outbreak involving 100,000 people in refugee camps in Burundi occurred in 1997, a small focus was reported in Russia in 1998, sporadic cases have been reported from Algeria, and annual outbreaks have occurred in Peru. The global reemergence of the disease is due to proliferation of body lice. In the United States, sporadic cases of epidemic typhus are transmitted by flying-squirrel fleas. Eastern flying-squirrel (*Glaucomys volans*) lice and fleas have been found to be infected with *R. prowazekii*. The flying-squirrel fleas occasionally bite humans.

Brill-Zinsser disease is a recrudescent, mild form of epidemic typhus occurring years after the acute disease, probably as a result of immunosuppression or old age. Nathan Brill first identified recrudescent typhus in New York in 1898. In 1933 Hans Zinsser noted that >90% of patients with recrudescent typhus had emigrated from typhus-endemic areas of Europe. Strains of *R. prowazekii* indistinguishable from classic strains were isolated from patients with recrudescent typhus. Furthermore, *R. prowazekii* was isolated from the lymph nodes of patients undergoing elective surgery who had had typhus years earlier. Thus the typhus rickettsiae can remain dormant for years and can reactivate with waning immunity.

Rickettsiae, particularly *R. prowazekii*, are potential agents of bioterrorism (Chap. 205). *R. prowazekii* and *R. rickettsii* have a high case-fatality ratio, cause diseases that are difficult to diagnose, and can be engineered to display complete antimicrobial resistance. A strain of tetracycline-resistant *R. prowazekii* was developed in the former Soviet Union. *R. prowazekii* and *R. typhi* have dormant forms that survive extracellularly for long periods, and all rickettsiae are highly infectious when inhaled as aerosols.

Clinical Manifestations After an incubation period of ~1 week (range, 7 to 14 days), the onset of illness is abrupt, with prostration, severe headache, and fever rising rapidly to 38.8° to 40.0°C (102° to 104°F). Cough is frequently prominent, occurring in 70% of patients. Myalgias are usually severe. In the outbreak in Burundi, the disease was referred to as *sutama* ("crouching"), the myalgias being so severe that patients crouched in an attempt to alleviate the pain. A rash begins on the upper trunk, usually on the fifth day, and then becomes generalized, involving all of the body except the face, palms, and soles. Initially, this rash is macular; without treatment, it becomes maculopapular, petechial, and confluent. The rash is frequently absent or not detected on black skin in Africa, where 60% of patients have *spotless epidemic typhus*. Photophobia, with considerable conjunctival injection and eye pain, is frequent. The tongue may be dry, brown, and furred. Confusion and coma are common. Skin necrosis and gangrene of the digits as well as interstitial pneumonia have been noted in severe cases. Untreated disease is fatal in 7 to 40% of cases, with outcome depending primarily on the condition of the host. Patients with untreated infections develop renal insufficiency and multiorgan involvement in which neurologic manifestations are frequently prominent. Overall, 12% of patients with epidemic typhus have neurologic involvement. North American *R. prowazekii* infection transmitted by flying-squirrel ectoparasites is a milder illness; whether this milder disease is due to host factors (e.g., better health status) or organism factors (e.g., attenuated virulence) is unknown.

Diagnosis and Treatment See Table 158-2. Epidemic typhus is sometimes misdiagnosed as typhoid fever in tropical countries (Chap. 137).

Prevention Prevention of epidemic typhus involves control of body lice. Clothes should be changed regularly, and insecticides should be used every 6 weeks to control the louse population.

SCRUB TYPHUS

The etiologic agent of scrub typhus is a small, obligately intracellular bacterium of the family Rickettsiaceae that differs substantially from other family members in its genetic makeup and in the composition of its cell wall (which, for example, lacks lipopolysaccharide and peptidoglycan). Consequently, this organism has been classified as a species in a separate genus, *Orientia tsutsugamushi*.

O. tsutsugamushi is maintained in nature by transovarian transmission in trombiculid mites, mainly of the genus *Leptotrombidium*. After hatching, infected larval mites (chiggers, the only stage that feeds on an animal host) inoculate organisms into the skin while feeding. Scrub typhus is found in environments that harbor the infected chiggers, particularly areas of heavy scrub vegetation—e.g., where the forest is regrowing after being cleared and along riverbanks. Infections occur during the wet season, when the mites lay their eggs. The disease is endemic in eastern and southern Asia, northern Australia, and islands of the western Pacific Ocean. Scrub typhus is also found in tropical areas of India, Sri Lanka, Bangladesh, Myanmar, Thailand, Malaysia, Laos, Vietnam, Kampuchea, China, Taiwan, the Philippines, Indonesia, Papua New Guinea, northern Australia, and islands of the South Pacific Ocean; in temperate areas of Japan, Korea, far-eastern Russia, Tadzhikistan, the mountains of northern India, Pakistan, and Nepal; and in nontropical areas of China, such as Tibet and Shangdong Province. Those infected include indigenous rural workers, residents of suburban areas, and westerners visiting endemic areas for professional or recreational purposes. Infections are more prevalent than the number of clinical diagnoses would suggest; in some areas >3% of the population is infected or reinfected each month. Immunity wanes over 1 to 3 years, and there is remarkable antigenic diversity.

Clinical Manifestations The illness varies in severity from mild and self-limiting to fatal. After an incubation period of 6 to 21 days (usually 8 to 10 days), the onset of disease is characterized by fever, headache, myalgia, cough, and gastrointestinal symptoms. Some patients develop no further signs or symptoms and recover spontaneously after a few days. The classic case description includes an eschar at the site of chigger feeding, regional lymphadenopathy, and a maculopapular rash—signs that are seldom observed in indigenous patients. Fewer than 50% of Westerners develop an eschar, and <40% develop a rash (on day 4 to 6 of illness). Severe cases typically include prominent encephalitis and interstitial pneumonia as key features of vascular injury. Severe illness in persons with G6PD deficiency has been accompanied by hemolysis. The case-fatality rate for untreated classic cases

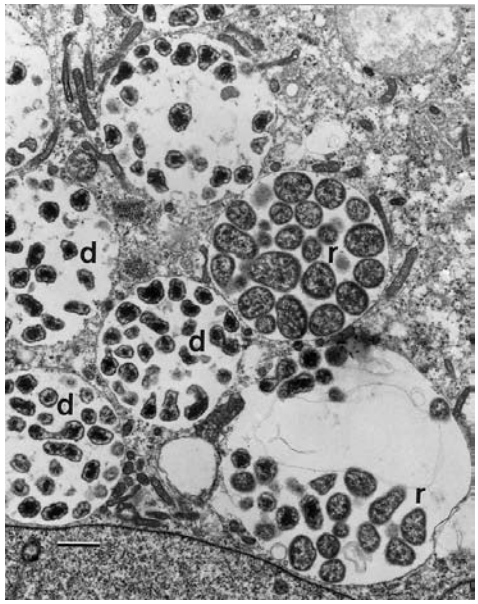

FIGURE 158-4 *Ehrlichia chaffeensis* microcolonies (morulae) within cytoplasmic vacuoles manifest as two morphologic forms: reticulate cells (r) and dense-core cells (d). Bar = 1 μm. (*Photo courtesy of Dr. Vsevolod L. Popov.*)

is 7% but would probably be lower if all relatively mild cases (which are underdiagnosed) were included.

Diagnosis and Treatment See Table 158-2. Some cases of scrub typhus in Thailand are caused by *O. tsutsugamushi* strains that are resistant to doxycycline or chloramphenicol. These strains are susceptible to rifampin, and azithromycin and clarithromycin have been used successfully in small numbers of patients.

EHRLICHIOSES AND ANAPLASMOSIS

Ehrlichiae are small, obligately intracellular bacteria with a gram-negative-type cell wall that grow in cytoplasmic vacuoles to form clusters called *morulae* (Fig. 158-4). Two distinct *Ehrlichia* species and one *Anaplasma* species cause human infections that can be severe and frequent (Table 158-3). *E. chaffeensis*, the agent of human monocytotropic ehrlichiosis (HME), infects predominantly mononuclear phagocytic cells in tissues and blood monocytes. *E. ewingii* and *A. phagocytophila* infect cells of myeloid lineage, particularly neutrophils. Confusion may arise from the facts that *Anaplasma phagocytophila* is the agent of the disease originally designated human granulocytotropic ehrlichiosis (HGE) and *Ehrlichia ewingii* is a human granulocytotropic pathogen. Such confusion can be avoided through use of the terms *human anaplasmosis* and *ehrlichiosis ewingii*, with avoidance of the ambiguous *HGE*. Both *E. chaffeensis* and *E. ewingii* are transmitted mainly by the Lone Star tick *Amblyomma americanum* and cause persistent infections in the same reservoir, the white-tailed deer. *A. phagocytophila* is transmitted, with little geographic overlap, by *Ixodes scapularis* in the northeastern and upper midwestern states and by *I. ricinus* in Europe. In California, both HME and *A. phagocytophila* infection have been documented, with apparent partial overlap of their vectors. In Eurasia, reports of human infection caused by an *I. persulcatus*–transmitted *E. muris*–like agent and of *A. phagocytophila* associated with *I. persulcatus* are beginning to appear. The worldwide prevalence of ehrlichioses and anaplasmoses is an important issue in the field of emerging infectious diseases.

Ehrlichiae were discovered by veterinarians during the investigation of hemolytic anemia of cattle before 1910. Researchers thereafter discerned that "marginal points" visible within erythrocytes were infectious and named the agent *Anaplasma marginale*. Subsequently, several other species generally considered to be ehrlichiae were detected as veterinary infectious agents, including *E. ruminantium*, *E. canis*, *E. ewingii*, *A. phagocytophila*, and *Neorickettsia risticii*.

The current taxonomic positions are determined by nucleic acid sequences of conserved and unique genes among these species. By analysis of 16S ribosomal RNA and other sequences, the family Anaplasmataceae can be divided into four genera: *Ehrlichia*, *Anaplasma*, *Wolbachia*, and *Neorickettsia*. Given the lack of transovarian transmission in ticks, the natural maintenance of the tick-borne ehrlichiae and anaplasmae clearly depends in part on prolonged or persistent infections in wild and feral mammalian reservoirs. Thus, *Ehrlichia* and *Anaplasma* are propagated by horizontal transmission that relies on a tick-mammal-tick cycle; humans are inadvertently infected when they impinge on the natural habitats occupied by the ticks and the reservoir hosts. Wolbachiae are associated with human diseases caused by filariae, with symbiosis in some instances. The wolbachiae are important for filarial viability and pathogenicity. Treatment of wolbachiae is now a strategy in the control of filariasis. Neorickettsiae parasitize flukes that in turn are parasites of aquatic snails, fish, and insects. Although only a single human neorickettsiosis, *sennetsu fever*, has been described, others may be discovered. Probably in association with the ingestion of raw fish containing *N. sennetsu*–infected flukes, patients develop an infectious mononucleosis–like illness that was first identified in 1953.

HUMAN MONOCYTOTROPIC EHRLICHIOSIS ■ Epidemiology More than 1363 cases of infections caused by *E. chaffeensis* had been reported to the Centers for Disease Control and Prevention (CDC) as of September 2002. However, since HME is not a reportable disease in most states, this figure is a gross underestimate. Most *E. chaffeensis* infections have been identified in the south-central, southeastern, and mid-Atlantic states, but cases have also been recognized in California. The vector is the Lone Star tick (*A. americanum*), which in all its life stages feeds on white-tailed deer—a major reservoir host. Dogs and coyotes have been discovered to be subclinically infected and may also be an important reservoir. Tick bites and exposures are reported by patients, frequently in rural areas and especially in the months May through July. The median age of HME patients is 44 years, and 75% of the affected individuals are male; however, severe and fatal infections in children are also well recognized. Active prospective surveillance has revealed that in rural areas inhabited by abundant deer and Lone Star ticks, HME is a common disease, with an incidence as high as 1000 cases per 1 million population.

TABLE 158-3 *Comparison of Three Human Ehrlichioses: Human Monocytotropic Ehrlichiosis (HME), Anaplasmosis, and Human Ehrlichiosis Ewingii*

Variable	HME	Human Anaplasmosis	Ehrlichiosis Ewingii
Etiologic agent	*E. chaffeensis*	*A. phagocytophila*	*E. ewingii*
Tick vector(s)	*Amblyomma americanum*, *Dermacentor variabilis* (dog tick)	*Ixodes scapularis* (deer tick), *I. ricinus*, *I. pacificus*	*A. americanum*
Seasonality	April through September	Year-round (peak: May, June, and July	April through September
Major target cell	Monocyte	Granulocyte	Neutrophil
Morulae seen	Rarely	Frequently	Rarely
Antigen used in IFA test	*E. chaffeensis*	*A. phagocytophila*	*E. chaffeensis* as surrogate
Diagnostic titer	Fourfold rise or a single titer of ≥1:128; cutoff for negative titer, 1:64	Fourfold rise; cutoff for negative titer, 1:80	No established criteria
Treatment of choice	Doxycycline	Doxycycline	Doxycycline
Mortality	2–3%	<1%	None reported

Note: IFA, indirect immunofluorescence assay.

Clinical Manifestations *E. chaffeensis* is inoculated into the dermal blood pool created by the feeding tick and subsequently disseminates via the blood to tissues. After a median incubation period of 8 days, illness develops. The classic clinical manifestations are not specific and include fever (97% of cases), headache (81%), myalgia (68%), and malaise (84%); less frequently observed are gastrointestinal involvement (nausea, vomiting, diarrhea; 25 to 68%), cough (25%), rash (36% overall, 6% at presentation), and confusion (20%). HME may be severe: 62% of patients with documented cases are hospitalized, and ~3% die. Severe complications include a toxic shock–like or septic shock–like syndrome, respiratory insufficiency and adult respiratory distress, meningoencephalitis, fulminant infection (in immunocompromised patients), severe opportunistic and nosocomial infections, and hemorrhage. Laboratory findings may be of value in the differential diagnosis; 60 to 74% of patients with HME have leukopenia (initially lymphopenia, later neutropenia), 72% have thrombocytopenia, and nearly 90% have elevations in serum levels of hepatic aminotransferases. With effective therapy, rebound lymphocytosis (mainly γ/δ T cells) is common. In spite of abnormal blood counts, examinations reveal hypercellular bone marrow, and noncaseating granulomas may be present. Vasculitis is not a component of HME.

Diagnosis Because HME can be fatal, empirical antibiotic therapy should be instituted on the basis of a clinical diagnosis. This diagnosis may be suggested by fever in the setting of known tick exposure during the preceding 3 weeks, leukopenia and/or thrombocytopenia, and increased aminotransferase concentrations in serum. Morulae are rarely demonstrated in peripheral blood smears unless an intensive examination is performed; even then, an experienced microscopist is required. The active phase of HME may be diagnosed by PCR amplification of *E. chaffeensis* nucleic acids from EDTA-anticoagulated blood obtained before the start of doxycycline therapy. Retrospective serologic diagnosis requires a consistent clinical picture and detection of a fourfold increase in *E. chaffeensis* antibody titer (to ≥1:64) by indirect immunofluorescence in paired serum samples obtained ~3 weeks apart. It must be underscored that separate specific diagnostic tests for HME and HGE are necessary.

EHRLICHIOSIS EWINGII *Ehrlichia ewingii*, originally identified as a neutrophil pathogen that causes febrile lameness in dogs, resembles HME in many respects, including its tick vector (*A. americanum*) and its vertebrate hosts (white-tailed deer and dogs). The illness caused by *E. ewingii* is similar to HME but is somewhat less severe. The majority of cases have been diagnosed in immunocompromised patients.

TREATMENT

Tetracycline is effective therapy for HME or ehrlichiosis ewingii. Either tetracycline (250 to 500 mg given orally every 6 h) or doxycycline (100 mg given orally or intravenously twice daily) is associated with a lowered rate of hospitalization and a shortened duration of fever. The use of chloramphenicol is controversial, and *E. chaffeensis* is not susceptible to this drug in vitro. While a few reports document the persistence of *E. chaffeensis* in patients after the acute phase of illness, such persistence is very infrequent; most infections are cured by relatively short courses of tetracycline therapy (continuing for 3 to 5 days after defervescence).

Prevention HME and ehrlichiosis ewingii are prevented by the avoidance of ticks in endemic areas. The use of protective clothing and tick repellents, careful tick searches after exposures, and prompt removal of attached ticks are practices that markedly diminish risk.

HUMAN ANAPLASMOSIS ■ Epidemiology As of 2002, 1278 cases of HGE had been reported to the CDC, most of them from upper midwestern and northeastern states; the distribution of cases was similar to that for Lyme disease. Most cases were identified within the range of various *I. persulcatus*–complex ticks, particularly *I. scapularis*. White-footed deer mice and white-tailed deer in the United States as well as red deer in Europe appear to play a role in maintaining HGE in nature. The incidence of HGE peaks in May, June, and July, but the disease may occur throughout the year in conjunction with human exposure to *Ixodes* ticks. HGE affects predominantly males (79%) and older persons (median age, 58 years).

Clinical Manifestations Because of high seroprevalence rates in endemic regions, it seems likely that only a minority of infected individuals develop clinical manifestations. The incubation period for HGE varies between 4 and 8 days, and the disease manifests as fever (94 to 100% of cases), myalgia (78 to 98%), headache (61 to 85%), and malaise (98%)—findings suggestive of an influenza-like illness. A minority of patients develop gastrointestinal involvement, including nausea, vomiting, or diarrhea (22 to 39%); rash (2 to 11%); cough (27%); and confusion (17%). Severe complications occur most often in the elderly, but even children may be severely affected. Respiratory insufficiency, with adult respiratory distress syndrome, a toxic shock–like syndrome, and life-threatening opportunistic infections, are the most worrisome complications. Meningoencephalitis has not yet been conclusively recognized with HGE. The case-fatality rate is probably <1%, but nearly 7% of ill patients may require intensive care. As in HME, laboratory findings are of great assistance; most patients develop leukopenia and/or thrombocytopenia with increased serum levels of hepatic aminotransferases. The pancytopenia observed in HGE presumably relates to sequestration or destruction of platelets and leukocytes, since the bone marrow is ordinarily normo- or hypercellular. Vasculitis is not a component of HGE. Unlike HME, HGE is not associated with granulomas. While clear evidence exists for co-infections with *Borrelia burgdorferi* and *Babesia microti*, which are transmitted by the same tick vector(s), there is little evidence of comorbidity or of a persistent or chronic phase for HGE.

Diagnosis HGE should be included in the differential diagnosis for patients who have been exposed to ticks and who develop an influenza-like illness during the season of *Ixodes* tick activity (May through December). The concurrent detection of thrombocytopenia, leukopenia, and/or elevations in serum aminotransferase activities further increases the likelihood of HGE. A substantial proportion of patients with HGE develop serologic reactions considered diagnostic of Lyme disease in the absence of clear clinical findings consistent with that diagnosis. Thus, HGE should be considered in the differential diagnosis of atypical severe presentations of Lyme disease. Although not highly sensitive, a thorough peripheral blood film examination for morulae in neutrophils may identify 20 to 75% of infections. PCR testing of EDTA-anticoagulated blood collected before the initiation of tetracycline therapy from patients with active disease is a sensitive and specific method for early confirmation. Serodiagnosis is based mostly upon the retrospective demonstration of a fourfold increase in *A. phagocytophila* group antibody titer to a minimum of 1:80 in paired serum samples obtained ~1 month apart. IgM antibodies may be detected in many patients within the first 1.5 months after illness. Approximately 15 to 40% of infected persons have a detectable antibody titer at presentation, but, in regions where seroprevalence is high, a single acute-phase polyvalent titer may be misleading.

TREATMENT

Doxycycline (100 mg by mouth twice daily) is an effective therapeutic agent, while rifampin has been associated with clinical improvement in pregnant patients with HGE. No prospective studies of any therapy for HGE have been conducted. Most treated patients defervesce within 24 to 48 h.

Prevention Prevention of HGE requires tick avoidance. The Lyme disease vaccine offers no protection against HGE, and no other vaccine is available.

Q FEVER

Q fever results from infection with *C. burnetii*. This small gram-negative microorganism (0.2 μm by 0.7 μm) exists in two antigenic forms: phase I and phase II. When *C. burnetii* is passaged in cell cultures or embryonated eggs, its lipopolysaccharide undergoes truncation that results in an antigenic change called *phase variation*. The phase I form is extremely infectious and exists in humans and other animals. Passage in cell culture or embryonated eggs results in a shift to the phase II form, which is avirulent. The ability of *C. burnetii* to form spores allows the organism to survive in harsh environments. Indeed, it can survive for >40 months in skim milk at room temperature and is readily recovered from soil up to 1 month after contamination. Three different plasmids have been described in various isolates of *C. burnetii*. Q fever encompasses two broad clinical syndromes: acute and chronic infection. It is likely that the host's immune response (rather than characteristics of the infecting strain) determines whether or not chronic Q fever develops. Attachment of the virulent form (phase I) of *C. burnetii* to monocytes requires $\alpha_v \beta_3$ integrin only, whereas attachment of the avirulent form (phase II) requires both $\alpha_v \beta_3$ and CR_3 integrins. The transendothelial migration of monocytes infected by virulent *C. burnetii* is impaired, while that of monocytes infected by the avirulent form is not. Production of tumor necrosis factor (TNF) by monocytes is initiated by virulent *C. burnetii* through a mechanism involving both $\alpha_v \beta_3$ integrin and interaction with bacterial lipopolysaccharide. *C. burnetii* survives in monocytes from patients with chronic Q fever but not in monocytes from patients with acute Q fever or from seronegative control subjects. Impairment of the bactericidal activity of the *C. burnetii*–infected monocyte seems to be due to dysregulation of the cytokine network, as TNF in monocyte supernatants from these patients depresses the microbicidal activity of monocytes. The soluble TNF receptor TNF-R75 is upregulated in monocytes from patients with chronic Q fever. This upregulation is due to overproduction of interleukin 10, antibodies to which restore the microbicidal activity of these monocytes in vitro. The CD4+/CD8+ ratio is decreased in patients with Q fever endocarditis. All of the above findings translate into the observations that very few organisms and a strong cellular response are seen in patients with acute Q fever, while many organisms and a moderate cellular response are seen in patients with chronic Q fever.

Epidemiology Q fever is a zoonosis. The primary sources of human infection are infected cattle, sheep, and goats. However, infected cats, rabbits, pigeons, and dogs have also been shown to transmit *C. burnetii* to humans. The extensive wildlife reservoir for *C. burnetii* includes mammals, birds, and ticks. In the infected female mammal, *C. burnetii* localizes to the uterus and the mammary glands. Infection is reactivated during pregnancy, and high concentrations of *C. burnetii* are found in the placenta. At parturition, *C. burnetii* is dispersed as an aerosol, and infection follows inhalation of aerosolized organisms by a susceptible host. Soil is contaminated during parturition, and *C. burnetii* aerosols can be generated weeks to months later during wind storms. Individuals up to 18 km from the source may be infected. Infected female animals shed the organism in milk for weeks to months after parturition. In rare instances, human-to-human transmission has followed delivery of an infant to an infected woman or autopsy on an infected individual. *C. burnetii* has been transmitted via blood transfusion. Persons who are at risk for Q fever include abattoir workers, veterinarians, and other individuals who have vocational or avocational contact with infected animals. Exposure to infected newborn animals or to infected products of conception poses the highest risk. Sexual transmission has been demonstrated experimentally in mice, as has transmission during artificial insemination in cattle. Some evidence suggests that *C. burnetii* can be sexually transmitted among humans. The ingestion of contaminated milk in some areas probably represent a major route of transmission to humans, although the experimental evidence on this point is contradictory. In any event, the vast majority of Q fever cases result from inhalation of contaminated aerosols. Q fever in children is uncommon, accounting for only 1 to 2% of cases.

Infections due to *C. burnetii* occur in most countries. Indeed, the only areas known to be free of *C. burnetii* are New Zealand and Antarctica. The primary manifestation of acute Q fever differs from place to place. For example, the primary manifestation is pneumonia in Nova Scotia (Canada), granulomatous hepatitis in Marseille (France), and both of these conditions in the Basque region of Spain. These differences may reflect the route of infection; i.e., the ingestion of contaminated milk may result in hepatitis and the inhalation of contaminated aerosols in pneumonia.

In New South Wales, Australia, 2351 cases of Q fever were reported in 1991 to 2000, and the number of cases per 100,000 persons varied from 6.7 in 1996 to 1.8 in 2000. Males accounted for 84% of the cases and children for 1.5%. In Australia each year, Q fever costs the meat industry almost $1 million and >1700 weeks of time lost from work.

Clinical Manifestations ■ *ACUTE Q FEVER* The incubation period for acute Q fever ranges from 3 to 30 days. The clinical presentations include flulike syndromes, prolonged fever, pneumonia, hepatitis, pericarditis, myocarditis, meningoencephalitis, and infection during pregnancy. A study of 1383 cases of Q fever from southern France gives an indication of the spectrum of the clinical manifestations of Q fever. Among the 1070 patients with acute Q fever, 40% had hepatitis, 20% had both pneumonia and hepatitis, 17% had pneumonia, 14% had isolated fever, 2% had central nervous system involvement, 1% had pericarditis, and 1% had myocarditis; in 3% of patients, the clinical presentation was not defined.

The symptoms of acute Q fever are nonspecific; common among them are fever, extreme fatigue, and severe headache. Other symptoms include chills, sweats, nausea, vomiting, and diarrhea, which occur in 5 to 20% of patients. Cough develops in about half of patients with Q fever pneumonia. Neurologic manifestations of acute Q fever are uncommon; however, in one outbreak in the West Midlands, United Kingdom, 23% of 102 patients had neurologic signs and symptoms as the major manifestation. A nonspecific rash may be evident in 4 to 18% of patients. The white blood cell count is usually normal. Thrombocytopenia is detected in ~25% of patients, and reactive thrombocytosis [with platelet counts of up to 1 million/μL (1×10^{12}/L)] frequently develops during recovery. This thrombocytosis may account for cases of deep vein thrombophlebitis complicating acute Q fever in some series. Uncommon manifestations of acute Q fever include optic neuritis, extrapyramidal neurologic disease, Guillain-Barré syndrome, inappropriate secretion of antidiuretic hormone, epididymitis, orchitis, priapism, hemolytic anemia, hemolytic-uremic syndrome, mediastinal lymphadenopathy mimicking lymphoma, spontaneous rupture of the spleen, pancreatitis, erythema nodosum, and mesenteric panniculitis. Chest radiography may show an opacity that is indistinguishable from that seen in pneumonia of other etiologies. Multiple rounded opacities are common; in the appropriate epidemiologic setting (e.g., exposure to a parturient cat), they are highly suggestive of Q fever pneumonia. However, right-sided endocarditis resulting in septic pulmonary emboli can produce the same radiographic appearance.

Up to 70% of the uncommon cases of Q fever in children are asymptomatic. Symptomatic cases in children result in a spectrum of disease similar to that in adults, although only a few cases of Q fever endocarditis in children have been reported.

In Australia and the United Kingdom, a prolonged fatigue state (lasting 5 to 10 years) has followed Q fever in some cases. Low levels of *C. burnetii* DNA have been noted in the affected patients 0.75 to 5 years after infection.

CHRONIC Q FEVER Chronic Q fever, which is uncommon, almost always implies endocarditis. This infection usually occurs in patients with previous valvular heart disease, immunosuppression, or chronic renal

insufficiency. Fever is usually absent or low grade. Patients may have nonspecific symptoms for up to 1 year before diagnosis. Valvular vegetations have been seen in only 12% of patients with transthoracic echocardiograms, but the rate of detection may be higher with the use of transesophageal echocardiography. The vegetations in chronic Q fever endocarditis are different from those in bacterial endocarditis, manifesting as nodules on the valve. A high index of suspicion is necessary for a correct diagnosis. The disease should be suspected in all patients with culture-negative endocarditis. In addition, all patients with valvular heart disease and an unexplained purpuric eruption, renal insufficiency, stroke, and/or progressive heart failure should be tested for *C. burnetii* infection. Patients with chronic Q fever have hepatomegaly and/or splenomegaly. These two findings, especially in combination with positive rheumatoid factor, high erythrocyte sedimentation rate, high C-reactive protein level, and/or increased γ-globulin concentrations (up to 60 to 70 g/L), suggest this diagnosis. Other manifestations of chronic Q fever include infection of vascular prostheses, aneurysms, and bone and as well as chronic sternal wound infection.

Diagnosis *C. burnetii* can be isolated from buffy-coat blood samples or tissue specimens by a shell-vial technique; however, most laboratories are not permitted to attempt the isolation of *C. burnetii* since it is considered highly infectious. PCR can be used to amplify *C. burnetii* DNA from tissue or biopsy specimens. This technique can also be used on paraffin-embedded tissues. Serology, however, is the most commonly used diagnostic tool. Three techniques are available: complement fixation, indirect immunofluorescence, and enzyme-linked immunosorbent assay. Indirect immunofluorescence is sensitive and specific and is the method of choice. Rheumatoid factor should be adsorbed from the specimen before testing. An IgG titer of ≥1:800 to phase I antigen is suggestive of chronic Q fever. In almost all instances of chronic Q fever, the antibody titer to phase I antigen is much higher than that to phase II antigen. The reverse is true in acute Q fever. In addition, in acute Q fever, it is usually possible to demonstrate a fourfold rise in titer between acute- and convalescent-phase serum samples.

Rx TREATMENT

Treatment of acute Q fever with doxycycline (100 mg twice daily for 14 days) is usually successful. Quinolones are also effective. If Q fever is diagnosed during pregnancy, treatment with trimethoprim-sulfamethoxazole is recommended for the duration of the pregnancy. Treatment of chronic Q fever should include at least two antibiotics active against *C. burnetii*. Rifampin (300 mg once daily) combined with doxycycline (100 mg twice daily) or ciprofloxacin (750 mg twice daily) has been used with success. The optimal duration of antibiotic therapy for chronic Q fever remains undetermined. We recommend at least 3 years of treatment, with discontinuation only if the phase I IgA antibody titer is ≤1:50 and the IgG phase I titer is ≤1:200. Another therapeutic option under investigation is the combination of doxycycline (100 mg twice daily) with hydroxychloroquine (600 mg once daily). With this combination, therapy can be completed in 18 months. It is necessary to monitor hydroxychloroquine levels and to adjust the dosage to maintain a plasma concentration of 0.8 to 1.2 μg/mL. In vitro, the addition of 1 mg of hydroxychloroquine/mL renders doxycycline bactericidal against *C. burnetii*. Resistance to ciprofloxacin has been associated with substitution of glutamine for lysine at the position corresponding to amino acid 87 in resistant strains of *Escherichia coli*.

Prevention A vaccine has been shown to be effective in preventing Q fever in abattoir workers in Australia.

159 INFECTIONS DUE TO MYCOPLASMAS

William M. McCormack

Mycoplasmas, the smallest free-living organisms known, are prokaryotes that are bounded only by a plasma membrane. Their lack of a cell wall is associated with cellular pleomorphism and resistance to cell wall–active antimicrobial agents, such as penicillins and cephalosporins. The organisms' small genome limits biosynthesis and explains the difficulties encountered with in vitro cultivation. Mycoplasmas typically colonize mucosal surfaces of the respiratory and urogenital tracts of many animal species. Sixteen species of mycoplasmas have been recovered from humans. Most are commensals. *Mycoplasma pneumoniae* causes upper and lower respiratory tract infections. *M. genitalium* and *Ureaplasma urealyticum* are established causes of urethritis and have been implicated in other genital conditions. *M. hominis* and *U. urealyticum* are part of the complex microbial flora of bacterial vaginosis (Chap. 115).

MECHANISMS OF PATHOGENICITY

Adherence of mycoplasmas to the surface of the host cell is necessary for colonization and infection. Some pathogenic mycoplasmas are flask-shaped, with specialized tips that enhance adherence. *M. pneumoniae* adheres via a network of interactive adhesins and accessory proteins and produces hydrogen peroxide, which may cause injury to host cells. *M. hominis* metabolizes arginine, with the production of potentially cytotoxic amounts of ammonia. Ureaplasmas have been placed in a separate genus because of their unique urease activity; the metabolism of urea also produces ammonia. *M. pneumoniae* may evoke IgM autoantibodies that agglutinate human erythrocytes at 4°C. These cold agglutinins can cause anemia and other complications.

MYCOPLASMA PNEUMONIAE

EPIDEMIOLOGY *M. pneumoniae* causes upper and lower respiratory tract symptoms in all age groups, with the highest attack rates in 5- to 20-year-olds. The infection is acquired by inhalation of aerosols. The incubation period is 2 to 3 weeks, considerably longer than that of most other respiratory infections. Although epidemics have taken place in closed populations, such as schools and military installations, most cases occur sporadically or in families. In families, cases typically occur serially, with 2- to 3-week intervals between cases. Infections in adults are often the result of contact with children.

Infection with *M. pneumoniae* is worldwide. Cases occur throughout the year, with epidemics every few years. Some studies have noted an increase in the number of cases during the autumn months in temperate climates. Although pneumonia is the classic presentation, non-

pneumonic infection is considerably more common. In very young children, most infections result only in upper respiratory symptoms, whereas children >5 years of age and adults may have bronchitis and pneumonia.

CLINICAL PRESENTATION After a prolonged incubation period, fever and constitutional symptoms develop along with headache and cough, both of which can be prominent and distressing. Symptoms typically progress less rapidly than those of viral respiratory tract infections. In the minority (perhaps 5 to 10%) of infected individuals who develop tracheobronchitis or pneumonia, cough becomes more prominent. Sputum, if produced at all, is usually white and may be tinged with blood. The temperature seldom rises above 38.9° to 39.4°C (102° to 103°F). Shaking chills, myalgias, and gastrointestinal symptoms (e.g., nausea, vomiting, and diarrhea) are unusual. Chest muscle soreness may result from frequent and prolonged coughing, but true pleuritic pain is uncommon.

Pharyngeal injection is often noted. Cervical lymph node enlargement is unusual. Ear pain due to bullous myringitis (blisters on the tympanic membrane) is a unique but uncommon manifestation. As in other "atypical" pneumonias, findings on auscultation of the lung may be normal or nearly normal despite striking radiographic abnormalities. Pleural effusions develop in fewer than 20% of patients.

M. pneumoniae infection may be particularly severe in patients who have sickle cell disease and other hemoglobin S–related hemoglobinopathies. The functional asplenia seen in sickle cell disease may contribute to severe mycoplasmal disease as it does in pneumococcal infection. Severe respiratory distress and large pleural effusions may occur.

EXTRAPULMONARY MANIFESTATIONS A broad array of extrapulmonary abnormalities have been associated with *M. pneumoniae* infection. Although these events are unusual, they complicate other respiratory diseases even more rarely and often provide the only clue that an otherwise-unremarkable respiratory infection may be mycoplasmal.

Erythema multiforme (Stevens-Johnson syndrome; see Fig. 46-9) typically occurs in young male patients with *M. pneumoniae* infection. Other dermatologic manifestations, such as maculopapular and vesicular exanthems, erythema nodosum, and urticaria, have been reported, but none is as clearly linked to *M. pneumoniae* as is erythema multiforme. Digital necrosis has been seen in patients with sickle cell disease who develop very high titers of cold agglutinins.

Cardiac abnormalities reported in conjunction with *M. pneumoniae* infection include myocarditis and pericarditis, which may result in abnormalities of conduction. Of the wide variety of neurologic conditions associated with *M. pneumoniae*, most have been documented in case reports, where establishment of a cause-and-effect relationship is problematic. Central nervous system abnormalities that have been associated with *M. pneumoniae* include encephalitis, cerebellar ataxia, Guillain-Barré syndrome, transverse myelitis, and peripheral neuropathies. Arthralgias are not unusual in patients who have mycoplasmal pneumonia; mycoplasmal arthritis is rare except in patients who have hypogammaglobulinemia. Hematologic abnormalities associated with *M. pneumoniae* include hemolytic anemia and coagulopathies.

The pathogenesis of the extrapulmonary manifestations of *M. pneumoniae* infection is controversial. Occasional reports have described the identification of *M. pneumoniae* or its nucleic acids in involved tissues. The fact that most attempts at detection have yielded negative results, however, suggests that these extrapulmonary complications have an immunologic basis. Mycoplasmas, including *M. pneumoniae*, can nonspecifically stimulate B lymphocytes. *M. pneumoniae*–infected individuals can develop autoantibodies, including those reactive with brain, heart, and muscle.

DIAGNOSIS Most infections with *M. pneumoniae* are not diagnosed, as they are indistinguishable from upper and lower respiratory tract infections caused by myriad other viral and bacterial pathogens. When the diagnosis is suspected, it is usually because illness is prolonged or extrapulmonary manifestations develop. The white blood cell count is generally somewhat elevated, with few immature cells. Gram's stain of sputum shows leukocytes without a predominance of any bacterial morphologic type. Since *M. pneumoniae* lacks a cell wall, it cannot be detected on Gram's stain. In patients who have pneumonia, the chest radiograph may show reticulonodular or interstitial infiltration, primarily in the lower lobes. As in other "atypical" pneumonias, radiographic abnormalities may be more prominent than would be predicted by auscultation of the chest.

M. pneumoniae can be grown on artificial media, but the process is exacting, requires special media, and takes upwards of 2 weeks. Thus, mycoplasmal cultures do not provide timely information to aid in patient management. The same, unfortunately, is true of serologic diagnosis. Specific antibodies can be detected by enzyme-linked immunoassays, indirect immunofluorescence, or complement fixation but do not develop early enough to guide decisions regarding treatment. As with most serologic tests, examination of paired acute- and convalescent-phase serum specimens is required for good sensitivity and specificity.

Cold agglutinins are nonspecific but develop within the first 7 to 10 days in more than half of patients with *M. pneumoniae* pneumonia and may be detectable when the patient presents to a health care provider. In a patient with a compatible clinical picture, a cold agglutinin titer of ≥1:32 supports the diagnosis of mycoplasmal pneumonia. Cold agglutinin determinations are readily available from diagnostic laboratories. The test can also be performed at the bedside by the addition of 1 mL of the patient's blood to a tube containing anticoagulant (e.g., a tube used to collect blood for determination of prothrombin activity). Before cooling, the nonaggregated red blood cells coat the sides of the inverted tube. The blood is cooled to 4°C when the tube is placed in an ice bath for 3 to 5 min or in a standard refrigerator. In a positive test, clumps of red blood cells can be observed when the tube is inverted. Rewarming of the sample to 37°C in an incubator or by exposure to body heat should reverse the agglutination. A positive "bedside" cold agglutinin test is equivalent to a laboratory titer of ≥1:64.

The lack of sensitive, specific, and timely diagnostic tests has prompted the development of a variety of antigen detection tests that do not involve serology or the cultivation of live organisms. Such tests include antigen capture, indirect enzyme immunoassays, DNA probing, and nucleic acid amplification. Since many viral and bacterial infections result in clinical presentations similar to that caused by *M. pneumoniae*, examination of specimens for single antigens is unlikely to be useful. Rather, tests that examine an individual specimen for multiple antigens are needed. Multiplex nucleic acid amplification tests that examine a single throat swab or sputum sample for all of the most likely causative microorganisms are feasible with current technology. Prototype multiplex polymerase chain reaction (PCR) assays have already been developed. If such tests become available clinically, more precise etiologic diagnosis of upper and lower respiratory tract infections will be possible.

TREATMENT

Pneumonia due to *M. pneumoniae* is usually self-limited and is seldom life-threatening. Effective antimicrobial agents do shorten the duration of illness and, by reducing coughing, may conceivably render the patient less infectious. Although symptoms are alleviated by antimicrobial treatment, the organism usually is not eradicated. Cultures positive for *M. pneumoniae* may persist for months despite clinically effective antimicrobial therapy. The beneficial effects, if any, of such treatment on extrapulmonary manifestations of *M. pneumoniae* infection are unknown.

Because most mycoplasmal infections are not specifically diagnosed, management is directed at one of two syndromes: upper respiratory tract infection or community-acquired pneumonia. Upper respiratory infections, whether caused by viruses or by *M. pneumoniae*, do not require antimicrobial treatment. Community-acquired

pneumonia (Chap. 239) may be caused by bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* or by "atypical" agents such as *Chlamydia pneumoniae*, *Legionella pneumophila*, and *M. pneumoniae*. Recommended treatment regimens are detailed in Tables 159-1 and 159-2. Treatment of documented *M. pneumoniae* pneumonia is usually continued for 14 to 21 days.

GENITAL MYCOPLASMAS (See also Chap. 115)

EPIDEMIOLOGY *M. hominis* and *U. urealyticum* are the most prevalent genital mycoplasmas. Infants may become colonized with one or both of these organisms during passage through a colonized birth canal. Neonatal colonization tends not to persist. Only ~10% of prepubertal girls and even fewer prepubertal boys are colonized with ureaplasmas. After puberty, colonization occurs mainly as a result of sexual activity. Among adults, disadvantaged populations have higher colonization rates. Ureaplasmas can be cultured from the vaginas of ~80% of women cared for in public clinics and about half of women cared for by private obstetricians and gynecologists. Similarly, vaginal *M. hominis* is found in ~50% of women attending public clinics and in ~20% of private patients. Men have somewhat lower rates of genital colonization than women. In short, both *U. urealyticum* and *M. hominis* are frequently detected in genital specimens from healthy, sexually experienced adults. Evaluation of the role of these organisms in human disease must take into account their high prevalence among healthy people.

M. fermentans colonizes both the respiratory and genital tracts in more than 20% of adults. There is no convincing evidence that *M. fermentans* causes human disease; although it had been implicated as a possible determinant of HIV-1 disease progression, more recent data do not support such a role. *M. genitalium* is a fastidious organism that is difficult to cultivate. PCR studies have identified the organism more successfully. Little is known about the epidemiology of *M. genitalium*.

ASSOCIATION WITH HUMAN DISEASE ■ Nongonococcal Urethritis (NGU) *Chlamydia trachomatis* is the organism most firmly implicated in the etiology of NGU. There is no doubt that sexually transmitted *U. urealyticum* and *M. genitalium* also cause some cases of NGU. The ubiquity of ureaplasmas among men who do not have urethritis and the difficulty of identifying *M. genitalium* do not allow precise estimation of the proportion of cases of NGU caused by each of these mycoplasmas. *U. urealyticum* and *M. genitalium* do, however, appear to cause most of the nonchlamydial cases.

Epididymitis and Prostatitis Ureaplasmas may be an occasional cause of epididymitis. *M. hominis* has not been implicated in this disease. Neither organism has been convincingly associated with prostatitis.

Pelvic Inflammatory Disease (PID) *M. hominis* and *U. urealyticum* are both prominent components of the complex microbial flora of bacterial vaginosis. Since bacterial vaginosis is associated with PID, it is difficult to determine whether either organism plays an independent role in this condition. Although *M. genitalium* is not associated with bacterial vaginosis, preliminary studies have linked it to PID in women who are not infected with either *Neisseria gonorrhoeae* or *C. trachomatis*.

TABLE 159-1 Oral Antimicrobial Agents for the Treatment of Ambulatory Patients with Community-Acquired Pneumonia

Agent	Dose and Schedule
Doxycycline	100 mg bid
Erythromycin	500 mg qid
Clarithromycin	500 mg bid
Azithromycin	500 mg qd
Levofloxacin	500 mg qd
Gatifloxacin	400 mg qd
Moxifloxacin	400 mg qd

Note: Treatment of documented *M. pneumoniae* pneumonia is usually continued for 14 to 21 days.

TABLE 159-2 Antimicrobial Agents for the Treatment of Hospitalized Patients with Community-Acquired Pneumonia

1. Intravenous ceftriaxone (1.0 g/d) *or*
   Intravenous cefotaxime (1.0 g q8h) *or*
   Intravenous ampicillin/sulbactam (1.5–3.0 g q6h)
   plus
   Intravenous or oral erythromycin (500 mg qid) *or*
   Intravenous or oral azithromycin (500 mg qd) *or*
   Oral clarithromycin (500 mg bid)
2. Intravenous or oral levofloxacin (500 mg qd)
3. Intravenous or oral gatifloxacin (400 mg qd)
4. Intravenous or oral moxifloxacin (400 mg qd)

Note: Treatment of documented *M. pneumoniae* pneumonia is usually continued for 14 to 21 days.

Disorders of Reproduction Ureaplasmas have been considered as causes of involuntary infertility in both men and women, but there is no convincing evidence for such an association. These organisms have been associated with chorioamnionitis and late abortion. Given the close association of ureaplasmas with bacterial vaginosis, a condition that is strongly associated with chorioamnionitis and late abortion, it is difficult to define an independent role for ureaplasmas in this condition. In infants of very low birth weight, ureaplasmas have been shown to cause pneumonia and chronic lung disease.

Extragenital Infections Sexually acquired reactive arthritis and Reiter's syndrome may be triggered by ureaplasmas, although *C. trachomatis* is the usual triggering agent. Patients who have hypogammaglobulinemia may develop chronic arthritis due to ureaplasmas and some other mycoplasmal species. *M. hominis* has been identified in patients with postthoracotomy sternal wound infection and in rare instances of prosthetic heart valve and prosthetic joint infection.

DIAGNOSIS There is seldom any reason to examine specimens from the lower genital tract (vagina, male urethra) for mycoplasmas. The ubiquity of the organisms among healthy individuals makes a positive result uninterpretable. The organisms should be sought only in specimens from normally sterile areas, such as joint fluid with evidence of inflammation and cultures negative for conventional microorganisms.

M. hominis can replicate in many routine blood culture media without changing the appearance of the media; although it forms nonhemolytic pinpoint colonies on blood agar, organisms cannot be visualized in gram-stained smears of these colonies. Neither *U. urealyticum* nor *M. genitalium* will grow in ordinary microbiologic media.

Microbiologic diagnosis of genital mycoplasmal infection requires specially prepared media and is beyond the capability of all but reference and research laboratories. Nucleic acid amplification tests such as PCR have been developed and may become commercially available.

℞ TREATMENT

Ureaplasmas, *M. genitalium*, and *M. hominis* are usually susceptible to tetracyclines (e.g., doxycycline). Infections caused by tetracycline-resistant ureaplasmas can be treated with erythromycin, while those due to tetracycline-resistant strains of *M. hominis* respond to treatment with clindamycin. As noted above, a specific microbiologic diagnosis of mycoplasmal infection is seldom made. Appropriate treatment provides antimicrobial coverage for the organisms that cause the particular syndrome. Accordingly, NGU is treated with doxycycline (100 mg orally twice a day for 7 days) or azithromycin (1.0 g as a single oral dose) to provide activity against *C. trachomatis*, *U. urealyticum*, and *M. genitalium*. Recommended regimens for the treatment of PID provide antimicrobial activity against gonococci, chlamydiae, and anaerobes as well as genital mycoplasmas.

160 CHLAMYDIAL INFECTIONS

Walter E. Stamm

The genus *Chlamydia* contains three species that infect humans: *Chlamydia psittaci*, *C. trachomatis*, and *C. pneumoniae* (formerly the TWAR agent). *C. psittaci* is widely distributed in nature, producing genital, conjunctival, intestinal, or respiratory infections in many mammalian and avian species. Genital infections with *C. psittaci* have been well characterized in several species and cause abortion and infertility. Although mammalian strains of *C. psittaci* are not known to infect humans, avian strains occasionally do so, causing pneumonia and the systemic illness known as *psittacosis*.

C. pneumoniae is a fastidious chlamydial species that appears to be a common cause of upper respiratory tract infection and pneumonia, primarily in children and young adults, and is a cause of recurrent respiratory infections in older adults. Studies have also linked *C. pneumoniae* infection to atherosclerotic cardiovascular disease and perhaps to asthma and sarcoidosis. No animal reservoir has been identified for *C. pneumoniae*; it appears to be an exclusively human pathogen spread via the respiratory route through close personal contact. To date, all strains of *C. pneumoniae* studied have been serologically homologous.

C. trachomatis is also an exclusively human pathogen and was identified as the cause of trachoma in the 1940s. Since then, *C. trachomatis* has been recognized as a major cause of sexually transmitted and perinatal infection.

Chlamydiae are obligate intracellular bacteria that are classified in their own order (Chlamydiales). They possess both DNA and RNA, have a cell wall and ribosomes similar to those of gram-negative bacteria, and are inhibited by antibiotics such as tetracycline.

A unique feature of all chlamydiae is their complex reproductive cycle. Two forms of the microorganism—the extracellular elementary body and the intracellular reticulate body—participate in this cycle. The elementary body is adapted for extracellular survival and is the infective form transmitted from one person to another. Elementary bodies attach to susceptible target cells (usually columnar or transitional epithelial cells) and enter the cells inside a phagosome. Within 8 h of cell entry, the elementary bodies reorganize into reticulate bodies, which are adapted to intracellular survival and multiplication. They undergo binary fission, eventually producing numerous replicates contained within the intracellular membrane-bound "inclusion body," which occupies much of the infected host cell. Chlamydial inclusions resist lysosomal fusion until late in the developmental cycle. After 24 h, the reticulate bodies condense and form elementary bodies still contained within the inclusion. The inclusion then ruptures, releasing elementary bodies from the cell to initiate infection of adjacent cells or transmission to another person.

Studies with monoclonal antibodies to and nucleotide sequencing of the major outer-membrane protein have delineated at least 20 serotypes of *C. trachomatis*. According to the classification of Wang and Grayston, strains associated with trachoma have generally been those of the A, B, Ba, and C serovars, while serovars D through K have largely been associated with sexually transmitted and perinatally acquired infections. Serovars L_1, L_2, and L_3 produce lymphogranuloma venereum (LGV) and hemorrhagic proctocolitis. The LGV strains demonstrate unique biologic behavior in that they are more invasive than the other serovars, produce disease in lymphatic tissue, grow readily in cell culture systems and macrophages, and are lethal when inoculated intracerebrally into mice and monkeys. Non-LGV strains of *C. trachomatis* characteristically produce infections involving the superficial columnar epithelium of the eye, genitalia, and respiratory tract.

C. trachomatis has been reported as an infrequent cause of endocarditis, peritonitis, pleuritis, and possibly periappendicitis and may occasionally cause respiratory infections in older children and adults. Some immunosuppressed patients with pneumonia have had either serologic or cultural evidence of *C. trachomatis* infection, but more data are necessary to define a pathogenic role for *Chlamydia* in these patients.

C. TRACHOMATIS INFECTIONS

C. TRACHOMATIS GENITAL INFECTIONS

Genital infections caused by *C. trachomatis* represent the most common bacterial sexually transmitted diseases (STDs) in the United States (Chap. 115). An estimated 4 million cases occur each year. In adults, the clinical spectrum of sexually transmitted *C. trachomatis* infections parallels that of gonococcal infections. Both infections have been associated with urethritis, proctitis, and conjunctivitis in both sexes; with epididymitis in men; and with mucopurulent cervicitis (MPC), acute salpingitis, bartholinitis, and the Fitz-Hugh–Curtis syndrome (perihepatitis) in women. Moreover, both types of infection can be associated with septic arthritis. In general, however, chlamydial infections produce fewer symptoms and signs than corresponding gonococcal infections at the same anatomic site; in fact, chlamydial infections are often totally asymptomatic. Increasing evidence suggests that many chlamydial infections of the genital tract, especially in women, persist for months without producing symptoms. Simultaneous infection with *C. trachomatis* often occurs in women with cervical gonococcal infection and in heterosexual men with gonococcal urethritis.

Epidemiology Infections due to *C. trachomatis* have been reportable in the United States since 1985, and national incidence data show steadily rising numbers of reported infections, undoubtedly reflecting both increased testing and increased reporting. Most testing to date has focused upon women, and thus the reported incidence is severalfold greater among women than among men; this difference likely represents a surveillance artifact.

