Overall, cholecystectomy is a very successful operation that provides total or near-total relief of preoperative symptoms in 75 to 90% of patients. The most common cause of persistent postcholecystectomy symptoms is an overlooked symptomatic nonbiliary disorder (e.g., reflux esophagitis, peptic ulceration, pancreatitis, or—most often—irritable bowel syndrome). In a small percentage of patients, however, a disorder of the extrahepatic bile ducts may result in persistent symptomatology. These so-called postcholecystectomy syndromes may be due to (1) biliary strictures, (2) retained biliary calculi, (3) cystic duct stump syndrome, (4) stenosis or dyskinesia of the sphincter of Oddi, or (5) bile salt–induced diarrhea or gastritis.

CYSTIC DUCT STUMP SYNDROME In the absence of cholangiographically demonstrable retained stones, symptoms resembling biliary pain or cholecystitis in the postcholecystectomy patient have frequently been attributed to disease in a long (>1 cm) cystic duct remnant (cystic duct stump syndrome). Careful analysis, however, reveals that postcholecystectomy complaints are attributable to other causes in almost all patients in whom the symptom complex was originally thought to result from the existence of a long cystic duct stump. Accordingly, considerable care should be taken to investigate the possible role of other factors in the production of postcholecystectomy symptoms before attributing them to cystic duct stump syndrome.

PAPILLARY DYSFUNCTION, PAPILLARY STENOSIS, SPASM OF THE SPHINCTER OF ODDI, AND BILIARY DYSKINESIA Symptoms of biliary colic accompanied by signs of recurrent, intermittent biliary obstruction may be produced by papillary stenosis, papillary dysfunction, spasm of the sphincter of Oddi, and biliary dyskinesia. Papillary stenosis is thought to result from acute or chronic inflammation of the papilla of Vater or from glandular hyperplasia of the papillary segment. Five criteria have been used to define papillary stenosis: (1) upper abdominal pain, usually RUQ or epigastric; (2) abnormal liver tests; (3) dilatation of the common bile duct upon ERCP examination; (4) delayed (>45 min) drainage of contrast material from the duct; and (5) increased basal pressure of the sphincter of Oddi, a finding that may be of only minor significance. An alternative to ERCP is magnetic resonance cholangiography (MRC) if ERCP and/or biliary manometry are either unavailable or not feasible. In patients with papillary stenosis, quantitative hepatobiliary scintigraphy has revealed delayed transit from the common bile duct to the bowel, ductal dilatation, and abnormal time-activity dynamics. This technique can also be used before and after sphincterotomy to document improvement in biliary emptying. Treatment consists of endoscopic or surgical sphincteroplasty to ensure wide patency of the distal portions of both the bile and pancreatic ducts. The greater the number of the preceding criteria present, the greater the likelihood that a patient does have a degree of papillary stenosis sufficient to justify correction. The factors usually considered as indications for sphincterotomy include (1) prolonged duration of symptoms, (2) lack of response to symptomatic treatment, (3) presence of severe disability, and (4) the patient's choice of sphincterotomy over surgery (given a clear understanding on his or her part of the risks involved in both procedures).

Criteria for diagnosing dyskinesia of the sphincter of Oddi are even more controversial than those for papillary stenosis. Proposed mechanisms include spasm of the sphincter, denervation sensitivity resulting in hypertonicity, and abnormalities of the sequencing or frequency rates of sphincteric contraction waves. When thorough evaluation has failed to demonstrate another cause for the pain, and when cholangiographic and manometric criteria suggest a diagnosis of biliary dyskinesia, medical treatment with nitrites or anticholinergics to attempt pharmacologic relaxation of the sphincter has been proposed. Endoscopic biliary sphincterotomy (EBS) or surgical sphincteroplasty may be indicated in patients who fail to respond to a 2- to 3-month trial of medical therapy, especially if basal sphincter of Oddi pressures are elevated. EBS has become the procedure of choice for removing bile duct stones and for other biliary and pancreatic problems. A study of EBS found four key findings: (1) Dysfunction of the sphincter of Oddi was associated with an increased rise of complications, especially pancreatitis; (2) pancreatitis was more frequent in young patients; (3) difficulty in cannulating the bile duct and the use of "precut" sphincterotomy were important technique-related risk factors for complications; and (4) experience in the volume of procedures proved to be important; endoscopists who perform more than one EBS per week had lower complication rates than endoscopists who performed a smaller number of procedures.

Bile Salt–Induced Diarrhea and Gastritis Postcholecystectomy patients may develop symptoms of dyspepsia, which have been attributed to duodenogastric reflux of bile. However, firm data linking these symptoms to bile gastritis after surgical removal of the gallbladder are lacking. Cholecystectomy induces persistent changes in gut transit, and these changes effect a noticeable modification of bowel habits. Cholecystectomy shortens gut transit time by accelerating passage of the fecal bolus through the colon with marked acceleration in the right colon, thus causing an increase in colonic bile acid output and a shift in bile acid composition toward the more diarrheagenic secondary bile acids. Diarrhea that is severe enough, i.e., three or more watery movements per day, can be classified as postcholecystectomy diarrhea, and this occurs in 5 to 10% of patients undergoing elective cholecystectomy. Treatment with bile acid sequestering agents such as cholestyramine or colestipol is often effective in ameliorating troublesome diarrhea.

THE HYPERPLASTIC CHOLECYSTOSES The term *hyperplastic cholecystoses* is used to denote a group of disorders of the gallbladder characterized by excessive proliferation of normal tissue components.

Adenomyomatosis is characterized by a benign proliferation of gallbladder surface epithelium with glandlike formations, extramural sinuses, transverse strictures, and/or fundal nodule ("adenoma" or "adenomyoma") formation. Outpouchings of mucosa termed *Rokitansky-Aschoff sinuses* may be seen on oral cholecystography in conjunction with hyperconcentration of contrast medium. Characteristic dimpled filling defects also may be seen.

Cholesterolosis is characterized by abnormal deposition of lipid, especially cholesteryl esters within macrophages in the lamina propria of the gallbladder wall. In its diffuse form ("strawberry gallbladder"), the gallbladder mucosa is brick red and speckled with bright yellow flecks of lipid. The localized form shows solitary or multiple "cholesterol polyps" studding the gallbladder wall. Cholesterol stones of the gallbladder are found in nearly half the cases. Cholecystectomy is indicated in both adenomyomatosis and cholesterolosis when symptomatic or when cholelithiasis is present.

The prevalence of gallbladder polyps in the adult population is about 5%, with a marked male predominance. Few significant changes have been found over a 5-year period in asymptomatic patients with gallbladder polyps <10 mm in diameter. Cholecytstectomy is recommended in symptomatic patients, as well as in asymptomatic patients over 50 years of age, or in those whose polyps are >10 mm in diameter or associated with gallstones or polyp growth on serial ultrasonography.

DISEASES OF THE BILE DUCTS

CONGENITAL ANOMALIES ■ Biliary Atresia and Hypoplasia Atretic and hypoplastic lesions of the extrahepatic and major intrahepatic bile ducts are the most common biliary anomalies of clinical relevance encountered in infancy. The clinical picture is one of severe obstructive jaun-

dice during the first month of life, with pale stools. When biliary atresia is suspected on the basis of clinical, laboratory, and imaging findings the diagnosis is confirmed by surgical exploration and operative cholangiography. The diagnosis is confirmed by surgical exploration with operative cholangiography. Approximately 10% of cases of biliary atresia are treatable with roux-en-Y choledochojejunostomy, with the Kasai procedure (hepatic portoenterostomy) being attempted in the remainder in an effort to restore some bile flow. Most patients, even those having successful biliary-enteric anastomoses, eventually develop chronic cholangitis, extensive hepatic fibrosis, and portal hypertension.

Choledochal Cysts Cystic dilatation may involve the free portion of the CBD, i.e., choledochal cyst, or may present as diverticulum formation in the intraduodenal segment. In the latter situation, chronic reflux of pancreatic juice into the biliary tree can produce inflammation and stenosis of the extrahepatic bile ducts leading to cholangitis or biliary obstruction. Because the process may be gradual, approximately 50% of patients present with onset of symptoms after age 10. The diagnosis may be made by ultrasound, abdominal CT, MRC, or cholangiography. Only one-third of patients show the classic triad of abdominal pain, jaundice, and an abdominal mass. Ultrasonographic detection of a cyst separate from the gallbladder should suggest the diagnosis of choledochal cyst, which can be confirmed by demonstrating the entrance of extrahepatic bile ducts into the cyst. Surgical treatment involves excision of the "cyst" and biliary-enteric anastomosis. Patients with choledochal cysts are at increased risk for the subsequent development of cholangiocarcinoma.

Congenital Biliary Ectasia Dilatation of intrahepatic bile ducts may involve either the major intrahepatic radicles (Caroli's disease), the inter- and intralobular ducts (congenital hepatic fibrosis), or both. In Caroli's disease, clinical manifestations include recurrent cholangitis, abscess formation in and around the affected ducts, and, often, gallstone formation within portions of ectatic intrahepatic biliary radicles. Ultrasound, MRC, and CT are of great diagnostic value in demonstrating cystic dilatation of the intrahepatic bile ducts. Treatment with ongoing antibiotic therapy is usually undertaken in an effort to limit the frequency and severity of recurrent bouts of cholangitis. Progression to secondary biliary cirrhosis with portal hypertension, extrahepatic biliary obstruction, cholangiocarcinoma, or recurrent episodes of sepsis with hepatic abscess formation is common.

CHOLEDOCHOLITHIASIS ■ Pathophysiology and Clinical Manifestations Passage of gallstones into the CBD occurs in approximately 10 to 15% of patients with cholelithiasis. The incidence of common duct stones increases with increasing age of the patient, so that up to 25% of elderly patients may have calculi in the common duct at the time of cholecystectomy. Undetected duct stones are left behind in approximately 1 to 5% of cholecystectomy patients. The overwhelming majority of bile duct stones are cholesterol stones formed in the gallbladder, which then migrate into the extrahepatic biliary tree through the cystic duct. Primary calculi arising de novo in the ducts are usually pigment stones developing in patients with (1) hepatobiliary parasitism or chronic, recurrent cholangitis; (2) congenital anomalies of the bile ducts (especially Caroli's disease); (3) dilated, sclerosed, or strictured ducts; or (4) an *MDR3* gene defect leading to impaired biliary phospholipids secretion. Common duct stones may remain asymptomatic for years, may pass spontaneously into the duodenum, or (most often) may present with biliary colic or a complication.

Complications ■ *CHOLANGITIS* Cholangitis may be acute or chronic, and symptoms result from inflammation, which usually requires at least partial obstruction to the flow of bile. Bacteria are present on bile culture in approximately 75% of patients with acute cholangitis early in the symptomatic course. The characteristic presentation of acute cholangitis involves biliary pain, jaundice, and spiking fevers with chills (Charcot's triad). Blood cultures are frequently positive, and leukocytosis is typical. *Nonsuppurative acute cholangitis* is most common and may respond relatively rapidly to supportive measures and to treatment with antibiotics. In *suppurative acute cholangitis*, however, the presence of pus under pressure in a completely obstructed ductal system leads to symptoms of severe toxicity—mental confusion, bacteremia, and septic shock. Response to antibiotics alone in this setting is relatively poor, multiple hepatic abscesses are often present, and the mortality rate approaches 100% unless prompt endoscopic or surgical relief of the obstruction and drainage of infected bile are carried out. Endoscopic management of bacterial cholangitis is as effective as surgical intervention. ERCP with endoscopic sphincterotomy is safe and the preferred initial procedure for both establishing a definitive diagnosis and providing effective therapy.

OBSTRUCTIVE JAUNDICE Gradual obstruction of the CBD over a period of weeks or months usually leads to initial manifestations of jaundice or pruritus without associated symptoms of biliary colic or cholangitis. Painless jaundice may occur in patients with choledocholithiasis, but this manifestation is much more characteristic of biliary obstruction secondary to malignancy of the head of the pancreas, bile ducts, or ampulla of Vater.

In patients whose obstruction is secondary to choledocholithiasis, associated chronic calculous cholecystitis is very common, and the gallbladder in this setting may be relatively indistensible. The absence of a palpable gallbladder in most patients with biliary obstruction from duct stones is the basis for *Courvoisier's law*, i.e., that the presence of a palpably enlarged gallbladder suggests that the biliary obstruction is secondary to an underlying malignancy rather than to calculous disease. Biliary obstruction causes progressive dilatation of the intrahepatic bile ducts as intrabiliary pressures rise. Hepatic bile flow is suppressed, and reabsorption and regurgitation of conjugated bilirubin into the bloodstream lead to jaundice accompanied by dark urine (bilirubinuria) and light-colored (acholic) stools.

CBD stones should be suspected in any patient with cholecystitis whose serum bilirubin level exceeds 85.5 μmol/L (5 mg/dL). The maximum bilirubin level is seldom over 256.5 μmol/L (15.0 mg/dL) in patients with choledocholithiasis unless concomitant hepatic disease or another factor leading to marked hyperbilirubinemia exists. Serum bilirubin levels of 342.0 μmol/L (20 mg/dL) or more should suggest the possibility of neoplastic obstruction. The serum alkaline phosphatase level is almost always elevated in biliary obstruction. A rise in alkaline phosphatase often precedes clinical jaundice and may be the only abnormality in routine liver function tests. There may be a two- to tenfold elevation of serum aminotransferases, especially in association with acute obstruction. Following relief of the obstructing process, serum aminotransferase elevations usually return rapidly to normal, while the serum bilirubin level may take 1 to 2 weeks to return to normal. The alkaline phosphatase level usually falls slowly, lagging behind the decrease in serum bilirubin.

PANCREATITIS The most common associated entity discovered in patients with nonalcoholic acute pancreatitis is biliary tract disease. Biochemical evidence of pancreatic inflammation complicates acute cholecystitis in 15% of cases and choledocholithiasis in over 30%, and the common factor appears to be the passage of gallstones through the common duct. Coexisting pancreatitis should be suspected in patients with symptoms of cholecystitis who develop (1) back pain or pain to the left of the abdominal midline, (2) prolonged vomiting with paralytic ileus, or (3) a pleural effusion, especially on the left side. Surgical treatment of gallstone disease is usually associated with resolution of the pancreatitis.

SECONDARY BILIARY CIRRHOSIS Secondary biliary cirrhosis may complicate prolonged or intermittent duct obstruction with or without recurrent cholangitis. Although this complication may be seen in patients with choledocholithiasis, it is more common in cases of prolonged obstruction from stricture or neoplasm. Once established, secondary biliary cirrhosis may be progressive even after correction of the obstructing process, and increasingly severe hepatic cirrhosis may lead to portal hypertension or to hepatic failure and death. Prolonged biliary obstruc-

tion may also be associated with clinically relevant deficiencies of the fat-soluble vitamins A, D, E, and K.

Diagnosis and Treatment The diagnosis of choledocholithiasis is usually made by cholangiography (Table 292-3), either preoperatively by ERCP or intraoperatively at the time of cholecystectomy. As many as 15% of patients undergoing cholecystectomy will prove to have CBD stones. With the advent of laparoscopic cholecystectomy, the management of CBD stones in the presence of gallstones is gradually being clarified. Preoperative ERCP with endoscopic papillotomy and stone extraction is the preferred approach. It not only provides stone clearance but also defines the anatomy of the biliary tree in relationship to the cystic duct. ERCP is indicated in gallstone patients who have any of the following risk factors: (1) a history of jaundice or pancreatitis, (2) abnormal tests of liver function, and (3) ultrasonographic evidence

TABLE 292-3 *Diagnostic Evaluation of the Bile Ducts*

Diagnostic Advantages	*Diagnostic Limitations*	*Contraindications*	*Complications*	*Comment*
HEPATOBILIARY ULTRASOUND				
Rapid Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts Not limited by jaundice, pregnancy Guidance for fine-needle biopsy	Bowel gas Massive obesity Ascites Barium Partial bile duct obstruction Poor visualization of distal CBD	None	None	Initial procedure of choice in investigating possible biliary tract obstruction
COMPUTED TOMOGRAPHY				
Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts, masses Not limited by jaundice, gas, obesity, ascites High-resolution image Guidance for fine-needle biopsy	Extreme cachexia Movement artifact Ileus Partial bile duct obstruction	Pregnancy	Reaction to iodinated contrast, if used	Indicated for evaluation of hepatic or pancreatic masses Procedure of choice in investigating possible biliary obstruction if diagnostic limitations prevent HBUS
MAGNETIC RESONANCE CHOLANGIOPANCREATOGRAPHY				
Useful modality for visualizing pancreatic and biliary ducts Has excellent sensitivity for bile duct dilatation, biliary stricture, and intraductal abnormalities Can identify pancreatic duct dilatation or stricture, pancreatic duct stenosis, and pancreas divisum	Cannot offer therapeutic intervention High cost	Claustrophobia Certain metals (iron)	None	
PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAM				
Extremely successful when bile ducts dilated Best visualization of proximal biliary tract Bile cytology/culture Percutaneous transhepatic drainage	Nondilated or sclerosed ducts	Pregnancy Uncorrectable coagulopathy Massive ascites ? Hepatic abscess	Bleeding Hemobilia Bile peritonitis Bacteremia, sepsis	Indicated when ERCP is contraindicated or failed
ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAM				
Simultaneous pancreatography Best visualization of distal biliary tract Bile or pancreatic cytology Endoscopic sphincterotomy and stone removal Biliary manometry	Gastroduodenal obstruction ? Roux en Y biliary-enteric anastomosis	Pregnancy ? Acute pancreatitis ? Severe cardiopulmonary disease	Pancreatitis Cholangitis, sepsis Infected pancreatic pseudocyst Perforation (rare) Hypoxemia, aspiration	Cholangiogram of choice in: Absence of dilated ducts ? Pancreatic, ampullary or gastroduodenal disease Prior biliary surgery Endoscopic sphincterotomy a treatment possibility
ENDOSCOPIC ULTRASOUND				
Most sensitive method to detect ampullary stones				Can be used in pregnancy

Note: GB, gallbladder; CBD, common bile duct; HBUS, hepatobiliary ultrasound; ERCP, endoscopic retrograde cholangiopancreatography. Intravenous cholangiography is an obsolete technique because 40% of common duct stones are missed and there is poor resolution even with tomography. There are few indications for its use, especially since other cholangiographic techniques are usually available.

of a dilated CBD or stones in the duct. Alternatively, if intraoperative cholangiography reveals retained stones, postoperative ERCP can be carried out. The need for preoperative ERCP is expected to decrease further as laparoscopic techniques improve.

The widespread use of laparoscopic cholecystectomy and ERCP has decreased the incidence of complicated biliary tract disease and the need for choledocholithotomy and T-tube drainage of the bile ducts. EBS followed by spontaneous passage or stone extraction is the treatment of choice in the management of patients with common duct stones, especially in elderly or poor-risk patients.

TRAUMA, STRICTURES, AND HEMOBILIA Approximately 95% of benign strictures of the extrahepatic bile ducts result from surgical trauma and occur in about 1 in 500 cholecystectomies. Strictures may present with bile leak or abscess formation in the immediate postoperative period or with biliary obstruction or cholangitis as long as 2 years or more following the inciting trauma. The diagnosis is established by percutaneous or endoscopic cholangiography. Endoscopic brushing of biliary strictures may be helpful in establishing the nature of the lesion and is more accurate than bile cytology alone. When positive exfoliative cytology is obtained, the diagnosis of a neoplastic stricture is established. This procedure is especially important in patients with primary sclerosing cholangitis (PSC) who are predisposed to the development of cholangiocarcinomas. Successful operative correction of non-PSC bile duct strictures by a skillful surgeon with duct-to-bowel anastomosis is usually possible, although mortality rates from surgical complications, recurrent cholangitis, or secondary biliary cirrhosis are high.

Hemobilia may follow traumatic or operative injury to the liver or bile ducts, intraductal rupture of a hepatic abscess or aneurysm of the hepatic artery, biliary or hepatic tumor hemorrhage, or mechanical complications of choledocholithiasis or hepatobiliary parasitism. Diagnostic procedures such as liver biopsy, PTC, and transhepatic biliary drainage catheter placement may also be complicated by hemobilia. Patients often present with a classic triad of biliary pain, obstructive jaundice, and melena or occult blood in the stools. The diagnosis is sometimes made by cholangiographic evidence of blood clot in the biliary tree, but selective angiographic verification may be required. Although minor episodes of hemobilia may resolve without operative intervention, surgical ligation of the bleeding vessel is frequently required.

EXTRINSIC COMPRESSION OF THE BILE DUCTS Partial or complete biliary obstruction may sometimes be produced by extrinsic compression of the ducts. The most common cause of this form of obstructive jaundice is carcinoma of the head of the pancreas. Biliary obstruction may also occur as a complication of either acute or chronic pancreatitis or involvement of lymph nodes in the porta hepatis by lymphoma or metastatic carcinoma. The latter should be distinguished from cholestasis resulting from massive replacement of the liver by tumor.

HEPATOBILIARY PARASITISM Infestation of the biliary tract by adult helminths or their ova may produce a chronic, recurrent pyogenic cholangitis with or without multiple hepatic abscesses, ductal stones, or biliary obstruction. This condition is relatively rare but does occur in inhabitants of southern China and elsewhere in Southeast Asia. The organisms most commonly involved are trematodes or flukes, including *Clonorchis sinensis*, *Opisthorchis viverrini* or *O. felineus*, and *Fasciola hepatica*. The biliary tract also may be involved by intraductal migration of adult *Ascaris lumbricoides* from the duodenum or by intrabiliary rupture of hydatid cysts of the liver produced by *Echinococcus* spp. The diagnosis is made by cholangiography and the presence of characteristic ova on stool examination. When obstruction is present, the treatment of choice is laparotomy under antibiotic coverage, with common duct exploration and a biliary drainage procedure. It should be emphasized that in the Far East, one also sees cholangiohepatitis associated with pigment lithiasis, which may, in fact, be more common than cholangitis due to parasites.

SCLEROSING CHOLANGITIS Primary or idiopathic sclerosing cholangitis is characterized by a progressive, inflammatory, sclerosing, and obliterative process affecting the extrahepatic and/or the intrahepatic bile ducts. The disorder occurs in about 70% in association with inflammatory bowel disease, especially ulcerative colitis. It may also be associated (albeit rarely) with multifocal fibrosclerosis syndromes such as retroperitoneal, mediastinal, and/or periureteral fibrosis; Riedel's struma; or pseudotumor of the orbit.

Patients with primary sclerosing cholangitis often present with signs and symptoms of chronic or intermittent biliary obstruction: RUQ abdominal pain, pruritus, jaundice, or acute cholangitis. Late in the course, complete biliary obstruction, secondary biliary cirrhosis, hepatic failure, or portal hypertension with bleeding varices may occur. The diagnosis is usually established by finding multifocal, diffusely distributed strictures with intervening segments of normal or dilated ducts, producing a beaded appearance on cholangiography (Fig. 292-2*D*). The cholangiographic technique of choice in suspected cases is ERCP, since intrahepatic ductal involvement may make PTC difficult. When a diagnosis of sclerosing cholangitis has been established, a search for associated diseases, especially for chronic inflammatory bowel disease, should be carried out.

A recent study describes the natural history and outcome for 305 patients of Swedish descent with primary sclerosing cholangitis; 134 (44%) of the patients were asymptomatic at the time of diagnosis and, not surprisingly, had a significantly higher survival rate with a median follow-up time of 63 months. The independent predictors of a bad prognosis were age, serum bilirubin concentration, and liver histologic changes. Cholangiocarcinoma was found in 24 patients (8%). Inflammatory bowel disease was closely associated with primary sclerosing cholangitis and had a prevalence of 81% in this study population.

Small duct PSC is defined by the presence of chronic cholestasis and hepatic histology consistent with PSC but with normal findings on cholangiography. Small duct PSC is found in about 5% of patients with PSC and may represent an earlier stage of PSC associated with a significantly better long-term prognosis. However, such patients may progress to classic PSC and/or end-stage liver disease with consequent necessity of liver transplantation.

In patients with AIDS, cholangiopancreatography may demonstrate a broad range of biliary tract changes as well as pancreatic duct obstruction and occasionally pancreatitis (Chap. 173). Further, biliary tract lesions in AIDS include infection and cholangiopancreatographic changes similar to those of PSC. Changes noted include: (1) diffuse involvement of intrahepatic bile ducts alone, (2) involvement of both intra- and extrahepatic bile ducts, (3) ampullary stenosis, (4) stricture of the intrapancreatic portion of the common bile duct, and (5) pancreatic duct involvement. Associated infectious organisms include *Cryptosporidium*, *Mycobacterium avium-intracellulare*, cytomegalovirus, *Microsporidia*, and *Isospora*. In addition, acalculous cholecystitis occurs in up to 10% of patients. ERCP sphincterotomy, while not without risk, provides significant pain reduction in patients with AIDS-associated papillary stenosis. Secondary sclerosing cholangitis may occur as a long-term complication of choledocholithiasis, cholangiocarcinoma, operative or traumatic biliary injury, or contiguous inflammatory processes.

Rx TREATMENT

Therapy with cholestyramine may help control symptoms of pruritus, and antibiotics are useful when cholangitis complicates the clinical picture. Vitamin D and calcium supplementation may help prevent the loss of bone mass frequently seen in patients with chronic cholestasis. Glucocorticoids, methotrexate, and cyclosporine have not been shown to be efficacious in PSC. UDCA in high dosage (20 mg/kg) improves serum liver tests, but an effect on survival has not been documented. In cases where high-grade biliary obstruction (dominant strictures) has occurred, balloon dilatation or stenting may be appropriate. Only rarely is surgical intervention indicated. Efforts at biliary-enteric anastomosis or stent placement may, however, be complicated by recurrent

cholangitis and further progression of the stenosing process. The prognosis is unfavorable, with a median survival of 9 to 12 years following the diagnosis, regardless of therapy. Four variables (age, serum bilirubin level, histologic stage, and splenomegaly) predict survival in patients with PSC and serve as the basis for a risk score. PSC is one of the most common indications for liver transplantation.

293 APPROACH TO THE PATIENT WITH PANCREATIC DISEASE

Phillip P. Toskes, Norton J. Greenberger

GENERAL CONSIDERATIONS

Inflammatory disease of the pancreas may be acute or chronic. Although good data exist concerning the frequency of acute pancreatitis (about 5000 new cases per year in the United States, with a mortality rate of about 10%), the number of patients who suffer with recurrent acute pancreatitis or chronic pancreatitis is largely undefined. Only one prospective study on the incidence of chronic pancreatitis is available; it showed an incidence of 8.2 new cases per 100,000 per year and a prevalence of 26.4 cases per 100,000. These numbers probably underestimate considerably the true incidence and prevalence, because non-alcohol-induced pancreatitis was largely ignored. At autopsy, the prevalence of chronic pancreatitis ranges from 0.04 to 5%. The relative inaccessibility of the pancreas to direct examination and the nonspecificity of the abdominal pain associated with pancreatitis make the diagnosis of pancreatitis difficult and usually dependent on elevation of blood amylase levels. Many patients with chronic pancreatitis do not have elevated blood amylase levels. Some patients with chronic pancreatitis develop signs and symptoms of pancreatic exocrine insufficiency, and thus objective evidence for pancreatic disease can be demonstrated. However, there is a very large reservoir of pancreatic exocrine function. More than 90% of the pancreas must be damaged before maldigestion of fat and protein is manifested. Even the secretin stimulation test, which is the most sensitive method of assessing pancreatic exocrine function, is probably abnormal only when >60% of exocrine function has been lost. Noninvasive, indirect tests of pancreatic exocrine function (fecal elastase, serum trypsinogen) are much more likely to give abnormal results in patients with obvious pancreatic disease, i.e., pancreatic calcification, steatorrhea, or diabetes mellitus, than in patients with occult disease. Thus, the number of patients who have subclinical exocrine dysfunction (<90% loss of function) is unknown.

The clinical manifestations of acute and chronic pancreatitis and pancreatic insufficiency are protean. Thus, patients may present with hypertriglyceridemia, vitamin B_{12} malabsorption, hypercalcemia, hypocalcemia, hyperglycemia, ascites, pleural effusions, and chronic abdominal pain with normal blood amylase levels. Indeed, if the clinician considers pancreatitis as a possible diagnosis only when presented with a patient having classic symptoms (i.e., severe, constant epigastric pain that radiates through to the back, along with an elevated blood amylase level), only a minority of patients with pancreatitis will be diagnosed correctly.

As emphasized in Chap. 294, the etiologies as well as the clinical manifestations of pancreatitis are quite varied. Although it is well appreciated that pancreatitis is frequently secondary to alcohol abuse and biliary tract disease, it can also be caused by drugs, trauma, and viral infections and is associated with metabolic and connective tissue disorders. In approximately 30% of patients with acute pancreatitis and 25 to 40% of patients with chronic pancreatitis, the etiology is obscure.

TESTS USEFUL IN THE DIAGNOSIS OF PANCREATIC DISEASE

Several tests have proved of value in the evaluation of pancreatic exocrine function. Examples of specific tests and their usefulness in the diagnosis of acute and chronic pancreatitis are summarized in Table 293-1 and Fig. 293-1. At most institutions, pancreatic function tests are performed if the diagnosis of pancreatic disease remains a possibility after noninvasive tests [ultrasound, computed tomography (CT)] and invasive tests [endoscopic retrograde cholangiopancreatography (ERCP)] have given normal or inconclusive results. In this regard, tests employing *direct* stimulation of the pancreas are the most sensitive.

PANCREATIC ENZYMES IN BODY FLUIDS The serum amylase level is widely used as a screening test for acute pancreatitis in the patient with acute abdominal pain or back pain. A value >65 U/L should raise the question of acute pancreatitis. Levels >130 U/L make the diagnosis more likely, and values greater than three times normal virtually clinch the diagnosis if gut perforation or infarction is excluded. In acute pancreatitis, the serum amylase is usually elevated within 24 h of onset and remains so for 1 to 3 days. Levels return to normal within 3 to 5 days unless there is extensive pancreatic necrosis, incomplete ductal obstruction, or pseudocyst formation. Approximately 85% of patients with acute pancreatitis have an elevated serum amylase level. This index may be normal, however, if (1) there is a delay (of 2 to 5 days) before blood samples are obtained, (2) the underlying disorder is chronic pancreatitis rather than acute pancreatitis, or (3) hypertriglyceridemia is present. Patients with hypertriglyceridemia and proven pancreatitis have been found to have spuriously low levels of amylase and perhaps lipase activity.

The serum amylase is often elevated in other conditions (Table 293-2), in part because the enzyme is found in many organs in addition to the pancreas (salivary glands, liver, small intestine, kidney, fallopian tube) and can be produced by various tumors (carcinomas of the lung, esophagus, breast, and ovary). An assay of serum trypsinogen (performed by several commercial laboratories) is quite helpful in this regard. Since this enzyme is secreted specifically by the pancreas, a normal serum trypsinogen level in a patient with minimal elevation of serum amylase essentially rules out acute pancreatitis. Urinary amylase measurements, including the amylase/creatinine clearance ratio, are no more sensitive or specific than blood amylase levels.

Elevation of ascitic fluid amylase occurs in acute pancreatitis as well as in (1) pancreatogenous ascites due to disruption of the main pancreatic duct or a leaking pseudocyst and (2) other abdominal disorders that simulate pancreatitis (e.g., intestinal obstruction, intestinal infarction, and perforated peptic ulcer). Elevation of pleural fluid am-

TABLE 293-1 *Tests Useful in the Diagnosis of Acute and Chronic Pancreatitis and Pancreatic Tumors*

Test	Principle	Comment
PANCREATIC ENZYMES IN BODY FLUIDS		
Amylase		
1. Serum	Pancreatic inflammation leads to increased enzyme levels	Simple; 20–40% false negatives and positives; reliable if test results are three times the upper limit of normal
2. Urine	Renal clearance of amylase is increased in acute pancreatitis	May be abnormal when serum levels normal; false negatives and positives
3. Ascitic fluid	Disruption of gland or main pancreatic duct leads to increased amylase concentration	Can establish diagnosis of pancreatitis; false positives occur with intestinal obstruction and perforated ulcer
4. Pleural fluid	Exudative pleural effusion with pancreatitis	False positives occur with carcinoma of the lung and esophageal perforation
5. Isoenzymes	P isoamylases arise from the pancreas; S isoamylases are from other sources	More specific than total serum amylase in diagnosis of acute pancreatitis; useful in identifying nonpancreatic causes of hyperamylasemia
Serum lipase	Pancreatic inflammation leads to increased enzyme levels	New methods have greatly simplified determination; positive in 70–85% of cases
Serum trypsinogen	Pancreatic inflammation leads to increased levels	*Elevated* in acute pancreatitis; *decreased* in chronic pancreatitis *with* steatorrhea; normal in chronic pancreatitis *without* steatorrhea and in steatorrhea with normal pancreatic function
STUDIES PERTAINING TO PANCREATIC STRUCTURE		
Radiologic and radionuclide tests		
1. Plain film of the abdomen	Abnormal in acute and chronic pancreatitis	Simple; normal in >50% of cases of both acute and chronic pancreatitis
2. Upper gastrointestinal x-rays	Abnormally thickened duodenal folds; displacement of stomach or widening of duodenal loop suggests a pancreatic mass (inflammatory, neoplastic, cystic)	Simple; frequently normal; largely superseded by US and CT scanning
3. Ultrasonography (US)	Can provide information on edema, inflammation, calcification, pseudocysts, and mass lesions	Simple, noninvasive; sequential studies quite feasible; useful in diagnosis of pseudocyst
4. CT scan	Permits detailed visualization of pancreas and surrounding structures	Useful in the diagnosis of pancreatic calcification, dilated pancreatic ducts, and pancreatic tumors; may not be able to distinguish between inflammatory and neoplastic mass lesions
5. Selective angiography	Can identify pancreatic neoplasms (1) by sheathing of celiac or superior mesenteric branches by tumor or (2) by tumor staining; displacement of vessels by tumor	Indicated (1) in suspected islet cell tumors and (2) before pancreatic or duodenal resection; most reliable features reflect nonresectable pancreatic cancer
6. Endoscopic retrograde cholangiopancreatography (ERCP)	Cannulation of pancreatic and common bile duct permits visualization of pancreatic-biliary ductal system	Provides diagnostic data in 60–85% of cases; differentiation of chronic pancreatitis from pancreatic carcinoma may be difficult
7. Endoscopic ultrasonography (EUS)	High-frequency transducer employed with EUS can produce very high resolution images and depict changes in the pancreatic duct and parenchyma with better detail	Exact role of EUS versus ERCP and CT not yet fully defined; sensitivity and specificity under study
8. Magnetic resonance cholangiopancreatography	Three-dimensional rendering has been used to produce very good images of the pancreatic duct by a noninvasive technique	May be used to evaluate patients judged to be at high risk for ERCP, such as the elderly; may replace ERCP as a diagnostic test, although large controlled studies need to be done
Pancreatic biopsy with US or CT guidance	Percutaneous biopsy with skinny needle and localization of lesion by US	High diagnostic yield; laparotomy avoided; requires special technical skills
TESTS OF EXOCRINE PANCREATIC FUNCTION		
Direct stimulation of the pancreas with analysis of duodenal contents		
1. Secretin-pancreozymin (CCK) test	Secretin leads to increased output of pancreatic juice and HCO_3^-; CCK leads to increased output of pancreatic enzymes; pancreatic secretory response is related to the functional mass of pancreatic tissue	Sensitive enough to detect occult disease; involves duodenal intubation and fluoroscopy; poorly defined normal enzyme response; overlap in chronic pancreatitis; large secretory reserve capacity of the pancreas
Measurement of intraluminal digestion products		
1. Microscopic examination of stool for undigested meat fibers and fat	Lack of proteolytic and lipolytic enzymes causes decreased digestion of meat fibers and triglycerides	Simple, reliable; not sensitive enough to detect milder cases of pancreatic insufficiency
2. Quantitative stool fat determination	Lack of lipolytic enzymes brings about impaired fat digestion	Reliable, reference standard for defining severity of malabsorption; does not distinguish between maldigestion and malabsorption
3. Fecal nitrogen	Lack of proteolytic enzymes leads to impaired protein digestion, resulting in an increase in stool nitrogen	Does not distinguish between maldigestion and malabsorption; low sensitivity

(continued)

TABLE 293-2—*(Continued)*

Test	Principle	Comment
Measurement of pancreatic enzymes in feces		
1. Elastase	Pancreatic secretion of proteolytic enzymes	Excellent specificity; sensitivity similar to that of serum trypsinogen
Miscellaneous tests		
1. Dual-labeled Schilling test	Intrinsic factor [^{57}Co]cobalamin and Hog R protein [^{58}Co]cobalamin are given together. Since proteases are necessary to cleave R protein, the ratio of labeled cobalamin excreted in urine is an index of exocrine dysfunction.	Time-consuming and expensive

ylase occurs in acute pancreatitis, chronic pancreatitis, carcinoma of the lung, and esophageal perforation.

Lipase may now be the single best enzyme to measure for the diagnosis of acute pancreatitis. Improvements in substrates and technology offer clinicians improved options, especially when a turbidimetric assay is used. The newer lipase assays have colipase as a cofactor and are fully automated.

An assay for trypsinogen (or for trypsin-like immunoreactivity) has a theoretical advantage over amylase and lipase determinations in that the pancreas is the only organ that contains this enzyme. The test appears to be useful in the diagnosis of both acute and chronic pancreatitis. Sensitivity and specificity are comparable to those of amylase and lipase determinations. Since trypsinogen is also excreted by the kidney, elevated serum values are found in renal failure, as is the case with serum amylase and lipase levels. *No single blood test is reliable for the diagnosis of acute pancreatitis in patients with renal failure.* Determining whether a patient with renal failure and abdominal pain has pancreatitis remains a difficult clinical problem. A recent study found that serum amylase levels were elevated in patients with renal dysfunction only when creatinine clearance was <50 mL/min. In such patients, the serum amylase level was invariably <500 IU/L in the absence of objective evidence of acute pancreatitis. In that study, serum lipase and trypsin levels paralleled serum amylase values.

A recent study evaluated the sensitivity and specificity of five assays used to diagnose acute pancreatitis: two for amylase, one for lipase, one for trypsin-like immunoreactivity (TLI), and one for pancreatic isoamylase. The data obtained (1) show that, if the best cutoff level is used, all these assays have similar specificities and (2) suggest that total serum amylase is as good an indicator of acute pancreatitis as any of the alternatives. However, inherent in many such studies is the problem that the recognition and diagnosis of acute pancreatitis hinge on the finding of an elevated serum amylase level. The question arises as to whether any diagnostic test result can be proved superior to the total serum amylase level if hyperamylasemia is required for the diagnosis. In other studies, when "objective" confirmation of the clinical diagnosis of pancreatitis was required (ultrasonography, CT, laparotomy), the sensitivity of the serum amylase has been found to be as low as 68%. With these limitations in mind, the recommended screening tests for acute pancreatitis are *total serum amylase* and *serum lipase activities*. Serum amylase values greater than three times normal are highly specific.