The age of peak incidence of genital *C. trachomatis* infections, as of other sexually transmitted infections, is the late teens and early twenties. The prevalence of chlamydial urethral infection among young men is at least 3 to 5% for those seen in general medical settings or in urban high schools, >10% for asymptomatic soldiers undergoing routine physical examination, and 15 to 20% for heterosexual men seen in STD clinics. In areas where chlamydial control programs have been implemented, prevalence may be markedly reduced. In short, prevalence varies widely with the population group studied and with the geographic locale. With the newer, more sensitive nucleic acid amplification tests such as polymerase chain reaction (PCR) and ligase chain reaction (LCR), prevalences in most populations have been 10 to 30% higher than those measured with older, less sensitive tests.

The prevalence of cervical infection among women is ~5% for asymptomatic college students and prenatal patients in the United States, >10% for women seen in family planning clinics, and >20% for women seen in STD clinics. As in men, prevalence varies substantially by geographic locale, with the highest rates in the southeast. However, substantial prevalences (~8%) of asymptomatic chlamydial

infection have been demonstrated among young female military recruits from all parts of the United States. In this country, the prevalence of *C. trachomatis* in the cervix of pregnant women is 5 to 10 times higher than that of *Neisseria gonorrhoeae*. The prevalence of genital infection with either agent is highest among individuals who are between the ages of 18 and 24, single, and non-Caucasian (e.g., African American or Latino). Recurrent chlamydial infections occur frequently in these same risk groups, often acquired from untreated sexual partners. Oral contraceptive pill use and the presence of cervical ectopy also confer an increased risk of chlamydial infection. The proportion of infections that are asymptomatic appears to be higher for *C. trachomatis* than for *N. gonorrhoeae*, and symptomatic *C. trachomatis* infections are clinically less severe. Mild or asymptomatic chlamydial infections of the fallopian tubes nonetheless cause ongoing tubal damage and infertility. Furthermore, because the total number of *C. trachomatis* infections exceeds the total number of *N. gonorrhoeae* infections in industrialized countries, the total morbidity caused by *C. trachomatis* genital infections in these countries equals or exceeds that caused by *N. gonorrhoeae*. The prevalence of *C. trachomatis* is higher than that of *N. gonorrhoeae* in industrialized countries, in part because measures such as treatment of sex partners and routine cultures for case detection in asymptomatic individuals have been applied much longer and more effectively to the control of gonorrhea than to the control of *C. trachomatis* infection.

Pathogenesis *C. trachomatis* preferentially infects the columnar epithelium of the eye and the respiratory and genital tracts. The infection induces an immune response but often persists for months or years in the absence of antimicrobial therapy. Serious sequelae often occur in association with repeated or persistent infections. The precise mechanism through which repeated infection elicits an inflammatory response that leads to tubal scarring and damage in the female upper genital tract is not yet clear. One antigen, the chlamydial 60-kDa heat-shock protein, may be involved in inducing the pathologic immune response or may elicit antibodies that cross-react with human heat-shock proteins. The recent sequencing of the chlamydial genome may soon offer further insights into the pathogenic mechanisms of *C. trachomatis*.

Clinical Manifestations ■ *NONGONOCOCCAL AND POSTGONOCOCCAL URETHRITIS* Nongonococcal urethritis (NGU) is a diagnosis of exclusion that is applied to men with symptoms and/or signs of urethritis who do not have gonorrhea. Postgonococcal urethritis (PGU) refers to nongonococcal urethritis developing in men 2 to 3 weeks after treatment of gonococcal urethritis with single doses of agents such as amoxicillin or cephalosporins that lack antimicrobial activity against chlamydiae. Since current treatment regimens for gonorrhea also include tetracycline, doxycycline, or azithromycin for possible concomitant chlamydial infection, both the incidence of PGU and the causative role of chlamydiae in this syndrome have declined. *C. trachomatis* causes 20 to 40% of cases of NGU in heterosexual men but is less commonly isolated from homosexual men with this syndrome. The cause of most of the remaining cases is uncertain; considerable evidence suggests that *Ureaplasma urealyticum* and *Mycoplasma genitalium* cause many cases of NGU, while *Trichomonas vaginalis* and herpes simplex virus (HSV) cause some cases.

NGU is diagnosed by documentation of a leukocytic urethral exudate and by exclusion of gonorrhea by Gram's staining or culture. *C. trachomatis* urethritis is generally less severe than gonococcal urethritis, although in an individual patient these two forms of urethritis cannot be reliably differentiated solely on clinical grounds. Symptoms include urethral discharge (often whitish and mucoid rather than frankly purulent), dysuria, and urethral itching. Physical examination may reveal meatal erythema and tenderness and a urethral exudate that is often demonstrable only by stripping of the urethra.

At least one-third of males with *C. trachomatis* urethral infection have no demonstrable signs or symptoms of urethritis. Use of nucleic acid amplification assays on first-void urine specimens to diagnose chlamydial infections in men has facilitated more broadly based testing for asymptomatic infection in males. As a result, asymptomatic chlamydial urethritis has been demonstrated in 5 to 10% of sexually active adolescent males screened in school-based clinics or community centers. Such patients generally have first-glass pyuria (≥15 leukocytes per 400× microscopic field in the sediment of first-void urine), a positive leukocyte esterase test, or an increased number of leukocytes on Gram-stained smear prepared from a urogenital swab inserted 1 to 2 cm into the anterior urethra. For the enumeration of leukocytes, the smear is first scanned at low power to identify areas of the slide containing the highest concentration of leukocytes. These areas are then examined under oil immersion (1000×). An average of four or more leukocytes in at least three of five 1000× (oil-immersion) fields is indicative of urethritis and correlates with the recovery of *C. trachomatis*. To differentiate between true urethritis and functional symptoms among symptomatic patients or to make a presumptive diagnosis of *C. trachomatis* infection in "high-risk" but asymptomatic men (e.g., male patients in STD clinics, sex partners of women with nongonococcal salpingitis or MPC, fathers of children with inclusion conjunctivitis), the examination of an endourethral specimen for increased leukocytes is useful if specific diagnostic tests for chlamydiae are not available. Alternatively, noninvasive screening for urethritis can be accomplished by testing of a first-void urine sample for pyuria, either by microscopy or by the leukocyte esterase test. Urine can also be directly tested for chlamydiae or gonococci by DNA amplification methods, as described below.

EPIDIDYMITIS *C. trachomatis* is the foremost cause of epididymitis in sexually active heterosexual men <35 years of age, accounting for ~70% of cases. *N. gonorrhoeae* causes most of the remaining cases, and some men have simultaneous infections with both pathogens, usually accompanied by asymptomatic urethritis as defined above. In homosexual men, sexually transmitted coliform infection acquired via insertive rectal intercourse may cause epididymitis. Coliform bacteria and *Pseudomonas aeruginosa*, usually in association with preceding urologic instrumentation or surgery, are the most common causes of epididymitis in men over 35. Men with chlamydial epididymitis typically present with unilateral scrotal pain, fever, and epididymal tenderness or swelling on examination. The illness may be mild enough to treat on an outpatient basis with oral antibiotics or severe enough to require hospitalization and parenteral therapy. Testicular torsion should be excluded promptly by radionuclide scan, Doppler flow study, or surgical exploration in a teenager or young adult who presents with acute unilateral testicular pain without urethritis. The possibility of testicular tumor or chronic infection (e.g., tuberculosis) should be excluded when a patient with unilateral intrascrotal pain and swelling does not respond to appropriate antimicrobial therapy.

REITER'S SYNDROME Reiter's syndrome consists of conjunctivitis, urethritis (or cervicitis in females), arthritis, and characteristic mucocutaneous lesions (Chap. 305). *C. trachomatis* has been recovered from the urethra of up to 70% of men with untreated nondiarrheal Reiter's syndrome and associated urethritis. In the absence of overt urethritis, it is important to exclude subclinical urethritis in the men in whom this diagnosis is suspected.

The pathogenesis of Reiter's syndrome remains obscure. However, since more than 80% of affected patients have the HLA-B27 phenotype and since other mucosal infections (with *Salmonella*, *Shigella*, or *Campylobacter*, for example) produce an identical syndrome, chlamydial infection is thought to initiate an aberrant and hyperactive immune response that produces inflammation at the involved target organs in these genetically predisposed individuals. Evidence of exaggerated cell-mediated and humoral immune responses to chlamydial antigens in Reiter's syndrome supports this hypothesis. The presumptive demonstration of chlamydial elementary bodies and chlamydial DNA in the joint fluid and synovial tissue of patients with Reiter's syndrome suggests that chlamydiae may actually spread from genital to joint tissues in these patients, perhaps in macrophages.

PROCTITIS *C. trachomatis* strains of either the genital immunotypes D through K or the LGV immunotypes cause proctitis in homosexual men who practice receptive anorectal intercourse. In the United States, the vast majority of cases are due to immunotypes D through K and present either as asymptomatic infection or as mild proctitis not unlike gonococcal proctitis. These infections may develop in heterosexual women as well. Patients present with mild rectal pain, mucous discharge, tenesmus, and (occasionally) bleeding. Nearly all have neutrophils in their rectal Gram's stain. Anoscopy in these non-LGV cases of chlamydial proctitis reveals mild, patchy mucosal friability and mucopurulent discharge, and the disease process is limited to the distal rectum. LGV strains produce more severe ulcerative proctitis or proctocolitis that can be confused clinically with HSV proctitis (severe rectal pain, bleeding, discharge, and tenesmus) and that histologically resembles Crohn's disease in that giant cell formation and granulomas can be seen (Chap. 276). In the United States, these cases occur almost exclusively in homosexual men.

MUCOPURULENT CERVICITIS Although many women with *C. trachomatis* infection of the cervix have no symptoms or signs, a careful speculum examination reveals evidence of MPC in 30 to 50% of cases. As is discussed more fully in Chap. 115, MPC is associated with yellow mucopurulent endocervical discharge and with ≥20 neutrophils per 1000× microscopic field within strands of cervical mucus on a thinly smeared, Gram-stained preparation of endocervical exudate. Other characteristic findings include edema of the zone of cervical ectopy and a propensity of the mucosa to bleed on minor trauma—e.g., when specimens are collected with a swab. A Pap smear shows increased numbers of neutrophils as well as a characteristic pattern of mononuclear inflammatory cells, including plasma cells, transformed lymphocytes, and histiocytes. Cervical biopsy shows a predominantly mononuclear cell infiltrate of the subepithelial stroma, often with follicular cervicitis.

PELVIC INFLAMMATORY DISEASE (PID) (See also Chap. 115) In the United States, *C. trachomatis* has been identified in the fallopian tubes or endometrium of up to 50% of women with PID, and its role as an important etiologic agent in this syndrome is well accepted. PID occurs via ascending intraluminal spread of *C. trachomatis* from the lower genital tract. MPC is thus followed by endometritis, endosalpingitis, and finally pelvic peritonitis. Evidence of MPC is usually found in women with laparoscopically verified salpingitis. Similarly, endometritis, demonstrated by endometrial biopsy showing plasma cell infiltration of the endometrial epithelium, is documented in most women with laparoscopically verified chlamydial (or gonococcal) salpingitis. Chlamydial endometritis can also occur in the absence of clinical evidence of salpingitis: ~40 to 50% of women with MPC have plasma cell endometritis. Histologic evidence of endometritis has been correlated with an "endometritis syndrome" consisting of vaginal bleeding, lower abdominal pain, and uterine tenderness in the absence of adnexal tenderness. Chlamydial salpingitis produces milder symptoms than does gonococcal salpingitis and may be associated with less marked adnexal tenderness. Thus mild adnexal or uterine tenderness in sexually active women with cervicitis suggests PID.

Infertility associated with fallopian-tube scarring has been strongly linked to antecedent *C. trachomatis* infection in serologic studies. Since many infertile women with tubal scarring and antichlamydial antibody have no history of PID, it appears that subclinical tubal infection ("silent salpingitis") may produce scarring. Studies in animals and humans with salpingitis and tubal scarring suggest the continuing presence of persistent, slowly replicating chlamydial infection in tubal tissue. While the pathogenesis of *Chlamydia*-induced tubal scarring remains poorly understood, antibodies to the chlamydial 60-kDa heat-shock protein have been correlated with tubal infertility, ectopic pregnancy, and Fitz-Hugh–Curtis syndrome (see below). Thus this antigen may initiate an immune-mediated process that ultimately damages the fallopian tube. Host genetic susceptibility, as defined by HLA type, may also play an important role.

Perihepatitis, or the Fitz-Hugh–Curtis syndrome, was originally described as a complication of gonococcal PID. The syndrome should be suspected whenever a young, sexually active woman presents with an illness resembling cholecystitis (fever and right-upper-quadrant pain of subacute or acute onset). Symptoms and signs of salpingitis may be minimal. Cultural and/or serologic evidence of *C. trachomatis* infection is found in three-quarters of women with this syndrome.

URETHRAL SYNDROME IN WOMEN In the absence of infection with uropathogens such as coliforms or *Staphylococcus saprophyticus*, *C. trachomatis* is the pathogen most commonly isolated from college women with dysuria, frequency, and pyuria (Chap. 269). *Chlamydia* can also be isolated from the urethra of women without symptoms of urethritis, and up to 25% of female STD clinic patients with chlamydial urogenital infection have cultures positive for *C. trachomatis* from the urethra only.

C. TRACHOMATIS INFECTION IN PREGNANCY AND THE NEONATAL PERIOD Studies in the United States have demonstrated that 5 to 25% of pregnant women have *C. trachomatis* infections of the cervix. In these studies, approximately one-half to two-thirds of children exposed during birth have acquired *C. trachomatis* infection. Roughly half of the infected infants (or 25% of the group exposed) have developed clinical evidence of inclusion conjunctivitis. In addition to infecting the eye, *C. trachomatis* has been isolated frequently and persistently from the nasopharynx, rectum, and vagina of such infants, occasionally for periods exceeding 1 year in the absence of treatment. Pneumonia develops in ~10% of children infected perinatally, and otitis media may in some cases result from perinatally acquired chlamydial infection.

Neonatal chlamydial conjunctivitis has an acute onset 5 to 14 days after birth and often produces a profuse mucopurulent discharge. However, it is impossible to differentiate chlamydial conjunctivitis from other forms of neonatal conjunctivitis (such as that due to *N. gonorrhoeae*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, or HSV) on clinical grounds; thus laboratory diagnosis is required. Inclusions within epithelial cells are often detected in Giemsa-stained conjunctival smears, but these smears are considerably less sensitive than cultures, antigen detection tests, or nucleic acid hybridization tests for chlamydiae. Gram-stained smears may show gonococci or occasional small gram-negative coccobacilli in *Haemophilus* conjunctivitis, but smears should be accompanied by cultures for these agents.

C. trachomatis causes a distinctive pneumonia syndrome in infants. Recent epidemiologic studies have linked chlamydial pulmonary infection in infants with increased occurrence of subacute lung disease (bronchitis, asthma, wheezing) in later childhood.

Lymphogranuloma Venereum ■ *DEFINITION* LGV is a sexually transmitted infection caused by *C. trachomatis* strains of the L_1, L_2, and L_3 serovars. In the United States, most cases are caused by L_2 organisms. Acute LGV is characterized by a transient primary genital lesion followed by multilocular suppurative regional lymphadenopathy. Patients exposed via insertive rectal intercourse may develop hemorrhagic proctitis with regional lymphadenitis. Acute LGV is almost always associated with systemic symptoms such as fever and leukocytosis but is rarely associated with systemic complications such as meningoencephalitis. After a period of years, late complications include genital elephantiasis due to lymphatic involvement; strictures; and fistulas of the penis, urethra, and rectum.

EPIDEMIOLOGY LGV is usually sexually transmitted, but occasional transmission by nonsexual personal contact, fomites, or laboratory accidents has been documented. Laboratory work involving the creation of aerosols of LGV organisms (e.g., sonication, homogenization) must be conducted only with appropriate measures for biologic containment.

The peak incidence of LGV corresponds to the age of greatest sexual activity: the second and third decades of life. The worldwide incidence of LGV is falling, but the disease is still endemic and a major cause of morbidity in Asia, Africa, South America, and parts of

the Caribbean. In the Bahamas, an apparent outbreak of LGV has been described in association with a concurrent increase in heterosexual infection with HIV. However, the reported incidence of LGV in the United States has been only 0.1 case per 100,000 persons for more than a decade.

The frequency of infection following exposure is believed to be much lower than that for gonorrhea and syphilis. Early manifestations are recognized far more often in men than in women, who usually present with late complications. In the United States, where the reported male-to-female ratio of cases is 3.4:1, most cases have involved homosexually active men and persons returning from abroad (travelers, sailors, and military personnel). The main reservoir of infection, although it has not been directly demonstrated, is presumed to be asymptomatically infected individuals.

CLINICAL MANIFESTATIONS A *primary genital lesion* develops from 3 days to 3 weeks after exposure. It is a small, painless vesicle or nonindurated ulcer or papule located on the penis in men and on the labia, posterior vagina, or fourchette in women. The primary lesion is noticed by fewer than one-third of men with LGV and only rarely by women. It heals in a few days without scarring and, even when noticed, is usually recognized as LGV only in retrospect. LGV strains of *C. trachomatis* have occasionally been recovered from genital ulcers and from the urethra of men and the endocervix of women who present with inguinal adenopathy; these areas may be the primary site of infection in some cases.

Primary anal or *rectal infection* develops after receptive anorectal intercourse. In women, rectal infection with LGV (or non-LGV) strains of *C. trachomatis* presumably can also arise by the contiguous spread of infected secretions along the perineum (as in rectal gonococcal infections in women) or perhaps by spread to the rectum via the pelvic lymphatics.

From the site of the primary urethral, genital, anal, or rectal infection, the organism spreads via the regional lymphatics. Penile, vulvar, or anal infection can lead to inguinal and femoral lymphadenitis. Rectal infection produces hypogastric and deep iliac lymphadenitis. Upper vaginal or cervical infection results in enlargement of the obturator and iliac nodes.

The most common presenting picture in heterosexual men is the *inguinal syndrome*, which is characterized by painful inguinal lymphadenopathy beginning 2 to 6 weeks after presumed exposure; in rare instances, the onset comes after a few months. The inguinal adenopathy is unilateral in two-thirds of cases, and palpable enlargement of the iliac and femoral nodes is often evident on the same side as the enlarged inguinal nodes. The nodes are initially discrete, but progressive periadenitis results in a matted mass of nodes that becomes fluctuant and suppurative. The overlying skin becomes fixed, inflamed, and thin and finally develops multiple draining fistulas. Extensive enlargement of chains of inguinal nodes above and below the inguinal ligament ("the sign of the groove") is not specific and, although not uncommon, is documented in only a minority of cases. On histologic examination, infected nodes are initially found to have characteristic small stellate abscesses surrounded by histiocytes. These abscesses coalesce to form large, necrotic, suppurative foci. Spontaneous healing usually takes place after several months; inguinal scars or granulomatous masses of various sizes persist for life. Massive pelvic lymphadenopathy may lead to exploratory laparotomy.

As cultures and serologic tests for *C. trachomatis* are being used more often, increasing numbers of cases of LGV proctitis are being recognized in homosexual men. Such patients present with anorectal pain and mucopurulent, bloody rectal discharge. Although these patients may complain of diarrhea, they are often referring not to diarrhea but rather to frequent, painful, unsuccessful attempts at defecation (tenesmus). Sigmoidoscopy reveals ulcerative proctitis or proctocolitis, with purulent exudate and mucosal bleeding. The histopathologic findings in the rectal mucosa include granulomas with giant cells, crypt abscesses, and extensive inflammation. These clinical, sigmoidoscopic, and histopathologic findings may closely resemble those of Crohn's disease of the rectum.

Constitutional symptoms are common during the stage of regional lymphadenopathy and, in cases of proctitis, may include fever, chills, headache, meningismus, anorexia, myalgias, and arthralgias. These findings in the presence of lymphadenopathy are sometimes mistakenly interpreted as representing malignant lymphoma. Other systemic complications are infrequent but include arthritis with sterile effusion, aseptic meningitis, meningoencephalitis, conjunctivitis, hepatitis, and erythema nodosum. Chlamydiae have been recovered from the cerebrospinal fluid and in one case were isolated from the blood of a patient with severe constitutional symptoms—a result indicating the dissemination of infection. Laboratory-acquired infections suspected of being due to the inhalation of aerosols have been associated with mediastinal lymphadenitis, pneumonitis, and pleural effusion.

Complications of untreated anorectal infection include perirectal abscess; fistula in ano; and rectovaginal, rectovesical, and ischiorectal fistulas. Secondary bacterial infection probably contributes to these complications. Rectal stricture is a late complication of anorectal infection and usually develops 2 to 6 cm from the anal orifice—i.e., at a site within reach on digital rectal examination. Proximal extension of the stricture for several centimeters may lead to a mistaken clinical and radiographic diagnosis of carcinoma.

A small percentage of cases of LGV in men present as chronic progressive infiltrative, ulcerative, or fistular lesions of the penis, urethra, or scrotum. Associated lymphatic obstruction may produce elephantiasis. When urethral stricture occurs, it usually involves the posterior urethra and causes incontinence or difficulty with urination.

Approach to the Diagnosis and Treatment of *C. trachomatis* Genital Infections

Four types of laboratory procedure are available to confirm *C. trachomatis* infection: direct microscopic examination of tissue scrapings for typical intracytoplasmic inclusions or elementary bodies; isolation of the organism in cell culture; detection of chlamydial antigens or nucleic acid by immunologic or hybridization methods; and detection of antibody in serum or in local secretions.

Except in conjunctivitis, direct microscopic examination of Giemsa-stained cell scrapings for typical inclusions has an unacceptably low degree of sensitivity, and false-positive interpretations by inexperienced observers are common. Even for conjunctivitis, this approach has been replaced by direct fluorescent antibody staining of conjunctival smears to identify chlamydial elementary bodies with specific monoclonal antibodies (see below).

Cell culture techniques for isolation of *C. trachomatis* are available in most large medical centers but not in other clinical settings. In addition to limited availability, other disadvantages of cell culture include its low and variable level of sensitivity (60 to 80%), its requirement for rigorous transport conditions, and its high cost and technically demanding nature. Therefore, nonculture alternatives involving antigen detection or nucleic acid hybridization have been developed. In the direct immunofluorescent antibody (DFA) slide test, potentially infected genital or ocular secretions are smeared onto a slide, fixed, and stained with fluorescein-conjugated monoclonal antibody specific for chlamydial antigens. The observation of fluorescing elementary bodies confirms the diagnosis. Enzyme-linked immunosorbent assay (ELISA) techniques for the detection of chlamydial antigens provide another alternative to culture. The reported sensitivity and specificity of these tests for genital infections (as compared with culture) have been 60 to 80% and 97 to 99%, respectively, in high-risk populations. Assays with nucleic acid probes have also been developed for chlamydial diagnosis. One such test uses DNA-RNA hybridization and appears to be approximately equal to the best ELISAs in terms of sensitivity and specificity. Nucleic acid probes have also been developed for use in amplification assays such as LCR and PCR. These tests are now the most sensitive chlamydial diagnostic methods available, being the first nonculture assays to surpass culture itself in sensitivity. In addition, the ability of these tests to detect chlamydial genes in

urine with a high degree of sensitivity and specificity allows—for the first time—the use of urine specimens rather than conventional urethral and cervical swabs. The use of urine specimens is particularly appealing for public-health chlamydial screening programs because of the ease of sample collection, even in community-based settings.

Serologic tests are of limited usefulness in the diagnosis of chlamydial oculogenital infections. The complement fixation test with heat-stable, genus-specific antigen has been used with some success to diagnose LGV but is insensitive in infections due to non-LGV strains of *C. trachomatis*. The microimmunofluorescence (micro-IF) test with *C. trachomatis* antigens is more sensitive but is generally available only in research laboratories. The test measures antibodies by serovar specificity and by immunoglobulin class (IgM, IgG, IgA, secretory IgA) in both serum and local secretions. Serologic diagnosis by the micro-IF test may be useful in infant pneumonia (in which high-titer IgM antibody and/or fourfold rises in titer are often demonstrated), in chlamydial salpingitis (especially Fitz-Hugh–Curtis syndrome), and in LGV. In all of these more invasive syndromes, high antibody levels are present.

Table 160-1 summarizes the diagnostic tests of choice for patients with suspected *C. trachomatis* infection. It is clear that, in most settings and for most purposes, sensitivity and specificity will be greatest with nucleic acid amplification techniques. For patients to whom medicolegal considerations may apply (victims of sexual or child abuse), cultures or nucleic acid amplification methods should always be used. In men with suspected urethritis, PCR or LCR testing of a first-void urine specimen offers a more sensitive and noninvasive diagnostic method than the use of urethral swabs. For the diagnosis of urogenital (cervical or urethral) infections in women, testing of a first-void urine specimen by nucleic acid amplification methods is at least as sensitive as testing of a cervical swab. Patient-collected vaginal swabs tested by PCR or LCR have also been used successfully. Since chlamydial diagnostic testing has become more widely available and is now more sensitive and specific than in the past, its use for specific diagnosis in patients with suspected chlamydial syndromes (such as MPC, NGU, and PID) and their partners should be promoted. High priority should also be given to the screening of asymptomatic high-risk women who would not otherwise receive treatment for presumptive chlamydial infection, especially those seen in high-risk settings (e.g., STD clinics or abortion clinics) and those with a high-risk profile (e.g., sexually active and ≤21 years of age, new sex partner within the preceding 2 months, or more than one current sex partner). Similar screening programs should be used to detect and treat asymptomatic urethritis in high-risk adolescent males. Where implemented, screening programs of this type have been associated with reductions in the prevalence of chlamydial infection and of its complications, such as PID.

Rx TREATMENT

Until the introduction of azithromycin, chlamydial infections could not be eradicated by single-dose or short-term antimicrobial regimens. In most uncomplicated infections in adults, a 7-day course of treatment

TABLE 160-1 *Diagnostic Tests for Sexually Transmitted and Perinatal Chlamydia trachomatis Infection*

Infection	Suggestive Signs/Symptoms	Presumptive Diagnosis[a]	Confirmatory Test of Choice
MEN			
NGU, PGU	Discharge, dysuria	Gram's stain with >4 neutrophils per oil-immersion field; no gonococci	Urethral culture or nonculture test for *C. trachomatis*; urine or urethral NAAT for *C. trachomatis*
Epididymitis	Unilateral intrascrotal swelling, pain, tenderness; fever; NGU	Gram's stain with >4 neutrophils per oil-immersion field; no gonococci; urinalysis with pyuria	Urethral culture or nonculture test for *C. trachomatis*; urine or urethral NAAT for *C. trachomatis*
WOMEN			
Cervicitis	Mucopurulent cervical discharge, bleeding and edema of the zone of cervical ectopy	Cervical Gram's stain with ≥20 neutrophils per oil-immersion field in cervical mucus	Cervical culture or nonculture test for *C. trachomatis*; urine or cervical NAAT for *C. trachomatis*
Salpingitis	Lower abdominal pain, cervical motion tenderness, adnexal tenderness or masses	*C. trachomatis* always potentially present in salpingitis	Cervical culture or nonculture test for *C. trachomatis*; urine or cervical NAAT for *C. trachomatis*
Urethritis	Dysuria and frequency without urgency or hematuria	MPC; sterile pyuria; negative routine urine culture	Urethral and cervical cultures or nonculture test for *C. trachomatis*; urine NAAT for *C. trachomatis*
ADULTS OF EITHER SEX			
Proctitis	Rectal pain, discharge, tenesmus, bleeding; history of receptive anorectal intercourse	Negative gonococcal culture and Gram's stain; at least 1 neutrophil per oil-immersion field in rectal Gram's stain	Rectal culture or direct immunofluorescence test for *C. trachomatis*
Reiter's syndrome	NGU, arthritis, conjunctivitis, typical skin lesions	Gram's stain with >4 neutrophils per oil-immersion field; lack of gonococci indicative of NGU	Urethral culture or nonculture test for *C. trachomatis*
LGV	Regional adenopathy, primary lesion, proctitis, systemic symptoms	None	Isolation of LGV strain from node or rectum, occasionally from urethra or cervix; LGV CF titer, ≥1:64; micro-IF titer, ≥1:512
NEONATES			
Conjunctivitis	Purulent conjunctival discharge 6 to 18 days postdelivery	Negative culture and Gram's stain for gonococci, *Haemophilus* spp., pneumococci, staphylococci	Conjunctival culture or nonculture test for *C. trachomatis*; FA-stained scraping of conjunctival material
Infant pneumonia	Afebrile, staccato cough, diffuse rales, bilateral hyperinflation, interstitial infiltrates	None	Chlamydial culture of sputum, pharynx, eye, rectum; micro-IF antibody to *C. trachomatis*—fourfold change in IgG or IgM antibody titer

[a] A presumptive diagnosis of chlamydial infection is often made in the syndromes listed when gonococci are not found. A positive test for *Neisseria gonorrhoeae* does not exclude the involvement of *C. trachomatis*, which often is present in patients with gonorrhea.

Note: CF, complement-fixing; FA, fluorescent antibody; LGV, lymphogranuloma venereum; micro-IF, microimmunofluorescence; MPC, mucopurulent cervicitis; NAAT, nucleic acid amplification test; NGU, nongonococcal urethritis; PGU, postgonococcal urethritis.

with doxycycline or tetracycline must be given for genital infections. A 2-week course is recommended for complicated chlamydial infections (e.g., PID, epididymitis) and at least a 3-week course of doxycycline (100 mg orally bid) or erythromycin base (500 mg orally qid) for LGV. Failure of treatment of genital infections with a tetracycline usually indicates poor compliance or reinfection rather than the involvement of a drug-resistant strain. To date, clinically significant drug resistance has not been observed in *C. trachomatis* infection.

Therapy for *C. trachomatis* urethritis is more efficacious than therapy for nonchlamydial NGU. *C. trachomatis* is eradicated from the urethra in nearly all cases by treatment with tetracycline hydrochloride (500 mg qid for 7 days) or doxycycline (100 mg by mouth bid for 7 days).

Eradication of *C. trachomatis* from the cervix by tetracycline and doxycycline, with doses and durations similar to those specified above for urethritis, has been demonstrated. Erythromycin base (500 mg qid for 10 to 14 days) is the regimen of choice for pregnant women with *C. trachomatis* infection. Amoxicillin (500 mg tid for 10 days) has also been used successfully in pregnant women. Tetracycline hydrochloride (500 mg qid) or doxycycline (100 mg bid) for 14 days produces clinical and microbiologic cure of epididymitis and PID associated with *C. trachomatis* infection, but in this situation a tetracycline should always be used together with a drug that is highly effective against gonorrhea.

Azithromycin is highly active against *C. trachomatis*, exhibits prolonged bioavailability, is concentrated intracellularly, and has made possible single-dose therapy for chlamydial infection for the first time. In comparative trials, a 1-g single dose of azithromycin has been as effective as 7 days of doxycycline therapy for uncomplicated chlamydial infection. Azithromycin causes fewer adverse gastrointestinal reactions than do older macrolides such as erythromycin. The single-dose regimen of azithromycin has great appeal for the treatment of patients with uncomplicated chlamydial infection (especially those without symptoms and those with a likelihood of poor compliance) and of sexual partners of infected patients. These advantages must be weighed against the considerably greater cost of azithromycin. Whenever possible, the single 1-g dose should be given as directly observed therapy. Although not approved by the U.S. Food and Drug Administration for the treatment of pregnant women, the 1-g single-dose regimen of azithromycin appears to be safe and effective for this purpose.

Of the newer fluoroquinolones, ofloxacin (300 mg by mouth bid for 7 days) has been shown to be as effective as doxycycline for the treatment of chlamydial infection and appears to be safe and well tolerated. It cannot be used in pregnancy.

Treatment of Sex Partners The continued high prevalence of chlamydial infections in most parts of the United States is due primarily to the failure to diagnose—and therefore treat—patients with symptomatic or asymptomatic infection and their sex partners. *C. trachomatis* urethral or cervical infection has been well documented in a high proportion of the sex partners of patients with NGU, epididymitis, Reiter's syndrome, salpingitis, or endocervicitis. If possible, confirmatory laboratory tests for *Chlamydia* should be undertaken in these individuals, but even those without positive tests or evidence of clinical disease who have recently been exposed to proven or possible chlamydial infection (e.g., NGU) should be offered therapy.

Treatment of Neonates and Infants In neonates with conjunctivitis or infants with pneumonia, erythromycin ethylsuccinate or estolate can be given orally in a dose of 50 mg/kg per day, preferably in four divided doses, for 2 weeks. Careful attention must be given to compliance with therapy—a frequent problem. Relapses of eye infection are common following treatment with topical erythromycin or tetracycline ophthalmic ointment and may also occur after oral erythromycin therapy. Thus follow-up cultures should be performed after treatment. Both parents should be examined for *C. trachomatis* infection and, if diagnostic testing is not readily available, should be treated with doxycycline or azithromycin.

Prevention Efforts to develop a vaccine for chlamydial infection have not yet been successful. Early diagnosis and treatment shorten the duration of infectiousness and therefore constitute primary prevention of chlamydial infection. By the early 1990s, one of the 10 regions of the United States (Region X, the Pacific Northwest) had formally undertaken a chlamydial control program involving widespread screening of women attending family planning clinics. Approximately 500,000 tests per year were conducted at 150 such clinics throughout the region in women meeting the criteria for high risk. Within 5 years, the prevalence of chlamydial infection had been reduced by >30% in this population. While most regions of the United States have now initiated similar programs, some family planning and STD clinics still do not offer chlamydial testing. The availability of highly sensitive and specific diagnostic tests that can be done with urine specimens and of single-dose therapy makes it feasible to mount an effective chlamydial control program nationwide, with screening of high-risk persons both in traditional health care settings and in novel community- and school-based settings.

TRACHOMA AND ADULT INCLUSION CONJUNCTIVITIS

Definition Trachoma is a chronic conjunctivitis associated with infection by *C. trachomatis* serovar A, B, Ba, or C. It has been responsible for an estimated 20 million cases of blindness throughout the world and remains an important cause of preventable blindness. Inclusion conjunctivitis is an acute ocular infection caused by sexually transmitted *C. trachomatis* strains (usually serovars D through K) in adults exposed to infected genital secretions and in their newborn offspring.

Epidemiology In trachoma-endemic areas where the classic eye disease is seen, transmission is from eye to eye via hands, flies, towels, and other fomites and usually involves serovar A, B, Ba, or C. The worldwide incidence and severity of trachoma have decreased dramatically during the past 35 years, mainly as a result of improving hygienic and economic conditions. Endemic trachoma is still the major cause of preventable blindness in northern Africa, sub-Saharan Africa, the Middle East, and parts of Asia. Transmission occurs primarily through close personal contact, particularly among young children in rural communities with limited water supplies. In endemic areas, trachoma is associated with repeated exposure and reinfection, but the infection can also become chronic and persistent. Acute relapse of old trachoma occasionally follows treatment with cortisone eye ointment or develops in very old persons who were exposed in their youth.

Clinical Manifestations Both endemic trachoma and adult inclusion conjunctivitis present initially as a conjunctivitis characterized by small lymphoid follicles in the conjunctiva. In regions with hyperendemic classic blinding trachoma, the disease usually starts insidiously before the age of 2 years. Reinfection is common and probably contributes to the pathogenesis of trachoma. Studies using PCR techniques indicate that chlamydial DNA is often present in the ocular secretions of patients with trachoma, even in the absence of positive cultures. Thus persistent infection may be more common than was previously thought.

The cornea becomes involved, with inflammatory leukocytic infiltrations and superficial vascularization (pannus formation). As the inflammation continues, conjunctival scarring eventually distorts the eyelids, causing them to turn inward so that the inturned lashes constantly abrade the eyeball (trichiasis and entropion); eventually the corneal epithelium is abraded and may ulcerate, with subsequent corneal scarring and blindness. Destruction of the conjunctival goblet cells, lacrimal ducts, and lacrimal gland may produce a "dry-eye" syndrome, with resultant corneal opacity due to drying (xerosis) or secondary bacterial corneal ulcers.

Communities with blinding trachoma often experience seasonal epidemics of conjunctivitis due to *H. influenzae* that contribute to the intensity of the inflammatory process. In such areas the active infectious process usually resolves spontaneously in affected persons be-

tween 10 and 15 years of age, but the conjunctival scars continue to shrink, producing trichiasis and entropion and subsequent corneal scarring in adults. In areas with milder and less prevalent disease, the process may be much slower, with active disease continuing into adulthood; blindness is rare in these cases.

Eye infection with genital *C. trachomatis* strains in sexually active young adults presents as the acute onset of unilateral follicular conjunctivitis and preauricular lymphadenopathy similar to that seen in acute adenovirus or herpesvirus conjunctivitis. If untreated, the disease may persist for 6 weeks to 2 years. It is frequently associated with corneal inflammation in the form of discrete opacities ("infiltrates"), punctate epithelial erosions, and minor degrees of superficial corneal vascularization. Very rarely, conjunctival scarring and eyelid distortion occur, particularly in patients treated for many months with topical glucocorticoids. Recurrent eye infections develop most often in patients whose sexual consorts are not treated with antimicrobials.

Diagnosis The clinical diagnosis of classic trachoma can be made if two of the following signs are present: (1) lymphoid follicles on the upper tarsal conjunctiva; (2) typical conjunctival scarring; (3) vascular pannus; or (4) limbal follicles or their sequelae, Herbert's pits.

The clinical diagnosis of endemic trachoma should be confirmed by laboratory tests in children with more marked degrees of inflammation. Intracytoplasmic chlamydial inclusions are found in 10 to 60% of Giemsa-stained conjunctival smears in such populations, but chlamydial PCR or LCR is more sensitive and is often positive when smears or cultures are negative. Follicular conjunctivitis in adult Europeans or Americans living in trachomatous regions is rarely due to trachoma.

℞ TREATMENT

Public health control programs for endemic trachoma have consisted of the mass application of tetracycline or erythromycin ointment to the eyes of all children in affected communities for 21 to 60 days or on an intermittent schedule. These programs also include surgical correction of inturned eyelids by a mobile surgical team that visits each locale. Mass treatment of entire villages with single-dose azithromycin may be an alternative approach.

Adult inclusion conjunctivitis responds well to treatment with full doses of oral tetracycline or erythromycin administered for 3 weeks. Simultaneous treatment of all sexual consorts of the patient is also necessary to prevent ocular reinfection and to avoid genital disease due to chlamydial infection. Topical antibiotic treatment is not required for patients who receive systemic antibiotics.

Prevention Efforts to develop a trachoma vaccine have not yet been successful. General hygienic measures associated with improved living standards are effective in the elimination of endemic trachoma. An adequate water supply for personal cleanliness may be a key factor. In some areas the reduction of numbers of flies in the household is important.

C. PSITTACI INFECTIONS

Definition Psittacosis is primarily an infectious disease of birds and mammals that is caused by *C. psittaci*. Transmission of infection from birds to humans results in a febrile illness characterized by pneumonitis and systemic manifestations. Inapparent infections or mild influenza-like illnesses may also occur. The term *ornithosis* is sometimes applied to infections contracted from birds other than parrots or parakeets, but *psittacosis* is the preferred generic term for all forms of the disease.

Epidemiology Almost any avian species can harbor *C. psittaci*. Psittacine birds (parrots, parakeets, budgerigars) are most commonly infected, but human cases have been traced to contact with pigeons, ducks, turkeys, chickens, and many other birds. Psittacosis may be considered an occupational disease of pet-shop owners, poultry workers, pigeon fanciers, taxidermists, veterinarians, and zoo attendants. During the past 20 years, there has been an increase in incidence, with cases and outbreaks occurring primarily among employees of poultry-processing plants. It is suspected that many cases go undiagnosed and unreported.

The agent is present in nasal secretions, excreta, tissues, and feathers of infected birds. Although the disease can be fatal, infected birds frequently show only minor evidence of illness, such as ruffled feathers, lethargy, and anorexia. Asymptomatic avian carriers are common, and complete recovery may be followed by continued shedding of the organism for many months.

Psittacosis is almost always transmitted to humans by the respiratory route. On rare occasions the disease may be acquired from the bite of a pet bird. Prolonged contact is not essential for transmission of the disease; a few minutes spent in an environment previously occupied by an infected bird has resulted in human infection. In one outbreak, gardening rather than direct exposure to birds was associated with infection. A psittacosis-like agent has been transmitted among hospital personnel, with severe and sometimes fatal infections. There is evidence that these "human" strains are more virulent than avian organisms. There is no record of infection acquired by the ingestion of poultry products.

Pathogenesis The psittacosis agent gains entrance to the body through the upper part of the respiratory tract, spreads via the bloodstream, and eventually localizes in the pulmonary alveoli and in the reticuloendothelial cells of the spleen and liver. Invasion of the lung probably takes place by way of the bloodstream rather than by direct extension from the upper air passages. A lymphocytic inflammatory response occurs on both the interstitial and the respiratory surfaces of the alveoli as well as in the perivascular spaces. The alveolar walls and interstitial tissues of the lung are thickened, edematous, necrotic, and occasionally hemorrhagic. Histologic examination of the affected areas reveals alveolar spaces filled with fluid, erythrocytes, and lymphocytes. The picture is not pathognomonic of psittacosis unless macrophages containing characteristic cytoplasmic inclusion bodies (Levinthal-Coles-Lillie bodies) can be identified. The respiratory epithelium of the bronchi and bronchioles usually remains intact.

Clinical Manifestations The clinical manifestations and course of psittacosis are extremely variable. After an incubation period of 7 to 14 days or longer, the disease may start abruptly with shaking chills and fever, with temperatures ranging as high as 40.5°C (105°F); however, the onset is often gradual, with fever increasing over a 3- to 4-day period. Headache is almost always a prominent symptom; it is usually diffuse and excruciating and is often the patient's chief complaint.

Many patients present with a dry hacking cough that is usually nonproductive, but small amounts of mucoid or bloody sputum may be raised as the disease progresses. Cough may begin early in the course of the disease or as late as 5 days after the onset of fever. Chest pain, pleurisy with effusion, or a friction rub may all occur but are rare. Pericarditis and myocarditis have been reported. Most patients have a normal or slightly increased respiratory rate; marked dyspnea with cyanosis occurs only in severe psittacosis with extensive pulmonary involvement. In psittacosis, as in mycoplasmal pneumonias, the physical signs of pneumonitis tend to be less prominent than symptoms and x-ray findings would suggest. The initial examination may reveal fine sibilant rales, or clinical evidence of pneumonia may be completely lacking. Rales usually become audible and more numerous as the illness progresses. Signs of frank pulmonary consolidation are usually absent. Symptoms of upper respiratory tract infection are not prominent, although mild sore throat, pharyngitis, and cervical adenopathy are often documented; on occasion, the last may be the only manifestation of illness. Epistaxis is encountered early in the course of nearly one-fourth of cases. Photophobia is also a common complaint.

Patients often report generalized myalgia, and spasm and stiffness of the muscles of the back and neck may lead to an erroneous diagnosis of meningitis. Lethargy, mental depression, agitation, insomnia, and disorientation have been prominent features of the illness in some

epidemics but not in others; delirium and stupor develop near the end of the first week in severe cases. Occasional patients are comatose when first seen, and the diagnosis of psittacosis may be elusive in these cases. Gastrointestinal manifestations such as abdominal pain, nausea, vomiting, or diarrhea are noted in some cases; constipation and abdominal distention sometimes occur as late complications. Icterus, the result of severe hepatic involvement, is a rare and ominous finding. A faint macular rash (Horder's spots) resembling the rose spots of typhoid fever has been described.

Patients without cough or other clinical evidence of respiratory involvement present with fever of unknown origin (Chap. 18). The pulse rate is slow in relation to the fever. When splenomegaly is noted in a patient with acute pneumonitis, psittacosis should be considered; the reported incidence of splenomegaly in this disease ranges from 10 to 70%. Nontender hepatic enlargement also occurs, but jaundice is rare. Thrombophlebitis is not unusual during convalescence; indeed, pulmonary infarction is sometimes a late complication and may be fatal.

In untreated cases of psittacosis, sustained or mildly remittent fever persists for 10 days to 3 weeks or occasionally for as long as 3 months. Over this period, the respiratory manifestations gradually abate. Psittacosis contracted from parrots or parakeets is more likely to be a severe, prolonged illness than infection acquired from pigeons or barnyard fowl. Relapses occur but are rare. Occasional patients develop endocarditis, and *C. psittaci* infection should be considered in cases of culture-negative endocarditis. Secondary bacterial infections are uncommon. Immunity to reinfection is probably permanent.

Laboratory Findings The chest x-ray in psittacosis is nonspecific and may show pneumonic lesions that are usually patchy in appearance but can be hazy, diffuse, homogeneous, lobar, atelectatic, wedge-shaped, nodular, or miliary. The white blood cell count is normal or moderately decreased in the acute phase of the disease but may rise in convalescence. The erythrocyte sedimentation rate frequently is not elevated. Transient proteinuria is common. The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal. Despite hepatomegaly, the results of liver function tests are generally normal or only mildly elevated.

The diagnosis can be confirmed only by isolation of the causative microorganism or by serologic studies. The agent is present in the blood during the acute phase of the disease and in the bronchial secretions for weeks or sometimes years after infection, but it is difficult to isolate. Further, the organism is hazardous to work with in the laboratory, and most clinical laboratories do not offer culture for *C. psittaci*. Thus psittacosis is most readily diagnosed by the demonstration of a rising titer of complement fixation antibody in the serum of a patient with a compatible clinical syndrome. Both an acute-phase and a convalescent-phase specimen should always be tested. *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* all share a genus-specific "group" antigen, which is the basis of the complement fixation test. Thus acute infections with *C. trachomatis* or *C. pneumoniae* can also produce titer rises in this test. However, these three species have different major outer-membrane proteins that are the principal antigens in the micro-IF test. If there is doubt as to the interpretation of the complement fixation test, the micro-IF test can be used to differentiate among these antigens. The prompt initiation of treatment with tetracycline has been shown to delay an antibody rise in convalescence for several weeks or months.

Differential Diagnosis A history of exposure to birds may be the only clinical basis for differentiating psittacosis from a variety of infectious and noninfectious febrile disorders. The list of pulmonary diseases that may be confused with psittacosis includes *Mycoplasma* pneumonia, *C. pneumoniae* pneumonia, legionellosis, viral pneumonia, Q fever, coccidioidomycosis, tuberculosis, enterovirus infection, carcinoma of the lung with bronchial obstruction, and common bacterial pneumonias. In the early stages, before pneumonitis appears, psittacosis may be mistaken for influenza, typhoid fever, miliary tuberculosis, or infectious mononucleosis.

Rx TREATMENT

The tetracyclines are consistently effective in the treatment of psittacosis. Defervescence and alleviation of symptoms usually take place within 24 to 48 h after the institution of therapy with 2 g daily in four divided doses. To avoid relapse, treatment should probably be continued for at least 7 to 14 days after defervescence. In severe cases, hospitalization and pulmonary intensive care may be indicated. Sulfonamides are not active against *C. psittaci*. Erythromycin can be used in patients allergic to or intolerant of tetracyclines.

C. PNEUMONIAE INFECTIONS

Definition A third chlamydial species that causes disease in humans, *C. pneumoniae*, has been described in the past quarter century. *C. pneumoniae* can be distinguished from the other two species on the basis of DNA hybridization and elementary body morphology. Although *C. pneumoniae* can be grown in a variety of cell cultures, it is considerably more difficult to culture than other chlamydiae, especially from clinical specimens. HL cells appear to be the most effective cell line for isolation of *C. pneumoniae*.

Epidemiology Knowledge of the epidemiology of *C. pneumoniae* infections has been derived primarily from serologic studies. Infections begin to occur in late childhood, achieve peak incidence in young adults, but continue throughout adult life. Seroprevalence in the many adult populations that have been tested throughout the world exceeds 40%—a figure suggesting that *C. pneumoniae* infections are ubiquitous. Secondary episodes (reinfections) appear to occur commonly in older adults throughout life. *C. pneumoniae* also produces epidemics of pneumonia and respiratory illness, especially in close residential quarters such as military barracks. The incidence of infections outside of epidemics remains poorly defined. Transmission appears to be from person to person, probably primarily in schools and family units.

Pathogenesis Little is known about the pathogenesis of *C. pneumoniae* infection. The infection begins in the upper respiratory tract and in many persons is a long-lived asymptomatic condition of the upper respiratory mucosal surfaces. However, in at least some individuals, the organism is transported to distant sites—perhaps within macrophages—since evidence exists for replication within arteries and synovial membranes of joints. A *C. pneumoniae* outer-membrane protein may induce host immune responses whose cross-reaction with human proteins results in an autoimmune reaction.

Clinical Manifestations The clinical spectrum of *C. pneumoniae* infection includes acute pharyngitis, sinusitis, bronchitis, and pneumonitis, primarily in young adults. The clinical manifestations of primary infection appear to be more severe and prolonged than those of reinfection. The pneumonitis resembles that of *M. pneumoniae* pneumonia in that leukocytosis is frequently lacking and patients often have prominent antecedent upper respiratory tract symptoms, fever, nonproductive cough, a mild to moderate degree of illness, minimal findings on chest auscultation, and small segmental infiltrates on chest x-ray. In elderly patients, pneumonia due to *C. pneumoniae* can be especially severe and may necessitate hospitalization and respiratory support.

Epidemiologic studies have demonstrated an association between serologic evidence of *C. pneumoniae* infection and atherosclerotic disease of the coronary and other arteries. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by electron microscopy, DNA hybridization, and immunocytochemistry. The organism has been recovered in culture from atheromatous plaque—a result indicating the presence of viable replicating bacteria in vessels. Evidence from animal models supports the hypothesis that *C. pneumoniae* infection of the upper respiratory tract is followed by recovery of the organism from atheromatous lesions in the aorta and that the infection accelerates the process of atherosclerosis, especially in hypercholes-

terolemic animals. Antimicrobial treatment of the infected animals reverses the increased risk of atherosclerosis. In humans, two small trials in patients with unstable angina or recent myocardial infarction also suggested that antibiotics reduce subsequent untoward cardiac events. Larger trials have been initiated to determine more definitively whether antibiotics affect the risk of atherosclerosis.

Diagnosis Diagnosis of *C. pneumoniae* infection is currently difficult because cell culture techniques are not available for routine clinical use and nonculture tests using antigen detection methods or DNA probes have not been developed for commercial use. Acute- and convalescent-phase sera can be tested for chlamydial complement fixation antibody to make a retrospective diagnosis. However, this test does not distinguish *C. pneumoniae* infection from infection due to *C. trachomatis* or *C. psittaci*.

Rx TREATMENT

Although controlled treatment trials have not been conducted, *C. pneumoniae* is inhibited in vitro by erythromycin and tetracycline. Recommended therapy consists of 2 g per day of either agent for 10 to 14 days. Other macrolides, such as azithromycin, and some fluoroquinolones, such as levofloxacin, also appear to be effective.

Section 11 Viral Diseases: General Considerations

161 MEDICAL VIROLOGY

Fred Wang, Elliott Kieff

DEFINING A VIRUS

Viruses consist of a nucleic acid surrounded by one or more proteins. Some viruses also have an outer-membrane envelope. Viruses are obligate intracellular parasites: they can replicate only within cells since their nucleic acids do not encode the many enzymes necessary for protein, carbohydrate, or lipid metabolism and for the generation of high-energy phosphates. Typically, viral nucleic acids encode proteins necessary for replicating and packaging the nucleic acids within the biochemical milieu of host cells.

Viruses differ from viroids, prions, and virusoids. *Virusoids* are nucleic acids that depend on helper viruses to package their nucleic acids into virus-like particles. *Viroids* are naked, cyclical, mostly double-stranded, small RNAs. Viroids, which appear to be restricted to plants, spread from cell to cell and are replicated by cellular RNA polymerase II. *Prions* (Chap. 362) are abnormal protein molecules that can spread and change the structure of their normal counterparts (cellular proteins). Prions have been implicated in neurodegenerative conditions such as Creutzfeldt-Jakob disease, Gerstmann-Straüssler disease, kuru, and human bovine spongiform encephalopathy ("mad cow disease").

VIRAL STRUCTURE

Viruses have from a few to several hundred genes. These genes may be in a single-strand or double-strand DNA genome or in a single-strand sense, a single-strand or segmented antisense, or a double-strand segmented RNA genome. Sense-strand RNA genomes can be translated directly into protein. Sense and antisense genomes are also referred to as positive-strand and negative-strand genomes, respectively. The viral nucleic acid is usually associated with one or more virus-encoded nucleoproteins in the core of the viral particle. The viral nucleic acid and nucleoproteins are almost always enclosed in a protein shell called a *capsid*. Because of the limited genetic complexity of viruses, their capsids are usually composed of multimers of identical capsomers. Capsomers are in turn composed of one or a few proteins. Capsids have icosahedral or helical symmetry. Icosahedral structures approximate spheres but have two-, three-, and fivefold axes of symmetry, while helical structures have only a twofold axis of symmetry. The entire structural unit of nucleic acid, nucleoprotein(s), and capsid is called a *nucleocapsid*. Many human viruses are simply composed of a core and a capsid. For these viruses, the outer surface of the capsid mediates contact with uninfected cells. Other viruses are more complex and have an outer lipid-containing envelope derived from virus-modified membranes of the infected cell. The piece of infected-cell membrane that becomes the viral envelope has usually been modified during infection by the insertion of virus-encoded glycoproteins. Virus-encoded glycoproteins usually mediate contact of enveloped viruses with uninfected cells. Matrix or tegument proteins fill the space between the nucleocapsid and the envelope in many enveloped viruses. In general, enveloped viruses are sensitive to lipid solvents and nonionic detergents that can dissolve the envelope, while viruses that consist only of nucleocapsids are somewhat resistant. A schematic diagram for large and complex herpesviruses is shown in Fig. 161-1. Prototypical pathogenic human viruses are listed in Table 161-1. The relative sizes and structures of typical pathogenic human viruses are shown in Fig. 161-2.

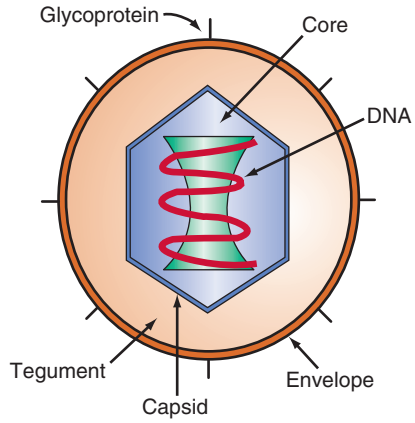

FIGURE 161-1 Schematic diagram of an enveloped herpesvirus with an icosahedral nucleocapsid. The approximate respective dimensions of the nucleocapsid and the enveloped particles are 110 and 180 nm. The capsid is composed of 162 capsomeres: 150 with sixfold and 12 with fivefold axes of symmetry.

TABLE 161-1 *Virus Families Pathogenic for Humans*

Family	Representative Viruses	Type of RNA/DNA	Lipid Envelope
RNA VIRUSES			
Picornaviridae	Poliovirus Coxsackievirus Echovirus Enterovirus Rhinovirus Hepatitis A virus	(+) RNA	No
Caliciviridae	Norwalk agent Hepatitis E virus	(+) RNA	No
Togaviridae	Rubella virus Eastern equine encephalitis virus Western equine encephalitis virus	(+) RNA	Yes
Flaviviridae	Yellow fever virus Dengue virus St. Louis encephalitis virus West Nile virus Hepatitis C virus Hepatitis G virus	(+) RNA	Yes
Coronaviridae	Coronaviruses[a]	(+) RNA	Yes
Rhabdoviridae	Rabies virus Vesicular stomatitis virus	(−) RNA	Yes
Filoviridae	Marburg virus Ebola virus	(−) RNA	Yes
Paramyxoviridae	Parainfluenza virus Respiratory syncytial virus Newcastle disease virus Mumps virus Rubeola (measles) virus	(−) RNA	Yes
Orthomyxoviridae	Influenza A, B, and C viruses	(−) RNA, 8 segments	Yes
Bunyaviridae	Hantavirus California encephalitis virus Sandfly fever virus	(−) RNA, 3 circular segments	Yes
Arenaviridae	Lymphocytic choriomeningitis virus Lassa fever virus South American hemorrhagic fever virus	(−) RNA, 2 circular segments	Yes
Reoviridae	Rotavirus Reovirus Colorado tick fever virus	ds RNA, 10–12 segments	No
Retroviridae	Human T-lymphotropic virus types I and II Human immunodeficiency virus types 1 and 2	(+) RNA, 2 identical segments	Yes
DNA VIRUSES			
Hepadnaviridae	Hepatitis B virus	ds DNA with ss portions	Yes
Parvoviridae	Parvovirus B19	ss DNA	No
Papovaviridae	Human papillomaviruses JC virus BK virus	ds DNA	No
Adenoviridae	Human adenoviruses	ds DNA	No
Herpesviridae	Herpes simplex virus types 1 and 2[b] Varicella-zoster virus[c] Epstein-Barr virus[d] Cytomegalovirus[e] Human herpesvirus 6 Human herpesvirus 7 Kaposi's sarcoma–associated herpesvirus[f]	ds DNA	Yes
Poxviridae	Variola (smallpox) virus Orf virus Molluscum contagiosum virus	ds DNA	Yes

[a] Including the coronavirus causing severe acute respiratory syndrome (SARS).
[b] Also called human herpesvirus (HHV) 1 and 2, respectively; [c] also called HHV-3; [d] also called HHV-4; [e] also called HHV-5; [f] also called HHV-8
Abbreviations: ds, double-strand; ss, single-strand.

TAXONOMY OF PATHOGENIC HUMAN VIRUSES

As is apparent from Table 161-1 and Fig. 161-2, the classification of viruses into orders and families is based on nucleic acid composition, nucleocapsid size and symmetry, and presence or absence of an envelope. Viruses of a single family have similar types of genomes and are often morphologically indistinguishable in electron micrographs. Further subclassification into genus is dependent on similarities in epidemiology and biologic effects and on the degree of colinear nucleic acid sequence homology. Most human viruses have a common name related to their pathologic effects or the circumstances of their discovery. Formal species names have been assigned by the International Committee on Taxonomy of Viruses. The latter designation consists of the name of the host followed by the family or genus of the virus and a number. This dual terminology has created a confusing situation in which viruses are referred to and referenced by either name—e.g., varicella-zoster virus (VZV) or human herpesvirus (HHV) 3.

VIRAL INFECTION IN VITRO

STAGES OF VIRAL INFECTION AT THE CELLULAR LEVEL

■ **Viral Interactions with the Cell Surface and Cell Entry** Viral infection is initiated by adsorption of the virus to the cell surface. Adsorption results from the molecular interaction of viral surface proteins with receptors on the cell's plasma membrane. For example, a poliovirus capsid protein binds to a cell plasma-membrane protein of the immunoglobulin superfamily type. A rhinovirus capsid protein binds to intracellular adhesion molecule 1. An echovirus capsid protein binds to an integrin. The influenza A virus envelope hemagglutinin protein binds to sialic acid. The HIV envelope glycoprotein binds to CD4 and then engages one of several chemokine receptors that function as coreceptors for the virus. Herpes simplex virus (HSV) envelope glycoproteins bind to heparan sulfate on cell surfaces and then engage one of several immunoglobulin superfamily or tumor necrosis factor (TNF) receptors. Epstein-Barr virus (EBV) glycoprotein gp350 binds to the B lymphocyte complement receptor CD21. Adsorption characteristically proceeds almost as well at 4°C as at 37°C. Adsorbed virus can still be neutralized by antibody. Adsorption frequently initiates changes in virion surface proteins that destabilize the viral surface proteins and prepare the way for the next stage of entry into the cell.

After adsorption, viruses penetrate the cell membrane by fusing with the membrane. The fusion reaction results in the virus's partial decomposition. The virus becomes insensitive to neutralizing antibody as it penetrates, becomes uncoated, and enters the cytoplasm. Penetration and uncoating result in viral nucleocapsid or nucleoprotein entry into the cytoplasm. Penetration and uncoating as well as subsequent steps in viral replication depend on the cell's energy metabolism and on biochemical changes in the cell's plasma membrane and cytoskeleton. Therefore, penetration proceeds slowly at temperatures <37°C. Interaction of viral surface proteins with cell receptors can induce receptor aggregation at the site of adsorption. Receptor aggregation can trigger signaling events within the cytoplasm and changes in the plasma membrane. The cell frequently misperceives that the receptor has encountered its "normal ligand." Aggregated receptor may be internalized with the attached virus in an endocytic process. Viral endocytosis may proceed through clathrin-coated pits. Endocy-

tosis is important in the entry of viruses as diverse as picornaviruses, influenza viruses, HIV, adenoviruses, and herpesviruses. In many cases, entry of the virus into the cytoplasm depends on acidification of the viral endosome.

One of the best-studied examples of the effect of low pH on viral penetration is influenza virus. Influenza hemagglutinin mediates adsorption, receptor aggregation, and endocytosis. In low-pH endosomes, changes in the conformation of the hemagglutinin expose amphipathic domains that interact chemically with the cell membrane and initiate fusion of the viral and cellular membranes. The HIV envelope glycoprotein undergoes similar conformational changes after interaction with CD4 and chemokine receptors. For influenza virus, the M2 membrane protein also plays a key role in the uncoating of the viral envelope by providing an ion channel in the envelope. Fusion of viral and cell membranes results in the mixture of viral envelope lipids and proteins with cell membrane lipids and proteins and the penetration of the influenza nucleocapsid into the cytoplasm. With more complex viruses, such as herpesviruses, different glycoproteins interact with specific receptors on different cell types or on different surfaces of polarized epithelial cells. Viral glycoproteins other than the protein that mediates initial adsorption may be critical in mediating envelope fusion with cell membranes. The fusion of viral proteins with cell membranes is a crucial step in viral infection, which involves hydrophobic interactions. Hydrophobic interactions can be susceptible to chemical inhibition or blockade.

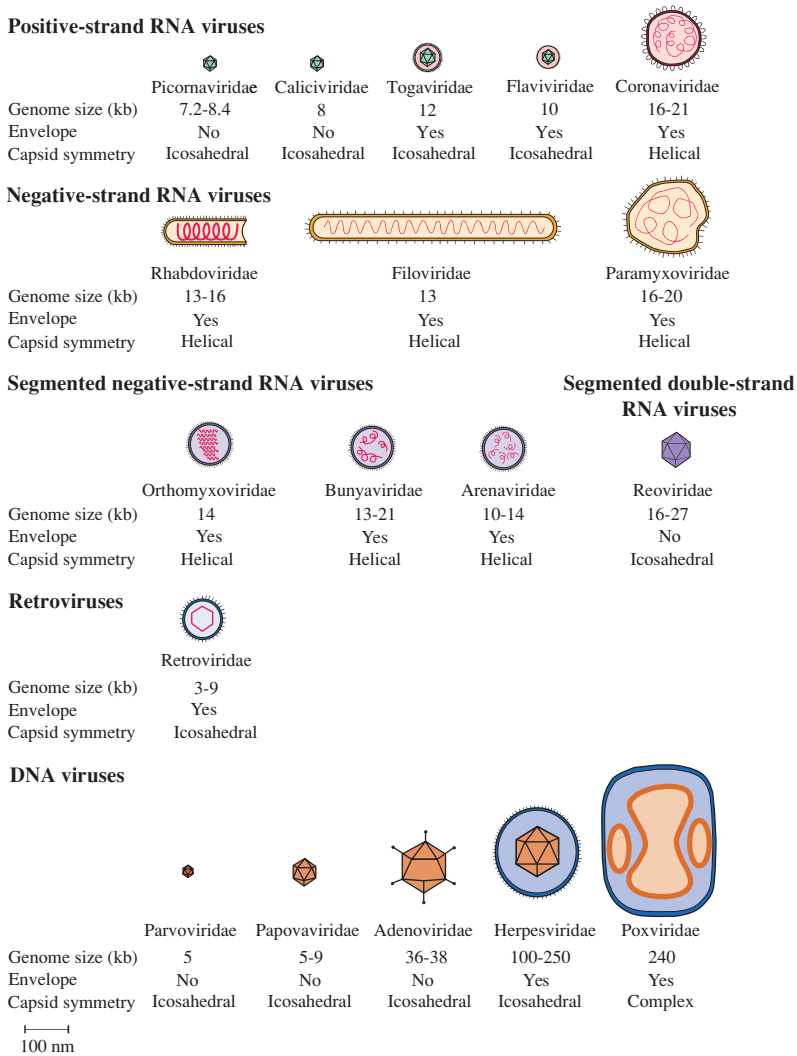

FIGURE 161-2 Schematic diagrams of the major virus families including species that infect humans. The viruses are grouped by genome type and are drawn approximately to scale. Prototype viruses of each family that cause human disease are listed in Table 161-1.

Viral Gene Expression and Replication After uncoating and release of viral nucleoprotein into the cytoplasm, the viral genome is transported to a site for expression and replication. In order to produce infectious progeny, viruses must (1) produce proteins necessary to replicate their nucleic acid, (2) produce structural proteins, and (3) assemble the nucleic acid and proteins into progeny virions. Different viruses use different strategies and gene repertoires to accomplish these goals. DNA viruses, except for poxviruses, replicate their nucleic acid and assemble into nucleocapsid complexes in the cell nucleus. RNA viruses, except for influenza viruses, transcribe and replicate their nucleic acid and assemble entirely in the cytoplasm. Thus, the replication strategies of DNA and RNA viruses are presented separately below. Positive-strand and negative-strand RNA viruses are discussed separately. Medically important viruses of each group are used for illustrative purposes.

POSITIVE-STRAND RNA VIRUSES Medically important positive-strand RNA viruses include picornaviruses, flaviviruses, togaviruses, caliciviruses, and coronaviruses. Genomic RNA from positive-strand RNA viruses is released into the cytoplasm without associated enzymes. Cell ribosomes recognize and associate with an internal ribosome entry sequence in the viral genomic RNA and translate a polyprotein that is a fusion of many or all of the viral proteins. The viral RNA polymerase and other viral proteins are cleaved from the polyprotein by protease components of the polyprotein. Antigenomic RNA is then transcribed from the genomic RNA template. Positive-strand genomes and mRNAs are next transcribed from the antigenomic RNA by the viral RNA polymerase. Positive-strand genomic RNA is encapsidated in the cytoplasm.

NEGATIVE-STRAND RNA VIRUSES Medically important negative-strand RNA viruses include rhabdoviruses, filoviruses, paramyxoviruses, myxoviruses, and bunyaviruses. Negative-strand RNA virus genomes are released into the cytoplasm with an associated RNA polymerase and one or more accessory proteins. Some of these genomes are segmented. Except for influenza viruses, negative-strand RNA viruses replicate entirely in the cytoplasm. The viral RNA polymerase transcribes messenger RNAs (mRNAs) as well as full-length antigenomic RNA, which is the template for replication of genomic RNA. These mRNAs encode for the viral RNA polymerase and accessory factors as well as for viral structural proteins. Influenza virus is an unusual negative-strand RNA virus that transcribes its mRNAs and antigenomic RNAs in the cell's nucleus. The influenza genome RNA snatches cellular mRNA cap sequences to enhance translation of viral mRNAs and uses cell splicing machinery to encode additional viral mRNAs. All negative-strand RNA viruses, including influenza viruses, assemble in the cytoplasm.

DOUBLE-STRAND SEGMENTED RNA VIRUSES These viruses, which are taxonomically grouped in the reovirus family, have 10 to 12 RNA segments that make up their genome. The medically important viruses in this group are rotaviruses and Colorado tick fever virus. Reovirus virions include an RNA polymerase complex. Reoviruses replicate and assemble in the cytoplasm.

DNA VIRUSES Medically important DNA viruses include parvoviruses, papovaviruses (e.g., human papillomaviruses, or HPVs, and polyomaviruses), adenoviruses, herpesviruses, and poxviruses. Other than poxviruses, most DNA viruses must get to the cell's nucleus for DNA transcription by cellular RNA polymerase II. For example, after receptor binding and fusion, herpesvirus nucleocapsids are released into the cytoplasm along with tegument proteins. The complex is then transported along microtubules to nuclear pores, and the DNA is released into the nucleus.

Transcriptional regulation and mRNA processing for nuclear DNA viruses depend on both viral and cellular proteins. For herpesviruses, the viral tegument protein activates transcription of viral immediate-early genes, a class of genes expressed immediately after infection. Transcription of immediate-early genes requires the viral tegument protein and preexisting cellular transcription factors. One of the key preexisting cellular factors for HSV-1 immediate-early gene transcription is docked in the cytoplasm in neurons. Nuclear absence of this critical cell factor important for viral gene transcription may explain why HSV-1 goes into a latent state in neurons and how lytic infection is activated by signaling in a latently infected cell.

DNA virus gene transcription is usually regulated and proceeds in an organized cascade. Transcription and expression of adenovirus and herpesvirus immediate-early genes turn on the promoters for early genes in a sequential fashion, whereas poxvirus virions carry all the factors necessary for early-gene transcription. Smaller DNA viruses are not as dependent on transactivators encoded from the viral genome for early-gene transcription. Most early genes encode proteins that are necessary for viral DNA synthesis and for the turn-on of late-gene transcription. Late genes encode mostly viral structural proteins or viral proteins necessary for the assembly and egress of the virus from the infected cell. Late-gene transcription is continuously dependent on DNA replication. Therefore, inhibitors of DNA replication also stop late-gene transcription.

Each DNA virus family uses unique mechanisms for replicating its DNA. Herpesvirus DNAs are linear in the virion but circularize in the infected cell. In lytic virus infection, circular herpesvirus genomes are replicated into linear concatemers through a "rolling-circle" mechanism. Herpesviruses encode a DNA polymerase and at least six other viral proteins necessary for viral DNA replication; these viruses also encode several enzymes that increase the pool of precursor deoxynucleotide triphosphates. Adenovirus genomes are linear in the virion and are replicated into complementary linear copies by a virus-encoded DNA polymerase and an initiator protein complex. The double-strand circular papovavirus genomes are replicated into progeny circular DNA molecules by cellular DNA replication enzymes. Two viral early proteins contribute to viral DNA replication and to the persistence of papovavirus DNA in latently infected cells. Early papovavirus proteins stimulate cells to remain in cycle, thus facilitating viral DNA replication. Occasionally, HPVs integrate into the host chromosome; overexpression of viral early proteins and excessive stimulation of cellular growth can result. Sometimes the consequence is the development of malignancies such as cervical cancer (see "Persistent Viral Infections and Cancer," below).

Parvoviruses are the smallest DNA viruses: their genomes are half the size of the papovavirus genomes and include only two genes. Parvoviruses have negative single-strand DNA genomes. The replication of autonomous parvoviruses, such as B19, depends on cellular DNA replication and requires the virus-encoded Rep protein. Other parvoviruses, such as adeno-associated virus (AAV), are not autonomous and require helper viruses of the adenovirus or herpesvirus family for their replication. AAV has been touted as a potentially safe human gene therapy vector because its Rep protein causes its integration at a single chromosomal site.

Poxviruses are the largest DNA viruses and are unique among DNA viruses in replicating and assembling in the cytoplasm. Poxviruses encode transcription factors and an RNA polymerase as well as enzymes for RNA capping and polyadenylation and for DNA synthesis. Poxvirus DNA also has a unique structure. The two strands of the double-strand linear DNA are covalently linked at the ends so that the genome is also a covalently closed single-strand circle. In addition, there are inverted repeats at the ends of the DNA. During DNA replication, the genome is cleaved within the terminal inverted repeat, and the inverted repeats self-prime complementary-strand synthesis by the virus-encoded DNA polymerase. Like herpesviruses, poxviruses encode several enzymes that increase deoxynucleotide triphosphate precursor levels and thus facilitate viral DNA synthesis.

VIRUSES WITH BOTH RNA AND DNA GENOMES Retroviruses and hepatitis B virus (HBV) are not purely RNA or DNA viruses. Retroviruses are enveloped RNA viruses with two identical sense-strand genomes and associated reverse transcriptase and integrase enzymes. Retroviruses differ from all other viruses in that they reverse-transcribe themselves into partially duplicated double-strand DNA copies and then routinely integrate into the host genome as part of their replication strategy. Cellular RNA polymerase II and transcription factors regulate transcription from the integrated provirus genome. Some retroviruses also encode for regulators of transcription and RNA processing, such as Tax and Rex in human T-lymphotropic virus (HTLV) types I and II and Tat and Rev in HIV-1 and HIV-2. HIV genomes also encode for the additional accessory proteins Vpr, Vpu, and Vif, which are important for efficient infection and immune escape. Full-length proviral transcripts are made from a promoter in the viral terminal repeat and serve as both genomic RNAs that will be packaged in the nucleocapsids and mRNAs that encode for the viral Gag protein, polymerase/integrase protein, and envelope glycoprotein. The Gag protein includes a protease that cleaves it into several components, including a viral matrix protein that coats the viral RNA. Viral RNA polymerase/integrase, matrix protein, and cellular tRNA are key components of the viral nucleocapsid. The HIV Gag protease has been an important target for inhibition of HIV replication. Remnants and even complete copies of simple retroviral DNA in the human genome indicate that there may be replication-competent simple human retroviruses. However, replication has not been documented or associated with any disease. Integrated retroviral DNAs are also present in other animal species, such as pigs. These porcine retroviruses are a potential cause for concern in xenotransplantation because retroviral replication could cause disease in humans. Since the retroviral DNA is integrated into the porcine genome, special pathogen-free breeding practices cannot cleanse the donor herd of retroviral infection.

HBV is unique because virion DNA expression in infected cells results in the packaging of reverse transcriptase and genomic RNA in the virion. The genomic RNA is then copied into an incomplete double-strand circular DNA genome before the virion matures and is released from the infected cell. On entry of HBV into the cytoplasm of an infected cell, the virion reverse transcriptase/DNA polymerase completes DNA synthesis, and the covalently closed circular genome resides in the nucleus. Viral mRNAs are transcribed from the closed circular viral episome by cellular RNA polymerase II. A capped and polyadenylated, full-genome-length, terminally redundant transcript is packaged into virus core particles in the cytoplasm of infected cells. This RNA associates with the viral reverse transcriptase. The reverse transcriptase converts the full-length, terminally redundant, core-particle, encapsidated RNA genome into partially double-strand DNA. HBV is believed to mature by budding through the cell's plasma membrane, which has been modified by the insertion of viral surface antigen protein.

Viral Assembly and Egress For most viruses, nucleic acid and structural protein synthesis are accompanied by the assembly of protein and nucleic acid complexes. The assembly and egress of mature infectious virus mark the end of the eclipse phase of infection, during which infectious virus cannot be recovered from the infected cell. Nucleic acids from RNA viruses and poxviruses assemble into nucleocapsids in the cytoplasm. For all DNA viruses except poxviruses, viral DNA assembles into nucleocapsids in the nucleus. In general, the capsid proteins of viruses with icosahedral nucleocapsids can self-assemble into densely packed and highly ordered capsid structures. Herpesviruses require an assemblin protein as a scaffold for capsid assembly. Viral nucleic acid then spools into the assembled capsid. For herpesviruses, a full unit of the viral DNA genome is packaged into the capsid, and a capsid-associated nuclease cleaves the viral DNA at both ends. In the case of viruses with helical nucleocapsids, the protein

component appears to assemble around the nucleic acid, which contributes to capsid organization.

Viruses must egress from the infected cell and not bind back to the outer surface of the plasma membrane. In many cases, enveloped viruses simply egress and acquire their envelope by budding through the cell's plasma membrane. Excess viral membrane glycoproteins are synthesized to saturate cell receptors and facilitate virus separation from the infected cell. Some viruses encode membrane proteins with enzymatic activity for receptor destruction. Influenza virus, for example, encodes a glycoprotein with neuraminidase activity, which destroys sialic acid on the infected cell's plasma membrane. Herpesvirus nucleocapsids acquire their initial envelope by assembling in the nucleus and then budding through the nuclear membrane into the endoplasmic reticular space. The enveloped herpesvirus is then released from the cell either by maturation in cytoplasmic vesicles, which fuse with the plasma membrane and release the virus by exocytosis, or by "de-envelopment" into the cytoplasm and "re-envelopment" at the plasma membrane. In most instances, nonenveloped viruses appear to depend on the death and dissolution of the infected cell for their release.

FIDELITY OF VIRAL REPLICATION Cells grow by doubling their genome and dividing, whereas viruses typically make large quantities of viral nucleic acid and structural proteins, and thousands of progeny may be produced from a single virus-infected cell. Many particles partially assemble and never mature into virions. Many mature-appearing virions are imperfect and have only incomplete or nonfunctional genomes. Despite the inefficiency of assembly, a typical virus-infected cell releases 10 to 1000 infectious progeny. Some of these progeny may contain genomes that differ from those of the virus that infected the cell. Smaller, "defective" virus genomes have been noted with the replication of many RNA and DNA viruses. Virions with defective genomes can be produced in large numbers through packaging of incompletely synthesized nucleic acid. Adenovirus packaging is notoriously inefficient, and a high particle-to-infectious virus ratio may limit the amount of recombinant adenovirus that can be administered for gene therapy. Mutant viral genomes are also produced and can be of medical significance. In general, viral nucleic acid replication is more error-prone than cellular nucleic acid replication. RNA polymerases and reverse transcriptases are significantly more error-prone than DNA polymerases. Mutant viruses can be virulent and may preferentially cause disease through evasion of the host immune response or through resistance to antiviral drugs. Persistent hepatitis C virus (HCV) infection appears to be due to genome mutation and persistent immune escape. Viral nucleic acids can also mutate by recombination or reassortment between two related viruses in a single cell. While this occurrence is unusual under most circumstances of natural infection, the changes can be substantial and can significantly alter virulence or epidemiology. Reassortment of an avian or mammalian influenza A hemagglutinin gene into a human influenza background is believed to play a role in the emergence of new epidemic influenza A strains.

VIRAL GENES NOT REQUIRED FOR VIRAL REPLICATION Viruses frequently have genes encoding proteins that are not directly involved in replication or packaging of the viral nucleic acid, in virion assembly, or in regulation of the transcription of viral genes involved in those processes. Most of these proteins fall into five classes: (1) proteins that directly or indirectly alter cell growth; (2) proteins that inhibit cellular RNA or protein synthesis so that viral mRNA can be efficiently transcribed or translated; (3) proteins that promote cell survival or inhibit apoptosis so that progeny virus can mature and escape from the infected cell; (4) proteins that inhibit the host interferon response; and (5) proteins that downregulate host inflammatory or immune responses so that virus infection can proceed in an infected person to the maximum extent consistent with the survival of the virus and its efficient transmission to a new host. More complex viruses of the poxvirus or herpesvirus family encode many proteins that serve these functions. Some of these viral proteins have motifs similar to those of cell proteins, while others are quite novel. Virology has increasingly focused on these more sophisticated strategies evolved by viruses to permit the establishment of long-term infection in humans and other animals. These strategies often provide unique insights into the control of cell growth, cell survival, macromolecular synthesis, proteolytic processing, immune or inflammatory suppression, immune resistance, cytokine mimicry, or cytokine blockade.

HOST RANGE The concept of host range was originally based on the cell types in which a virus replicated in tissue culture. For the most part, the host range is limited by specific cell-surface proteins required for viral adsorption or penetration. Another common basis for host-range limitation is transcription from viral promoters. Most DNA viruses depend not only on cellular RNA polymerase II and the basal components of the cellular transcription complex but also on activated components and transcriptional accessory factors, both of which differ among differentiated tissues, among cells at various phases of the cell cycle, and between resting and cycling cells.

The concept of host range for virus infection in humans includes these factors and others since (1) most viruses infect more than one cell type in vivo, and (2) the viral life cycle and extent of viral replication can be affected by the differentiation and activation state of a given cell type. This point is particularly relevant for human papovavirus, herpesvirus, and lentivirus infections, in which vigorous replication during initial infection may be followed by quiescent or latent infection—a situation that allows the virus to persist.

VIRAL CYTOPATHIC EFFECTS AND INHIBITORS OF APOPTOSIS The replication of almost all viruses has adverse effects on the infected cell, inhibiting cellular synthesis of DNA, RNA, or proteins. This inhibitory effect probably stems from the viruses' need to prevent or limit nonspecific, innate host resistance factors, including interferon (IFN). Most commonly, viruses specifically inhibit host protein synthesis by attacking a component of the translational initiation complex—frequently, a component that is not required for efficient translation of viral RNAs. Poliovirus protease 2A, for example, cleaves a cellular component of the complex that ordinarily facilitates translation of cell mRNAs by interacting with their cap structure. Poliovirus RNA is efficiently translated without a cap since it has an internal ribosome entry sequence. Influenza virus inhibits the processing of mRNA by snatching cap structures from nascent cell RNAs and using them as primers in the synthesis of viral mRNA. HSV has a virion tegument protein that inhibits cellular mRNA translation.

Apoptosis is the expected consequence of virus-induced inhibition of cellular macromolecular synthesis and viral nucleic acid replication. While the induction of apoptosis may be important for the release of some viruses (particularly nonenveloped viruses), many viruses have acquired genes or parts of genes that enable them to forestall infected-cell apoptosis. This delay may be advantageous in allowing the completion of viral replication. Adenoviruses and herpesviruses encode analogues of the cellular Bc12 protein, which blocks mitochondrial enhancement of proapoptotic stimuli. Poxviruses and some herpesviruses encode caspase inhibitors. Many viruses, including HPVs and adenoviruses, encode proteins that inhibit p53 or its downstream proapoptotic effects.

VIRAL INFECTION IN VIVO

The capsid and envelope of a virus protect its genome and permit its efficient transmission from cell to cell and to prospective hosts. Most common viral infections are spread by aerosolized particles, by ingestion of contaminated water or food, or by direct contact. In all these situations, infection begins on an epithelial or mucosal surface and spreads along it or from it to deeper tissues. Infection may then spread through the body via the bloodstream, lymphatics, or neural circuits. Parenteral inoculation also serves to transmit some viral infections among humans or from animals, including insects, to humans.

PRIMARY INFECTION The first (primary) episode of viral infection usually lasts from several days to several weeks. During this period, the concentration of virus at sites of infection rises and then falls, usually to unmeasurable levels. The rate at which the intensity of viral infection rises and falls at a given site depends on the accessibility of that organ or tissue to both the virus and systemic immune effectors, the intrinsic ability of the virus to replicate at that site, and endogenous nonspecific and specific resistance. Typically, infections with enterovirus, mumps virus, measles virus, rubella virus, rotavirus, influenza virus, AAV, adenovirus, HSV, and VZV are cleared from almost all sites within 3 to 4 weeks. Some of these viruses are especially proficient in altering or evading the innate and acquired immune responses; thus primary infection with AAV, EBV, or cytomegalovirus (CMV) can last for several months. Characteristically extending beyond several weeks are primary infections due to HBV, HCV, hepatitis D virus (HDV), HIV, HPV, and molluscum contagiosum virus. For some of these viruses (e.g., HPV, HBV, HCV, HDV, and molluscum contagiosum virus), the primary phase of infection is almost indistinguishable from the persistent phase.

Disease manifestations usually arise as a consequence of viral replication and the resultant inflammatory response at a specific site but do not necessarily correlate with levels of replication at that site. For example, the clinical manifestations of limited infection with poliovirus, enterovirus, rabies virus, measles virus, mumps virus, or HSV in neural cells are severe relative to the level of viral replication at mucosal surfaces. Similarly, significant morbidity may accompany in utero fetal infection with rubella virus or CMV.

Primary infections are cleared by nonspecific innate and specific adaptive immune responses. Thereafter, an immunocompetent host is usually immune to the disease manifestations of reinfection by the same virus. Immunity frequently does not prevent transient surface colonization on reexposure, persistent colonization, or even limited deeper infection.

PERSISTENT AND LATENT INFECTIONS Relatively few viruses cause persistent or latent infections. HBV, HCV, rabies virus, measles virus, HIV, HTLV, HPV, HHV, and some poxviruses are notable exceptions. The mechanisms for persistent infection vary widely. In persistent HCV infection and to a lesser extent in HIV infection, the high mutation rates in viral genome replication or reverse transcription significantly facilitate persistent infection, continuously yielding mutant viruses that have lost antigenic determinants to which the host has developed effective immune responses. HIV is also directly immunosuppressive, depleting CD4+ T lymphocytes and compromising CD8+ cytotoxic T-cell immune responsiveness. Moreover, HIV encodes a Nef protein that downmodulates major histocompatibility complex (MHC) class I expression, rendering HIV-infected cells partially resistant to immune CD8+ cytolysis. The high mutation rate and the magnitude of the viral load conspire to promote persistent infection with drug-resistant HIV mutants.

In contrast, DNA viruses have much lower mutation rates. Their persistence is due to their ability to establish latent infection and to reactivate from latency. In this instance, latency is defined as a state of infection in which the virus is not replicating. The complete viral genome is present and may be replicated by cellular DNA polymerase in conjunction with the cell genome replication. Viral genes associated with lytic infection are not expressed and infectious virus is not made. HPVs establish latent infection in basal epithelial cells, which replicate. Some of the progeny cells provide a stable supply of latently infected basal cells, while others go on to squamous differentiation and, in the process, become permissive for lytic viral infection. For herpesviruses, latent infection is established in nonreplicating neural cells (HSV and VZV) or in replicating cells of hematopoietic lineages [EBV and probably CMV, HHV-6, HHV-7, and Kaposi's sarcoma–associated herpesvirus (KSHV, also known as HHV-8)]. Reactivation from neural latency appears to be an intermittent process provoked by external stimuli, whereas reactivation from hematopoietic precursors appears to be a more continuous process. In their latent stage, HPV and herpesvirus genomes are largely hidden from the normal immune response. It is still not fully understood how partially latent and reactivated HPV and herpesvirus infections escape immediate and effective immune responses in highly immune hosts. HPV, HSV, and VZV may be somewhat protected because of their replication in middle and upper layers of the squamous epithelium—sites not routinely visited by immune and inflammatory cells. HSV and CMV are also known to encode proteins that downregulate MHC class I expression and antigenic peptide presentation on infected cells, thereby enabling these cells to escape CD8+ T lymphocyte cytotoxicity. Latent infection and intermittent reactivation perpetuate herpesvirus infections in human populations by allowing the viruses to persist in immune hosts and to be transmitted to the next generation of naive hosts.

Like other poxviruses, molluscum contagiosum virus cannot establish latent infection but rather causes persistent infection in hypertrophic lesions that last for months or years. This virus encodes a chemokine homologue that probably blocks inflammatory responses and an MHC class I analogue that may block cytotoxic T lymphocyte attack.

PERSISTENT VIRAL INFECTIONS AND CANCER Persistent viral infection is estimated to be the root cause of as many as 20% of human malignancies. For the most part, cancer is an accidental and highly unusual or long-term effect of infection with oncogenic human viruses. In these malignancies, viral infection is a critical and ultimately determinative early step, putting infected cells into cycle and enhancing their survival. An unusual virus-infected cell undergoes the subsequent genetic changes that permit the enhanced autonomous growth and survival characteristic of a highly malignant cell.

Most hepatocellular carcinoma is now believed to be caused by chronic inflammatory, immune, and regenerative responses to HBV or HCV infection. Epidemiologic data firmly link HBV and HCV infection to hepatocellular carcinoma. Studies in murine experimental models indicate that chronic liver injury and repair induced by virus-encoded proteins can result in hepatocellular cancer. In rare instances, HBV DNA integrates into cellular DNA—an event that probably contributes to the development of some tumors.

Almost all cervical carcinoma is caused by long-term persistent replication of "high-risk" genital HPV strains. Persistent, high-level HPV replication can result in the integration of a small fragment of the HPV genome encoding the HPV E6 and E7 proteins into chromosomal DNA. Integrations that result in overexpression of HPV type 16 or 18 E6 and E7 cause the loss of at least two major tumor-suppressive functions mediated by pRb and p53. This loss in turn causes profound changes in cell growth and survival. Nevertheless, subsequent chromosomal changes must occur over ensuing cycles of cell growth if a sufficiently malignant cell is to invade the surrounding tissues.

Similarly, long-term EBV infection and expression of the EBV oncogene LMP1 in latently infected epithelial cells appear to be critical early steps in the evolution of anaplastic nasopharyngeal carcinoma, a common malignancy in Chinese and North African populations. High-level LMP1 expression is also a hallmark of many cases of Hodgkin's disease. Among younger age groups, >50% of Hodgkin's disease tumors are clonally derived from an EBV-infected cell. The HTLV-I Tax and Rex proteins appear to be critical to the initiation of cutaneous adult T cell lymphoma/leukemias that may occur long after primary HTLV-I infection.

The EBV-related herpesvirus KSHV was identified in a search for the postulated sexually transmitted etiologic agent of Kaposi's sarcoma in HIV-infected individuals. Molecular data confirm the presence of KSHV DNA in all Kaposi's tumors, including those associated with HIV infection, transplantation, and familial transmission. KSHV infection is also etiologically implicated in pleural-effusion lymphomas and multicentric Castleman's disease, which are more common among HIV-infected than among HIV-uninfected people.

Evidence supporting a causal role of viral infection in these malignancies includes epidemiologic data, the presence of viral DNA in all tumor cells, the ability of the viruses to transform human cells in culture, the results of in vitro assays for transforming effects of specific viral genes on cell growth, and pathologic data indicating the expression of transforming viral genes in premalignant or malignant cells in vivo.

EBV is a unique example of a human virus that relies on the normal immune response to contain the potentially unrestrained growth of infected cells. In the initial stages of normal primary EBV infection, EBV "latently" infects B lymphocytes and expresses at least eight viral proteins that play no role in viral replication but cause the expansion of latently infected cells. These infected cells can grow indefinitely. Most of the viral proteins that cause this proliferative state are highly antigenic. These virus-infected cells, which can transiently constitute 10% of the circulating B lymphocyte population, are met with an overwhelming helper and cytotoxic T cell response during primary infection. The number of virus-infected cells then falls rapidly, and the one EBV-infected cell in a million that persists does not express most of the viral proteins that cause B cell proliferation. These persisting cells are the site of normal latent infection. Breakthrough growth of the EBV-infected B lymphocytes almost never occurs in immunocompetent hosts. However, in immunosuppressed AIDS patients or organ transplant recipients, EBV-infected B lymphocytes expressing the full set of growth-transforming genes may grow and cause self-sustained and potentially fatal lymphoproliferative disease. Clinical investigation has resulted in novel strategies for treating these virus-induced malignancies with EBV-specific T cells or with antibody to B cells.

RESISTANCE TO VIRAL INFECTIONS Resistance to viral infection is initially provided by factors that are not virus-specific. Physical protection is afforded by the cornified layers of the skin and by mucous secretions that continuously sweep over mucosal surfaces. Once the first cell is infected, viral infection induces IFNs, which are important local resistance factors. Viral infection may also trigger the release of other cytokines from infected cells; these cytokines may be chemotactic to inflammatory and immune cells. Viral protein epitopes expressed on the cell surface in the context of MHC class I and II HLA proteins attract T cells with appropriate receptors. Cytokines, inflammatory agents, and antigens released by virus-induced cell death further attract inflammatory cells, dendritic cells, granulocytes, natural killer (NK) cells, and B lymphocytes to the sites of initial infection and to draining lymph nodes. IFNs and NK cells are particularly important in containing viral infection for the first several days. Granulocytes and macrophages are also important in the phagocytosis and degradation of viruses, especially after an initial antibody response.

Some 7 to 10 days after infection, virus-specific antibody responses, virus-specific HLA class II–restricted CD4+ helper T lymphocyte responses, and virus-specific HLA class I–restricted CD8+ cytotoxic T lymphocyte responses emerge. These responses, whose magnitude typically increases over the second and third weeks of infection, are important in rapid recovery. Between the second and third weeks of infection, the antibody type usually changes from IgM to IgG; IgA antibody can then be detected at initially infected mucosal surfaces. Antibody may directly neutralize virus by binding to its surface and preventing its adsorption or penetration. Complement usually enhances antibody-mediated virus neutralization. Antibody and complement can also lyse virus-infected cells that express viral proteins on their surface. A cell infected with an enveloped virus usually expresses viral envelope glycoprotein components on its surface and is subject to destruction by antibodies and complement.

Antibody and CD4+/CD8+ T lymphocyte responses tend to persist for several months after primary infection. Antibody-producing lymphocytes persist in small numbers as memory cells and begin to proliferate rapidly in response to a second infection, providing an early barrier to reinfection with the same virus. Immunologic memory for T cell responses appears to be shorter-lived. Redevelopment of T cell immunity may take longer than secondary antibody responses, particularly when many years have elapsed between primary infection and reexposure. Persistent or latent and reactivating viral infections can result in sustained high-level T cell responses.

Some viruses have genes that alter innate and acquired host defenses. Adenoviruses encode small RNAs that inhibit IFN shutoff of infected-cell protein synthesis. Adenovirus E1A inhibits IFN-mediated changes in cell gene transcription. Adenovirus E3 proteins prevent TNF-induced cytolysis and block HLA class I antigen synthesis by the infected cell. HSV ICP47 and CMV US11 block class I antigen presentation. EBV encodes an interleukin (IL) 10 homologue that inhibits NK and T cell responses. Vaccinia virus B15R is an IL-1 receptor decoy. Vaccinia virus B8R is a soluble TNF receptor that blocks the effects of TNF. Vaccinia virus CrmA inhibits the ability of CD8+ cytotoxic cells to kill virus-infected cells. Some poxviruses and herpesviruses encode blockers of chemokines and thereby inhibit cellular inflammatory responses. The adoption of these strategies by viruses highlights the importance of these host resistance factors in containing viral infection as well as the importance of redundancy in host resistance. The ultimate success of a virus requires a live host to help it disseminate infection.

Much has been written about the role of specific aspects of the host immune response in containment of specific virus infections. Certainly, T lymphocyte disorders and T cell immunosuppression for the purpose of transplantation or as a consequence of HIV infection are associated with severe primary and reactivated herpesvirus infections. Antibody responses are important in most viral infections and may be fully protective in many RNA virus infections. Specific immunoglobulin therapy can ameliorate even herpesvirus infections. T lymphocyte responses may play a significant role in resistance to RNA virus infections. Cytotoxic T cells specific for influenza virus nucleoprotein may provide a measure of protection that is independent of viral changes in hemagglutinin.

Host resistance does not come without a price. Clearly, aspects of the host response contribute to the pathophysiologic manifestations and symptoms of viral infection. Inflammation at sites of viral infection can increase rates of local cell death. Moreover, immune responses to viral infection could, in principle, result in immune attack of related epitopes on normal cells, with consequent autoimmunity. While such effects have been demonstrated in experimental models, their role in the autoimmune manifestations of primary or recurrent human viral infections is uncertain.

INTERFERONS All human cells can synthesize IFN-α or -β in response to viral infection. These IFN responses are usually induced by the presence of double-strand viral RNA, which can be made by both RNA and DNA viruses. IFN-γ is not highly related to IFN-α or -β and is produced mainly by NK cells and by immune T lymphocytes responding to IL-12. IFN-α and -β bind to the IFN-α receptor, while IFN-γ binds to a different but related receptor. Both receptors signal through receptor-associated JAK kinases and other cytoplasmic proteins, including "STAT" proteins. STAT proteins are tyrosine-phosphorylated by JAK kinases, translocate to the nucleus, and transactivate promoters for specific cell genes. Three types of antiviral effects are induced by IFN at the transcriptional level. The first effect is attributable to the induction of 2′-5′ oligo(A) synthetases, which require double-strand RNA for their activation. Activated synthetase polymerizes oligo(A) and thereby activates RNAse L, which in turn degrades single-strand RNA. The second effect takes place through the induction of PKR, a serine and threonine kinase that is also activated by double-strand RNA. PKR phosphorylates and negatively regulates the translational initiation factor eIF2-α, shutting down protein synthesis in the infected cell. A third effect is initiated through the induction of Mx proteins, a family of GTPases that is particularly important in inhibiting the replication of influenza virus and vesicular stomatitis virus (VSV). None of these IFN effects is directed specifically against the virus; infected-cell RNA and protein synthesis are globally inhibited by inhibiting

cell protein synthesis. IFN probably contributes to the death of the infected cell.

DIAGNOSTIC VIROLOGY A wide variety of methods are now used to diagnose viral infection. Serology and viral isolation in tissue culture remain important standards. Acute- and convalescent-phase sera with rising titers of antibody to virus-specific antigens and a shift from IgM to IgG antibodies are generally accepted as diagnostic of acute viral infection. Traditionally, virus-specific antibodies have been detected by hemadsorption, hemagglutination, or indirect immunofluorescence. Immunofluorescence assays use fixed virus-infected cells as a target for serum antibodies. Hemadsorption and hemagglutination assays measure the ability of serum antibodies to inhibit RNA virus–induced erythrocyte adsorption or agglutination. Serologic diagnosis is based on a greater-than-fourfold rise in IgG antibody concentration when acute- and convalescent-phase serum samples are analyzed at the same time. A simultaneous fall in IgM antibody confirms recent primary viral infection. Immunofluorescence, hemadsorption, and hemagglutination assays for antiviral antibodies are labor-intensive and are being replaced by enzyme-linked immunosorbent assays (ELISAs). ELISAs generally use specific viral proteins purified from virus-infected cells or produced by recombinant DNA technology. These viral antigens are attached to a solid phase, where they can be incubated with serum, washed to eliminate nonspecific antibodies, and reacted with an enzyme-linked reagent to detect human IgG or IgM antibody specifically adhering to the viral antigen on the solid phase. The amount of antibody can then be quantitated by the intensity of a color reaction mediated by the linked enzyme. ELISAs can be sensitive and automated. Western blots can confirm the presence of antibody to multiple specific viral proteins simultaneously. The proteins are separated by size and transferred to an inert membrane, where they are incubated with serum antibodies. Western blots have an internal specificity control, since the level of reactivity for viral proteins can be compared with that for cellular proteins in the same sample. Western blots require individual evaluation and are inherently difficult to quantitate or automate.

Virus isolation in tissue culture is dependent on the infection of susceptible cells and amplification by viral replication in infected cells. Virus growing in tissue culture cells can frequently be identified by its effect under light microscopy. For example, HSV produces a typical cytopathic effect in rabbit kidney cells within 3 days. Other viral cytopathic effects may not be as diagnostically useful. Identification may require confirmation by staining with virus-specific monoclonal antibodies. Viruses growing in tissue culture can also be identified by hemadsorption or by interference; e.g., rubella virus–infected cells resist lysis by echovirus. Electron microscopy can identify the type of virus in tissue or tissue culture (assuming that the specimen has altered cell morphology, as observed by ordinary light microscopy).

The efficiency and speed of virus identification can be enhanced by combining short-term culture with immune detection. In assays with "shell vials" of tissue culture cells growing on a coverslip, viral infection can be detected by staining of the culture with a monoclonal antibody to a specific viral protein expressed early in viral replication. Thus, virus-infected cells can be detected within hours or days of inoculation; several rounds of infection would be required to produce a visible cytopathic effect.

Virus isolation in tissue culture depends on the collection of specimens from the appropriate site and the rapid transport of these specimens in the appropriate medium to the virology laboratory. Rapid transport maintains viral viability and limits bacterial and fungal overgrowth. Lipid-enveloped viruses are generally much more sensitive to freezing and thawing than nonenveloped viruses. The most appropriate site for culture depends on the pathogenesis of the virus in question. Nasopharyngeal, tracheal, or endobronchial aspirates are most appropriate for the identification of respiratory viruses. Sputum cultures generally are less appropriate because bacterial contamination and viscosity threaten tissue-culture cell viability. Aspirates of vesicular fluid are useful for isolation of HSV and VZV. Nasopharyngeal aspirates and stool specimens may be useful when the patient has fever and a rash and an enteroviral infection is suspected. Adenoviruses can be cultured from the urine of patients with hemorrhagic cystitis. CMV can frequently be isolated from cultures of urine or buffy coat. Biopsy material can be effectively cultured when viruses infect major organs, as in HSV encephalitis or adenovirus pneumonia. Virus isolation does not necessarily establish disease causality. Viruses can persistently or intermittently colonize normal human mucosal surfaces. Saliva can be positive for herpesviruses, and normal urine samples can be positive for CMV. Isolations from blood, cerebrospinal fluid (CSF), or tissue are more often diagnostic of significant viral infection.

Another method aimed at increasing the speed of viral diagnosis is direct testing for antigen or cytopathic effects. Virus-infected cells from the patient may be detected by staining with virus-specific monoclonal antibodies; e.g., epithelial cells obtained by nasopharyngeal aspiration can be stained with a variety of monoclonal antibodies to respiratory viruses. The Tzanck preparation can be used to detect multinucleated giant cells in HSV- or VZV-induced lesions. Tzanck preparations can be enhanced by the use of HSV- or VZV-specific monoclonal antibodies. Monoclonal antibodies can also be used in histopathology to identify virus-infected cells.

Advances in nucleic acid technology are revolutionizing diagnostic virology. The speed and sensitivity of tests that directly amplify minute amounts of viral nucleic acids present in specimens mean that detection no longer depends on viable virus and its replication. For example, amplification and detection of HSV nucleic acids in the CSF of patients with HSV encephalitis is a more sensitive detection method than culture of virus from CSF. The extreme sensitivity of these tests can be a problem, since subclinical infection or contamination can lead to false-positive results. Detection of viral nucleic acids does not necessarily indicate virus-induced disease. Herpesviruses can cause persistent asymptomatic infection.

Measurement of the amount of viral RNA or DNA in peripheral blood is becoming an important means for determining which patients are at increased risk for virus-induced disease and for evaluating clinical responses to antiviral chemotherapy. Nucleic acid technologies for RNA quantification are routinely used in AIDS patients to evaluate responses to antiviral agents and to detect resistance to or noncompliance with therapy. Viral-load measurements may also be useful for evaluating the treatment of patients with HBV and HCV infections. Direct staining with CMV-specific monoclonal antibodies to quantitate virus-infected cells in the peripheral blood or CMV antigenemia can be useful in identifying which immunosuppressed patients may be at risk for CMV-induced disease. CMV assays employing nucleic acid technologies for the same purpose have been approved for clinical use.

DRUG TREATMENT FOR VIRAL INFECTIONS Specific antiviral drugs have revolutionized treatment of herpes and HIV infections. Effective drugs have also been developed for influenza A and moderately effective drugs for respiratory syncytial virus and HCV infections. However, the emergence of drug-resistant strains in treated patients can limit therapeutic efficacy. The increased number of antiviral agents with different viral targets has made the identification of drug-resistant viruses clinically relevant, especially for HIV infection. Drug resistance in herpesviruses is a more unusual problem. HIV genotyping is a new method for the rapid identification of drug-resistant viruses. Resistance to reverse transcriptase or protease inhibitors has been associated with specific mutations in the reverse transcriptase or protease genes. Identification of these mutations by polymerase chain reaction amplification and nucleic acid sequencing can be clinically useful for determining which antiviral agents may still be effective. HCV genotyping may also identify patients who can benefit from combination chemotherapy.

IMMUNIZATION FOR THE PREVENTION OF VIRAL INFECTIONS Viral vaccines are among the outstanding accomplishments of medical science. Smallpox has been eradicated except as a potential weapon of biolog-

ical warfare or bioterrorism (Chap. 205). Poliovirus eradication may soon follow. Measles can be contained or eliminated. Excess mortality due to influenza virus epidemics can be prevented, and the threat of influenza pandemics has decreased. Widespread HBV vaccination has dramatically lessened the frequency of acute and chronic hepatitis and is expected to lead to a dramatic decrease in the incidence of hepatocellular carcinoma. Rubella, mumps, and chickenpox viruses have been attenuated in culture, formulated into vaccines, and widely administered in the developed world. Purified proteins, genetically engineered live virus vaccines, and recombinant DNA-based strategies will make it possible to prevent severe infections with many other viruses. The evolutionary divergence of HIV and HCV and repeated high-level exposure in some populations complicate the development of effective vaccines for these agents. Immunogens that incorporate multiple B and T cell epitopes are likely to be useful for low-level exposures. Concerns about the use of smallpox and other viruses as weapons may create a need to maintain immunity to agents that are not naturally encountered.