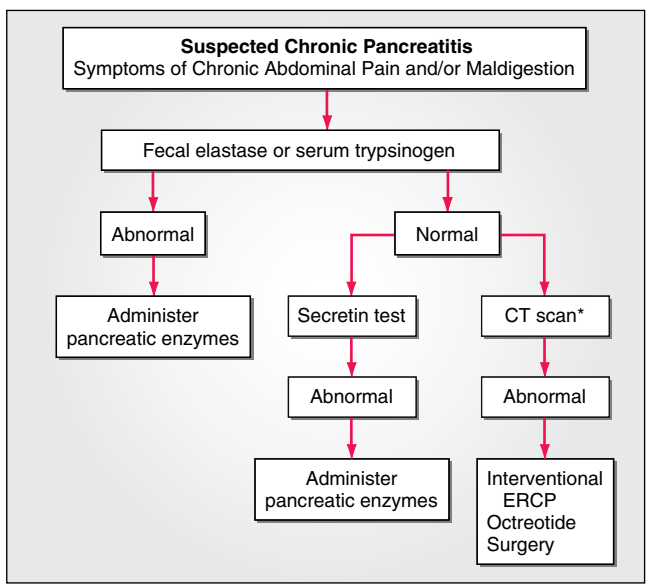

FIGURE 293-1 An approach to the patient with suspected chronic pancreatitis. EUS and MRCP are appropriate diagnostic alternatives.

STUDIES PERTAINING TO PANCREATIC STRUCTURE ■ Radiologic Tests Plain films of the abdomen provide useful information in 30 to 50% of patients with acute pancreatitis. The most frequent abnormalities include (1) a localized ileus, usually involving the jejunum ("sentinel loop"); (2) a generalized ileus with air-fluid levels; (3) the "colon cutoff sign," which results from isolated distention of the transverse colon; (4) duodenal distention with air-fluid levels; and (5) a mass, which is frequently a pseudocyst. In chronic pancreatitis, an important radiographic finding is pancreatic calcification, which characteristically is localized adjacent to and superimposed on the second lumbar vertebra (Fig. 294-3*A*).

TABLE 293-2 *Causes of Hyperamylasemia and Hyperamylasuria*

PANCREATIC DISEASE

I. Pancreatitis
  A. Acute
  B. Chronic: ductal obstruction
  C. Complications of pancreatitis
    1. Pancreatic pseudocyst
    2. Pancreatogenous ascites
    3. Pancreatic abscess
    4. Pancreatic necrosis
II. Pancreatic trauma
III. Pancreatic carcinoma

NONPANCREATIC DISORDERS

I. Renal insufficiency
II. Salivary gland lesions
  A. Mumps
  B. Calculus
  C. Irradiation sialadenitis
  D. Maxillofacial surgery
III. "Tumor" hyperamylasemia
  A. Carcinoma of the lung
  B. Carcinoma of the esophagus
  C. Breast carcinoma, ovarian carcinoma
IV. Macroamylasemia
V. Burns
VI. Diabetic ketoacidosis
VII. Pregnancy
VIII. Renal transplantation
IX. Cerebral trauma
X. Drugs: morphine

OTHER ABDOMINAL DISORDERS

I. Biliary tract disease: cholecystitis, choledocholithiasis
II. Intraabdominal disease
  A. Perforated or penetrating peptic ulcer
  B. Intestinal obstruction or infarction
  C. Ruptured ectopic pregnancy
  D. Peritonitis
  E. Aortic aneurysm
  F. Chronic liver disease
  G. Postoperative hyperamylasemia

Upper gastrointestinal x-rays may reveal displacement of the stomach by the retroperitoneal mass (Fig. 294-2*A*) or widening and effacement of the duodenal C loop, which also suggest the presence of a pancreatic mass, which could be inflammatory, cystic, or neoplastic. However, the use of x-ray films has been largely superseded by ultrasound.

Ultrasonography can provide important information in patients with acute pancreatitis, chronic pancreatitis, pancreatic calcification, pseudocyst, and pancreatic carcinoma. Echographic appearances can indicate the presence of edema, inflammation, and calcification (not obvious on plain films of the abdomen), as well as pseudocysts, mass lesions, and gallstones (Figs. 294-2*B* and 294-3*B*). In acute pancreatitis, the pancreas is characteristically enlarged. In pancreatic pseudocyst, the usual appearance is that of an echo-free, smooth, round fluid collection. Pancreatic carcinoma distorts the usual landmarks, and mass lesions >3.0 cm are usually detected as localized, echo-free solid lesions. Ultrasound is often the initial investigation for most patients with suspected pancreatic disease. However, obesity, excess small- and large-bowel gas, and recently performed barium contrast examinations can interfere with ultrasound studies.

CT is the best imaging study for initial evaluation of a suspected chronic pancreatic disorder and for the complications of acute and chronic pancreatitis. It is especially useful in the detection of pancreatic tumors, fluid-containing lesions such as pseudocysts and abscesses, and calcium deposits (Figs. 294-3*C* and 294-4*A*). Most lesions are characterized by (1) enlargement of the pancreatic outline, (2) distortion of the pancreatic contour, and/or (3) a fluid filling that has a different attenuation coefficient than normal pancreas. However, it is occasionally difficult to distinguish between inflammatory and neoplastic lesions. Oral water-soluble contrast agents may be used to opacify the stomach and duodenum during CT scans; this strategy permits more precise delineation of various organs as well as mass lesions. Dynamic CT (using rapid intravenous administration of contrast) is useful in estimating the degree of pancreatic necrosis and in predicting morbidity and mortality. Spiral (helical) CT provides clear images much more rapidly and essentially negates artifact caused by patient movement (Fig. 294-2*D*).

Endoscopic ultrasonography (EUS) produces high-resolution images of the pancreatic parenchyma and pancreatic duct with a transducer fixed to an endoscope that can be directed onto the surface of the pancreas through the stomach or duodenum. EUS is replacing ERCP for diagnostic purposes in many centers. EUS allows one to obtain information about the pancreatic duct as well as the parenchyma and has no complications associated with it, in contrast to the 5 to 20% of post-ERCP pancreatitis observed. EUS is also very good in detecting common bile duct stones. Pancreatic masses can be biopsied via EUS and one can deliver nerve blocks through EUS. Figures 294-2*A*–*C* show the value of EUS in demonstrating pancreatic calcification, pancreatic pseudocysts, and dilation of the main pancreatic duct. Although criteria for abnormalities on EUS in severe pancreatic disease have been developed, the true sensitivity and specificity of this procedure has yet to be determined. In particular, it is not clear whether EUS can detect early pancreatic disease before abnormalities appear on more conventional radiograph tests such as ultrasonography or CT. The exact role of EUS versus ERCP and CT has yet to be defined.

Magnetic resonance cholangiopancreatography (MRCP) is now being used to view both the bile duct and the pancreatic duct. Non-breath-holding and three-dimensional turbo spin-echo techniques are being utilized to produce superb MRCP images. The main pancreatic duct and common bile duct can be seen well, but there is still a question as to whether changes can be detected consistently in the secondary ducts. MRCP may be particularly useful to evaluate the pancreatic duct in high-risk patients such as the elderly because this is a noninvasive procedure.

Both EUS and MRCP may replace ERCP in some patients. As these techniques become more refined, they may well be the diagnostic tests of choice to evaluate the pancreatic duct. ERCP is still needed to perform therapy of bile duct and pancreatic duct lesions.

Selective catheterization of the celiac and superior mesenteric arteries combined with superselective catheterization of others arteries, such as the hepatic, splenic, and gastroduodenal arteries, permits visualization of the pancreas and detection of pancreatic neoplasms and pseudocysts. Pancreatic neoplasms can be identified by the sheathing of blood vessels by a mass lesion (Fig. 294-1*D*). Hormone-producing pancreatic tumors are especially likely to exhibit increased vascularity and tumor staining. Angiographic abnormalities are noted in many patients with pancreatic carcinoma but are uncommon in patients without pancreatic disease. Angiography complements ultrasonography and ERCP in the study of patients with a suspected pancreatic lesion and may be carried out if ERCP is either unsuccessful or nondiagnostic.

ERCP may provide useful information on the status of the pancreatic ductal system and thus aid in the differential diagnosis of pancreatic disease (Figs. 294-1*C*, 294-3*D*, and 294-4*B*). Pancreatic carcinoma is characterized by stenosis or obstruction of either the pancreatic duct or the common bile duct; both ductal systems are often abnormal. In chronic pancreatitis, ERCP abnormalities include (1) luminal narrowing; (2) irregularities in the ductal system with stenosis, dilation, sacculation, and ectasia; and (3) blockage of the pancreatic duct by calcium deposits. The presence of ductal stenosis and irregularity can make it difficult to distinguish chronic pancreatitis from carcinoma. It is important to be aware that ERCP changes interpreted as indicating chronic pancreatitis actually may be due to the effects of aging on the pancreatic duct or to the fact that the procedure was performed within several weeks of an attack of acute pancreatitis. Although aging may cause impressive ductal alterations, it does not affect the results of pancreatic function tests (i.e., the secretin test). Elevated serum and/or urine amylase levels after ERCP have been reported in 25 to 75% of patients, but clinical pancreatitis is uncommon. If no lesion is found in the biliary and/or pancreatic ducts in a patient with repeated attacks of acute pancreatitis, manometric studies of the sphincter of Oddi may be indicated. Such studies, however, do increase the risk of post-ERCP/manometry acute pancreatitis. Such pancreatitis appears to be more common in patients with a nondilated pancreatic duct.

Pancreatic Biopsy with Radiologic Guidance Percutaneous aspiration biopsy of a pancreatic mass often distinguishes a pancreatic inflammatory mass from a pancreatic neoplasm.

TESTS OF EXOCRINE PANCREATIC FUNCTION

Pancreatic function tests (Table 293-1) can be divided into the following:

1. *Direct stimulation of the pancreas* by intravenous infusion of secretin or secretin plus cholecystokinin (CCK) followed by collection and measurement of duodenal contents
2. Study of *intraluminal digestion products*, such as undigested meat fibers, stool fat, and fecal nitrogen
3. *Measurement of fecal pancreatic enzymes* such as elastase

The secretin test, used to detect diffuse pancreatic disease, is based on the physiologic principle that the pancreatic secretory response is directly related to the functional mass of pancreatic tissue. In the standard assay, secretin is given intravenously in a dose of 1 clinical unit (CU) per kilogram, as either a bolus or a continuous infusion. The results will vary with the secretin preparation used, the dose, the mode of administration, and the completeness with which the duodenal contents are collected. Normal values for the standard secretin test are (1) volume output > 2.0 mL/kg per hour, (2) bicarbonate (HCO_3^-) concentration > 80 meq/L, and (3) HCO_3^- output > 10 meq/L in 1 h. The most reproducible measurement, giving the highest level of discrimination between normal subjects and patients with chronic pancreatitis, appears to be the maximal bicarbonate concentration.

The *combined secretin-CCK test* permits measurement of pancreatic amylase, lipase, trypsin, and chymotrypsin. Although there is overlap in the distributions of enzyme output in normal subjects and

patients with pancreatitis in response to this test, markedly low enzyme outputs suggest advanced damage and destruction of acinar cells. With frank exocrine pancreatic insufficiency, there is usually an overall reduction in both HCO_3^- concentration and output of several enzymes. However, with lesser degrees of pancreatic damage there may be a dissociation between HCO_3^- concentration and enzyme output. There may also be a dissociation between the results of the secretin test and those of tests of absorptive function. For example, patients with chronic pancreatitis often have abnormally low outputs of HCO_3^- after secretin but have normal fecal fat excretion. Thus the secretin test measures the secretory capacity of ductular epithelium, while fecal fat excretion indirectly reflects intraluminal lipolytic activity. Steatorrhea does not occur until intraluminal levels of lipase are markedly reduced, underscoring the fact that only small amounts of enzymes are necessary for intraluminal digestive activities. An abnormal secretin test result suggests only that chronic pancreatic damage is present; it will not consistently distinguish between chronic pancreatitis and pancreatic carcinoma.

Another test of exocrine pancreatic function is the *bentiromide test*. This test is an indirect measure of pancreatic function and reflects intraluminal chymotrypsin activity. The test has excellent specificity but is not very sensitive. It no longer is available for clinical use in the United States.

The *serum trypsinogen level*, which is determined by radioimmunoassay, also has excellent specificity but is not very sensitive. It is a simple blood test that can detect severe damage to the exocrine pancreas. The normal values are 28 to 58 ng/mL, and any value <20 ng/mL reflects pancreatic steatorrhea.

Measurement of *intraluminal digestion products*, i.e., undigested muscle fibers, stool fat, and fecal nitrogen, is discussed in Chap. 275. The amount of elastase in stool reflects the pancreatic output of this proteolytic enzyme. Decreased elastase activity in stool has been reported in patients with chronic pancreatitis and cystic fibrosis. →***Tests useful in the diagnosis of exocrine pancreatic insufficiency and the differential diagnosis of malabsorption are also discussed in Chaps. 275 and 294.***

294 ACUTE AND CHRONIC PANCREATITIS

Norton J. Greenberger, Phillip P. Toskes

BIOCHEMISTRY AND PHYSIOLOGY OF PANCREATIC EXOCRINE SECRETION

GENERAL CONSIDERATIONS The pancreas secretes 1500 to 3000 mL of isosmotic alkaline (pH > 8.0) fluid per day containing about 20 enzymes and zymogens. The pancreatic secretions provide the enzymes needed to effect the major digestive activity of the gastrointestinal tract and provide an optimal pH for the function of these enzymes.

REGULATION OF PANCREATIC SECRETION The exocrine pancreas is influenced by intimately interacting hormonal and neural systems. *Gastric acid* is the stimulus for the release of secretin, which stimulates the secretion of pancreatic juice rich in water and electrolytes. Release of cholecystokinin (CCK) from the duodenum and jejunum is largely triggered by long-chain fatty acids, certain essential amino acids (tryptophan, phenylalanine, valine, methionine), and gastric acid itself. CCK evokes an enzyme-rich secretion from the pancreas. The *parasympathetic nervous system* (via the vagus nerve) exerts significant control over pancreatic secretion. Secretion evoked by secretin and CCK depends on permissive roles of vagal afferent and efferent pathways. This is particularly true for enzyme secretion, whereas water and bicarbonate secretion is heavily dependent on the hormonal effects of secretin and CCK. Also, vagal stimulation effects the release of vasoactive intestinal peptide (VIP), a secretin agonist. Bile salts also stimulate pancreatic secretion, thereby integrating the functions of the biliary tract, pancreas, and small intestine.

Pancreatic exocrine secretion is influenced by inhibitory neuropeptides such as somatostatin, pancreatic polypeptide, peptide YY, neuropeptide Y, enkephalin, pancreastatin, calcitonin gene–related peptides, glucagon, and galanin. Although pancreatic polypeptide and peptide YY may act primarily on nerves outside the pancreas, somatostatin acts at multiple sites. Nitric oxide is also an important neurotransmitter. The mechanism of action of these various factors has not been fully defined.

WATER AND ELECTROLYTE SECRETION Bicarbonate is the ion of primary physiologic importance within pancreatic secretion. The ductal cells secrete bicarbonate predominantly derived from plasma (93%) rather than intracellular metabolism (7%). Bicarbonate enters through the sodium bicarbonate co-transporter with depolarization caused by chloride efflux through the cystic fibrosis transductance regulator (CFTR). Secretin and VIP, both of which increase intracellular cyclic AMP, act on the ductal cells opening the CFTR in promoting secretion. CCK, acting as a neuromodulator, markedly potentiates the stimulatory effects of secretin. Acetylcholine also plays an important role in ductal cell secretion. Bicarbonate helps neutralize gastric acid and creates the appropriate pH for the activity of pancreatic enzymes.

ENZYME SECRETION The acinar cell is highly compartmentalized and is concerned with the secretion of pancreatic enzymes. Proteins synthesized by the rough endoplasmic reticulum are processed in the Golgi and then targeted to the appropriate site, whether that be zymogen granules, lysosomes, or other cell compartments. The pancreas secretes amylolytic, lipolytic, and proteolytic enzymes. *Amylolytic enzymes*, such as amylase, hydrolyze starch to oligosaccharides and to the disaccharide maltose. The *lipolytic enzymes* include lipase, phospholipase A, and cholesterol esterase. Bile salts inhibit lipase in isolation; but colipase, another constituent of pancreatic secretion, binds to lipase and prevents this inhibition. Bile salts activate phospholipase A and cholesterol esterase. *Proteolytic enzymes* include endopeptidases (trypsin, chymotrypsin), which act on internal peptide bonds of proteins and polypeptides; exopeptidases (carboxypeptidases, aminopeptidases), which act on the free carboxyl- and amino-terminal ends of peptides, respectively; and elastase. The proteolytic enzymes are secreted as inactive precursors (zymogens). Ribonucleases (deoxyribonucleases, ribonuclease) are also secreted. *Enterokinase*, an enzyme found in the duodenal mucosa, cleaves the lysine-isoleucine bond of trypsinogen to form trypsin. Trypsin then activates the other proteolytic zymogens in a cascade phenomenon. All pancreatic enzymes have pH optima in the alkaline range. The nervous system initiates pancreatic enzyme secretion. The neurologic stimulation is cholinergic, involving extrinsic innervation by the vagus nerve and subsequent innervation by intrapancreatic cholinergic nerves. The stimulatory neurotransmitters are acetylcholine and gastrin-releasing peptides. These neurotransmitters activate calcium-dependent second messenger systems resulting in the release of zymogen granules. VIP is present in intrapancreatic nerves and potentiates the effect of acetylcholine. In contrast to other species, there are no CCK receptors on acinar cells in humans. CCK in physiologic concentrations stimulates pancreatic secretion by stimulating central vagal and intrapancreatic nerves.

AUTOPROTECTION OF THE PANCREAS Autodigestion of the pancreas is prevented by the packaging of proteases in precursor form and by the synthesis of protease inhibitors. These protease inhibitors are found in the acinar cell, the pancreatic secretions, and the α_1- and α_2-globulin fractions of plasma.

EXOCRINE-ENDOCRINE RELATIONSHIPS Insulin appears to be needed locally for secretin and CCK to promote exocrine secretion; thus, it acts in a permissive role for these two hormones.

ENTEROPANCREATIC AXIS AND FEEDBACK INHIBITION Pancreatic enzyme secretion is controlled, at least in part, by a negative feedback mechanism induced by the presence of active serine proteases in the duodenum. To illustrate, perfusion of the duodenal lumen with phenylalanine causes a prompt increase in plasma CCK levels as well as increased secretion of chymotrypsin. However, simultaneous perfusion with trypsin blunts both responses. Conversely, perfusion of the duodenal lumen with protease inhibitors actually leads to enzyme hypersecretion. The available evidence supports the concept that the duodenum contains a peptide called *CCK-releasing factor* (CCK-RF) that is involved in stimulating CCK release. It appears that serine proteases inhibit pancreatic secretion by acting on a CCK-releasing peptide in the lumen of the small intestine. Thus the integrative result of both bicarbonate and enzyme secretion depends on a feedback process for both bicarbonate and pancreatic enzymes. Acidification of the duodenum releases secretin, which stimulates vagal-vagal and other neural pathways to activate pancreatic duct cells, which secrete bicarbonate. This bicarbonate then neutralizes the duodenal acid, and the feedback loop is completed. Duodenal proteins lead to a reduction in free proteases, thereby leading to an increase in free CCK-RF. CCK-RF is then released into the blood in physiologic concentrations, acting primarily through the neural pathways (vagal-vagal). This leads to acetylcholine-mediated pancreatic enzyme secretion. Proteases continue to be secreted from the pancreas until the protein within the duodenum and CCK-RF are digested. At this point, the free duodenal proteases rise again, thus completing this step in the feedback process.

ACUTE PANCREATITIS

GENERAL CONSIDERATIONS Pancreatic inflammatory disease may be classified as (1) acute pancreatitis and (2) chronic pancreatitis. The pathologic spectrum of acute pancreatitis varies from *edematous pancreatitis*, which is usually a mild and self-limited disorder, to *necrotizing pancreatitis*, in which the degree of pancreatic necrosis correlates with the severity of the attack and its systemic manifestations. The term *hemorrhagic pancreatitis* is less meaningful in a clinical sense because variable amounts of interstitial hemorrhage can be found in pancreatitis as well as in other disorders such as pancreatic trauma, pancreatic carcinoma, and severe congestive heart failure.

The incidence of pancreatitis varies in different countries and depends on cause, e.g., alcohol, gallstones, metabolic factors, and drugs (Table 294-1). The estimated incidence in England is 5.4/100,000 per year; in the United States it is 79.8/100,000 per year, thus resulting in 185,000 new cases of acute pancreatitis annually.

ETIOLOGY AND PATHOGENESIS There are many causes of acute pancreatitis (Table 294-1), but the mechanisms by which these conditions trigger pancreatic inflammation have not been identified. Gallstones continue to be the leading cause of acute pancreatitis in most series (30 to 60%). Alcohol is the second most common cause, responsible for 15 to 30% of cases in the United States. The incidence of pancreatitis in alcoholics is surprisingly low (5/100,000), indicating that in addition to the amount of alcohol ingested unknown factors affect a person's susceptibility to pancreatic injury. The mechanism of injury is not well understood. Hypertriglyceridemia is the cause of acute pancreatitis in 1.3 to 3.8% of cases; serum triglyceride levels are usually >11.3 mmol/L (>1000 mg/dL). Most patients with hypertriglyceridemia, when subsequently examined, show evidence of an underlying derangement in lipid metabolism, probably unrelated to pancreatitis. Patients with diabetes mellitus or who are on certain medications may also develop high triglyceride levels. Acute pancreatitis occurs in 5 to 20% of patients following endoscopic retrograde cholangiopancreatography (ERCP). Approximately 2 to 5% of cases of acute pancreatitis are drug-related. Drugs cause pancreatitis either by a hypersensitivity reaction or by the generation of a toxic metabolite, although in some cases it is not clear which of these mechanisms is operative. (Table 294-1).

TABLE 294-1 Causes of Acute Pancreatitis

Common Causes
- Gallstones (including microlithiasis)
- Alcohol (acute and chronic alcoholism)
- Hypertriglyceridemia
- Endoscopic retrograde cholangiopancreatography (ERCP), especially after biliary manometry
- Trauma (especially blunt abdominal trauma)
- Postoperative (abdominal and nonabdominal operations)
- Drugs (azathioprine, 6-mercaptopurine, sulfonamides, estrogens, tetracycline, valproic acid, anti-HIV medications)
- Sphincter of Oddi dysfunction

Uncommon causes
- Vascular causes and vasculitis (ischemic-hypoperfusion states after cardiac surgery)
- Connective tissue disorders and thrombotic thrombocytopenic purpura (TTP)
- Cancer of the pancreas
- Hypercalcemia
- Periampullary diverticulum
- Pancreas divisum
- Hereditary pancreatitis
- Cystic fibrosis
- Renal failure

Rare causes
- Infections (mumps, coxsackievirus, cytomegalovirus, echovirus, parasites)
- Autoimmune (e.g., Sjögren's syndrome)

Causes to consider in patients with recurrent bouts of acute pancreatitis without an obvious etiology
- Occult disease of the biliary tree or pancreatic ducts, especially microlithiasis, sludge
- Drugs
- Hypertriglyceridemia
- Pancreas divisum
- Pancreatic cancer
- Sphincter of Oddi dysfunction
- Cystic fibrosis
- Idiopathic

Autodigestion is one pathogenic theory, according to which pancreatitis results when proteolytic enzymes (e.g., trypsinogen, chymotrypsinogen, proelastase, and phospholipase A) are activated in the pancreas rather than in the intestinal lumen. A number of factors (e.g., endotoxins, exotoxins, viral infections, ischemia, anoxia, and direct trauma) are believed to activate these proenzymes. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but also can activate other enzymes, such as elastase and phospholipase.

Activation of Pancreatic Enzymes in the Pathogenesis of Acute Pancreatitis Several recent studies have suggested that pancreatitis is a disease that evolves in three phases. The initial phase is characterized by intrapancreatic digestive enzyme activation and acinar cell injury. Zymogen activation appears to be mediated by lysosomal hydrolases such as cathepsin B which become co-localized with digestive enzymes in intracellular organelles; it is currently believed that acinar cell injury is the consequence of zymogen activation. The second phase of pancreatitis involves the activation, chemoattraction, and sequestration of neutrophils in the pancreas resulting in an intrapancreatic inflammatory reaction of variable severity. Neutrophil depletion induced by prior administration of an antineutrophil serum has been shown to reduce the severity of experimentally induced pancreatitis. There is also evidence to support the concept that neutrophil sequestration can activate trypsinogen. Thus, intrapancreatic acinar cell activation of trypsinogen could be a two-step process, i.e., with a neutrophil-independent and a neutrophil-dependent phase. The third phase of pancreatitis is due to the effects of activated proteolytic enzymes and mediators, released by the inflamed pancreas, on distant organs. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but also activate other enzymes such as elastase and phospholipase. The active enzymes then digest cellular mem-

branes and cause proteolysis, edema, interstitial hemorrhage, vascular damage, coagulation necrosis, fat necrosis, and parenchymal cell necrosis. Cellular injury and death result in the liberation of bradykinin peptides, vasoactive substances, and histamine that can produce vasodilation, increased vascular permeability, and edema with profound effects on many organs, most notably the lung. The systemic inflammatory response syndrome (SIRS) and acute respiratory distress syndrome (ARDS) as well as multiorgan failure may occur as result of this cascade of local as well as distant effects.

CLINICAL FEATURES *Abdominal pain* is the major symptom of acute pancreatitis. Pain may vary from a mild and tolerable discomfort to severe, constant, and incapacitating distress. Characteristically, the pain, which is steady and boring in character, is located in the epigastrium and periumbilical region and often radiates to the back as well as to the chest, flanks, and lower abdomen. The pain is frequently more intense when the patient is supine, and patients often obtain relief by sitting with the trunk flexed and knees drawn up. Nausea, vomiting, and abdominal distention due to gastric and intestinal hypomotility and chemical peritonitis are also frequent complaints.

Physical examination frequently reveals a distressed and anxious patient. Low-grade fever, tachycardia, and hypotension are fairly common. Shock is not unusual and may result from (1) hypovolemia secondary to exudation of blood and plasma proteins into the retroperitoneal space (a "retroperitoneal burn"); (2) increased formation and release of kinin peptides, which cause vasodilation and increased vascular permeability; and (3) systemic effects of proteolytic and lipolytic enzymes released into the circulation. Jaundice occurs infrequently; when present, it usually is due to edema of the head of the pancreas with compression of the intrapancreatic portion of the common bile duct. Erythematous skin nodules due to subcutaneous fat necrosis may occur. In 10 to 20% of patients, there are pulmonary findings, including basilar rales, atelectasis, and pleural effusion, the latter most frequently left-sided. Abdominal tenderness and muscle rigidity are present to a variable degree, but, compared with the intense pain, these signs may be unimpressive. Bowel sounds are usually diminished or absent. A pancreatic pseudocyst may be palpable in the upper abdomen. A faint blue discoloration around the umbilicus (Cullen's sign) may occur as the result of hemoperitoneum, and a blue-red-purple or green-brown discoloration of the flanks (Turner's sign) reflects tissue catabolism of hemoglobin. The latter two findings, which are uncommon, indicate the presence of a severe necrotizing pancreatitis.

LABORATORY DATA The diagnosis of acute pancreatitis is usually established by the detection of an increased level of serum amylase. Values threefold or more above normal virtually clinch the diagnosis if overt salivary gland disease and gut perforation or infarction are excluded. However, there appears to be no definite correlation between the severity of pancreatitis and the degree of serum amylase elevation. After 48 to 72 h, even with continuing evidence of pancreatitis, total serum amylase values tend to return to normal. However, pancreatic isoamylase and lipase levels may remain elevated for 7 to 14 days. It will be recalled that amylase elevations in serum and urine occur in many conditions other than pancreatitis (Table 293-2). Importantly, patients with *acidemia* (arterial pH $\leq$ 7.32) may have spurious elevations in serum amylase. In one study, 12 of 33 patients with acidemia had elevated serum amylase, but only 1 had an elevated lipase value; in 9, salivary-type amylase was the predominant serum isoamylase. This finding explains why patients with diabetic ketoacidosis may have marked elevations in serum amylase without any other evidence of acute pancreatitis. Serum lipase activity increases in parallel with amylase activity, and measurement of both enzymes increases the diagnostic yield. An elevated serum lipase or trypsin value is usually diagnostic of acute pancreatitis; these tests are especially helpful in patients with nonpancreatic causes of hyperamylasemia (Table 293-2). Markedly increased levels of peritoneal or pleural fluid amylase [>1500 nmol/L (>5000 U/dL)] are also helpful, if present, in establishing the diagnosis.

Leukocytosis (15,000 to 20,000 leukocytes μL) occurs frequently. Patients with more severe disease may show hemoconcentration with hematocrit values exceeding 50% because of loss of plasma into the retroperitoneal space and peritoneal cavity. *Hyperglycemia* is common and is due to multiple factors, including decreased insulin release, increased glucagon release, and an increased output of adrenal glucocorticoids and catecholamines. *Hypocalcemia* occurs in approximately 25% of patients, and its pathogenesis is incompletely understood. Although earlier studies suggested that the response of the parathyroid gland to a decrease in serum calcium is impaired, subsequent observations have failed to confirm this idea. Intraperitoneal saponification of calcium by fatty acids in areas of fat necrosis occurs occasionally, with large amounts (up to 6.0 g) dissolved or suspended in ascitic fluid. Such "soap formation" may also be significant in patients with pancreatitis, mild hypocalcemia, and little or no obvious ascites. *Hyperbilirubinemia* [serum bilirubin > 68 μmol/L (>4.0 mg/dL)] occurs in approximately 10% of patients. However, jaundice is transient, and serum bilirubin levels return to normal in 4 to 7 days. Serum alkaline phosphatase and aspartate aminotransferase (AST) levels are also transiently elevated and parallel serum bilirubin values. Markedly elevated serum lactic dehydrogenase (LDH) levels [>8.5 μmol/L (>500 U/dL)] suggest a poor prognosis. Serum albumin is decreased to $\leq$30 g/L ($\leq$3.0 g/dL) in about 10% of patients; this sign is associated with more severe pancreatitis and a higher mortality rate (Table 294-2). *Hypertriglyceridemia* occurs in 15 to 20% of patients, and serum amylase levels in these individuals are often spuriously normal (Chap. 293). Approximately 25% of patients have *hypoxemia* (arterial $P_{O_2} \leq 60$ mmHg), which may herald the onset of ARDS. Finally, the electrocardiogram is occasionally abnormal in acute pancreatitis with ST-segment and T-wave abnormalities simulating myocardial ischemia.

Although one or more radiologic abnormalities are found in >50% of patients, the findings are inconstant and nonspecific. The chief value of conventional x-rays [chest films; kidney, ureter, and bladder (KUB) studies] in acute pancreatitis is to help exclude other diagnoses, especially a perforated viscus. Upper gastrointestinal tract x-rays have been superseded by ultrasonography and computed tomography (CT). A CT scan may confirm the clinical impression of acute pancreatitis even in the face of normal serum amylase levels. Importantly, CT is quite helpful in indicating the severity of acute pancreatitis and the risk of morbidity and mortality (see below). Sonography and radionuclide scanning [*N*-*p*-isopropylacetanilide-iminodiacetic acid (PIPIDA) scan; hepatic 2,6-dimethyliminodiacetic acid (HIDA) scan] are useful in acute pancreatitis to evaluate the gallbladder and biliary tree. →***Radiologic studies useful in the diagnosis of acute pancreatitis are discussed in Chap. 293 and listed in Table 293-1.***

DIAGNOSIS Any severe acute pain in the abdomen or back should suggest acute pancreatitis. The diagnosis is usually entertained when a patient with a possible predisposition to pancreatitis presents with se-

TABLE 294-2 Risk Factors That Adversely Affect Survival in Acute Pancreatitis

1. Organ failure[a]
   a. Cardiovascular: hypotension (systolic blood pressure < 90 mmHg) or tachycardia > 130 beats/min
   b. Pulmonary: $P_{O_2} < 60$ mmHg
   c. Renal: oliguria (<50 mL/h) or increasing BUN or creatinine
   d. Gastrointestinal bleeding
2. Pancreatic necrosis[a] (see Table 294-4)
3. Obesity[a] (BMI > 29); age > 70
4. Hemoconcentration[a] (hematocrit > 44%)
5. C-Reactive protein > 150 mg/L
6. Trypsinogen activation peptide

vere and constant abdominal pain, nausea, emesis, fever, tachycardia, and abnormal findings on abdominal examination. Laboratory studies frequently reveal leukocytosis, an abnormal appearance on x-rays of the abdomen and chest, hypocalcemia, and hyperglycemia. The diagnosis is usually confirmed by the finding of an elevated level of serum amylase and/or lipase. Not all the above features have to be present for the diagnosis to be established.

The *differential diagnosis* should include the following disorders: (1) perforated viscus, especially peptic ulcer; (2) acute cholecystitis and biliary colic; (3) acute intestinal obstruction; (4) mesenteric vascular occlusion; (5) renal colic; (6) myocardial infarction; (7) dissecting aortic aneurysm; (8) connective tissue disorders with vasculitis; (9) pneumonia; and (10) diabetic ketoacidosis. A penetrating duodenal ulcer can usually be identified by upper gastrointestinal x-rays and/or endoscopy. A perforated duodenal ulcer is readily diagnosed by the presence of free intraperitoneal air. It may be difficult to differentiate acute cholecystitis from acute pancreatitis, since an elevated serum amylase may be found in both disorders. Pain of biliary tract origin is more right-sided and gradual in onset, and ileus is usually absent; sonography and radionuclide scanning are helpful in establishing the diagnosis of cholelithiasis and cholecystitis. Intestinal obstruction due to mechanical factors can be differentiated from pancreatitis by the history of colicky pain, findings on abdominal examination, and x-rays of the abdomen showing changes characteristic of mechanical obstruction. Acute mesenteric vascular occlusion is usually evident in elderly debilitated patients with brisk leukocytosis, abdominal distention, and bloody diarrhea, in whom paracentesis shows sanguineous fluid and arteriography shows vascular occlusion. Serum as well as peritoneal fluid amylase levels are increased, however, in patients with intestinal infarction. Systemic lupus erythematosus and polyarteritis nodosa may be confused with pancreatitis, especially since pancreatitis may develop as a complication of these diseases. Diabetic ketoacidosis is often accompanied by abdominal pain and elevated total serum amylase levels, thus closely mimicking acute pancreatitis. However, the serum lipase and pancreatic isoamylase levels are not elevated in diabetic ketoacidosis.

TABLE 294-3 Complications of Acute Pancreatitis

LOCAL	
Necrosis	Pancreatic ascites
Sterile	Disruption of main pancreatic duct
Infected	Leaking pseudocyst
Pancreatic fluid collections	Involvement of contiguous organs by necrotizing pancreatitis
Pancreatic abscess	Massive intraperitoneal hemorrhage
Pancreatic pseudocyst	Thrombosis of blood vessels (splenic vein, portal vein)
Pain	Bowel infarction
Rupture	Obstructive jaundice
Hemorrhage	
Infection	
Obstruction of gastrointestinal tract (stomach, duodenum, colon)	
SYSTEMIC	
Pulmonary	Renal
Pleural effusion	Oliguria
Atelectasis	Azotemia
Mediastinal abscess	Renal artery and/or renal vein thrombosis
Pneumonitis	Acute tubular necrosis
Adult respiratory distress syndrome	Metabolic
Cardiovascular	Hyperglycemia
Hypotension	Hypertriglyceridemia
Hypovolemia	Hypocalcemia
Sudden death	Encephalopathy
Nonspecific ST-T changes in electrocardiogram simulating myocardial infarction	Sudden blindness (Purtscher's retinopathy)
Pericardial effusion	Central nervous system
Hematologic	Psychosis
Disseminated intravascular coagulation	Fat emboli
Gastrointestinal hemorrhage[a]	Fat necrosis
Peptic ulcer disease	Subcutaneous tissues (erythematous nodules)
Erosive gastritis	Bone
Hemorrhagic pancreatic necrosis with erosion into major blood vessels	Miscellaneous (mediastinum, pleura, nervous system)
Portal vein thrombosis, variceal hemorrhage	

[a] Aggravated by coagulation abnormalities (disseminated intravascular coagulation).

COURSE OF THE DISEASE AND COMPLICATIONS It is important to identify patients with acute pancreatitis who have an increased risk of dying. Multiple factor scoring systems (Ranson, Imrie, Apache II) are difficult to use, show poor predictive powers, and have not been uniformly embraced by clinicians. The key indicators of a severe attack of pancreatitis are listed in Table 294-2 and include age $>$ 70 years, body mass index (BMI) $>$ 30, hematocrit $>$ 44%, admission C-reactive protein $>$ 150 mg/L, and elevated levels of urine trypsinogen activation peptide (TAP). However, it is organ failure, in which respiratory failure (P_{O_2} $<$ 60 mmHg) dominates, that determines outcome in the majority of difficult to manage cases. The presence of shock (systolic blood pressure $<$ 90 mmHg or tachycardia $>$ 130), renal failure [serum creatinine $>$ 177 μmol/L ($>$2.0 mg/dL)], and gastrointestinal bleeding ($>$500 mL/24 h) are also key factors. The high mortality rate of such severely ill patients is due in large part to infection and warrants intensive radiologic intervention and monitoring and/or a combination of radiologic and surgical means, as discussed in detail below.

The local and systemic complications of acute pancreatitis are listed in Table 294-3. In the first 2 to 3 weeks after pancreatitis patients frequently develop an inflammatory mass, which may be due to pancreatic necrosis (with or without infection) or may represent an abscess or pseudocyst (see below). Systemic complications include pulmonary, cardiovascular, hematologic, renal, metabolic, and central nervous system abnormalities. Pancreatitis and hypertriglyceridemia constitute an association in which cause and effect remain incompletely understood. However, several reasonable conclusions can be drawn. First, hypertriglyceridemia can precede and apparently cause pancreatitis. Second, the vast majority ($>$80%) of patients with acute pancreatitis do not have hypertriglyceridemia. Third, almost all patients with pancreatitis and hypertriglyceridemia have preexisting abnormalities in lipoprotein metabolism. Fourth, many of the patients with this association have persistent hypertriglyceridemia after recovery from pancreatitis and are prone to recurrent episodes of pancreatitis. Fifth, any factor (e.g., drugs or alcohol) that causes an abrupt increase in serum triglycerides to levels $>$11 mmol/L (1000 mg/dL) can precipitate a bout of pancreatitis that can be associated with significant complications and even become fulminant. To avert the risk of triggering pancreatitis, a fasting serum triglyceride measurement should be obtained before estrogen replacement therapy is begun in postmenopausal women. Fasting levels $<$ 3.4 mmol/L (300 mg/dL) pose no risk, whereas levels $>$8.5 mmol/L (750 mg/dL) are associated with a high probability of developing pancreatitis. Finally, patients with a deficiency of apolipoprotein CII have an increased incidence of pancreatitis; apolipoprotein CII activates lipoprotein lipase, which is important in clearing chylomicrons from the bloodstream.

Purtscher's retinopathy, a relatively unusual complication, is manifested by a sudden and severe loss of vision in a patient with acute pancreatitis. It is characterized by a peculiar funduscopic appearance with cotton-wool spots and hemorrhages confined to an area limited by the optic disk and macula; it is believed to be due to occlusion of the posterior retinal artery with aggregated granulocytes.