VIRUSES AS NOVEL THERAPEUTIC AGENTS Viruses are being experimentally developed for the delivery of biotherapeutics or novel vaccines. Foreign genes can be inserted into viral nucleic acids, and the recombinant virus vectors can be used to infect the patient or the patient's cells ex vivo. Retroviruses integrate into the cell genome and have been used to functionally replace the abnormal gene in T cells of patients with severe combined immunodeficiency (SCID), thereby restoring immune function. Recombinant adenovirus, AAV, and retroviruses are being explored for use in diseases due to single-gene defects, such as cystic fibrosis and hemophilia. Recombinant poxviruses and adenoviruses are also being used experimentally as vaccine vectors. Viral vectors are being experimentally tested for expressing cytokines to improve immunity against tumor cells or for expressing proteins that can increase the sensitivity of tumor cells to chemotherapy.

For improved safety, nonreplicating viruses are frequently employed in clinical trial settings. Potential adverse events associated with virus-mediated gene transfer include the induction of inflammatory and antiviral immune responses. Adenoviruses contain many immunogenic proteins, and, since wild-type adenovirus infection is prevalent, immunity to adenovirus infection may reduce the efficacy of or enhance inflammatory responses to adenovirus gene therapy. Integration, another complication of virus-mediated gene therapy, is useful for permanent gene therapy, but integrations can induce disease by enhancing or interrupting the expression of important cellular genes.

162 ANTIVIRAL CHEMOTHERAPY, EXCLUDING ANTIRETROVIRAL DRUGS

Lindsey R. Baden, Raphael Dolin

The development of drugs for antiviral chemotherapy and chemoprophylaxis is a relatively recent but extremely active area of biomedical research. Significant progress has been made in recent years on new drugs for several viral infections. Despite these advances, the field of antiviral therapy—both the number of antiviral drugs and our understanding of their optimal use—continues to lag behind the field of antibacterial drug treatment, in which more than 60 years of experience have now been accumulated.

The development of antiviral drugs poses several challenges. Viruses replicate intracellularly and often employ host cell enzymes, macromolecules, and organelles for synthesis of viral particles. Therefore, useful antiviral compounds must discriminate between host and viral functions with a high degree of specificity; agents without such selectivity are likely to be too toxic for clinical use.

The development of laboratory assays to assist clinicians in the appropriate use of antiviral drugs is also in its infancy. Phenotypic and genotypic assays for resistance to antiviral drugs are becoming more widely available, and correlations of laboratory results with clinical outcomes in various settings are beginning to be defined. Of particular note has been the development of highly sensitive and specific methods to measure the concentration of virus in blood (*virus load*), which permit direct assessment of the antiviral effect of a given drug regimen in the host. Virus load measurements have been useful in recognizing the risk of disease progression in patients with certain viral infections and in identifying patients in whom antiviral chemotherapy might be of greatest benefit. Like any in vitro laboratory test, these tests yield results that are highly dependent on (and likely to vary with) the laboratory techniques employed.

Information regarding the pharmacokinetics of some antiviral drugs, particularly in diverse clinical settings, is limited. Assays to measure the concentrations of these drugs, especially of their active moieties within cells, are primarily research procedures and are not widely available to clinicians. Thus, there are relatively few guidelines for adjusting dosages of antiviral agents to maximize antiviral activity and minimize toxicity. Clinical use of antiviral drugs must therefore be accompanied by particular vigilance with regard to unanticipated adverse effects.

Like that of other infections, the course of viral infections is profoundly affected by an interplay of the pathogen with a complex set of host defenses. The presence or absence of preexisting immunity and the ability to mount humoral and/or cell-mediated immune responses are important determinants of the outcome of viral infections. The state of the host's defenses needs to be considered when antiviral agents are utilized or evaluated.

As with any therapy, the optimal use of antiviral compounds requires a specific and timely diagnosis. For some viral infections, such as herpes zoster, the clinical manifestations are so characteristic that a diagnosis can be made on clinical grounds alone. For other viral infections, such as influenza A, epidemiologic information (e.g., the documentation of a community-wide outbreak) can be used to make a presumptive diagnosis with a high degree of accuracy. However, for most other viral infections, including herpes simplex encephalitis, cytomegaloviral infections other than retinitis, and enteroviral infections, diagnosis on clinical grounds alone cannot be accomplished with certainty. For such infections, rapid viral diagnostic techniques are of great importance. Considerable progress has been made in recent years in the development of such tests, which are now widely available for a number of viral infections.

Despite these complexities, the efficacy of a number of antiviral compounds has been clearly established in rigorously conducted and controlled studies. As summarized in Table 162-1, this chapter reviews the antiviral drugs that are currently approved or are likely to be considered for approval in the near future for use against viral infections other than those caused by HIV. Antiretroviral drugs are reviewed in Chap. 173.

TABLE 162-1 *Antiviral Chemotherapy and Chemoprophylaxis*

Infection	Drug	Route	Dosage	Comment
Influenza A and B				
Prophylaxis	Amantadine[a] or rimantadine[a]	Oral	Adults: 200 mg/d for period at risk Children ≤9 yrs: 5 mg/kg per day (maximum, 150 mg/d)	Therapy must continue for duration of outbreak. Dosage should be reduced for amantadine and rimantadine in patients with renal failure and the elderly. Drugs can be administered along with inactivated vaccine.
	Oseltamivir	Oral	Children ≥13 yrs: 75 mg/d	
Treatment	Zanamivir	Inhaled orally	10 mg q12h for 5 days in adults and children ≥7 yrs old	Zanamivir and oseltamivir reduce symptoms by 1.0–1.5 and 1.3 days, respectively, in uncomplicated disease when started within 2 days of onset and are under study in complicated disease. Zanamivir may exacerbate bronchospasm in patients with asthma. Oseltamivir's side effects of nausea and vomiting can be reduced in frequency by administration with food. Both amantadine and rimantadine are effective in uncomplicated influenza. None of the above drugs has been thoroughly studied in complicated cases (e.g., pneumonia).
	Oseltamivir	Oral	75 mg bid for 5 days in adults and 2 mg/kg for 5 days up to a total of 45 mg bid in children 1–12 yrs old	
	Amantadine[a]	Oral	100–200 mg/d in adults and dosage for children as above for 5–7 days	
	Rimantadine[a]	Oral	100–200 mg/d for 5–7 days in adults	
RSV infection	Ribavirin	Small-particle aerosol	Administered continuously from reservoir containing 20 mg/mL for 3–6 days	Ribavirin is used for treatment of infants and young children hospitalized with RSV pneumonia and bronchiolitis.
CMV retinitis in immunocompromised host (AIDS)	Ganciclovir	IV	5 mg/kg bid for 14–21 days; then 5 mg/kg per day as maintenance dose	Ganciclovir, valganciclovir, foscarnet, and cidofovir are approved for treatment of CMV retinitis in patients with AIDS. They are also used for colitis, pneumonia, or ''wasting'' syndromes associated with CMV and for prevention of CMV disease in transplant recipients. Valganciclovir has largely supplanted oral ganciclovir and is frequently used in place of IV ganciclovir. Foscarnet is not myelosuppressive and is active against acyclovir- and ganciclovir-resistant herpesviruses.
		Oral	1 g tid as maintenance dose	
	Valganciclovir	Oral	900 mg bid for 21 days; then 900 mg/d as maintenance dose	
	Foscarnet	IV	60 mg/kg q8h for 14–21 days; then 90–120 mg/kg per day as maintenance dose	
	Cidofovir	IV	5 mg/kg once weekly for 2 weeks, then once every other week; given with probenecid	
Varicella				
Immunocompetent host	Acyclovir	Oral	20 mg/kg (maximum, 800 mg) 4 or 5 times daily for 5 days	Treatment confers modest clinical benefit when administered within 24 h of rash onset.
Immunocompromised host	Acyclovir	IV	500 mg/m^2 q8h for 7 days	A change to oral valacyclovir can be considered once fever has subsided and there is no evidence of visceral involvement.
Herpes simplex encephalitis	Acyclovir	IV	10 mg/kg q8h for 14–21 days	Results are optimal when therapy is initiated early. Some authorities recommend treatment for 21 days to prevent relapses.
Neonatal herpes simplex	Acyclovir	IV	10 mg/kg q8h for 14–21 days	Serious morbidity is frequent despite therapy. Prolonged oral administration of acyclovir after initial IV therapy has been suggested because of long-term sequelae associated with cutaneous recurrences of HSV infection.
Genital herpes simplex				
Primary (treatment)	Acyclovir	IV	5 mg/kg q8h for 5–10 days	The IV route is preferred for infections severe enough to warrant hospitalization or with neurologic complications.
		Oral	200 mg 5 times daily for 10 days	The oral route is preferred for patients whose condition does not warrant hospitalization. Adequate hydration must be maintained.
		Topical	5% ointment; 4–6 applications daily for 7–10 days	Topical use—largely supplemented by oral therapy—may obviate systemic administration to pregnant women. Systemic symptoms and untreated areas are not affected.
	Valacyclovir	Oral	1 g bid for 10 days	Valacyclovir appears to be as effective as acyclovir but can be administered less frequently.
	Famciclovir	Oral	250 mg bid for 5–10 days[b]	Famciclovir appears to be similar in effectiveness to acyclovir.
Recurrent (treatment)	Acyclovir	Oral	200 mg 5 times daily for 5 days	Clinical effect is modest and is enhanced if therapy is initiated early. Treatment does not affect recurrence rates.
	Famciclovir	Oral	125 mg bid for 5 days	
	Valacyclovir	Oral	500 mg bid for 3 days	

(continued)

TABLE 162-1 — *(Continued)*

Infection	Drug	Route	Dosage	Comment
Recurrent (suppression)	Acyclovir	Oral	400 mg bid for ≥12 months	Suppressive therapy is recommended only for patients with at least 6–10 recurrences per year. ''Breakthrough'' occasionally takes place, and asymptomatic shedding of virus occurs. The need for suppressive therapy should be reevaluated after 1 year. Suppression with valacyclovir reduces transmission of genital HSV among discordant couples.
	Valacyclovir	Oral	500–1000 mg daily	
	Famciclovir	Oral	125–250 mg bid	
Mucocutaneous herpes simplex in immunocompromised host				
Treatment	Acyclovir	IV	250 mg/m^2 q8h for 7 days	Choice of IV or oral route depends on severity of infection and patient's ability to take oral medication. Oral or IV treatment has supplanted topical therapy except for small, easily accessible lesions. Foscarnet is used for acyclovir-resistant viruses.
		Oral	400 mg 5 times daily for 10 days	
		Topical	5% ointment; 4–6 applications daily for 7 days or until healed	
	Valacyclovir	Oral	1 g tid for 7 days[b]	
	Famciclovir	Oral	500 mg bid for 4 days[c]	
Prevention of recurrences during intense immunosuppression	Acyclovir	Oral	200 mg qid	Treatment is administered during periods when intense immunosuppression is expected—e.g., during antitumor chemotherapy or after transplantation—and is usually continued for 2–3 months.
		IV	5 mg/kg q12h	
	Valacyclovir	Oral	1 g tid[b]	
	Famciclovir	Oral	500 mg bid[b]	
Herpes simplex orolabialis (recurrent)	Penciclovir	Topical	1.0% cream applied q2h during waking hours for 4 days	Treatment shortens healing time and symptoms by 0.5–1.0 day (compared with placebo).
	Valacyclovir	Oral	2 g q12h for 1 day	Therapy begun at earliest symptom reduces disease duration by 1 day.
	Famciclovir[b]	Oral	500 mg tid for 5 days	Therapy begun 48 h after UV light exposure decreases time to healing by 2 days.
	Docosonal[d]	Topical	10% cream 5 times daily until healed	Application at initial symptoms reduces healing time by 1 day.
Herpes simplex keratitis	Trifluridine	Topical	1 drop of 1% ophthalmic solution q2h while awake (maximum, 9 drops daily)	Therapy should be undertaken in consultation with an ophthalmologist.
	Vidarabine	Topical	0.5-in. ribbon of 3% ophthalmic ointment 5 times daily	
Herpes zoster				
Immunocompromised host	Acyclovir	IV	500 mg/m^2 q8h for 7 days	Effectiveness in localized zoster is most marked when treatment is given early. Foscarnet may be used for VZV infections that are resistant to acyclovir.
		Oral	800 mg 5 times daily for 7 days	
	Famciclovir	Oral	500 mg tid for 10 days[b]	
Immunocompetent host	Valacyclovir	Oral	1 g tid for 7 days	Valacyclovir may be more effective than acyclovir for pain relief; otherwise, it has a similar effect on cutaneous lesions and should be given within 72 h of rash onset.
	Famciclovir	Oral	500 mg q8h for 7 days	The duration of postherpetic neuralgia is shorter than with placebo. Famciclovir showed overall efficacy similar to that of acyclovir in a comparative trial. It should be given ≤72 h of rash onset.
	Acyclovir	Oral	800 mg 5 times daily for 7–10 days	Acyclovir causes faster resolution of skin lesions than placebo and provides some relief of acute symptoms if given within 72 h of rash onset. Combined with tapering doses of prednisone, acyclovir improves quality-of-life outcomes.
Herpes zoster ophthalmicus	Acyclovir	Oral	600 mg 5 times daily for 10 days	Treatment reduces ocular complications, including ocular keratitis and uveitis.
Condyloma acuminatum	IFN-α2b	Intralesional	1 million units per wart (maximum of 5) thrice weekly for 3 weeks)	Intralesional treatment frequently results in regression of warts, but lesions often recur. Parenteral administration may be useful if lesions are numerous.
	IFN-αn3	Intralesional	250,000 units per wart (maximum of 10) twice weekly for up to 8 weeks	
Chronic hepatitis B	IFN-α2b	SC or IM	5 million units daily or 10 million units thrice weekly for 16 weeks	Hepatitis B e antigen and DNA are eliminated in 33–37% of cases. Histopathologic improvement is also seen.
	Lamivudine	Oral	100 mg/d for 12–18 months; 150 mg bid as part of therapy	Efficacy similar to that of IFN but better tolerated. Resistance develops in 24% of recipients.

(continued)

TABLE 162-1 *Antiviral Chemotherapy and Chemoprophylaxis—(Continued)*

Infection	Drug	Route	Dosage	Comment
	Adefovir dipivoxil	Oral	10 mg/d for 12 months	A return of ALT levels to normal is documented in 48–72% of recipients, improved liver histopathology in 53–64%. Adefovir is effective in lamivudine-resistant hepatitis B. Renal functions should be monitored.
Chronic hepatitis C	IFN-α2a or -α2b	SC or IM	3 million units thrice weekly for 12–18 months	A return of ALT levels to normal is documented in 54% of recipients but is sustained in only 28%. Improvement in liver histopathology is seen.
	IFN-α2b/ribavirin	SC or IM (IFN)/ oral (ribavirin)	3 million units thrice weekly (IFN)/1000–1200 mg daily (ribavirin) for 6–12 months	Combination therapy results in sustained responses in up to 40–50% of all recipients.
	Pegylated-IFN-α2b	SC	1 μg/kg weekly for 12–24 months	The slower clearance of pegylated IFNs than of standard IFNs permits once-weekly administration. The pegylated formulations appear to be superior to standard IFNs in tolerability and efficacy, both as monotherapy and in combination with ribavirin. Sustained virologic responses were seen in 42–46% of genotype 1 patients and in 76–82% of those with genotype 2 or 3.
	Pegylated-IFN-α2a	SC	180 μg/kg weekly for 12–24 months	
	Pegylated-IFN-α2b/ribavirin	SC (IFN)/oral (ribavirin)	1 μg/kg weekly (IFN)/800–1200 mg daily (ribavirin) for 12–24 months	
	Pegylated-IFN-α2a/ribavirin	SC (IFN)/oral (ribavirin)	180 μg/kg weekly (IFN)/1000–1200 mg daily (ribavirin) for 12–24 months	
	IFN alfacon	SC	9–15 μg thrice weekly for 6–12 months	Doses of 9 and 15 μg are equivalent to IFN-α2a or -α2b doses of 3 million units and 5 million units, respectively.
Chronic hepatitis D	IFN-α2a or -α2b	SC or IM	9 million units thrice weekly for 12 months	The overall efficacy and the optimal regimen and duration of therapy have not been established. Responses are usually not sustained when therapy is stopped.

[a] Influenza A only.
[b] Not approved for this indication by the U.S. Food and Drug Administration (FDA).
[c] Approved by the FDA for treatment of HIV-infected individuals.
[d] Active ingredient: behenyl alcohol. Available without prescription.
Abbreviations: ALT, alanine aminotransferase; CMV, cytomegalovirus; HSV, herpes simplex virus; IFN, interferon; RSV, respiratory syncytial virus; UV, ultraviolet.

ANTIVIRAL DRUGS ACTIVE AGAINST RESPIRATORY INFECTIONS

AMANTADINE AND RIMANTADINE Amantadine and the closely related compound rimantadine are primary symmetric amines. Their antiviral activity is limited to influenza A viruses, whose replication they inhibit by interfering with the uncoating of virus after infection of the cell. This interference is attributable to the agents' interaction with the influenza A M2 matrix protein, during which the ion channel function of M2 is inhibited. A substitution of a single amino acid at critical sites in the M2 protein can result in a virus that is resistant to amantadine and rimantadine.

Amantadine and rimantadine have been demonstrated to be effective in the prophylaxis of influenza A in large-scale studies of young adults and in less extensive studies of children and elderly subjects. In such studies, efficacy rates of 55 to 80% in the prevention of influenza-like illness were noted, and even higher rates were reported when virus-specific attack rates were calculated. Amantadine and rimantadine have also been demonstrated to be effective in the treatment of influenza A infection in studies involving predominantly young adults and, to a lesser extent, children. Administration of these compounds within 24 to 72 h after the onset of illness has resulted in a reduction of the duration of signs and symptoms by ~50% from that in a placebo-treated group. The effect on signs and symptoms of illness is superior to that of commonly used antipyretic-analgesics. Only anecdotal reports are available concerning the efficacy of amantadine or rimantadine in the prevention or treatment of complications of influenza (e.g., pneumonia).

Amantadine and rimantadine are available only in oral formulations and are ordinarily administered to adults once or twice daily, with a dosage of 100 to 200 mg/d. Despite their structural similarities, the pharmacokinetics of the two compounds are different. Amantadine is not metabolized and is excreted almost entirely by the kidney, with a half-life of 12 to 17 h and peak plasma concentrations of 0.4 μg/mL. Rimantadine is extensively metabolized to hydroxylated derivatives and has a half-life of 30 h. Only 30 to 40% of an orally administered dose is recovered in the urine. The peak plasma levels of rimantadine are approximately half those of amantadine, but rimantadine is concentrated in respiratory secretions to a greater extent than amantadine. For prophylaxis, the compounds must be administered daily for the period at risk (i.e., the peak duration of the outbreak). For therapy, amantadine or rimantadine is generally administered for 5 to 7 days.

Although these compounds are generally well tolerated, 5 to 10% of amantadine recipients experience mild central nervous system side effects consisting primarily of dizziness, anxiety, insomnia, and difficulty in concentrating. These effects are rapidly reversible upon cessation of the drug's administration. At a dose of 200 mg/d, rimantadine is better tolerated than amantadine; in a large-scale study of young adults, adverse effects were no more frequent among rimantadine recipients than among placebo recipients. Seizures and worsening of congestive heart failure have also been reported in patients treated with amantadine, although a causal relationship has not been established. The dosage of amantadine should be reduced to $\leq$100 mg/d in patients with renal insufficiency [i.e., a creatinine clearance (Cr_{Cl}) rate of $<$50 mL/min] and in the elderly. A rimantadine dose of 100 mg/d should be used for patients with a Cr_{Cl} of $<$10 mL/min and in the elderly. Resistance to amantadine and rimantadine can be induced readily in vitro. The emergence and probable transmission of virus resistant to these drugs have also been noted in vivo after their use for the treatment of children or adults. In the United States, both amantadine and rimantadine are approved for the prophylaxis and treatment of influenza A in adults and for prophylaxis in children. Amantadine is also approved for the treatment of influenza A in children.

ZANAMIVIR AND OSELTAMIVIR Influenza viral neuraminidase is essential for release of the virus from infected cells and for its subsequent spread throughout the respiratory tract of the infected host. The enzyme cleaves terminal sialic acid residues, thus destroying the cellular receptors recognized by the viral hemagglutinin. Zanamivir, a sialic acid

analogue, is a highly active and specific inhibitor of the neuraminidases of influenza A and B viruses. Oseltamivir is another neuraminidase inhibitor that is a transition-state analogue of sialic acid cleavage. Its antineuraminidase activity is similar to that of zanamivir. Oseltamivir phosphate is an ethyl ester prodrug that is converted to oseltamivir carboxylate by esterases in the liver. Both zanamivir and oseltamivir act through competitive and reversible inhibition of the active site of influenza A and B viral neuraminidases and have relatively little effect on mammalian cell enzymes. As would be expected from their different mechanisms of action, zanamivir and oseltamivir are active against strains of influenza A virus that are resistant to amantadine and rimantadine.

Zanamivir has low oral bioavailability. It is inhaled orally via a hand-held inhaler. By this route, ~15% of the dose is deposited in the lower respiratory tract, and low plasma levels of the drug are detected. Orally administered oseltamivir has a bioavailability of >60% and a plasma half-life of 7 to 9 h. The drug is excreted unmetabolized, primarily by the kidneys.

Intranasal inhaled zanamivir is generally well tolerated, although exacerbations of asthma may occur. The toxicities most frequently encountered with orally administered oseltamivir are nausea, gastrointestinal discomfort, and (less commonly) vomiting. Gastrointestinal discomfort is usually transient and is less likely if the drug is administered with food. No serious clinical or laboratory toxicities have yet been reported with zanamivir or oseltamivir in clinical trials.

Inhaled zanamivir and orally administered oseltamivir have been effective in the treatment of naturally occurring influenza A or B in otherwise-healthy adults. In placebo-controlled studies, illness has been shortened by 1 to 1.5 days of therapy with either of these drugs when administered within 2 days of onset. Once-daily inhaled zanamivir or orally administered oseltamivir provides effective prophylaxis against laboratory-documented influenza A–associated illness. The emergence of viruses resistant to zanamivir or oseltamivir appears to be infrequent in clinical studies carried out thus far.

Zanamivir and oseltamivir have been approved by the U.S. Food and Drug Administration (FDA) for treatment of influenza in adults and in children (those ≥7 years old for zanamivir and those ≥1 year old for oseltamivir) who have been symptomatic for ≤2 days. Oseltamivir is approved for prophylaxis of influenza in individuals ≥13 years of age.

RIBAVIRIN Ribavirin is a synthetic nucleoside analogue that inhibits a wide range of RNA and DNA viruses. The mechanism of action of ribavirin is not completely defined and may be different for different groups of viruses. Ribavirin-5′-monophosphate blocks the conversion of inosine-5′-monophosphate to xanthosine-5′-monophosphate and interferes with the synthesis of guanine nucleotides as well as that of both RNA and DNA. Ribavirin-5′-monophosphate also inhibits capping of virus-specific messenger RNA in certain viral systems. In studies demonstrating the effectiveness of ribavirin in the treatment of respiratory syncytial virus (RSV) infection in infants, the compound has been administered as a small-particle aerosol. It has been used less extensively to treat parainfluenza virus infections in children and influenza A and B virus infections in young adults. In infants with RSV infection who were given ribavirin by continuous aerosol for 3 to 6 days, illness and lower respiratory tract signs resolved more rapidly and arterial oxygen desaturation was less pronounced than in placebo-treated groups. Ribavirin has also had a beneficial clinical effect in infants with RSV infection who require mechanical ventilation. Aerosolized ribavirin has been administered to older children and adults with severe RSV and parainfluenza virus infections (including immunosuppressed patients), but the benefit of this treatment, if any, is unclear. In RSV infections in immunosuppressed patients, ribavirin is often given in combination with immunoglobulins.

Orally administered ribavirin has not been effective in the treatment of influenza A virus infections. Intravenous or oral ribavirin has reduced mortality among patients with Lassa fever; it has been particularly effective in this regard when given within the first 6 days of illness. Intravenous ribavirin has been reported to be of clinical benefit in the treatment of hemorrhagic fever with renal syndrome caused by Hantaan virus and as therapy for Argentinian hemorrhagic fever. Moreover, oral ribavirin has been recommended for the treatment and prophylaxis of Congo-Crimean hemorrhagic fever. Intravenous ribavirin is being evaluated as therapy for the hemorrhagic fever with pulmonary syndrome caused by newly described hantaviruses in the United States. Oral administration of ribavirin reduces serum aminotransferase levels in patients with chronic hepatitis C virus (HCV) infection; since it appears not to reduce serum HCV RNA levels, the mechanism of this effect is unclear. The drug provides an added beneficial effect when given by mouth in doses of 800 to 1200 mg/d in combination with interferon (IFN) α2b or α2a (see below), and the ribavirin/IFN combination has been approved for the treatment of patients with chronic HCV infection.

Large doses of ribavirin administered orally (800 to 1000 mg/d) have been associated with reversible hematopoietic toxicity. This effect has not been observed with aerosolized ribavirin, apparently because little drug is absorbed systemically. Aerosolized administration of ribavirin is generally well tolerated but occasionally is associated with bronchospasm, rash, or conjunctival irritation. Aerosolized ribavirin has been licensed for treatment of RSV infection in infants and should be administered under close supervision—particularly in the setting of mechanical ventilation, where precipitation of the drug is possible. Health care workers exposed to the drug have experienced minor toxicity, including eye and respiratory tract irritation. Because ribavirin is mutagenic, teratogenic, and embryotoxic, its use is generally contraindicated in pregnancy. Its administration as an aerosol poses a risk to pregnant health care workers.

PLECONARIL Pleconaril is an investigational drug active in vitro against picornavirus replication, including >90% of the most commonly isolated enterovirus types and 80% of rhinovirus serotypes. Its mechanism of action is through binding to a specific hydrophobic pocket in the viral capsid, which prevents attachment and/or uncoating of the virus. Pleconaril is poorly water soluble and is formulated as an oral suspension. It is generally well tolerated; the most frequently reported adverse effects are headache, nausea, diarrhea, and gastrointestinal discomfort, which have occurred at rates similar to those among placebo recipients. Pleconaril treatment of adults with enterovirus meningitis decreased the overall duration of illness and headache and reduced the use of analgesics from that by placebo recipients. A large-scale clinical study demonstrated a mild therapeutic effect on rhinovirus-associated colds, but pleconaril was deemed to be of insufficient benefit to gain approval by an FDA advisory panel.

ANTIVIRAL DRUGS ACTIVE AGAINST HERPESVIRUS INFECTIONS

ACYCLOVIR AND VALACYCLOVIR Acyclovir is a highly potent and selective inhibitor of the replication of certain herpesviruses, including herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). It is relatively ineffective in the treatment of human cytomegalovirus (CMV) infections; however, some studies have indicated its effectiveness in the prevention of CMV-associated disease in immunosuppressed patients. Valacyclovir, the L-valyl ester of acyclovir, is converted almost entirely to acyclovir by intestinal and hepatic hydrolysis after oral administration. Valacyclovir has pharmacokinetic advantages over orally administered acyclovir: it exhibits significantly greater oral bioavailability, results in higher blood levels, and can be given less frequently than acyclovir (two or three rather than five times daily).

The high degree of selectivity of acyclovir is related to its mechanism of action, which requires that the compound first be phosphorylated to acyclovir monophosphate. This phosphorylation occurs efficiently in herpesvirus-infected cells by means of a virus-coded

thymidine kinase. In uninfected mammalian cells, little phosphorylation of acyclovir occurs, and the drug is therefore concentrated in herpesvirus-infected cells. Acyclovir monophosphate is subsequently converted by host cell kinases to a triphosphate that is a potent inhibitor of virus-induced DNA polymerase but has relatively little effect on host cell DNA polymerase. Acyclovir triphosphate can also be incorporated into viral DNA, with early chain termination.

Acyclovir is available in intravenous, oral, and topical forms, while valacyclovir is available in an oral formulation. Intravenous acyclovir is markedly effective in the treatment of mucocutaneous HSV infections in immunocompromised hosts, reducing time to healing, duration of pain, and virus shedding. When administered prophylactically during periods of intense immunosuppression (e.g., related to chemotherapy for leukemia or transplantation) and before the development of lesions, intravenous acyclovir reduces the frequency of HSV-associated disease. After prophylaxis is discontinued, HSV lesions recur. Intravenous acyclovir is also effective in the treatment of HSV encephalitis; two comparative trials have indicated that acyclovir is more effective than vidarabine for this indication (see below). Because VZV is generally less sensitive to acyclovir than is HSV, higher doses of acyclovir must be used to treat VZV infections. In immunocompromised patients with herpes zoster, intravenous acyclovir reduces the frequency of cutaneous dissemination and visceral complications and—in one comparative trial—was more effective than vidarabine. Acyclovir, administered orally at doses of 800 mg five times a day, had a modest beneficial effect on localized herpes zoster lesions in both immunocompromised and immunocompetent patients. Combination of acyclovir with a tapering regimen of prednisone appeared to be more effective than acyclovir alone in terms of quality-of-life outcomes in immunocompetent herpes zoster patients over age 50. A comparative study of acyclovir (800 mg orally five times daily) and valacyclovir (1 g orally tid) in immunocompetent patients with herpes zoster indicated that the latter drug may be more effective in eliciting the resolution of zoster-associated pain. Orally administered acyclovir (600 mg five times a day) reduced complications of herpes zoster ophthalmicus in a placebo-controlled trial.

In normal children with chickenpox, acyclovir—administered at 20 mg/kg (up to a maximum of 800) four times daily, within 24 h of the onset of rash—resulted in a modest overall clinical benefit. Intravenous acyclovir has also been reported to be effective in the treatment of immunocompromised children with chickenpox.

The most widespread use of acyclovir is in the treatment of genital HSV infections. Intravenous or oral acyclovir or oral valacyclovir has shortened the duration of symptoms, reduced virus shedding, and accelerated healing when employed for the treatment of primary genital HSV infections. Oral acyclovir and valacyclovir have also had a modest effect in treatment of recurrent genital HSV infections. However, the failure of treatment of either primary or recurrent disease to reduce the frequency of subsequent recurrences has indicated that acyclovir is ineffective in eliminating latent infection. Chronic oral administration of acyclovir 1 to 6 years or longer or of valacyclovir for 1 year or longer has reduced the frequency of recurrences markedly during therapy; once the drug is discontinued, lesions recur. In one study, suppressive therapy with valacyclovir (500 mg once daily for 8 months) reduced transmission of HSV-2 genital infections among discordant couples by 50%. A modest effect on herpes labialis (i.e., a reduction of disease duration by 1 day) was seen when valacyclovir was administered upon detection of the first symptom of a lesion at a dose of 2 g every 12 h for 1 day. In AIDS patients, chronic or intermittent administration of acyclovir has been associated with the development of HSV and VZV strains resistant to the action of the drug and with clinical failures. The most common mechanism of resistance is a deficiency of the virus-induced thymidine kinase. Patients with HSV or VZV infections resistant to acyclovir have frequently responded to foscarnet.

With the availability of the oral and intravenous forms, there are few indications for topical acyclovir, although treatment with this formulation has been modestly beneficial in primary genital HSV infections and in mucocutaneous HSV infections in immunocompromised hosts.

Overall, acyclovir is remarkably well tolerated and is generally free of toxicity. The most frequently encountered form of toxicity is renal dysfunction, particularly after rapid intravenous administration or with inadequate hydration. Central nervous system changes, including lethargy and tremors, are occasionally reported, primarily in immunosuppressed patients. However, whether these changes are related to acyclovir, to concurrent administration of other therapy, or to underlying infection remains unclear. Acyclovir is excreted primarily unmetabolized by the kidney, via both glomerular filtration and tubular secretion. Approximately 15% of a dose of acyclovir is metabolized to 9-[(carboxymethoxy)methyl]guanine or other minor metabolites. Reduction in dosage is indicated in patients with a Cr_{Cl} of <50 mL/min per 1.73 m^2. The half-life of acyclovir is ~3 h in normal adults, and the peak plasma concentration after a 1-h infusion of a dose of 5 mg/kg is 9.8 μg/mL. Approximately 22% of an orally administered acyclovir dose is absorbed, and peak plasma concentrations of 0.3 to 0.9 μg/mL are attained after administration of a 200-mg dose. Acyclovir penetrates relatively well into the cerebrospinal fluid (CSF), with concentrations approaching half of those found in plasma.

Acyclovir causes chromosomal breakage at high doses, but its administration to pregnant women has not been associated with fetal abnormalities. Nonetheless, the potential risks and benefits of acyclovir should be carefully assessed before the drug is used in pregnancy.

Valacyclovir exhibits three to five times greater bioavailability than acyclovir. The concentration-time curve for valacyclovir, given as 1 g by mouth three times daily, is similar to that for acyclovir, given as 5 mg/kg intravenously every 8 h. The safety profiles of valacyclovir and acyclovir are similar, although thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome has been reported in immunocompromised patients who have received high doses (8 g/day) of valacyclovir. Valacyclovir is approved for the treatment of herpes zoster and for initial and recurrent episodes of genital HSV infections in immunocompetent adults as well as for suppressive treatment of genital herpes. Although it has not been extensively studied in other herpesvirus infections, many consultants use valacyclovir rather than oral acyclovir in clinical settings where the latter has been approved because of valacyclovir's superior pharmacokinetics and more convenient dosing schedule.

CIDOFOVIR Cidofovir is a phosphonate nucleotide analogue of cytosine. Its major use is in CMV infections, particularly retinitis, but it is active against a broad range of herpesviruses, including HSV, human herpesvirus (HHV) type 6, HHV-8, and certain other DNA viruses such as polyomaviruses, papillomaviruses, adenoviruses, and poxviruses, including variola (smallpox) and vaccinia. Cidofovir does not require initial phosphorylation by virus-induced kinases; the drug is phosphorylated by host cell enzymes to cidofovir diphosphate, which is a competitive inhibitor of viral DNA polymerases and, to a lesser extent, of host cell DNA polymerases. Incorporation of cidofovir diphosphate slows or terminates nascent DNA chain elongation. Cidofovir is active against HSV isolates that are resistant to acyclovir because of absent or altered thymidine kinase and against CMV isolates that are resistant to ganciclovir because of UL97 mutations. Cidofovir is usually active against foscarnet-resistant CMV, although cross-resistance to foscarnet as well as to ganciclovir has been described.

Cidofovir has poor oral availability and is administered intravenously. It is excreted primarily by the kidney and has a plasma half-life of 2.6 h. Cidofovir diphosphate's intracellular half-life of >48 h is the basis for the recommended dosing regimen of 5 mg/kg once a week for the initial 2 weeks and then 5 mg/kg every other week. The major toxic effect of cidofovir is proximal renal tubular injury, as manifested by elevated serum creatinine levels and proteinuria. The risk of nephrotoxicity can be reduced by vigorous saline hydration and by concomitant oral administration of probenecid. Neutropenia, rashes, and gastrointestinal tolerance may also occur.

Intravenous cidofovir has been approved for the treatment of CMV retinitis in AIDS patients who are intolerant of ganciclovir or foscarnet or in whom those drugs have failed. In a controlled study, a maintenance dosage of 5 mg/kg a week administered to AIDS patients reduced the progression of CMV retinitis from that seen at 3 mg/kg. Intravenous cidofovir has been reported anecdotally to be effective therapy for acyclovir-resistant mucocutaneous HSV infections. Likewise, topically administered cidofovir is reportedly beneficial against these infections in HIV patients; it is also being studied for the treatment of anogenital warts. Intravenous cidofovir is being evaluated as therapy for progressive multifocal leukoencephalopathy and for Kaposi's sarcoma. An ophthalmic formulation is being studied as treatment for adenoviral keratoconjunctivitis. Intravitreal cidofovir has been used to treat CMV retinitis but has been associated with significant toxicity.

FOMIVIRSEN Fomivirsen is the first antisense oligonucleotide approved by the FDA for therapy in humans. This phosphorothioate oligonucleotide, 21 nucleotides in length, inhibits CMV replication through interaction with CMV messenger RNA. Fomivirsen is complementary to messenger transcripts of the major immediate early region 2 (IE2) of CMV, which codes for proteins regulating viral gene expression. In addition to its antisense mechanism of action, fomivirsen may exert activity against CMV through inhibition of viral adsorption to cells as well as direct inhibition of viral replication. Because of its different mechanism of action, fomivirsen is active against CMV isolates that are resistant to nucleoside or nucleotide analogues, such as ganciclovir, foscarnet, or cidofovir.

Fomivirsen has been approved for intravitreal administration in the treatment of CMV retinitis in AIDS patients who have failed to respond to other treatments or cannot tolerate them. Injections of 330 mg every 2 weeks have resulted in significant reductions in the rate of progression of CMV retinitis. The major toxicity is ocular inflammation, including vitritis and iritis, which usually responds to topically administered glucocorticoids.

GANCICLOVIR AND VALGANCICLOVIR An analogue of acyclovir, ganciclovir is active against HSV and VZV and is markedly more active than acyclovir against CMV. Ganciclovir triphosphate inhibits CMV DNA polymerase and can be incorporated into CMV DNA, whose elongation it eventually terminates. In HSV- and VZV-infected cells, ganciclovir is phosphorylated by virus-encoded thymidine kinases; in CMV-infected cells, it is phosphorylated by a viral kinase encoded by the UL97 gene. Ganciclovir triphosphate is present in tenfold higher concentrations in CMV-infected cells than in uninfected cells. Ganciclovir is approved for the treatment of CMV retinitis in immunosuppressed patients and for the prevention of CMV disease in transplant recipients. It is widely used for the treatment of other CMV-associated syndromes, including pneumonia, esophagogastrointestinal infections, hepatitis, and "wasting" illness.

Ganciclovir is available for intravenous or oral administration. Because its oral bioavailability is low (5 to 9%), relatively large doses (1 g three times daily) must be administered by this route. Oral ganciclovir has largely been supplanted by valganciclovir, which is the L-valyl ester of ganciclovir. Valganciclovir is well absorbed orally, with a bioavailability of 60%, and is rapidly hydrolyzed to ganciclovir in the intestine and liver. The area under the curve for a 900-mg dose of valganciclovir is equivalent to that for 5 mg/kg of ganciclovir given intravenously, although peak serum concentrations are ~40% lower for valganciclovir. The serum half-life is 3.5 h after intravenous administration of ganciclovir and 4.0 h after oral administration of valganciclovir. Ganciclovir is excreted primarily by the kidneys in unmetabolized form, and its dosage should be reduced in cases of renal failure. The most commonly employed dosage for initial intravenous therapy is 5 mg/kg every 12 h for 14 to 21 days; this regimen is followed by an intravenous maintenance dose of 5 mg/kg per day or five times per week, possibly for as long as immunosuppression persists. For oral therapy with valganciclovir, the dose is 900 mg twice daily for 21 days followed by 900 mg once a day for maintenance, with dose adjustment in patients with renal dysfunction. Intraocular ganciclovir, given by either intravitreal injection or intraocular implantation, has also been used to treat CMV retinitis.

Ganciclovir is effective as prophylaxis against CMV-associated disease in organ and bone marrow transplant recipients. Oral ganciclovir administered prophylactically to AIDS patients with CD4+ cell counts of $<100/\mu L$ has provided protection against the development of CMV retinitis. However, the long-term benefits of this approach to prophylaxis in AIDS patients have not been established, and most experts do not recommend the use of oral ganciclovir for this purpose. As already mentioned, valganciclovir has supplanted oral ganciclovir in settings where oral prophylaxis or therapy is considered.

The administration of ganciclovir has been associated with profound bone marrow suppression, particularly neutropenia, which significantly limits the drug's use in many patients. Bone marrow toxicity is potentiated when other bone marrow suppressants, such as zidovudine, are used concomitantly.

Resistance has been noted in CMV isolates obtained after therapy with ganciclovir, especially in patients with AIDS. Such resistance may develop through a mutation in either the viral UL97 gene or the viral DNA polymerase. Ganciclovir-resistant isolates are usually sensitive to foscarnet (see below) or cidofovir (see above).

FAMCICLOVIR AND PENCICLOVIR Famciclovir is the diacetyl 6-deoxyester of the guanosine analogue penciclovir. Famciclovir is well absorbed orally, has a bioavailability of 77%, and is rapidly converted to penciclovir by deacetylation and oxidation in the intestine and liver. Penciclovir's spectrum of activity and mechanism of action are similar to those of acyclovir; thus penciclovir is usually not active against acyclovir-resistant viruses. Penciclovir is phosphorylated initially by a virus-encoded thymidine kinase and subsequently by cellular kinases to penciclovir triphosphate, which inhibits HSV-1, HSV-2, and VZV DNA polymerases as well as hepatitis B virus (HBV). The serum half-life of penciclovir is 2 h, but the intracellular half-life of penciclovir triphosphate is 7 to 20 h—markedly longer than that of acyclovir triphosphate. The latter is the basis for the less frequent (twice-daily) dosing schedule for famciclovir than for acyclovir. Penciclovir is eliminated primarily in the urine by both glomerular filtration and tubular secretion. The usually recommended dosage interval should be adjusted for renal insufficiency.

Clinical trials involving immunocompetent adults with herpes zoster showed that famciclovir was superior to placebo in eliciting the resolution of skin lesions and virus shedding and in shortening the duration of postherpetic neuralgia; moreover, it was at least as effective as acyclovir administered orally at a dose of 800 mg five times daily. Famciclovir was also effective in the treatment of herpes zoster in immunosuppressed patients. Clinical trials have demonstrated its effectiveness in the suppression of genital HSV infections for up to 1 year and in the treatment of initial and recurrent episodes of genital herpes. Famciclovir is effective as therapy for mucocutaneous HSV infections in HIV-infected patients. Application of a 1% penciclovir cream reduces the duration of signs and symptoms of herpes labialis in immunocompetent patients (by 0.5 to 1.0 day) and has been approved for that purpose by the FDA. Famciclovir is generally well tolerated, with occasional headache, nausea, and diarrhea reported in frequencies similar to those among placebo recipients. The administration of high doses of famciclovir for 2 years was associated with an increased incidence of mammary adenocarcinomas in female rats, but the clinical significance of this effect is unknown. Intravenous penciclovir is being investigated for the treatment of mucocutaneous HSV infections in immunosuppressed patients.

FOSCARNET Foscarnet (phosphonoformic acid) is a pyrophosphate-containing compound that potently inhibits herpesviruses, including CMV. This drug inhibits DNA polymerases at the pyrophosphate binding site at concentrations that have relatively little effect on cellular polymerases. Foscarnet does not require phosphorylation to exert its

antiviral activity and is therefore active against HSV and VZV isolates that are resistant to acyclovir because of deficiencies in thymidine kinase as well as against most ganciclovir-resistant strains of CMV. Foscarnet also inhibits the reverse transcriptase of HIV and is active against HIV in vivo.

Foscarnet is poorly soluble and must be administered intravenously via an infusion pump in a dilute solution over 1 to 2 h. The plasma half-life of foscarnet is 3 to 5 h and increases with decreasing renal function, since the drug is eliminated primarily by the kidneys. It has been estimated that 10 to 28% of a dose may be deposited in bone, where it can persist for months. The most common initial dosage of foscarnet—60 mg/kg every 8 h for 14 to 21 days—is followed by a maintenance dose of 90 to 120 mg/kg once a day.

Foscarnet is approved for the treatment of CMV retinitis in patients with AIDS and of acyclovir-resistant mucocutaneous HSV infections. In a comparative clinical trial, the drug appeared to be about as efficacious as ganciclovir against CMV retinitis but was associated with a longer survival period, possibly because of its anti-HIV activity. Intraocular foscarnet has been used to treat CMV retinitis. Foscarnet has also been employed to treat acyclovir-resistant HSV and VZV infections as well as ganciclovir-resistant CMV infections, although resistance to foscarnet has been reported in CMV isolates obtained during therapy.

The major form of toxicity associated with foscarnet is renal impairment. Thus renal function should be monitored closely, particularly during the initial phase of therapy. Since foscarnet binds divalent metal ions, hypocalcemia, hypomagnesemia, hypokalemia, and hypo- or hyperphosphatemia can develop. Saline hydration and slow infusion appear to protect the patient against nephrotoxicity and electrolyte disturbances. Although hematologic abnormalities have been documented (most commonly anemia), foscarnet is not generally myelosuppressive and may be administered concomitantly with myelosuppressive medications such as zidovudine.

TRIFLURIDINE Trifluridine is a pyrimidine nucleoside active against HSV-1, HSV-2, and CMV. Trifluridine monophosphate irreversibly inhibits thymidylate synthetase, and trifluridine triphosphate inhibits viral and, to a lesser extent, cellular DNA polymerases. Because of systemic toxicity, its use is limited to topical therapy. Trifluridine is approved for treatment of HSV keratitis, for which trials have shown that it is more effective than topical idoxuridine but similarly effective to topical vidarabine. The drug has benefited some patients with HSV keratitis who have failed to respond to idoxuridine or vidarabine. Topical application of trifluridine to sites of acyclovir-resistant HSV mucocutaneous infections has also been beneficial in some cases.

VIDARABINE Vidarabine is a purine nucleoside analogue with activity against HSV-1, HSV-2, VZV, and EBV. Vidarabine inhibits viral DNA synthesis through its 5′-triphosphorylated metabolite, although its precise molecular mechanisms of action are not completely understood. Intravenously administered vidarabine has been shown to be effective in the treatment of herpes simplex encephalitis, mucocutaneous HSV infections, herpes zoster in immunocompromised patients, and neonatal HSV infections. Its use has been supplanted by that of intravenous acyclovir, which is more effective and easier to administer. Production of the intravenous preparation has been discontinued by the manufacturer, but vidarabine is available as an ophthalmic ointment, which is effective in the treatment of HSV keratitis.

ANTIVIRAL DRUGS ACTIVE AGAINST HEPATITIS VIRUSES

LAMIVUDINE Lamivudine is a pyrimidine nucleoside analogue that is used primarily in combination therapy against HIV infection (Chap. 173). It is also active against HBV through inhibition of the viral DNA polymerase and has been approved for the treatment of chronic HBV infection. At doses of 100 mg/d for 1 year, lamivudine was well tolerated and results in suppression of HBV DNA levels, normalization of serum aminotransferase levels in 50 to 70% of patients, and reduction of hepatic inflammation and fibrosis in 50 to 60% of patients. Loss of hepatitis B e antigen (HBeAg) occurred in 30% of patients. Resistance to lamivudine develops in 24% of patients treated for 1 year and is associated with changes in the YMDD motif of HBV DNA polymerase. This is an important limitation of monotherapy with the drug. Studies of lamivudine as a component of combination therapy for hepatitis B are under way. Lamivudine also appears to be useful in the prevention or suppression of HBV infection associated with liver transplantation.

ADEFOVIR Adefovir dipivoxil is an acyclic nucleotide analogue of adenosine monophosphate that has activity against HBV, HIV, HSV, and CMV. It is phosphorylated by cellular kinases to the active triphosphate moiety, which is a competitive inhibitor of HBV DNA polymerase and results in chain termination after incorporation into nascent viral DNA. Adefovir is administered orally and is eliminated primarily by the kidneys, with a plasma half-life of 7.5 h. In clinical studies, therapy with adefovir at a dose 10 μg/d for 48 weeks resulted in normalization of alanine aminotransferase (ALT) levels in 48 to 72% of patients and improved liver histology in 53 to 64%; it also resulted in a 3.6-$\log_{10}$ reduction in the number of HBV DNA copies per milliliter of plasma. Adefovir was effective in treatment-naive patients as well as in those infected with lamivudine-resistant HBV. This agent was generally well tolerated. Significant nephrotoxicity attributable to adefovir was uncommon at the dose employed in the treatment of HBV infections (10 μg/d) but was a treatment-limiting adverse effect at the higher doses used in the treatment of HIV infections (30 to 120 μg/d). In any case, renal function should be monitored in patients taking adefovir, even at the lower dose. Adefovir is approved only for treatment of chronic hepatitis B infection.

TENOFOVIR Tenofovir disoproxil fumarate is a nucleotide analogue with activity against both retroviruses and hepadnaviruses. In one small study of patients coinfected with HIV and HBV, tenofovir reduced HBV loads by $>10^4$ copies/mL at 24 weeks. The drug is approved only for treatment of HIV infection, but its use should be considered in HIV/HBV-coinfected patients. ***→For a more detailed discussion of tenofovir, see Chap. 173.***

INTERFERONS

Interferons are cytokines that exhibit a broad spectrum of antiviral activities as well as immunomodulating and antiproliferative properties. The IFNs are not available for oral administration but must be given intramuscularly, subcutaneously, or intravenously. Early studies with human leukocyte IFN demonstrated an effect in the prophylaxis of experimentally induced rhinovirus infections in humans and in the treatment of VZV infections in immunosuppressed patients. DNA recombinant technology has made available highly purified α, β, and γ IFNs that have been evaluated in a variety of viral infections. Results of such trials have confirmed the effectiveness of intranasally administered IFN in the prophylaxis of rhinovirus infections, although its use has been associated with nasal mucosal irritation. Studies have also demonstrated a beneficial effect of intralesionally or systemically administered IFNs on genital warts. The effect of systemic administration consists primarily of a reduction in the size of lesions, and this mode of therapy may be useful in persons who have numerous warts that cannot easily be treated by individual intralesional injections. However, lesions frequently recur after either intralesional or systemic IFN therapy is discontinued.

Interferons have undergone extensive study in the treatment of chronic HBV infection. The administration of IFN-α2b (5 million units daily or 10 million units three times a week for 16 weeks) to patients with stable chronic HBV infection resulted in loss of markers of HBV replication, such as HBeAg and HBV DNA, in 33 to 37% of cases; 8% of patients also became negative for hepatitis B surface antigen. In >80% of patients who lose HBeAg and HBV DNA markers, serum aminotransferases return to normal levels, and both short- and long-term improvements in liver histopathology have been described. Predictors of a favorable response to therapy include low pretherapy levels

of HBV DNA, high pretherapy serum levels of ALT, a short duration of chronic HBV infection, and active inflammation in liver histopathology. Poor responses are seen in immunosuppressed patients, including those with HIV infection. Adverse effects of the above dose of IFN are common and include fever, chills, myalgia, fatigue, neurotoxicity (primarily manifested as somnolence and confusion), and leukopenia. Approximately 25% of patients receiving a daily dose of 5 million units require dose reduction, but <5% require discontinuation of therapy.

Several IFN preparations, including IFN-α2a, IFN-α2b, IFN-alfacon-1, and IFN-αm1 (lymphoblastoid), have been studied as therapy for chronic HCV infections. A variety of regimens have been employed, of which the most common is IFN-α2b or -α2a at 3 million units three times per week for 12 to 18 months. The addition of oral ribavirin to IFN-α2b—either as initial therapy or after failure of interferon therapy alone—results in significantly higher rates of sustained virologic and/or serum ALT responses (40 to 50%) than were obtained with monotherapy. *Pegylated* IFN-α2b or -α2a, in which the IFNs are covalently linked with monomethoxy polyethylene glycol, have been approved by the FDA for the treatment of chronic HCV infection. These interferons have a markedly reduced clearance rate and can therefore be administered less frequently than standard IFNs (i.e., once a week). Comparative studies indicate that pegylated IFN therapy may be more effective than standard IFN treatment against chronic HCV infection. The combination of intramuscular pegylated IFN and oral ribavirin appears to be a particularly convenient and effective regimen for treatment of chronic hepatitis C. Prognostic factors for a favorable response include an age of <45 years, a short duration of disease, low levels of HCV RNA, and infection with HCV genotypes other than 1. IFN alfacon, a synthetic "consensus" α interferon, appears to produce response rates similar to those elicited by IFN-α2a or -α2b alone and is also approved in the United States for the treatment of chronic hepatitis C. In early clinical trials, pegylated IFN alfas also appear promising as therapy for hepatitis B.

Treatment of acute hepatitis C with IFN has been investigated relatively little. In one study, the administration of IFN-α2b to patients recently infected with HCV (with a dose of 5 million units per day for 4 weeks followed by 3 million units per week for 20 weeks) resulted in clearance of HCV from blood and normalization of ALT levels in 43 of 44 patients at 48 weeks. Additional studies are required to establish the role of IFN therapy in this setting.

The efficacy of IFN-α treatment for chronic hepatitis D remains unestablished. Anecdotal reports suggested that doses of 5 million units daily to 9 million units three times per week for 12 months elicited biochemical and virologic responses. Results from small controlled trials have been inconsistent, and observed responses have not generally been sustained.

Section 12 Infections Due to DNA Viruses

163 HERPES SIMPLEX VIRUSES

Lawrence Corey

DEFINITION Herpes simplex viruses (HSV-1, HSV-2; *Herpesvirus hominis*) produce a variety of infections involving mucocutaneous surfaces, the central nervous system (CNS), and—on occasion—visceral organs. Prompt recognition and treatment reduce the morbidity and mortality of HSV infections.

ETIOLOGIC AGENT The genome of HSV is a linear, double-stranded DNA molecule (molecular weight, $\sim 100 \times 10^6$ units) that encodes >90 transcription units with 84 identified proteins. The genomic structures of the two HSV subtypes are similar, and the overall sequence homology between HSV-1 and HSV-2 is ~50%. The homologous sequences are distributed over the entire genome map, and most of the polypeptides specified by one viral type are antigenically related to polypeptides of the other viral type. Many type-specific regions unique to HSV-1 and HSV-2 proteins do exist, however, and a number of them appear to be important in host immunity. These type-specific regions have been used to develop serologic assays that distinguish between the two viral subtypes. Either restriction endonuclease analysis of viral DNA or DNA sequencing can be used to distinguish between the two subtypes and among strains of each subtype. The variability of nucleotide sequences from clinical strains of HSV-1 and HSV-2 is such that HSV isolates obtained from two individuals can be differentiated by restriction enzyme patterns or genomic sequences unless the isolates are from epidemiologically related sources, such as sexual partners, mother-infant pairs, or persons involved in a common-source outbreak.

The viral genome is packaged in a regular icosahedral protein shell (capsid) composed of 162 capsomers. The outer covering of the virus is a lipid-containing membrane (envelope) derived from modified cell membrane and acquired as the DNA-containing capsid buds through the inner nuclear membrane of the host cell. Between the capsid and lipid bilayer of the envelope is the tegument. Viral replication has both nuclear and cytoplasmic phases. Attachment and fusion between the viral envelope and the cell membrane involve several ubiquitous heparin-like surface receptors. Replication is highly regulated. After fusion and entry, the nucleocapsid enters the cytoplasm and several viral proteins are released from the virion. Some of these viral proteins shut off host protein synthesis (by increasing cellular RNA degradation), while others "turn on" the transcription of early genes of HSV replication. These early gene products, designated α *genes*, are required for synthesis of the subsequent polypeptide group, the β polypeptides, many of which are regulatory proteins and enzymes required for DNA replication. Most current antiviral drugs interfere with β proteins, such as the viral DNA polymerase enzyme. The third (γ) class of HSV genes requires viral DNA replication for expression and constitutes most of the structural proteins specified by the virus.

After replication of the viral genome and synthesis of structural proteins, nucleocapsids are assembled in the nucleus of the cell. En-

velopment occurs as the nucleocapsids bud through the inner nuclear membrane into the perinuclear space. In some cells, viral replication in the nucleus forms two types of inclusion bodies: type A basophilic Feulgen-positive bodies that contain viral DNA and an eosinophilic inclusion body that is devoid of viral nucleic acid or protein and represents a "scar" of viral infection. Virions are then transported via the endoplasmic reticulum and the Golgi apparatus to the cell surface.

HSV infection of some neuronal cells does not result in cell death. Instead, viral genomes are maintained by the cell in a repressed state compatible with survival and normal activities of the cell, a condition called *latency*. Latency is associated with transcription of only a limited number of virus-encoded proteins. Subsequently, the viral genome may become activated; its activation results in the normal pattern of regulated viral gene expression, replication, and release of HSV. The release of virus from the neuron and its subsequent entry into epithelial cells result in viral replication and reappearance of virus on mucosal surfaces. This process is termed *reactivation*. Whereas infectious virus is rarely recovered from sensory or autonomic nervous system ganglia dissected from cadavers, maintenance and growth of the neural cells in tissue culture result in production of infectious virions (*explantation*) and in subsequent permissive infection of susceptible cells (*cocultivation*). The mechanisms by which latency is established, maintained, or recovered are incompletely understood. Two RNA "latency-associated" transcripts that overlap the immediate early (α) gene products, called *ICP-O*, are found in abundance in the nuclei of latently infected neurons. Deletion mutants of this region that can become latent have been made. However, the efficiency of their later reactivation is reduced; thus, the antisense transcripts may play a role in maintaining rather than in establishing latency. Data from animal models suggest that HSV-specific T cell immunity may influence the process of reactivation in neuronal cells. At present, strategies to interrupt latency or to maintain molecular latency in neurons are not available. In experimental animals, ultraviolet light, systemic and local immunosuppression, and trauma to the skin or ganglia are associated with reactivation.

PATHOGENESIS Exposure to HSV at mucosal surfaces or abraded skin sites permits entry of the virus and initiation of its replication in cells of the epidermis and dermis. HSV infections are usually acquired subclinically. Both clinical acquisition and subclinical acquisition are associated with sufficient viral replication to permit infection of either sensory or autonomic nerve endings. On entry into the neuronal cell, the virus—or, more likely, the nucleocapsid—is transported intraaxonally to the nerve cell bodies in ganglia. In humans, the interval from inoculation of virus in peripheral tissue to spread to the ganglia is unknown. During the initial phase of infection, viral replication occurs in ganglia and contiguous neural tissue. Virus then spreads to other mucosal skin surfaces through centrifugal migration of infectious virions via peripheral sensory nerves. This mode of spread helps explain the large surface area involved, the high frequency of new lesions distant from the initial crop of vesicles that is characteristic in patients with primary genital or oral-labial HSV infection, and the recovery of virus from neural tissue distant from neurons innervating the inoculation site. Contiguous spread of locally inoculated virus also may take place and allow further mucosal extension of disease.

Analysis of the DNA from sequentially isolated strains of HSV or from isolates from multiple infected ganglia in any one individual has revealed similar, if not identical, restriction endonuclease or DNA sequence patterns in most persons. Occasionally (most frequently in immunocompromised persons), multiple strains of the same viral subtype are detected in one individual. As exposure to mucosal shedding is relatively common during a person's lifetime, these data suggest that exogenous infection with different strains of the same subtype is possible, albeit very uncommon.

IMMUNITY Host responses to infection with HSV influence the acquisition of disease, the severity of infection, resistance to the development of latency, the maintenance of latency, and the frequency of recurrences. Both antibody-mediated and cell-mediated reactions are clinically important. Immunocompromised patients with defects in cell-mediated immunity experience more severe and more extensive HSV infections than those with deficits in humoral immunity, such as agammaglobulinemia. Experimental ablation of lymphocytes indicates that T cells play a major role in preventing lethal disseminated disease, although antibodies help reduce virus titers in neural tissue. Some of the clinical manifestations of HSV disease appear to be related to the host immune response (e.g., stromal opacities associated with recurrent herpetic keratitis). The surface viral glycoproteins have been shown to be antigens recognized by antibodies mediating neutralization and immune-mediated cytolysis (antibody-dependent cell-mediated cytotoxicity). Monoclonal antibodies specific for each of the known viral glycoproteins have, in experimental infections, conferred protection against subsequent neurologic disease or ganglionic latency. However, the use of subunit glycoprotein vaccines in humans has been, up to the present, only partially successful in reducing acquisition of infection. Multiple cell populations, including natural killer cells, macrophages, and a variety of T lymphocytes, play a role in host defenses against HSV infections, as do lymphokines generated by T lymphocytes. In animals, passive transfer of primed lymphocytes confers protection from subsequent challenge. Maximum protection usually requires the activation of multiple T cell subpopulations, including cytotoxic T cells and T cells responsible for delayed hypersensitivity. The latter cells may confer protection by the antigen-stimulated release of lymphokines (e.g., interferons), which may have a direct antiviral effect and may activate and enhance a variety of specific and nonspecific effector cells. Increasing evidence suggests that HSV-specific CD8+ T cell responses are critical for clearance of virus from lesions. In addition, immunosuppressed patients with frequent and prolonged HSV lesions have fewer functional CD8+ T cells directed at HSV. The HSV virion contains a variety of genes that are directed at the inhibition of host responses. These include gene no. 12 (*US-12*), which can bind to the cellular transporter-activating protein TAP-1 and reduce the ability of this protein to bind HSV peptides to HLA class I, thereby reducing recognition of viral proteins by cytotoxic T cells of the host. This effect can be overcome by the addition of interferon γ, but this reversal requires 24 to 48 h; thus, the virus has time to replicate and invade other host cells. Prior HSV-1 infection appears not to reduce the frequency of acquisition of HSV-2, as measured by seroconversion. However, persons with prior HSV-1 infection who acquire HSV-2 appear to have a higher frequency of subclinical acquisition. These data suggest that type-specific immune responses are central to the control of HSV infection.

EPIDEMIOLOGY Seroepidemiologic studies have documented HSV infections worldwide. Serologic assays with whole-virus antigen preparations, such as complement fixation, neutralization, indirect immunofluorescence, passive hemagglutination, radioimmunoassay, and enzyme-linked immunosorbent assay, are useful for differentiating uninfected (seronegative) persons from those with past HSV-1 or HSV-2 infection, but they do not reliably distinguish between the two viral subtypes. Serologic assays that identify antibodies to type-specific surface proteins (epitopes) of the two viral subtypes have been developed and can distinguish reliably between the human antibody responses to HSV-1 and HSV-2. The most commonly used assays are those that measure antibodies to glycoprotein G of HSV-1 (gG1) and HSV-2 (gG2). A western blot assay that can detect several HSV type-specific proteins can also be used.

Infection with HSV-1 is acquired more frequently and earlier than infection with HSV-2. More than 90% of adults have antibodies to HSV-1 by the fifth decade of life. In populations of low socioeconomic status, most persons acquire HSV-1 infection before the third decade of life.

Antibodies to HSV-2 are not detected routinely until puberty. Antibody prevalence rates correlate with past sexual activity and vary greatly among different population groups. Serosurveys indicate that

~20% of the U.S. population has antibodies to HSV-2. In most routine obstetric and family planning clinics, 25% of women have HSV-2 antibodies, although only 10% report a history of genital lesions. As many as 50% of heterosexual adults attending sexually transmitted disease clinics have antibodies to HSV-2. A wide variety of serologic surveys have indicated a similar or even higher seroprevalence of HSV-2 in most parts of Europe, Central and South America, and Africa. Antibody prevalence rates average ~5% higher among women than among men. Several studies suggest that much of this "asymptomatic" infection is largely unrecognized: when "asymptomatic" seropositive persons are shown pictures of genital lesions, more than 60% subsequently identify episodes of symptomatic reactivation. Most important, these asymptomatic seropositive persons with reactivation shed virus on mucosal surfaces as frequently as those with symptomatic disease. The large reservoir of unidentified carriers of HSV-2 and the frequent asymptomatic reactivation of virus from the genital tract have fostered the continued spread of genital herpes throughout the world. HSV-2 infection is an independent risk factor for the acquisition and transmission of infection with HIV type 1. Among coinfected persons, HIV-1 virions can be shed from herpetic lesions of the genital region. This shedding may facilitate the spread of HIV through sexual contact.

HSV infections occur throughout the year. Transmission can result from contact with persons with active ulcerative lesions or with persons without clinical manifestations of infection who are shedding HSV or on whose mucosal surfaces the virus is replicating. Studies using the polymerase chain reaction (PCR) have shown that HSV reactivation on mucosal surfaces is much more frequent than previously recognized. Among immunocompetent adults, HSV-2 can be isolated by culture from the genital tract on 2 to 10% of days, and HSV DNA can be detected on 20 to 30% of days by PCR. Corresponding figures for HSV-1 in oral secretions are similar. Shedding rates are highest during the initial years after acquisition, and viral shedding may occur on as many as 30 to 50% of days during this period. Immunosuppressed patients shed HSV on mucosal sites at even higher frequency (20 to 70% of days). Daily antiviral chemotherapy can markedly reduce shedding rates, as measured by PCR. These data indicate that potential exposure to HSV from sexual or other close contact (kissing, sharing of glasses or silverware) is common, and these high rates of mucosal reactivation are consistent with the continuing spread and high seroprevalence of HSV infections worldwide.

CLINICAL SPECTRUM HSV has been isolated from nearly all visceral and mucocutaneous sites. The clinical manifestations and course of HSV infection depend on the anatomical site involved, the age and immune status of the host, and the antigenic type of the virus. Primary HSV infections (i.e., first infections with either HSV-1 or HSV-2 in which the host lacks HSV antibodies in acute-phase serum) are frequently accompanied by systemic signs and symptoms. Primary infections involve both mucosal and extramucosal sites; compared with recurrent episodes of disease, they are characterized by a longer duration of symptoms and virus isolation from lesions as well as a higher rate of complications. The incubation period ranges from 1 to 26 days (median, 6 to 8 days). Both viral subtypes can cause genital and oral-facial infections, and the infections caused by the two subtypes are clinically indistinguishable. However, the frequency of reactivation of infection is influenced by anatomical site and virus type. Genital HSV-2 infection is twice as likely to reactivate and recurs 8 to 10 times more frequently than genital HSV-1 infection. Conversely, oral-labial HSV-1 infection recurs more frequently than oral-labial HSV-2 infection. Asymptomatic shedding rates follow the same pattern.

Oral-Facial Infections Gingivostomatitis and pharyngitis are the most frequent clinical manifestations of first-episode HSV-1 infection, while recurrent herpes labialis is the most frequent clinical manifestation of reactivation HSV infection. HSV pharyngitis and gingivostomatitis usually result from primary infection and are most commonly seen in children and young adults. Clinical symptoms and signs, which include fever, malaise, myalgias, inability to eat, irritability, and cervical adenopathy, may last from 3 to 14 days. Lesions may involve the hard and soft palate, gingiva, tongue, lip, and facial area. HSV-1 or HSV-2 infection of the pharynx usually results in exudative or ulcerative lesions of the posterior pharynx and/or tonsillar pillars. Lesions of the tongue, buccal mucosa, or gingiva may occur later in the course in one-third of cases. Fever lasting from 2 to 7 days and cervical adenopathy are common. It can be difficult to differentiate HSV pharyngitis clinically from bacterial pharyngitis, *Mycoplasma pneumoniae* infections, and pharyngeal ulcerations of noninfectious etiologies (e.g., Stevens-Johnson syndrome). No substantial evidence suggests that reactivation oral-labial HSV infection is associated with symptomatic recurrent pharyngitis.

Reactivation of HSV from the trigeminal ganglia may be associated with asymptomatic virus excretion in the saliva, development of intraoral mucosal ulcerations, or herpetic ulcerations on the vermilion border of the lip or external facial skin. About 50 to 70% of seropositive patients undergoing trigeminal nerve root decompression and 10 to 15% of those undergoing dental extraction develop oral-labial HSV infection a median of 3 days after these procedures.

In immunosuppressed patients, infection may extend into mucosal and deep cutaneous layers. Friability, necrosis, bleeding, severe pain, and inability to eat or drink may result. The lesions of HSV mucositis are clinically similar to mucosal lesions caused by cytotoxic drug therapy, trauma, or fungal or bacterial infections. Persistent ulcerative HSV infections are among the most common infections in patients with AIDS. HSV and *Candida* infections often occur concurrently. Systemic antiviral therapy speeds the rate of healing and relieves the pain of mucosal HSV infections in immunosuppressed patients. The frequency of HSV reactivation during the early phases of transplantation or induction chemotherapy is high (50 to 90%), and prophylactic systemic antiviral agents such as intravenous acyclovir or penciclovir are used to reduce reactivation rates. Patients with atopic eczema may also develop severe oral-facial HSV infections (eczema herpeticum), which may rapidly involve extensive areas of skin and occasionally disseminate to visceral organs. Extensive eczema herpeticum has resolved promptly with the administration of intravenous acyclovir. Erythema multiforme may also be associated with HSV infections (see Fig. 46-9); some evidence suggests that HSV infection is the precipitating event in ~75% of cases of cutaneous erythema multiforme. HSV antigen has been demonstrated both in circulatory immune complexes and in skin lesion biopsy samples from these cases. Patients with severe HSV-associated erythema multiforme are candidates for chronic suppressive oral antiviral therapy.

HSV-1 and varicella-zoster virus (VZV) have been implicated in the etiology of Bell's palsy (flaccid paralysis of the mandibular portion of the facial nerve). Although uniform recommendations for treatment of this entity are not available, recent evidence suggests that antiviral chemotherapy, usually with a short course of glucocorticoids, may improve outcome.

Genital Infections First-episode primary genital herpes is characterized by fever, headache, malaise, and myalgias. Pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy are the predominant local symptoms. Widely spaced bilateral lesions of the external genitalia are characteristic (Fig. 163-1). Lesions may be present in varying stages, including vesicles, pustules, or painful erythematous ulcers. The cervix and urethra are involved in >80% of women with first-episode infections. First episodes of genital herpes in patients who have had prior HSV-1 infection are associated with less frequent systemic symptoms and faster healing than primary genital herpes. The clinical courses of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections are similar. However, the recurrence rates of genital disease differ with the viral subtype: the 12-month recurrence rates among patients with first-episode HSV-2 and HSV-1 infections are ~90% and ~55%, respectively (median number of recurrences, 4 and <1, respectively). Recurrence rates

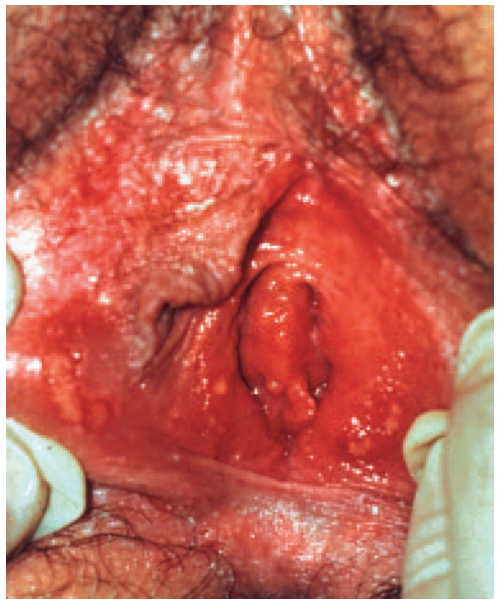

FIGURE 163-1 Bilateral serpiginous ulcerative lesions of the labia minora and majora in a woman with extensive primary genital HSV-2 infection.

for genital HSV-2 infections vary greatly among individuals and over time within the same individual. HSV has been isolated from the urethra and urine of men and women without external genital lesions. A clear mucoid discharge and dysuria are characteristics of symptomatic HSV urethritis. HSV has been isolated from the urethra of 5% of women with the dysuria-frequency syndrome. Occasionally, HSV genital tract disease is manifested by endometritis and salpingitis in women and by prostatitis in men. About 15% of cases of HSV-2 acquisition are associated with these nonlesional clinical syndromes, such as aseptic meningitis, cervicitis, or urethritis. →***A more complete discussion of the differential diagnosis of genital herpes is presented in Chap. 115.***

Both HSV-1 and HSV-2 can cause symptomatic or asymptomatic rectal and perianal infections. HSV proctitis is usually associated with rectal intercourse. However, subclinical perianal shedding of HSV is detected both in heterosexual men and in women who report no rectal intercourse. This phenomenon is due to the establishment of latency in the sacral dermatome from prior genital tract infection, with subsequent reactivation in epithelial cells in the perianal region. Such reactivations are often subclinical. Symptoms of HSV proctitis include anorectal pain, anorectal discharge, tenesmus, and constipation. Sigmoidoscopy reveals ulcerative lesions of the distal 10 cm of the rectal mucosa. Rectal biopsies show mucosal ulceration, necrosis, polymorphonuclear and lymphocytic infiltration of the lamina propria, and (in occasional cases) multinucleated intranuclear inclusion–bearing cells. Perianal herpetic lesions are also found in immunosuppressed patients receiving cytotoxic therapy. Extensive perianal herpetic lesions and/or HSV proctitis is common among patients with HIV infection.

Herpetic Whitlow Herpetic whitlow—HSV infection of the finger—may occur as a complication of primary oral or genital herpes by inoculation of virus through a break in the epidermal surface or by direct introduction of virus into the hand through occupational or some other type of exposure. Clinical signs and symptoms include the abrupt onset of edema, erythema, and localized tenderness of the infected finger. Vesicular or pustular lesions of the fingertip that are indistinguishable from lesions of pyogenic bacterial infection are seen. Fever, lymphadenitis, and epitrochlear and axillary lymphadenopathy are common. The infection may recur. Prompt diagnosis (to avoid unnecessary and potentially exacerbating surgical therapy and/or transmission) is essential. Antiviral chemotherapy (to speed the healing of the process) is usually recommended (see below).

Herpes Gladiatorum HSV may infect almost any area of skin. Mucocutaneous HSV infections of the thorax, ears, face, and hands have been described among wrestlers. Transmission of these infections is facilitated by trauma to the skin sustained during wrestling. Several recent outbreaks of this infection have illustrated the importance of prompt diagnosis and therapy, which are required to contain the spread of this infection.

Eye Infections HSV infection of the eye is the most frequent cause of corneal blindness in the United States. HSV keratitis presents with an acute onset of pain, blurring of vision, chemosis, conjunctivitis, and characteristic dendritic lesions of the cornea. Use of topical glucocorticoids may exacerbate symptoms and lead to involvement of deep structures of the eye. Debridement, topical antiviral treatment, and/or interferon therapy hastens healing. However, recurrences are common, and the deeper structures of the eye may sustain immunopathologic injury. Stromal keratitis due to HSV appears to be related to T cell–dependent destruction of deep corneal tissue. An HSV-1 epitope that is autoreactive with T cell–targeting corneal antigens has been postulated to be a factor in this infection. Chorioretinitis, usually a manifestation of disseminated HSV infection, may occur in neonates or in patients with HIV infection. HSV and VZV can cause acute necrotizing retinitis as an uncommon but severe manifestation.

Central and Peripheral Nervous System Infections HSV accounts for 10 to 20% of all cases of sporadic viral encephalitis in the United States. The estimated incidence is ~2.3 cases per 1 million persons per year. Cases are distributed throughout the year, and the age distribution appears to be biphasic, with peaks at 5 to 30 and >50 years of age. Subtype 1 virus causes >95% of cases of HSV encephalitis.

The pathogenesis of HSV encephalitis varies. In children and young adults, primary HSV infection may result in encephalitis; presumably, exogenously acquired virus enters the CNS by neurotropic spread from the periphery via the olfactory bulb. However, most adults with HSV encephalitis have clinical or serologic evidence of mucocutaneous HSV-1 infection before the onset of the CNS symptoms. In ~25% of the cases examined, the HSV-1 strains from the oropharynx and brain tissue of the same patient differ; thus some cases may result from reinfection with another strain of HSV-1 that reaches the CNS. Two theories have been proposed to explain the development of actively replicating HSV in localized areas of the CNS in persons whose ganglionic and CNS isolates are similar. Reactivation of latent HSV-1 infection in trigeminal or autonomic nerve roots may be associated with extension of virus into the CNS via nerves innervating the middle cranial fossa. HSV DNA has been demonstrated by DNA hybridization in brain tissue obtained at autopsy—even from healthy adults. Thus, reactivation of long-standing latent CNS infection may be another mechanism for the development of HSV encephalitis.

The clinical hallmark of HSV encephalitis has been the acute onset of fever and focal neurologic symptoms and signs, especially in the temporal lobe (Fig. 163-2). Clinical differentiation of HSV encephalitis from other viral encephalitides, focal infections, or noninfectious processes is difficult. The most sensitive noninvasive method for early diagnosis of HSV encephalitis is the demonstration of HSV DNA in cerebrospinal fluid (CSF) by PCR. Although titers of CSF and serum antibodies to HSV increase in most cases of HSV encephalitis, they rarely do so earlier than 10 days into the illness and therefore, while useful retrospectively, are generally not helpful in establishing an early clinical diagnosis. Demonstration of HSV antigen, HSV DNA, or HSV replication in brain tissue obtained by biopsy is highly sensitive and has a low complication rate; examination of such tissue also provides the best opportunity to identify alternative, potentially treatable causes of encephalitis. Antiviral chemotherapy reduces the rate of death from HSV encephalitis. Intravenous acyclovir is more effective than vidarabine. Even with therapy, however, neurologic sequelae are frequent, especially in persons >50 years of age. Most authorities recommend the administration of intravenous acyclovir to patients with presumed HSV encephalitis until the diagnosis is confirmed or an alternative diagnosis is made. Among proven cases of HSV encephalitis, intra-

venous therapy is usually recommended until HSV DNA levels in CSF are substantially reduced or at nearly undetectable levels.

HSV DNA has been detected in CSF from 3 to 15% of persons presenting to the hospital with aseptic meningitis. HSV meningitis, which is usually seen in association with primary genital HSV infection, is an acute, self-limited disease manifested by headache, fever, and mild photophobia and lasting from 2 to 7 days. Lymphocytic pleocytosis in the CSF is characteristic. Neurologic sequelae of HSV meningitis are rare. HSV is the most commonly identified cause of recurrent lymphocytic meningitis (Mollaret's meningitis). Demonstration of HSV antibodies in CSF or persistence of HSV DNA in CSF can establish the diagnosis. For persons with frequent recurrences of HSV meningitis, antiviral therapy has been successful in reducing the frequency of such episodes.

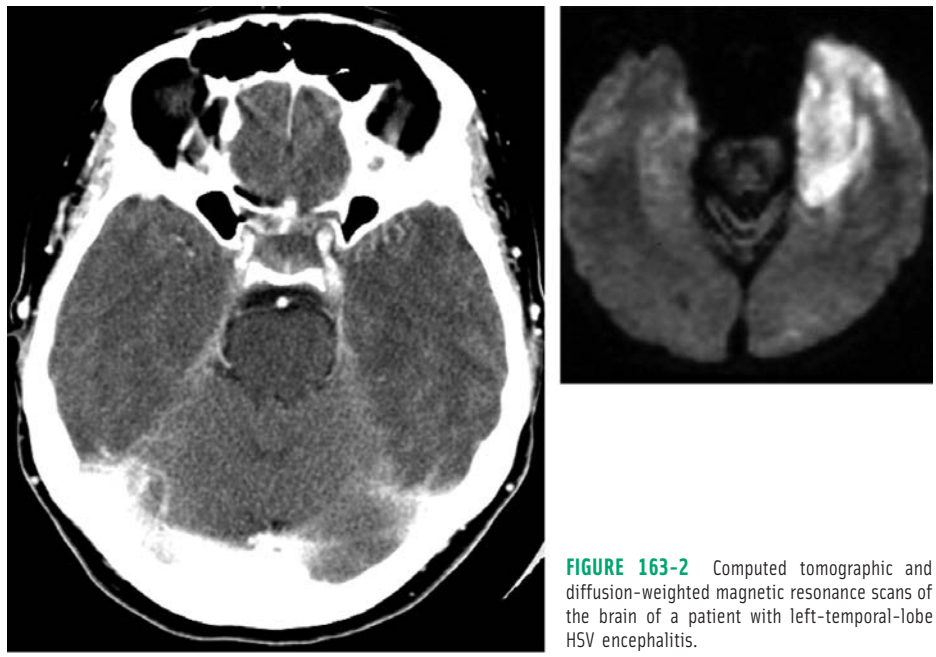

FIGURE 163-2 Computed tomographic and diffusion-weighted magnetic resonance scans of the brain of a patient with left-temporal-lobe HSV encephalitis.

Autonomic nervous system dysfunction, especially of the sacral region, has been reported in association with both HSV and VZV infections. Numbness, tingling of the buttocks or perineal areas, urinary retention, constipation, CSF pleocytosis, and (in males) impotence may occur. Symptoms appear to resolve slowly over days to weeks. Occasionally, hypesthesia and/or weakness of the lower extremities may persist for many months. Rarely, transverse myelitis manifested by a rapidly progressive symmetric paralysis of the lower extremities or a Guillain-Barré syndrome may follow HSV infection. Similarly, peripheral nervous system involvement (Bell's palsy) or cranial polyneuritis may also be related to reactivation of HSV-1 infection. Transitory hypesthesia of the area of skin innervated by the trigeminal nerve and vestibular system dysfunction as measured by electronystagmography are the predominant signs of disease. Studies to determine whether antiviral chemotherapy may abort these signs or reduce their frequency and severity are unavailable.

Visceral Infections HSV infection of visceral organs usually results from viremia, and multiple-organ involvement is common. Occasionally, however, the clinical manifestations of HSV infection involve only the esophagus, lung, or liver. HSV esophagitis may result from direct extension of oral-pharyngeal HSV infection into the esophagus or may occur de novo by reactivation and spread of HSV to the esophageal mucosa via the vagus nerve. The predominant symptoms of HSV esophagitis are odynophagia, dysphagia, substernal pain, and weight loss. There are multiple oval ulcerations on an erythematous base with or without a patchy white pseudomembrane. The distal esophagus is most commonly involved. With extensive disease, diffuse friability may spread to the entire esophagus. Neither endoscopic nor barium examination can reliably differentiate HSV esophagitis from *Candida* esophagitis or from esophageal ulcerations due to thermal injury, radiation, or corrosives. Endoscopically obtained secretions for cytologic examination and culture provide the most useful material for diagnosis. Systemic antiviral chemotherapy usually reduces symptoms and heals esophageal ulcerations.

HSV pneumonitis is uncommon except in severely immunosuppressed patients and may result from extension of herpetic tracheobronchitis into lung parenchyma. Focal necrotizing pneumonitis usually ensues. Hematogenous dissemination of virus from sites of oral or genital mucocutaneous disease may also occur and produce bilateral interstitial pneumonitis. Bacterial, fungal, and parasitic pathogens are commonly present in HSV pneumonitis. The mortality rate from untreated HSV pneumonia in immunosuppressed patients is high (>80%). HSV has also been isolated from the lower respiratory tract of persons with adult respiratory distress syndrome. However, the relationship between the isolation of HSV and the pathogenesis of this syndrome is unclear.

HSV is an uncommon cause of hepatitis in immunocompetent patients. HSV infection of the liver is associated with fever, abrupt elevations of bilirubin and serum aminotransferase levels, and leukopenia (<4000 white blood cells per microliter). Disseminated intravascular coagulation may also develop.

Other reported complications of HSV infection include monarticular arthritis, adrenal necrosis, idiopathic thrombocytopenia, and glomerulonephritis. Disseminated HSV infection in immunocompetent patients is rare. In immunocompromised, burned, or malnourished patients, HSV occasionally disseminates to other visceral organs, such as the adrenal glands, pancreas, small and large intestines, and bone marrow. Rarely, primary HSV infection in pregnancy disseminates and may be associated with the death of both mother and fetus. This uncommon event is usually related to the acquisition of primary infection in the third trimester.

Neonatal HSV Infection Of all HSV-infected populations, neonates (infants younger than 6 weeks) have the highest frequency of visceral and/or CNS infection. Without therapy, the overall rate of death from neonatal herpes is 65%; <10% of neonates with CNS infection develop normally. Although skin lesions are the most commonly recognized features of disease, many infants do not develop lesions until well into the course of disease. Neonatal infection is usually acquired perinatally from contact with infected genital secretions at the time of delivery. Congenitally infected infants have been reported. In most series, 30% of neonatal HSV infections are due to HSV-1 and 70% to HSV-2. The risk of developing neonatal HSV infection is 10 times higher for an infant born to a mother who has recently acquired HSV than for other infants. Neonatal HSV-1 infections may also be acquired through postnatal contact with immediate family members who have symptomatic or asymptomatic oral-labial HSV-1 infection or through nosocomial transmission within the hospital. All neonates with presumed neonatal herpes should be treated with intravenous acyclovir (see below). Antiviral chemotherapy has reduced the rate of death from neonatal herpes to 25%. However, the rate of morbidity, especially among infants with HSV-2 infection involving the CNS, is still very high.

DIAGNOSIS Both clinical and laboratory criteria are useful for establishing the diagnosis of HSV infections. A clinical diagnosis can be made accurately when characteristic multiple vesicular lesions on an erythematous base are present. However, it is increasingly being recognized that herpetic ulcerations may clinically resemble skin ulcer-

ations of other etiologies. Mucosal HSV infections may also present as urethritis or pharyngitis without cutaneous lesions. Thus, laboratory studies to confirm the diagnosis and to guide therapy are recommended. While staining of scrapings from the base of the lesions with Wright's, Giemsa's (Tzanck preparation), or Papanicolaou's stain to detect giant cells or intranuclear inclusions of *Herpesvirus* infection is a well-described procedure, few clinicians are skilled in these techniques. Moreover, these cytologic methods do not differentiate between HSV and VZV infections.

HSV infection is best confirmed in the laboratory by isolation of the virus in tissue culture or by demonstration of HSV antigens or DNA in scrapings from lesions. HSV causes a discernible cytopathic effect in a variety of cell culture systems, and this effect can be identified within 48 to 96 h after inoculation. Spin-amplified culture with subsequent staining for HSV antigen has shortened the time needed to identify HSV to <24 h. Increasingly, PCR is being used for the detection of HSV DNA, and several studies have shown this assay to be more sensitive than culture for detection of HSV in CSF and at mucosal sites. The sensitivity of viral isolation and of antigen or DNA detection depends on the stage of the lesions (with higher sensitivity in vesicular than in ulcerative lesions), on whether the patient has a first or a recurrent episode of the disease (with higher sensitivity in first than in recurrent episodes), and on whether the sample is from an immunosuppressed or an immunocompetent patient (with more antigen in immunosuppressed patients). Laboratory confirmation permits subtyping of the virus; information on subtype may be useful epidemiologically and may help to predict the frequency of reactivation after first-episode oral-labial or genital HSV infection.

Acute- and convalescent-phase serum can be useful in demonstrating seroconversion during primary HSV-1 or HSV-2 infection. However, only 5% of patients with recurrent mucocutaneous HSV infections have a fourfold or greater rise in titer of antibody to HSV in the interval between the collection of the first and second samples. Serologic assays, especially type-specific assays, should be used to identify asymptomatic carriers of HSV-1 or HSV-2 infection.

Several studies have shown that persons seropositive for HSV-2 to whom the clinical manifestations of HSV have been explained are able to identify symptomatic reactivations. Individuals seropositive for HSV-2 should be told about the high frequency of subclinical reactivation in mucosal surfaces not visible to the eye (e.g., cervix, urethra, perianal skin) or in microscopic ulcerations that may not be clinically symptomatic. Transmission of infection during such episodes is well established. HSV-2-seropositive persons should be educated about the high likelihood of subclinical shedding and the role condoms (male or female) may play in reducing transmission. Antiviral therapy with the drug valacyclovir (500 mg once daily) has been shown to reduce the transmission of HSV-2 between sexual partners.

Rx TREATMENT

Many aspects of mucocutaneous and visceral HSV infections are amenable to antiviral chemotherapy. For mucocutaneous infections, acyclovir and its congeners famciclovir and valacyclovir have been the mainstay of therapy. Several antiviral agents are available for topical use in HSV eye infections: idoxuridine, trifluorothymidine, topical vidarabine, and cidofovir. For HSV encephalitis and neonatal herpes, intravenous acyclovir is the treatment of choice.

All licensed antiviral agents for use against HSV inhibit the viral DNA polymerase. One class of drugs, typified by the drug acyclovir, is made up of substrates for the HSV enzyme thymidine kinase. Acyclovir, ganciclovir, famciclovir, and valacyclovir are all selectively phosphorylated to the monophosphate form in virus-infected cells. Cellular enzymes convert the monophosphate form of the drug to the triphosphate, which is then incorporated into the viral DNA chain.

Acyclovir is the most frequently used agent for the treatment of HSV infections and is available in intravenous, oral, and topical formulations. Valacyclovir is the valyl ester of acyclovir and offers greater bioavailability than acyclovir. Famciclovir, the oral formulation of penciclovir, is clinically effective in the treatment of a variety of HSV-1 and HSV-2 infections. Ganciclovir is active against both HSV-1 and HSV-2; however, it is more toxic than acyclovir, valacyclovir, and famciclovir and generally is not recommended for the treatment of HSV infections.

All three recommended compounds—acyclovir, valacyclovir, and famciclovir—have proven effective in shortening the duration of symptoms and lesions of mucocutaneous HSV infections in both immunocompromised and immunocompetent patients (Table 163-1). Intravenous and oral formulations prevent reactivation of HSV in seropositive immunocompromised patients during induction chemotherapy or in the period immediately after bone marrow or solid organ transplantation. Chronic daily suppressive therapy reduces the frequency of reactivation disease among patients with frequent genital or oral-labial herpes. Only valacyclovir has been shown to reduce transmission of HSV-2 infection between sexual partners.

Intravenous acyclovir (30 mg/kg per day, given as a 10-mg/kg infusion over 1 h at 8-h intervals) is effective in reducing rates of death and morbidity from HSV encephalitis. Early initiation of therapy is a critical factor in outcome. The major side effect associated with intravenous acyclovir is transient renal insufficiency, usually due to crystallization of the compound in the renal parenchyma. This adverse reaction can be avoided if the medication is given slowly over 1 h and the patient is well hydrated. Because CSF levels of acyclovir average only 30 to 50% of plasma levels, the dosage of acyclovir used for treatment of CNS infection (30 mg/kg per day) is double that used for treatment of mucocutaneous or visceral disease (15 mg/kg per day). Even higher doses of intravenous acyclovir are used for neonatal HSV infection (60 mg/kg per day in 3 divided doses).

Among immunocompetent patients, recent studies have shown the effectiveness of short-course oral therapy to reduce the signs and symptoms of oral and genital HSV infection. These regimens include valacyclovir (1 or 3 days) for oral-labial HSV and acyclovir (2 days) or valacyclovir (3 days) for recurrent-episode genital herpes (Table 163-1).

Suppression of Mucocutaneous Herpes Recognition of the high frequency of subclinical reactivation has provided an ever-greater rationale for the use of daily antiviral therapy to suppress reactivations of HSV, especially in persons with frequent clinical reactivations (e.g., those with recently acquired genital HSV infection). Immunosuppressed persons, including those with HIV infection, may also benefit from daily antiviral therapy. Of the various regimens used, famciclovir (500 mg twice daily) and valacyclovir (1 g twice daily) are two of the most common; valacyclovir at a dose of 4 g daily was associated with thrombotic thrombocytopenic purpura in one study of HIV-infected persons.

Reduction in Transmission of HSV to Sexual Partners Once-daily valacyclovir (500 mg) has been shown to reduce transmission of HSV-2 between sexual partners. Transmission rates are higher from males to females and among persons with frequent HSV-2 reactivation. Serologic screening can be used to identify at-risk couples.

Acyclovir Resistance Acyclovir-resistant strains of HSV have been identified. Most of these strains have an altered substrate specificity for phosphorylating acyclovir. Thus, cross-resistance to famciclovir and valacyclovir is usually found. Occasionally, an isolate with altered thymidine kinase (TK) specificity arises and is sensitive to famciclovir but not to acyclovir. In some patients infected with TK-deficient virus, higher doses of acyclovir are associated with clearing of lesions. In others, clinical disease progresses despite high-dose therapy. Almost all clinically significant acyclovir resistance has been seen in immunocompromised patients, and HSV-2 isolates are more often resistant than HSV-1 strains. A study by the Centers for Disease Control and Prevention indicated that ~5% of HSV-2 isolates from HIV-positive persons exhibit some degree of in vitro resistance to acyclovir. Among immunocompetent patients attending sexually transmitted disease clin-

TABLE 163-1 Antiviral Chemotherapy for HSV Infection

I. Mucocutaneous HSV infections
  A. Infections in immunosuppressed patients:
    1. Acute symptomatic first or recurrent episodes: IV acyclovir (5 mg/kg q8h) or oral acyclovir (400 mg qid), famciclovir (500 mg tid), or valacyclovir (500 mg bid). Treatment duration may vary from 7 to 14 days.
    2. Suppression of reactivation disease: IV acyclovir (5 mg/kg q8h) or oral valacyclovir (500 mg bid) or acyclovir (400–800 mg 3–5 times per day) prevents recurrences during the 30-day period immediately after transplantation. Longer-term HSV suppression is often used for persons with continued immunosuppression. In bone marrow and renal transplant recipients, oral valacyclovir (2 g/d) is also effective in preventing cytomegalovirus infection. Oral valacyclovir at a dose of 4 g/d has been associated with thrombotic thrombocytopenic purpura after extended use in HIV-positive persons. In HIV-infected persons, oral famciclovir (500 mg bid) is effective in reducing clinical and subclinical reactivations of HSV-1 and HSV-2.
  B. Genital herpes:
    1. First episodes: Oral acyclovir (200 mg 5 times per day or 400 mg tid), valacyclovir (1 g bid), or famciclovir (250 mg bid) for 10–14 days is effective. IV acyclovir (5 mg/kg q8h for 5 days) is given for severe disease or neurologic complications such as aseptic meningitis.
    2. Symptomatic recurrent genital herpes: Oral acyclovir (200 mg 5 times per day for 5 days, 800 mg tid for 2 days), valacyclovir (500 mg bid for 3 or 5 days), or famciclovir (125 mg bid for 5 days) is effective in shortening lesion duration.
    3. Suppression of recurrent genital herpes: Oral acyclovir (200-mg capsules tid or qid, 400 mg bid, or 800 mg qd), famciclovir (250 mg bid), or valacyclovir (500 mg or 1 g qd or 500 mg bid) prevents symptomatic reactivation. Persons with frequent reactivation but <9 episodes per year can take valacyclovir (500 mg PO daily); those with >9 episodes per year should take 1 g PO daily or 500 mg PO bid.
  C. Oral-labial HSV infections:
    1. First episode: Oral acyclovir (200 mg) is given 4 or 5 times per day. Oral famciclovir (250 mg bid) or valacyclovir (1 g bid) has been used clinically.
    2. Recurrent episodes: Oral valacyclovir (1 g bid for 1 day or 500 mg bid for 3 days) is effective in reducing pain and speeding healing. Self-initiated therapy with 6-times-daily topical penciclovir cream is effective in speeding the healing of oral-labial HSV. Topical acyclovir cream has also been shown to speed healing.
    3. Suppression of reactivation of oral-labial HSV: Oral acyclovir (400 mg bid), if started before exposure and continued for the duration of exposure (usually 5–10 days), will prevent reactivation of recurrent oral-labial HSV infection associated with severe sun exposure.
  D. Herpetic whitlow: Oral acyclovir (200 mg) is given 5 times daily for 7–10 days.
  E. HSV proctitis: Oral acyclovir (400 mg 5 times per day) is useful in shortening the course of infection. In immunosuppressed patients or in patients with severe infection, IV acyclovir (5 mg/kg q8h) may be useful.
  F. Herpetic eye infections: In acute keratitis, topical trifluorothymidine, vidarabine, idoxuridine, acyclovir, penciclovir, and interferon are all beneficial. Debridement may be required; topical steroids may worsen disease.

II. CNS HSV infections
  A. HSV encephalitis: IV acyclovir (10 mg/kg q8h; 30 mg/kg per day) for at least 10 days.
  B. HSV aseptic meningitis: No studies of systemic antiviral chemotherapy exist. If therapy is to be given, IV acyclovir (15–30 mg/kg per day) should be used.
  C. Autonomic radiculopathy: No studies are available. Most authorities recommend a trial of IV acyclovir.

III. Neonatal HSV infections
  Oral acyclovir (60 mg/kg per day, divided into 3 doses) is given. The recommended duration of treatment is 21 days. Monitoring for relapse should be undertaken, and some authorities recommend continued suppression with oral acyclovir suspension for 3 to 4 months.

IV. Visceral HSV infections
  A. HSV esophagitis: IV acyclovir (15 mg/kg per day). In some patients with milder forms of immunosuppression, oral therapy with valacyclovir or famciclovir is effective.
  B. HSV pneumonitis: No controlled studies exist. IV acyclovir (15 mg/kg per day) should be considered.

V. Disseminated HSV infections
  No controlled studies exist. Intravenous acyclovir nevertheless should be tried. No definite evidence indicates that therapy will decrease the risk of death.

VI. Erythema multiforme–associated HSV
  Anecdotal observations suggest that oral acyclovir (400 mg bid or tid) or valacyclovir (500 mg bid) will suppress erythema multiforme.

VII. Surgical prophylaxis
  Several surgical procedures (e.g., laser skin resurfacing, trigeminal nerve root decompression, and lumbar disk surgery) have been associated with HSV reactivation. Intravenous or oral acyclovir (800 mg bid) or oral valacyclovir (500 mg bid) or famciclovir (250 mg bid) is effective in reducing reactivation. Therapy should be initiated 48 h before surgery and continued for 3–7 days.

VIII. Infections due to acyclovir-resistant HSV
  IV foscarnet (40 mg/kg q8h) should be given until lesions heal. The optimal duration of therapy and the usefulness of its continuation to suppress lesions are unclear. Some patients may benefit from cutaneous application of trifluorothymidine or 5% cidofovir gel.

ics, <0.5% of HSV-2 isolates show reduced in vitro sensitivity to acyclovir. The lack of appreciable change in the frequency of detection of such isolates in the past 20 years probably reflects the reduced transmission of TK-deficient mutants. Isolation of HSV from lesions persisting despite adequate dosages and blood levels of acyclovir should raise the suspicion of acyclovir resistance. Therapy with the antiviral drug foscarnet is useful (Chap. 162). Because of its toxicity and cost, this drug is usually reserved for patients with extensive mucocutaneous infections. Cidofovir is a nucleotide analogue and exists as a phosphonate or monophosphate form. Most TK-deficient strains of HSV are sensitive to cidofovir. Cidofovir ointment speeds healing of acyclovir-resistant lesions. No well-controlled trials of systemic cidofovir have been reported. True TK-negative variants of HSV appear to have a reduced capacity to spread because of altered neurovirulence—a feature important in the relatively infrequent presence of such strains in immunocompetent populations, even with increasing use of antiviral drugs.

PREVENTION The success of efforts to control HSV disease on a population basis through suppressive antiviral chemotherapy and/or educational programs will be limited.

Barrier forms of contraception (especially condoms) decrease the likelihood of transmission of HSV infection, particularly during periods of asymptomatic viral excretion. When lesions are present, HSV infection may be transmitted by skin-to-skin contact despite the use of a condom. Nevertheless, the available data suggest that consistent condom use is an effective means of reducing the risk of genital HSV-2 transmission. Recent studies have shown that chronic daily antiviral therapy with valacyclovir can also be partially effective in reducing acquisition of HSV-2, especially among susceptible women. There are no comparative efficacy studies of valacyclovir versus condom use. Most authorities suggest both approaches. Several candidate HSV vaccines are under investigation.

Prevention of neonatal HSV requires the prevention of acquisition of HSV by women in the third trimester of pregnancy. Identification

of women or couples susceptible to acquisition of HSV in pregnancy through serologic screening is receiving increasing attention, and such screening is being used with increasing frequency.

164 VARICELLA-ZOSTER VIRUS INFECTIONS

Richard J. Whitley

DEFINITION Varicella-zoster virus (VZV) causes two distinct clinical entities: varicella (chickenpox) and herpes zoster (shingles). Chickenpox, a ubiquitous and extremely contagious infection, is usually a benign illness of childhood characterized by an exanthematous vesicular rash. With reactivation of latent VZV (which is most common after the sixth decade of life), herpes zoster presents as a dermatomal vesicular rash, usually associated with severe pain.

ETIOLOGY A clinical association between varicella and herpes zoster has been recognized for nearly 100 years. Early in the twentieth century, similarities in the histopathologic features of skin lesions resulting from varicella and herpes zoster were demonstrated. Viral isolates from patients with chickenpox and herpes zoster produced similar alterations in tissue culture—specifically, the appearance of eosinophilic intranuclear inclusions and multinucleated giant cells. These results suggested that the viruses were biologically similar. Restriction endonuclease analyses of viral DNA from a patient with chickenpox who subsequently developed herpes zoster verified the molecular identity of the two viruses responsible for these different clinical presentations.

VZV is a member of the family Herpesviridae, sharing with other members such structural characteristics as a lipid envelope surrounding a nucleocapsid with icosahedral symmetry, a total diameter of ~180 to 200 nm, and centrally located double-stranded DNA that is ~125,000 bp in length.

PATHOGENESIS AND PATHOLOGY ■ Primary Infection Transmission is most likely to take place by the respiratory route; the subsequent localized replication of the virus at an undefined site (presumably the nasopharynx) leads to seeding of the reticuloendothelial system and ultimately to the development of viremia. Viremia in patients with chickenpox is reflected in the diffuse and scattered nature of the skin lesions and can be verified in selected cases by the recovery of VZV from the blood or routinely by polymerase chain reaction (PCR). Vesicles involve the corium and dermis, with degenerative changes characterized by ballooning, the presence of multinucleated giant cells, and eosinophilic intranuclear inclusions. Infection may involve localized blood vessels of the skin, resulting in necrosis and epidermal hemorrhage. With the evolution of disease, the vesicular fluid becomes cloudy because of the recruitment of polymorphonuclear leukocytes and the presence of degenerated cells and fibrin. Ultimately, the vesicles either rupture and release their fluid (which includes infectious virus) or are gradually reabsorbed.

Recurrent Infection The mechanism of reactivation of VZV that results in herpes zoster is unknown. Presumably, the virus infects the dorsal root ganglia during chickenpox, where it remains latent until reactivated. Histopathologic examination of representative dorsal root ganglia during active herpes zoster demonstrates hemorrhage, edema, and lymphocytic infiltration.

Active replication of VZV in other organs, such as the lung or the brain, can occur during either chickenpox or herpes zoster but is uncommon in the immunocompetent host. Pulmonary involvement is characterized by interstitial pneumonitis, multinucleated giant cell formation, intranuclear inclusions, and pulmonary hemorrhage. Central nervous system (CNS) infection leads to histopathologic evidence of perivascular cuffing similar to that encountered in measles and other viral encephalitides. Focal hemorrhagic necrosis of the brain, characteristic of herpes simplex virus encephalitis, is uncommon in VZV infection.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS ■ Chickenpox Humans are the only known reservoir for VZV. Chickenpox is highly contagious, with an attack rate of at least 90% among susceptible (seronegative) individuals. Persons of both sexes and all races are infected equally often. The virus is endemic in the population at large; however, it becomes epidemic among susceptible individuals during seasonal peaks—namely, late winter and early spring in the temperate zone. Historically, children between the ages of 5 and 9 are most commonly affected and account for 50% of all cases. Most other cases involve children aged 1 to 4 and those aged 10 to 14. Approximately 10% of the population of the United States over the age of 15 is susceptible to infection. VZV vaccination during the second year of life is dramatically changing the epidemiology of infection.

The incubation period of chickenpox ranges from 10 to 21 days but is usually between 14 and 17 days. Secondary attack rates in susceptible siblings within a household are between 70 and 90%. Patients are infectious ~48 h prior to the onset of the vesicular rash, during the period of vesicle formation (which generally lasts 4 to 5 days), and until all vesicles are crusted.