The two most common causes of acute pancreatitis are biliary tract disease and alcoholism; other causes are listed in Table 294-1. The risk of acute pancreatitis in patients with at least one gallstone $<$5 mm in diameter is fourfold greater than that in patients with larger stones. However, after a conventional workup, a specific cause is not identified

in about 30% of patients. It is important to note that ultrasound examinations fail to detect gallstones, especially microlithiasis and/or sludge, in 4 to 7% of patients. In one series of 31 patients diagnosed initially as having idiopathic acute pancreatitis, 23 were found to have occult gallstone disease. Thus, approximately two-thirds of patients with recurrent acute pancreatitis without an obvious cause actually have occult gallstone disease due to microlithiasis. Examination of duodenal aspirates in such cases often reveals cholesterol crystals, which confirm the diagnosis. Other diseases of the biliary tree and pancreatic ducts that can cause acute pancreatitis include choledochocele; ampullary tumors; pancreas divisum; and pancreatic duct stones, stricture, and tumor. Approximately 2 to 4% of patients with pancreatic carcinoma present with acute pancreatitis.

Recurrent Pancreatitis Approximately 25% of patients who have had an attack of acute pancreatitis have a recurrence. The two most common etiologic factors are alcohol and cholelithiasis. In patients with recurrent pancreatitis without an obvious cause the differential diagnosis should encompass occult biliary tract disease including microlithiasis, hypertriglyceridemia, drugs, sphincter of Oddi dysfunction, pancreas divisum, cystic fibrosis, and pancreatic cancer (Table 294-1).

Pancreatitis in Patients with AIDS The incidence of acute pancreatitis is increased in patients with AIDS for two reasons: (1) the high incidence of infections involving the pancreas, such as infections with cytomegalovirus, *Cryptosporidium*, and the *Mycobacterium avium* complex; and (2) the frequent use by patients with AIDS of medications such as didanosine, pentamidine, and trimethoprim-sulfamethoxazole (Chap. 173).

TREATMENT

In most patients (approximately 85 to 90%) with acute pancreatitis, the disease is self-limited and subsides spontaneously, usually within 3 to 7 days after treatment is instituted. Conventional measures include (1) analgesics for pain, (2) intravenous fluids and colloids to maintain normal intravascular volume, (3) no oral alimentation, and (4) nasogastric suction to decrease gastrin release from the stomach and prevent gastric contents from entering the duodenum. Recent controlled trials, however, have shown that nasogastric suction offers no clear-cut advantages in the treatment of mild to moderately severe acute pancreatitis. Its use, therefore, must be considered elective rather than mandatory.

It has been demonstrated that CCK-stimulated pancreatic secretion is almost abolished in four different experimental models of acute pancreatitis. This finding probably explains why drugs to block pancreatic secretion in acute pancreatitis have failed to have any therapeutic benefit. For this and other reasons, anticholinergic drugs are not indicated in acute pancreatitis. In addition to nasogastric suction and anticholinergic drugs, other therapies designed to "rest the pancreas" by inhibiting pancreatic secretion have not changed the course of the disease. Although antibiotics have been used in the treatment of acute pancreatitis, randomized, prospective trials have shown no benefit from their use in acute pancreatitis of mild to moderate severity.

However, current evidence favors the use of prophylactic antibiotics in necrotizing acute pancreatitis. A recent meta-analysis of controlled trials comparing antibiotic prophylaxis with no prophylaxis in patients with acute necrotizing pancreatitis showed significant reduction in sepsis by 21% [number needed to treat (NNT) = 5] and mortality by 12% (NNT = 8). Early antibiotic prophylaxis in patients with documented pancreatic necrosis is recommended; however, the optimal drug(s) and duration of therapy remain incompletely defined. The current recommendation is the use of a systemic antibiotic such as imipenem-cilastatin, 500 mg thrice daily for 2 weeks. In addition, because secondary infection of necrotic pancreatic tissue (abscess, pseudocyst or obstructed biliary passages, ascending cholangitis complicating choledocholithiasis) contributes to many of the late deaths from pancreatitis, appropriate antibiotic therapy of established infections is quite important.

Several other drugs have been evaluated by prospective controlled trials and found ineffective in the treatment of acute pancreatitis. The list, by no means complete, includes glucagon, H_2 blockers, protease inhibitors such as aprotinin, glucocorticoids, calcitonin, nonsteroidal anti-inflammataory drugs (NSAIDs), and lexiplafant, a platelet-activating factor inhibitor. A recent meta-analysis of somatostatin, ocreotide, and the antiprotease gabexate mesilate in therapy of acute pancreatitis suggested (1) a reduced mortality rate but no change in complications with octreotide, and (2) no effect on the mortality rate but reduced pancreatic damage with gabexate.

Intraabdominal *Candida* infection during acute necrotizing pancreatitis is increasing in frequency and is associated with an increased mortality rate. In one representatitve trial, intraabdominal *Candida* infection was found in 13 of 37 cases and was associated with a mortality rate fourfold greater than that associated with intraabdominal bacterial infection alone. Given the impact of *Candida* infection on the mortality rate in acute necrotizing pancreatitis and the apparent benefit of prophylactic chemotherapy, these data suggest earlier use of fungicides.

A CT scan, especially a contrast-enhanced dynamic CT (CECT) scan, provides valuable information on the severity and prognosis of acute pancreatitis (Fig. 294-1 and Table 294-4). In particular, a CECT scan allows estimation of the presence and extent of pancreatic necrosis. Recent studies suggest that the likelihood of prolonged pancreatitis or a serious complication is negligible when the CT severity index is 1 or 2 and low with scores of 3 to 6. However, patients with scores of 7 to 10 had a 92% morbidity rate and a 17% mortality rate. Necrosis is present in 20 to 30% of patients. Those with necrosis have a morbidity rate >20%, whereas those without necrosis have a morbidity rate <10% and a negligible mortality rate. A few retrospective studies have raised concern that the use of intravenous contrast early in the course of acute pancreatitis might intensify pancreatic necrosis. However, since prospective human studies are not available, it is reasonable to reserve CECT scans for patients with severe pancreatitis or suspected local septic complications. The patient with mild to moderate pancreatitis usually requires treatment with intravenous fluids, fasting, and possibly nasogastric suction for 2 to 4 days. A clear liquid diet is frequently started on the third to sixth day, and a regular diet by the fifth to seventh day. The decision to reintroduce oral intake is usually based on the following criteria: (1) a decrease in or resolution of abdominal pain; (2) the patient is hungry; and (3) organ dysfunction, if present, has improved. Elevation of serum amylase/lipase or persistent inflammatory changes seen on CT scans should not discourage feeding a hungry asymptomatic patient. In this regard, persistence of inflammatory changes on CT scans or persistent elevations in serum amylase/lipase may not normalize for weeks to months. The patient with unremitting *fulminant pancreatitis* usually requires inordinate amounts of fluid and close attention to complications such as cardiovascular collapse, respiratory insufficiency, and pancreatic infection. The latter should be managed by a combination of radiologic and surgical means (see below). While earlier uncontrolled studies suggested that *peritoneal lavage* through a percutaneous dialysis catheter was helpful in severe pancreatitis, subsequent studies indicate that this treatment does not influence the outcome of such attacks. Aggressive surgical pancreatic debridement (necrosectomy) should be undertaken soon after confirmation of the presence of infected necrosis, and multiple operations may be required. Since the mortality rate from sterile acute necrotizing pancreatitis is approximately 10%, laparotomy with adequate drainage and removal of necrotic tissue should be considered if conventional therapy does not halt the patient's deterioration. The use of parenteral nutrition makes it possible to give nutritional support to patients with severe, acute, or protracted pancreatitis who are unable to eat normally. Several studies have demonstrated that enteral feeding via a nasojejunal tube infused distal to the ligament of Treitz is associated with a decreased rate of complications, including infection, when compared to total parenteral nutrition. Patients with severe gallstone-induced pancreatitis may improve dramatically if papillotomy is

FIGURE 294-1 Acute pancreatitis: CT evolution. *A*. Contrast-enhanced CT scan of the abdomen performed on admission of a patient with clinical evidence of acute pancreatitis. Note the mildly decreased density of the body of the pancreas to the left of the midline (*arrow*). There are a few linear strands in the peripancreatic fat, suggesting inflammation (*open arrows*). A small amount of fluid is seen in the anterior pararenal space (*arrowhead*). *B*. Nine days after admission, there is a marked worsening with severe inflammation of the pancreas evidenced by anterior displacement of the posterior gastric wall (*arrows*), increased inflammation of the peripancreatic fat, and increased pancreatic effusion in the anterior perirenal space and around the splenic vein (*open arrows*). *(Courtesy of Dr. PR Ros, University of Florida College of Medicine.)*

carried out within the first 36 to 72 h of the attack. Studies indicate that only those patients with gallstone pancreatitis who are in the very severe group should be considered for urgent ERCP. Finally, the treatment for patients with hypertriglyceridemia-associated pancreatitis includes (1) weight loss to ideal weight, (2) a lipid-restricted diet, (3) exercise, (4) avoidance of alcohol and of drugs that can elevate serum triglycerides (i.e., estrogens, vitamin A, thiazides, and beta-blockers), and (5) control of diabetes.

INFECTED PANCREATIC NECROSIS, ABSCESS, AND PSEUDOCYST Infected pancreatic necrosis should be differentiated from pancreatic abscess. The former is a diffuse infection of an acutely inflamed, necrotic pancreas occurring in the first 1 to 2 weeks after the onset of pancreatitis. In contrast, a pancreatic abscess is an ill-defined, liquid collection of pus that evolves over a longer period, often 4 to 6 weeks. It tends to be less life-threatening and is associated with a lower rate of surgical mortality. Infected pancreatic necrosis should be treated by surgical debridement because the solid component of the infected pancreas is not amenable to effective radiologically guided percutaneous evacuation. Pancreatic abscess can be treated surgically or, in selected cases, by percutaneous drainage. The necrotic pancreas becomes secondarily infected in 40 to 60% of patients, most frequently with gram-negative bacteria of alimentary origin. Whether infection occurs depends on several factors, including the extent of pancreatic and peripancreatic necrosis, the degree of pancreatic ischemia and hypoperfusion, and the presence of organ or multiorgan failure.

The early diagnosis of pancreatic infection can be accomplished by CT-guided needle aspiration. In one study, 60 patients, representing 5% of all admissions for acute pancreatitis, were suspected of harboring a pancreatic infection on the basis of fever, leukocytosis, and an abnormal CT scan (pseudocyst or extrapancreatic fluid collection). Importantly, 60% of these patients had a pancreatic infection, and 55% of these infections developed in the first 2 weeks. These findings suggest that only guided aspiration can reliably distinguish sterile from infected pancreatic necrosis. The following are guidelines for patients meeting the above selection criteria: (1) Pseudocysts should be aspirated promptly, because more than half may be infected; (2) extrapancreatic fluid collections need not be aspirated promptly, because most are sterile; (3) if a necrotic pancreas is found initially to be sterile but fever and leukocytosis persist, several days of observation should be allowed to pass before reaspiration is considered, as clinical improvement frequently occurs; and (4) if fever and leukocytosis recur after an interval of well-being, reaspiration should be considered.

Severe pancreatitis with the presence of key risk factors, postoperative pancreatitis, early oral feeding, early laparotomy, and perhaps injudicious use of antibiotics predispose to the development of pancreatic abscess, which occurs in 3 to 4% of patients with acute pancreatitis. Pancreatic abscess may also develop because of a communication between a pseudocyst and the colon, inadequate surgical drainage of a pseudocyst, or needling of a pseudocyst. The characteristic signs of abscess are fever, leukocytosis, ileus, and rapid deterioration in a patient previously recovering from pancreatitis. Sometimes, however, the only manifestations are persistent fever and signs of continuing pancreatic inflammation. Drainage of pancreatic abscesses by percutaneous catheter techniques, using CT guidance, has been only moderately successful (resolution in 50 to 60% of patients). Accordingly, laparotomy with radical sump drainage and possibly resection of necrotic tissue is usually required, because the mortality rate for undrained pancreatic abscess approaches 100%. Multiple abscesses are common, and reoperation is frequently necessary.

Pseudocysts of the pancreas are collections of tissue, fluid, debris, pancreatic enzymes, and blood which develop over a period of 1 to 4 weeks after the onset of acute pancreatitis; they form in approximately 15% of patients with acute pancreatitis. In contrast to true cysts, pseudocysts do not have an epithelial lining; their walls consist of necrotic tissue, granulation tissue, and fibrous tissue. Disruption of the pancre-

TABLE 294-4 *Severity Index in Acute Pancreatitis*

	Points

Necrosis of more than one-half of pancreas	6
CT severity index (CTSI) = CT grade + necrosis score (0–10)	

atic ductal system is common. However, the subsequent course of this disruption varies widely, ranging from spontaneous healing to continuous leakage of pancreatic juice, which results in tense ascites. Pseudocysts are preceded by pancreatitis in 90% of cases and by trauma in 10%. Approximately 85% are located in the body or tail of the pancreas and 15% in the head. Some patients have two or more pseudocysts. Abdominal pain, with or without radiation to the back, is the usual presenting complaint. A palpable, tender mass may be found in the middle or left upper abdomen. The serum amylase level is elevated in 75% of patients at some point during their illness and may fluctuate markedly.

On x-ray examination, 75% of pseudocysts can be seen to displace some portion of the gastrointestinal tract (Fig. 294-2). Sonography, however, is reliable in detecting pseudocysts. Sonography also permits differentiation between an edematous, inflamed pancreas, which can give rise to a palpable mass, and an actual pseudocyst. Furthermore, serial ultrasound studies will indicate whether a pseudocyst has resolved. CT complements ultrasonography in the diagnosis of pancreatic pseudocyst (Fig. 294-2), especially when the pseudocyst is infected.

In studies with sonography, pseudocysts were seen to resolve in 25 to 40% of patients. Pseudocysts that are >5 cm in diameter and that persist for >6 weeks should be considered for drainage. Recent natural history studies have suggested that noninterventional, expectant management is the best course in selected patients with minimal symptoms and no evidence of active alcohol use in whom the pseudocyst appears mature by radiography and does not resemble a cystic neoplasm. A significant number of these pseudocysts resolve spontaneously more than 6 weeks after their formation. Also, these studies demonstrate that large pseudocyst size is not an absolute indication for interven-

Behind the large pseudocyst is seen the calcified head of the pancreas. A dilated common bile duct (*asterisk*) is noted. *C*. CT scan showing pseudocyst. Note the large, lobulated fluid collection (*arrows*) surrounding the tail of the pancreas (*arrowheads*). Note also the dense, thin rim in the periphery representing the fibrous capsule of the pseudocyst. *D*. Spiral CT showing a pseudocyst (*small arrow*) with a pseudoaneurysm (light area in pseudocyst). Note the demonstration of the main pancreatic duct (*big arrow*), even though this duct is minimally dilated by ERCP. *(A, B courtesy of Dr. CE Forsmark, University of Florida College of Medicine; C, D courtesy of Dr. PR Ros, University of Florida College of Medicine.)*

tional therapy and that many peripancreatic fluid collections detected on CT in cases of acute pancreatitis resolve spontaneously. A pseudocyst that does not resolve spontaneously may lead to serious complications, such as (1) pain caused by expansion of the lesion and pressure on other viscera, (2) rupture, (3) hemorrhage, and (4) abscess. Rupture of a pancreatic pseudocyst is a particularly serious complication. Shock almost always supervenes, and mortality rates range from 14% if the rupture is not associated with hemorrhage to over 60% if hemorrhage has occurred. Rupture and hemorrhage are the prime causes of death from pancreatic pseudocyst. A triad of findings—an increase in the size of the mass, a localized bruit over the mass, and a sudden decrease in hemoglobin level and hematocrit without obvious external blood loss—should alert one to the possibility of hemorrhage from a pseudocyst. Thus, in patients who are stable and free of complications and in whom serial ultrasound studies show that the pseudocyst is shrinking, conservative therapy is indicated. Conversely, if the pseudocyst is expanding and is complicated by rupture, hemorrhage, or abscess, the patient should be operated on. With ultrasound or CT guidance, sterile chronic pseudocysts can be treated safely with single or repeated needle aspiration or more prolonged catheter drainage with a success rate of 45 to 75%. The success rate of these techniques for infected pseudocysts is considerably less (40 to 50%). Patients who do not respond to drainage require surgical therapy for internal or external drainage of the cyst.

Pseudoaneurysms develop in up to 10% of patients with acute pancreatitis at sites reflecting the distribution of pseudocysts and fluid collections (Fig. 294-2*D*). The splenic artery is most frequently involved, followed by the inferior and superior pancreatic duodenal arteries. This diagnosis should be suspected in patients with pancreatitis who develop upper gastrointestinal bleeding without an obvious cause or in whom thin-cut CT scanning reveals a contrast-enhanced lesion within or adjacent to a suspected pseudocyst. Arteriography is necessary to confirm the diagnosis.

PANCREATIC ASCITES AND PANCREATIC PLEURAL EFFUSIONS Pancreatic ascites is usually due to disruption of the main pancreatic duct, often by an internal fistula between the duct and the peritoneal cavity or a leaking pseudocyst (Chap. 39). This diagnosis is suggested in a patient with an elevated serum amylase level in whom the ascites fluid has both increased levels of albumin [>30 g/L (>3.0 g/dL)] and a markedly elevated level of amylase. The fluid in true pancreatic ascites usually has an amylase concentration of >20,000 U/L as a result of the ruptured duct or leaking pseudocyst. Lower amylase elevations may be found in the peritoneal fluid of patients with acute pancreatitis. In addition, ERCP often demonstrates passage of contrast material from a major pancreatic duct or a pseudocyst into the peritoneal cavity. As many as 15% of patients with pseudocysts have concurrent pancreatic ascites. The differential diagnosis should include intraperitoneal carcinomatosis, tuberculous peritonitis, constrictive pericarditis, and Budd-Chiari syndrome.

If the pancreatic duct disruption is posterior, an internal fistula may develop between the pancreatic duct and the pleural space, producing a pleural effusion, which is usually left-sided and often massive. This complication often requires thoracentesis or chest tube drainage.

℞ TREATMENT

Treatment usually requires the use of nasogastric suction and parenteral alimentation to decrease pancreatic secretion. In addition, paracentesis is performed to keep the peritoneal cavity free of fluid and, it is hoped, to effect sealing of the leak. The long-acting somatostatin analogue octreotide, which inhibits pancreatic secretion, is useful in cases of pancreatic ascites and pleural effusion. If ascites continues to recur after 2 to 3 weeks of medical management, the patient should be operated on after pancreatography to define the anatomy of the abnormal duct. A disrupted main pancreatic duct can also be treated effectively by stenting. Patients in whom ERCP identifies two or more sites of extravasation are unlikely to respond to conservative management and/or stenting.

CHRONIC PANCREATITIS AND PANCREATIC EXOCRINE INSUFFICIENCY

GENERAL AND ETIOLOGIC CONSIDERATIONS Chronic inflammatory disease of the pancreas may present as episodes of acute inflammation in a previously injured pancreas or as chronic damage with persistent pain or malabsorption. The causes of relapsing chronic pancreatitis are similar to those of acute pancreatitis (Table 294-1), except that there is an appreciable incidence of cases of undetermined origin. In addition, the pancreatitis associated with gallstones is predominantly acute or relapsing-acute in nature. A cholecystectomy is almost always performed in patients after the first or second attack of gallstone-associated pancreatitis. Patients with chronic pancreatitis may present with persistent abdominal pain, with or without steatorrhea; some (~15%) present with steatorrhea and no pain.

Patients with chronic pancreatitis in whom there is extensive destruction of the pancreas (<10% of exocrine function remaining) have steatorrhea and azotorrhea. Among American adults, alcoholism is the most common cause of clinically apparent pancreatic exocrine insufficiency, while cystic fibrosis is the most frequent cause in children. In up to 25% of American adults with chronic pancreatitis, the cause is not known; that is, they have idiopathic chronic pancreatitis. Indeed, idiopathic chronic pancreatitis is the leading cause of nonalcoholic chronic pancreatitis in adults in the United States. In a recent series, genetic testing was done on 39 patients with idiopathic chronic pancreatitis. Seventeen patients had CFTR mutations and 9 had mutations in a trypsin inhibitor gene (PSTI). Pancreatitis risk was increased 14-fold by having the PSTI mutation, 40-fold by having two abnormal copies of CFTR, and 600-fold by having both. Thus, the risk of pancreatitis showed complex inheritance and was highest in individuals who had abnormalities in both the pancreatic ducts (CFTR) and acini (PSTI). These findings suggest that PSTI is a modifier gene for CFTR-related idiopathic chronic pancreatitis. Current knowledge indicates that about 15% of patients with idiopathic chronic pancreatitis have a genetic basis for this disorder. The therapeutic and prognostic implication of these findings remain to be determined. In other parts of the world, severe protein-calorie malnutrition is a common cause.

In certain countries, particularly Japan and Italy, there has been an increased interest in autoimmune chronic pancreatitis. The Japanese describe a distinct entity that is associated with the presence of autoantibodies in the blood, elevated levels of serum IgG, association with other autoimmune disorders such as primary biliary cirrhosis and inflammatory bowel disease, diffuse enlargement of the pancreas, and irregular narrowing of the main pancreatic duct. Symptoms are usually mild without acute relapsing attacks of pancreatitis, and patients usually experience a good therapeutic response to glucocorticoids. It is noteworthy that pancreatic pseudocysts and calcification within the pancreas are unusual. Although this kind of pancreatitis is not very common in the United States, all major medical centers are seeing examples of autoimmune chronic pancreatitis. Table 294-5 lists other causes of pancreatic exocrine insufficiency, but they are relatively uncommon.

PATHOPHYSIOLOGY The events that initiate an inflammatory process in the pancreas are still not well understood, and the many hypotheses will not be reviewed here. In the case of alcohol-induced pancreatitis, it has been suggested that the primary defect may be the precipitation of protein (inspissated enzymes) in the ducts. The resulting ductal obstruction could lead to duct dilation, diffuse atrophy of the acinar cells, fibrosis, and eventual calcification of some of the protein plugs. However, the fact that some alcoholic patients with recurrent acute pancreatitis show no evidence of chronic pancreatitis does not support this hypothesis. In fact, experimental and clinical observations have shown that alcohol has direct toxic effects on the pancreas. While patients with alcohol-induced pancreatitis generally consume large amounts of alcohol, some consume very little (≤50 g/d). Thus prolonged consumption of "socially acceptable" amounts of alcohol is

TABLE 294-5 Causes of Pancreatic Exocrine Insufficiency

Alcohol, chronic alcoholism
Idiopathic pancreatitis
Cystic fibrosis
Hypertriglyceridemia
Severe protein-calorie malnutrition with hypoalbuminemia
Tropical pancreatitis (Africa, Asia)
Pancreatic and duodenal neoplasms
Pancreatic resection
Gastric surgery
Subtotal gastrectomy with Billroth I anastomosis
Subtotal gastrectomy with Billroth II anastomosis
Truncal vagotomy and pyloroplasty
Gastrinoma (Zollinger-Ellison syndrome)
Hereditary pancreatitis
Traumatic pancreatitis
Autoimmune pancreatitis
Abdominal radiotherapy
Hemochromatosis
Primary sclerosing cholangitis
Primary biliary cirrhosis
Shwachman's syndrome (pancreatic insufficiency and bone marrow dysfunction)
Trypsinogen deficiency
Enterokinase deficiency
Isolated deficiencies of amylase, lipase, or proteases
α_1-Antitrypsin deficiency

compatible with the development of pancreatitis. In addition, the finding of extensive pancreatic fibrosis in patients who died during their first attack of clinical acute alcohol-induced pancreatitis supports the concept that such patients already have chronic pancreatitis.

CLINICAL FEATURES Patients with relapsing chronic pancreatitis may present with symptoms identical to those of acute pancreatitis, but pain may be continuous, intermittent, or absent. The pathogenesis of this pain is poorly understood. Although the classic description is of epigastric pain radiating through the back, the pain pattern is often atypical; the pain may be worst in the right or left upper quadrant of the back or may be diffuse throughout the upper abdomen; it may even be referred to the anterior chest or flank. Characteristically it is persistent, deep-seated, and unresponsive to antacids. It often is worsened by ingestion of alcohol or a heavy meal (especially one rich in fat). Often the pain is severe enough to necessitate the frequent use of narcotics.

Weight loss, abnormal stools, and other signs or symptoms suggestive of malabsorption (Chap. 275) are common in chronic pancreatitis. However, clinically apparent deficiencies of fat-soluble vitamins are surprisingly rare. The physical findings in these patients are usually not impressive, so that there is a disparity between the severity of the abdominal pain and the physical signs (other than some abdominal tenderness and mild temperature elevation).

DIAGNOSTIC EVALUATION (See also Chap. 293) In contrast to relapsing acute pancreatitis, the serum amylase and lipase levels are usually not elevated in chronic pancreatitis. Elevations of serum bilirubin and alkaline phosphatase levels may indicate cholestasis secondary to chronic inflammation around the common bile duct (Fig. 294-3). Many patients demonstrate impaired glucose tolerance, and some have an elevated fasting blood glucose level.

The classic triad of pancreatic calcification, steatorrhea, and diabetes mellitus usually establishes the diagnosis of chronic pancreatitis and exocrine pancreatic insufficiency but is found in fewer than one-third of chronic pancreatitis patients. Accordingly, it is often necessary to perform an intubation test such as the *secretin stimulation test*, which usually gives abnormal results when 60% or more of pancreatic exocrine function has been lost. Approximately 40% of patients with chronic pancreatitis have *cobalamin* (*vitamin* B_{12}) malabsorption, which can be corrected by the administration of oral pancreatic enzymes. There is usually a marked excretion of fecal fat (Chap. 275), which can be reduced by the administration of oral pancreatic enzymes. The serum trypsinogen (Chap. 293) and the D-xylose urinary excretion test are useful in patients with "pancreatic steatorrhea," since the trypsinogen level will be abnormal, and D-xylose excretion is usually normal. A decreased serum trypsinogen (<20 ng/mL) or a fecal elastase level of <100 μg/mg of stool strongly suggests severe pancreatic exocrine insufficiency.

The radiographic hallmark of chronic pancreatitis is the presence of scattered calcification throughout the pancreas (Fig. 294-3). Diffuse pancreatic calcification indicates that significant damage has occurred and obviates the need for a secretin test. While alcohol is by far the most common cause, pancreatic calcification may also be seen in cases of severe protein-calorie malnutrition, hereditary pancreatitis, posttraumatic pancreatitis, hyperparathyroidism, islet cell tumors, and idiopathic chronic pancreatitis. A large prospective study has shown convincingly that pancreatic calcification decreases or even disappears spontaneously in one-third of patients with severe chronic pancreatitis; this outcome may also follow ductal decompression. Pancreatic calcification is a dynamic process that is incompletely understood.

Sonography, CT, and ERCP greatly aid the diagnosis of pancreatic disease. In addition to excluding pseudocysts and pancreatic cancer, sonography and CT may show calcification or dilated ducts associated with chronic pancreatitis (Fig. 294-4). ERCP and endoscopic ultrasound (EUS) are procedures that provide information about the main pancreatic duct and the smaller ducts. EUS is also useful in evaluating the pancreatic parenchyma. In patients with alcohol-induced pancreatitis, ERCP may reveal a pseudocyst missed by sonography or CT.

COMPLICATIONS OF CHRONIC PANCREATITIS The complications of chronic pancreatitis are protean. Cobalamin (vitamin B_{12}) malabsorption occurs in 40% of patients with alcohol-induced chronic pancreatitis and in virtually all with cystic fibrosis. It is consistently corrected by the administration of pancreatic enzymes (containing proteases). It may be due to excessive binding of cobalamin by cobalamin-binding proteins other than intrinsic factor, which ordinarily are destroyed by pancreatic proteases and therefore do not compete with intrinsic factor for cobalamin binding. Although most patients show impaired glucose tolerance, diabetic ketoacidosis and coma are uncommon. Similarly, end-organ damage (retinopathy, neuropathy, nephropathy) is also uncommon, and the appearance of these complications should raise the question of concomitant genetic diabetes mellitus. A nondiabetic retinopathy, peripheral in location and secondary to vitamin A and/or zinc deficiency, is common in these patients. Effusions containing high concentrations of amylase may occur into the pleural, pericardial, or peritoneal space. Gastrointestinal bleeding may occur from peptic ulceration, gastritis, a pseudocyst eroding into the duodenum, or ruptured varices secondary to splenic vein thrombosis due to inflammation of the tail of the pancreas. Icterus may occur, caused either by edema of the head of the pancreas, which compresses the common bile duct, or by chronic cholestasis secondary to a chronic inflammatory reaction around the intrapancreatic portion of the common bile duct (Fig. 294-3). The chronic obstruction may lead to cholangitis and ultimately to biliary cirrhosis. Subcutaneous fat necrosis may appear as tender red nodules on the lower extremities. Bone pain may be secondary to intramedullary fat necrosis. Inflammation of the large and small joints of the upper and lower extremities may occur. The incidence of pancreatic carcinoma is increased in patients with chronic pancreatitis who have been followed for 2 or more years. Twenty years after the diagnosis of chronic pancreatitis, the cumulative risk of pancreatic carcinoma is 4%. Perhaps the most common and troublesome complication is addiction to narcotics.

Rx TREATMENT

Therapy for patients with chronic pancreatitis is directed toward two major problems—pain and maldigestion. Patients with intermittent attacks of pain are treated essentially like those with acute pancreatitis

A

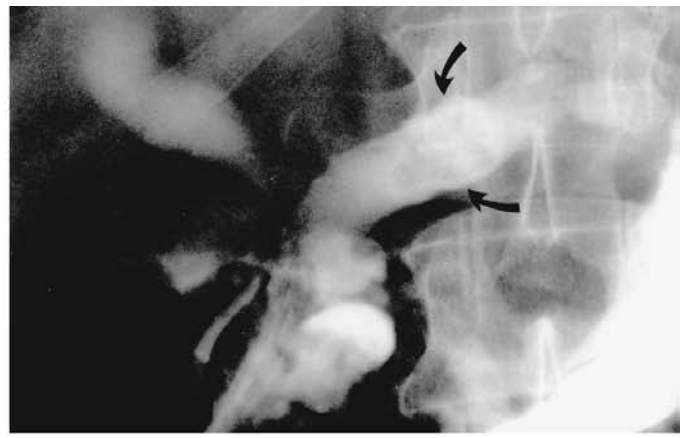
FIGURE 294-3 Radiologic abnormalities in chronic pancreatitis. *A*. Pancreatic calcification (*arrows*) and stenosis (tapering) of the intrahepatic portion of the common bile duct demonstrated by percutaneous transhepatic cholangiography. *B*. Pancreatic calcification (*large white arrow)* demonstrated by sonography. Note dilated pancreatic duct (*thin white arrow*) and splenic vein (*open arrow*). *C*. Pancreatic calcification (*vertical arrows*) and dilated pancreatic duct (*horizontal arrow*) demonstrated by CT scan. *D*. Endoscopic retrograde cholangiogram shows grossly dilated pancreatic ducts (*arrows*) in a patient with long-standing pancreatitis.

A



B

FIGURE 294-4 Chronic pancreatitis and pancreatic calculi: CT scan and ERCP appearance. *A*. In this contrast-enhanced CT scan of the abdomen, there is evidence of an atrophic pancreas with multiple calcifications (*arrows*). Note the markedly dilated pancreatic duct seen in this section through the body and tail (*open arrows*). *B*. ERCP in the same patient demonstrates the dilated pancreatic duct as well as an intrapancreatic duct calculus (*arrows*). These findings correlate nicely with the CT scan appearance.

(see above). Patients with severe and persistent pain should avoid alcohol completely and avoid large meals rich in fat. Since the pain is often severe enough to require frequent use of narcotics (and hence addiction), a number of surgical procedures have been developed for pain relief. ERCP allows the surgeon to plan the operative approach. If there is a stricture of the pancreatic duct, a local resection may ameliorate the pain. Unfortunately, isolated localized strictures are not common. In most patients with alcohol-induced disease, the pancreas is diffusely involved, and surgically correctible localized ductal disease is rare. When there is primary ductal obstruction and dilation, ductal decompression may provide effective pain palliation. Short-term pain relief may be achieved in up to 80% of patients, while long-term pain relief occurs in approximately 50%. In some of these patients, however, pain relief can be achieved only by resecting 50 to 95% of the gland. Although pain relief is achieved in three-quarters of these patients, they tend to develop pancreatic endocrine and exocrine insufficiency and must be treated with pancreatic enzyme replacement therapy. It is important to screen patients carefully, for such radical surgery is contraindicated in those who are severely depressed or suicidal or who continue to drink. Procedures such as splanchnicectomy, celiac ganglionectomy, and nerve blocks usually bring only temporary relief and are not recommended. Endoscopic treatment of chronic pancreatitis may involve sphincterotomy of the minor or major pancreatic sphincter, dilatation of strictures, removal of calculi, or stenting of the ventral or dorsal pancreatic duct. Although many of these techniques are technically impressive, none has been subjected to a randomized trial in patients with chronic pancreatitis. In addition, significant complications—acute pancreatitis, pancreatic abscess, damage to the pancreatic duct, and death—have occurred in up to 36% of patients after stent placement.

Three double-blind trials have demonstrated that administration of pancreatic enzymes decreases abdominal pain in selected patients with chronic pancreatitis. In these trials, approximately 75% of the patients evaluated experienced pain relief. The patients most likely to respond are those with mild to moderate exocrine pancreatic dysfunction, as evidenced by an abnormal secretin test, normal fat absorption, and minimal abnormalities on ERCP examination. These clinical observations seem to fit with data from humans and experimental animals demonstrating a negative feedback regulation for pancreatic exocrine secretion controlled by the amount of proteases within the lumen of the proximal small intestine. It seems reasonable to use the following approach for patients with severe, persistent, or continuous abdominal pain thought to be caused by chronic pancreatitis. After other causes of abdominal pain (peptic ulcer, gallstones, etc.) have been excluded, a pancreatic sonogram should be done. If no mass is found, a secretin test may be performed, because its results are usually abnormal in cases of chronic pancreatitis with pain. If the results are abnormal (i.e., decreased bicarbonate concentration or volume output), a 3- to 4-week trial of pancreatic enzyme administration is appropriate. Four to eight conventional tablets or capsules are taken at meals and at bedtime. There are a number of studies suggesting that patients may have small-duct chronic pancreatitis and chronic abdominal pain with a normal appearance on radiographic evaluations (ultrasound, CT, ERCP) but abnormal results on hormone stimulation tests (secretin test) and/or abnormal pancreatic histology. Such minimal-change chronic pancreatitis may respond well to pancreatic enzyme therapy (non-enteric-coated) for relief of abdominal pain. If no relief is obtained, and especially if the volume secreted during the secretin test is very low, ERCP or EUS should be performed. If a pseudocyst or a localized ductal obstruction is found, surgery should be considered. A patient who has dilated ducts may be a candidate for a surgical ductal decompression procedure. This procedure provides short-term relief in up to 80% of patients, although long-term results are closer to 50%. Some studies have shown octreotide to be effective in decreasing abdominal pain in patients with severe large-duct disease. If no surgically remediable lesion is found and severe pain continues despite abstinence from alcohol, subtotal pancreatic resection may be necessary.

The treatment of maldigestion rests on the use of pancreatic enzyme replacement therapy. Diarrhea and steatorrhea are usually improved by this treatment, although the steatorrhea may not be completely corrected. The major problem is delivering enough active enzyme into the duodenum. Steatorrhea could be abolished if 10% of the normal amount of lipase could be delivered to the duodenum at the proper time. This concentration of lipase cannot be achieved with the current preparations of pancreatic enzymes, even if the latter are given in large doses. The reason for these poor results may be that lipase is inactivated by gastric acid, that food empties from the stomach faster than do the pancreatic enzymes, and that batches of commercially available pancreatic extracts vary in enzyme activity.

For the usual patient, two or three enteric-coated capsules or eight conventional (non-enteric-coated) tablets of a potent enzyme preparation should be administered with meals. Some patients using conventional tablets require adjuvant therapy to improve enzyme replacement treatment. H_2 receptor antagonists, sodium bicarbonate, and proton pump inhibitors are effective adjuvants. Antacids containing calcium carbonate or magnesium hydroxide are not effective and may actually result in increased steatorrhea. Several publications have reported colonic strictures in patients with cystic fibrosis receiving extraordinarily high doses of high-potency pancreatic enzyme preparations. Such lesions have not been reported in adults with chronic pancreatitis.

Supportive measures include diet restriction and pain medications. The diet should be moderate in fat (30%), high in protein (24%), and low in carbohydrate (40%). Restriction of long-chain triglyceride intake can help patients who do not respond satisfactorily to pancreatic enzyme therapy. Use of foods containing mainly medium-chain fatty acids, which do not require lipase for digestion, may be beneficial. Nonnarcotic analgesics should be emphasized. Patients taking narcotic drugs for pain relief often become addicted and continue to have pain.

Patients with severe exocrine pancreatic insufficiency secondary to alcohol who continue to drink have a high mortality rate (in one series, 50% of patients who were followed for 5 to 12 years died during this period) and significant morbidity (weight loss, lassitude, vitamin deficiency, and narcotic addiction). Chronic pancreatitis carries significant medical and social costs. A recent study found that pancreatitis led to retirement in 11% of patients with the disease, accounting for 45% of all retirements. In 87% of patients with chronic pancreatitis unable to maintain gainful employment, alcoholism was a contributing factor. Patients with chronic pancreatitis also use substantial medical resources. In 1987 in the United States, this diagnosis accounted for 122,000 recorded outpatient visits and 56,000 hospital admissions. Pain may abate if progressive severe exocrine insufficiency continues. Patients who abstain from alcohol and use vigorous replacement therapy for maldigestion do reasonably well.

HEREDITARY PANCREATITIS Hereditary pancreatitis is a rare disease that is similar to chronic pancreatitis except for an early age of onset and evidence of hereditary factors (involving an autosomal dominant gene with incomplete penetrance). A genome-wide search using genetic linkage analysis identified the hereditary pancreatitis gene on chromosome 7. Mutations in ion codons 29 (exon 2) and 122 (exon 3) of the cationic trypsinogen gene cause autosomal dominant forms of hereditary pancreatitis. The codon 122 mutations lead to a substitution of the corresponding arginine with another amino acid, usually histidine. This substitution, when it occurs, eliminates a fail-safe trypsin self-destruction site necessary to eliminate trypsin that is prematurely activated within the acinar cell. These patients have recurring attacks of severe abdominal pain which may last from a few days to a few weeks. The serum amylase and lipase levels may be elevated during acute attacks but are usually normal. Patients frequently develop pancreatic calcification, diabetes mellitus, and steatorrhea, and, in addition, they have an increased incidence of pancreatic carcinoma, with the cumulative incidence being as high as 40% by age 70. Such patients often require ductal decompression for pain relief. Abdominal

complaints in relatives of patients with hereditary pancreatitis should raise the question of pancreatic disease.

Pancreatic Secretory Trypsin Inhibitor (PSTI) Gene Mutations PSTI, or SPINK1, is a 56-amino-acid peptide that specifically inhibits trypsin by physically blocking its active site. SPINK1 acts as the first line of defense against prematurely activated trypsinogen in the acinar cell. Recently, it has been shown that the frequency of SPINK1 mutations in patients with idiopathic chronic pancreatitis is markedly increased, suggesting that these mutations may be associated with pancreatitis.

PANCREATIC ENDOCRINE TUMORS

→*Pancreatic endocrine tumors are discussed in Chap. 329.*

OTHER CONDITIONS

ANNULAR PANCREAS When the ventral pancreatic anlage fails to migrate correctly to make contact with the dorsal anlage, the result may be a ring of pancreatic tissue encircling the duodenum. Such an annular pancreas may cause intestinal obstruction in the neonate or the adult. Symptoms of postprandial fullness, epigastric pain, nausea, and vomiting may be present for years before the diagnosis is entertained. The radiographic findings are symmetric dilation of the proximal duodenum with bulging of the recesses on either side of the annular band, effacement but not destruction of the duodenal mucosa, accentuation of the findings in the right anterior oblique position, and lack of change on repeated examinations. The differential diagnosis should include duodenal webs, tumors of the pancreas or duodenum, postbulbar peptic ulcer, regional enteritis, and adhesions. Patients with annular pancreas have an increased incidence of pancreatitis and peptic ulcer. Because of these and other potential complications, the treatment is surgical even if the condition has been present for years. Retrocolic duodenojejunostomy is the procedure of choice, although some surgeons advocate Billroth II gastrectomy, gastroenterostomy, and vagotomy.

PANCREAS DIVISUM Pancreas divisum occurs when the embryologic ventral and dorsal pancreatic anlagen fail to fuse, so that pancreatic drainage is accomplished mainly through the accessory papilla. Pancreas divisum is the most common congenital anatomic variant of the human pancreas. Current evidence indicates that this anomaly does not predispose to the development of pancreatitis in the great majority of patients who harbor it. However, the combination of pancreas divisum and a small accessory orifice could result in dorsal duct obstruction. The challenge is to identify this subset of patients with dorsal duct pathology. Cannulation of the dorsal duct by ERCP is not as easily done as is cannulation of the ventral duct. Patients with pancreatitis and pancreas divisum demonstrated by ERCP should be treated with conservative measures. In many of these patients, pancreatitis is idiopathic and unrelated to the pancreas divisum. Endoscopic or surgical intervention is indicated only when the above methods fail. If marked dilation of the dorsal duct can be demonstrated, surgical ductal decompression should be performed. The appropriate therapy for patients without dilation of the dorsal duct is not yet defined. It should be stressed that the ERCP appearance of pancreas divisum—i.e., a small-caliber ventral duct with an arborizing pattern—may be mistaken as representing an obstructed main pancreatic duct secondary to a mass lesion.

MACROAMYLASEMIA In macroamylasemia, amylase circulates in the blood in a polymer form too large to be easily excreted by the kidney. Patients with this condition demonstrate an elevated serum amylase value, a low urinary amylase value, and a C_{am}/C_{cr} ratio of $<1\%$. The presence of macroamylase can be documented by chromatography of the serum. The prevalence of macroamylasemia is 1.5% of the nonalcoholic general adult hospital population. Usually macroamylasemia is an incidental finding and is not related to disease of the pancreas or other organs.

Macrolipasemia has now been documented in a few patients with cirrhosis or non-Hodgkin's lymphoma. In these patients, the pancreas appeared normal on ultrasound and CT examination. Lipase was shown to be complexed with immunoglobulin A. Thus, the possibility of *both* macroamylasemia and macrolipasemia should be considered in patients with elevated blood levels of these enzymes.

ACKNOWLEDGMENT

This chapter represents a revised version of the chapter by Dr. Norton J. Greenberger, Dr. Phillip P. Toskes, and Dr. Kurt J. Isselbacher that was in the previous editions of Harrison's.

PART XIII DISORDERS OF THE IMMUNE SYSTEM, CONNECTIVE TISSUE, AND JOINTS

Section 1 The Immune System in Health and Disease

295 INTRODUCTION TO THE IMMUNE SYSTEM

Barton F. Haynes, Anthony S. Fauci

DEFINITIONS

- *Adaptive immune system*—recently evolved system of immune responses mediated by T and B lymphocytes. Immune responses by these cells are based on specific antigen recognition by clonotypic receptors that are products of genes that rearrange during development and throughout the life of the organism. Additional cells of the adaptive immune system include various types of antigen-presenting cells (Table 295-9).
- *Antibody*—B cell–produced molecules encoded by genes that rearrange during B cell development consisting of immunoglobulin heavy and light chains that together form the central component of the B cell receptor for antigen. Antibody can exist as B cell surface antigen-recognition molecules or as secreted molecules in plasma and other body fluids (Table 295-10).
- *Antigens*—foreign or self molecules that are recognized by the adaptive and innate immune systems resulting in immune cell triggering, T cell activation, and/or B cell antibody production.
- *Antimicrobial peptides*—small peptides <100 amino acids in length that are produced by cells of the innate immune system and have anti-infectious agent activity (Table 295-2).
- *Apoptosis*—the process of *programmed cell death* whereby signaling through various "death receptors" on the surface of cells [e.g., tumor necrosis factor (TNF) receptors, CD95] leads to a signaling cascade that involves activation of the caspase family of molecules and leads to DNA cleavage and cell death. Apoptosis, which does not lead to induction of inordinate inflammation, is to be contrasted with *cell necrosis*, which does lead to induction of inflammatory responses.
- *B lymphocytes*—bone marrow–derived or bursal-equivalent lymphocytes that express surface immunoglobulin (the B cell receptor for antigen) and secrete specific antibody after interaction with antigen (Figs. 295-8, 295-10).
- *B cell receptor for antigen*—complex of surface molecules that rearrange during postnatal B cell development, made up of surface immunoglobulin (Ig) and associated Ig $\alpha\beta$ chain molecules that recognize nominal antigen via Ig heavy and light chain variable regions, and signal the B cell to terminally differentiate to make antigen-specific antibody (Figs. 295-7, 295-9).
- *CD classification of human lymphocyte differentiation antigens*—the development of monoclonal antibody technology led to the discovery of a large number of new leukocyte surface molecules. In 1982, the First International Workshop on Leukocyte Differentiation Antigens was held to establish a nomenclature for cell-surface molecules of human leukocytes. From this and subsequent leukocyte differentiation workshops has come the *cluster of differentiation (CD) classification* of leukocyte antigens (Table 295-1).
- *Complement*—cascading series of plasma enzymes and effector proteins whose function is to lyse pathogens and/or target them to be phagocytized by neutrophils and monocyte/macrophage lineage cells of the reticuloendothelial system (Fig. 295-4, Table 295-7).
- *Co-stimulatory molecules*—molecules of antigen-presenting cells (such as B7-1 and B7-2 or CD40) that lead to T cell activation when bound by ligands on activated T cells (such as CD28 or CD40 ligand) (Fig. 295-6).
- *Cytokines*—soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate normal and pathologic inflammatory and immune responses (Tables 295-5, 295-8).
- *Dendritic cells*—myeloid and/or lymphoid lineage antigen-presenting cells of the adaptive immune system. Immature dendritic cells, or dendritic cell precursors, are key components of the innate immune system by responding to infections with production of high levels of cytokines. Dendritic cells are key initiators both of innate immune responses via cytokine production and of adaptive immune responses via presentation of antigen to T lymphocytes (Figs. 295-10, 295-11, Table 295-4).
- *Innate immune system*—ancient immune recognition system of host cells bearing germ line–encoded pattern recognition receptors (PRRs) that recognize pathogens and trigger a variety of mechanisms of pathogen elimination. Cells of the innate immune system include natural killer (NK) cell lymphocytes, monocytes/macrophages, dendritic cells, neutrophils, basophils, eosinophils, tissue mast cells, and epithelial cells (Tables 295-2, 295-3, 295-4, 295-6, 295-7).
- *Large granular lymphocytes*—lymphocytes of the innate immune system with azurophilic cytotoxic granules that have NK cell activity capable of killing foreign and host cells with little or no self major histocompatibility complex (MHC) class I molecules (Fig. 295-3).
- *Natural killer cells*—large granular lymphocytes that kill target cells that express little or no HLA class I molecules, such as malignantly transformed cells and virally infected cells. NK cells express receptors that inhibit killer cell function when self MHC class I is present (Fig. 295-3).
- *Pathogen-associated molecular patterns* (PAMPs)—Invariant molecular structures expressed by large groups of microorganisms that are recognized by host cellular pattern recognition receptors in the mediation of innate immunity (Fig. 295-2).
- *Pattern recognition receptors* (PRRs)—germ line–encoded receptors expressed by cells of the innate immune system that recognize pathogen-associated molecular patterns (Table 295-3).
- *T cells*—thymus-derived lymphocytes that mediate adaptive cellular immune responses including T helper, T regulatory, and cytotoxic T lymphocyte effector cell functions (Figs. 295-5, 295-6, 295-10, 295-11).
- *T cell receptor for antigen*—complex of surface molecules that rearrange during postnatal T cell development made up of clonotypic T cell receptor (TCR) α and β chains that are associated with the CD3 complex composed of invariant γ, δ, ε, ζ, and η chains. The clonotypic TCR-α and -β chains recognize peptide fragments of protein antigen physically bound in antigen-presenting cell MHC class I or II molecules, leading to signaling via the CD3 complex to mediate effector functions (Fig. 295-6).
- *Tolerance*—B and T cell nonresponsiveness to antigens that results from encounter with foreign or self antigens by B and T lymphocytes in the absence of expression of antigen-presenting cell co-stimulatory molecules. Tolerance to antigens may be induced and maintained by multiple mechanisms either centrally (in the thymus) or peripherally at sites throughout the peripheral immune system.

TABLE 295-1 *Human Leukocyte Surface Antigens—the CD Classification of Leukocyte Differentiation Antigens*

Surface Antigen (Other Names)	Family	Molecular Mass, kDa	Distribution	Ligand(s)	Function
CD1a (T6, HTA-1)	Ig	49	CD, cortical thymocytes, Langerhans type of dendritic cells	TCR$\gamma\delta$ T cells	CD1 molecules present lipid antigens of intracellular bacteria such as *M. leprae* and *M. tuberculosis* to TCR$\gamma\delta$ T cells.
CD1b	Ig	45	CD, cortical thymocytes, Langerhans type of dendritic cells	TCR$\gamma\delta$ T cells	
CD1c	Ig	43	DC, cortical thymocytes, subset of B cells, Langerhans type of dendritic cells	TCR$\gamma\delta$ T cells	
CD1d	Ig	?	Cortical thymocytes, intestinal epithelium, Langerhans type of dendritic cells	TCR$\gamma\delta$ T cells	
CD2 (T12, LFA-2)	Ig	50	T, NK	CD58, CD48, CD59, CD15	Alternative T cell activation, T cell anergy, T cell cytokine production, T- or NK-mediated cytolysis, T cell apoptosis, cell adhesion
CD3 (T3, Leu-4)	Ig	γ:25–28, δ:21–28, ε:20–25, η:21–22, ζ:16	T	Associates with the TCR	T cell activation and function; ζ is the signal transduction components of the CD3 complex
CD4 (T4, Leu-3)	Ig	55	T, myeloid	MHC-II, HIV, gp120, IL-16, SABP	T cell selection, T cell activation, signal transduction with p56*lck*, primary receptor for HIV
CD7 (3A1, Leu-9)	Ig	40	T, NK	K-12 (CD7L)	T and NK cell signal transduction and regulation of IFN-γ, TNF-α production
CD8 (T8, Leu-2)	Ig	34	T	MHC-I	T cell selection, T cell activation, signal transduction with p56*lck*
CD14 (LPS-receptor)	LRG	53–55	M, G (weak), not by myeloid progenitors	Endotoxin (lipopolysaccharide), lipoteichoic acid, PI	TLR4 mediates with LPS and other PAMP activation of innate immunity
CD19 B4	Ig	95	B (except plasma cells), FDC	Not known	Associates with CD21 and CD81 to form a complex involved in signal transduction in B cell development, activation, and differentiation
CD20 (B1)	Unassigned	33–37	B (except plasma cells)	Not known	Cell signaling, may be important for B cell activation and proliferation
CD21 (B2, CR2, EBV-R, C3dR)	RCA	145	Mature B, FDC, subset of thymocytes	C3d, C3dg, iC3b, CD23, EBV	Associates with CD19 and CD81 to form a complex involved in signal transduction in B cell development, activation, and differentiation; Epstein-Barr virus receptor
CD22 (BL-CAM)	Ig	130–140	Mature B	CDw75	Cell adhesion, signaling through association with p72*sky*, p53/56*lyn*, PI3 kinase, SHP1, fLCγ
CD23 (FcεRII, B6, Leu-20, BLAST-2)	C-type lectin	45	B, M, FDC	IgE, CD21, CD11b, CD11c	Regulates IgE synthesis, cytokine release by monocytes
CD28	Ig	44	T, plasma cells	CD80, CD86	Co-stimulatory for T cell activation; involved in the decision between T cell activation and anergy
CD40	TNFR	48–50	B, DC, EC, thymic epithelium, MP, cancers	CD154	B cell activation, proliferation, and differentiation, formation of GCs, isotype switching, rescue from apoptosis
CD45 (LCA, T200, B220)	PTP	180, 200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	T and B activation, thymocyte development, signal transduction, apoptosis
CD45RA	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 4 (A), restricted to a subset of T cells

(continued)

TABLE 295-1 — *(Continued)*

Surface Antigen (Other Names)	Family	Molecular Mass, kDa	Distribution	Ligand(s)	Function
CD45RB	PTP	200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 5 (B)
CD45RC	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 6 (C), restricted to a subset of T cells
CD45RO	PTP	180	Subset T, cortical thymocytes, "memory" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing no differentially spliced exons, restricted to a subset of T cells
CD80 (B7-1, BB1)	Ig	60	Activated B and T, MP, DC	CD28, CD152	Co-regulator of T cell activation; signaling through CD28 stimulates and through CD152 inhibits T cell activation
CD86 (B7-2, B70)	Ig	80	Subset B, DC, EC, activated T, thymic epithelium	CD28, CD152	Co-regulator of T cell activation; signaling through CD28 stimulates and through CD152 inhibits T cell activation
CD95 (APO-1, Fas)	TNFR	135	Activated T and B	Fas ligand	Mediates apoptosis
CD152 (CTLA-4)	Ig	30–33	Activated T	CD80, CD86	Inhibits T cell proliferation
CD154 (CD40L)	TNF	33	Activated CD4+ T, subset CD8+ T, NK, M, basophil	CD40	Co-stimulatory for T cell activation, B cell proliferation and differentiation

Note: CTLA, cytotoxic T lymphocyte–associated protein; DC, dendritic cells; EBV, Epstein-Barr virus; EC, endothelial cells; ECM, extracellular matrix; FcγRIIIA, low-affinity IgG receptor isoform A; FDC, follicular dendritic cells; G, granulocytes; GC, germinal center; GPI, glycosyl phosphotidylinositol; HTA, human thymocyte antigen; IgG, immunoglobulin G; LCA, leukocyte common antigen; LPS, lipopolysaccharide; MHC-I, major histocompatibility complex class I; MP, macrophages; Mr, relative molecular mass; NK, natural killer cells; P, platelets; PBT, peripheral blood T cells; PI, phosphotidylinositol; PI3K, phosphotidylinositol 3-kinase; PLC, phospholipase C; PTP, protein tyrosine phosphatase; TCR, T cell receptor; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor. INTRODUCTION The human immune system has evolved over millions of years from both invertebrate and vertebrate organisms to develop sophisticated defense mechanisms to protect the host from microbes and their virulence factors. From invertebrates, humans have inherited the innate immune system, an ancient defense system that uses germ line–encoded proteins to recognize pathogens. Cells of the innate immune system, such as macrophages, dendritic cells, and NK lymphocytes, recognize pathogen molecular motifs that are highly conserved among many microbes (PAMPs) and use a diverse set of receptor molecules (PRRs). Important components of the recognition of microbes by the innate immune system are: (1) recognition by germ line–encoded host molecules, (2) recognition of key microbe virulence factors but not recognition of self molecules, and (3) nonrecognition of benign foreign molecules or microbes. Upon contact with pathogens, macrophages and NK cells may kill pathogens directly or may activate a series of events that both slows the infection and recruits the more recently evolved arm of the human immune system, the adaptive immune system.

Adaptive immunity is found only in vertebrates and is based on the generation of antigen receptors on T and B lymphocytes by germline gene rearrangements, such that individual T or B cells express unique antigen receptors on their surface capable of specifically recognizing diverse antigens of the myriad of infectious agents in the environment. Coupled with finely tuned specific recognition mechanisms that maintain tolerance (nonreactivity) to self antigens, T and B lymphocytes bring both *specificity* and *immune memory* to vertebrate host defenses.

This chapter describes the cellular components, molecules (Table 295-1), and mechanisms that make up the innate and adaptive immune systems, and describes how adaptive immunity is recruited to the defense of the host by innate immune responses. An appreciation of the cellular and molecular bases of innate and adaptive immune responses is critical to understanding the pathogenesis of inflammatory, autoimmune, infectious, and immunodeficiency diseases.

THE INNATE IMMUNE SYSTEM All multicellular organisms, including humans, have developed the use of a limited number of germ line–encoded molecules that recognize large groups of pathogens. Because of the myriad human pathogens, host molecules of the human innate immune system sense "danger signals" and either recognize PAMPs, the common molecular structures shared by many pathogens, or recognize host cell molecules produced in response to infection such as heat shock proteins and fragments of the extracellular matrix. PAMPs must be conserved structures vital to pathogen virulence and survival, such as bacterial endotoxin, so that pathogens cannot mutate molecules of PAMPs to evade human innate immune responses. PPRs are host proteins of the innate immune system that recognize PAMPs or host danger signal molecules (Tables 295-2, 295-3). Thus, recognition of pathogen molecules by hematopoietic and nonhematopoietic cell types leads to activation/production of the complement cascade, cytokines, and antimicrobial peptides as effector molecules. In addition, pathogen PAMPs and host danger signal molecules activate dendritic cells to mature and to express molecules on the dendritic cell surface that optimize antigen presentation to respond to foreign antigens.

PATTERN RECOGNITION Major PRR families of proteins include C-type lectins, leucine-rich proteins, macrophage scavenger receptor proteins, plasma pentraxins, lipid transferase, and integrins (Table 295-3). A major group of PRR collagenous glycoproteins with C-type lectin do-

TABLE 295-2 *Major Components of the Innate Immune System*

Pattern recognition receptors (PRR)	C type lectins, leucine-rich proteins, scavenger receptors, pentraxins, lipid transferases, integrins
Antimicrobial peptides	α-Defensins, β-defensins, cathelin, protegrin, granulsyin, histatin, secretory leukoprotease inhibitor, and probiotics
Cells	Macrophages, dendritic cells, NK cells, NK-T cells, neutrophils, eosinophils, mast cells, basophils, and epithelial cells
Complement components	Classic and alternative complement pathway, and proteins that bind complement components
Cytokines	Autocrine, paracrine, endocrine cytokines that mediate host defense and inflammation, as well as recruit, direct, and regulate adaptive immune responses

Note: NK cells, natural killer cells.

TABLE 295-3 *Major Pattern Recognition Receptors (PRR) of the Innate Immune System*

PRR Protein Family	Sites of Expression	Examples	Ligands (PAMPs)	Functions of PRR
C-type lectins				
Humoral	Plasma proteins	Collectins, mannose-binding lectin	Bacterial and viral carbohydrates	Opsonization of bacteria and virus, activation of complement
Cellular	Macrophages, dendritic cell	Macrophage mannose receptor	Terminal mannose	Phagocytosis of pathogens
	Natural killer (NK) cells	NKG2-A	Carbohydrate on HLA molecules	Inhibits killing of host cells expressing HLA+ self peptides
Leucine-rich proteins	Macrophages, dendritic cells, epithelial cells	CD14	Lipopolysaccharide (LPS)	Binds LPS and Toll proteins
	Macrophages, dendritic cells, epithelial cells, many others	Toll-like receptors 1–9	Lipopolysaccharide	Binds multiple TLR ligands and activates the cell to produce cytokines to activate adaptive immunity. TLR ligands bind macrophages, dendritic cells, or B cell induces B7-1 (CD80) and B7-2 (CD86) co-stimulatory molecules that are required for T and B cell antigen presentation in adaptive immune responses
Scavenger receptors	Macrophage	Macrophage scavenger receptors	Bacterial cell walls	Phagocytosis of bacteria
Pentraxins	Plasma protein	C-creative proteins	Phosphatidyl choline	Opsonization of bacteria, activation of complement
	Plasma protein	Serum amyloid P	Bacterial cell walls	Opsonization of bacteria, activation of complement
Lipid transferases	Plasma protein	LPS binding protein	LPS	Binds LPS, transfers LPS to CD14
Integrins	Macrophages, dendritic cells, NK cells	CD11b,c; CD18	LPS	Signals cells, activates phagocytosis

Note: PAMPs, pathogen-associated molecular patterns.

mains are termed *collectins* and include the serum protein, mannose-binding lectin (MBL). MBL and other collectins, as well as two other protein families—the pentraxins (such as C-reactive protein and serum amyloid P) and macrophage scavenger receptors—all have the property of opsonizing (coating) bacteria for phagocytosis by macrophages and can also activate the complement cascade to lyse bacteria. Integrins are cell-surface adhesion molecules that signal cells after cells bind bacterial lipopolysacchride (LPS) and activate phagocytic cells to ingest pathogens.

A series of recent discoveries has revealed the mechanisms of connection between the innate and adaptive immune systems; these include (1) the plasma protein, LPS-binding protein, which binds and transfers LPS to the macrophage LPS receptor, CD14; and (2) a human family of proteins called *Toll-like receptor proteins* (TLR), which are associated with CD14, bind LPS, and signal epithelial cells, dendritic cells, and macrophages to produce cytokines and upregulate cell-surface molecules that signal the initiation of adaptive immune responses (Fig. 295-1, Table 295-3, and Table 295-4). Proteins in the Toll family (TLR 1–9) can be expressed on macrophages, dendritic cells, and B cells as well as on a variety of non-hematopoietic cell types including respiratory epithelial cells. Upon ligation, these receptors activate a series of intracellular events that lead to the killing of bacteria- and virus-infected cells as well as to the recruitment and ultimate activation of antigen-specific T and B lymphocytes (Fig. 295-1). Importantly, signaling by massive amounts of LPS through TLR4 leads to the release of large amounts of cytokines that mediate LPS-induced shock. Mutations in TLR4 proteins in mice protect from LPS shock, and TLR mutations in humans protect from LPS-induced inflammatory diseases such as LPS-induced asthma (Fig. 295-2).

Cells of invertebrates and vertebrates produce antimicrobial small peptides containing fewer than 100 amino acids that can act as endogenous antibodies (Table 295-2). Some of these peptides are produced by epithelia that line various organs, while others are found in macrophages or neutrophils that ingest pathogens. Antimicrobial peptides have been identified that kill bacteria such as *Pseudomonas* spp., *Escherichia coli*, and *Mycobacterium tuberculosis*.

EFFECTOR CELLS OF INNATE IMMUNITY Cells of the innate immune system and their roles in the first line of host defense are described in Table 295-4. Equally important as their roles in the mediation of innate immune responses are the roles that each cell type plays in recruiting T and B lymphocytes of the adaptive immune system to engage in specific antipathogen responses.

Monocytes-Macrophages Monocytes arise from precursor cells within bone marrow (Fig. 295-2) and circulate with a half-life ranging from 1 to 3 days. Monocytes leave the peripheral circulation by marginating in capillaries and migrating into a vast extravascular pool. Tissue macrophages arise from monocytes that have migrated out of the circulation and by in situ proliferation of macrophage precursors in tissue. Common locations where tissue macrophages (and certain of their specialized forms) are found are lymph node, spleen, bone marrow, perivascular connective tissue, serous cavities such as the peritoneum, pleura, skin connective tissue, lung (alveolar macrophage), liver (Kupffer cell), bone (osteoclast), central nervous system (microglia), and synovium (type A lining cell).

In general, monocytes-macrophages are on the first line of defense associated with innate immunity; however, they also play a major role in recruitment of adaptive immune responses by mediation of functions such as binding LPS, the presentation of antigen to T lymphocytes, and the secretion of factors such as interleukin (IL) 1, TNF, IL-12, and IL-6, which are central to antigen-specific activation of T and B lymphocytes (Fig. 295-1). Although monocytes-macrophages were originally thought to be the major antigen-presenting cells (APCs) of the immune system, it is now clear that dendritic cells are

the most potent and effective APCs in the body (see below). Monocytes-macrophages mediate innate immune effector functions such as destruction of antibody-coated bacteria, tumor cells, or even normal hematopoietic cells in certain types of autoimmune cytopenias. Monocytes-macrophages ingest bacteria or are infected by viruses, and in doing so, frequently undergo apoptosis. Macrophages that are "stressed" by intracellular infectious agents are recognized by dendritic cells as infected and apoptotic cells and are phagocytosed by dendritic cells. In this manner, dendritic cells "cross-present" infectious agent antigens of macrophages to T cells. Activated macrophages can also mediate antigen-nonspecific lytic activity and eliminate cell types such as tumor cells in the absence of antibody. This activity is largely mediated by cytokines (i.e., TNF-α and IL-1). Monocytes-macrophages express lineage-specific molecules (e.g., the cell-surface LPS receptor, CD14) as well as surface receptors for a number of molecules, including the Fc region of IgG, activated complement components, and various cytokines (Table 295-5). Finally, macrophage secretory products are more diverse than those of any other cell of the immune system. Among monocyte-macrophage-secreted products are hydrolytic enzymes, products of oxidative metabolism, TNF-α, IL-1, -6, -10, -12, -15, -18, and a number of chemoattractant cytokines (chemokines) involved in the orchestration of an immune response in tissues (Table 295-5).

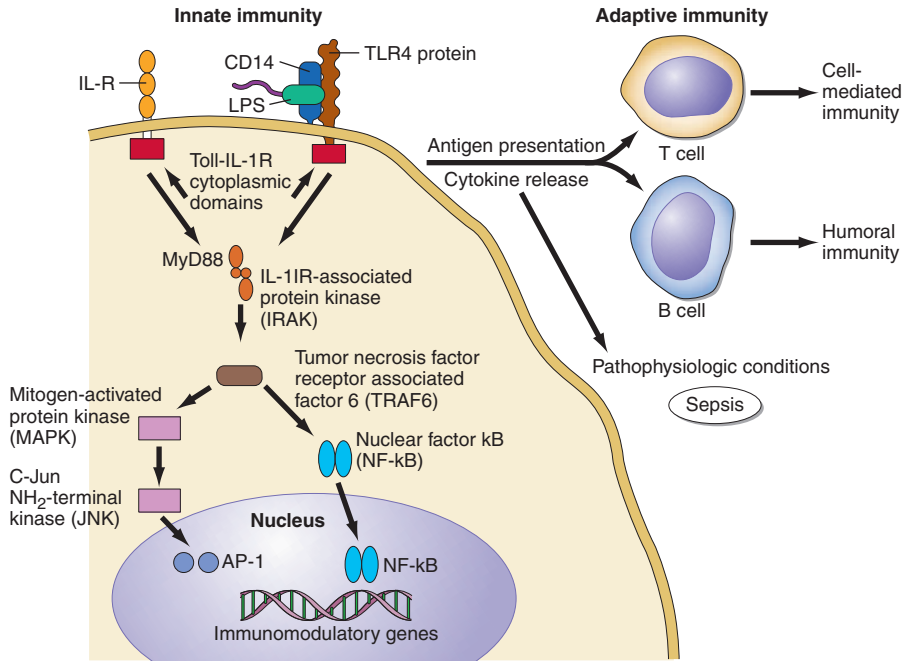

FIGURE 295-1 Role of Toll-like receptors (TLR) in the regulation of the response of macrophages to bacterial lipopolysaccharide (LPS). Lipopolysaccharide, a component of the cell wall of gram-negative bacteria, binds with high affinity to CD14, a glycosyl phosphatidylinositol–linked protein expressed on the surface of macrophages, and to TLR4 protein. This leads to activation of the transmembrane TLR4 protein, initiating an intracellular signaling cascade. Signaling through TLRs goes through the same signaling pathway as does interleukin (IL)1α and β signaling through the IL-1 receptor (R). The cytoplasmic domains of TRLs and IL-1R are highly homologous and are each called Toll-IL-1R cytoplasmic domains (TIR). Signaling by the TLR4 protein to the transcriptional regulatory complex of NF-κB and IκB occurs through the recruitment of MyD88 (a transcription factor) and the IL-1R-associated kinase (IRAK) and involves the adapter tumor necrosis factor receptor–associated factor 6 (TRAF-6) and the transcription factor NF-κB. Mitogen-activated protein kinase (MAPK) activates c-jun NH2-terminal kinase (Jnk), which in turn activates the nuclear transcription factor AP-1. AP-1 and NF-κB pass into the nucleus and bind to specific sequences in the promoter regions of immunomodulatory genes such as cytokine genes. This leads to the expression of immunomodulatory genes, including cytokines and co-stimulatory molecules. These gene products act on T and B cells to initiate the adaptive immune response. Under pathophysiologic conditions, high levels of immune system activation by bacterial LPS may lead to septic shock. *(Adapted from Modlin et al: N Engl J Med 340:1834, 1999; with permission.)*

Dendritic Cells Dendritic cells are bone marrow–derived APCs that are distinct from monocytes-macrophages and are derived from both lymphoid and myeloid lineages. They generally lack the standard T, B, NK, and monocyte cell markers but do express CD83 and other molecules that aid in their identification. They can be expanded in culture, and their function is enhanced by the cytokines granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-1, IL-4, and TNF-α. They are distinguished by an exceptional ability to present antigen, by expression of high levels of MHC class II and co-stimulatory molecules, and by dendritic morphology with multiple thin membrane projections (veils).

Lymphoid dendritic cells are also called *plasmacytoid dendritic cells*. They express some lymphoid markers, are present in T cell zones of lymphoid organs, and circulate in blood. Plasmacytoid dendritic cells are the most potent producers of interferon (IFN)-α and are also important presenters of antigen to T cells. INF-α is a potent antiviral cytokine; it activates NK cells to kill virally infected cells and drives T_H1 helper T cell responses to respond to viral and bacterial infections (see below for T helper types of responses).

There are two types of myeloid dendritic cells: *interstitial dendritic cells* (also called *follicular dendritic cells*) and *Langerhans dendritic cells*. Myeloid interstitial dendritic cells express myeloid markers, secrete IL-12 and IL-10, and are important APCs for both T and B cells. They circulate in blood and are located in T cell zones of lymphoid organs; in germinal centers of B cell follicles; and in tissue interstices of lung, heart, and kidney. Interstitial, or follicular, dendritic cells have extensive, thin, finger-like projections that surround the B cells in the germinal centers, allowing for maximal exposure of trapped antigen. The retention of antigen on the surface of interstitial dendritic cell membranes is critical for the selection and growth of high-affinity clones of B cells and for the maintenance of B cell memory. Of note, HIV is trapped in large quantities on the processes of interstitial dendritic cells in lymphoid organs, allowing the lymphoid tissue to serve as a reservoir of virus and a source of infection for CD4+ T cells migrating into the area to provide help to B cells in the initiation and propagation of an HIV-specific humoral response (Chap. 173). Langerhans dendritic cells express the CD1a antigen in addition to myeloid markers; circulate in blood; and populate T cell zones of lymph node, the thymus medulla, and skin and gut epithelial layers. They produce IL-12 and are key APCs for T cell activation at epithelial and other sites.

When dendritic cells come in contact with bacterial products, viral proteins, or host proteins released as danger signals from distressed host cells (Fig. 295-2), they bind to various TLRs and activate dendritic cells to release cytokines that drive cells of the innate immune system to become activated to respond to the invading organism, and recruit T and B cells of the adaptive immune system to respond. TLR engagement on dendritic cells upregulates dendritic cell MHC class II, B7-1 (CD80), and B7-2 (CD86) that enhance specific antigen presentation and induce dendritic cell cytokine production (Table 295-1). Thus, plasmacytoid and myeloid dendritic cells are important bridges between early (innate) and later (adaptive) immunity.

Large Granular Lymphocytes/Natural Killer Cells Large granular lymphocytes (LGLs) account for ~5 to 10% of peripheral blood lymphocytes. LGLs are nonadherent, nonphagocytic cells with large azurophilic cytoplasmic granules. LGLs express surface receptors for the Fc portion of IgG (CD16) and for NCAM-I (CD56), and many LGLs express some T lineage markers, particularly CD8, and proliferate in response

TABLE 295-4 *Cells of the Innate Immune System and Their Major Roles in Triggering Adaptive Immunity*

Cell Type	Major Role in Innate Immunity	Major Role in Adaptive Immunity
Macrophages	Phagocytose and kill bacteria; produce antimicrobial peptides; bind lipopolysaccharide (LPS); produce inflammatory cytokines	Produce interleukin (IL) 1 and tumor necrosis factor (TNF) α to upregulate lymphocyte adhesion molecules and chemokines to attract antigen-specific lymphocytes; produce IL-12 to recruit T_H1 helper T cell responses; upregulate co-stimulatory and MHC molecules to facilitate T and B lymphocyte recognition and activation; macrophages and dendritic cells, after LPS signaling, upregulate co-stimulatory molecules B7-1 (CD80) and B7-2 (CD86) required for activation of antigen-specific antipathogen T cells; there are also Toll-like proteins on B cells and dendritic cells that after LPS ligation induce CD80 and CD86 on these cells for T cell antigen presentation.
Plasmacytoid dendritic cells (DCs) of lymphoid lineage	Produce large amounts of interferon (IFN)α, which has antitumor and antiviral activity, and are found in T cell zones of lymphoid organs; they circulate in blood	IFN-α is a potent activator of macrophage and mature DCs to phagocytose invading pathogens and present pathogen antigens to T and B cells
Myeloid dendritic cells are of two types: interstitial and Langerhans-derived	Interstitial DCs are strong producers of IL-12 and IL-10 and are located in T cell zones of lymphoid organs, circulate in blood, and are present in the interstices of the lung, heart, and kidney; Langerhans DCs are strong producers of IL-12; are located in T cell zones of lymph nodes, skin epithelia, and the thymic medulla; and circulate in blood	Interstitial DCs are potent antigen-presenting cells for T cells and are potent primers of B cell activation for antibody production; Langerhans DCs are potent antigen-presenting cells for T cell priming
Natural killer (NK) cells	Kill foreign and host cells that have low levels of MHC+ self peptides. Express NK receptors that inhibit NK function in the presence of high expression of self-MHC.	Produce TNF-α and IFN-γ that recruit T_H1 helper T cell responses
NK-T cells	Lymphocytes with both T cell and NK surface markers that recognize lipid antigens of intracellular bacteria such as *M. tuberculosis* by CD1 molecules and kill host cells infected with intracellular bacteria.	Produce IL-4 to recruit T_H2 helper T cell responses, IgG1 and IgE production
Neutrophils	Phagocytose and kill bacteria, produce antimicrobial peptides	Produce nitric oxide synthase and nitric oxide that inhibit apoptosis in lymphocytes and can prolong adaptive immune responses
Eosinophils	Kill invading parasites	Produce IL-5 that recruits Ig-specific antibody responses
Mast cells and basophils	Release TNF-α, IL-6, IFN-γ in response to a variety of bacterial PAMPs	Produce IL-4 that recruits T_H2 helper T cell responses and recruit IgG1- and IgE-specific antibody responses
Epithelial cells	Produce anti-microbial peptides; tissue specific epithelia produce mediator of local innate immunity, e.g. lung epithelial cells produce surfactant proteins (proteins within the collectin family) that bind and promote clearance of lung invading microbes	Produce TGF-β that triggers IgA-specific antibody responses

Note: MHC, major histocompatibility complex; PAMP, pathogen-associated molecular patterns.

to IL-2. LGLs arise in both bone marrow and thymic microenvironments.

Functionally, LGLs share features with both monocytes-macrophages and neutrophils in that LGLs mediate both antibody-dependent cellular cytotoxicity (ADCC) and NK activity. ADCC is the binding of an opsonized (antibody-coated) target cell to an Fc receptor–bearing effector cell via the Fc region of antibody, resulting in lysis of the target by the effector cell. NK cell activity is the nonimmune (i.e., effector cell never having had previous contact with the target), MHC-unrestricted, non-antibody-mediated killing of target cells, which are usually malignant cell types, transplanted foreign cells, or virus-infected cells. Thus, LGLs that mediate NK cell activity may play an important role in immune surveillance and destruction of cells that spontaneously undergo malignant transformation in vivo. Subsets of NK cells may play a role in hematopoietic cell engraftment; some subsets stimulate bone marrow stem cells, and others stimulate engraftment. Lymphokine-activated killer (LAK) cells are NK lymphocytes that proliferate in vitro to high concentrations of IL-2 and develop the ability to kill tumor cells more efficiently than unstimulated NK cells. Rare patients with complete absence of NK cells have been described who lack both NK cell activity and CD56+, CD16+ lymphocytes but have normal T and B cell function. NK cell hyporesponsiveness is also observed in patients with the *Chédiak-Higashi syndrome*, an autosomal recessive disease associated with fusion of cytoplasmic granules and defective degranulation of neutrophil lysosomes.

The ability of NK cells to kill target cells is inversely related to target cell expression of MHC class I molecules. Thus, NK cells kill target cells with low or no levels of MHC class I expression and are prevented from killing target cells with high levels of class I expression. Recent studies have demonstrated the presence of NK receptors (NK-Rs) or killer immunoglobulin-like receptors (KIRs) that bind to either classic MHC class I molecules in a polymorphic way or the MHC-class Ib molecule HLA-E (Fig. 295-3). In every person, NK cells express at least one NK-R that recognizes a self–MHC class I allele. NK-Rs of the Ig superfamily bind specific MHC class I molecules;

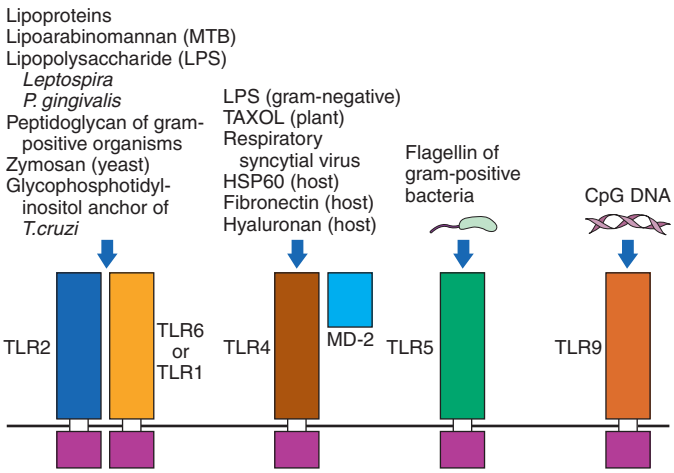

FIGURE 295-2 Toll-like receptors and their ligands. Certain pathogen-associated molecular patterns and host-derived products utilize Toll-like receptor (TLR) family members as critical signal transducers. TLR2 recognizes a variety of microbial products. TLR4 is essential for signaling via lipopolysaccharide (LPS) from Gram-negative bacteria; the exceptions are *Leptospira* and *Pseudomonas gingivalis*, the LPS of which is recognized by TLR2. TLR4 recognizes not only viral and plant products, but also endogenous host-derived products, such as heat shock protein 60 (HSP60) and fragments from fibronectin and hyaluronan. Compared with TLR2 and TLR4, recognition by TLR5 and TLR9 is more restricted and is required for flagellin and CpG DNA-mediated signaling, respectively. *(From S Akira et al: Nat Immunol 2:675, 2001; with permission.)*

e.g., the NK-R p140 binds HLA-A3, and NK-R p70 binds HLA-B27 (Fig. 295-3). A second NK-R of the C-type lectin family of proteins is termed *CD94/NKG2A* and binds the MHC-related protein HLA-E (Fig. 295-3). HLA-E has an MHC class I structure but exclusively binds the leader sequence peptides of classic MHC class I molecules in the HLA-E MHC-like "notch" (see "Molecular Basis of T Cell Recognition of Antigen," below). In this manner, CD94/NKG2A NK cell molecules survey and monitor the total level of classic MHC class I molecules on the surface of host cells. When cell-surface levels of host MHC class I molecules decrease, such as occurs during malignant transformation or viral infection of host cells, the altered host cell with diminished MHC class I expression is recognized by NK-Rs, and the NK cell is activated to kill the host tumor or virally infected cells. The ability of NK-Rs to bind to self-MHC and inhibit NK killing of normal host cells is a key protective mechanism for prevention of NK cell–mediated autoimmune disease. In addition, when HLA-E-positive cells become "stressed," such as occurs during viral infections, the leader sequence of heat shock protein-60 (HSP-60) is processed and inserted in the notch of HLA-E, yet this particular peptide/HLA-E complex is not recognized by NK cells. In this manner, NK cells can detect and recognize stressed virally infected cells for elimination.