Clinically, chickenpox presents as a rash, low-grade fever, and malaise, although a few patients develop a prodrome 1 to 2 days before onset of the exanthem. In the immunocompetent patient, this is usually a benign illness that is associated with lassitude and with body temperatures of 37.8° to 39.4°C (100° to 103°F) of 3 to 5 days' duration. The skin lesions—the hallmark of the infection—include maculopapules, vesicles, and scabs in various stages of evolution (Fig. 164-1). These lesions, which evolve from maculopapules to vesicles over hours to days, appear on the trunk and face and rapidly spread to involve other areas of the body. Most are small and have an erythematous base with a diameter of 5 to 10 mm. Successive crops appear over a 2- to 4-day period. Lesions can also be found on the mucosa of the pharynx and/or the vagina. Their severity varies from one person to another. Some individuals have very few lesions, while others have

FIGURE 164-1 Numerous varicella lesions at various stages of evolution: vesicles on an erythematous base, umbilical vesicles, and crusts.

as many as 2000. Younger children tend to have fewer vesicles than older individuals. Secondary and tertiary cases within families are associated with a relatively large number of vesicles. Immunocompromised patients—both children and adults, particularly those with leukemia—have lesions (often with a hemorrhagic base) that are more numerous and take longer to heal than those of immunocompetent patients. Immunocompromised individuals are also at greater risk for visceral complications, which occur in 30 to 50% of cases and are fatal 15% of the time in the absence of antiviral therapy.

The most common infectious complication of varicella is secondary bacterial superinfection of the skin, which is usually caused by *Streptococcus pyogenes* or *Staphylococcus aureus*. This complication may result from excoriation of skin lesions after scratching. Gram's staining of skin lesions should help clarify the etiology of unusually erythematous and pustulated lesions.

The most common extracutaneous site of involvement in children is the CNS. The syndrome of acute cerebellar ataxia and meningeal irritation generally appears ~21 days after the onset of the rash and rarely develops in the preeruptive phase. The cerebrospinal fluid (CSF) contains lymphocytes and elevated levels of protein. CNS involvement is a benign complication of VZV infection in children and generally does not require hospitalization. Aseptic meningitis, encephalitis, transverse myelitis, Guillain-Barré syndrome, and Reye's syndrome can also occur. Encephalitis is reported in 0.1 to 0.2% of children with chickenpox. Other than supportive care, no specific therapy is available for patients with CNS involvement.

Varicella pneumonia is the most serious complication following chickenpox, developing more commonly in adults (up to 20% of cases) than in children. It usually has its onset 3 to 5 days into the illness and is associated with tachypnea, cough, dyspnea, and fever. Cyanosis, pleuritic chest pain, and hemoptysis are frequent. Roentgenographic evidence of disease consists of nodular infiltrates and interstitial pneumonitis. Resolution of pneumonitis parallels improvement of the skin rash; however, patients may have persistent fever and compromised pulmonary function for weeks.

Other complications of chickenpox include myocarditis, corneal lesions, nephritis, arthritis, bleeding diatheses, acute glomerulonephritis, and hepatitis. Hepatic involvement, distinct from Reye's syndrome and usually asymptomatic, is common in chickenpox and is generally characterized by elevated levels of liver enzymes, particularly aspartate and alanine aminotransferases.

Perinatal varicella is associated with a high mortality rate when maternal disease develops within 5 days before delivery or within 48 h thereafter. Because the newborn does not receive protective transplacental antibodies and has an immature immune system, the illness may be unusually severe. The reported mortality rate has been as high as 30% in this group. *Congenital varicella*, with clinical manifestations of limb hypoplasia, cicatricial skin lesions, and microcephaly at birth, is extremely uncommon.

Herpes Zoster Herpes zoster, a sporadic disease, is the consequence of reactivation of latent VZV from the dorsal root ganglia. Most patients have no history of recent exposure to other individuals with VZV infection. Herpes zoster occurs at all ages, but its incidence is highest (5 to 10 cases per 1000 persons) among individuals in the sixth decade of life and beyond. Recurrent herpes zoster is exceedingly rare except in immunocompromised hosts, especially those with AIDS.

Herpes zoster, also called shingles, is characterized by a unilateral vesicular eruption within a dermatome, often associated with severe pain. The dermatomes from T3 to L3 are most frequently involved. If the ophthalmic branch of the trigeminal nerve is involved, zoster ophthalmicus results. The factors responsible for the reactivation of VZV are not known. In children reactivation is usually benign, whereas in adults it can be debilitating. The continuum of pain from onset to resolution is known as *zoster-associated pain*. The onset of disease is heralded by pain within the dermatome that may precede lesions by 48 to 72 h; an erythematous maculopapular rash evolves rapidly into vesicular lesions (Fig. 164-2). In the normal host, these lesions may remain few in number and continue to form only for a period of 3 to 5 days. The total duration of disease is generally between 7 and 10 days; however, it may take as long as 2 to 4 weeks for the skin to return to normal. Patients with herpes zoster can transmit infection to seronegative individuals, with consequent chickenpox. In a few patients, characteristic localization of pain to a dermatome with serologic evidence of herpes zoster has been reported in the absence of skin lesions. When branches of the trigeminal nerve are involved, lesions may appear on the face, in the mouth, in the eye, or on the tongue. Zoster ophthalmicus is usually a debilitating condition that can result in blindness in the absence of antiviral therapy. In the Ramsay Hunt syndrome, pain and vesicles appear in the external auditory canal, and patients lose their sense of taste in the anterior two-thirds

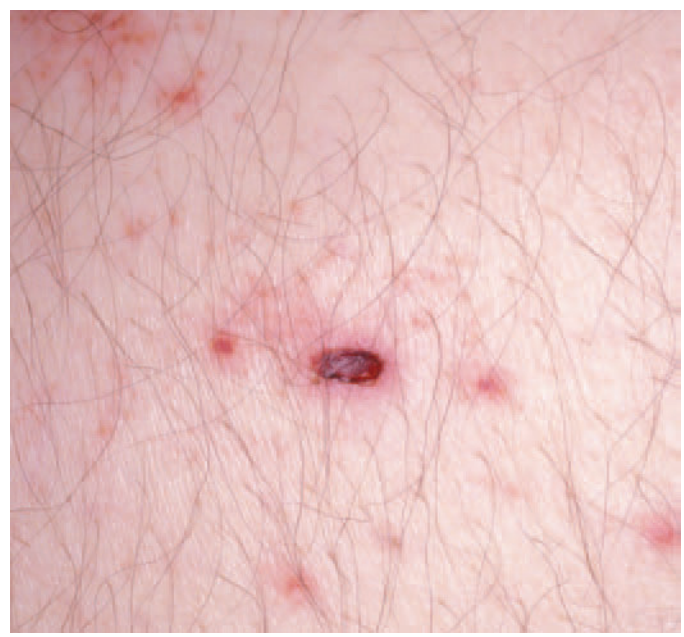

FIGURE 164-2 Close-up of lesions of disseminated zoster. Note lesions at different stages of evolution, including pustules and crusting. (*Photo courtesy of Lindsey Baden.*)

of the tongue while developing ipsilateral facial palsy. The geniculate ganglion of the sensory branch of the facial nerve is involved.

The most debilitating complication of herpes zoster, in both the normal and the immunocompromised host, is pain associated with acute neuritis and postherpetic neuralgia. Postherpetic neuralgia is uncommon in young individuals; however, at least 50% of patients over age 50 with zoster report some degree of pain in the involved dermatome months after the resolution of cutaneous disease. Changes in sensation in the dermatome, resulting in either hypo- or hyperesthesia, are common.

CNS involvement may follow localized herpes zoster. Many patients without signs of meningeal irritation have CSF pleocytosis and moderately elevated levels of CSF protein. Symptomatic meningoencephalitis is characterized by headache, fever, photophobia, meningitis, and vomiting. A rare manifestation of CNS involvement is granulomatous angiitis with contralateral hemiplegia, which can be diagnosed by cerebral arteriography. Other neurologic manifestations include transverse myelitis with or without motor paralysis.

Like chickenpox, herpes zoster is more severe in the immunocompromised host than in the normal individual. Lesions continue to form for over a week, and scabbing is not complete in most cases until 3 weeks into the illness. Patients with Hodgkin's disease and non-Hodgkin's lymphoma are at greatest risk for progressive herpes zoster. Cutaneous dissemination (Fig. 164-3) develops in ~40% of these patients. Among patients with cutaneous dissemination, the risk of pneumonitis, meningoencephalitis, hepatitis, and other serious complications is increased by 5 to 10%. However, even in immunocompromised patients, disseminated zoster is rarely fatal.

Patients who have received a bone marrow transplant are at particularly high risk of VZV infection. Thirty percent of cases of posttransplantation VZV infection occur within 1 year (50% of these within 9 months); 45% of the patients involved have cutaneous or visceral dissemination. The mortality rate in this situation is 10%. Postherpetic neuralgia, scarring, and bacterial superinfection are especially frequent in VZV infections occurring within 9 months of transplantation. Among infected patients, concomitant graft-versus-host disease increases the chance of dissemination and/or death.

DIFFERENTIAL DIAGNOSIS The diagnosis of chickenpox is not difficult. The characteristic rash and a history of recent exposure should lead to a prompt diagnosis. Other viral infections that can mimic chickenpox include disseminated herpes simplex virus infection in patients with atopic dermatitis and the disseminated vesiculopapular lesions sometimes associated with coxsackievirus infection, echovirus infection, or atypical measles. However, these rashes are more commonly morbilliform with a hemorrhagic component rather than vesicular or vesiculopustular. Rickettsialpox (Chap. 158) can be confused with chickenpox; however, it can be distinguished easily by detection of the "herald spot" at the site of the mite bite and the development of a more pronounced headache. Serologic testing is also useful in differentiating rickettsialpox from varicella. Concern about smallpox has recently increased because of the threat of bioterrorism (Chap. 205). The lesions of smallpox are larger than those of chickenpox and are all at the same stage of evolution.

FIGURE 164-3 Herpes zoster is seen in this HIV-infected patient as hemorrhagic vesicles and pustules on an erythematous base grouped in a dermatomal distribution.

Unilateral vesicular lesions in a dermatomal pattern should lead rapidly to the diagnosis of herpes zoster, although the occurrence of shingles without a rash has been reported. Both herpes simplex virus infections and coxsackievirus infections can cause dermatomal vesicular lesions. Supportive diagnostic virology and fluorescent staining of skin scrapings with monoclonal antibodies are helpful in ensuring the proper diagnosis. In the prodromal stage of herpes zoster, the diagnosis can be exceedingly difficult and may be made only after lesions have appeared or by retrospective serologic assessment.

LABORATORY FINDINGS Unequivocal confirmation of the diagnosis is possible only through the isolation of VZV in susceptible tissue-culture cell lines, the demonstration of either seroconversion or a fourfold or greater rise in antibody titer between convalescent- and acute-phase serum specimens, or the detection of VZV DNA by PCR. A rapid impression can be obtained by a Tzanck smear, with scraping of the base of the lesions in an attempt to demonstrate multinucleated giant cells, although the sensitivity of this method is low (~60%). PCR technology for the detection of viral DNA in vesicular fluid is available in a limited number of diagnostic laboratories. Direct immunofluorescent staining of cells from the lesion base or detection of viral antigens by other assays (such as the immunoperoxidase assay) is also useful, although these tests are not commercially available. The most frequently employed serologic tools for assessing host response are the immunofluorescent detection of antibodies to VZV membrane antigens, the fluorescent antibody to membrane antigen (FAMA) test, immune adherence hemagglutination, and enzyme-linked immunosorbent assay (ELISA). The FAMA test and the ELISA appear to be the most sensitive.

Rx TREATMENT

Medical management of chickenpox in the immunologically normal host is directed toward the prevention of avoidable complications. Obviously, good hygiene includes daily bathing and soaks. Secondary bacterial infection of the skin can be avoided by meticulous skin care, particularly with close cropping of fingernails. Pruritus can be decreased with topical dressings or the administration of antipruritic drugs. Tepid water baths and wet compresses are better than drying lotions for the relief of itching. Aluminum acetate soaks for the management of herpes zoster can be both soothing and cleansing. Administration of aspirin to children with chickenpox should be avoided because of the association of aspirin derivatives with the development of Reye's syndrome. Acyclovir therapy (800 mg by mouth five times daily for 5 to 7 days) is recommended for adolescents and adults with chickenpox of ≤24 h duration. Likewise, acyclovir therapy may be of benefit to children <12 years of age if initiated early in the disease (<24 h) at a dose of 20 mg/kg every 6 h.

Patients with herpes zoster benefit from oral antiviral therapy, as evidenced by accelerated healing of lesions and resolution of zoster-associated pain with acyclovir, valacyclovir, or famciclovir. Acyclovir, now off patent, is administered at a dosage of 800 mg five times daily for 7 to 10 days. Famciclovir, the prodrug of penciclovir, is at least as effective as acyclovir and perhaps more so. One study showed twofold faster resolution of postherpetic neuralgia in famciclovir-treated patients with zoster than in recipients of placebo. The dose is 500 mg by mouth three times daily for 7 days. Valacyclovir, the prodrug of acyclovir, accelerates healing and resolution of zoster-associated pain more promptly than acyclovir. The dose is 1 g by mouth three times

daily for 5 to 7 days. Both famciclovir and valacyclovir offer the advantage of a lower dosing frequency than acyclovir.

In the immunocompromised host, both chickenpox and herpes zoster (including disseminated disease) should be treated with intravenous acyclovir, which reduces the occurrence of visceral complications but has no effect on healing of skin lesions or pain. The dose is 10 to 12.5 mg/kg every 8 h for 7 days. Oral acyclovir therapy is not recommended for the treatment of VZV infections in immunocompromised patients. Concomitant with the administration of intravenous acyclovir, it is desirable to attempt to wean these patients from immunosuppressive treatment.

Patients with varicella pneumonia may require removal of bronchial secretions and ventilatory support. Persons with zoster ophthalmicus should be referred immediately to an ophthalmologist. Therapy for this condition consists of the administration of analgesics for severe pain and the use of atropine. Acyclovir accelerates healing.

The management of acute neuritis and/or postherpetic neuralgia can be particularly difficult. In addition to the judicious use of analgesics, ranging from nonnarcotics to narcotic derivatives, drugs such as gabapentin, amitriptyline hydrochloride, lidocaine patches, and fluphenazine hydrochloride have been reported to be beneficial for pain relief. In one study, glucocorticoid therapy administered early in the course of localized herpes zoster significantly accelerated such quality-of-life improvements as a return to usual activity and termination of analgesia. The dose of prednisone administered orally was 60 mg/d on days 1 through 7, 30 mg/d on days 8 through 14, and 15 mg/d on days 15 through 21. This regimen is appropriate only for relatively healthy elderly persons who have moderate or severe pain at presentation. Patients with osteoporosis, diabetes mellitus, glycosuria, or hypertension may not be appropriate candidates. Glucocorticoids should not be used without concomitant antiviral therapy.

PREVENTION Three methods are used for the prevention of VZV infections. First, a live attenuated varicella vaccine (OKA) is recommended for all children >1 year of age (up to 12 years of age) who have not had chickenpox and for adults known to be seronegative for VZV. A single dose of vaccine is administered to children, whereas adults require two doses. The vaccine is both safe and efficacious. Breakthrough cases are mild and may result in spread of the vaccine virus to susceptible contacts. The universal vaccination of children is resulting in a decreased incidence of chickenpox in sentinel communities. Furthermore, inactivation of the vaccine virus significantly decreases the occurrence of herpes zoster after human stem-cell transplantation. A vaccine study is being performed in individuals >60 years of age to determine its impact on the incidence and severity of shingles.

A second approach is to administer varicella-zoster immune globulin (VZIg) to individuals who are susceptible, are at high risk for developing complications of varicella, and have had a significant exposure. This product should be given within 96 h (preferably within 72 h) of the exposure. Indications for administration of VZIg appear in Table 164-1.

Lastly, antiviral therapy can be given as prophylaxis to individuals at high risk who are ineligible for vaccine or beyond the 96-h window after direct contact. While the initial studies have used acyclovir, similar benefit can be anticipated with either valacyclovir or famciclovir. Therapy is instituted 7 days after intense exposure. At this time, the host is midway into the incubation period. This approach significantly decreases disease severity, if not totally preventing disease.

TABLE 164-1 Recommendations for VZIg Administration

Exposure criteria

1. Exposure to person with chickenpox or zoster
   a. Household: residence in the same household
   b. Playmate: face-to-face indoor play
   c. Hospital
      Varicella: same 2- to 4-bed room or adjacent beds in large ward, face-to-face contact with infectious staff member or patient, visit by a person deemed contagious
      Zoster: intimate contact (e.g., touching or hugging) with a person deemed contagious
   d. Newborn infant: onset of varicella in the mother ≤5 days before delivery or ≤48 h after delivery; VZIg is not indicated if the mother has zoster
2. Patient should receive VZIg as soon as possible but not >96 h after exposure

Candidates (provided they have significant exposure) include:

1. Immunocompromised susceptible children without history of varicella or varicella immunization
2. Susceptible pregnant women
3. Newborn infants whose mother had onset of chickenpox within 5 days before or within 48 h after delivery
4. Hospitalized premature infant (≥28 weeks of gestation) whose mother lacks a reliable history of chickenpox or serologic evidence of protection against varicella
5. Hospitalized premature infant (<28 weeks of gestation or ≤1000-g birth weight), regardless of maternal history of varicella or varicella-zoster virus serologic status

165 EPSTEIN-BARR VIRUS INFECTIONS, INCLUDING INFECTIOUS MONONUCLEOSIS

Jeffrey I. Cohen

DEFINITION Epstein-Barr virus (EBV) is the cause of heterophile-positive infectious mononucleosis (IM), which is characterized by fever, sore throat, lymphadenopathy, and atypical lymphocytosis. EBV is also associated with several human tumors, including nasopharyngeal carcinoma, Burkitt's lymphoma, Hodgkin's disease, and (in patients with immunodeficiencies) B cell lymphoma. The virus, a member of the family Herpesviridae, consists of a linear DNA core surrounded by a nucleocapsid and an envelope that contains glycoproteins. The two types of EBV that are widely prevalent in nature are not distinguishable by conventional serologic tests.

EPIDEMIOLOGY EBV infections occur worldwide. These infections are most common in early childhood, with a second peak during late adolescence. By adulthood, more than 90% of individuals have been infected and have antibodies to the virus. IM is usually a disease of young adults. In lower socioeconomic groups and in areas of the world with lower standards of hygiene (e.g., developing countries), EBV tends to infect children at an early age, and symptomatic IM is uncommon. In areas with higher standards of hygiene, infection with EBV is often delayed until adulthood, and IM is more prevalent.

EBV is spread by contact with oral secretions. The virus is frequently transmitted from asymptomatic adults to infants and among young adults by transfer of saliva during kissing. Transmission by less intimate contact is rare. EBV has been transmitted by blood transfusion and by bone marrow transplantation. More than 90% of asymptomatic seropositive individuals shed the virus in oropharyngeal secretions.

PATHOGENESIS EBV is transmitted by salivary secretions. The virus infects the epithelium of the oropharynx and the salivary glands and is shed from these cells. While B cells may become infected after contact with epithelial cells, studies suggest that lymphocytes in the tonsillar crypts can be infected directly. The virus then spreads through the bloodstream. The proliferation and expansion of EBV-infected B cells along with reactive T cells during IM result in enlargement of lymphoid tissue. Polyclonal activation of B cells leads to the production of antibodies to host-cell and viral proteins. During the acute phase of IM, up to 1 in every 100 B cells in the peripheral blood is infected by EBV, while after recovery, about 1 in every million B cells is infected. During IM there is an inverted CD4+/CD8+ T cell ratio. The percentage of CD4+ T cells decreases, while there are large clonal expansions of CD8+ T cells; up to 40% of CD8+ T cells are directed against EBV antigens during acute infection. Data suggest that memory B cells, not epithelial cells, are the reservoir for EBV in the body. When patients are treated with acyclovir, shedding of EBV from the oropharynx stops but the virus persists in B cells.

The EBV receptor (CD21), present on the surface of B cells, is also the receptor for the C3d component of complement. EBV infection of epithelial cells results in viral replication and production of virions. When B cells are infected by EBV in vitro, they become transformed and can proliferate indefinitely. During latent infection of B cells, only the EBV nuclear antigens (EBNAs), latent membrane proteins (LMPs), and small EBV RNAs are expressed in vitro. EBV-transformed B cells secrete immunoglobulin; only a small fraction of cells produce virus.

Cellular immunity is more important than humoral immunity in controlling EBV infection. In the initial phase of infection, suppressor T cells, natural killer cells, and nonspecific cytotoxic T cells are important in controlling the proliferation of EBV-infected B cells. Levels of markers of T cell activation and serum interferon γ are elevated. Later in infection, HLA-restricted cytotoxic T cells that recognize EBNAs and LMPs and destroy EBV-infected cells are generated. Studies have shown that one of the late genes expressed during EBV replication, *BCRF1*, is a homologue of interleukin 10 and can inhibit the production of interferon γ by mononuclear cells in vitro.

If T cell immunity is compromised, EBV-infected B cells may begin to proliferate. When EBV is associated with lymphoma, virus-induced proliferation is but one step in a multistep process of neoplastic transformation. In many EBV-containing tumors, LMP-1 mimics members of the tumor necrosis factor receptor family (e.g., CD40), transmitting growth-proliferating signals.

CLINICAL MANIFESTATIONS Most EBV infections in infants and young children either are asymptomatic or present as mild pharyngitis with or without tonsillitis. In contrast, up to 75% of infections in adolescents present as IM.

Signs and Symptoms The incubation period for IM in young adults is ~4 to 6 weeks. A prodrome of fatigue, malaise, and myalgia may last for 1 to 2 weeks before the onset of fever, sore throat, and lymphadenopathy. Fever is usually low-grade and is most common in the first 2 weeks of the illness; however, it may persist for >1 month. Common signs and symptoms are listed along with their frequencies in Table 165-1. Lymphadenopathy and pharyngitis are most prominent during the first 2 weeks of the illness, while splenomegaly is more prominent during the second and third weeks. Lymphadenopathy most often affects the posterior cervical nodes but may be generalized. Enlarged lymph nodes are frequently tender and symmetric but are not fixed in place. Pharyngitis, often the most prominent sign, can be accompanied by enlargement of the tonsils with an exudate resembling that of streptococcal pharyngitis. A morbilliform or papular rash, usually on the arms or trunk, develops in ~5% of cases. Most patients treated with ampicillin develop a macular rash; this rash is not predictive of future adverse reactions to penicillins. Erythema nodosum and erythema multiforme have also been described (Chap. 48). Most patients have symptoms for 2 to 4 weeks, but malaise and difficulty concentrating can persist for months.

Symptomatic IM is uncommon in infants and young children. IM in the elderly presents relatively often as nonspecific symptoms, including prolonged fever, fatigue, myalgia, and malaise; in contrast, pharyngitis, lymphadenopathy, splenomegaly, and atypical lymphocytes are relatively rare in elderly patients.

Laboratory Findings The white blood cell count is usually elevated and peaks at 10,000 to 20,000/μL during the second or third week of illness. Lymphocytosis is usually demonstrable, with >10% atypical lymphocytes. The latter cells are enlarged lymphocytes that have abundant cytoplasm, vacuoles, and indentations of the cell membrane. CD8+ cells predominate among the atypical lymphocytes. Low-grade neutropenia and thrombocytopenia are common during the first month

TABLE 165-1 Signs and Symptoms of Infectious Mononucleosis

Manifestation	Median Percentage of Patients (Range)
Symptoms	
Sore throat	75 (50–87)
Malaise	47 (42–76)
Headache	38 (22–67)
Abdominal pain, nausea, or vomiting	17 (5–25)
Chills	10 (9–11)
Signs	
Lymphadenopathy	95 (83–100)
Fever	93 (60–100)
Pharyngitis or tonsillitis	82 (68–90)
Splenomegaly	51 (43–64)
Hepatomegaly	11 (6–15)
Rash	10 (0–25)
Periorbital edema	13 (2–34)
Palatal enanthem	7 (3–13)
Jaundice	5 (2–10)

of illness. Liver function is abnormal in more than 90% of cases. Serum levels of aminotransferases and alkaline phosphatase are usually mildly elevated; the serum concentration of bilirubin is elevated in ~40% of cases.

Complications Most cases of IM are self-limited. Deaths are very rare and most often are due to central nervous system (CNS) complications, splenic rupture, upper airway obstruction, or bacterial superinfection.

When CNS complications develop, they usually do so during the first 2 weeks of EBV infection; in some patients, especially children, they are the only clinical manifestations of IM. Heterophile antibodies and atypical lymphocytes may be absent. Meningitis and encephalitis are the most common neurologic abnormalities, and patients may present with headache, meningismus, or cerebellar ataxia; acute hemiplegia and psychosis have also been described. The cerebrospinal fluid (CSF) contains mainly lymphocytes, with occasional atypical lymphocytes. Most cases resolve without neurologic sequelae. Acute EBV infection has also been associated with cranial nerve palsies (especially ones involving cranial nerve VII), Guillain-Barré syndrome, acute transverse myelitis, and peripheral neuritis.

Autoimmune hemolytic anemia occurs in ~2% of cases during the first 2 weeks. In most cases the anemia is Coombs'-test positive, with cold agglutinins directed against the i red blood cell antigen. Most patients with hemolysis have mild anemia that lasts for 1 or 2 months, but some patients have severe disease with hemoglobinuria and jaundice. Nonspecific antibody responses may also include rheumatoid factor, antinuclear antibodies, anti–smooth muscle antibodies, antiplatelet antibodies, and cryoglobulins. IM has been associated with red-cell aplasia, severe granulocytopenia, thrombocytopenia, pancytopenia, and hemophagocytic syndrome. The spleen ruptures in fewer than 0.5% of cases. Splenic rupture is more common among males than among females and may be manifest as abdominal pain, referred shoulder pain, or hemodynamic compromise.

Hypertrophy of lymphoid tissue in the tonsils or adenoids can result in upper airway obstruction, as can inflammation and edema of the epiglottis, pharynx, or uvula. About 10% of patients with IM develop streptococcal pharyngitis after their initial sore throat resolves.

Other rare complications associated with acute EBV infection include hepatitis (which can be fulminant), myocarditis or pericarditis with electrocardiographic changes, pneumonia with pleural effusion, interstitial nephritis, genital ulcerations, and vasculitis.

OTHER DISEASES ASSOCIATED WITH EBV INFECTION EBV-associated lymphoproliferative disease has been described in patients with congenital or acquired immunodeficiency, including those with severe combined immunodeficiency, AIDS, and recipients of bone marrow or organ transplants who are receiving immunosuppressive drugs (especially cyclosporine). Proliferating EBV-infected B cells infiltrate lymph nodes and multiple organs, and patients present with fever and lymphadenopathy or gastrointestinal symptoms. Pathologic studies show B cell hyperplasia or poly- or monoclonal lymphoma. The X-linked lymphoproliferative syndrome (Duncan's disease) is a recessive disorder of young boys who have a normal response to childhood infections but develop fatal lymphoproliferative disorders after infection with EBV. The gene mutated in this syndrome, *SAP* or *SH2D1A*, has been identified; its product binds to a protein that mediates interactions of B and T cells. Most patients with this syndrome die of acute IM; others develop hypogammaglobulinemia, malignant B cell lymphomas, aplastic anemia, or agranulocytosis. IM has also proved fatal to some patients with no obvious preexisting immune abnormality.

Oral hairy leukoplakia (Fig. 165-1) is an early manifestation of infection with HIV in adults (Chap. 173). Most patients present with raised, white corrugated lesions on the tongue (and occasionally on the buccal mucosa) that contain EBV DNA. Children infected with HIV can develop lymphoid interstitial pneumonitis; EBV DNA is often found in lung tissue from these patients.

Patients with the chronic fatigue syndrome may have titers of antibody to EBV that are elevated but are not significantly different from those in healthy EBV-seropositive adults. While some patients have malaise and fatigue that persist for weeks or months after IM, persistent EBV infection is not a cause of the chronic fatigue syndrome. Chronic active EBV infection is very rare and is distinct from the chronic fatigue syndrome. The affected patients have an illness lasting >6 months with markedly elevated titers of antibody to EBV and evidence of organ involvement, including hepatosplenomegaly, lymphadenopathy, and pneumonitis, uveitis, or neurologic disease.

FIGURE 165-1 Oral hairy leukoplakia often presents as white plaques on the lateral surface of the tongue and is associated with Epstein-Barr virus infection.

EBV is associated with several malignancies. About 15% of cases of Burkitt's lymphoma in the United States and ~90% of those in Africa are associated with EBV (Chap. 97). African patients with Burkitt's lymphoma have high levels of antibody to EBV, and their tumor tissue usually contains viral DNA. EBV-containing Burkitt's lymphoma also occurs in patients with AIDS. Anaplastic nasopharyngeal carcinoma is uniformly associated with EBV; the affected tissues contain viral DNA and antigens. Patients with nasopharyngeal carcinoma often have elevated titers of antibody to EBV (Chap. 74).

EBV has been associated with Hodgkin's disease, especially the mixed-cellularity type (Chap. 97). Patients with Hodgkin's disease often have elevated titers of antibody to EBV, and in about half of cases viral DNA and antigens are found in Reed-Sternberg cells. In some cases, EBV DNA has been detected in tonsillar carcinoma, angioimmunoblastic lymphadenopathy, angiocentric nasal NK/T cell immunoproliferative lesions, T cell lymphoma, thymoma, gastric carcinoma, and CNS lymphoma from patients with no underlying immunodeficiency. Studies have demonstrated viral DNA in leiomyosarcomas from AIDS patients and in smooth-muscle tumors from organ transplant recipients. Virtually all CNS lymphomas in AIDS patients are associated with EBV. While serologic studies have shown higher levels of antibodies to EBV before the onset of multiple sclerosis, other studies (including measurement of EBV antibody titers in the CSF) are needed to ascertain a possible causal relationship.

DIAGNOSIS ■ Serologic Testing The heterophile test is used for the diagnosis of IM in children and adults (Table 165-2). In the test for this antibody, human serum is absorbed with guinea pig kidney, and the heterophile titer is defined as the greatest serum dilution that agglutinates sheep, horse, or cow erythrocytes. Although heterophile antibody binds to certain animal erythrocytes, it does not interact with EBV proteins. A titer of 40-fold or greater is diagnostic of acute EBV infection in a patient who has symptoms compatible with IM and atypical lymphocytes. Tests for heterophile antibodies are positive in 40% of patients with IM during the first week of illness and in 80 to 90% during the third week. Therefore, repeated testing may be necessary, especially if the initial test is performed early. Tests usually remain positive for 3 months after the onset of illness, but heterophile antibodies can persist for up to 1 year. These antibodies usually are not detectable in children <5 years of age, in the elderly, or in patients presenting with symptoms not typical of IM. The commercially available monospot test for heterophile antibodies is somewhat more sensitive than the classic heterophile test. The monospot test is ~75%

TABLE 165-2 *Serologic Features of EBV-Associated Diseases*

Condition	Result in Indicated Test[a]					
		Anti-VCA		Anti-EA		
	Heterophile	IgM	IgG	EA-D	EA-R	Anti-EBNA
Acute infectious mononucleosis	+	+	++	+	−	−
Convalescence	±	−	+	−	±	+
Past infection	−	−	+	−	−	+
Reactivation with immunodeficiency	−	−	++	+	+	±
Burkitt's lymphoma	−	−	+++	±	++	+
Nasopharyngeal carcinoma	−	−	+++	++	±	+

[a] VCA, viral capsid antigen; EA, early antigen; EA-D antibody, antibody to early antigen in diffuse pattern in nucleus and cytoplasm of infected cells; EA-R antibody, antibody to early antigen restricted to the cytoplasm; and EBNA, Epstein-Barr nuclear antigen.

Source: Adapted from Okano, 1988.

sensitive and ~90% specific compared with EBV-specific serologies. False-positive monospot results are more common in persons with connective tissue disease, lymphoma, viral hepatitis, and malaria.

EBV-specific antibody testing is used for patients with suspected acute EBV infection who lack heterophile antibodies and for patients with atypical infections (Table 165-2). Serologic tests are particularly useful in young children, who often do not develop heterophile antibodies. Titers of IgM and IgG antibodies to viral capsid antigen (VCA) are elevated in the serum of more than 90% of patients at the onset of disease. IgM antibody to VCA is most useful for the diagnosis of acute IM because it is present at elevated titers only during the first 2 to 3 months of the disease; in contrast, IgG antibody to VCA is usually not useful for diagnosis of IM but is often used to assess exposure to EBV in the past because it persists for life. Seroconversion to EBNA positivity is also useful for the diagnosis of acute infection with EBV. Antibodies to EBNA are detectable relatively late (3 to 6 weeks after the onset of symptoms) in nearly all cases of acute EBV infection and persist for the lifetime of the patient. These antibodies may be lacking in immunodeficient patients and in those with chronic active EBV infection.

Titers of other antibodies may also be elevated in IM; however, these elevations are less useful for diagnosis. Antibodies to early antigens (EAs) are found either in a diffuse pattern in the nucleus and cytoplasm of infected cells (EA-D antibody) or restricted to the cytoplasm (EA-R antibody). These antibodies are detectable 3 to 4 weeks after the onset of symptoms in patients with IM. About 70% of individuals with IM have EA-D antibodies during the course of illness; the presence of EA-D antibodies is especially likely in those with relatively severe disease. These antibodies usually persist for only 3 to 6 months. Levels of EA-D antibodies are also elevated in patients with nasopharyngeal carcinoma or chronic active EBV infection. EA-R antibodies are only occasionally detected in patients with IM but are often found at elevated titers in patients with African Burkitt's lymphoma or chronic active EBV infection. IgA antibodies to EBV antigens have proved useful for the identification of patients with nasopharyngeal carcinoma and of persons at high risk for the disease.

TABLE 165-3 *Treatment Options for Posttransplantation EBV Lymphoproliferative Disease*

1. Reduction of immunosuppression, when possible
2. Excision of localized lesions
3. Interferon α
4. Monoclonal antibody to CD20 (rituximab)
5. Radiation therapy (especially for CNS lesions)
6. For stem cell transplant recipients: donor lymphocyte infusions or donor EBV-specific cytotoxic T cell infusions[a]
7. For solid organ transplant recipients: autologous or HLA-matched, EBV-specific, cytotoxic T cell infusions[a]
8. Cytotoxic chemotherapy

[a] Infused T cells must be HLA matched; lymphoproliferative lesions are usually of donor origin for stem cell transplant recipients and of recipient origin for solid organ transplant recipients.

Other Studies Detection of EBV DNA, RNA, or proteins has been valuable in demonstrating the association of the virus with various malignancies. The polymerase chain reaction has been used to detect EBV DNA in the CSF of some AIDS patients with lymphomas and to monitor the amount of EBV DNA in the blood of patients with lymphoproliferative disease. Culture of EBV from throat washings or blood is not helpful in the diagnosis of acute infection, since EBV commonly persists in the oropharynx and in B cells for the lifetime of the infected individual.

Differential Diagnosis The differential diagnosis of IM and atypical lymphocytosis includes acute infection with cytomegalovirus, *Toxoplasma*, HIV, human herpesvirus 6, and hepatitis viruses as well as drug hypersensitivity reactions. Cytomegalovirus is the most common cause of heterophile-negative mononucleosis, usually involves olderpatients, and is associated with a lower frequency of sore throat, splenomegaly, and lymphadenopathy than IM due to EBV. Other diseases that share some of the features of IM include rubella, acute infectious lymphocytosis in children, and lymphoma or leukemia.

TREATMENT

Therapy for IM consists of supportive measures, with rest and analgesia. Excessive physical activity during the first month should be avoided to reduce the possibility of splenic rupture. If splenic rupture occurs, splenectomy is required. Glucocorticoid therapy is not indicated for uncomplicated IM and in fact may predispose to bacterial superinfection. Prednisone (40 to 60 mg/d for 2 to 3 days, with subsequent tapering of the dose over 1 to 2 weeks) has been used for the prevention of airway obstruction in patients with severe tonsillar hypertrophy, for autoimmune hemolytic anemia, and for severe thrombocytopenia. Glucocorticoids have also been used in a few selected patients with severe malaise and fever and in patients with severe CNS or cardiac disease.

Acyclovir has had no significant clinical impact on IM in controlled trials. In one study, the combination of acyclovir and prednisolone had no significant effect on the duration of symptoms of IM. Acyclovir, at a dosage of 400 to 800 mg five times daily, has been effective for the treatment of oral hairy leukoplakia (despite common relapses) and some cases of chronic active EBV disease. The posttransplantation EBV lymphoproliferative syndrome (Chap. 117) generally does not respond to antiviral therapy. When possible, therapy should be directed toward reduction of immunosuppression (Table 165-3). Interferon α or antibody to CD20 has been effective in some cases. Infusions of donor lymphocytes are often effective for stem cell transplant recipients, although graft-versus-host disease can occur. Infusions of EBV-specific cytotoxic T cells have been used to prevent EBV lymphoproliferative disease in high-risk settings as well as to treat the disease.

The isolation of patients with IM is unnecessary. Vaccines directed against the major EBV glycoprotein have been effective in animal studies and are undergoing small-scale clinical trials.

166 CYTOMEGALOVIRUS AND HUMAN HERPESVIRUS TYPES 6, 7, AND 8

Martin S. Hirsch

CYTOMEGALOVIRUS

DEFINITION Cytomegalovirus (CMV), which was initially isolated from patients with congenital cytomegalic inclusion disease, is now recognized as an important pathogen in all age groups. In addition to inducing severe birth defects, CMV causes a wide spectrum of disorders in older children and adults, ranging from an asymptomatic, subclinical infection to a mononucleosis syndrome in healthy individuals to disseminated disease in immunocompromised patients. Human CMV is one of several related species-specific viruses that cause similar diseases in various animals. All are associated with the production of characteristic enlarged cells—hence the name *cytomegalovirus*.

CMV is a member of the β-herpesvirus group and has double-strand DNA, four species of mRNA, a protein capsid, and a lipoprotein envelope. Like other herpesviruses, CMV demonstrates icosahedral symmetry, replicates in the cell nucleus, and can cause either a lytic and productive or a latent infection. CMV can be distinguished from other herpesviruses by certain biologic properties, such as host range and type of cytopathology induced. Viral replication is associated with the production of large intranuclear inclusions and smaller cytoplasmic inclusions. The virus appears to replicate in a variety of cell types in vivo; in tissue culture it grows preferentially in fibroblasts. Although there is little evidence that CMV is oncogenic in vivo, the virus does transform fibroblasts in rare instances, and genomic transforming fragments have been identified.

EPIDEMIOLOGY CMV has a worldwide distribution. Approximately 1% of newborns in the United States are infected with CMV, and the percentage is higher in many less-developed countries. Communal living and poor personal hygiene facilitate early spread. Perinatal and early childhood infections are common. Virus may be present in breast milk, saliva, feces, and urine. Transmission of CMV has been identified among young children in day-care centers and has been traced from infected toddler to pregnant mother to developing fetus. When an infected child introduces CMV into a household, 50% of susceptible family members seroconvert within 6 months.

The virus is not readily spread by casual contact but requires repeated or prolonged intimate exposure for transmission. In late adolescence and young adulthood, CMV is often transmitted sexually, and asymptomatic viral carriage in semen or cervical secretions is common. CMV antibody is present at detectable levels in nearly 100% of female prostitutes and sexually active homosexual men. Sexually active adults may harbor several strains of CMV simultaneously. Transfusion of whole blood or certain blood products containing viable leukocytes may also transmit CMV, with a frequency of 0.14 to 10% per unit transfused.

Once infected, an individual probably carries CMV for life. The infection usually remains latent. However, CMV reactivation syndromes develop frequently when T lymphocyte–mediated immunity is compromised—for example, after organ transplantation or in association with lymphoid neoplasms and certain acquired immunodeficiencies (in particular, infection with HIV; Chap. 173). Most primary CMV infections in organ transplant recipients (Chap. 117) result from transmission of the virus in the graft itself. In CMV-seropositive transplant recipients, infection results from reactivation of latent virus or, less commonly, from reinfection by a new strain of CMV. CMV infection may be associated with coronary artery stenosis following heart transplantation or coronary angioplasty, but this association requires further validation.

PATHOGENESIS Congenital CMV infection can result from either primary or reactivation infection of the mother. However, clinical disease in the fetus or newborn is almost exclusively related to primary maternal infection (Table 166-1). The factors determining the severity of congenital infection are unknown; a deficient capacity to produce precipitating antibodies and to mount T cell responses to CMV is associated with relatively severe disease.

Primary infection in late childhood or adulthood is often associated with a vigorous T lymphocyte response that may contribute to the development of a mononucleosis syndrome similar to that observed following Epstein-Barr virus (EBV) infection (Chap. 165). The hallmark of such infection is the appearance of atypical lymphocytes in the peripheral blood; these cells are predominantly activated CD8+ T lymphocytes. Polyclonal activation of B cells by the virus contributes to the development of rheumatoid factors and other autoantibodies during CMV mononucleosis.

Once acquired by symptomatic or asymptomatic primary infection,

TABLE 166-1 *CMV in the Immunocompromised Host*

Population	Risk Factors	Principal Syndromes	Treatment	Prevention
Fetus	Primary maternal infection/early pregnancy	Cytomegalic inclusion disease	None (?ganciclovir)	Avoidance of exposure
Organ transplant recipient	Seropositive donor, seronegative recipient; intensive immunosuppression, particularly with antilymphocyte globulins, cyclosporine	Febrile leukopenia; pneumonia; gastrointestinal disease	Ganciclovir or valganciclovir	Donor matching; CMV immunoglobulin; ganciclovir or high-dose acyclovir
Bone marrow transplant recipient	Graft-vs.-host disease; older age; seropositive recipient; viremia	Pneumonia; gastrointestinal disease	Ganciclovir plus CMV immunoglobulin	Ganciclovir or high-dose acyclovir
Person with AIDS	<100 CD4+ cells per microliter; CMV seropositivity	Retinitis; gastrointestinal disease; neurologic disease	Foscarnet, ganciclovir, valganciclovir, or cidofovir	Oral ganciclovir

CMV persists indefinitely in tissues of the host. The sites of persistent or latent infection probably include multiple cell types and various organs. Transmission following blood transfusion or organ transplantation is due to silent infections in these tissues. Autopsy studies suggest that salivary glands and bowel may be areas of latent infection.

If the host's T cell responses become compromised by disease or by iatrogenic immunosuppression, latent virus can be reactivated to cause a variety of syndromes. Chronic antigenic stimulation in the presence of immunosuppression (for example, following tissue transplantation) appears to be an ideal setting for CMV activation and CMV-induced disease. Certain particularly potent suppressants of T cell immunity, such as antithymocyte globulin, are associated with a high rate of clinical CMV syndromes, which may follow either primary or reactivation infection. CMV may itself contribute to further T lymphocyte hyporesponsiveness, which often precedes superinfection with other opportunistic pathogens, such as *Pneumocystis*. CMV and *Pneumocystis* are frequently found together in immunosuppressed patients with severe interstitial pneumonia.

PATHOLOGY Cytomegalic cells in vivo (presumed to be infected epithelial cells) are two to four times larger than surrounding cells and often contain an 8- to 10-μm intranuclear inclusion that is eccentrically placed and is surrounded by a clear halo, producing an "owl's eye" appearance. Smaller granular cytoplasmic inclusions are demonstrated occasionally. Cytomegalic cells are found in a wide variety of organs, including salivary gland, lung, liver, kidney, intestine, pancreas, adrenal gland, and the central nervous system.

The cellular inflammatory response to infection consists of plasma cells, lymphocytes, and monocyte-macrophages. Granulomatous reactions occasionally develop, particularly in the liver. Immunopathologic reactions may contribute to CMV disease. Immune complexes have been detected in infected infants, sometimes in association with CMV-related glomerulopathies. Immune-complex glomerulopathy has been observed in some CMV-infected patients after renal transplantation.

CLINICAL MANIFESTATIONS ■ Congenital CMV Infection Fetal infections range from inapparent to severe and disseminated. Cytomegalic inclusion disease develops in ~5% of infected fetuses and is seen almost exclusively in infants born to mothers who develop primary infections during pregnancy. Petechiae, hepatosplenomegaly, and jaundice are the most common presenting features (60 to 80% of cases). Microcephaly with or without cerebral calcifications, intrauterine growth retardation, and prematurity are reported in 30 to 50% of cases. Inguinal hernias and chorioretinitis are less common. Laboratory abnormalities include elevated alanine aminotransferase levels, thrombocytopenia, conjugated hyperbilirubinemia, hemolysis, and elevated cerebrospinal fluid protein levels. The prognosis for severely infected infants is poor; the mortality rate is 20 to 30%, and few of the patients who survive escape intellectual or hearing difficulties later in childhood. The differential diagnosis of cytomegalic inclusion disease in infants includes syphilis, rubella, toxoplasmosis, infection with herpes simplex virus or enterovirus, and bacterial sepsis.

Most congenital CMV infections are clinically inapparent at birth. Between 5 and 25% of asymptomatically infected infants develop significant psychomotor, hearing, ocular, or dental abnormalities over the next several years.

Perinatal CMV Infection The newborn may acquire CMV at the time of delivery by passage through an infected birth canal or by postnatal contact with breast milk or other maternal secretions. Approximately 40 to 60% of infants who are breast-fed for >1 month by seropositive mothers become infected. Iatrogenic transmission can also result from neonatal blood transfusion. Screening of blood products before they are transfused into low-birth-weight seronegative infants or into seronegative pregnant women decreases the risk of infection.

The great majority of infants infected at or after delivery remain asymptomatic. However, protracted interstitial pneumonitis has been associated with perinatally acquired CMV infection, particularly in premature infants, and occasionally has been accompanied by infection with *Chlamydia trachomatis*, *Pneumocystis*, or *Ureaplasma urealyticum*. Poor weight gain, adenopathy, rash, hepatitis, anemia, and atypical lymphocytosis may also be found, and CMV excretion often persists for months or years.

CMV Mononucleosis The most common clinical manifestation of CMV infection in normal hosts beyond the neonatal period is a heterophil antibody–negative mononucleosis syndrome. This manifestation may develop spontaneously or may follow the transfusion of leukocyte-containing blood products. Although the syndrome occurs at all ages, it most often involves sexually active young adults. Incubation periods range from 20 to 60 days, and the illness generally lasts for 2 to 6 weeks. Prolonged high fevers, sometimes accompanied by chills, profound fatigue, and malaise, characterize this disorder. Myalgias, headache, and splenomegaly are frequent, but in CMV mononucleosis (as opposed to infectious mononucleosis caused by EBV), exudative pharyngitis and cervical lymphadenopathy are rare. Occasional patients develop rubelliform rashes, often after exposure to ampicillin. Less commonly observed are interstitial or segmental pneumonia, myocarditis, pleuritis, arthritis, and encephalitis. In rare cases, Guillain-Barré syndrome complicates CMV mononucleosis. The characteristic laboratory abnormality is relative lymphocytosis in peripheral blood, with more than 10% atypical lymphocytes. Total leukocyte counts may be low, normal, or markedly elevated. Although significant jaundice is uncommon, serum aminotransferase and alkaline phosphatase levels are often moderately elevated. Heterophil antibodies are absent; however, transient immunologic abnormalities are common and may include the presence of cryoglobulins, rheumatoid factors, cold agglutinins, and antinuclear antibodies. Hemolytic anemia, thrombocytopenia, and granulocytopenia complicate recovery in rare instances.

Most patients recover without sequelae, although postviral asthenia may persist for months. The excretion of CMV in urine, genital secretions, and/or saliva often continues for months or years. Rarely, CMV infection is fatal in immunocompetent hosts; even when such patients survive, they can have recurrent episodes of fever and malaise that are sometimes associated with autonomic nervous system dysfunction (e.g., attacks of sweating or flushing).

CMV Infection in the Immunocompromised Host (See also Table 166-1) CMV appears to be the most common and important viral pathogen complicating organ transplantation (Chap. 117). In recipients of kidney, heart, lung, and liver transplants, CMV induces a variety of syndromes, including fever and leukopenia, hepatitis, pneumonitis, esophagitis, gastritis, colitis, and retinitis. CMV disease may be an independent risk factor for both graft loss and death. The period of maximal risk is between 1 and 4 months after transplantation, although retinitis may be a later complication. Disease likelihood and levels of viral replication generally are greater after primary infection than after reactivation. In addition, molecular studies indicate that seropositive transplant recipients are susceptible to reinfection with donor-derived, genotypically variant CMV, and such infection often results in disease. Reactivation infection, although frequent, is less likely than primary infection to be important clinically. The risk of clinical disease is related to various factors, such as the degree of immunosuppression; the use of antibodies to T cell receptors; and co-infection with other pathogens, such as human herpesvirus type 6. The transplanted organ is particularly vulnerable as a target for CMV infection; thus, there is a tendency for CMV hepatitis to follow liver transplantation and for CMV pneumonitis to follow lung transplantation.

CMV pneumonia occurs in 15 to 20% of bone marrow transplant recipients, with a case-fatality rate of 84 to 88%. The risk is greatest between 5 and 13 weeks after transplantation, and the several risk factors identified include certain types of immunosuppressive therapy, acute graft-versus-host disease, older age, viremia, and seropositivity before transplantation.

CMV is recognized as an important pathogen in patients with advanced HIV infection (Chap. 173), in whom it often causes retinitis or disseminated disease, particularly when peripheral-blood CD4+ cell counts fall below 50 to 100/μL. As treatment for underlying HIV infection has improved, the incidence of serious CMV infections (e.g., retinitis) has decreased. However, institution of highly active antiretroviral regimens sometimes leads to acute flare-ups of CMV retinitis during the first few weeks of therapy.

Syndromes produced by CMV in the immunocompromised host often begin with prolonged fever, malaise, anorexia, fatigue, night sweats, and arthralgias or myalgias. Liver function abnormalities, leukopenia, thrombocytopenia, and atypical lymphocytosis may be observed during these episodes. The development of tachypnea, hypoxia, and unproductive cough signals respiratory involvement. Radiologic examination of the lung often reveals bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly; localized segmental, nodular, or alveolar patterns are less common. The differential diagnosis includes infection with *Pneumocystis*; infections due to other viral, bacterial, or fungal pathogens; pulmonary hemorrhage; and injury secondary to irradiation or to treatment with cytotoxic drugs.

Gastrointestinal CMV involvement may be localized or extensive and almost exclusively affects compromised hosts. Ulcers of the esophagus, stomach, small intestine, or colon may result in bleeding or perforation. CMV infection may lead to exacerbations of underlying ulcerative colitis. Hepatitis occurs frequently, particularly following liver transplantation, and CMV-associated acalculous cholecystitis and adrenalitis have been described.

CMV rarely causes meningoencephalitis in otherwise-healthy individuals. Two forms of CMV encephalitis are seen in patients with AIDS. One resembles HIV encephalitis and presents as progressive dementia; the other is a ventriculoencephalitis characterized by cranial-nerve deficits, nystagmus, disorientation, lethargy, and ventriculomegaly. In immunocompromised patients, CMV can also cause subacute progressive polyradiculopathy, which is often reversible if recognized and treated promptly.

CMV retinitis is an important cause of blindness in immunocompromised patients, particularly patients with advanced AIDS (Chap. 173). Early lesions consist of small, opaque, white areas of granular retinal necrosis that spread in a centrifugal manner and are later accompanied by hemorrhages, vessel sheathing, and retinal edema (Fig. 166-1). CMV retinopathy must be distinguished from that due to other conditions, including toxoplasmosis, candidiasis, and herpes simplex virus infection.

Fatal CMV infections are often associated with persistent viremia and the involvement of multiple organ systems. Progressive pulmonary infiltrates, pancytopenia, hyperamylasemia, and hypotension are characteristic features that are frequently found in conjunction with a terminal bacterial, fungal, or protozoan superinfection. Extensive adrenal necrosis with CMV inclusions is often documented at autopsy, as is CMV involvement of many other organs.

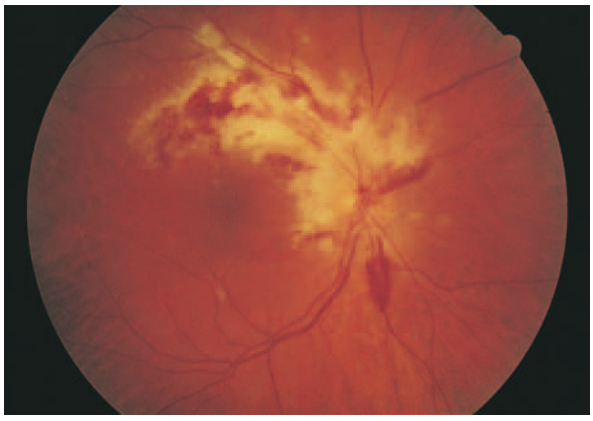

FIGURE 166-1 Cytomegalovirus in a patient with AIDS appears as an arcuate zone of retinitis with hemorrhages and optic disk swelling. Often CMV is confined to the retinal periphery, beyond view of the direct ophthalmoscope.

DIAGNOSIS The diagnosis of CMV infection usually cannot be made reliably on clinical grounds alone. Isolation of the virus or detection of CMV antigens or DNA from appropriate clinical specimens is the preferred diagnostic approach. Virus excretion or viremia is readily detected by culture of appropriate specimens on human fibroblast monolayers. If viral titers are high, as is frequently the case in congenital disseminated infection or in patients with AIDS, characteristic cytopathic effects may be detected within a few days. However, in some situations—such as CMV mononucleosis—viral titers are low, and cytopathic effects may take several weeks to appear. Many laboratories expedite diagnosis with an overnight tissue-culture method (shell vial assay) involving centrifugation and an immunocytochemical detection technique employing monoclonal antibodies to an immediate-early CMV antigen. Isolation of virus from urine or saliva does not, by itself, constitute proof of acute infection, since excretion from these sites may continue for months or years after illness. Detection of CMV viremia is a better predictor of acute infection.

Detection of CMV antigens (pp65) in peripheral-blood leukocytes or of CMV DNA in blood or tissues may hasten the diagnosis of CMV disease in certain populations, including organ transplant recipients and persons with AIDS. Such assays may yield a positive result several days earlier than culture methods. The most sensitive way to detect CMV in blood or other fluids may be by amplifying CMV DNA by polymerase chain reaction (PCR) assays. PCR detection of CMV DNA in blood may predict the risk for disease progression, and PCR detection of CMV DNA in cerebrospinal fluid is useful in the diagnosis of CMV encephalitis or polyradiculopathy.

A variety of serologic assays are available to detect increases in titers of antibody to CMV antigens. An increased antibody level may not be detectable for up to 4 weeks after primary infection, and titers often remain high for years after infection. For this reason, single-sample antibody determinations are of no value in assessing the acuteness of infection. Detection of CMV-specific IgM is sometimes useful in the diagnosis of recent or active infection; circulating rheumatoid factors may result in occasional false-positive IgM tests.

Rx TREATMENT

Several prophylactic measures are useful for the prevention of CMV infection in patients at high risk. The use of blood from seronegative donors or of blood that has been frozen, thawed, and deglycerolized greatly decreases the rate of transfusion-associated transmission of CMV. Similarly, matching of organ or bone marrow transplants by CMV serology, with exclusive use of organs from seronegative donors in seronegative recipients, reduces rates of primary infection following transplantation. Both live attenuated and CMV subunit vaccines have been evaluated, but neither is close to approval for general use.

CMV immune globulin has been reported to reduce rates of CMV-associated syndromes and of fungal or parasitic superinfections among seronegative renal transplant recipients. Studies in bone marrow transplant recipients have produced conflicting results. Prophylactic acyclovir or valacyclovir may reduce rates of CMV infection and disease in certain seronegative renal transplant recipients, although neither drug is effective in the treatment of active CMV disease.

Ganciclovir is a guanosine derivative that has considerably more activity against CMV than its congener acyclovir. After intracellular conversion by a viral phosphotransferase encoded by CMV gene region UL97, ganciclovir triphosphate is a selective inhibitor of CMV DNA polymerase. Several clinical studies have indicated response rates of 70 to 90% among patients with AIDS given ganciclovir for the treatment of CMV retinitis or colitis. In bone marrow transplant recipients with CMV pneumonia, ganciclovir is less effective when given alone, but it elicits a favorable clinical response 50 to 70% of the time when it is combined with CMV immune globulin. Prophy-

lactic or suppressive ganciclovir may be useful in high-risk bone marrow or organ transplant recipients (e.g., those who are CMV-seropositive before transplantation or who are CMV culture–positive afterward). In many patients with AIDS, persistently low CD4+ cell counts, and CMV disease, clinical and virologic relapses occur promptly if treatment with ganciclovir is discontinued. Therefore, prolonged maintenance regimens are recommended for such patients. Resistance to ganciclovir is common among patients treated for >3 months and is usually related to mutations in the CMV UL97 gene.

Valganciclovir is an orally bioavailable prodrug that is rapidly metabolized to ganciclovir in intestinal tissues and the liver. Approximately 60% of an oral dose of valganciclovir is absorbed. An oral valganciclovir dose of 900 mg results in ganciclovir blood levels similar to those obtained with an intravenous ganciclovir dose of 5 mg/kg. Oral valganciclovir appears to be as effective as intravenous ganciclovir for both CMV retinitis induction and maintenance regimens. Furthermore, the adverse-event profiles and rates of resistance development for the two drugs are similar.

Ganciclovir or valganciclovir therapy for CMV retinitis consists of a 14- to 21-day induction course (5 mg/kg intravenously twice daily for ganciclovir or 900 mg twice daily for valganciclovir) followed by a prolonged maintenance regimen. For parenteral maintenance, the ganciclovir dose is 5 mg/kg daily or 6 mg/kg 5 days per week; for oral maintenance, 900 mg of valganciclovir once daily is recommended. Peripheral-blood neutropenia develops in 16 to 29% of treated patients but may be ameliorated by granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor. Discontinuation of maintenance therapy should be considered in patients with AIDS who, while receiving antiretroviral therapy, have a sustained (>6-month) increase in CD4 cell counts to >100–150/μL.

Foscarnet (sodium phosphonoformate) also acts against CMV infection by inhibiting viral DNA polymerase. Because this agent does not require phosphorylation to be active, it is also effective against most ganciclovir-resistant CMV isolates. Foscarnet is less well tolerated than ganciclovir and causes considerable toxicity, including renal dysfunction, hypomagnesemia, hypokalemia, hypocalcemia, genital ulcers, dysuria, nausea, and paresthesia. Moreover, foscarnet administration requires the use of an infusion pump and close clinical monitoring. With aggressive hydration and dose adjustments for renal dysfunction, the toxicity of foscarnet can be reduced. The use of foscarnet should be avoided when a saline load cannot be tolerated (e.g., in cardiomyopathy). The approved induction regimen is 60 mg/kg every 8 h for 2 weeks, although 90 mg/kg every 12 h is equally effective and no more toxic. Maintenance infusions should deliver 90 to 120 mg/kg once daily; no oral preparation is available. Foscarnet-resistant viruses may emerge during extended therapy.

Ganciclovir may also be administered via a slow-release pellet sutured into the eye. Although this intraocular device provides good local protection, contralateral eye disease and disseminated disease are not affected, and early retinal detachment is possible. A combination of intraocular and systemic therapy may be better than the intraocular implant alone.

Cidofovir is a nucleotide analogue with a long intracellular half-life that allows intermittent intravenous administration. Induction regimens of 5 mg/kg weekly for 2 weeks are followed by maintenance regimens of 3 to 5 mg/kg every 2 weeks. Cidofovir can cause severe nephrotoxicity through dose-dependent proximal tubular cell injury; however, this adverse effect can be ameliorated somewhat by saline hydration and probenecid.

It is still not clear whether universal prophylaxis or preemptive therapy in immunocompromised hosts with CMV seropositivity is the preferable approach. For patients with advanced HIV infection (CD4 cell counts of <50/μL), some authorities have advocated prophylaxis with oral ganciclovir or valganciclovir. However, side effects, lack of proven benefit, possible induction of viral resistance, and cost have precluded the wide acceptance of this practice. Similar questions have arisen concerning prophylaxis in organ transplant recipients. As techniques for identifying individuals at risk improve (e.g., quantification of CMV DNA by PCR), it may become possible to preemptively treat those at highest risk to prevent end-organ disease.

HUMAN HERPESVIRUS TYPES 6, 7, AND 8

Human herpesvirus (HHV) type 6 was first isolated in 1986 from peripheral-blood leukocytes of six persons with various lymphoproliferative disorders. The virus has a worldwide distribution, and two genetically distinct variants (HHV-6A and HHV-6B) are now recognized.

Infection with HHV-6 frequently develops during infancy as maternal antibody wanes. Congenital infections have also been described. HHV-6 (mostly variant B) can cause exanthem subitum (roseola infantum), a common illness characterized by fever with subsequent rash. This virus is also a major cause of febrile seizures without rash during infancy. In older age groups, HHV-6 has been associated with mononucleosis syndromes, focal encephalitis, and (in immunocompromised hosts) pneumonitis and disseminated disease. In transplant recipients, HHV-6 infection may be associated with graft dysfunction. As many as 80% of adults are seropositive for HHV-6. The virus may be transmitted by saliva and possibly by genital secretions. Like many other viruses, HHV-6 has been implicated in the pathogenesis of multiple sclerosis, although further study is needed to distinguish between association and etiology.

HHV-7 was isolated in 1990 from T lymphocytes from the peripheral blood of a healthy 26-year-old man. Other isolates have since been obtained. It appears that the virus is frequently acquired during childhood and is commonly present in the saliva of healthy adults. No human disease has yet been definitively linked to HHV-7, although some cases of exanthem subitum, other childhood febrile illnesses, and neurologic syndromes (encephalitis, flaccid paralysis) have been associated with HHV-7 infection. An association has been made between HHV-7 and pityriasis rosea, but further studies must confirm this relationship.

HHV-6, HHV-7, and CMV infections may cluster in transplant recipients, making it difficult to sort out the roles of the various agents in individual clinical syndromes. HHV-6 and HHV-7 appear to be susceptible to ganciclovir and foscarnet, although definitive evidence of clinical responses is lacking.

Unique herpesvirus-like DNA sequences were reported during 1994 and 1995 in tissues derived from Kaposi's sarcoma (KS) and body cavity–based lymphoma occurring in patients with AIDS. The virus from which these sequences were derived has now been cultured and is designated HHV-8 or Kaposi's sarcoma–associated herpesvirus (KSHV). HHV-8, which infects certain B lymphocytes and endothelium-derived spindle cells, appears to be causally related not only to KS but also to a subgroup of AIDS-related B-cell body-cavity-based lymphomas and to multicentric Castleman's disease, a lymphoproliferative disorder of B cells.

Unlike other herpesvirus infections, HHV-8 infection is more common in some geographic areas (e.g., central and southern Africa) than in others (North America, Asia, northern Europe). Concurrent epidemics of HIV-1 and HHV-8 infections among certain populations (e.g., homosexual and bisexual men) in the late 1970s and early 1980s appear to have resulted in the frequent association of AIDS and KS. Both viruses appear to be sexually transmitted, and HHV-8 may be transmitted in saliva as well. Transmission of HHV-8 may also be associated with organ transplantation and injection drug use. Among individuals with intact immunity, asymptomatic infection is the rule, and neoplastic disorders develop only after immunocompromise. Effective antiretroviral therapy for HIV-infected individuals has led to a marked reduction in rates of KS among individuals dually infected with HHV-8 and HIV in resource-rich areas. HHV-8 itself is susceptible in vitro to ganciclovir, foscarnet, and cidofovir, although clinical evidence for benefit of these agents is lacking.

167 MOLLUSCUM CONTAGIOSUM AND OTHER POXVIRUSES, EXCLUDING SMALLPOX VIRUS

Fred Wang

The poxviruses include a large number of related DNA viruses that infect various vertebrate hosts. The poxviruses responsible for infections in humans, along with the main manifestations of these infections, are listed in Table 167-1. Systemic human disease can result from infection with smallpox (variola major) virus, a poxvirus that infects only humans (Chap. 205), or from zoonotic infection with monkeypox virus. Other poxvirus infections cause primarily localized skin disease in humans. Molluscum contagiosum virus (MCV) is an obligate human pathogen that causes distinctive proliferative skin lesions; molluscum contagiosum is the most frequent human disease resulting from poxvirus infection. Exposure to animals infected with other poxviruses can also cause localized skin disease in humans.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is generally a benign disease consisting of pearly, flesh-colored, umbilicated skin lesions 2 to 5 mm in diameter with a characteristic dimple at the center (Fig. 167-1). A relative lack of inflammation and necrosis distinguishes these proliferative lesions from other poxvirus lesions. The lesions occur singly or in clusters. MCV is a human poxvirus that is transmitted by close contact, including sexual intercourse. Swimming pools are a common vector for transmission. Atopy and compromise of skin integrity increase the risk of infection. Lesions may be found anywhere on the body except the palms and soles and may be associated with an eczematous rash. The incubation period ranges from 2 weeks to 6 months, with an average of 2 to 7 weeks. In most cases, the disease is self-limited and regresses spontaneously after 3 to 4 months in immunocompetent hosts. There are no systemic complications, but skin lesions may persist for 3 to 5 years. Molluscum contagiosum develops especially often in association with the advanced stages of HIV infection, with a prevalence of 5 to 18% among HIV-infected patients (Chap. 173). The disease is often more generalized, severe, and persistent in AIDS patients than in other groups, frequently involving the face and upper body. Extensive molluscum contagiosum has also been reported in conjunction with other types of immunodeficiency.

TABLE 167-1 *Poxviruses and Human Infections*

Genus	Species	Human Disease
Orthopoxvirus	Variola[a]	Smallpox, systemic
	Monkeypox	Smallpox-like, systemic
	Vaccinia	Local pox lesion, occasionally systemic
	Cowpox	Local pox lesions
Molluscipoxvirus	Molluscum contagiosum	Molluscum contagiosum, multiple cutaneous lesions
Parapoxvirus	Orf	Contagious pustular dermatitis, local pox lesions
	Pseudocowpox	Milker's nodule, local pox lesions
Yatapoxvirus	Tanapox	Local pox lesions

[a] See Chap. 205.

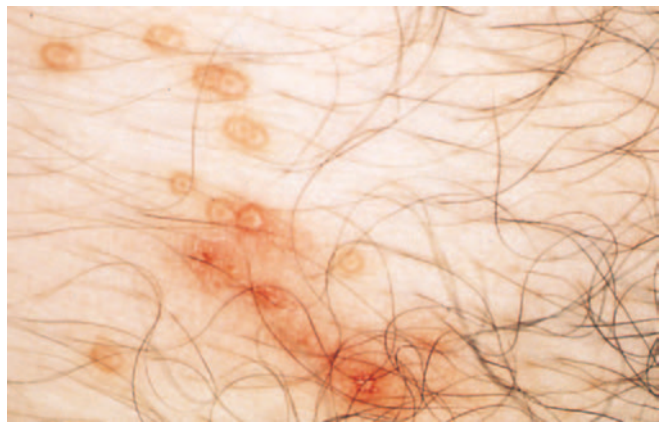

FIGURE 167-1 Molluscum contagiosum is a cutaneous poxvirus infection characterized by multiple umbilicated flesh-colored or hypopigmented papules.

The diagnosis of molluscum contagiosum is typically made by its clinical presentation and can be confirmed by histologic demonstration of the cytoplasmic eosinophilic inclusions, or *molluscum bodies*, that are characteristic of poxvirus replication. MCV cannot be propagated in vitro, but electron microscopy and molecular studies can be used for its identification.

There is no specific systemic treatment for molluscum contagiosum, but a variety of techniques for physical ablation have been used. Molluscum contagiosum may respond to effective control of HIV infection with highly active antiretroviral therapy. Cidofovir displays in vitro activity against many poxviruses, including smallpox virus and MCV, and case reports suggest that parenteral or topical cidofovir may have some efficacy in the treatment of recalcitrant molluscum contagiosum in immunosuppressed hosts.

ZOONOTIC POXVIRUS INFECTIONS

Monkeypox virus naturally infects nonhuman primates in the tropical rain forests of western and central Africa and can infect humans who come into direct contact with infected animals. Human disease is rare and is characterized by a systemic illness and vesicular rash similar to those of variola. A large outbreak of monkeypox occurred between February 1996 and October 1997 in central Africa, with a case-fatality ratio of 3%. The prolonged period of active cases suggested a potential

for sustained person-to-person transmission, and the higher proportion of younger case-patients suggested the possible consequences of discontinued smallpox vaccination. Clinical presentations were occasionally confused with the more common varicella-zoster virus infection. Compared with the lesions of this herpesvirus infection, monkeypox lesions tend to be more uniform (i.e., in the same stage of development at the same time), diffuse, and peripheral in distribution.

The first outbreak of monkeypox infection in the Western Hemisphere occurred in the midwestern United States during May and June 2003. Monkeypox virus infections were diagnosed in several people who had close contact with ill prairie dogs, a Gambian rat, and a rabbit purchased as pets from a common animal distributor. Patients presented most frequently with fever, respiratory symptoms, and lymphadenopathy ~12 days after exposure. The typical vesicular rash developed with or shortly (1 to 3 days) after the fever. The Centers for Disease Control and Prevention recommended smallpox vaccination for persons having close or intimate contact with a documented case of human or animal monkeypox infection in order to reduce the risk of spread. Vaccination can be given up to 14 days after exposure.

Orf virus and pseudocowpox virus are parapoxviruses that naturally infect sheep and cattle. Direct contact with infected animals can result in infections in humans, typically on the hands, with the development of a nodular, highly vascular proliferative lesion that may ulcerate. Human orf virus infection is also called *ecthyma contagiosum*, and human pseudocowpox virus infection causes "milker's nodules." Zoonotic infection with cowpox virus, an orthopoxvirus, causes painful hemorrhagic lesions, mostly on the hands or face, with fever or flulike symptoms and lymphadenitis. Lesions generally resolve in 6 to 8 weeks. Human infection with tanapox virus occurs after contact with infected monkeys. In most cases, a febrile prodrome is followed by eruption of a single nodular lesion on the exposed area, but multiple lesions have also been reported. The lesions are relatively large, often break down to form an ulcer, and resolve in 5 to 6 weeks.

168 PARVOVIRUS

Neil R. Blacklow

DEFINITION The parvovirus group includes several species-specific viruses of animals. One parvovirus, designated B19, is known to be a human pathogen. B19 is a small (diameter, 20 to 25 nm), icosahedral, nonenveloped, single-stranded DNA virus with an outer capsid formed by two structural proteins. Individual virus particles contain DNA strands of positive or negative polarity. The virus is stable and retains infectivity after incubation at 60°C for 16 h. It has failed to grow in conventional cell culture lines and animal model systems but does replicate in vitro in erythroid progenitor cells derived from human bone marrow, umbilical cord, peripheral blood, or fetal liver sources.

During the 1980s, it was discovered that B19 causes a variety of disorders ranging from erythema infectiosum and acute arthropathy in otherwise healthy hosts to transient aplastic crisis and chronic anemia in compromised patients to fetal infection manifested by death or hydrops fetalis. Many of the severe manifestations of B19 viremia relate to the propensity of the virus to infect and lyse erythroid precursor cells in the bone marrow. The name B19 is derived from the code number of the human serum in which the virus was discovered.

PATHOGENESIS Two studies of adult volunteers have provided a basis for understanding the pathogenesis of B19 infection, which has two phases. The first phase is characterized by viremia that develops approximately 6 days after intranasal inoculation of B19 into susceptible individuals who lack serum antibodies to the virus (Fig. 168-1). The viremia lasts about 1 week; its clearance is correlated with the development of IgM antibodies to B19, which remain detectable for up to a few months. IgG antibodies develop several days later and persist indefinitely. Nonspecific systemic symptoms lasting 2 or 3 days occur early during the viremic phase; these symptoms include headache, malaise, myalgia, fever, chills, and pruritus and are accompanied by reticulocytopenia and excretion of the virus from the respiratory tract. Several days after the onset of symptoms, a clinically insignificant decline in hemoglobin concentration is noted; the decreased level is maintained for 7 to 10 days, during which time examination of bone marrow samples reveals a marked depletion of erythroid precursor cells. Transient mild lymphopenia, neutropenia, and a drop in platelet count also may be found. A second phase of illness begins around 17 or 18 days after virus inoculation (after the clearance of viremia, the cessation of viral shedding in throat secretions, and the resolution of reticulocytopenia). This illness mimics erythema infectiosum in adults, with 2 or 3 days of fine maculopapular rash accompanied by arthralgias and arthritis that last another 1 or 2 days. This phase occurs in the presence of rising serum titers of antibody to B19.

The studies just described indicate that B19 disease in the otherwise *healthy host*, manifested by self-limited erythema infectiosum and/or arthropathy, is almost certainly an immune-complex disorder. This concept is supported by the induction of erythema infectiosum through the infusion of immunoglobulins into chronically viremic patients. In contrast, B19 disease in the *compromised host* (chronic hemolytic disease or immunodeficiency syndromes) is often serious, resulting from the destruction by B19 of erythroid precursor cells. Normal hosts can tolerate 7 to 10 days of shutoff of erythropoiesis; however, patients with hemolytic disease who require increased production of erythrocytes do not tolerate erythroid cell destruction and thus usually develop severe transient aplastic crisis. Patients who are immunodeficient may fail to clear B19 viremia, the results being persistent infection of red blood cells and chronic severe anemia. The fetus requires a higher level of red cell production than do adults and has an immature immune system; both these factors could explain B19-induced hydrops fetalis.

B19 binds specifically to a cellular receptor, erythrocyte P antigen; this specific binding explains the tropism of B19 for erythroid progenitor cells, particularly pronormoblasts and normoblasts. The few persons who lack P antigen cannot be infected with B19.

EPIDEMIOLOGY Although B19 infections occur year-round, they appear most commonly as outbreaks of erythema infectiosum in schools during winter and spring months. Between 20 and 60% of children in outbreaks are symptomatic, and many are asymptomatically infected. Seroepidemiologic studies indicate that approximately half of adults possess serum antibodies to B19. Antibody prevalence (reflecting prior exposure and probable immunity to the virus) rises rapidly between the ages of 5 and 18 years and continues to increase with age—a pattern probably indicating ongoing exposure during adulthood. B19 can be detected in throat swabbings, respiratory tract secretions, and serum, and its detection at these sites probably correlates with infectiousness. Patients with transient aplastic crisis have viremia and shed virus and therefore are highly infectious. Their infectivity has been firmly documented as the source of one well-defined nosocomial outbreak of erythema infectiosum among nurses. In contrast, individuals with erythema infectiosum are much less infectious. The usual route of viral transmission under natural conditions is unknown but may be

respiratory or through direct contact. B19 can be transmitted during therapy with clotting factor concentrate and other plasma derivatives, even after exposure to detergent, steam, or dry heat. It has been recommended that polymerase chain reaction (PCR) testing for B19 be used for screening and that potentially infectious material be discarded.

CLINICAL MANIFESTATIONS ■ Erythema Infectiosum

Erythema infectiosum is the most common manifestation of B19 infection and occurs predominantly in children. This entity is also called *fifth disease* because it was classified in the late nineteenth century as the fifth in a series of six exanthems of childhood. Normally a mild illness, erythema infectiosum typically presents as a facial rash with a "slapped-cheek" appearance that is sometimes preceded by low-grade fever. The rash may develop quickly on the arms and legs and usually has a lacy, reticular, erythematous appearance (Fig. 168-2). The trunk, palms, and soles are less commonly involved. Occasionally, the rash appears with maculopapular, morbilliform, vesicular, purpuric, or pruritic characteristics. The typical rash resolves in about a week but can recur intermittently for several weeks, particularly after stress, exercise, exposure to sunlight, bathing, or change in environmental temperature. Arthralgia and arthritis are uncommon among children but are frequent among adults, in whom the rash is often absent or nonspecific, with a lack of the characteristic facial erythema.

Arthropathy B19 infection in adults most commonly presents as acute arthralgias and arthritis, sometimes accompanied by rash. The arthritis is characteristically symmetric and peripheral, involving the wrists, hands, and knees most frequently. It normally resolves in about 3 weeks and is nondestructive. However, a small percentage of patients have arthritis persisting for months or even (in rare cases) for years. It is not known whether these individuals have persistent infection or an abnormal immune response to the virus.

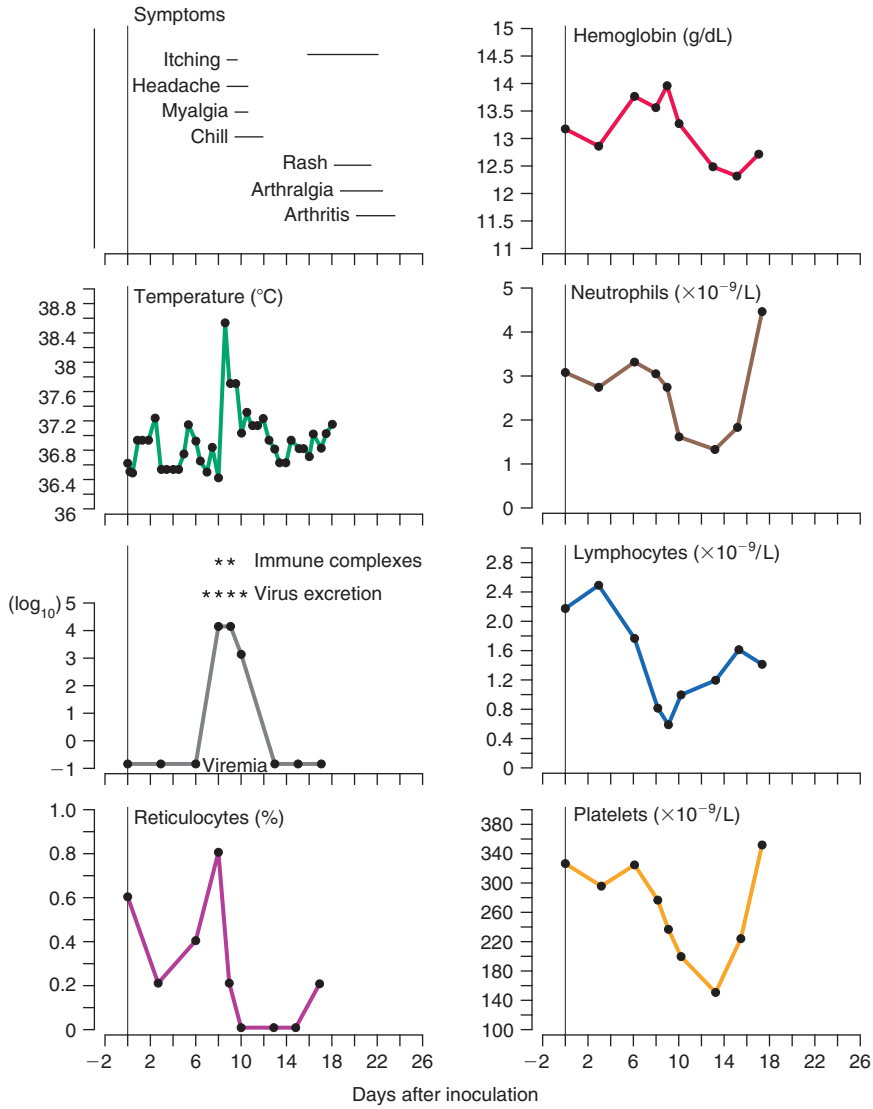

FIGURE 168-1 Features of primary parvovirus infection in a seronegative volunteer inoculated with B19 virus intranasally on day 0. Asterisks indicate days on which immune complexes and virus excretion are detected. Lines refer to the time frame in which the symptoms are detected. *(From Anderson et al, with permission.)*

Transient Aplastic Crisis B19 infection is the cause in most instances of transient aplastic crisis developing suddenly in patients with chronic hemolytic disease. Nearly all hemolytic conditions can be affected by B19 infection, including sickle cell disease, erythrocyte enzyme deficiencies, hereditary spherocytosis, thalassemias, paroxysmal nocturnal hemoglobinuria, and autoimmune hemolysis. B19-induced aplastic crisis can also occur in the setting of acute blood loss. Patients present with weakness, lethargy, pallor, and severe anemia, a syndrome often preceded by a few days of nonspecific symptoms. These patients have intense reticulocytopenia lasting 7 to 10 days, and their bone marrow contains no erythroid precursor cells despite a normal myeloid series. Transient aplastic crisis can produce life-threatening anemia and may require urgent transfusion therapy. Unlike patients with erythema infectiosum or arthropathy, those with transient aplastic crisis are viremic and can readily transmit B19 infection to other people.

Chronic Anemia in Immunodeficient Patients Immunodeficient patients may be unable to eliminate B19 infection, probably because they cannot produce adequate levels of virus-specific IgG antibodies. The result is persistent infection with destruction of erythroid precursor cells in the bone marrow and chronic transfusion-dependent anemia. This condition has been described occasionally in patients with immunodeficiency related to infection with HIV, congenital immunodeficiencies, and acute lymphoblastic leukemia during maintenance chemotherapy as well as in recipients of bone marrow, heart, liver, lung, and kidney transplants. In addition, some cases of idiopathic pure red-cell aplasia probably are caused by persistent B19 infection. B19-induced chronic anemia may be the presenting finding of an otherwise unrecognized immunodeficiency. Chronic anemia may fluctuate in intensity over time and may be cured or controlled by immunoglobulin therapy. Both the spectrum of immunodeficiencies associated with B19-induced chronic anemia and the frequency of the association remain to be determined.

Fetal and Congenital Infection Maternal B19 infections usually do not adversely affect the fetus. More often than not, in fact, the fetus remains uninfected. Therefore, couples in which the pregnant woman is infected should be counseled as to the relatively low risk of fetal infection. It is estimated that fewer than 10% of maternal B19 infections in the first 20 weeks of pregnancy lead to fetal death; when fetal death does occur, it is usually attributable to the development of nonimmune hydrops fetalis, wherein the fetus succumbs to severe anemia and congestive heart failure. In these instances, B19 can be detected in fetal tissues, with predominant infection of erythroblasts. One unconfirmed report suggests that B19 causes late second-trimester and third-trimester nonhydropic fetal deaths. Pregnant women with known exposure to B19 should have their serum monitored for IgM antibodies to the virus and for elevated levels of α-fetoprotein and human chorionic gonadotropin; ultrasonic examinations of the fetus for hydrops should

FIGURE 168-2 Lacy reticular rash of erythema infectiosum (fifth disease).

also be conducted. Some hydropic fetuses survive B19 infection and appear normal at delivery. Rarely, fetal infection with hydrops results in congenital anemia and hypogammaglobulinemia that is unresponsive to immunoglobulin therapy.

Possible Clinical Associations Case studies suggest a link—as yet inconclusive—between B19 and several rheumatic diseases, most notably rheumatoid arthritis but also vasculitis (including polyarteritis, Wegener's granulomatosis, Raynaud's phenomenon, and giant cell arteritis), lupus erythematosus, dermatomyositis, and juvenile rheumatoid arthritis. Other associations include those involving multiple systems: cardiac (myocarditis), hematologic (hemophagocytic syndrome, idiopathic thrombocytopenic purpura), hepatic (fulminant hepatitis), neurologic (meningoencephalitis), renal (glomerulonephritis), and respiratory (pneumonia).

DIAGNOSIS Diagnosis most commonly relies on measurements of B19-specific IgM and IgG antibodies, which can be detected with commercially available immunoassay kits. The virus, its DNA, or its antigens are also detected in the serum or infected tissues of some patients. Acute infection can be proven by B19-compatible symptoms and the presence of IgM antibodies or virus itself, whereas past infection is documented by IgG antibodies. Individuals with erythema infectiosum and acute arthropathy usually have IgM antibodies without detectable virus in serum. Those with transient aplastic crisis may have IgM antibodies but typically possess high titers of virus and its DNA in serum; the bone marrow of these patients shows characteristic giant pronormoblasts and hypoplasia. Immunodeficient patients with anemia often lack readily detectable antibodies but have viral particles and DNA detectable by PCR in serum. Fetal infection may be recognized by hydrops fetalis and the presence of B19 DNA in amniotic fluid or fetal blood in association with maternal IgM antibodies to B19.

TREATMENT

Erythema infectiosum usually requires no treatment; the same is true for many cases of arthropathy. More severe cases of arthritis, particularly those involving chronic symptoms, can be treated with nonsteroidal anti-inflammatory agents. Transient aplastic crisis is usually treated with erythrocyte transfusions. In immunodeficient anemic patients, B19 infection should be treated with commercial intravenous immunoglobulin, which is known to contain IgG antibodies to B19. This therapy controls and may cure B19 infection.

PROPHYLAXIS Prophylaxis of B19 infection with immunoglobulin should be considered for patients with chronic hemolysis or immunodeficiency and for pregnant women. The risk of infection for these persons may be reduced by hand washing before eating or after contact with respiratory or other secretions when B19 is known to be present in a community. Patients with transient aplastic crisis or chronic B19 infection (but not those with erythema infectiosum or arthropathy) pose a serious risk for nosocomial transmission of infection. They should be hospitalized in a private room with contact and respiratory isolation precautions. It is not known whether pre- or postexposure administration of immunoglobulin prevents infection. No vaccine for B19 is currently available; however, noninfectious B19 capsid proteins have been given safely to healthy volunteers, who developed high levels of B19-specific neutralizing antibodies.

169 HUMAN PAPILLOMAVIRUS INFECTIONS

Richard C. Reichman

DEFINITION Human papillomaviruses (HPVs) selectively infect the epithelium of skin and mucous membranes. These infections may be asymptomatic, produce warts, or be associated with a variety of both benign and malignant neoplasias.

ETIOLOGIC AGENT Papillomaviruses are members of the family Papillomaviridae. They are nonenveloped, measure 50 to 55 nm in diameter, have icosahedral capsids composed of 72 capsomeres, and contain a double-stranded circular DNA genome of ~7900 base pairs. The genomic organization of all papillomaviruses is similar and consists of an early (E) region, a late (L) region, and a noncoding upstream regulatory region (URR). Oncogenic HPV types can immortalize human keratinocytes, and this activity has been mapped to products of early genes E6 and E7. E6 protein facilitates the degradation of the p53 tumor-suppressor protein, and E7 protein binds the retinoblastoma gene product and related proteins. The E1 and E2 proteins modulate viral DNA replication and regulate gene expression. The L1 gene codes for the major capsid protein, which makes up 80% of the virion mass. L2 codes for a minor capsid protein. Type-specific conformational antigenic determinants are located on the virion surface. Papillomavirus types are distinguished from one another by the degree of nucleic acid sequence homology. Distinct types share <90% of their DNA sequences in L1. More than 100 HPV types are recognized, and individual types are associated with specific clinical manifestations. For example, HPV-1 causes plantar warts, HPV-6 causes anogenital warts, and HPV-16 infection can produce cervical dysplasia and invasive cervical cancer. HPVs are species-specific and have not been

propagated in tissue culture or in common experimental animals. However, some HPV types have been produced in human tissues implanted in immunodeficient mice.

EPIDEMIOLOGY There are few good studies of the incidence or prevalence of human warts in well-defined populations. Common warts (verruca vulgaris) are found in as many as 25% of some groups and are most prevalent among young children. Plantar warts (verruca plantaris) are also widely prevalent; they occur most often among adolescents and young adults. Condyloma acuminatum (anogenital warts) is one of the most common sexually transmitted diseases in the United States. HPV infection of the uterine cervix produces the squamous cell abnormalities most frequently detected on Papanicolaou smears.

Most anogenital HPV infections are transmitted through direct contact with infectious lesions. However, characteristics of infectious lesions, including appearance, have not been defined, and individuals without obvious disease may transmit infection. Close personal contact is also assumed to play a role in the transmission of most cutaneous warts; the importance of fomites in this setting is not clear. Minor trauma at the site of inoculation may facilitate transmission. Recurrent respiratory papillomatosis in young children is an uncommon disease that is acquired from maternal genital tract infection; in adults, orogenital sexual contact may transmit the disease.

According to a consensus panel gathered by the World Health Organization, a large body of epidemiologic and biologic data has established that some HPV infections cause cervical cancer. For example, >95% of cervical cancers contain HPV DNA of oncogenic (high-risk) types, such as 16, 18, 31, 33, and 45. HPV DNA is also present in the precursor lesions of cervical cancer (cervical intraepithelial neoplasias). Such lesions containing DNA of oncogenic types are more likely to progress than those associated with low-risk HPV types, such as 6 and 11. HPV DNA is transcribed in tumor tissues, and many epidemiologic studies have confirmed a strong relationship between HPV infection (with or without cofactors) and the development of cervical cancer. However, it is important to realize that most cervical HPV infections, including those caused by high-risk types, are self-limited. Infection with specific HPV types has also been associated with squamous cell carcinomas and dysplasias of the penis, anus, vagina, and vulva. In patients with epidermodysplasia verruciformis, squamous cell cancers develop frequently at sites infected with specific HPV types, including 5 and 8.

Serologic studies employing virus-like particles as antigens have demonstrated type-specific antibodies in most patients with HPV genital tract infections.

CLINICAL MANIFESTATIONS The clinical manifestations of HPV infection depend on the location of lesions and the type of virus. Common warts usually occur on the hands as flesh-colored to brown, exophytic, and hyperkeratotic papules. Plantar warts may be quite painful; they can be differentiated from calluses by paring of the surface to reveal thrombosed capillaries. Flat warts (verruca plana) are most common among children and occur on the face, neck, chest, and flexor surfaces of the forearms and legs.

Anogenital warts develop on the skin and mucosal surfaces of external genitalia and perianal areas (Fig. 169-1). Among circumcised men, warts are most commonly found on the penile shaft. Lesions frequently occur at the urethral meatus and may extend proximally. Receptive anal intercourse predisposes both men and women to the development of perianal warts, but such lesions occasionally develop without such a history. In women, warts appear first at the posterior introitus and adjacent labia. They then spread to other parts of the vulva and commonly involve the vagina and cervix. External warts in both sexes are suggestive of the presence of internal lesions, although internal lesions may be present without external warts, particularly among women. The differential diagnosis of anogenital warts includes condylomata lata of secondary syphilis, molluscum contagiosum, hirsutoid papillomatosis (pearly penile papules), fibroepitheliomas, and a variety of benign and malignant mucocutaneous neoplasms. Respiratory papillomatosis in young children, which may be life-threatening, presents as hoarseness, stridor, or respiratory distress. The disease in adults is usually milder.

FIGURE 169-1 Condylomata acuminata are lesions produced by human papillomavirus and in this patient are seen as multiple verrucous papules coalescing into plaques.

Immunosuppressed patients, particularly those undergoing organ transplantation, often develop pityriasis versicolor–like lesions, from which DNA of several HPV types has been extracted. Occasionally, such lesions appear to undergo malignant transformation. Patients infected with HIV frequently have severe clinical manifestations of HPV infection and appear to be at unusually high risk for cervical and anal dysplasia as well as for potentially invasive cancer. HPV disease in patients with HIV infection is difficult to treat and often recurs.

Epidermodysplasia verruciformis is a rare autosomal recessive disease characterized by an inability to control HPV infection. Patients are often infected with unusual HPV types and frequently develop cutaneous squamous cell malignancies, particularly in sun-exposed areas. The lesions resemble flat warts or macules similar to those of pityriasis versicolor.

The complications of warts include itching and occasionally bleeding. In rare cases warts become secondarily infected with bacteria or fungi. Large masses of warts may cause mechanical problems, such as obstruction of the birth canal. Dysplasias of the uterine cervix are generally asymptomatic until frank carcinoma develops. Patients with anogenital HPV disease may develop serious psychological symptoms due to anxiety and depression over this condition.

PATHOGENESIS The incubation period of HPV disease is usually 3 to 4 months (range, 1 month to 2 years). All types of squamous epithelium can be infected by HPV, and the gross and histologic appearances of individual lesions vary with the site of infection and the type of virus. The replication of HPV begins with the infection of basal cells. As cellular differentiation proceeds, HPV DNA replicates and is transcribed. Ultimately, virions are assembled in the nucleus and released when keratinocytes are shed. This process is associated with proliferation of all epidermal layers except the basal layer and produces acanthosis, parakeratosis, and hyperkeratosis. Koilocytes—large round cells with pyknotic nuclei—appear in the granular layer. Histologically normal epithelium may contain HPV DNA, and residual DNA after treatment can be associated with recurrent disease.

Episomal HPV DNA is present in the nuclei of infected cells in benign lesions caused by HPV. However, in severe dysplasias and cancers, HPV DNA is generally integrated, with disruption of the E1/E2 open reading frames. This disruption leads to upregulation of E6 and E7 and subsequent interference with cellular tumor-suppressor proteins.

Host defense responses to HPV infection are incompletely under-

stood, and immune correlates of protection from infection and resolution of disease have not been established. Because patients with defects in cell-mediated immune responses, including transplant recipients and patients with HIV infection, frequently develop severe HPV disease, such responses are probably important for the control of virus replication. Histologic studies demonstrating an epidermal lymphomonocytic infiltrate in resolving warts suggest that local immunity may be of particular importance in the resolution of disease. HPV infection can also elicit a serologic response; antibodies to the viral capsid have been found in sera of patients with anogenital warts, cutaneous warts, and respiratory papillomatosis. Antibodies to E-region proteins, most notably E7, have been detected among patients with cervical carcinoma. In one prophylactic vaccine study, induction of a serologic response was associated with protection from cervical HPV infection in a group of immunocompetent young women.

DIAGNOSIS Most warts that are visible to the naked eye can be diagnosed correctly by history and physical examination alone. The use of a colposcope is invaluable in assessing vaginal and cervical lesions and is helpful in the diagnosis of oral and cutaneous HPV disease as well. Application of 3 to 5% solutions of acetic acid may aid in the visualization of lesions, although the sensitivity and specificity of this procedure are unknown. Papanicolaou smears prepared from cervical or anal scrapings often show cytologic evidence of HPV infection. Persistent or atypical lesions should be biopsied and examined by routine histologic methods. The most sensitive and specific methods of virologic diagnosis entail the use of techniques such as the polymerase chain reaction or the hybrid capture assay to detect HPV nucleic acids and to identify specific virus types. Such tests may be useful in the diagnosis and management of cervical HPV disease, although their utility may vary according to the prevalence of disease and the availability of traditional cytologic and histologic testing. Serologic techniques to diagnose HPV infection are not helpful in individual cases and are not widely available.

Rx TREATMENT (Table 169-1)

Decisions regarding the initiation of therapy should be made with the knowledge that currently available modes of treatment are not completely effective and some have significant side effects. In addition, treatment may be expensive, and many HPV lesions resolve spontaneously. Frequently used therapies include cryosurgery, application of caustic agents, electrodesiccation, surgical excision, and ablation with a laser. Topical antimetabolites such as 5-fluorouracil have also been used. Both failure and recurrence have been well documented with all of these methods of treatment. Cryosurgery is the initial treatment of choice for condyloma acuminatum. Topically applied podophyllum preparations as well as podofilox may also be used. Various interferon preparations have been employed with modest success in the treatment of respiratory papillomatosis and condyloma acuminatum. A topically applied interferon inducer, imiquimod, is also of benefit in the treatment of condyloma acuminatum. The diagnosis and management of anogenital dysplasias and of internal anogenital warts require special skills and resources, and patients with such lesions should be referred to a qualified specialist.

TABLE 169-1 Treatment of External, Exophytic Anogenital Warts

I. Administered by provider
  A. Cryotherapy with liquid nitrogen or cryoprobe weekly
  B. Podophyllin resin, 10–25% weekly for up to 4 weeks
  C. Trichloroacetic acid or bichloroacetic acid, 80–90% weekly
  D. Surgical excision
  E. Other regimens
    1. Intralesionally administered interferon
    2. Laser surgery
II. Administered by patient
  A. Podofilox, 0.5% solution or gel twice daily for 3 days, followed by 4 days without therapy. This cycle may be repeated four times.
  B. Imiquimod, 5% cream 3 times per week for up to 16 weeks

Source: Modified from Centers for Disease Control and Prevention: MMWR 51(RR-6):1, 2002 (*http://www.cdc.gov/mmwr/PDF/RR/RR5106.pdf*).

PREVENTION Apart from the avoidance of contact with infectious lesions, no effective methods for the prevention of HPV infections are available at present. Barrier methods of contraception may be helpful in preventing transmission of condyloma acuminatum and other anogenital HPV-associated diseases. Vaccines consisting of virus-like particles (VLPs) can prevent papillomavirus disease in animal models. One study of an HPV-16 VLP vaccine in uninfected women has shown protection from cervical infection with the homologous virus. More extensive clinical trials of these preparations are likely to demonstrate reductions in rates of cervical HPV disease.

170 COMMON VIRAL RESPIRATORY INFECTIONS AND SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

Raphael Dolin

GENERAL CONSIDERATIONS Acute viral respiratory illnesses are among the most common of human diseases, accounting for one-half or more of all acute illnesses. The incidence of acute respiratory disease in the United States is from 3 to 5.6 cases per person per year. The rates are highest among children <1 year old (6.1 to 8.3 cases per year) and remain high until age 6, when a progressive decrease begins. Adults have 3 to 4 cases per person per year. Morbidity from acute respiratory illnesses accounts for 30 to 50% of time lost from work by adults and for 60 to 80% of time lost from school by children. The use of antibacterial agents to treat viral respiratory infections represents a major source of abuse of that category of drugs.

It has been estimated that two-thirds to three-fourths of cases of acute respiratory illnesses are caused by viruses. More than 200 antigenically distinct viruses from 9 different genera have been reported to cause acute respiratory illness, and it is likely that additional agents will be described in the future. The vast majority of these viral infections involve the upper respiratory tract, but lower respiratory tract disease can also develop, particularly in younger age groups and in certain epidemiologic settings.

The illnesses caused by respiratory viruses traditionally have been divided into multiple distinct syndromes, such as the "common cold," pharyngitis, croup (laryngotracheobronchitis), tracheitis, bronchiolitis, bronchitis, and pneumonia. Each of these general categories of illness has a certain epidemiologic and clinical profile; for example, croup occurs exclusively in very young children and has a characteristic clinical course. Some types of respiratory illness are more likely to be associated with certain viruses (e.g., the common cold with rhinoviruses), while others occupy characteristic epidemiologic niches (e.g., adenovirus infections in military recruits). The syndromes most commonly associated with infections with the major respiratory virus groups are summarized in Table 170-1. Most respiratory viruses clearly have the potential to cause more than one type of respiratory illness, and frequently features of several types of illness are found in the same patient. Moreover, the clinical illnesses induced by these viruses are rarely sufficiently distinctive to permit an etiologic diagnosis on clinical grounds alone, although the epidemiologic setting increases the likelihood that one group of viruses rather than another is involved. In general, laboratory methods must be relied on to establish a specific viral diagnosis.

This chapter reviews viral infections caused by six of the major groups of respiratory viruses: rhinoviruses, coronaviruses, respiratory syncytial viruses, metapneumoviruses, parainfluenza viruses, and adenoviruses. The recent extraordinary outbreaks of lower respiratory tract disease associated with coronaviruses (severe acute respiratory syndrome, or SARS) are also discussed. Influenza viruses, which are a major cause of mortality as well as morbidity, are reviewed in Chap. 171. Herpesviruses, which occasionally cause pharyngitis and which also cause lower respiratory tract disease in immunosuppressed patients, are reviewed in Chap. 163. Enteroviruses, which account for occasional respiratory illnesses during the summer months, are reviewed in Chap. 175.

RHINOVIRUS INFECTIONS

ETIOLOGIC AGENT Rhinoviruses are members of the Picornaviridae family, small (15 to 30 nm) nonenveloped viruses that contain a single-stranded RNA genome. In contrast to other members of the picornavirus family, such as enteroviruses, rhinoviruses are acid-labile and are almost completely inactivated at pH ≤ 3. Rhinoviruses grow preferentially at 33° to 34°C—the temperature of the human nasal passages—rather than at the higher temperature (37°C) of the lower respiratory tract. A total of 102 distinct serotypes of rhinovirus are recognized. Of these serotypes, 91 use intercellular adhesion molecule 1 (ICAM-1) as a cellular receptor and comprise the "major" receptor

TABLE 170-1 *Illnesses Associated with Respiratory Viruses*

	Frequency of Respiratory Syndromes		
Virus	*Most Frequent*	*Occasional*	*Infrequent*
Rhinoviruses	Common cold	Exacerbation of chronic bronchitis and asthma	Pneumonia in children
Coronaviruses[a]	Common cold	Exacerbation of chronic bronchitis and asthma	Pneumonia and bronchiolitis
Respiratory syncytial virus	Pneumonia and bronchiolitis in young children	Common cold in adults	Pneumonia in elderly and immunosuppressed patients
Parainfluenza viruses	Croup and lower respiratory tract disease in young children	Pharyngitis and common cold	Tracheobronchitis in adults; lower respiratory tract disease in immunosuppressed patients
Adenoviruses	Common cold and pharyngitis in children	Outbreaks of acute respiratory disease in military recruits[b]	Pneumonia in children; lower respiratory tract and disseminated disease in immunosuppressed patients
Influenza A viruses	Influenza[c]	Pneumonia and excess mortality in high-risk patients	Pneumonia in healthy individuals
Influenza B viruses	Influenza[c]	Rhinitis and pharyngitis alone	Pneumonia
Enteroviruses	Acute undifferentiated febrile illnesses[d]	Rhinitis and pharyngitis	Pneumonia
Herpes simplex viruses	Gingivostomatitis in children; pharyngotonsillitis in adults	Tracheitis and pneumonia in immunocompromised patients	Disseminated infection in immunocompromised patients
Human metapneumoviruses[e]	—	—	—

[a] SARS-associated coronavirus (SARS-CoV) caused epidemics of pneumonia from November 2002 to July 2003 (see text).
[b] Serotypes 4 and 7.
[c] Fever, cough, myalgia, malaise.
[d] May or may not have a respiratory component.
[e] Newly recognized human metapneumoviruses that cause upper and lower respiratory tract illnesses; their relative frequency has not yet been established.

group, 10 use the low-density lipoprotein receptor and comprise the "minor" receptor group, and 1 uses a sialoprotein cellular receptor.

EPIDEMIOLOGY Rhinoviruses are a major cause of the common cold and have been isolated from 15 to 40% of adults with common cold–like illnesses. Overall rates of infection with rhinoviruses are higher among infants and young children and decrease with increasing age. Rhinovirus infections occur throughout the year, with seasonal peaks in early fall and spring in temperate climates. These infections are most often introduced into families by preschool or grade-school children <6 years old. Between 25 and 70% of initial illnesses in family settings are followed by secondary cases, with the highest attack rates among the youngest siblings at home. Attack rates also increase with family size.

Rhinoviruses appear to spread through direct contact with infected secretions, usually respiratory droplets. In some studies of volunteers, transmission was most efficient by hand-to-hand contact, with subsequent self-inoculation of the conjunctival or nasal mucosa. In other studies, transmission by large- or small-particle aerosol was demonstrated. Virus can also be recovered from plastic surfaces inoculated 1 to 3 h previously; this observation suggests that environmental surfaces contribute to transmission. In studies of married couples in which neither partner had detectable serum antibody, transmission was associated with prolonged contact (≥122 h) during a 7-day period. Transmission was infrequent unless virus was recoverable from the donor's hands and nasal mucosa, at least 1000 $TCID_{50}$ of virus was present in nasal washes from the donor, and the donor was at least moderately symptomatic with the "cold." Despite anecdotal observations, exposure to cold temperatures, fatigue, or sleep deprivation has not been associated with increased rates of rhinovirus-induced illness in volunteers, although some studies have suggested that psychologically defined "stress" may contribute to development of symptoms.