Some NK cells express CD3 and are termed *NK/T cells*. NK/T cells can also express oligoclonal forms of the TCR for antigen that can recognize lipid molecules of intracellular bacteria when presented in the context of CD1 molecules on APCs. This mode of recognition of intracellular bacteria such as *Listeria monocytogenese* and *M. tuberculosis* by NK/T cells is thought to be an important defense mechanism against these organisms that, via usage of a clonal form of TCRs for antigen, incorporates components of both the innate and adaptive immune systems.

Neutrophils, Eosinophils, and Basophils Granulocytes are present in nearly all forms of inflammation and are amplifiers and effectors of innate immune responses. Unchecked accumulation and activation of granulocytes can lead to host tissue damage, as seen in neutrophil- and eosinophil-mediated *systemic necrotizing vasculitis*. Granulocytes are derived from stem cells in bone marrow. Each type of granulocyte (neutrophil, eosinophil, or basophil) is derived from a different subclass of progenitor cell, which is stimulated to proliferate by colony-stimulating factors (Table 295-5). During terminal maturation of granulocytes, class-specific nuclear morphology and cytoplasmic granules appear that allow for histologic identification of granulocyte type.

Neutrophils express Fc receptors for IgG (CD16) and receptors for activated complement components (C3b or CD35). Upon interaction of neutrophils with opsonized bacteria or immune complexes, azurophilic granules (containing myeloperoxidase, lysozyme, elastase, and other enzymes) and specific granules (containing lactoferrin, lysozyme, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated at the neutrophil surface. The generation of superoxide leads to inflammation by direct injury to tissue and by alteration of macromolecules such as collagen and DNA.

Eosinophils express Fc receptors for IgG (CD32) and are potent cytotoxic effector cells for various parasitic organisms. In *Nippostrongylus brasiliensis* helminth infection, eosinophils are key cytotoxic effector cells in removal of these parasites. Key to regulation of eosinophil cytotoxicity to *N. brasiliensis* worms are antigen-specific T helper cells that produce IL-4, thus providing an example of regulation of innate immune responses by adaptive immunity antigen-specific T cells. Intracytoplasmic contents of eosinophils, such as major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin, are capable of directly damaging tissues and may be responsible in part for the organ system dysfunction in the *hypereosinophilic syndromes* (Chap. 55). Since the eosinophil granule contains anti-inflammatory types of enzymes (histaminase, arylsulfatase, phospholipase D), eosinophils may homeostatically downregulate or terminate ongoing inflammatory responses.

The normal functions of basophils and tissue mast cells are not completely understood; they are potent reservoirs of cytokines such as IL-4. The capacity of basophil cytokines and mediators to increase local delivery of antibodies and complement by increasing vascular permeability is hypothetical. Thus, the basophil is identified principally with allergic reactions and some delayed cutaneous hypersensitivity states. Certainly, the promotion of increased vascular permeability by basophils is important in the genesis of inflammatory lesions in some vasculitis syndromes (Chap. 306). Basophils express high-affinity surface receptors for IgE (FcRI) and, upon cross-linking of basophil-bound IgE by antigen, release histamine, eosinophil chemotactic factor of anaphylaxis, and neutral protease—all mediators of immediate (anaphylaxis) hypersensitivity responses (Table 295-6). In addition, basophils express surface receptors for activated complement components (C3a, C5a), through which mediator release can be directly effected. →***For further discussion of tissue mast cells, see Chap. 298.***

THE COMPLEMENT SYSTEM The complement system, an important soluble component of the innate immune system, is a series of plasma enzymes, regulatory proteins, and proteins that are activated in a cascading fashion, resulting in cell lysis. There are four pathways of the complement system: the classic activation pathway activated by antigen/antibody immune complexes, the mannose-binding lectin (a serum collectin; Table 295-3) activation pathway activated by microbes with terminal mannose groups, the alternative activation pathway activated by microbes or tumor cells, and the terminal pathway that is common to the first three pathways and leads to the membrane attack complex that lyses cells (Fig. 295-4). The series of enzymes of the complement system are serine proteases.

Activation of the classic complement pathway via immune complex binding to C1q links the innate and adaptive immune systems via specific antibody in the immune complex. The alternative complement activation pathway is antibody-independent and is activated by binding of C3 directly to pathogens and "altered self" such as tumor cells. In the renal glomerular inflammatory disease, *IgA nephropathy*, IgA activates the alternative complement pathway and causes glomerular damage and decreased renal function. Activation of the classic complement pathway via C1, C4, and C2 and activation of the alternative pathway via factor D, C3, and factor B both lead to cleavage and

TABLE 295-5 *Cytokines and Cytokine Receptors*

Cytokine	Receptor	Cell Source	Cell Target	Biologic Activity
IL-1α,β	Type 1 IL-1R, type 2 IL-1R	Monocytes/macrophages, B cells, fibroblasts, most epithelial cells including thymic epithelium, endothelial cells	All cells	Upregulates adhesion molecule expression, neutrophil and macrophage emigration; mimics shock, fever; upregulates hepatic acute-phase protein production; facilitates hematopoiesis
IL-2	IL-2R α,β, common γ	T cells	T cells, B cells, NK cells, monocytes/macrophages	T cell activation and proliferation, B cell growth, NK cell proliferation and activation, enhanced monocyte/macrophage cytolytic activity
IL-3	IL-3R, common β	T cells, NK cells, mast cells	Monocytes/macrophages, mast cells, eosinophils, bone marrow progenitors	Stimulation of hematopoietic progenitors
IL-4	IL-4R α, common γ	T cells, mast cells, basophils	T cells, B cells, NK cells, monocytes/macrophages, neutrophils, eosinophils, endothelial cells, fibroblasts	Stimulates T_H2 helper T cell differentiation and proliferation; stimulates B cell Ig class switch to IgG1 and IgE; anti-inflammatory action on T cells, monocytes
IL-5	IL-5R α, common β	T cells, mast cells, and eosinophils	Eosinophils, basophils, murine B cells	Regulates eosinophil migration and activation
IL-6	IL-6R, gp130	Monocytes/macrophages, B cells, fibroblasts, most epithelium including thymic epithelium, endothelial cells	T cells, B cells, epithelial cells, hepatocytes, monocytes/macrophages	Induction of acute-phase protein production, T and B cell differentiation and growth, myeloma cell growth, osteoclast growth and activation
IL-7	IL-7R α, common γ	Bone marrow, thymic epithelial cells	T cells, B cells, bone marrow cells	Differentiation of B, T, and NK cell precursors, activation of T and NK cells
IL-8	CXCR1, CXCR2	Monocytes/macrophages, T cells, neutrophils, fibroblasts, endothelial cells, epithelial cells	Neutrophils, T cells, monocytes/macrophages, endothelial cells, basophils	Induces neutrophil, monocyte, and T cell migration; induces neutrophil adherance to endothelial cells and histamine release from basophils; stimulates angiogenesis; suppresses proliferation of hepatic precursors
IL-10	IL-10R	Monocytes/macrophages, T cells, B cells, keratinocytes, mast cells	Monocytes/macrophages, T cells, B cells, NK cells, mast cells	Inhibits macrophage proinflammatory cytokine production; downregulates cytokine class II antigen and B7-1 and B7-2 expression; inhibits differentiation of T_H1 helper T cells; inhibits NK cell function; stimulates mast cell proliferation and function and B cell activation and differentiation
IL-11	IL-11R, gp130	Bone marrow stromal cells	Megakaryocytes, B cells, hepatocytes	Induces megakaryocyte colony formation and maturation; enhances antibody responses; stimulates acute-phase protein production
IL-12 (35-kDa and 40-kDa subunits)	IL-12R	Activated macrophages, dendritic cells, neutrophils	T cells, NK cells	Induces T_H1 T helper cell formation and lymphokine-activated killer cell formation; increases CD8+ CTL activity
IL-13	IL-13/IL-4R	T cells (T_H2)	Monocytes/macrophages, B cells, endothelial cells, keratinocytes	Upregulation of VCAM-1 and C-C chemokine expression on endothelial cells; B cell activation and differentiation; inhibits macrophage proinflammatory cytokine production
IL-17	IL17R	CD4+ T cells	Fibroblasts, endothelium, epithelium	Enhanced cytokine secretion that promotes a predominant T_H1 response
IL-18	IL-18R (IL-1R-related protein)	Keratinocytes, macrophages	T cells, B cells, NK cells	Upregulated IFN-γ production, enhanced NK cell cytotoxicity
IFN-α	Type I interferon receptor	All cells	All cells	Antiviral activity; stimulates T cell, macrophage, and NK cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions

(continued)

TABLE 295-5 — *(Continued)*

Cytokine	Receptor	Cell Source	Cell Target	Biologic Activity
IFN-β	Type I interferon receptor	All cells	All cells	Antiviral activity; stimulates T cell, macrophage, and NK cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions
IFN-γ	Type II interferon receptor	T cells, NK cells	All cells	Regulates macrophage and NK cell activation; stimulates immunoglobulin secretion by B cells; induction of class II histocompatibility antigens; T_H1 T cell differentiation
TNF-α	TNF-RI, TNF-RII	Monocytes/macrophages, mast cells, basophils, eosinophils, NK cells, B cells, T cells, keratinocytes, fibroblasts, thymic epithelial cells	All cells except erythrocytes	Fever, anorexia, shock, capillary leak syndrome, enhanced leukocyte cytotoxicity, enhanced NK cell function, acute-phase protein synthesis, proinflammatory cytokine induction
G-CSF	G-CSFR; gp130	Monocytes/macrophages, fibroblasts, endothelial cells, thymic epithelial cells, stromal cells	Myeloid cells, endothelial cells	Regulates myelopoiesis; enhances survival and function of neutrophils; clinical use in reversing neutropenia after cytotoxic chemotherapy
GM-CSF	GM-CSFR; common β	T cells, monocytes/macrophages, fibroblasts, endothelial cells, thymic epithelial cells	Monocytes/macrophages, neutrophils, eosinophils, fibroblasts, endothelial cells	Regulates myelopoiesis; enhances macrophage bactericidal and tumoricidal activity; mediator of dendritic cell maturation and function; upregulates NK cell function; clinical use in reversing neutropenia after cytotoxic chemotherapy
M-CSF	M-CSFR (c-*fms* proto-oncogene)	Fibroblasts, endothelial cells, monocytes/macrophages, T cells, B cells, epithelial cells including thymic epithelium	Monocytes/macrophages	Regulates monocyte/macrophage production and function
Fractalkine	CX3CR1	Activated endothelial cells	NK cells, T cells, monocytes/macrophages	Cell surface chemokine/mucin hybrid molecule that functions as a chemoattractant, leukocyte activator, and cell adhesion molecule

Note:1 CSF, colony-stimulating factor; CXCR, CXC-type chemokine receptor; G-CSF, granulocyte CSF; GM-CSF, granulocyte-macrophage CSF; IFN, interferon; IL, interleukin; IP, IFN-γ-inducible protein; M-CSF, macrophage CSF; MDC, macrophage-derived chemokine; MHC, major histocompatibility complex; NK, natural killer; PMBC, peripheral blood mononuclear cells; PF, platelet factor; SCF, stem cell factor; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule. activation of C3. C3 activation fragments, when bound to target surfaces such as bacteria and other foreign antigens, are critical for opsonization (coating by antibody and complement) in preparation for phagocytosis. The MBL pathway substitutes MBL-associated serine proteases (MASP) 1 and 2 for C1q, C1r, and C1s to activate C4. The MBL activation pathway is activated by mannose on the surface of bacteria and viruses.

The three pathways of complement activation all converge on the final common terminal pathway. C3 cleavage by each pathway results in activation of C5, C6, C7, C8, and C9 resulting in the membrane attack complex that physically inserts into the membranes of target cells or bacteria and lyses them.

Thus, complement activation is a critical component of innate immunity for responding to microbial infection. The functional consequences of complement activation by the three initiating pathways and the terminal pathway are shown in Fig. 295-4 and Table 295-7. In general the cleavage products of complement components facilitate microbe or damaged cell clearance (C1q, C4, C3), promote activation and enhancement of inflammation (anaphylatoxins, C3a, C5a), and promote microbe or opsonized cell lysis (membrane attack complex).

CYTOKINES Cytokines are soluble proteins produced by a wide variety of hematopoietic and nonhematopoietic cell types (Table 295-5). They are critical for both normal innate and adaptive immune responses, and their expression may be perturbed in most immune, inflammatory, and infectious disease states.

Cytokines are involved in the regulation of the growth, development, and activation of immune system cells and in the mediation of the inflammatory response. In general, cytokines are characterized by considerable redundancy in that different cytokines have similar functions. In addition, many cytokines are pleiotropic in that they are capable of acting on many different cell types. This pleiotropism results from the expression on multiple cell types of receptors for the same cytokine (see below), leading to the formation of "cytokine networks." The action of cytokines may be: (1) autocrine when the target cell is the same cell that secretes the cytokine, (2) paracrine when the target cell is nearby, and (3) endocrine when the cytokine is secreted into the circulation and acts distal to the source.

Cytokines have been named based on presumed targets or based on presumed functions. Those cytokines that are thought to primarily target leukocytes have been named interleukins (IL-1, -2, -3, etc.). Many cytokines that were originally described as having a certain function have retained those names (granulocyte colony-stimulating factor or G-CSF, etc.). Cytokines belong in general to four major structural families, the four α-helix bundle family, the IL-1 family, the IL-17 family, and the chemokine family (Table 295-8). The four α-helix group is the largest family whose members have a three-dimensional core with four bundles of α-helices. Within this family are three sub-

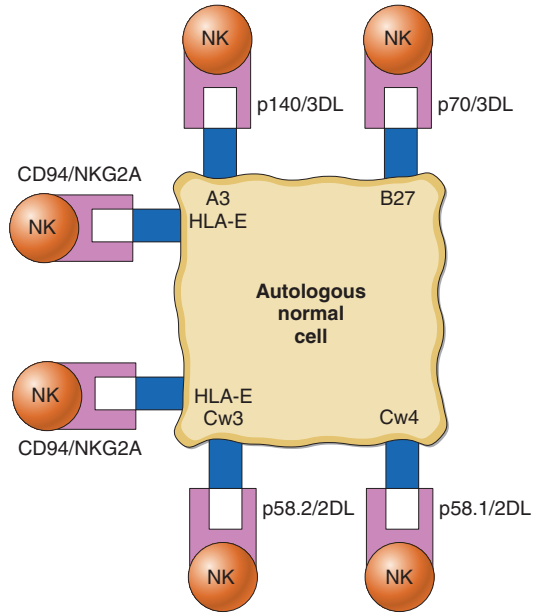

FIGURE 295-3 A schematic representation of the human natural killer (NK) receptor repertoire. The NK cells of a given individual express clonally distributed NK-Rs for self-HLA class I molecules. In this representative donor (HLA haplotype: HLA-A1, A3; HLA-B7, B27; HLA-Cw3, Cw4), NK cells express at least one inhibitory receptor that interacts with self-HLA alleles. The NK-Rs depicted in white are those belonging to the Ig superfamily that recognize allelic forms of HLA class I molecules. CD94/NKG2A receptors (stippled blue) bind to the MHC class I–like molecules, HLA-E, that present leader sequence peptides of classic MHC class I molecules to CD94/NKG2A molecules. The receptors belonging to the Ig superfamily do not cover the whole set of HLA class I alleles and are not expressed by 100% of NK cells. CD94/NKG2A receptors play important roles in monitoring the total level of MHC class I molecules on viral and malignantly transformed cells. *(Adapted from A Moretta et al: Immunol Rev 155:105, 1997; with permission. For nomenclature, see EO Long et al: Protein Rev at www.ncbi.nlm.nih.gov/prow/guide 679664748_g.htm, 1999.)*

families, the IL-2, IFN, and IL-10 subfamilies. The second group of cytokines is the IL-1 family, made up of IL-1α, IL-1β, and IL-18, all of which share about 25% sequence homology to each other. Most of the IL-17 family of cytokines promote T_H1 types of T cell responses that lead to cytotoxic T cell effector function. Finally, chemokines are cytokines that regulate cell movement and trafficking. Chemokines act through G protein–coupled receptors and have a distinctive three-dimensional structure. IL-8 is the only chemokine that early on was named an interleukin.

TABLE 295-6 *Mediators Released from Human Mast Cells and Basophils*

Mediator	Actions
Histamine	Smooth-muscle contraction, increased vascular permeability
Slow-reacting substance of anaphylaxis (SRSA) (leukotriene C4, D4, E4)	Smooth-muscle contraction
Eosinophil chemotactic factor of anaphylaxis (ECF-A)	Chemotactic attraction of eosinophils
Platelet-activating factor	Activates platelets to secrete serotonin and other mediators: smooth-muscle contraction; induces vascular permeability
Neutrophil chemotactic factor (NCF)	Chemotactic attraction of neutrophils
Leukotactic activity (leukotriene B4)	Chemotactic attraction of neutrophils
Heparin	Anticoagulant
Basophil kallikrein of anaphylaxis (BK-A)	Cleaves kininogen to form bradykinin

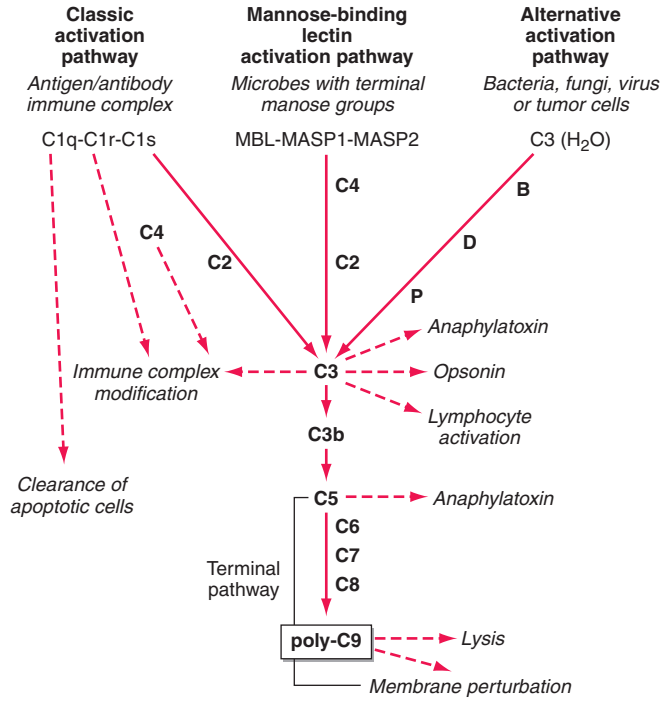

FIGURE 295-4 The four pathways and the effector mechanisms of the complement system. Dashed arrows indicate the functions of pathway components. *(After BJ Morley, MJ Walport: The Complement Facts Books. London, Academic Press, Chap 2, 2000; with permission.)*

In general, cytokines exert their effects by influencing gene activation that results in cellular activation, growth, differentiation, functional cell-surface molecule expression, and cellular effector function. In this regard, cytokines can have dramatic effects on the regulation of immune responses and the pathogenesis of a variety of diseases. Indeed, T cells have been categorized on the basis of the pattern of cytokines that they secrete that results in either humoral immune response (T_H2) or a cell-mediated immune response (T_H1).

Cytokine receptors can be grouped into five general families based on similarities in their extracellular amino acid sequences and conserved structural domains. The *immunoglobulin (Ig) superfamily* represents a large number of cell-surface and secreted proteins. The IL-1 receptors (type 1, type 2) are examples of cytokine receptors with extracellular Ig domains.

TABLE 295-7 *Biologic Activities of Some Complement Components*

Component	Activity
C4a weak anaphylatoxin	Evokes histamine release from basophils and mast cells
C3a	Anaphylatoxin; evokes histamine release from basophils and mast cells
C5a	Anaphylatoxin; evokes histamine release from basophils and mast cells; potent chemoattractant for monocytes and neutrophils
C3b, C3bi	Enhancement of phagocytosis by neutrophils and monocytes; promotes immune-complex binding to cells within monocyte-macrophage system, as well as neutrophils; C3b with Bb forms alternative pathway C3 convertase and amplifies alternative pathway; promotes solubilization of immune complexes
C5–9	Membrane attack complex; forms transmembrane channels leading to cell destruction

Source: After S Ruddy, in WN Kelley et al (eds): *Textbook of Rheumatology*, 4th ed. Philadelphia, Saunders, 1993, with permission.

The hallmark of the *hematopoietic growth factor (type 1) receptor* family is that the extracellular regions of each receptor contain two conserved motifs. One motif located at the N terminus is rich in cysteine residues. The other motif is located at the C terminus proximal to the transmembrane region and comprises five amino acid residues, tryptophan-serine-X-tryptophan-serine (WSXWS). This family can be grouped on the basis of the number of receptor subunits they have and on the utilization of shared subunits. A number of cytokine receptors, i.e., IL-6, IL-11, IL-12, and leukemia inhibitory factor, are paired with gp130. There is also a common 150-kDa subunit shared by IL-3, IL-5, and GM-CSF receptors. The gamma chain (γ_c) of the IL-2 receptor is common to the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. Thus, the specific cytokine receptor is responsible for ligand-specific binding, while the subunits such as gp130, the 150-kDa subunit, and γ_c are important in signal transduction. The γ_c gene is on the X chromosome, and mutations in the γ_c protein result in the *X-linked form of severe combined immune deficiency syndrome (X-SCID)* (Chap. 297).

TABLE 295-8 Four Major Structural Families of Cytokines

Four α-helix bundle family	Interleukin 2 (IL-2) Subfamily Interleukin: IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, IL-23 Not called interleukins: Colony-stimulating factor-1 (CSF1), granulocyte-macrophage colony-stimulating factor (CSF2), Flt-3 ligand, erythropoietin (EPO), thrombopoietin (THPO), leukocyte inhibitory factor (LIF) Not Interleukins: Growth hormone (GH1), prolactin (PRL), leptin (LEP), cardiotrophin (CTF1), ciliary neurotrophic factor (CNTF), cytokine receptor-like factor 1 (CLC or CLF) Interferon (IFN) subfamily IFN-β, IFN-α IL-10 subfamily IL-10, IL-19, IL-20, IL-22, IL-24 and IL-26
IL-1 Family	IL-1α (IL1A), IL-1β, (IL1B), IL-18 (IL-18), and paralogues
IL-17 Family	IL-17A, IL-17B, IL-17C, IL-17D, IL-17E, IL-17F
Chemokines	IL-8, MCP-1, MCP-2, MCP-3, MCP-4, eotaxin, TARC, LARC/MIP-3α, MDC, MIP-1α, MIP-1β, RANTES, MIP-3β, I-309, SLC, PARC, TECK, GROα, GROβ, NAP-2, IP-10, MIG, SDF-1, PF4

Note: GRO, growth-related peptide; IL, interleukin; IP, IFNδ-inducible protein; LARC, liver and activation-regulated chemokine; MCP, monocyte chemotactic protein; MDC, macrophage-derived chemokine; MIG, monoteine-induced by IFNδ; MIP, macrophage inflammatory protein; NAP, neutrophil-activating protein; PARC, pulmonary and activation-regulated chemokine; PF4, platelet factor; RANTES, regulated on activation normally T cell expressed and secreted; SDF, stromal-cell derived factor; SLC, secondary lymphoid tissue chemokine; TARC, thymus and activation-regulated chemokine; TECK, thymus-express chemokine.

The members of the *interferon (type II) receptor* family include the receptors for IFN-γ, and -β, which share a similar 210-amino-acid binding domain with conserved cysteine pairs at both the amino and carboxy termini. The members of the *TNF (type III) receptor family* share a common binding domain composed of repeated cysteine-rich regions. Members of this family include the p55 and p75 receptors for TNF (TNFR1 and TNFR2, respectively); CD40 antigen, which is an important B cell–surface marker involved in immunoglobulin isotype switching; fas/Apo-1, whose triggering induces apoptosis; CD27 and CD30, which are found on activated T cells and B cells; and nerve growth factor receptor.

The common motif for the *seven transmembrane helix family* was originally found in receptors linked to GTP-binding proteins. This family includes receptors for chemokines, β-adrenergic receptors, and retinal rhodopsin. It is important to note that two members of the chemokine receptor family, CXC chemokine receptor type 4 (CXCR4) and β chemokine receptor type 5 (CCR5), have recently been found to serve as the two major coreceptors for binding and entry of HIV into CD4-expressing host cells (Chap. 173).

Significant advances have been made in defining the signaling pathways through which cytokines exert their effects intracellularly. The Janus family of protein tyrosine kinases (JAK) is a critical element involved in signaling via the hematopoietin receptors. Four JAK kinases, JAK1, JAK2, JAK3, and Tyk2, preferentially bind different cytokine receptor subunits. Cytokine binding to its receptor brings the cytokine receptor subunits into apposition and allows a pair of JAKs to transphosphorylate and activate one another. The JAKs then phosphorylate the receptor on the tyrosine residues and allow signaling molecules to bind to the receptor, where these molecules become phosphorylated. Signaling molecules bind the receptor because they have domains (SH2, or src homology 2 domains) that can bind phosphorylated tyrosine residues. There are a number of these important signaling molecules that bind the receptor, such as the adapter molecule SHC, which can couple the receptor to the activation of the mitogen-activated protein kinase pathway. In addition, an important class of substrate of the JAKs is the signal transducers and activators of transcription (STAT) family of transcription factors. STATs have SH2 domains that enable them to bind to phosphorylated receptors, where they are then phosphorylated by the JAKs. It appears that different STATs have specificity for different receptor subunits. The STATs then dissociate from the receptor and translocate to the nucleus, bind to DNA motifs that they recognize, and regulate gene expression. The STATs preferentially bind DNA motifs that are slightly different from one another and thereby control transcription of specific genes. The importance of this pathway is particularly relevant to lymphoid development. Mutations of JAK3 itself also result in a disorder identical to X-SCID; however, since JAK3 is found on chromosome 19 and not on the X chromosome, JAK3 deficiency occurs in boys and girls (Chap. 297).

THE ADAPTIVE IMMUNE SYSTEM Adaptive immunity is characterized by antigen-specific responses to a foreign antigen or pathogen. A key feature of adaptive immunity is that following the initial contact with antigen (*immunologic priming*), subsequent antigen exposure leads to more rapid and vigorous immune responses (*immunologic memory*). The adaptive immune system consists of dual limbs of cellular and humoral immunity. The principal effectors of cellular immunity are T lymphocytes, while the principal effectors of humoral immunity are B lymphocytes (Table 295-9). Both B and T lymphocytes derive from a common stem cell.

The proportion and distribution of immunocompetent cells in various tissues reflect cell traffic, homing patterns, and functional capabilities. Bone marrow is the major site of maturation of B cells, monocytes-macrophages, and granulocytes and contains pluripotent stem cells which, under the influence of various colony stimulating factors, are capable of giving rise to all hematopoietic cell types. T cell precursors also arise from hematopoietic stem cells and home to

TABLE 295-9 Components of the Adaptive Immune System

Cellular: Thymus-derived (T) lymphocytes—T cell precursors in the thymus; naive mature T lymphocytes before antigen exposure; memory T lymphocytes after antigen contact; helper T lymphocytes for B and T cell responses; cytotoxic T lymphocytes that kill pathogen-infected target cells

Humoral: Bone-marrow-derived (B) lymphocytes—B cell precursors in bone marrow; naive B cells prior to antigen recognition, memory B cells after antigen contact; plasma cells that secrete specific antibody

Cytokines: Soluble proteins that direct, focus, and regulate specific T versus B lymphocyte immune responses

the thymus for maturation. Mature T lymphocytes, B lymphocytes, monocytes, and dendritic/Langerhans cells enter the circulation and home to peripheral lymphoid organs (lymph nodes, spleen) and the gut-associated lymphoid tissue (tonsil, Peyer's patches, and appendix) as well as the skin and mucous membranes and await activation by foreign antigen.

T Cells The pool of effector T cells is established in the thymus early in life and is maintained throughout life both by new T cell production in the thymus and by antigen-driven expansion of virgin peripheral T cells into "memory" T cells that reside in peripheral lymphoid organs. The thymus exports ~2% of the total number of thymocytes per day throughout life, with the total number of daily thymic emigrants decreasing by ~3% per year during the first four decades of life. Thymic emigrants can be identified by the expression of certain combinations of T cell surface markers and by the presence in nuclei of excised (deleted) pieces of rearranged TCR DNA, called *T cell receptor excision circles*.

Mature T lymphocytes constitute 70 to 80% of normal peripheral blood lymphocytes (only 2% of the total-body lymphocytes are contained in peripheral blood), 90% of thoracic duct lymphocytes, 30 to 40% of lymph node cells, and 20 to 30% of spleen lymphoid cells. In lymph nodes, T cells occupy deep paracortical areas around B cell germinal centers, and in the spleen, they are located in periarteriolar areas of white pulp (Chap. 54). T cells are the primary effectors of cell-mediated immunity, with subsets of T cells maturing into CD8+ cytotoxic T cells capable of lysis of virus-infected or foreign cells. In general, CD4+ T cells are also the primary regulatory cells of T and B lymphocyte and monocyte function by the production of cytokines and by direct cell contact. In addition, T cells regulate erythroid cell maturation in bone marrow, and through cell contact (CD40 ligand) have an important role in activation of B cells and induction of Ig isotype switching.

Human T cells express cell-surface proteins that mark stages of intrathymic T cell maturation or identify specific functional subpopulations of mature T cells. Many of these molecules mediate or participate in important T cell functions (Table 295-1; Fig. 295-5).

The earliest identifiable T cell precursors in bone marrow are CD34+ pro-T cells (i.e., cells in which TCR genes are neither rearranged nor expressed). In the thymus, CD34+ T cell precursors begin cytoplasmic (c) synthesis of components of the CD3 complex of TCR-associated molecules (Fig. 295-5.) Within T cell precursors, TCR for antigen gene rearrangement begins under the influence of IL-7 and yields two T cell lineages, expressing either TCR$\alpha\beta$ chains or TCR$\gamma\delta$ chains. T cells expressing the TCR$\alpha\beta$ chains comprise the majority of peripheral T cells in blood, lymph node, and spleen and terminally differentiate into either CD4+ or CD8+ cells. Cells expressing TCR$\gamma\delta$ chains circulate as a minor population in blood; their functions, although not fully understood, have been postulated to be those of immune surveillance at epithelial surfaces and cellular defenses against mycobacterial organisms and other intracellular bacteria (see below). Immature cortical thymocytes express both CD4 and CD8 (i.e., they are double positive); however, upon reaching functional maturity, T cell CD4 and CD8 are reciprocally expressed (i.e., T cells become single positive for either CD4 or CD8).

In the thymus, the recognition of self-peptides on thymic epithelial cells, thymic macrophages, and dendritic cells plays an important role in shaping the T cell repertoire to recognize foreign antigen (*positive selection*) and in eliminating highly autoreactive T cells (*negative selection*). As immature cortical thymocytes begin to express surface TCR for antigen, autoreactive thymocytes are destroyed (negative selection), thymocytes with TCRs capable of interacting with foreign antigen peptides in the context of self–MHC antigens are activated and develop to maturity (positive selection), and thymocytes with TCR that are incapable of binding to self–MHC antigens die of attrition (*no selection*). Mature thymocytes that are positively selected are either

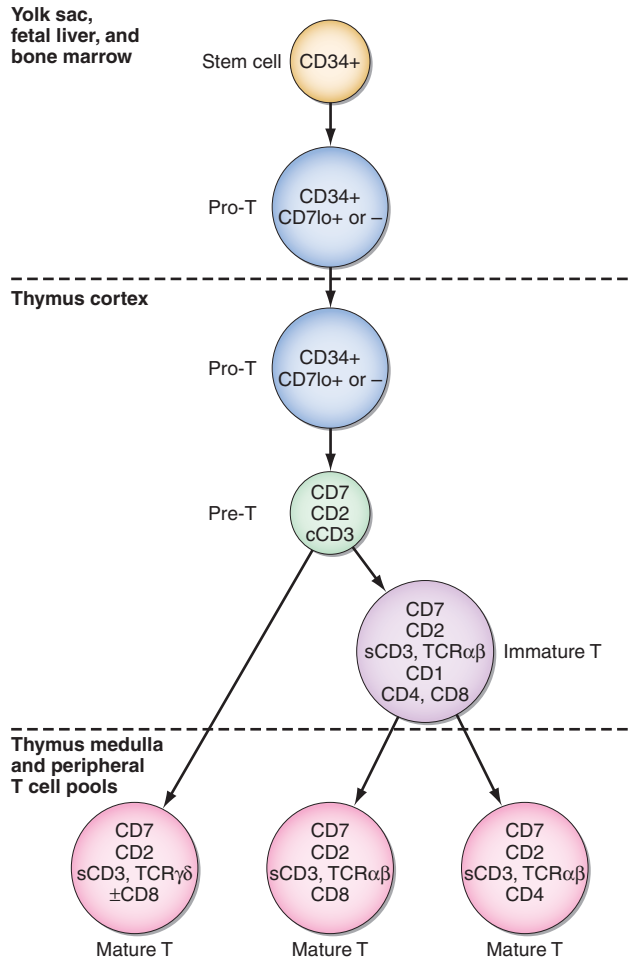

FIGURE 295-5 Human T cell maturation. sCD3, surface CD3 expression; cCD3, cytoplasmic CD3 expression; TCR, T cell receptor.

CD4+ helper T cells or MHC class II–restricted cytotoxic (killer) T cells, or they are CD8+ T cells destined to become MHC class I–restricted cytotoxic T cells. *MHC class I– or class II–restricted* means that T cells recognize antigen peptide fragments only when they are presented in the antigen-recognition site of a class I or class II MHC molecule, respectively (see below).

After thymocyte maturation and selection, CD4 and CD8 thymocytes leave the thymus and migrate to the peripheral immune system. It is important to note that the adult thymus continues to function, albeit with decreasing output, well into adult life. Thus, the thymus continues to be a contributor to the peripheral immune system, both normally and when the peripheral T cell pool is damaged, such as occurs in AIDS and cancer chemotherapy.

MOLECULAR BASIS OF T CELL RECOGNITION OF ANTIGEN The TCR for antigen is a complex of molecules consisting of an antigen-binding heterodimer of either $\alpha\beta$ or $\gamma\delta$ chains noncovalently linked with five CD3 subunits (γ, δ, ϵ, ζ, and η) (Fig. 295-6). The CD3 ζ chains are either disulfide-linked homodimers (CD3-ζ_2) or disulfide-linked heterodimers composed of one ζ chain and one η chain. TCR$\alpha\beta$ or TCR$\gamma\delta$ molecules must be associated with CD3 molecules to be inserted into the T cell surface membrane, TCRα being paired with TCRβ and TCRγ being paired with TCRδ. Molecules of the CD3 complex mediate transduction of T cell activation signals via TCRs, while TCRα and -β or -γ and -δ molecules combine to form the TCR antigen-binding site.

The α, β, γ, and δ TCR for antigen molecules have amino acid sequence homology and structural similarities to immunoglobulin heavy and light chains and are members of the *immunoglobulin gene superfamily* of molecules. The genes encoding TCR molecules are encoded as clusters of gene segments that rearrange during the course of T cell maturation. This creates an efficient and compact mechanism

for housing the diversity requirements of antigen receptor molecules. The TCRα chain is on chromosome 14 and consists of a series of V (variable), J (joining), and C (constant) regions. The TCRβ chain is on chromosome 7 and consists of multiple V, D (diversity), J, and C TCRβ loci. The TCRγ chain is on chromosome 7, and the TCRδ chain is in the middle of the TCRα locus on chromosome 14. Thus, molecules of the TCR for antigen have constant (framework) and variable regions, and the gene segments encoding the α, β, γ, and δ chains of these molecules are recombined and selected in the thymus, culminating in synthesis of the completed molecule. In both T and B cell precursors (see below), DNA rearrangements of antigen receptor genes involve the same enzymes, recombinase activating gene (RAG)1 and RAG2, both DNA-dependent protein kinases.

TCR diversity is created by the different V, (D), and J segments that are possible for each receptor chain by the many permutations of V, D, and J segment combinations, by "N-region diversification" due to the addition of nucleotides at the junction of rearranged gene segments, and the pairing of individual chains to form a TCR dimer. As T cells mature in the thymus, the repertoire of antigen-reactive T cells is modified by selection processes that eliminate many autoreactive T cells, enhance the proliferation of cells that function appropriately with self-MHC molecules and antigen, and allow T cells with nonproductive TCR rearrangements to die.

TCR$\alpha\beta$ cells do not recognize native protein or carbohydrate antigens. Instead, T cells recognize only short (~9 to 13 amino acids) peptide fragments derived from protein antigens taken up or produced in APCs. Foreign antigens may be taken up by endocytosis into acidified intracellular vesicles or by phagocytosis and degraded into small peptides that associate with MHC class II molecules (exogenous antigen-presentation pathway). Other foreign antigens arise endogenously in the cytosol (such as from replicating viruses) and are broken down into small peptides that associate with MHC class I molecules (endogenous antigen-presenting pathway). Thus, APCs proteolytically degrade foreign proteins and display peptide fragments embedded in the MHC class I or II antigen-recognition site on the MHC molecule surface, where foreign peptide fragments are available to bind to TCR$\alpha\beta$ or TCR$\gamma\delta$ chains of reactive T cells. CD4 molecules act as an adhesive and, by direct binding to MHC class II (DR, DQ, or DP) molecules, stabilize the interaction of TCR with peptide antigen (Fig. 295-6). Similarly, CD8 molecules also act as adhesives to stabilize the TCR-antigen interaction by direct CD8 molecule binding to MHC class I (A, B, or C) molecules.