Infection with rhinoviruses is worldwide in distribution. By the time they reach adulthood, nearly all individuals have neutralizing antibodies to multiple serotypes, although the prevalence of antibody to any one serotype varies widely. Multiple serotypes circulate simultaneously, and generally no single serotype or group of serotypes has been more prevalent than the others.

PATHOGENESIS Rhinoviruses infect cells through attachment to specific cellular receptors; as mentioned above, most serotypes attach to ICAM-1, while a few use the low-density lipoprotein receptor. Relatively limited information is available on the histopathology and pathogenesis of acute rhinovirus infections in humans. Examination of biopsy specimens obtained during experimentally induced and naturally occurring illness indicates that the nasal mucosa is edematous, is often hyperemic, and—during acute illness—is covered by a mucoid discharge. There is a mild infiltrate with inflammatory cells, including neutrophils, lymphocytes, plasma cells, and eosinophils. Mucus-secreting glands in the submucosa appear hyperactive; the nasal turbinates are engorged, a condition that may lead to obstruction of nearby openings of sinus cavities. Several mediators, such as bradykinin, lysylbradykinin, prostaglandins, histamine, and interleukins 1, 6, and 8, have been linked to the development of signs and symptoms in rhinovirus-induced colds.

The incubation period for rhinovirus illness is short, generally 1 or 2 days. Virus shedding coincides with the onset of illness or may begin shortly before symptoms develop. The mechanisms of immunity to rhinovirus are not well worked out. In some studies, the presence of homotypic antibody has been associated with significantly reduced rates of subsequent infection and illness, but data conflict regarding the relative importance of serum and local antibody in protection from rhinovirus infection.

CLINICAL MANIFESTATIONS The most common clinical manifestations of rhinovirus infections are those of the common cold. Illness usually begins with rhinorrhea and sneezing accompanied by nasal congestion. The throat is frequently sore, and in some cases sore throat is the initial complaint. Systemic signs and symptoms, such as malaise and headache, are mild or absent, and fever is unusual. Illness generally lasts for 4 to 9 days and resolves spontaneously without sequelae. In children, bronchitis, bronchiolitis, and bronchopneumonia have been reported; nevertheless, it appears that rhinoviruses are not major causes of lower respiratory tract disease in children. Rhinoviruses may cause exacerbations of asthma and chronic pulmonary disease in adults. The vast majority of rhinovirus infections resolve without sequelae, but complications related to obstruction of the eustachian tubes or sinus ostia, including otitis media or acute sinusitis, can develop. In immunosuppressed patients, particularly bone marrow transplant recipients, severe and even fatal pneumonias have been associated with rhinovirus infections.

DIAGNOSIS Although rhinoviruses are the most frequently recognized cause of the common cold, similar illnesses are caused by a variety of other viruses, and the etiologic diagnosis cannot be made on clinical grounds alone. Rather, rhinovirus infection is diagnosed by isolation of the virus from nasal washes or nasal secretions in tissue culture. In practice, this procedure is rarely undertaken because of the benign, self-limited nature of the illness. In most settings, detection of rhinovirus RNA by polymerase chain reaction (PCR) is more sensitive than that by tissue culture; however, this PCR is largely a research procedure. Given the many serotypes of rhinovirus, diagnosis by serum antibody tests is currently impractical. Likewise, common laboratory tests, such as white cell count and sedimentation rate, are not helpful.

℞ TREATMENT

Rhinovirus infections are generally mild and self-limited, so treatment is not usually necessary. Therapy in the form of first-generation antihistamines and nonsteroidal anti-inflammatory drugs may be beneficial in patients with particularly pronounced symptoms, and an oral decongestant may be added if nasal obstruction is particularly troublesome. Reduction of activity is prudent in instances of significant discomfort or fatigability. Antibacterial agents should be used only if bacterial complications such as otitis media or sinusitis develop. Specific antiviral therapy is not available.

PREVENTION Application of interferon sprays intranasally has been effective in the prophylaxis of rhinovirus infections but is also associated with local irritation of the nasal mucosa. Studies of the prevention of rhinovirus infection by administration of antibodies to ICAM-1 or by the soluble purified receptors themselves have yielded disappointing results. Experimental vaccines to certain rhinovirus serotypes have been generated, but their usefulness is questionable because of the myriad serotypes and the uncertainty about mechanisms of immunity. Thorough hand washing, environmental decontamination, and protection against autoinoculation may help to reduce rates of transmission of infection.

CORONAVIRUS INFECTIONS, INCLUDING SARS

ETIOLOGIC AGENT Coronaviruses are pleomorphic, single-strand RNA viruses that measure 100 to 150 nm in diameter. The name derives from the crownlike appearance produced by the club-shaped projections that stud the viral envelope. Coronaviruses infect a wide variety of animal species and have been divided into three antigenic groups. Previously recognized coronaviruses that infect humans fell into two of these groups (I and II), which are represented by prototype isolates HCoV-229E and HCoV-OC43, respectively. The coronavirus associated with SARS (SARS-CoV) appears to be of a novel and distinct group (Fig. 170-1). To date, the SARS-CoV strains that have been fully sequenced have shown only minimal variation.

In general, human coronaviruses have been difficult to cultivate in vitro, and some strains grow only in human tracheal organ cultures rather than in tissue culture. SARS-CoV is an exception whose ready growth in African green monkey kidney (Vero E6) cells greatly facilitates its study.

EPIDEMIOLOGY Generally, human coronavirus infections are present throughout the world. Seroprevalence studies of strains HCoV-229E and HCoV-OC43 have demonstrated that serum antibodies are acquired early in life and increase in prevalence with advancing age, so that >80% of adult populations have antibodies as measured by en zyme-linked immunosorbent assay (ELISA). Overall, coronaviruses account for 10 to 35% of common colds, depending on the season. Coronavirus infections appear to be particularly prevalent in late fall, winter, and early spring—times when rhinovirus infections are less common.

The epidemic of the coronavirus-associated illness known as SARS apparently began in Guangdong Province of China in November 2002 and possibly originated from contact with semidomesticated animals such as the palm civet or the dog raccoon. These animals are prized as edible delicacies in the area and harbor infections with coronaviruses related to SARS-CoV. Between November 16, 2002, and February 28, 2003, 792 cases of apparent SARS were noted in Guangdong, and it was recognized that health care workers and their contacts accounted for many of the cases. A physician from Guangdong who traveled to Hong Kong to visit his family 5 days after the onset of his illness may represent the index case that introduced SARS into Hong Kong. In March 2003, a large number of cases of severe respiratory disease were reported to the World Health Organization (WHO) from Hong Kong. Many of the patients had had contact with the putative index case, had stayed at the hotel where he resided, or had had contact with secondary cases. At nearly the same time, similar cases were noted in Singapore, Thailand, Vietnam, Taiwan, and Toronto (Canada), initially in travelers from Hong Kong or Guangdong. Ultimately, 8422 cases were identified by WHO in 28 countries of Asia, Europe, and North America, although ~90% of cases occurred in China and Hong Kong. Case-fatality rates varied among the outbreaks, with an overall figure of ~11%. The disease appeared to be somewhat milder in cases in the United States and was clearly less severe among children (see below).

The mechanisms of transmission of SARS are incompletely understood. Clusters of cases suggest that spread may occur by both large and small aerosols and perhaps by the fecal-oral route as well. The outbreak of illness in a large apartment complex in Hong Kong suggested that environmental sources, such as sewage or water, may also play a role in transmission. Some ill individuals appeared to be hyperinfectious ("super-spreaders") and were capable of transmitting infection to 10 to 40 contacts, although most infections resulted in spread either to no one or to up to three individuals.

PATHOGENESIS Coronaviruses that cause the common cold (e.g., strains HCoV-229E and HCoV-OC43) infect ciliated epithelial cells in the nasopharynx. Viral replication leads to damage of ciliated cells and induction of chemokines and interleukins, which result in common-cold symptoms similar to those induced by rhinoviruses.

The pathogenesis of SARS is that of a systemic illness in which virus likely enters and infects cells of the respiratory tract but is also found in the bloodstream, in the urine, and (for up to 2 months) in the stool. Virus persists in the respiratory tract for 2 to 3 weeks, and titers peak ~10 days after the onset of systemic illness. Pulmonary pathology consists of hyaline membrane formation, desquamation of pneumocytes in alveolar spaces, and an interstitial infiltrate consisting of lymphocytes and mononuclear cells. Giant cells are frequently seen, and coronavirus particles have been detected in type II pneumocytes.

CLINICAL MANIFESTATIONS After an incubation period that generally lasts 2 to 7 days (range, 1 to 10 days), SARS usually begins as a systemic illness marked by the onset of fever, which is often accompanied by malaise, headache, and myalgias and is followed in 1 to 2 days by a nonproductive cough and dyspnea. Approximately 25% of patients have diarrhea. Chest x-rays can show a variety of infiltrates, including patchy areas of consolidation—most frequently in peripheral and lower lung fields—or interstitial infiltrates, which can progress to diffuse involvement (Fig. 170-2).

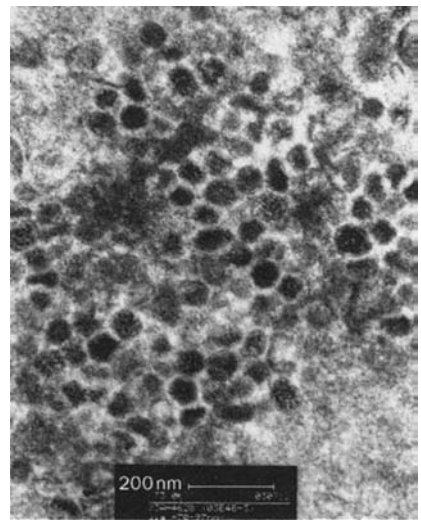

FIGURE 170-1 Electron micrograph of SARS-associated coronavirus (SARS-CoV) isolated in fetal rhesus kidney tissue culture from a lung biopsy sample from a patient with SARS. Viral particles are 55 to 90 mm in diameter. [*Reprinted with permission from Elsevier (JSM Peiris et al., Lancet 361:1319, 2003).*]

In severe cases, respiratory function may worsen during the second week of illness and progress to frank adult respiratory distress syndrome (ARDS) accompanied by multiorgan dysfunction. Risk factors for severity of disease include an age of >50 and comorbidities such as cardiovascular disease, diabetes, or hepatitis. Illness in pregnant women may be particularly severe, but SARS-CoV infection appears to be milder in children than in adults.

The clinical features of common colds caused by human coronaviruses are similar to those of illness caused by rhinoviruses. In studies of volunteers, the mean incubation period of colds induced by coronaviruses (3 days) is somewhat longer than that of illness caused by rhinoviruses, and the duration of illness is somewhat shorter (mean, 6 to 7 days). In some studies, the amount of nasal discharge was somewhat greater in colds induced by coronaviruses than in those induced by rhinoviruses. Coronaviruses other than SARS-CoV have been recovered occasionally from infants with pneumonia and from military recruits with lower respiratory tract disease and have been associated with worsening of chronic bronchitis.

LABORATORY FINDINGS AND DIAGNOSIS Laboratory abnormalities in SARS include lymphopenia, which is present in ~50% of cases and which mostly affects CD4+ T cells but also involves CD8+ T cells and NK cells. Total white blood cell counts are normal or slightly low, and thrombocytopenia may develop as the illness progresses. Elevated serum levels of aminotransferases, creatine kinase, and lactate dehydrogenase have been reported.

The WHO and the Centers for Disease Control and Prevention have developed case definitions for diagnosis of SARS. These definitions include clinical, epidemiologic, and laboratory features, which are being refined as additional information on SARS is gathered. SARS-CoV can be grown from respiratory tract samples by inoculation into Vero E6 tissue culture cells, in which a cytopathic effect can be seen within days. A rapid diagnosis can be made by reverse-transcriptase PCR (RT-PCR) of respiratory tract samples and plasma early in illness and of urine and stool later on. RT-PCR appears to be more sensitive than tissue culture, but only around one-third of cases are positive by PCR at initial presentation. Serum antibodies can be detected by ELISA or immunofluorescence, and nearly all patients develop detectable serum antibodies within 28 days after the onset of illness.

Laboratory diagnosis of coronavirus-induced colds is rarely required. Coronaviruses that cause those illnesses are frequently difficult to cultivate in vitro but can be detected in clinical samples by ELISA or immunofluorescence assays or by RT-PCR for viral RNA. These research procedures can be used to detect coronaviruses in unusual clinical settings.

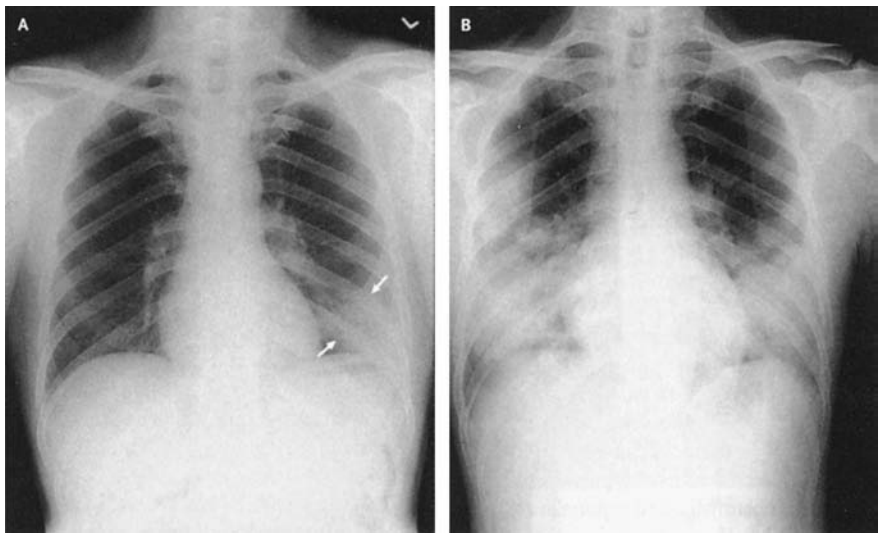

FIGURE 170-2 Chest x-rays of a 46-year-old man with SARS. The left lower lung infiltrate seen initially (*A*) progressed to multiple bilateral opacities (*B*). (*Reprinted with permission from L Lee et al. © 2003 Massachusetts Medical Society.*)

TREATMENT

There is no specific therapy of established efficacy for SARS. Although ribavirin has frequently been used, it has little if any activity against SARS-CoV in vitro, and no beneficial effect on the course of illness has been demonstrated. Because of suggestions that immunopathology may contribute to the disease, glucocorticoids have also been widely used, but their benefit, if any, is likewise unestablished. Supportive care to maintain pulmonary and other organ system functions remains the mainstay of therapy.

The approach to the treatment of common colds caused by coronaviruses is similar to that discussed above for rhinovirus-induced illnesses.

PREVENTION The recognition of SARS led to a worldwide mobilization of public health resources to apply infection control practices and thus to contain the disease. Case definitions were established, travel advisories were proposed, and quarantines were imposed in certain locales. In line with criteria based on the absence of new cases for 30 days (three times the estimated incubation period of 10 days for the disease), all travel advisories have been lifted as of this writing (February 2004). It remains unknown whether the disappearance of cases is a result of the above control measures, whether it is part of a seasonal or otherwise unexplained epidemiologic pattern of SARS, and when or whether SARS might reemerge. The frequent transmission of the disease to health care workers makes it mandatory that strict infection control practices be employed by health care facilities to prevent airborne, droplet, and contact transmission from any suspected cases of SARS in the fruture.

Vaccines have been developed against several animal coronaviruses but not against known human coronaviruses. The emergence of SARS-CoV has emphasized the importance of the development of vaccines against such agents.

RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

ETIOLOGIC AGENT Respiratory syncytial virus (RSV) is a member of the Paramyxoviridae family (genus *Pneumovirus*). RSV, an enveloped virus ~150 to 300 nm in diameter, is so named because its replication in vitro leads to the fusion of neighboring cells into large multinucleated syncytia. The single-stranded RNA genome codes for 11 virus-specific proteins. Viral RNA is contained in a helical nucleocapsid surrounded by a lipid envelope bearing two glycoproteins: the G protein, by which the virus attaches to cells, and the F (fusion) protein, which facilitates entry of the virus into the cell by fusing host and viral membranes. RSV was once considered to be of a single antigenic type, but two distinct groups (A and B) and multiple subtypes within each group have now been described. Antigenic diversity is reflected by differences in the G protein, while the F protein is highly conserved. Both antigenic groups can circulate simultaneously in outbreaks, although the relative proportions of each vary. Infections with group B viruses may be somewhat milder than those with group A viruses.

EPIDEMIOLOGY RSV is the major respiratory pathogen of young children and the foremost cause of lower respiratory disease in infants. Infection with RSV is seen throughout the world in annual epidemics that occur in late fall, winter, or spring and last up to 5 months. The virus is rarely encountered during the summer. Rates of illness are highest among infants 1 to 6 months of age, peaking between 2 and 3 months of age. The attack rates among susceptible infants and children are extraordinarily high, approaching 100% in settings such as day-care centers where large numbers of susceptible infants are present. By age 2, virtually all children will have been infected with RSV. RSV accounts for 20 to 25% of hospital admissions of young infants and children for pneumonia and for up to 75% of cases of bronchiolitis in this age group. It has been estimated that more than half of infants who are at risk will become infected during an RSV epidemic.

In older children and adults, reinfection with RSV is frequent but disease is milder than in infancy. A common cold–like syndrome is the illness most commonly associated with RSV infection in adults. Severe lower respiratory tract disease with pneumonitis can occur in elderly (often institutionalized) adults and in patients with immunocompromising disorders or treatment, including recipients of bone-marrow and solid-organ transplants. RSV is also an important nosocomial pathogen; during an outbreak, it can infect pediatric patients and up to 25 to 50% of the staff on pediatric wards. The spread of virus among families is efficient: up to 40% of siblings may become infected when RSV is introduced into the family setting.

RSV is transmitted primarily by close contact with contaminated fingers or fomites and by self-inoculation of the conjunctiva or anterior nares. Virus may also be spread by coarse aerosols produced by coughing or sneezing, but it is inefficiently spread by fine-particle aerosols. The incubation period is ~4 to 6 days, and virus shedding may last for ≥2 weeks in children and for shorter periods in adults. In immunosuppressed patients, shedding can be prolonged for multiple weeks.

PATHOGENESIS Little is known about the histopathology of minor RSV infection. Severe bronchiolitis or pneumonia is characterized by necrosis of the bronchiolar epithelium and a peribronchiolar infiltrate of lymphocytes and mononuclear cells. Interalveolar thickening and filling of alveolar spaces with fluid can also be found. The correlates of protective immunity to RSV are incompletely understood. Because reinfection occurs frequently and is often associated with illness, the immunity that develops after single episodes of infection clearly is not complete or long-lasting. However, the cumulative effect of multiple reinfections is to temper subsequent disease and to provide some temporary measure of protection against infection. Studies of experimentally induced disease in healthy volunteers indicate that the presence of nasal IgA neutralizing antibody correlates more closely with protection than does the presence of serum antibody. Studies in infants, however, suggest that maternally acquired antibody provides some protection from lower respiratory tract disease, although illness can be severe even in infants who have moderate levels of maternally derived

serum antibody. The relatively severe disease observed in immunosuppressed patients and experimental animal models indicates that cell-mediated immunity is an important mechanism of host defense against RSV. Evidence suggests that class I MHC-restricted cytotoxic T cells may be particularly important in this regard.

CLINICAL MANIFESTATIONS RSV infection leads to a wide spectrum of respiratory illnesses. In infants, 25 to 40% of infections result in lower respiratory tract involvement, including pneumonia, bronchiolitis, and tracheobronchitis. In this age group, illness begins most frequently with rhinorrhea, low-grade fever, and mild systemic symptoms, often accompanied by cough and wheezing. Most patients recover gradually over 1 to 2 weeks. In more severe illness, tachypnea and dyspnea develop, and eventually frank hypoxia, cyanosis, and apnea can ensue. Physical examination may reveal diffuse wheezing, rhonchi, and rales. Chest radiography shows hyperexpansion, peribronchial thickening, and variable infiltrates ranging from diffuse interstitial infiltrates to segmental or lobar consolidation. Illness may be particularly severe in children born prematurely and in those with congenital cardiac disease, bronchopulmonary dysplasia, nephrotic syndrome, or immunosuppression. One study documented a 37% mortality rate for infants with RSV pneumonia and congenital cardiac disease.

In adults, the most common symptoms of RSV infection are those of the common cold, with rhinorrhea, sore throat, and cough. Illness is occasionally associated with moderate systemic symptoms such as malaise, headache, and fever. RSV has also been reported to cause lower respiratory tract disease with fever in adults, including severe pneumonia in the elderly—particularly in nursing-home residents, among whom its impact can rival that of influenza. RSV pneumonia can be a significant cause of morbidity and mortality in patients undergoing bone-marrow and solid-organ transplantation, where case-fatality rates of 20 to 80% have been reported. Sinusitis, otitis media, and worsening of chronic obstructive and reactive airway disease have also been associated with RSV infection.

LABORATORY FINDINGS AND DIAGNOSIS The diagnosis of RSV infection can be suspected on the basis of a suggestive epidemiologic setting—that is, severe illness among infants during an outbreak of RSV in the community. Infections in older children and adults cannot be differentiated with certainty from those caused by other respiratory viruses. The specific diagnosis is established by isolation of RSV from respiratory secretions, such as sputum, throat swabs, or nasopharyngeal washes. Virus is isolated in tissue culture and is identified specifically by immunofluorescence, ELISA, or other immunologic techniques. Rapid viral diagnosis is available by immunofluorescence techniques or ELISA of nasopharyngeal washes, aspirates, and (less satisfactorily) nasopharyngeal swabs. In children, these techniques have sensitivities and specificities of 80 to 95%; they are somewhat less sensitive in specimens from adults. Serologic diagnosis may be made by comparison of acute- and convalescent-phase serum specimens by ELISA, neutralization, or complement-fixation tests. These tests may be useful in older children and adults but are less sensitive in children <4 months of age.

Rx TREATMENT

Treatment of upper respiratory tract RSV infection is aimed primarily at the alleviation of symptoms and is similar to that for other viral infections of the upper respiratory tract. For lower respiratory tract infections, respiratory therapy, including hydration, suctioning of secretions, and administration of humidified oxygen and antibronchospastic agents, is given as needed. In severe hypoxia, intubation and ventilatory assistance may be required. Studies of infants with RSV infection who were given aerosolized ribavirin, a nucleoside analogue active in vitro against RSV, have demonstrated a beneficial effect on the resolution of lower respiratory tract illness, including alleviation of blood-gas abnormalities. Treatment with aerosolized ribavirin is recommended for infants who are severely ill or who are at high risk for complications of RSV infection; included are premature infants and those with bronchopulmonary dysplasia, congenital heart disease, or immunosuppression. The efficacy of ribavirin in older children and adults with RSV pneumonia, including those with immunosuppression, has not been established. Administration of standard immunoglobulin, immunoglobulin with high antibody titers to RSV (RSVIg), or chimeric mouse-human monoclonal IgG against RSV (palivizumab) has not been found to be beneficial in the treatment of RSV pneumonia. Combined therapy with aerosolized ribavirin and palivizumab is being evaluated in the treatment of immunosuppressed patients with RSV pneumonia.

PREVENTION Monthly administration of RSVIg or palivizumab has been approved as prophylaxis against RSV for children <2 years of age who have bronchopulmonary dysplasia or were born prematurely. Considerable interest exists in the development of vaccines against RSV. Inactivated whole-virus vaccines have been ineffective; in one study, they actually potentiated the disease in infants. Other approaches include immunization with purified F and G surface glycoproteins of RSV or generation of stable, live attenuated virus vaccines. In settings such as pediatric wards where rates of transmission are high, barrier methods for the protection of hands and conjunctivae may be useful in reducing the spread of virus.

METAPNEUMOVIRUS INFECTIONS

Human metapneumovirus (HMPV) is a newly described viral respiratory pathogen that has been assigned to the Paramyxoviridae family (genus *Metapneumovirus*). Its morphology and genomic organization are similar to those of avian metapneumoviruses, which are recognized respiratory pathogens of turkeys. HMPV particles may be spherical, filamentous, or pleomorphic in shape and measure 60 to 280 nm in diameter. Particles contain 15-nm projections from the surface that are similar in appearance to those of other Paramyxoviridae. Studies of the RNA genome indicate that there are at least two genetic subgroups or genotypes of HMPV.

HMPV was initially detected in nasal aspirates from 28 children hospitalized with lower respiratory tract illnesses over a 20-year period (1981–2001) in the Netherlands. HMPV infections have since been reported in a wide variety of age groups, including elderly adults, and in both immunocompetent and immunosuppressed hosts. Initial seroepidemiologic studies suggest that HMPV infections are worldwide in distribution, are most frequent during the winter, and occur early in life, so that serum antibodies to the virus are present in nearly all children by the age of 5. The spectrum of clinical illnesses associated with HMPV is similar to that associated with RSV and includes both upper and lower respiratory tract illnesses, such as bronchiolitis, croup, and pneumonia.

HMPV can be detected in nasal aspirates and respiratory secretions by PCR or by growth in rhesus monkey kidney (LLC-MK2) tissue cultures. Serologic diagnosis can be made by ELISA, which utilizes HMPV-infected tissue culture lysates as sources of antigens.

Preliminary studies indicate that HMPV infections account for 4% of respiratory tract illnesses requiring hospitalization of children and for 2 to 4% of acute respiratory illnesses in ambulatory adults and elderly patients. HMPV has been detected in a few cases of SARS, but its role (if any) in these illnesses has not been established. Assessment of the overall significance of HMPV infections awaits the conduct of large-scale epidemiologic studies.

PARAINFLUENZA VIRUS INFECTIONS

ETIOLOGIC AGENT Parainfluenza viruses belong to the Paramyxoviridae family (genera *Respirovirus* and *Rubulavirus*). They are 150 to 200 nm in diameter, are enveloped, and contain a single-stranded RNA genome. The envelope is studded with two glycoproteins: one possesses both hemagglutinin and neuraminidase activity and the other

contains fusion activity. The viral RNA genome is enclosed in a helical nucleocapsid and codes for six structural and several accessory proteins. All four distinct serotypes of parainfluenza viruses share certain antigens with other members of the Paramyxoviridae family, including mumps and Newcastle disease viruses.

EPIDEMIOLOGY Parainfluenza viruses are distributed throughout the world; infection with type 4 (subtypes 4A and 4B) has been reported less widely, probably because type 4 is more difficult to grow in tissue culture. Infection is acquired in early childhood, so that by 5 years of age most children have antibodies to serotypes 1, 2, and 3. Types 1 and 2 cause epidemics during the fall, often occurring in an alternate-year pattern. Type 3 infection has been detected during all seasons of the year, but epidemics have occurred annually in the spring.

The contribution of parainfluenza infections to respiratory disease varies with both the location and the year. In studies conducted in the United States, parainfluenza virus infections have accounted for 4.3 to 22% of respiratory illnesses in children. In adults, parainfluenza infections are generally mild and account for <10% of respiratory illnesses. The major importance of parainfluenza viruses is as a cause of respiratory illness in young children, in whom they rank second only to RSV as causes of lower respiratory tract illness. Parainfluenza virus type 1 is the most frequent cause of croup (laryngotracheobronchitis) in children, while serotype 2 causes similar, although generally less severe, disease. Type 3 is an important cause of bronchiolitis and pneumonia in infants, while illnesses associated with type 4 have generally been mild. Unlike types 1 and 2, type 3 frequently causes illness during the first month of life, when passively acquired maternal antibody is still present. Parainfluenza viruses are spread through infected respiratory secretions, primarily by person-to-person contact and/or by large droplets. The incubation period has varied from 3 to 6 days in experimental infections but may be somewhat shorter for naturally occurring disease in children.

PATHOGENESIS Immunity to parainfluenza viruses is incompletely understood, but evidence suggests that immunity to infections with serotypes 1 and 2 is mediated by local IgA antibodies in the respiratory tract. Passively acquired serum neutralizing antibodies also confer some protection against infection with types 1, 2, and—to a lesser degree—3. Studies in experimental animal models and in immunosuppressed patients suggest that T cell–mediated immunity may also be important in parainfluenza virus infections.

CLINICAL MANIFESTATIONS Parainfluenza virus infections occur most frequently among children, in whom initial infection with serotype 1, 2, or 3 is associated with an acute febrile illness 50 to 80% of the time. Children may present with coryza, sore throat, hoarseness, and cough that may or may not be croupy. In severe croup, fever persists, with worsening coryza and sore throat. A brassy or barking cough may progress to frank stridor. Most children recover over the next 1 or 2 days, although progressive airway obstruction and hypoxia ensue occasionally. If bronchiolitis or pneumonia develops, progressive cough accompanied by wheezing, tachypnea, and intercostal retractions may occur. In this setting, sputum production increases modestly. Physical examination shows nasopharyngeal discharge and oropharyngeal injection, along with rhonchi, wheezes, or coarse breath sounds. Chest x-rays can show air trapping and occasionally interstitial infiltrates.

In older children and adults, parainfluenza infections tend to be milder, presenting most frequently as a common cold or as hoarseness, with or without cough. Lower respiratory tract involvement in older children and adults is uncommon, but tracheobronchitis in adults has been reported. Severe, prolonged, and even fatal parainfluenza infection has been reported in children and adults with severe immunosuppression, including bone-marrow and solid-organ transplant recipients.

LABORATORY FINDINGS AND DIAGNOSIS The clinical syndromes caused by parainfluenza viruses (with the possible exception of croup in young children) are not sufficiently distinctive to be diagnosed on clinical grounds alone. A specific diagnosis is established by detection of virus in respiratory tract secretions, throat swabs, or nasopharyngeal washings. Viral growth in tissue culture is detected either by hemagglutination or by a cytopathic effect. Rapid viral diagnosis may be made by identification of parainfluenza antigens in exfoliated cells from the respiratory tract with immunofluorescence or ELISA, although these techniques appear to be less sensitive than tissue culture. Highly specific and sensitive PCR assays have also been described. Serologic diagnosis can be established by hemagglutination inhibition, complement-fixation, or neutralization tests of acute- and convalescent-phase specimens. However, as frequent heterotypic responses occur among the parainfluenza serotypes, the serotype causing illness often cannot be identified by serologic techniques alone.

Acute epiglottitis caused by *Haemophilus influenzae* type b must be differentiated from viral croup. Influenza A virus is also a common cause of croup during epidemic periods.

TREATMENT

For upper respiratory tract illness, symptoms can be treated as discussed for other viral respiratory tract illnesses. If complications such as sinusitis, otitis, or superimposed bacterial bronchitis develop, appropriate antibiotics should be administered. Mild cases of croup should be treated with bed rest and moist air generated by vaporizers. More severe cases require hospitalization and close observation for the development of respiratory distress. If acute respiratory distress develops, humidified oxygen and intermittent racemic epinephrine are usually administered. Aerosolized or systemically administered glucocorticoids are beneficial; the latter have a more profound effect. No specific antiviral therapy is available, although ribavirin is active against parainfluenza viruses in vitro and anecdotal reports describe its use clinically, particularly in immunosuppressed patients. Effective vaccines against parainfluenza viruses have not been developed.

ADENOVIRUS INFECTIONS

ETIOLOGIC AGENT Adenoviruses are complex DNA viruses that measure 70 to 80 nm in diameter. Human adenoviruses belong to the genus *Mastadenovirus*, which includes 51 serotypes. Adenoviruses have a characteristic morphology consisting of an icosahedral shell composed of 20 equilateral triangular faces and 12 vertices. The protein coat (capsid) consists of hexon subunits with group-specific and type-specific antigenic determinants and penton subunits at each vertex primarily containing group-specific antigens. A fiber with a knob at the end projects from each penton; this fiber contains type-specific and some group-specific antigens. Human adenoviruses have been divided into six subgenera (A through F) on the basis of the homology of DNA genomes and other properties. The adenovirus genome is a linear double-stranded DNA that codes for structural and nonstructural polypeptides. The replicative cycle of adenovirus may result either in lytic infection of cells or in the establishment of a latent infection (primarily involving lymphoid cells). Some adenovirus types can induce oncogenic transformation, and tumor formation has been observed in rodents; however, despite intensive investigation, adenoviruses have not been associated with tumors in humans.

EPIDEMIOLOGY Adenovirus infections most frequently affect infants and children. Infections occur throughout the year but are most common from fall to spring. Adenoviruses account for ~10% of acute respiratory infections in children but for <2% of respiratory illnesses in civilian adults. Nearly 100% of adults have serum antibody to multiple serotypes—a finding indicating that infection is common in childhood. Types 1, 2, 3, and 5 are the most frequent isolates from children. Certain adenovirus serotypes—particularly 4 and 7 but also 3, 14, and 21—are associated with outbreaks of acute respiratory disease in military recruits in winter and spring. Adenovirus infection can

be transmitted by inhalation of aerosolized virus, by inoculation of virus into conjunctival sacs, and probably by the fecal-oral route as well. Type-specific antibody generally develops after infection and is associated with protection, albeit incomplete, against infection with the same serotype.

CLINICAL MANIFESTATIONS In children, adenoviruses cause a variety of clinical syndromes. The most common is an acute upper respiratory tract infection, with prominent rhinitis. On occasion, lower respiratory tract disease, including bronchiolitis and pneumonia, also develops. Adenoviruses, particularly types 3 and 7, cause pharyngoconjunctival fever, a characteristic acute febrile illness of children that occurs in outbreaks, most often in summer camps. The syndrome is marked by bilateral conjunctivitis in which the bulbar and palpebral conjunctivae have a granular appearance. Low-grade fever is frequently present for the first 3 to 5 days, and rhinitis, sore throat, and cervical adenopathy develop. The illness generally lasts for 1 to 2 weeks and resolves spontaneously. Febrile pharyngitis without conjunctivitis has also been associated with adenovirus infection. Adenoviruses have been isolated from cases of whooping cough with or without *Bordetella pertussis*; the significance of adenovirus in that disease is unknown.

In adults, the most frequently reported illness has been acute respiratory disease caused by adenovirus types 4 and 7 in military recruits. This illness is marked by a prominent sore throat and the gradual onset of fever, which often reaches 39°C (102.2°F) on the second or third day of illness. Cough is almost always present, and coryza and regional lymphadenopathy are frequently seen. Physical examination may show pharyngeal edema, injection, and tonsillar enlargement with little or no exudate. If pneumonia has developed, auscultation and x-ray of the chest may indicate areas of patchy infiltration.

Adenoviruses have been associated with a number of non–respiratory tract diseases, including acute diarrheal illness caused by types 40 and 41 in young children and hemorrhagic cystitis caused by types 11 and 21. Epidemic keratoconjunctivitis, caused most frequently by types 8, 19, and 37, has been associated with contaminated common sources such as ophthalmic solutions and roller towels. Adenoviruses have also been implicated in disseminated disease and pneumonia in immunosuppressed patients, including recipients of solid-organ or bone-marrow transplants. In bone-marrow transplant recipients, adenovirus infections have manifested as pneumonia, hepatitis, nephritis, colitis, encephalitis, and hemorrhagic cystitis. In solid-organ transplant recipients, adenovirus infection may involve the organ transplanted (e.g., hepatitis in liver transplants, nephritis in renal transplants) but can disseminate to other organs as well. In patients with AIDS, high-numbered and intermediate adenovirus serotypes have been isolated, usually in the setting of low CD4+ cell counts, but their isolation frequently has not been clearly linked to disease manifestations. Adenovirus nucleic acids have been detected in myocardial cells from patients with "idiopathic" myocardiopathies, and adenoviruses have been suggested as causative agents in some cases.

LABORATORY FINDINGS AND DIAGNOSIS Adenovirus infection should be suspected in the epidemiologic setting of acute respiratory disease in military recruits and in certain of the clinical syndromes (such as pharyngoconjunctival fever or epidemic keratoconjunctivitis) in which outbreaks of characteristic illnesses occur. In most cases, however, illnesses caused by adenovirus infection cannot be differentiated from those caused by a number of other viral respiratory agents and *Mycoplasma pneumoniae*. A definitive diagnosis of adenovirus infection is established by detection of the virus in tissue culture (as evidenced by cytopathic changes) and by specific identification with immunofluorescence or other immunologic techniques. Rapid viral diagnosis can be established by immunofluorescence or ELISA of nasopharyngeal aspirates, conjunctival or respiratory secretions, urine, or stool. Highly sensitive and specific PCR assays or nucleic acid hybridization is also available. Adenovirus types 40 and 41, which have been associated with diarrheal disease in children, require special tissue-culture cells for isolation, and these serotypes are most commonly detected by direct ELISA of stool. Serum antibody rises can be demonstrated by complement-fixation or neutralization tests, ELISA, radioimmunoassay, or (for those adenoviruses that hemagglutinate red cells) hemagglutination inhibition tests.

TREATMENT

Only symptom-based treatment and supportive therapy are available for adenovirus infections, and no clinically useful antiviral compounds have been identified. Ribavirin and cidofovir have activity in vitro against adenoviruses, and anecdotes of their use in disseminated infection have been reported.

PREVENTION Live vaccines have been developed against adenovirus types 4 and 7 and have been used to control illness in military recruits. These vaccines consist of live, unattenuated virus administered in enteric-coated capsules. Infection of the gastrointestinal tract with types 4 and 7 does not cause disease but stimulates local and systemic antibodies that are protective against subsequent acute respiratory disease due to those serotypes. This vaccine has not been produced since 1999, and outbreaks of acute respiratory illness caused by adenovirus types 4 and 7 have emerged again among military recruits. Vaccines prepared from purified subunits of adenovirus are being investigated. Adenoviruses are also being studied as live-virus vectors for the delivery of vaccine antigens and for gene therapy.

171 INFLUENZA

Raphael Dolin

DEFINITION Influenza is an acute respiratory illness caused by infection with influenza viruses. The illness affects the upper and/or lower respiratory tract and is often accompanied by systemic signs and symptoms such as fever, headache, myalgia, and weakness. Outbreaks of illness of variable extent and severity occur nearly every winter. Such outbreaks result in significant morbidity in the general population and in increased mortality rates among certain high-risk patients, mainly as a result of pulmonary complications.

ETIOLOGIC AGENT Influenza viruses are members of the Orthomyxoviridae family, of which influenza A, B, and C viruses constitute three separate genera. The designation of influenza viruses as type A, B, or C is based on antigenic characteristics of the nucleoprotein (NP) and matrix (M) protein antigens. Influenza A viruses are further subdivided (subtyped) on the basis of the surface hemagglutinin (H) and neuraminidase (N) antigens (see below); individual strains are designated according to the site of origin, isolate number, year of isolation, and subtype—for example, influenza A/Moscow/10/99 (H3N2). Influenza A has 15 distinct H and 9 distinct N subtypes, of which only H1, H2, H3, N1, and N2 have been associated with extensive outbreaks of disease in humans. Influenza B and C viruses are similarly designated, but H and N antigens from these viruses do not receive subtype designations, since intratypic variations in influenza B antigens are less extensive than those in influenza A viruses and may not occur with influenza C virus.

Influenza A and B viruses are major human pathogens and the most extensively studied of the Orthomyxoviridae. The type A and type B viruses are morphologically similar. The virions are irregularly shaped spherical particles, 80 to 120 nm in diameter, and have a lipid envelope from the surface of which the H and N glycoproteins project (Fig. 171-1). The hemagglutinin is the site by which virus binds to cell receptors, whereas the neuraminidase degrades the receptor and plays a role in the release of virus from infected cells after replication has taken place. Influenza viruses enter cells by receptor-mediated endocytosis, forming a virus-containing endosome. The viral hemagglutinin mediates fusion of the endosomal membrane with the virus envelope, and viral nucleocapsids are subsequently released into the cytoplasm. Antibodies to the H antigen are the major determinants of immunity to influenza virus, while those to the N antigen limit viral spread and contribute to reduction of the infection. The inner surface of the lipid envelope contains the M proteins M1 and M2, which are involved in stabilization of the lipid envelope and in virus assembly. The virion also contains the NP antigen, which is associated with the viral genome, as well as three polymerase (P) proteins that are essential for transcription and synthesis of viral RNA. Two nonstructural proteins function as an interferon antagonist and posttranscriptional regulator (NS1) and a nuclear export factor (NS2 or NEP).

The genomes of influenza A and B viruses consist of eight single-stranded RNA segments, which code for the structural and nonstructural proteins. Because the genome is segmented, the opportunity for gene reassortment during infection is high; reassortment often occurs during infection of cells with more than one influenza A virus.

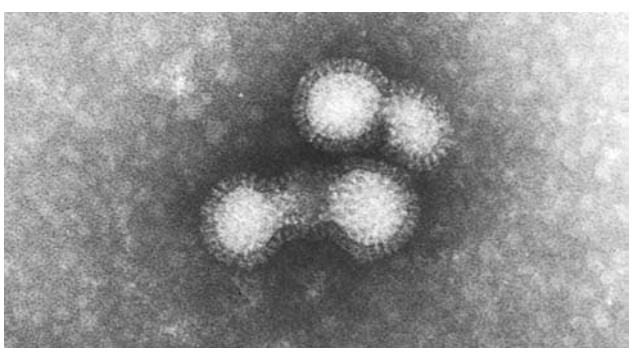

FIGURE 171-1 An electron micrograph of influenza A virus (×140,000).

EPIDEMIOLOGY Influenza outbreaks are recorded virtually every year, although their extent and severity vary widely. Localized outbreaks take place at variable intervals, usually every 1 to 3 years. Except in the past 25 years, global epidemics or pandemics have occurred approximately every 10 to 15 years since the 1918–1919 pandemic (Table 171-1).

The most extensive and severe outbreaks are caused by influenza A viruses, in part because of the remarkable propensity of the H and N antigens of these viruses to undergo periodic antigenic variation. Major antigenic variations, called *antigenic shifts*, may be associated with pandemics and are restricted to influenza A viruses. Minor variations are called *antigenic drifts*. These types of antigenic variation may involve the hemagglutinin alone or both the hemagglutinin and the neuraminidase. An example of an antigenic shift involving both the hemagglutinin and the neuraminidase is that of 1957, when the predominant influenza A virus subtype shifted from H1N1 to H2N2; this shift resulted in a severe pandemic, with an estimated 70,000 excess deaths (i.e., deaths in excess of the number expected without an influenza epidemic) in the United States alone. In 1968, an antigenic shift involving only the hemagglutinin occurred (H2N2 to H3N2); the subsequent pandemic was less severe than that of 1957. In 1977, an H1N1 virus emerged and caused a pandemic that primarily affected younger individuals (i.e., those born after 1957). As can be seen in Table 171-1, H1N1 viruses circulated from 1918 to 1956; thus, individuals born prior to 1957 would be expected to have some degree of immunity to H1N1 viruses. During most outbreaks of influenza A, a single subtype has circulated at a time. However, since 1977, H1N1 and H3N2 viruses have circulated simultaneously, resulting in outbreaks of varying severity. In some outbreaks, influenza B viruses have also circulated simultaneously with influenza A viruses.

The origin of pandemic strains is unknown. Given the marked differences between the primary structures of the hemagglutinins of different subtypes of influenza A viruses (H1, H2, and H3), it seems unlikely that antigenic shifts result from spontaneous mutations in the hemagglutinin gene. Because the segmented genome of influenza viruses may result in high rates of reassortment, it has been suggested that pandemic strains may emerge by reassortment of genes between human and animal influenza A viruses that are known to have a broad host range of infection. There was concern that such reassortment might have occurred in 1997 in Hong Kong, where cases of infection caused by influenza virus A/H5N1 were detected in humans during an extensive outbreak of avian influenza A/H5N1 in poultry. However, only a few cases of A/H5N1 influenza in humans were documented, and the infection did not spread into the community. Recently, H9N2 viruses, which circulate in poultry and swine, have also been associated with limited infections in humans. Influenza B viruses have a much more restricted host range and do not undergo antigenic shifts, although they do undergo antigenic drift.

TABLE 171-1 *Emergence of Antigenic Subtypes of Influenza A Virus Associated with Pandemic or Epidemic Disease*

Years	Subtype	Extent of Outbreak
1889–90	H2N8[a]	Severe pandemic
1900–03	H3N8[a]	?Moderate epidemic
1918–19	H1N1[b] (formerly HswN1)	Severe pandemic
1933–35	H1N1[b] (formerly H0N1)	Mild epidemic
1946–47	H1N1	Mild epidemic
1957–58	H2N2	Severe pandemic
1968–69	H3N2	Moderate pandemic
1977–78[c]	H1N1	Mild pandemic

[a] As determined by retrospective serologic survey of individuals alive during those years ("seroarcheology").
[b] Hemagglutinins formerly designated as Hsw and H0 are now classified as variants of H1.
[c] From this time until the present (2002–2003), viruses of the H1N1 and H3N2 subtypes have circulated either in alternating years or concurrently.

Pandemics provide the most dramatic evidence of the impact of influenza. However, illnesses that occur between pandemics account for greater total mortality and morbidity, albeit over a longer period. From 1972 through the present, influenza has been associated with at least 20,000 excess deaths during more than half of the interpandemic epidemics in the United States; >40,000 influenza-associated deaths occurred in each of six of these epidemics. Influenza A viruses that circulate between pandemics demonstrate antigenic drifts in the H antigen. These antigenic drifts apparently result from point mutations involving the RNA segment that codes for the hemagglutinin, which occurs most frequently in five hypervariable regions. Epidemiologically significant strains—that is, those with the potential to cause widespread outbreaks—exhibit changes in amino acids in at least two of the major antigenic sites in the hemagglutinin molecule. Since two point mutations are unlikely to occur simultaneously, it is believed that antigenic drifts result from point mutations occurring sequentially during the spread of virus from person to person. Antigenic drifts have been reported nearly annually since 1977 for H1N1 viruses and since 1968 for H3N2 viruses.

Influenza A epidemics begin abruptly, peak over a 2- to 3-week period, generally last for 2 to 3 months, and often subside almost as rapidly as they began. The first indication of influenza activity in a community is an increase in the number of children with febrile respiratory illnesses who present for medical attention. This increase is followed by increases in rates of influenza-like illnesses among adults and eventually by an increase in hospital admissions for patients with pneumonia, worsening of congestive heart failure, and exacerbations of chronic pulmonary disease. Rates of absence from work and school also rise at this time. An increase in the number of deaths caused by pneumonia and influenza is generally a late observation in an outbreak. Attack rates have been highly variable from outbreak to outbreak but most commonly are in the range of 10 to 20% of the general population. During the pandemic of 1957, it was estimated that the attack rate of clinical influenza exceeded 50% in urban populations and that an additional 25% or more of individuals in these populations may have been subclinically infected with influenza A virus. Among institutionalized populations and in semiclosed settings with many susceptible individuals, even higher attack rates have been reported.

Epidemics of influenza occur almost exclusively during the winter months in the temperate zones of the northern and southern hemispheres. In those locations, it is highly unusual to detect influenza A virus at other times, although serologic rises or even outbreaks have been noted rarely during warm-weather months. In contrast, influenza virus infections occur throughout the year in the tropics. Where or how influenza A virus persists between outbreaks in temperate zones is unknown. It is possible that influenza A viruses are maintained in the human population on a worldwide basis by person-to-person transmission and that large population clusters support a low level of interepidemic transmission. Alternatively, human strains may persist in animal reservoirs. Convincing evidence to support either explanation is not available. In the modern era, rapid transportation may contribute to the transmission of viruses among widespread geographic locales.

The factors that result in the inception and termination of outbreaks of influenza are incompletely understood. A major determinant of the extent and severity of an outbreak is the level of immunity in the population at risk. With the emergence of an antigenically novel influenza virus to which little or no antibody is present in a community, extensive outbreaks may occur. When the absence of antibody is worldwide, epidemic disease may spread around the globe, resulting in a pandemic. Such pandemic waves can continue for several years, until immunity in the population reaches a high level. In the years following pandemic influenza, antigenic drifts among influenza viruses result in outbreaks of variable severity in populations with high levels of immunity to the pandemic strain that circulated earlier. This situation persists until another antigenically novel pandemic strain emerges. On the other hand, outbreaks sometimes end despite the persistence of a large pool of susceptible individuals in the population.

Occasionally, the emergence of a significantly different antigenic variant will result only in a localized outbreak. The swine influenza outbreak of 1976 in the United States, caused by an A/H1N1 virus antigenically similar to the virus that circulated in 1918–1919, may be an example, although this outbreak may have represented simply the introduction of a swine influenza virus into a crowded human population without spread beyond that setting. The cluster of human infections with influenza A/H5N1 in Hong Kong in 1997 may also be an example of this phenomenon. It has been suggested that certain viruses, such as recently circulating A/H1N1 strains, may be intrinsically less virulent and cause less severe disease than other variants, even in immunologically virgin subjects. If so, then other (undefined) factors besides the level of preexisting immunity must play a role in the epidemiology of influenza.

Influenza B virus causes outbreaks that are generally less extensive and are associated with less severe disease than those caused by influenza A virus. The hemagglutinin and neuraminidase of influenza B virus undergo less frequent and less extensive variation than those of influenza A viruses; this characteristic may account, in part, for the lesser extent of disease. Influenza B outbreaks are seen most frequently in schools and military camps, although outbreaks in institutions in which elderly individuals reside have also been noted on occasion. The most serious complication of influenza B virus infection is Reye's syndrome (Chap. 290). In contrast to influenza A and B viruses, influenza C virus appears to be a relatively minor cause of disease in humans. It has been associated with common cold–like symptoms and occasionally with lower respiratory tract illness. The wide prevalence of serum antibody to this virus indicates that asymptomatic infection may be common.

The morbidity and mortality caused by influenza outbreaks continue to be substantial. Most individuals who die in this setting have underlying diseases that place them at high risk for complications of influenza. Excess hospitalizations for adults and children with high-risk medical conditions have ranged from 56 to 1900 per 100,000 during recent outbreaks of influenza. The most prominent high-risk conditions are chronic cardiac and pulmonary diseases and old age. Mortality among individuals with chronic metabolic, renal, and certain immunosuppressive diseases has also been elevated, although lower than that among patients with chronic cardiopulmonary diseases. The morbidity attributable to influenza in the general population is considerable. It is estimated that interpandemic outbreaks of influenza currently incur annual costs of $12 billion in the United States. If a pandemic were to occur, it is estimated that annual costs would range from $71 to $167 billion for attack rates of 15 to 35%.

PATHOGENESIS AND IMMUNITY The initial event in influenza is infection of the respiratory epithelium with influenza virus acquired from respiratory secretions of acutely infected individuals. In all likelihood, transmission occurs via aerosols generated by coughs and sneezes, although hand-to-hand contact, other personal contact, and even fomite transmission may take place. Experimental evidence suggests that infection by a small-particle aerosol (particle diameter $<10\ \mu$m) is more efficient than that by larger droplets. Initially, viral infection involves the ciliated columnar epithelial cells, but it may also involve other respiratory tract cells, including alveolar cells, mucous gland cells, and macrophages. In infected cells, virus replicates within 4 to 6 h, after which infectious virus is released to infect adjacent or nearby cells. In this way, infection spreads from a few foci to a large number of respiratory cells over several hours. In experimentally induced infection, the incubation period of illness has ranged from 18 to 72 h, depending on the size of the viral inoculum. Histopathologic study reveals degenerative changes, including granulation, vacuolization, swelling, and pyknotic nuclei, in infected ciliated cells. The cells eventually become necrotic and desquamate; in some areas, previously columnar epithelium is replaced by flattened and metaplastic epithelial cells. The severity of illness is correlated with the quantity of virus shed in secretions; thus, the degree of viral replication itself may be an important

factor in pathogenesis. Despite the frequent development of systemic signs and symptoms such as fever, headache, and myalgias, influenza virus has only rarely been detected in extrapulmonary sites (including the bloodstream). Evidence suggests that the pathogenesis of systemic symptoms in influenza may be related to the induction of certain cytokines, particularly tumor necrosis factor α, interferon α, and interleukin 6, in respiratory secretions and in the bloodstream.