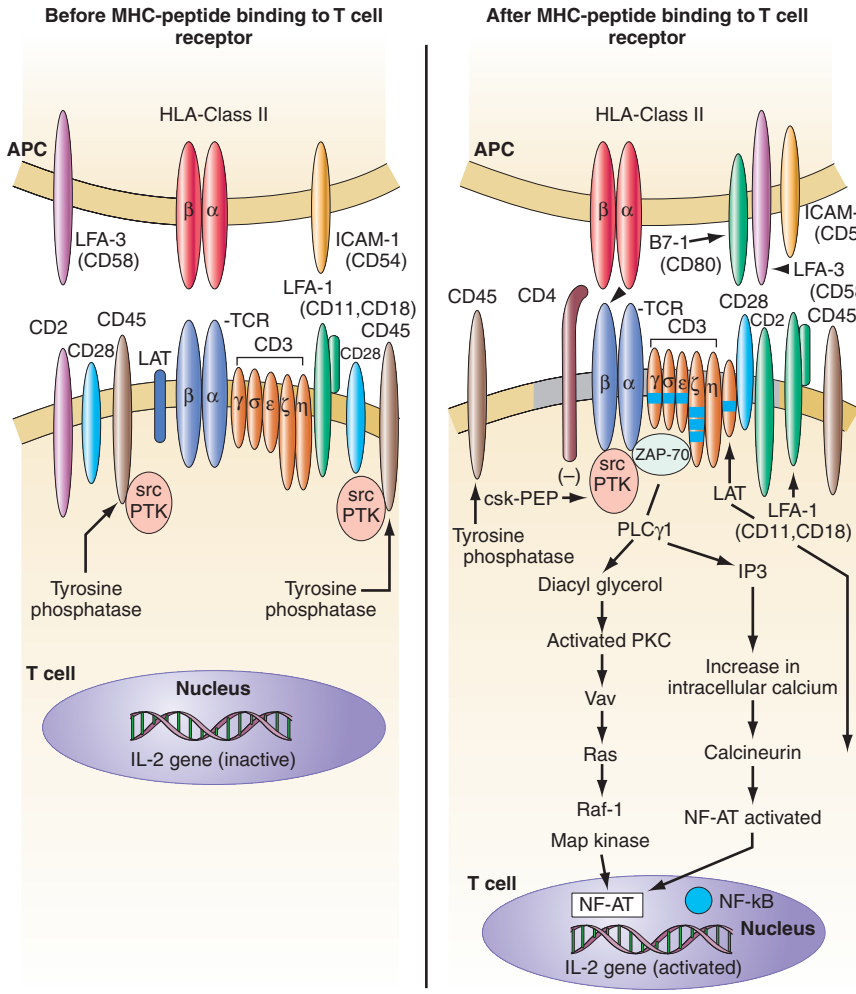

FIGURE 295-6 Molecules involved in human T cell recognition of antigen and in human T cell activation. *A*. Schematic arrangement of antigen-presenting cell (APC) molecules (top cell) and T cell molecules (bottom cell) before MHC-peptide binding to T cell receptor (TCR). *B*. The changes that occur in T cell and APC molecules after MHC-peptide binding to TCR. The black triangle at the tip of the $\alpha\beta$ chains of MHC class II molecules represents a peptide fragment of "processed" protein antigen. After TCR ligation, src protein tyrosine kinase (PTK) is activated via dephosphorylation and the TCR complex is joined by CD4, CD2, and CD28 as well as the linker for activated T lymphocytes (LAT) in a lipid microdomain area (gray area). Activation signals are mediated via immunoreceptor tyrosine-based activation (ITAM) sequences in LAT and CD3 chains (blue bars) that bind to enzymes and transduce activation signals to the nucleus via the indicated intracellular activation pathways. See text for details of the activation and signal transduction process. *(Adapted from A Weiss and DR Littman: Cell 76:263, 1995; with permission.)*

Antigens that arise in the cytosol and are processed via the endogenous antigen-presentation pathway are cleaved into small peptides by a 28-subunit complex of proteases called the *proteasome*. From the proteasome, antigen peptide fragments are transported from the cytosol into the lumen of the endoplasmic reticulum by a heterodimeric complex termed *transporters associated with antigen processing*, or TAP proteins. There, MHC class I molecules in the endoplasmic reticulum membrane physically associate with processed cytosolic peptides. Following peptide association with class I molecules, peptide–class I complexes are exported to the Golgi apparatus, and then to the cell surface, for recognition by CD8+ T cells.

Antigens taken up from the extracellular space via endocytosis into intracellular acidified vesicles are degraded by vesicle proteases into peptide fragments. Intracellular vesicles containing MHC class II molecules fuse with peptide-containing vesicles, thus allowing peptide fragments to physically bind to MHC class II molecules. Peptide–MHC class II complexes are then transported to the cell surface for recognition by CD4+ T cells.

Whereas it is generally agreed that the TCR$\alpha\beta$ receptor recognizes peptide antigens in the context of MHC class I or class II molecules, lipids in the cell wall of intracellular bacteria such as *M. tuberculosis* can also be presented to a wide variety of T cells, including subsets of CD4−, CD8− TCR$\alpha\beta$ T cells, TCR$\gamma\delta$ T cells, and a subset of CD8+ TCR$\alpha\beta$ T cells. Importantly, bacterial lipid antigens are not presented in the context of MHC class I or II molecules, but rather are presented in the context of MHC-related CD1 molecules. Some $\gamma\delta$ T cells that recognize lipid antigens via CD1 molecules have very restricted TCR usage, do not need antigen priming to respond to bacterial lipids, and may actually be a form of innate rather than acquired immunity to intracellular bacteria.

Just as foreign antigens are degraded and their peptide fragments presented in the context of MHC class I or class II molecules on APCs, endogenous self-proteins are also degraded and self-peptide fragments

are presented to T cells in the context of MHC class I or class II molecules on APCs. In peripheral lymphoid organs, T cells are present that are capable of recognizing self-protein fragments but normally are *anergic* or *tolerant*, i.e., nonresponsive to self-antigenic stimulation, due to lack of self-antigen upregulating APC *co-stimulatory molecules* such as B7-1 and B7-2 (see below).

Once engagement of mature T cell TCR by foreign peptide occurs in the context of self–MHC class I or class II molecules, binding of non-antigen-specific adhesion ligand pairs such as CD54-CD11/CD18 and CD58-CD2 stabilizes MHC peptide–TCR binding and the expression of these adhesion molecules is upregulated (Fig. 295-6). Once antigen ligation of the TCR occurs, the T cell membrane is partitioned into *lipid membrane microdomains*, or *lipid rafts*, that coalesce the key signaling molecules TCR/CD3 complex, CD28, CD2, LAT (linker for activation of T cells), intracellular activated (dephosphorylated) src family protein tyrosine kinases (PTKs), and the key CD3ζ-associated protein-70 (ZAP-70) PTK (Fig. 295-7). Importantly, during T cell activation, the dephosphorylating molecule, CD45, with protein tyrosine phosphatase activity is partitioned away from the TCR complex to allow activating phosphorylation events to occur. The coalescence of signaling molecules of activated T lymphocytes in *microdomains* has suggested that T cell–APC interactions can be considered *immunologic synapses*, analogous in function to neuronal synapses.

After TCR-MHC binding is stabilized, activation signals are transmitted through the cell to the nucleus that lead to the expression of gene products important in mediating the wide diversity of T cell functions such as the secretion of IL-2. The TCR does not have intrinsic signaling activity but is linked to a variety of signaling pathways via immunoreceptor tyrosine-based activation motifs (ITAMs) expressed on the various CD3 chains that bind to proteins that mediate signal transduction. Each of the pathways results in the activation of particular transcription factors that control the expression of cytokine and cytokine receptor genes. Thus, antigen-MHC binding to the TCR induces the activation of the src family of PTKs, fyn and lck (lck is associated with CD4 or CD8 co-stimulatory molecules); phosphorylation of CD3ζ chain; activation of the related tyrosine kinases ZAP-70 and syk; and downstream activation of the calcium-dependent calcineurin pathway, the ras pathway, and the protein kinase C pathway. Each of these pathways leads to activation of specific families of transcription factors (including NF-AT, fos and jun, and rel/NF-κB) that form heteromultimers capable of inducing expression of IL-2, IL-2 receptor, IL-4, TNF-α, and other T cell mediators. The src family kinases require dephosphorylation of an inactivation site by CD45 phosphatase before they can be phosphorylated on an activation site. Furthermore, the activity through the receptor is downregulated by the csk-PEP enzyme, a phosphatase that inactivates the src family kinases.

In addition to the signals delivered to the T cell from the TCR complex and CD4 and CD8, molecules on the T cell such as CD28 and inducible co-stimulator (ICOS) and molecules on dendritic cells such as B7-1 (CD80) and B7-2 (CD86) also deliver important co-stimulatory signals that upregulate T cell cytokine production and are essential for T cell activation. If signaling through CD28 or ICOS does not occur, or if CD28 is blocked, the T cell becomes *anergic* (nonresponsive, or *tolerant*) rather than activated (see "Immune Tolerance and Autoimmunity," below).

T CELL SUPERANTIGENS Conventional antigens bind to MHC class I or II molecules in the groove of the $\alpha\beta$ heterodimer and bind to T cells via the V regions of the TCRα and -β chains (Fig. 295-6). In contrast, superantigens bind directly to the lateral portion of the TCRβ chain and MHC class II β chain and stimulate T cells based solely on the Vβ gene segment utilized independent of the D, J, and Vα sequences present. *Superantigens* are protein molecules capable of activating up to 20% of the peripheral T cell pool, whereas conventional antigens activate <1 in 10,000 T cells. T cell superantigens include staphylococcal enterotoxins, other bacterial products, and certain nonhuman retroviral proteins. Superantigen stimulation of human peripheral T cells occurs in the clinical setting of the *staphylococcal toxic shock syndrome*, leading to massive overproduction of T cell cytokines that leads to hypotension and shock (Chap. 120).

B Cells Mature B cells comprise 10 to 15% of human peripheral blood lymphocytes, 50% of splenic lymphocytes, and ~10% of bone marrow lymphocytes. B cells express on their surface intramembrane immunoglobulin (Ig) molecules that function as B cell receptors (BCRs) for antigen in a complex of Ig-associated α and β signaling molecules with properties similar to those described in T cells (Fig. 295-7). Unlike T cells, which recognize only processed peptide fragments of conventional antigens embedded in the notches of MHC class I and class II antigens of APCs, B cells are capable of recognizing and proliferating to whole unprocessed native antigens via antigen binding to B cell surface Ig (sIg) receptors. B cells also express surface receptors for the Fc region of IgG molecules (CD32) as well as receptors for activated complement components (C3d or CD21, C3b or CD35). The primary function of B cells is to produce antibodies. B cells also serve as APCs and are highly efficient at antigen processing. Their antigen-presenting function is enhanced by a variety of cytokines. Mature B cells are derived from bone marrow precursor cells that arise continuously throughout life (Figs. 295-2, 295-10).

B lymphocyte development can be separated into antigen-independent and antigen-dependent phases. Antigen-independent B cell development occurs in primary lymphoid organs and includes all stages of B cell maturation up to the sIg+ mature B cell. Antigen-dependent B cell maturation is driven by the interaction of antigen with the mature B cell sIg, leading to memory B cell induction, Ig class switching, and plasma cell formation. Antigen-dependent stages of B cell maturation occur in secondary lymphoid organs, including lymph node, spleen, and gut Peyer's patches. In contrast to the T cell repertoire that is generated intrathymically before contact with foreign antigen, the repertoire of B cells expressing diverse antigen-reactive sites is modified by further alteration of Ig genes after stimulation by antigen—a process called *somatic mutation*—which occurs in lymph node germinal centers.

During B cell development, diversity of the antigen-binding variable region of Ig is generated by an ordered set of Ig gene rearrangements that are similar to the rearrangements undergone by TCR α, β, γ, and δ genes. For the heavy chain, there is first a rearrangement of D segments to J segments, followed by a second rearrangement between a V gene segment and the newly formed D-J sequence; the C segment is aligned to the V-D-J complex to yield a functional Ig heavy chain gene (V-D-J-C). During later stages, a functional κ or λ light

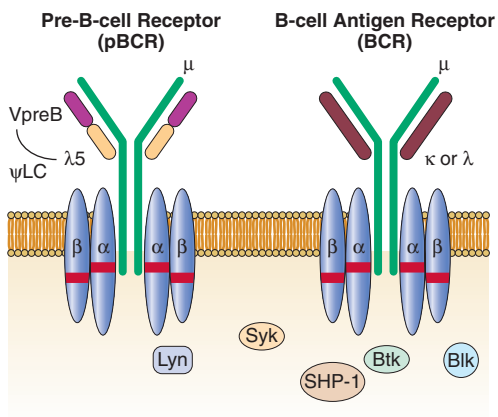

FIGURE 295-7 The pre-B cell receptor and B-cell antigen receptor associate with the signal-transducing heterodimer Igα/Igβ. Solid horizontal bars in α and β chains denote the immunoreceptor tyrosine-based activation motif (ITAM). Signals from the antigen receptors are further propagated downstream by other signaling molecules such as the syk and the src family of tyrosine kinases (fyn, lyn, blk, and btk), as well as by the phosphatase, SHP-1. *(Adapted from K-P Lam, K Rajewsky: Inflammation: Basic Principles and Clinical Correlates, 3d ed., Philadelphia, Lippincott Williams & Wilkins, pp 151–166, 1999; with permission.)*

chain gene is generated by rearrangement of a V segment to a J segment, ultimately yielding an intact Ig molecule composed of heavy and light chains.

The process of Ig gene rearrangement is regulated and results in a single antibody specificity produced by each B cell, with each Ig molecule comprising one type of heavy chain and one type of light chain. Although each B cell contains two copies of Ig light and heavy chain genes, only one gene of each type is productively rearranged and expressed in each B cell, a process termed *allelic exclusion*.

There are ~300 V_κ genes and 5 J_κ genes, resulting in the pairing of V_κ and J_κ genes to create >1500 different light chain combinations. The number of distinct κ light chains that can be generated is increased by somatic mutations within the V_κ and J_κ genes, thus creating large numbers of possible specificities from a limited amount of germ-line genetic information. As noted above, in heavy chain Ig gene rearrangement, the VH domain is created by the joining of three types of germ-line genes called V_H, D_H, and J_H, thus allowing for even greater diversity in the variable region of heavy chains than of light chains.

The most immature B cell precursors (early pro-B cells) lack cytoplasmic Ig (cIg) and sIg (Fig. 295-8). The large pre-B cell is marked by the acquisition of the surface pre-BCR composed of μ heavy (H) chains and a pre-B light chain, termed ψLC (Fig. 295-7). ψLC is a surrogate light chain receptor encoded by the nonrearranged V pre-B and the λ5 light chain locus (the pre-BCR). Pro- and pre-B cells are driven to proliferate and mature by signals from bone marrow stroma, in particular, IL-7. Light chain rearrangement occurs in the small pre-B cell stage such that the full BCR is expressed at the immature B cell stage. Immature B cells have rearranged Ig light chain genes and express sIgM. As immature B cells develop into mature B cells, sIgD is expressed as well as sIgM. At this point, B lineage development in bone marrow is complete, and B cells exit into the peripheral circulation and migrate to secondary lymphoid organs to encounter specific antigens.

Random rearrangements of Ig genes occasionally generate self-reactive antibodies, and mechanisms must be in place to correct these mistakes. One such mechanism is BCR editing, whereby autoreactive BCRs are mutated to not react with self-antigens. If receptor editing is unsuccessful in eliminating autoreactive B cells, then autoreactive B cells undergo negative selection in the bone marrow through induction of apoptosis after BCR engagement of self-antigen.

After leaving the bone marrow, B cells populate peripheral B cell sites, such as lymph node and spleen, and await contact with foreign antigens that react with each B cell's clonotypic receptor. As antigen-driven B cell activation occurs through the BCR, a process known as *somatic hypermutation* takes place whereby point mutations in rearranged H- and L-genes give rise to mutant sIg molecules, some of which bind antigen better than the original sIg molecules. Somatic hypermutation, therefore, is a process whereby memory B cells in peripheral lymph organs have the best binding, or the highest affinity antibodies. This overall process of generating the best antibodies is called *affinity maturation of antibody*.

Lymphocytes that synthesize IgG, IgA, and IgE are derived from sIgM+, sIgD+ mature B cells. Ig class switching occurs in lymph node and other peripheral lymphoid tissue germinal centers. CD40 on B cells and CD40 ligand on T cells comprise a critical co-stimulatory receptor-ligand pair of immune-stimulatory molecules. Pairs of CD40+ B cells and CD40 ligand+ T cells bind and drive B cell Ig switching via T cell–produced cytokines such as IL-4 and transforming growth factor (TGF) β. IL-1, -2, -4, -5, and -6 synergize to drive mature B cells to proliferate and differentiate into Ig-secreting cells.

Humoral Mediators of Adaptive Immunity: Immunoglobulins Immunoglobulins are the products of differentiated B cells and mediate the humoral arm of the immune response. The primary functions of antibodies are to bind specifically to antigen and bring about the inactivation or removal of the offending toxin, microbe, parasite, or other foreign substance from the body. The structural basis of Ig molecule function and Ig gene organization has provided insight into the role of antibodies in normal protective immunity, pathologic immune-mediated damage by immune complexes, and autoantibody formation against host determinants.

All immunoglobulins have the basic structure of two heavy and two light chains (Figs. 295-7 and 295-9). Immunoglobulin isotype (i.e., G, M, A, D, E) is determined by the type of Ig heavy chain present. IgG and IgA isotypes can be divided further into subclasses (G1, G2, G3, G4, and A1, A2) based on specific antigenic determinants on Ig heavy chains. The characteristics of human immunoglobulins are outlined in Table 295-10. The four chains are covalently linked by disulfide bonds. Each chain is made up of a V region and C regions (also called *domains*), themselves made up of units of ~110 amino

	Stem cell	Early pro-B cell	Late pro-B cell	Large pre-B cell	Small pre-B cell	Immature B cell	Mature B cell
H-chain genes	Germ line	DJ rearranged	VDJ rearranged	VDJ rearranged	VDJ rearranged	VDJ rearranged	VDJ rearranged
L-chain genes	Germ line	Germ line	Germ line	Germ line	VJ rearranged	VJ rearranged	VJ rearranged
Surface Ig	Absent	Absent	Absent	μ H-chain at surface as part of pre-β receptor	μ H-chain in cytoplasm and at surface	IgM expressed on cell surface	IgD and IgM made from alternatively spliced H-chain transcripts
Surface marker proteins	CD34	CD34 CD10 CD19 CD38	CD10 CD19 CD20 CD38 CD40	CD19 CD20 CD38 CD40	CD19 CD20 CD38 CD40	CD19 CD20 CD40	CD19 CD20 CD21 CD40

FIGURE 295-8 Developmental stages of B cells. Elements of the developing B cell receptor for antigen (BCR) are shown schematically. The classification into the various stages of B cell development is primarily defined by rearrangement of the immunoglobulin (Ig), heavy (H), and light (L) chain genes and by the absence or presence of specific surface markers. *[Adapted from CA Janeway et al (eds): Immunobiology. The Immune System in Health and Disease, 4th ed, New York, Garland, 1999; with permission.]*

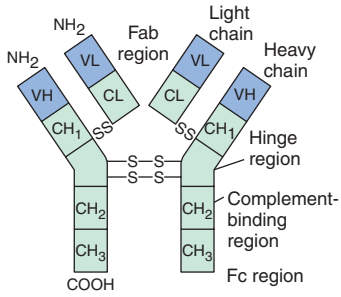

FIGURE 295-9 Schematic structure of the immunoglobulin G (IgG) molecule.

acids. Light chains have one variable (V_L) and one constant (C_L) unit; heavy chains have one variable unit (V_H) and three or four constant (C_H) units, depending on isotype. As the name suggests, the constant, or C, regions of Ig molecules are made up of homologous sequences and share the same primary structure as all other Ig chains of the same isotype and subclass. Constant regions are involved in biologic functions of Ig molecules. The C_{H2} domain of IgG and the C_{H4} units of IgM are involved with the binding of the C1q portion of C1 during complement activation. The C_H region at the carboxy-terminal end of the IgG molecule, the Fc region (Fig. 295-9), binds to surface Fc receptors (CD16, CD32, CD64) of macrophages, LGLs, B cells, neutrophils, and eosinophils.

Variable regions (V_L and V_H) constitute the antibody-binding (Fab) region of the molecule. Within the V_L and V_H regions are hypervariable regions (extreme sequence variability) that constitute the antigen-binding site unique to each Ig molecule. The idiotype is defined as the specific region of the Fab portion of the Ig molecule to which antigen binds. Antibodies against the idiotype portion of an antibody molecule are called *anti-idiotype antibodies*. The formation of such antibodies in vivo during a normal B cell antibody response may generate a negative (or "off") signal to B cells to terminate antibody production.

IgG comprises ~75 to 85% of total serum immunoglobulin. The four IgG subclasses are numbered in order of their level in serum, IgG1 being found in greatest amounts and IgG4 the least. IgG subclasses have clinical relevance in their varying ability to bind macrophage and neutrophil Fc receptors and to activate complement (Table 295-10). Moreover, selective deficiencies of certain IgG subclasses give rise to clinical syndromes in which the patient is inordinately susceptible to bacterial infections. IgG antibodies are frequently the predominant antibody made after rechallenge of the host with antigen (secondary antibody response).

IgM antibodies normally circulate as a 950-kDa pentamer with 160-kDa bivalent monomers joined by a molecule called the *J chain*, a 15-kDa nonimmunoglobulin molecule that also effects polymerization of IgA molecules. IgM is the first immunoglobulin to appear in the immune response (primary antibody response) and is the initial type of antibody made by neonates. Membrane IgM in the monomeric form also functions as a major antigen receptor on the surface of mature B cells (Fig. 295-9). IgM is an important component of immune complexes in autoimmune diseases. For example, IgM antibodies against IgG molecules (rheumatoid factors) are present in high titers in *rheumatoid arthritis*, other collagen diseases, and some infectious diseases (*subacute bacterial endocarditis*).

IgA comprises only 7 to 15% of total serum immunoglobulin but is the predominant class of immunoglobulin in secretions. IgA in secretions (tears, saliva, nasal secretions, gastrointestinal tract fluid, and human milk) is in the form of secretory IgA (sIgA), a polymer consisting of two IgA monomers, a joining molecule, again called the J chain, and a glycoprotein called the *secretory protein*. Of the two IgA subclasses, IgA1 is primarily found in serum, whereas IgA2 is more prevalent in secretions. IgA fixes complement via the alternative complement pathway and has potent antiviral activity in humans by prevention of virus binding to respiratory and gastrointestinal epithelial cells.

IgD is found in minute quantities in serum and, together with IgM, is a major receptor for antigen on the B cell surface. IgE, which is present in serum in very low concentrations, is the major class of immunoglobulin involved in arming mast cells and basophils by binding to these cells via the Fc region. Antigen cross-linking of IgE molecules on basophil and mast cell surfaces results in release of mediators of the immediate hypersensitivity response (Table 295-6).

TABLE 295-10 *Physical, Chemical, and Biologic Properties of Human Immunoglobulins*

Property	IgG	IgA	IgM	IgD	IgE
Usual molecular form	Monomer	Monomer, dimer	Pentamer, hexamer	Monomer	Monomer
Other chains	None	J chain, SC	J chain	None	None
Subclasses	G1, G2, G3, G4	A1, A2	None	None	None
Heavy chain allotypes	Gm (=30)	No A1, A2m (2)	None	None	None
Molecular mass, kDa	150	160, 400	950, 1150	175	190
Sedimentation constant, Sw20	6.6S	7S, 11S	19S	7S	8S
Carbohydrate content, %	3	7	10	9	13
Serum level in average adult, mg/mL	9.5–12.5	1.5–2.6	0.7–1.7	0.04	0.0003
Percentage of total serum Ig	75–85	7–15	5–10	0.3	0.019
Serum half-life, days	23	6	5	3	2.5
Synthesis rate, mg/kg per day	33	65	7	0.4	0.016
Antibody valence	2	2,4	10,12	2	2
Classical complement activation	+(G1, 2?, 3)	–	++	–	–
Alternate complement activation	+(G4)	+	–	+	–
Binding cells via Fc	Macrophages, neutrophils, large granular lymphocytes	Lymphocytes	Lymphocytes	None	Mast cells, basophils, B cells
Biologic properties	Placental transfer, secondary Ab for most antipathogen responses	Secretory immunoglobulin	Primary Ab responses	Marker for mature B cells	Allergy, antiparasite responses

CELLULAR INTERACTIONS IN REGULATION OF NORMAL IMMUNE RESPONSES The net result of activation of the humoral (B cell) and cellular (T cell) arms of the adaptive immune system by foreign antigen is the elimination of antigen directly by specific effector T cells or in concert with specific antibody. Figure 295-10 is a simplified schematic diagram of the T and B cell responses indicating some of these cellular interactions.

The expression of adaptive immune cell function is the result of a complex series of immunoregulatory events that occur in phases. Both T and B lymphocytes mediate immune functions, and each of these cell types, when given appropriate signals, passes through stages, from activation and induction through proliferation, differentiation, and ultimately effector functions. The effector function expressed may be at the end point of a response, such as secretion of antibody by a differentiated plasma cell, or it might serve a regulatory function that modulates other functions, such as is seen with CD4+ and CD8+ T lymphocytes that modulate both differentiation of B cells and activation of CD8+ cytotoxic T cells.

CD4 helper T cells can be subdivided on the basis of cytokines produced (Figs. 295-10 and 295-11). Activated T_H1-type helper T cells secrete IL-2, IFN-γ, IL-3, TNF-α, GM-CSF, and TNF-β, while activated T_H2-type helper T cells secrete IL-3, -4, -5, -6, -10, and -13. T_H1 CD4+ T cells, through elaboration of IFN-γ, have a central role in mediating intracellular killing by a variety of pathogens. T_H1 CD4+ T cells also provide T cell help for generation of cytotoxic T cells and some types of opsonizing antibody, and generally respond to antigens that lead to delayed hypersensitivity types of immune responses for many intracellular viruses and bacteria (such as HIV or *M. tuberculosis*). In contrast, T_H2 cells have a primary role in regulatory humoral immunity and isotype switching. In addition, T_H2 cells, through production of IL-4 and IL-10, have a regulatory role in limiting proinflammatory responses mediated by T_H1 cells (Table 295-5). In addition, T_H2 CD4+ T cells provide help to B cells for specific Ig production and respond to antigens that require high antibody levels for foreign antigen elimination (extracellular encapsulated bacteria such as *Streptococcus pneumoniae* and certain parasite infections). The type of T cell response generated in an immune response is determined by the microbe PAMPs presented to the dentritic cells, the TLRs on the dendritic cells that become activated, the types of dendritic cells that are activated, and the cytokines that are produced. Commonly, myeloid dendritic cells produce IL-12 and activate T_H1 T cell responses that result in IFN-γ and cytotoxic T cell induction, and plasmacytoid dendritic cells product IFN-α and lead to T_H2 responses that result in IL-4 production and enhanced antibody responses.

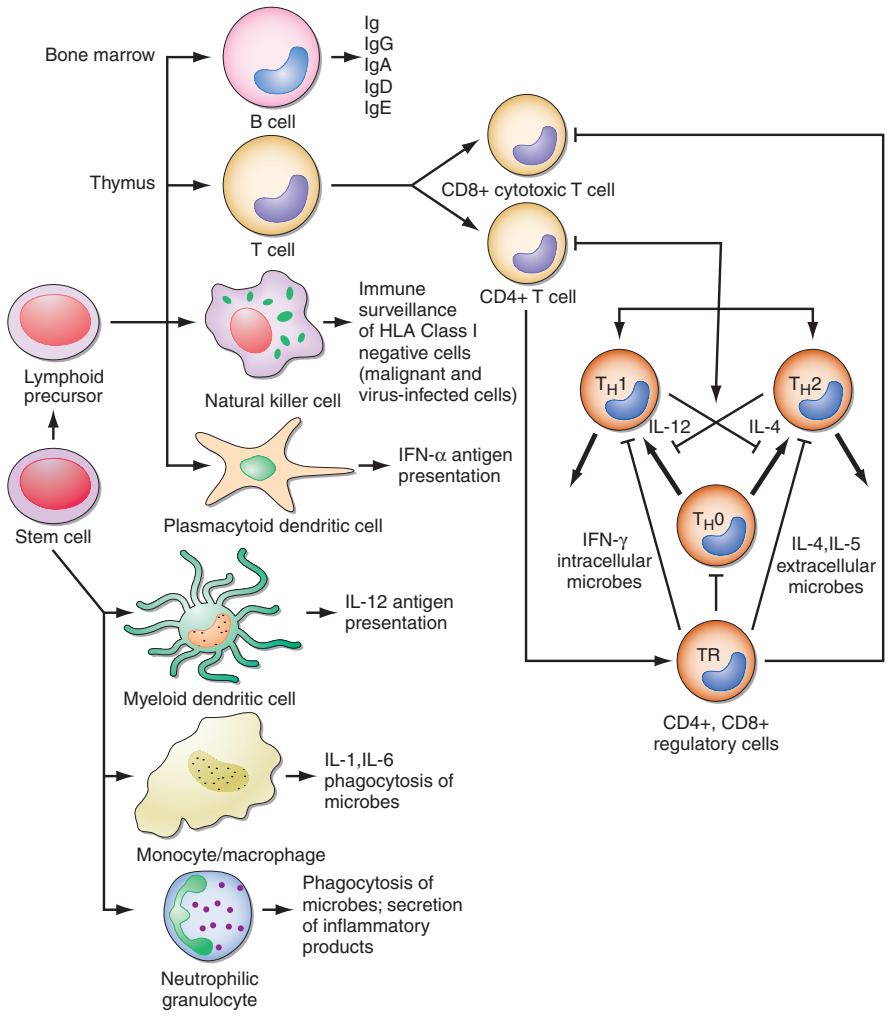

FIGURE 295-10 Schematic model of intercellular interactions of adaptive immune system cells. In this figure the arrows denote that cells develop from precursor cells or produce cytokines or antibodies; lines ending with bars indicate suppressive intercellular interactions. Stem cells differentiate into either T cells, antigen-presenting dendritic cells, natural killer cells, macrophages, granulocytes, or B cells. Foreign antigen is processed by dendritic cells, and peptide fragments of foreign antigen are presented to CD4+ and/or CD8+ T cells. CD8+ T cell activation leads to induction of cytotoxic T lymphocyte (CTL) or killer T cell generation, as well as induction of cytokine-producing CD8+ cytotoxic T cells. For antibody production against the same antigen, active antigen is bound to sIg within the B cell receptor complex and drives B cell maturation into plasma cells that secrete Ig. T_H1 or T_H2 CD4+ T cells producing interleukin (IL) 4, IL-5, or interferon (IFN)γ regulate the Ig class switching and determine the type of antibody produced. CD4+, CD25+ T regulatory cells produce IL-10 and downregulate T and B cell responses once the microbe has been eliminated. GM-CSF, granulocyte-macrophage colony stimulating factor; TNF, tumor necrosis factor.

As shown in Figs. 295-10 and 295-11, upon activation by dendritic cells, T cell subsets that produce IL-2, IL-3, IFN-γ, and/or IL-4, -5, -6, -10, and -13 are generated that exert positive and negative influences on effector T and B cells. For B cells, trophic effects are mediated by a variety of cytokines, particularly T cell–derived IL-3, -4, -5, and -6, that act at sequential stages of B cell maturation, resulting in B cell proliferation, differentiation, and ultimately antibody secretion. For cytotoxic T cells, trophic factors include inducer T cell secretion of IL-2, IFN-γ, and IL-12. In addition, B cells themselves are capable of serving as APCs, processing and presenting antigens to T cells, and secreting TNF-α and IL-6.

An important type of immunomodulatory T cell that controls immune responses are *CD4+ and CD8+ T regulatory cells*. These cells constitutively express the α chain of the IL-2 receptor (CD25), produce large amounts of IL-10, and can suppress both T and B cell responses. T regulatory cells are induced by immature dendritic cells and play key roles in maintaining tolerance to self-antigens in the periphery. Loss of T regulatory cells is the cause of organ-specific autoimmune disease in mice such as autoimmune thyroiditis, adrenalitis, and oophoritis (see "Immune Tolerance and Autoimmunity," below). T regulatory cells also play key roles in controlling the magnitude and duration of immune responses to microbes. Normally, after the initial immune response to a microbe has eliminated the invader, T regulatory cells are activated to suppress the anti-microbe response and prevent host injury. Some microbes have adapted to induce T regulatory cell activation at the site of infection to promote parasite infection and survival. In *Leishmania* infection, the parasite locally induces T regulatory cell accumulation at skin infection sites that dampens anti-*Leishmania* T cell responses and prevents elimination of the parasite.

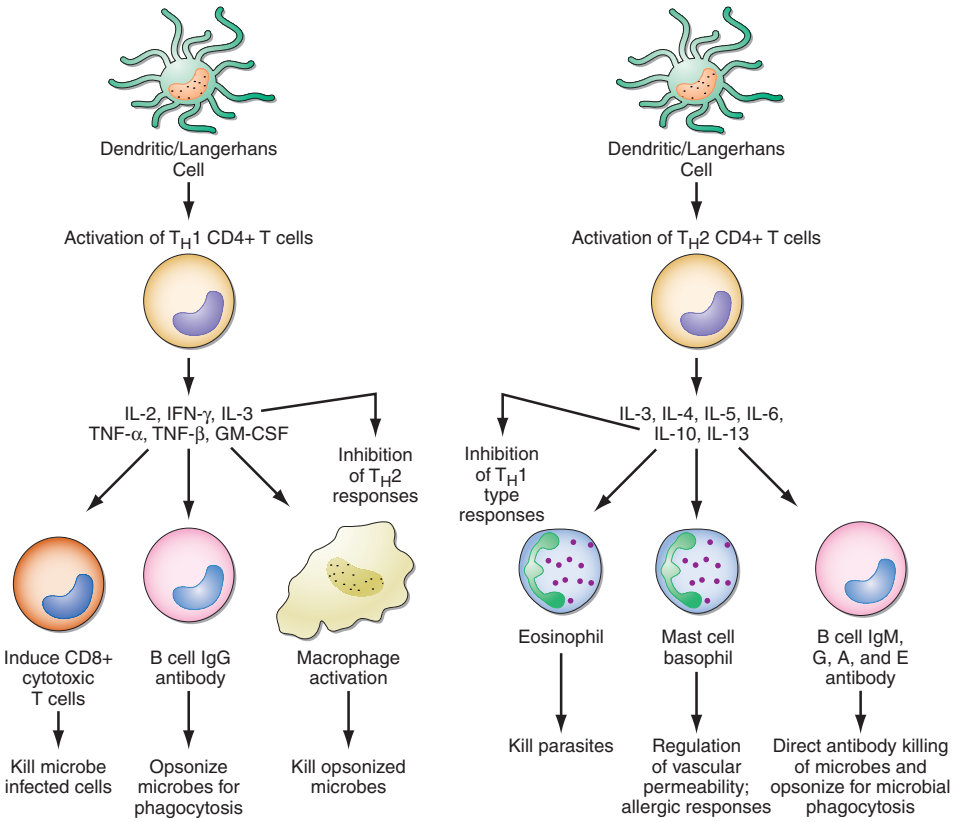

FIGURE 295-11 CD4+ helper T 1 (T_H1) cells and T_H2 T cells secrete distinct but overlapping sets of cytokines. T_H1 CD4+ cells are frequently activated in immune and inflammatory reactions against intracellular bacteria or viruses, while T_H2 CD4+ cells are frequently activated for certain types of antibody production against parasites and extracellular encapsulated bacteria; they are also activated in allergic diseases. GM-CSF, granulocyte-macrophage colony stimulating factor; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor. *[Adapted from S Romagnani: CD4 effector cells, in J Gallin, R Snyderman (eds): Inflammation: Basic Principles and Clinical Correlates, 3d ed. Philadelphia, Lippincott Williams & Wilkins, 1999; with permission.]*

It is thought that many chronic infections such as by *M. tuberculosis* are associated with abnormal T regulatory cell activation that prevents elimination of the microbe.

Although B cells recognize native antigen via B cell surface Ig receptors, B cells require T cell help to produce high-affinity antibody of multiple isotypes that are the most effective in eliminating foreign antigen. This T cell dependence likely functions in the regulation of B cell responses and in protection against excessive autoantibody production. T cell–B cell interactions that lead to high-affinity antibody production require: (1) processing of native antigen by B cells and expression of peptide fragments on the B cell surface for presentation to T_H cells, (2) the ligation of B cells both by the TCR complex and the CD40 ligand, (3) induction of the process termed *antibody isotype switching* in antigen-specific B cell clones, and (4) induction of the process of *affinity maturation* of antibody in the germinal centers of B cell follicles of lymph node and spleen.

Naive B cells express cell-surface IgD and IgM, and initial contact of naive B cells with antigen is via binding of native antigen to B cell–surface IgM. T cell cytokines, released following T_H2 cell contact with B cells or by a "bystander" effect, induce changes in Ig gene conformation that promote recombination of Ig genes. These events then result in the "switching" of expression of heavy chain exons in a triggered B cell, leading to the secretion of IgG, IgA, or, in some cases, IgE antibody with the same V region antigen specificity as the original IgM antibody, for response to a wide variety of extracellular bacteria, protozoa, and helminths. CD40 ligand expression by activated T cells is critical for induction of B cell antibody isotype switching and for B cell responsiveness to cytokines. Patients with mutations in T cell CD40 ligand have B cells that are unable to undergo isotype switching, resulting in lack of memory B cell generation and the immunodeficiency syndrome of *X-linked hyper-IgM syndrome* (Chap. 297).

IMMUNE TOLERANCE AND AUTOIMMUNITY *Immune tolerance* is defined as the absence of activation of pathogenic autoreactivity. *Autoimmune diseases* are syndromes caused by the activation of T or B cells or both, with no evidence of other causes such as infections or malignancies (Chap. 299). Once thought to be mutually exclusive, immune tolerance and autoimmunity are now both recognized to be present normally in health, and when abnormal, represent extremes from the normal state. For example, it is now known that low levels of autoreactivity of T and B cells with self-antigens in the periphery are critical to their survival. Similarly, low levels of autoreactivity and thymocyte recognition of self-antigens in the thymus are the mechanisms whereby (1) normal T cells are positively selected to survive and leave the thymus to respond to foreign microbes in the periphery, and (2) T cells highly reactive to self-antigens are negatively selected and die to prevent overly self-reactive T cells from getting into the periphery (central tolerance). However, not all self-antigens are expressed in the thymus to delete highly self-reactive T cells, and there are mechanisms for peripheral tolerance induction of T cells as well. Unlike the presentation of microbial antigens by mature dendritic cells, the presentation of self-antigens by immature dendritic cells neither activates nor matures the dendritic cells to express high levels of co-stimulatory molecules such as B7-1 (CD80) or B7-2 (CD86). When peripheral T cells are stimulated by dendritic cells expressing self-antigens in the context of HLA molecules, sufficient stimulation of T cells occurs to keep them alive, but otherwise they remain anergic, or nonresponsive, until they contact a dendritic cell with high levels of co-stimulatory molecules expressing microbial antigens. In the latter setting, normal T cells then become activated to respond to the microbe. If B cells have high self-reactivity BCRs, they normally undergo receptor editing to express a less autoreactive receptor or are induced to die. Although many autoimmune diseases are characterized by the abnormal or pathogenic autoantibody production (Table 295-11), most autoimmune diseases are caused by a combination of excess T and B cell reactivity.

Multiple factors contribute to the genesis of clinical autoimmune disease syndromes including genetic susceptibility (Table 295-12), environmental immune stimulants such as drugs (e.g., procainamide and dilantin with drug-induced systemic lupus erythematosus), infectious agent triggers (such as Epstein-Barr virus and autoantibody production against red blood cells and platelets), and loss of T regulatory cells (leading to thyroiditis, adrenalitis, and oophoritis).

THE CELLULAR AND MOLECULAR CONTROL OF PROGRAMMED CELL DEATH The process of apoptosis (programmed cell death) plays a crucial role in regulating normal immune responses to antigen. In general, a wide variety of stimuli trigger one of several apoptotic pathways to eliminate microbe-infected cells, eliminate cells with damaged DNA, or eliminate activated immune cells that are no longer needed (Fig. 295-12). The largest known family of "death receptors" are the tumor necrosis factor receptor (TNF-R) family [TNF-R1, TNF-R2, Fas (CD95), death receptor 3 (DR3), death receptor 4 (TRAIL-R1), and death receptor 5 (DR5, TRAIL-R2)]; their ligands are all in the TNF-α family. Binding of ligands to these death receptors leads to a signaling cascade

TABLE 295-11 *Recombinant or Purified Autoantigens Recognized by Autoantibodies Associated with Human Autoimmune Disorders*

Autoantigen	Autoimmune Diseases	Autoantigen	Autoimmune Diseases
CELL- OR ORGAN-SPECIFIC AUTOIMMUNITY			
Acetylcholine receptor	Myasthenia gravis	Insulin receptor	Type B insulin resistance, acanthosis, systemic lupus erythematosus (SLE)
Actin	Chronic active hepatitis, primary bilary cirrhosis	Intrinsic factor type 1	Pernicious anemia
Adenine nucleotide translator (ANT)	Dilated cardiomyopathy, myocarditis	Leukocyte function-associated antigen (LFA-1)	Treatment-resistant Lyme arthritis
β-Adrenoreceptor	Dilated cardiomyopathy		
Aromatic L-amino acid decarboxylase	Autoimmune polyendocrine syndrome type 1 (APS-1)	Myelin-associated glycoprotein (MAG)	Polyneuropathy
		Myelin-basic protein	Multiple sclerosis, demyelinating diseases
Asialoglycoprotein receptor	Autoimmune hepatitis		
Bactericidal/permeability-increasing protein (Bpi)	Cystic fibrosis vasculitides	Myelin oligodendrocyte glycoprotein (MOG)	Multiple sclerosis
Calcium-sensing receptor	Acquired hypoparathyroidism	Myosin	Rheumatic fever
Cholesterol side-chain cleavage enzyme (CYPlla)	Autoimmune polyglandular syndrome-1	p-80-Collin	Atopic dermatitis
		Pyruvate dehydrogenase complex-E2 (PDC-E2)	Primary biliary cirrhosis
Collagen type IV-α3-chain	Goodpasture syndrome		
Cytochrome P450 2D6 (CYP2D6)	Autoimmune hepatitis	Sodium iodide symporter (NIS)	Graves' disease, autoimmune hypothyroidism
Desmin	Crohn disease, coronary artery disease		
Desmoglein 1	Pemphigus foliaceus	SOX-10	Vitiligo
Desmoglein 3	Pemphigus vulgaris	Thyroid and eye muscle shared protein	Thyroid-associated ophthalmopathy
F-actin	Autoimmune hepatitis	Thyroglobulin	Autoimmune thyroiditis
GM gangliosides	Guillain-Barré syndrome	Thyroid peroxidase	Autoimmune Hashimoto thyroiditis
Glutamate decarboxylase (GAD65)	Type 1 diabetes, stiff man syndrome	Throtropin receptor	Graves' disease
Glutamate receptor (GLUR)	Rasmussen encephalitis	Tissue transglutaminase	Celiac disease
H/K ATPase	Autoimmune gastritis	Transcription coactivator p75	Atopic dermatitis
17-α-Hydroxylase (CYP17)	Autoimmune polyglandular syndrome-1	Tryptophan hydroxylase	Autoimmune polyglandular syndrome-1
21-Hydroxylase (CYP21)	Addison disease	Tyrosinase	Vitiligo, metastatic melanoma
IA-2 (ICA512)	Type 1 diabetes	Tyrosine hydroxylase	Autoimmune polyglandular syndrome-1
Insulin	Type 1 diabetes, insulin hypoglycemic syndrome (Hirata disease)		
SYSTEMIC AUTOIMMUNITY			
ACTH	ACTH deficiency	Histone H2A-H2B-DNA	SLE
Aminoacyl-tRAN histidyl synthetase	Myositis, dermatomyositis	IgE receptor	Chronic idiopathic urticaria
Aminoacyl-tRNA synthetase (several)	Polymyositis, dermatomyositis	Keratin	RA
Cardiolipin	SLE	Ku-DNA-protein kinase	SLE
Carbonic anhydrase II	SLE, Sjögren syndrome, systemic sclerosis	Ku-nucleoprotein	Connective tissue syndrome
		La phosphoprotein (La 55-B)	Sjögren syndrome
Collagen (multiple types)	Rheumatoid arthritis (RA), SLE, progressive systemic sclerosis	Myeloperoxidase	Necrotizing and crescentic glomerulonephritis (NCGN), systemic vasculitis
Centromere-associated proteins	Systemic sclerosis		
DNA-dependent nucleosine-stimulated ATPase	Dermatomyositis	Proteinase 3 (PR3)	Wegener granulomatosis, Churg-Strauss syndrome
Fibrillarin	Scleroderma	RNA polymerase I–III (RNP)	Systemic sclerosis, SLE
Fibronectin	SLE, RA, morphea	Signal recognition protein (SRP54)	Polymyositis
Glucose-6-phosphate isomerase	RA	Topoisomerase-1 (Scl-70)	Scleroderma, Raynaud syndrome
β2-Glycoprotein I (B2-GPI)	Primary antiphospholipid syndrome	Tublin	Chronic liver disease, visceral leishmaniasis
Golgin (95, 97, 160, 180)	Sjögren syndrome, SLE, RA		
Heat shock protein	Various immune-related disorders	Vimentin	Systemic autoimmune disease
Hemidesmosomal protein 180	Bullous pemphigoid, herpes gastationis, cicatricial pemphigoid		
PLASMA PROTEIN AND CYTOKINE AUTOIMMUNITY			
C1 inhibitor	Autoimmune C1 deficiency	Glycoprotein IIb/IIIg and Ib/IX	Autoimmune thrombocytopenia purpura
C1q	SLE, membrane proliferative glomerulonephritis (MPGN)	IgA	Immunodeficiency associated with SLE, pernicious anemia, thyroiditis, Sjögren's syndrome and chronic active hepatitis
Cytokines (IL-1α, IL-1β, IL-6, IL-10, LIF)	RA, systemic sclerosis, normal subjects		
Factor II, factor V, factor VII, factor VIII, factor IX, factor X, factor XI, thrombin vWF	Prolonged coagulation time	Oxidized LDL (OxLDL)	Atherosclerosis
CANCER AND PARANEOPLASTIC AUTOIMMUNITY			
Amphiphysin	Neuropathy, small-cell lung cancer	p62 (IGF-II mRNA-binding protein)	Hepatocellular carcinoma (China)
Cyclin B1	Hepatocellular carcinoma	Recoverin	Cancer-associated retinopathy
DNA topoisomerase II	Liver cancer	Ri protein	Paraneoplastic opsoclonus myoclonus ataxia
Desmoplakin	Paraneoplastic pemphigus		
Gephyrin	Paraneoplastic stiff man syndrome	βIV spectrin	Lower motor neuron syndrome
Hu proteins	Paraneoplastic encephalomyelitis	Synaptotagmin	Lambert-Eaton myasthenic syndrome
Neuronal nicotinic acetylcholine receptor	Subacute autonomic neuropathy, cancer	Voltage-gated calcium channels	Lambert-Eaton myasthenic syndrome
		Yo protein	Paraneoplastic cerebellar degeneration
p53	Cancer, SLE

TABLE 295-12 *Immune System Molecule Defects in Animals or Humans that Cause Autoimmune or Malignant Syndromes*

Protein	Defect	Disease or Syndrome	Observation in Animal Models or Humans
CYTOKINES AND SIGNALING PROTEINS			
Tumor necrosis factor (TNF) α	Overexpression	Inflammatory bowel disease (IBD), arthritis, vasculitis	Mice
TNF-α	Underexpression	Systemic lupus erythematosus (SLE)	Mice
Interleukin-1-receptor antagonist	Underexpression	Arthritis	Mice
IL-2	Overexpression	IBD	Mice
IL-7	Overexpression	IBD	Mice
IL-10	Overexpression	IBD	Mice
IL-2 receptor	Overexpression	IBD	Mice
IL-10 receptor	Overexpression	IBD	Mice
IL-3	Overexpression	Demyelinating syndrome	Mice
Interferon-δ	Overexpression in skin	SLE	Mice
STAT-3	Underexpression	IBD	Mice
STAT-4	Overexpression	IBD	Mice
Transforming growth factor (TGF) β	Underexpression	Systemic wasting syndrome and IBD	Mice
TGF-β receptor in T cells	Underexpression	SLE	Mice
Programmed death (PD-1)	Underexpression	SLE-like syndrome	Mice
Cytotoxic T lymphocyte, antigen-4 (CTLA-4)	Underexpression	Systemic lymphoproliferative disease	Mice
IL-10	Underexpression	IBD (mouse) Type 1 diabetes, thyroid disease, primary (human)	Mice and humans
MAJOR HISTOCOMPATIBILITY LOCUS MOLECULES[a]			
HLA B27	Allele expression or over-expression	Inflammatory bowel disease	Rats and humans
Complement deficiency of C1,2,3 or 4	Underexpression	See Table 305-13	Humans
LIGHT (TNF superfamily 14)	Overexpression	Systemic lymphoproliferative (mouse) and autoimmunity	Mice
HLA class II DQB10301, DQB10302	Allele expression	Juvenile-onset diabetes	Human
HLA class II DQB10401, DQB10402	Allele expression	Rheumatoid arthritis	Humans
HLA class I B27	Allele expression	Ankylosing spondylitis, IBD	Rats and humans
APOPTOSIS PROTEINS			
TNFactor receptor 1 (TNF-R1)	Underexpression	Familial periodic fever syndrome	Humans
Fas (CD95; Apo-1)	Underexpression	Autoimmune lymphoproliferative syndrome type 1 (ALPS 1); malignant lymphoma; bladder cancer	Humans
Fas ligand	Underexpression	SLE (only one case identified)	Humans
Perforin	Underexpression	Familial hemophagocytic lymphohistiocytosis (FHL)	Humans
Caspase 10	Underexpression	Autoimmune lymphoproliferative syndrome type II (ALPS II)	Humans
bcl-10	Underexpression	Non-Hodgkin's lymphoma	Humans
P53	Underexpression	Various malignant neoplasms	Humans
Bax	Underexpression	Colon cancer; hematopoietic malignancies	Humans
bcl-2	Underexpression	Non-Hodgkin's lymphoma	Humans
c-IAP2	Underexpression	Low-grade MALT lymphoma	Humans
NAIP1	Underexpression	Spinal muscular atrophy	Humans

[a] Many autoimmune diseases are associated with a myriad of major compatibility complex gene allele (HLA) types. There are presented here as examples.

Note: MALT, mucosa-associated lymphoid tissue.

that involves activation of the *caspase* family of molecules that leads to DNA cleavage and cell death. Two other pathways of programmed cell death involve nuclear *p53* in the elimination of cells with abnormal DNA and *mitochondrial cytochrome c* to induce cell death in damaged cells (Fig. 295-12). A number of human diseases have now been described that result from, or are associated with, mutated apoptosis genes (Table 295-12). These include mutations in the TNF-R1 in *hereditary periodic fever* (*familial Mediterranean fever*) (Chap. 279), Fas and Fas ligand in autoimmune and lymphoproliferation syndromes, and multiple associations of mutations in genes in the apoptotic pathway with malignant syndromes.

MECHANISMS OF IMMUNE-MEDIATED DAMAGE TO MICROBES OR HOST TISSUES

Several responses by the host innate and adaptive immune systems to foreign microbes culminate in rapid and efficient elimination of microbes. In these scenarios, the classic weapons of the adaptive immune system (T cells, B cells) interface with cells (macrophages, dendritic cells, NK cells, neutrophils, eosinophils, basophils) and soluble products (microbial peptides, pentraxins, complement and coagulation systems) of the innate immune system (Chaps. 55 and 298).

There are five general phases of host defenses: (1) migration of leukocytes to sites of antigen localization; (2) antigen-nonspecific recognition of pathogens by macrophages and other cells and systems of the innate immune system; (3) specific recognition of foreign antigens mediated by T and B lymphocytes; (4) amplification of the inflammatory response with recruitment of specific and nonspecific effector cells by complement components, cytokines, kinins, arachidonic acid metabolites, and mast cell–basophil products; and (5) macrophage, neutrophil, and lymphocyte participation in destruction of antigen with ultimate removal of antigen particles by phagocytosis (by macrophages or neutrophils) or by direct cytotoxic mechanisms (involving macrophages, neutrophils, and lymphocytes). Under normal circumstances, orderly progression of host defenses through these phases results in a well-controlled immune and inflammatory response that protects the host from the offending antigen. However, dysfunction of

any of the host defense systems can damage host tissue and produce clinical disease. Furthermore, for certain pathogens or antigens, the normal immune response itself might contribute substantially to the tissue damage. For example, the immune and inflammatory response in the brain to certain pathogens such as *M. tuberculosis* may be responsible for much of the morbidity of this disease in that organ system (Chap. 150). In addition, the morbidity associated with certain pneumonias such as that caused by *Pneumocystis carinii* may be associated more with inflammatory infiltrates than with the tissue destructive effects of the microorganism itself (Chap. 191).

The Molecular Basis of Lymphocyte–Endothelial Cell Interactions The control of lymphocyte circulatory patterns between the bloodstream and peripheral lymphoid organs operates at the level of lymphocyte–endothelial cell interactions to control the specificity of lymphocyte subset entry into organs. Similarly, lymphocyte–endothelial cell interactions regulate the entry of lymphocytes into inflamed tissue. Adhesion molecule expression on lymphocytes and endothelial cells regulates the retention and subsequent egress of lymphocytes within tissue sites of antigenic stimulation, delaying cell exit from tissue and preventing reentry into the circulating lymphocyte pool. All types of lymphocyte migration begin with lymphocyte attachment to specialized regions of vessels, termed *high endothelial venules* (HEVs). An important concept is that adhesion molecules do not generally bind their ligand until a conformational change (ligand activation) occurs in the adhesion molecule that allows ligand binding. Induction of a conformation-dependent determinant on an adhesion molecule can be accomplished by cytokines or via ligation of other adhesion molecules on the cell.

The first stage of lymphocyte–endothelial cell interactions, *attachment and rolling*, occurs when lymphocytes leave the stream of flowing blood cells in a postcapillary venule and roll along venule endothelial cells (Fig. 295-13). Lymphocyte rolling is mediated by the L-selectin molecule (LECAM-1, LAM-1, CD62L) and slows cell transit time through venules, allowing time for activation of adherent cells.

The second stage of lymphocyte–endothelial cell interactions, *firm adhesion with activation-dependent stable arrest*, requires stimulation of lymphocytes by chemoattractants or by endothelial cell–derived cytokines. Cytokines thought to participate in adherent cell activation include members of the IL-8 family, platelet-activation factor, leukotriene B_4, and C5a. Following activation by chemoattractants, lymphocytes shed L-selectin from the cell surface and upregulate cell CD11b/18 (MAC-1) or CD11a/18 (LFA-1) molecules, resulting in firm attachment of lymphocytes to HEVs.

Lymphocyte homing to peripheral lymph nodes involves adhesion of L-selectin to carbohydrate of peripheral node HEVs, whereas homing of lymphocytes to intestine Peyer's patches primarily involves adhesion of the $\alpha 4,\beta 7$ integrin to MAdCAM-1 oligosaccharides on the Peyer's patch HEVs. However, for migration to mucosal Peyer's patch lymphoid aggregates, naive lymphocytes primarily use L-selectin, whereas memory lymphocytes use $\alpha 4,\beta 7$ integrin. $\alpha 4,\beta 1$ integrin (CD49d/CD29, VLA-4)–VCAM-1 interactions are important in the initial interaction of memory lymphocytes with HEVs of multiple organs in sites of inflammation.

The third stage of leukocyte emigration in HEVs is *sticking and arrest*. Sticking of the lymphocyte to endothelial cells and arrest at the site of sticking are mediated predominantly by ligation of $\alpha L,\beta 2$ integrin LFA-1 to the integrin ligand ICAM-1 on HEVs. While the first three stages of lymphocyte attachment to HEVs takes only a few seconds, the fourth stage of lymphocyte emigration, *transendothelial migration*, takes ~10 min. Although the molecular mechanisms that control lymphocyte transendothelial migration are not fully characterized, the HEV CD44 molecule and molecules of the HEV glycocalyx (extracellular matrix) are thought to play important regulatory roles in this process (Fig. 295-13). Finally, expression of matrix metalloproteases capable of digesting the subendothelial basement membrane,

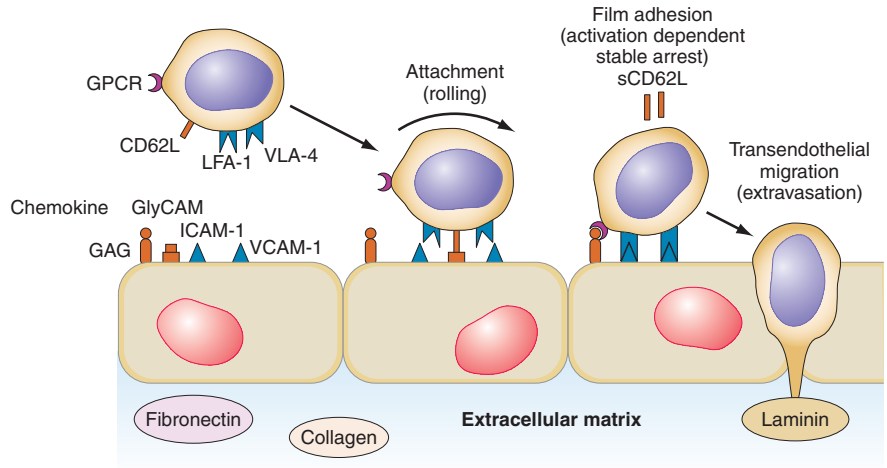

FIGURE 295-13 Schematic of the multistep model of leukocyte migration in high endothelial venules (HEV). The initial interaction of lymphocytes with HEV in peripheral lymph nodes is mediated by L-selectin (CD62L) that recognizes HEV mucin-like counterreceptors such as glycosylation-dependent cell adhesion molecule 1 (GlyCAM-1). Activation of lymphocyte adhesiveness occurs via G protein–coupled receptors (GPCR) that bind to chemokines anchored to endothelial cells by glycoaminoglycans (GAG). The integrin leukocyte function–associated molecule 1 (LFA-1) and very late antigen-4 (VLA-4) and their HEV counterreceptors, intercellular adhesion molecule 1 (ICAM-1; CD54) play a major role in lymphocyte arrest in HEV. The molecular mechanisms of lymphocyte extravasations are not completely worked out. *(From DD Patel, BF Haynes: Curr Dir Autoimmun 3:133, 2001; with permission.)*

rich in nonfibrillar collagen, appears to be required for the penetration of lymphoid cells into the extravascular sites.

Abnormal induction of HEV formation and use of the molecules discussed above have been implicated in the induction and maintenance of inflammation in a number of chronic inflammatory diseases. In animal models of type 1 diabetes mellitus, MAdCAM-1 and GlyCAM-1 have been shown to be highly expressed on HEVs in inflamed pancreatic islets, and treatment of these animals with inhibitors of L-selectin and α4 integrin function blocked the development of type 1 diabetes mellitus (Chap. 323). A similar role for abnormal induction of the adhesion molecules of lymphocyte emigration has been suggested in *rheumatoid arthritis* (Chap. 301), *Hashimoto's thyroiditis* (Chap. 320), *Graves' disease* (Chap. 320), *multiple sclerosis* (Chap. 262), *Crohn's disease* (Chap. 276), and *ulcerative colitis* (Chap. 276).

Immune-Complex Formation Clearance of antigen by immune-complex formation between antigen and antibody is a highly effective mechanism of host defense. However, depending on the level of immune complexes formed and their physicochemical properties, immune complexes may or may not result in host and foreign cell damage. After antigen exposure, certain types of soluble antigen-antibody complexes freely circulate and, if not cleared by the reticuloendothelial system, can be deposited in blood vessel walls and in other tissues such as renal glomeruli and cause *vasculitis* or *glomerulonephritis* syndromes (Chaps. 264 and 306).

Immediate-Type Hypersensitivity Helper T cells that drive anti-allergen IgE responses are usually T_H2-type inducer T cells that secrete IL-4, IL-5, IL-6, and IL-10. Mast cells and basophils have high-affinity receptors for the Fc portion of IgE (FcRI), and cell-bound antiallergen IgE effectively "arms" basophils and mast cells. Mediator release is triggered by antigen (allergen) interaction with Fc receptor–bound IgE; the mediators released are responsible for the pathophysiologic changes of *allergic diseases* (Table 295-6). Mediators released from mast cells and basophils can be divided into three broad functional types: (1) those that increase vascular permeability and contract smooth muscle (histamine, platelet-activating factor, SRS-A, BK-A), (2) those that are chemotactic for or activate other inflammatory cells (ECF-A, NCF, leukotriene B_4), and (3) those that modulate the release of other mediators (BK-A, platelet-activating factor) (Chap. 298).

Cytotoxic Reactions of Antibody In this type of immunologic injury, complement-fixing (C1-binding) antibodies against normal or foreign cells or tissues (IgM, IgG1, IgG2, IgG3) bind complement via the classic pathway and initiate a sequence of events similar to that initiated by immune-complex deposition, resulting in cell lysis or tissue injury. Examples of antibody-mediated cytotoxic reactions include red cell lysis in *transfusion reactions*, *Goodpasture's syndrome* with anti-glomerular basement membrane antibody formation, and *pemphigus vulgaris* with antiepidermal antibodies inducing blistering skin disease.

Classic Delayed-Type Hypersensitivity Reactions Inflammatory reactions initiated by mononuclear leukocytes and not by antibody alone have been termed *delayed-type hypersensitivity reactions*. The term *delayed* has been used to contrast a secondary cellular response that appears 48 to 72 h after antigen exposure with an *immediate* hypersensitivity response generally seen within 12 h of antigen challenge and initiated by basophil mediator release or preformed antibody. For example, in an individual previously infected with *M. tuberculosis* organisms, intradermal placement of tuberculin purified-protein derivative as a skin test challenge results in an indurated area of skin at 48 to 72 h, indicating previous exposure to tuberculosis.

The cellular events that result in classic delayed-type hypersensitivity responses are centered around T cells (predominantly, though not exclusively, IFN-γ, IL-2, and TNF-α-secreting T_H1-type helper T cells) and macrophages. First, local immune and inflammatory responses at the site of foreign antigen upregulate endothelial cell adhesion molecule expression, promoting the accumulation of lymphocytes at the tissue site. In the general scheme outlined in Figs. 295-10 and 295-11, antigen is processed by dendritic cells and presented to small numbers of CD4+ T cells expressing a TCR specific for the antigen. IL-12 produced by APCs induces T cells to produce IFN-γ (T_H-1 response). Macrophages frequently undergo epithelioid cell transformation and fuse to form multinucleated giant cells in response to IFN-γ. This type of mononuclear cell infiltrate is termed *granulomatous inflammation*. Examples of diseases in which delayed-type hypersensitivity plays a major role are fungal infections (*histoplasmosis*; Chap. 183), mycobacterial infections (*tuberculosis*, *leprosy*; Chaps. 150 and 151), chlamydial infections (*lymphogranuloma venereum*; Chap. 160), helminth infections (*schistosomiasis*; Chap. 203), reactions to toxins (*berylliosis*; Chap. 238), and hypersensitivity reactions to organic dusts (*hypersensitivity pneumonitis*; Chap. 237). In addition, delayed-type hypersensitivity responses play important roles in tissue damage in autoimmune diseases such as *rheumatoid arthritis*, *temporal arteritis*, and *Wegener's granulomatosis* (Chaps. 301 and 306).

CLINICAL EVALUATION OF IMMUNE FUNCTION Clinical assessment of immunity requires investigation of the four major components of the immune system that participate in host defense and in the pathogenesis of autoimmune diseases: (1) humoral immunity (B cells); (2) cell-mediated immunity (T cells, monocytes); (3) phagocytic cells of the reticuloendothelial system (macrophages), as well as polymorphonuclear leukocytes; and (4) complement. Clinical problems that require an evaluation of immunity include chronic infections, recurrent infection, unusual infecting agents, and certain autoimmune syndromes. The type of clinical syndrome under evaluation can provide information regarding possible immune defects (Chap. 297). Defects in cellular immunity generally result in viral, mycobacterial, and fungal infections. An extreme example of deficiency in cellular immunity is *AIDS* (Chap. 173). Antibody deficiencies result in recurrent bacterial infections, frequently with organisms such as *S. pneumoniae* and *Haemophilus influenzae* (Chap. 297). Disorders of phagocyte function are frequently manifested by recurrent skin infections, often due to *Staphylococcus aureus* (Chap. 55). Finally, deficiencies of early and late complement components are associated with autoimmune phenomena and recurrent *Neisseria* infections (Table 295-13). →***For further discussion of useful initial screening tests of immune function, see Chap. 297.***

IMMUNOTHERAPY Most current therapies for autoimmune and inflammatory diseases involve the use of nonspecific immune-modulating or

TABLE 295-13 *Complement Deficiencies and Associated Diseases*

Component	Associated Diseases
CLASSIC PATHWAY

Source: After JA Schifferli and DK Peters, Lancet 88:957, 1983; with permission.

immunosuppressive agents such as glucocorticoids or cytotoxic drugs. The goal of development of new treatments for immune-mediated diseases is to design ways to specifically interrupt pathologic immune responses, leaving nonpathologic immune responses intact. Novel ways to interrupt pathologic immune responses that are under investigation include: the use of anti-inflammatory cytokines or specific cytokine inhibitors as anti-inflammatory agents; the use of monoclonal antibodies against T or B lymphocytes as therapeutic agents; the induction of anergy by administration of soluble CTLA-4 protein; the use of intravenous Ig for certain infections and immune complex–mediated diseases; the use of specific cytokines to reconstitute components of the immune system; and bone marrow transplantation to replace the pathogenic immune system with a more normal immune system (Table 295-14) (Chaps. 55, 297, and 173).

Cytokines and Cytokine Inhibitors Recently a humanized mouse anti-TNF-α monoclonal antibody (MAb) has been tested in both rheumatoid arthritis and ulcerative colitis. Use of anti-TNF-α antibody therapy has resulted in clinical improvement in patients with these diseases and has opened the way for targeting TNF-α to treat other severe forms of autoimmune and/or inflammatory disease. Blockage of TNF-α has been effective in *rheumatoid arthritis*, *psoriasis*, *Crohn's disease*, and *ankylosing spondylitis*. Anti-TNF-α MAb (infliximab) has been approved for treatment of patients with rheumatoid arthritis.

Other cytokine inhibitors under investigation are recombinant soluble TNF-α receptor (R) fused to human Ig and soluble IL-1 receptor (termed *IL-1 receptor antagonist*, or IL-1 ra). Soluble TNF-αR (etanercept) and IL-1 ra act to inhibit the activity of pathogenic cytokines in rheumatoid arthritis, i.e., TNF-α and IL-1, respectively. Similarly, anti-IL-6, IFN-β, and IL-11 act to inhibit pathogenic proinflammatory cytokines. Anti-IL-6 inhibits IL-6 activity, while IFN-β and IL-11 decrease IL-1 and TNF-α production.

Recent studies have identified mutations in the IL-12 gene in patients susceptible to severe myobacterial infections. IL-12 is a critical cytokine for induction of IFN-γ and cytotoxic T lymphocytes (CTLs) against intracellular organisms; it is under study for treatment of severe infections such as that caused by *M. tuberculosis* and for treatment of various cancers. In this latter setting, IL-12 is being studied for its ability to enhance antitumor cellular immunity by enhancing the induction of antitumor CTL.

Of particular note has been the successful use of IFN-γ in the treat-

TABLE 295-14 *Current Status of Development of Immunomodulatory Agents*

Agents	Rationale	Status
CYTOKINES AND CYTOKINE INHIBITORS TO INHIBIT IMMUNE RESPONSES AND INFLAMMATION		
Anti-TNF-α monoclonal antibody: Humanized mouse chimeric MAb, infliximab Fully humanized MAb, adalimumab	Inhibit TNF-α	FDA approved for rheumatoid arthritis, Crohn's colitis (infliximab); FDA approved for rheumatoid arthritis (adalimumab)
Recombinant TNF-receptor-Ig fusion protein (etanercept)	Inhibit TNF-α	FDA approved for rheumatoid arthritis, juvenile rheumatoid arthritis, psoriasis
Recombinant IL-1 receptor antagonist (IL-1Ra) (anakinra)	Inhibit IL-1α and -β	FDA approved for rheumatoid arthritis
Anti-IL-6 monoclonal antibody	Inhibit IL-6	Tested in phase I trial in rheumatoid arthritis
Inferferon-β	Inhibit IL-1, decrease synovial T cells	In trials for use in rheumatoid arthritis
Interferon-γ	Induce monocyte/macrophage activation	Effective in treating monocyte/macrophage phagocytic defects in chronic granulomatous disease
IL-11	Inhibit TNF-α and IL-1 production	In trials for Crohn's colitis
IL-12	Stimulate anti-tumor and anti-viral or bacterial cytotoxic T lymphocyte responses	Trials underway for use in cancer patients; trials planned in humans to prevent/treat severe infections
MONOCLONAL ANTIBODIES AGAINST T OR B CELLS		
Anti-CD3 anti-T cell monoclonal antibody	Inhibit T cell function; induce T cell lymphopenia	FDA approved for treatment of cardiac and renal allograft rejection
Anti-CD4 monoclonal antibody	Inhibit CD4+ T cell function	In trials for rheumatoid arthritis
Anti-CD40 ligand (CD154) monoclonal antibody	Inhibit CD40-CD40 ligand interaction; induces T cell tolerance	In primate trials for prevention of renal allograft rejection
SOLUBLE T CELL MOLECULE		
Soluble CTLA-4 protein	Inhibit CD28-B7-1 and B7-2 interactions; induce tolerance to organ grafts; inhibit autoimmune T cell reactivity in autoimmune diseases	In trials for preventing GVHD in bone marrow transplantation and for treatment of psoriasis
INTRAVENOUS IMMUNOGLOBULIN		
IVIg	Reticuloendothelial cell blockage; complement inhibition; regulation of idiotype/anti-idiotype antibodies; modulation of cytokine production; modulation of lymphocyte production	FDA approved for Kawasaki's disease and immune thrombocytopenia purpura; treatment of GVHD, multiple sclerosis, myasthenia gravis, Guillain-Barré syndrome, and chronic inflammatory demylenating polyneuropathy supported by clinical trials
CYTOKINES FOR IMMUNE RECONSTITUTION		
IL-2	Induce proliferation of peripheral memory CD4+ and CD8+ T cells	In trial for treatment of HIV infection
IL-7	Induce renewed thymopoiesis	Under consideration for treatment of diseases associated with T cell deficiency
HEMATOPOIETIC STEM CELL TRANSPLANTATION		
Hematopoietic stem transplantation for immune reconstitution	Remove pathologic autoreactive immune system and replace with less autoreactive immunity	In clinical trials for systemic lupus erythematosus, multiple sclerosis, and scleroderma

Note: FDA, US Food and Drug Administration; GVHD, graft-versus-host disease.

ment of the phagocytic cell defect in *chronic granulomatous disease* (Chap. 55). Intermittent infusions of IL-2 in HIV-infected individuals in the early or intermediate stages of disease have resulted in substantial and sustained increases in CD4+ T cells.

Monoclonal Antibodies to T and B Cells The OKT3 MAb against human T cells has been used for several years as a T cell–specific immunosuppressive agent that can substitute for horse anti-thymocyte globulin (ATG) in the treatment of solid organ transplant rejection. OKT3 produces fewer allergic reactions than ATG but does induce human anti-mouse Ig antibody—thus limiting its use. Anti-CD4 MAb therapy has been used in trials to treat patients with rheumatoid arthritis. While inducing profound immunosuppression, anti-CD4 MAb treatment also induces susceptibility to severe infections. Treatment of patients with a MAb against the T cell molecule CD40 ligand (CD154) is under investigation to induce tolerance to organ transplants, with promising results reported in animal studies.

Tolerance Induction Specific immunotherapy has moved into a new era with the introduction of soluble CTLA-4 protein into clinical trials. Use of this molecule to block T cell activation via TCR/CD28 ligation during organ or bone marrow transplantation has showed promising results in animals and in early human clinical trials. Specifically, treatment of bone marrow with CTLA-4 protein reduces rejection of the graft in HLA-mismatched bone marrow transplantation. In addition, promising results with soluble CTLA-4 have been reported in the downmodulation of autoimmune T cell responses in the treatment of psoriasis.

Intravenous Immunoglobulin (IVIg) IVIg has been used successfully to block reticuloendothelial cell function and immune complex clearance in various immune cytopenias such as immune thrombocytopenia (Chap. 101). In addition, IVIg is useful for prevention of tissue damage in certain inflammatory syndromes such as Kawasaki's disease (Chap. 306) and as Ig replacement therapy for certain types of immunoglobulin deficiencies (Chap. 297). In addition, controlled clinical trials support the use of IVIg in selected patients with graft-versus-host disease, multiple sclerosis, myasthenia gravis, Guillain-Barré syndrome, and chronic demyelinating polyneuropathy (Table 295-14).

Stem Cell Transplantation Hematopoietic stem cell transplantation (SCT) is now being comprehensively studied to treat several autoimmune diseases, including systemic lupus erythematosus, multiple sclerosis, and scleroderma. The goal of immune reconstitution in autoimmune disease syndromes is to replace a dysfunctional immune system with a normally reactive immune cell repertoire. Preliminary results in patients with scleroderma and lupus have showed encouraging results. Controlled clinical trials in these three diseases are now being launched in the United States and Europe to compare the toxicity and efficacy of conventional immunosuppression therapy with that of myeloablative autologous SCT.

Thus, a number of recent insights into immune system function have spawned a new field of interventional immunotherapy and have enhanced the prospect for development of specific and nontoxic therapies for immune and inflammatory diseases.

296 THE MAJOR HISTOCOMPATIBILITY GENE COMPLEX

Gerald T. Nepom, Joel D. Taurog

THE HLA COMPLEX AND ITS PRODUCTS

The human major histocompatibility complex (MHC), commonly called the human leukocyte antigen (HLA) complex, is a 4-megabase (Mb) region on chromosome 6 (6p21.3) that is densely packed with expressed genes. The best known of these genes are the HLA class I and class II genes, whose products are critical for immunologic specificity and transplantation histocompatibility, and they play a major role in susceptibility to a number of autoimmune diseases. Many other genes in the HLA region are also essential to the innate and antigen-specific functioning of the immune system. The HLA region shows extensive conservation with the MHC of other mammals in terms of genomic organization, gene sequence, and protein structure and function. Much of our understanding of the MHC has come from investigation of the MHC in mice, which is termed the *H-2 complex*, and to a lesser degree from other species as well. Nonetheless, in this chapter discussion will be confined to information applicable to the MHC in humans.

The *HLA class I genes* are located in a 2-Mb stretch of DNA at the telomeric end of the HLA region (Fig. 296-1). The classic (MHC class Ia) HLA-A, -B, and -C loci, the products of which are integral participants in the immune response to intracellular infections, tumors, and allografts, are expressed in all nucleated cells and are highly polymorphic in the population. *Polymorphism* refers to a high degree

of allelic variation within a genetic locus that leads to extensive variation between different individuals expressing different alleles. Over 260 alleles at HLA-A, 500 at HLA-B, and 125 at HLA-C have been identified in different human populations, making this the most highly polymorphic segment known within the human genome. Each of the alleles at these loci encodes a *heavy chain* (also called an α *chain*) that associates noncovalently with the nonpolymorphic light chain β_2-*microglobulin*, encoded on chromosome 15.

The nomenclature of HLA genes and their products reflects the grafting of newer DNA sequence information on an older system based on serology. Among class I genes, alleles of the HLA-A, -B, and -C loci were originally identified in the 1950s, 1960s, and 1970s by alloantisera, derived primarily from multiparous women, who in the course of normal pregnancy produce antibodies against paternal antigens expressed on fetal cells. The serologic allotypes were designated by consecutive numbers, e.g., HLA-A1, HLA-B8. Currently, under World Health Organization (WHO) nomenclature, class I alleles are given a single designation that indicates locus, serologic specificity, and sequence-based subtype. For example, HLA-A*0201 indicates subtype 1 of the serologically defined allele HLA-A2. Subtypes that differ from each other at the nucleotide but not the amino acid sequence level are designated by an extra numeral, e.g., HLA-B*07021 and HLA-B*07022 are two variants of the HLA-B7 subtype of HLA-B*0702. The nomenclature of class II genes, discussed below, is made more complicated by the fact that both chains of a class II molecule are encoded by closely linked HLA-encoded loci, both of which may be polymorphic, and by the presence of differing numbers of isotypic DRB loci in different individuals. It has become clear that accurate HLA genotyping requires DNA sequence analysis, and the identification of alleles at the DNA sequence level has contributed greatly to the understanding of the role of HLA molecules as peptide-binding ligands, to the analysis of associations of HLA alleles with certain diseases, to the study of the populations genetics of HLA, and to a clearer understanding of the contribution of HLA differences to allograft rejection and graft-vs-host disease. Current databases of HLA class I and class II sequences can be accessed by internet (e.g., from the IMGT/HLA Database, *http://www.ebi.ac.uk/imgt/hla*), and frequent updates of HLA gene lists are published in several journals.

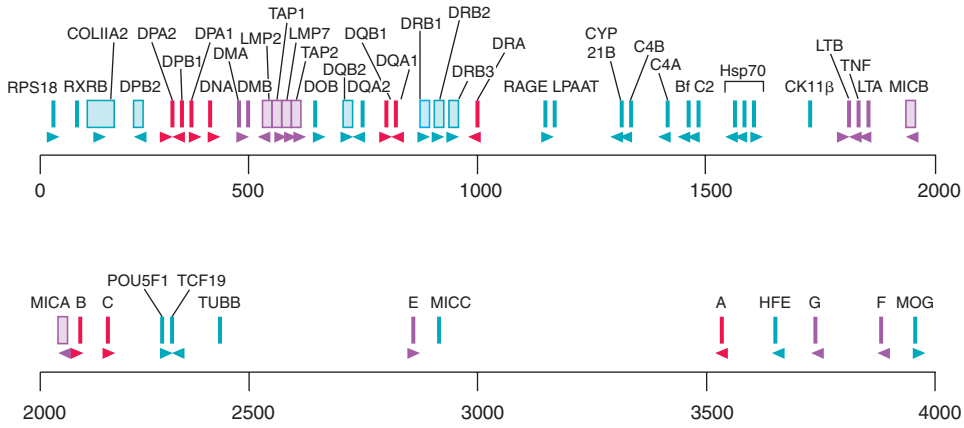

FIGURE 296-1 Physical map of the HLA region, showing the class I and class II loci, other immunologically important loci, and a sampling of other genes mapped to this region. Gene orientation is indicated by arrowheads. Scale is in kilobase (kb). The approximate genetic distance from DP to A is 3.2 cM. This includes 0.8 cM between A and B (including 0.2 cM between C and B), 0.4 to 0.8 cM between B and DR-DQ, and 1.6 to 2.0 cM between DR-DQ and DP.

As shown in Fig. 296-2 and discussed below in detail, two characteristic structural features in particular define the functional properties of class I and class II HLA molecules. First is the *peptide-binding groove* that enables these molecules to form highly stable complexes with a wide array of peptide sequences that can be recognized as antigens by T cells. Second is a site for binding either the CD8 (in the case of class I HLA molecules) or the CD4 (in the case of HLA class II) molecules, which are expressed on mature T lymphocytes. In the case of class I molecules, peptide binding provides a display on the cell surface of peptides derived from intracellular proteins and thus serve as a readout to CD8+ T cells of the proteins being produced within somatic cells. The polymorphism at the loci encoding these molecules predominantly affects the amino acid residues that make up the peptide-binding groove, further amplifying the array of peptides that can be bound by different HLA molecules and generating important functional immune differences and transplantation incompatibility among different individuals.

The nonclassic, or class Ib, MHC molecules, HLA-E, -F, and -G, are much less polymorphic than MHC Ia and appear to have distinct functions. The HLA-E molecule, which has a peptide repertoire restricted to signal peptides cleaved from classic MHC class I molecules, is the major self-recognition target for the natural killer (NK) cell inhibitory receptors NKG2A or NKG2C paired with CD94 (see below and Chap. 295); four HLA-E alleles are known. HLA-G is expressed selectively in extravillous trophoblasts, the fetal cell population directly in contact with maternal tissues. It binds a wide array of peptides, is expressed in six different alternatively spliced forms, and provides inhibitory signals to both NK cells and T cells, presumably in the service of maintaining maternofetal tolerance. The function of HLA-F remains largely unknown. Although HLA-C is considered a classic class I molecule, its degree of polymorphism and level of surface expression are significantly lower than those of HLA-A and HLA-B. Moreover, unlike HLA-A and -B molecules, which function primarily by presenting antigen to CD8+ T cells expressing $\alpha\beta$ T cell receptors, the primary function of HLA-C molecules appears to be to serve as targets of NK cell recognition (see below).

Additional class I–like genes have been identified, some HLA-linked and some encoded on other chromosomes, that show only distant homology to the class Ia and Ib molecules, but which share the three-dimensional class I structure. Those on chromosome 6p21 include MIC-A and MIC-B, which are encoded centromeric to HLA-B, and HLA-HFE, located 3 to 4 cM (centi-Morgan) telomeric of HLA-F. MIC-A and MIC-B do not bind peptide but are expressed on gut and other epithelium in a stress-inducible manner and serve as activation signals for certain $\gamma\delta$ T cells, NK cells, CD8 T cells, and activated macrophages, acting through the activating NKG2D receptors. Fifty-four MIC-A and seventeen MIC-B alleles are known, and additional diversification comes from variable alanine repeat sequences in the transmembrane domain. HLA-HFE encodes the gene defective in hereditary hemochromatosis (Chap. 336). Among the non-HLA, class I–like genes, CD1 refers to a family of molecules that present glycolipids or other nonpeptide ligands to certain T cells, including T cells with NK activity; FcRn binds IgG within lysosomes and protects it from catabolism (Chap. 295); and Zn-α_2-glycoprotein 1 binds a nonpeptide ligand and promotes catabolism of triglycerides in adipose tissue. Like the HLA-A, -B, -C, -E, -F, and -G heavy chains, each of which forms a heterodimer with β_2-microglobulin (Fig. 296-2), the class I–like molecules, HLA-HFE, FcRn, and CD1 also bind to β_2-microglobulin, but MIC-A, MIC-B, and Zn-α_2-glycoprotein 1 do not.

The *HLA class II region* is also illustrated in Fig. 296-1. Multiple class II genes are arrayed within the centromeric 1 Mb of the HLA region, forming distinct haplotypes. A *haplotype* refers to an array of alleles at polymorphic loci along a chromosomal segment. Multiple class II genes are present on a single haplotype, clustered into three major subregions: HLA-DR, -DQ, and -DP. Each of these subregions contains at least one functional alpha (A) locus and one functional beta (B) locus. Together these encode proteins which form the α and β polypeptide chains of a mature class II HLA molecule. Thus, the DRA and DRB genes encode an HLA-DR molecule; products of the DQA1

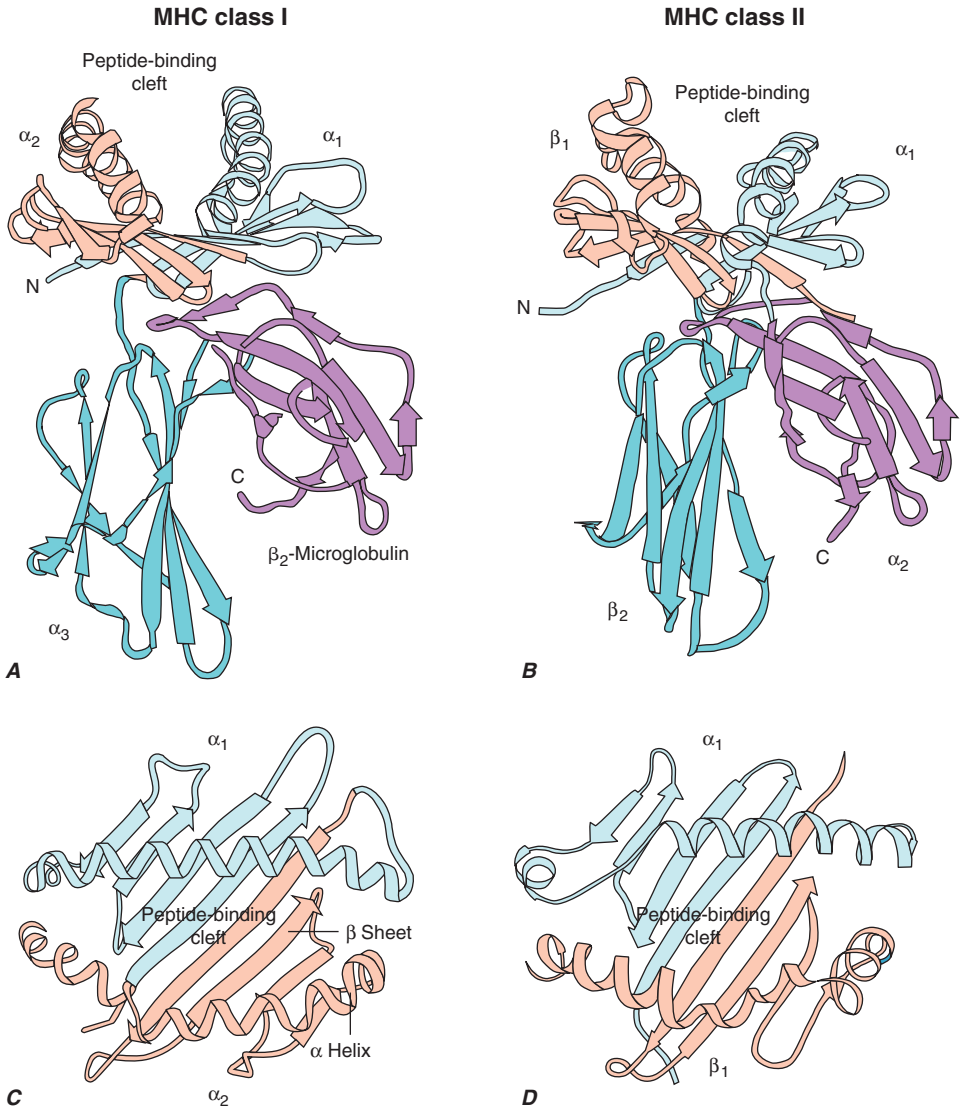

FIGURE 296-2 Side (*A*, *B*) and top (*C*, *D*) views of the MHC class I and class II molecules. The α_1 and α_2 domains of class I and the α_1 and β_1 domains of class II form a β-sheet platform that forms the floor of the peptide-binding groove, and α helices that form the sides of the groove. The α_3 (*A*) and β_2 domains (*B*) project from the cell surface and form the contact sites for CD8 and CD4, respectively. *(Adapted from C. Janeway et al, Immunobiology Bookshelf, 2d ed., Garland Publishing, New York, 1997, with permission.)*

and DQBl genes form an HLA-DQ molecule; and the DPAl and DPBl genes encode an HLA-DP molecule. There are several DRB genes (DRB1, DRB2, DRB3, etc.), so that two expressed DR molecules are encoded on most haplotypes by combining the α-chain product of the DRA gene with separate β chains. More than 325 alleles have been identified at the HLA-DRB1 locus, with most of the variation occurring within limited segments encoding residues that interact with antigens. Detailed analysis of sequences and population distribution of these alleles strongly suggests that this diversity is actively selected by environmental pressures associated with pathogen diversity.

The class II region was originally termed the *D-region*. The allelic gene products were first detected by their ability to stimulate lymphocyte proliferation by *mixed lymphocyte reaction*, and were named Dw1, Dw2, etc. Subsequently, serology was used to identify gene products on peripheral blood B cells, and the antigens were termed *DR* (D-related). After additional class II loci were identified, these came to be known as DQ and DP. In the DQ region, both DQA1 and DQB1 are polymorphic, with 22 DQA1 alleles and >50 DQB1 alleles. The current nomenclature is largely analogous to that discussed above for class I, using the convention "locus * allele." Thus, for example, subtypes of the serologically defined specificity DR4, encoded by the DRB1 locus, are termed DRB1*0401, -0402, etc. In addition to allelic polymorphism, products of different DQA1 alleles can, with some limitations, pair with products of different DQB1 alleles through both *cis* and *trans* pairing to create combinatorial complexity and expand the number of expressed class II molecules. Because of the enormous allelic diversity in the general population, most individuals are heterozygous at all of the class I and class II loci. Thus, most individuals express six classic class I molecules (two each of HLA-A, -B, and -C) and around eight class II molecules—two DP, two DR (more in the case of haplotypes with additional functional DRB genes), and up to four DQ (two *cis* and two *trans*).

The localization of polymorphic residues in class II molecules is similar to that for class I, i.e, it is predominantly in sites that affect peptide binding (see below). In the case of class II molecules, the peptides displayed on the cell surface are primarily derived from proteins acquired from the extracellular environment, processed through the endosomal-lysosomal pathway, and presented to CD4+ T cells.

OTHER GENES IN THE MHC In addition to the class I and class II genes themselves, there are numerous genes interspersed among the HLA loci that have interesting and important immunologic functions. Our current concept of the function of MHC genes now encompasses many of these additional genes. As discussed in more detail below, TAP and LMP genes are also polymorphic and encode molecules that participate in intermediate steps in the HLA class I biosynthetic pathway. Another set of HLA genes, DMA and DMB, perform an analogous function for the class II pathway. These genes encode an intracellular molecule that facilitates the proper complexing of HLA class II molecules with antigen (see below). The *HLA class III region* is a name given to a cluster of genes between the class I and class II complexes, which includes genes for the two closely related cytokines tumor necrosis factor (TNF)-α and lymphotoxin (TNF-β); the complement components C2, C4, and Bf; heat shock protein (HSP)70; and the enzyme 21-hydroxylase.

The class I genes HLA-A, -B, and -C are expressed in all nucleated cells, although generally to a higher degree on leukocytes than on nonleukocytes. In contrast, the class II genes show a more restricted distribution: HLA-DR and HLA-DP genes are constitutively expressed on most cells of the myeloid cell lineage, whereas all three class II gene families (HLA-DR, -DQ, and -DP) are inducible by certain stimuli provided by inflammatory cytokines such as interferon γ. Within the lymphoid lineage, expression of these class II genes is constitutive on B cells and inducible on human T cells. Most endothelial and epithelial cells in the body, including the vascular endothelium and the intestinal epithelium, are also inducible for class II gene expression. Thus, while these somatic tissues normally express only class I and not class II genes, during times of local inflammation they are recruited by cytokine stimuli to express class II genes as well, thereby becoming active participants in ongoing immune responses. Class II expression is controlled largely at the transcriptional level through a conserved

set of promoter elements that interact with a protein known as *CIITA*. Cytokine-mediated induction of CIITA is a principal method by which tissue-specific expression of HLA gene expression is controlled. Other HLA genes involved in the immune response, such as TAP and LMP, are also susceptible to upregulation by signals such as interferon γ. Sequence data for the entire HLA region can be accessed on the internet (e.g., *http://www.sanger.ac.uk/HGP/Chr6*). Many new genes have been discovered, the functions of which remain to be determined, as well as numerous microsatellite regions and other genetic elements. The gene density of the class II region is high, with approximately one protein encoded every 30 kb, and that of the class I and class III regions is even higher, with approximately one protein encoded every 15 kb.

LINKAGE DISEQUILIBRIUM In addition to extensive polymorphism at the class I and class II loci, another characteristic feature of the HLA complex is *linkage disequilibrium*. This is formally defined as a deviation from Hardy-Weinberg equilibrium for alleles at linked loci. This is reflected in the very low recombination rates between certain loci within the HLA complex. For example, recombination between DR and DQ loci is almost never observed in family studies, and characteristic haplotypes with particular arrays of DR and DQ alleles are found in every population. Similarly, the complement components C2, C4, and Bf are almost invariably inherited together, and the alleles at these loci are found in characteristic haplotypes. In contrast, there is a recombinational hotspot between DQ and DP, which are separated by 1 to 2 cM of genetic distance, despite their close physical proximity. Certain extended haplotypes encompassing the interval from DQ into the class I region are commonly found, the most notable being the haplotype DR3-B8-A1, which is found, in whole or in part, in 10 to 30% of northern European Caucasians. The genetic mechanisms that account for linkage disequilibrium in HLA have not been determined. It has been hypothesized that selective pressures may maintain certain haplotypes, but this remains to be determined. As discussed below under HLA and immunologic disease, one consequence of the phenomenon of linkage disequilibrium has been the resulting difficulty in assigning HLA-disease associations to a single allele at a single locus.

MHC STRUCTURE AND FUNCTION

Class I and class II molecules display a distinctive structural architecture, which contains specialized functional domains responsible for the unique genetic and immunologic properties of the HLA complex. The principal known function of both class I and class II HLA molecules is to bind antigenic peptides in order to present antigen to an appropriate T cell. The ability of a particular peptide to satisfactorily bind to an individual HLA molecule is a direct function of the molecular fit between the amino acid residues on the peptide with respect to the amino acid residues of the HLA molecule. The bound peptide forms a tertiary structure called the *MHC-peptide complex*, which communicates with T lymphocytes through binding to the T cell receptor (TCR) molecule. The first site of TCR-MHC-peptide interaction in the life of a T cell occurs in the thymus, where self-peptides are presented to developing thymocytes by MHC molecules expressed on thymic epithelium and hematopoietically derived antigen-presenting cells, which are primarily responsible for positive and negative selection, respectively (Chap. 295). Mature T cells encounter MHC molecules in the periphery both in the maintenance of tolerance (Chap. 299) and in the initiation of immune responses. Because most antibody responses and all T cell responses are T cell dependent (Chap. 295), the MHC-peptide-TCR interaction is the central event in the initiation of most antigen-specific immune responses, since it is the event that actually confers the specificity. Thus, the population of MHC–T cell complexes expressed in the thymus shapes the TCR repertoire. For potentially immunogenetic peptides, the ability of a given peptide to be generated and bound by an HLA molecule is a primary determinant of whether or not an immune response to that peptide can be generated, and the repertoire of peptides that a particular individual's HLA molecules can bind exerts a major influence over the specificity of that individual's immune response.

When a TCR molecule binds to an HLA-peptide complex, it forms intermolecular contacts with both the antigenic peptide and with the HLA molecule itself. The outcome of this recognition event depends on the density and duration of the binding interaction, accounting for a dual specificity requirement for activation of the T cell. That is, the TCR must be specific both for the antigenic peptide and for the HLA molecule. The polymorphic nature of the presenting molecules, and the influence that this exerts on the peptide repertoire of each molecule, results in the phenomenon of *MHC restriction* of the T cell specificity for a given peptide. The binding of CD8 or CD4 molecules to the class I or class II molecule, respectively, also contributes to the interaction between T cell and the HLA-peptide complex, by providing for the selective activation of the appropriate T cell.

CLASS I STRUCTURE (Fig. 296-2*A*) As noted above, MHC class I molecules provide a cell-surface display of peptides derived from intracellular proteins, and they also provide the signal for self-recognition by NK cells. Surface-expressed class I molecules consist of an MHC-encoded 44-kD glycoprotein heavy chain, a non-MHC-encoded 12-kD light chain β_2-microglobulin, and an antigenic peptide, typically 8 to 11 amino acids in length and derived from intracellularly produced protein. The heavy chain displays a prominent peptide-binding groove. In HLA-A and -B molecules, the groove is approximately 3 nm in length by 1.2 nm in maximum width (30 Å $\times$ 12 Å), whereas it is apparently somewhat wider in HLA-C. Antigenic peptides are noncovalently bound in an extended conformation within the peptide-binding groove, with both N- and C-terminal ends anchored in pockets within the groove (A and F pockets, respectively) and, in many cases, with a prominent kink, or arch, approximately one-third of the way from the N-terminus that elevates the peptide main chain off the floor of the groove.

A remarkable property of peptide binding by MHC molecules is the ability to form highly stable complexes with a wide array of peptide sequences. This is accomplished by a combination of peptide sequence–independent and peptide sequence–dependent bonding. The former consists of hydrogen bond and van der Waals interactions between conserved residues in the peptide-binding groove and charged or polar atoms along the peptide backbone. The latter is dependent upon the six side pockets that are formed by the irregular surface produced by protrusion of amino acid side chains from within the binding groove. The side chains lining the pockets interact with some of the peptide side chains. The sequence polymorphism among different class I alleles and isotypes predominantly affects the residues that line these pockets, and the interactions of these residues with peptide residues constitute the sequence-dependent bonding that confers a particular sequence "motif" on the range of peptides that can bind any given MHC molecule.

CLASS I BIOSYNTHESIS (Fig. 296-3*A*). The biosynthesis of the classic MHC class I molecules reflects their role in presenting endogenous peptides. The heavy chain is cotranslationally inserted into the membrane of the endoplasmic reticulum (ER), where it becomes glycosylated and associates sequentially with the chaperone proteins calnexin and ERp57. It then forms a complex with β_2-microglobulin, and this complex associates with the chaperone calreticulin and the MHC-encoded molecule tapasin, which physically links the class I complex to TAP, the MHC-encoded transporter associated with antigen processing. Meanwhile, peptides generated within the cytosol from intracellular proteins by the multisubunit, multicatalytic proteasome complex are actively transported into the ER by TAP, where they are trimmed by a peptidase known as *ERAAP* (ER aminopeptidase associated with antigen processing). At this point, peptides with appropriate sequence complementarity bind specific class I molecules to form complete, folded heavy chain–β_2-microglobulin–peptide trimer complexes. These are transported rapidly from the ER, through the *cis*- and *trans*-Golgi where the N-linked oligosaccharide is further processed, and thence to the cell surface.

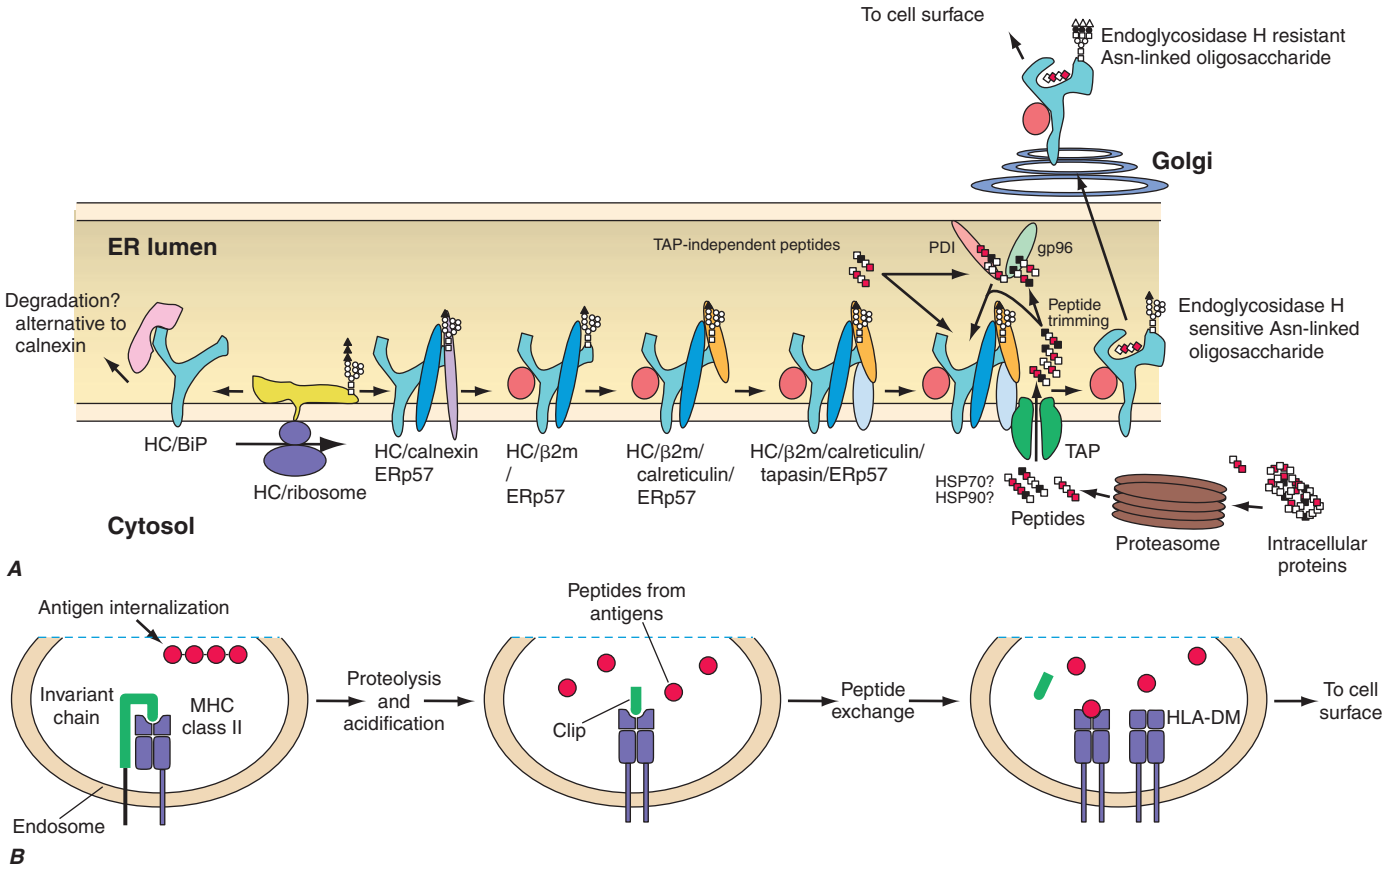

FIGURE 296-3 Biosynthesis of class I (*A*) and class II (*B*) molecules. *A*. Nascent heavy chain (HC) becomes associated with β_2-microglobulin (β2m) and peptide through interactions with a series of chaperones. Peptides generated by the proteasome are transported into the endoplasmic reticulum (ER) by TAP. Peptides undergo N-terminal trimming in the ER and become associated with chaperones, including gp96 and PDI. Once peptide binds to HC-β2m, the HC-β2m-peptide trimeric complex exits the ER and is transported by the secretory pathway to the cell surface. In the Golgi, the N-linked oligosaccharide undergoes maturation, with addition of sialic acid residues. Molecules are not necessarily drawn to scale. *B*. Pathway of HLA class II molecule assembly and antigen processing. After transport through the Golgi and post-Golgi compartment, the class II–invariant chain complex moves to an acidic endosome, where the invariant chain is proteolytically cleaved into fragments and displaced by antigenic peptides, facilitated by interactions with the DMA-DMB chaperone protein. This class II molecule–peptide complex is then transported to the cell surface.

Most of the peptides transported by TAP are produced in the cytosol by proteolytic cleavage of intracellular proteins by the multisubunit, multicatalytic protesasome, and inhibitors of the proteasome dramatically reduce expression of class I–presented antigenic peptides. A thiol-dependent oxidoreductase Erp57, which mediates disulfide bond rearrangements, also appears to play an important role in folding the class I–peptide complex into a stable multicomponent molecule. The MHC-encoded proteasome subunits LMP2 and LMP7 may influence the spectrum of peptides produced but are not essential for proteasome function.

CLASS I FUNCTION ■ Peptide Antigen Presentation On any given cell, a class I molecule occurs in 100,000 to 200,000 copies and binds several hundred to several thousand distinct peptide species. The vast majority of these peptides are self-peptides to which the host immune system is tolerant by one or more of the mechanisms that maintain tolerance, e.g., clonal deletion in the thymus or clonal anergy or clonal ignorance in the periphery (Chaps. 295 and 299). However, class I molecules bearing foreign peptides expressed in a permissive immunologic context activate CD8 T cells, which, if naïve, will then differentiate into cytolytic T lymphocytes (CTLs). These T cells and their progeny, through their $\alpha\beta$ TCRs, are then capable of Fas/CD95- and/or perforin-mediated cytotoxicity and/or cytokine secretion (Chap. 295) upon further encounter with the class I–peptide combination that originally activated it, and also with other combinations of class I molecule plus peptide that present a similar immunochemical stimulus to the TCR. As alluded to above, this phenomenon by which T cells recognize foreign antigens in the context of specific MHC alleles is termed *MHC restriction*, and the specific MHC molecule is termed the *restriction element*. The most common source of foreign peptides presented by class I molecules is viral infection, in the course of which peptides from viral proteins enter the class I pathway. The generation of a strong CTL response that destroys virally infected cells represents an important antigen-specific defense against many viral infections (Chap. 295). In the case of some viral infections—hepatitis B, for example—CTL-induced target cell apoptosis is thought to be a more important mechanism of tissue damage than any direct cytopathic effect of the virus itself. The importance of the class I pathway in the defense against viral infection is underscored by the identification of a number of viral products that interfere with the normal class I biosynthetic pathway and thus block the immunogenetic expression of viral antigens.

Other examples of intracellularly generated peptides that can be presented by class I molecules in an immunogenic manner include peptides derived from nonviral intracellular infectious agents (e.g., *Listeria*, *Plasmodium*), tumor antigens, minor histocompatibility antigens, and certain autoantigens. There are also situations in which cell surface–expressed class I molecules are thought to acquire and present exogenously derived peptides.

HLA Class I Receptors and NK Cell Recognition (Chap. 295) NK cells, which play an important role in innate immune responses, are activated to cytotoxicity and cytokine secretion by contact with cells that lack MHC class I expression, and NK cell activation is inhibited by cells that express MHC class I. In humans, the recognition of class I molecules by NK cells is carried out by three classes of receptor families, the killer cell–inhibitory cell receptor (KIR) family, the leukocyte Ig-like receptor (LIR) family, and the CD94/NKG2 family. The KIR family, also called CD158, is encoded on chromosome 19q13.4 and consists of glycoproteins of the immunoglobulin (Ig) superfamily, currently divided into two types, the inhibitor (L) and stimulatory (S)

KIRs. KIR molecules of the L class bind HLA class I molecules and inhibit NK cell–mediated cytotoxicity and are also expressed on subsets of T lymphocytes. An estimated 40 genes are divided into two subfamilies, 2DL and 3DL, which contain, respectively, either two or three Ig domains. The KIR2DL1 molecules primarily recognize alleles of HLA-C, which possess a lysine at position 80 (HLA-Cw2, -4, -7 and -8), while the KIR2DL2 and KIR2DL3 families primarily recognize alleles of HLA-C with asparagine at this position (HLA-Cw1, -3, -5 and -6). The KIR3D molecules predominantly recognize HLA-B alleles that fall into the HLA-Bw4 class determined by residues 77 to 83 in the α_1 domain of the heavy chain. Less is known about the stimulatory KIR receptors, and their primary specificity may be for nonclassic class I molecules or for related structures present on some pathogens. The most common KIR haplotype in Caucasians contains one activating KIR and six inhibitory KIR genes, although there is a great deal of diversity in the population, with at least 15 different haplotypes. It appears that most individuals have at least one inhibitory KIR for a self-HLA class I molecule, providing a structural basis for NK cell target specificity.

The LIR gene family (CD85, also called ILT) is encoded centromeric of the KIR locus on 19q13.4, and it encodes a variety of inhibitory immunoglobulin-like receptors expressed on many lymphocyte and other hematopoietic lineages. Interaction of LIR-1 (ILT2) with NK or T cells inhibits activation and cytotoxicity, mediated by many different HLA class I molecules, including HLA-G. HLA-F also appears to interact with LIR molecules, although the functional context for this is not understood.

The third family of NK receptors for HLA is encoded in the NK complex on chromosome 12p12.3-13.1 and consists of CD94 and five NKG2 genes, A/B, C, E/H, D, and F. These molecules are C-type (calcium-binding) lectins and most function as disulfide-bonded heterodimers between CD94 and one of the NKG2 glycoproteins. The principle ligand of CD94/NKG2A receptors is the HLA-E molecule, complexed to a peptide derived from the signal sequence of classic HLA class I molecules and HLA-G. Thus, analogous to the way in which KIR receptors recognize HLA-C, the NKG2 receptor monitors self–class I expression, albeit indirectly through peptide recognition in the context of HLA-E. NKG2C, -E, and -H appear to have similar specificities but act as activating receptors. NKG2D is expressed as a homodimer and functions as an activating receptor expressed on NK cells, $\gamma\delta$ TCR T cells, and activated CD8 T cells. When complexed with an adaptor called DAP10, NKG2D recognizes MIC-A and MIC-B molecules and activates the cytolytic response. NKG2D also binds a class of molecules known as *ULBP*, structurally related to class I molecules but not encoded in the MHC. →***The function of NK cells in immune responses is discussed in Chap. 295.***

CLASS II STRUCTURE (Fig. 296-2*B*) A specialized functional architecture similar to that of the class I molecules can be seen in the example of a class II molecule depicted in Fig. 296-2*B*, with an antigen-binding cleft arrayed above a supporting scaffold that extends the cleft toward the external cellular environment. However, in contrast to the HLA class I molecular structure, β_2-microglobulin is not associated with class II molecules. Rather, the class II molecule is a heterodimer, composed of a 29-kD α chain and a 34-kD β chain. The amino-terminal domains of each chain form the antigen-binding elements which, like the class I molecule, cradle a bound peptide in a groove bounded by extended α-helical loops, one encoded by the A (α chain) gene and one by the B (β chain) gene. Like the class I groove, the class II antigen-binding groove is punctuated by pockets that contact the side chains of amino acid residues of the bound peptide, but unlike the class I groove, it is open at both ends. Therefore, peptides bound by class II molecules vary greatly in length, since both the N- and C-terminal ends of the peptides can extend through the open ends of this groove. Approximately 11 amino acids within the bound peptide form intimate contacts with the class II molecule itself, with backbone hydrogen bonds and specific side chain interactions combining to provide, respectively, stability and specificity to the binding (Fig. 296-4).

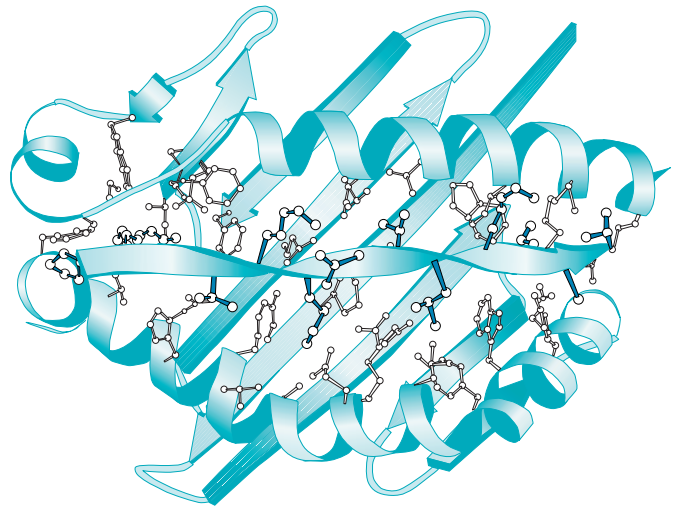

FIGURE 296-4 Top view of the HLA-DR1 molecule containing the peptide 296-318 from influenza hemagglutinin. The N terminus of the peptide is at left, and the peptide lies relatively flat within the peptide-binding groove in an extended conformation with a pronounced twist. Some 35% of the peptide surface is potentially available for interaction with the antigen receptor on T cells. Pockets in the peptide-binding site accommodate 5 of the 13 side chains of the bound peptide, manifesting the peptide specificity of HLA-DR1. Twelve hydrogen bonds between conserved HLA-DR1 residues and the main chain of the peptide provide a universal mode of peptide binding. The ends of the binding groove are open, and longer variants of the peptide can extend out from each end. In contrast, peptides bound to class I molecules are anchored into pockets at their N and C termini by conserved residues, and the middle portion of the peptide is typically kinked upwards out of the groove. *(Adapted from LJ Stern et al: Nature 368:215, 1994. Copyright 1994 Macmillan Magazines Ltd, with permission.)*

The genetic polymorphisms that distinguish different class II genes correspond to changes in the amino acid composition of the class II molecule, and these variable sites are clustered predominantly around the pocket structures within the antigen-binding groove. As with class I, this is a critically important feature of the class II molecule, which explains how genetically different individuals have functionally different HLA molecules.

As noted above, the class I–peptide complex is preferentially recognized by CD8 T cells, and the class II–peptide complex is preferentially recognized by CD4 T cells. These interactions provide an important signal for activation of specific T cell lineages during antigen-recognition events. The CD8 recognition site is located on the α_3 domain of the MHC class I molecule, and the CD4 recognition site is located on the β_2 domain of the class II molecule, in both cases remote from the peptide-binding site.

BIOSYNTHESIS AND FUNCTION OF CLASS II MOLECULES (Fig. 296-3*B*) The intracellular assembly of class II molecules occurs within a specialized compartmentalized pathway that differs dramatically from the class I pathway described above. As illustrated in Fig. 296-3*B*, the class II molecule assembles in the ER in association with a chaperone molecule, known as the *invariant chain*. The invariant chain performs at least two roles. First, it binds to the class II molecule and blocks the peptide-binding groove, thus preventing antigenic peptides from binding. This role of the invariant chain appears to account for one of the important differences between class I and class II MHC pathways, since it can explain why class I molecules present endogenous peptides from proteins newly synthesized in the ER but class II molecules generally do not. Second, the invariant chain contains molecular localization signals that direct the class II molecule to traffic into post-Golgi compartments known as *endosomes*, which develop into specialized acidic compartments where proteases cleave the invariant chain, and antigenic peptides can now occupy the class II groove. The specificity and tissue distribution of these proteases appear to be an important way in which the immune system regulates access to the peptide-

binding groove and T cells become exposed to specific self-antigens. Differences in protease expression in the thymus and in the periphery may in part determine which specific peptide sequences comprise the peripheral repertoire for T cell recognition. It is at this stage in the intracellular pathway, after cleavage of the invariant chain, that the MHC-encoded DM molecule catalytically facilitates the exchange of peptides within the class II groove to help optimize the specificity and stability of the MHC-peptide complex.

Once this MHC-peptide complex is deposited in the outer cell membrane it becomes the target for T cell recognition via a specific TCR expressed on lymphocytes. Because the endosome environment contains internalized proteins retrieved from the extracellular environment, the class II–peptide complex often contains bound antigens that were originally derived from extracellular proteins. In this way, the class II peptide–loading pathway provides a mechanism for immune surveillance of the extracellular space. This appears to be an important feature that permits the class II molecule to bind foreign peptides, distinct from the endogenous pathway of class I–mediated presentation.

ROLE OF HLA IN TRANSPLANTATION The development of modern clinical transplantation in the decades since the1950s provided a major impetus for elucidation of the HLA system, as allograft survival is highest when donor and recipient are HLA-identical. Although many molecular events participate in transplantation rejection, allogeneic differences at class I and class II loci play a major role. Class I molecules can promote T cell responses in several different ways. In the cases of allografts in which the host and donor are mismatched at one or more class I loci, host T cells can be activated by classic *direct alloreactivity*, in which the antigen receptors on the host T cells react with the foreign class I molecule expressed on the allograft. In this situation, the response of any given TCR may be dominated by the allogeneic MHC molecule, the peptide bound to it, or some combination of the two. Another type of host antigraft T cell response involves the uptake and processing of donor MHC antigens by host antigen-presenting cells and the subsequent presentation of the resulting peptides by host MHC molecules. This mechanism is termed *indirect alloreactivity*.

In the case of class I molecules on allografts that are shared by the host and the donor, a host T cell response may still be triggered because of peptides that are presented by the class I molecules of the graft but not of the host. The most common basis for the existence of these endogenous antigen peptides, called *minor histocompatibility antigens*, is a genetic difference between donor and host at a non-MHC locus encoding the structural gene for the protein from which the peptide is derived. These loci are termed *minor histocompatibility loci*, and nonidentical individuals typically differ at many such loci. CD4 T cells react to analogous class II variation, both direct and indirect, and class II differences alone are sufficient to drive allograft rejection.

ASSOCIATION OF HLA ALLELES WITH SUSCEPTIBILITY TO DISEASE It has long been postulated that infectious agents provide the driving force for the allelic diversification seen in the HLA system. An important corollary of this hypothesis is that resistance to specific pathogens may differ between individuals, based on HLA genotype. Observations of specific HLA genes associated with resistance to malaria or dengue fever, persistence of hepatitis B, and to disease progression in HIV infection are consistent with this model. Pathogen diversity is probably also the major selective pressure favoring HLA heterozygosity. The extraordinary scope of HLA allelic diversity increases the likelihood that most new pathogens will be recognized by some HLA molecules, helping to assure immune fitness to the host. However, another consequence of diversification is that some alleles may become preferentially selective for recognition of self-antigens as well. Indeed, particular HLA alleles are strongly associated with certain disease states, particularly for some common autoimmune diseases (Chap. 299). By comparing allele frequencies in patients with any particular disease and in control populations, a large number of such associations have been identified, some of which are listed in Table 296-1. The strength of genetic association is reflected in the term *relative risk*, which is a statistical odds ratio representing the risk of disease for an individual carrying a particular genetic marker compared with the risk for individuals in that population without that marker. The nomenclature shown in Table 296-1 reflects both the HLA serotype (e.g., DR3, DR4) and the HLA genotype (e.g., DRB1*0301, DRB1*0401). It very likely the class I and class II alleles themselves are the true susceptibility alleles for most of these associations. However, as discussed below, because of the extremely strong linkage disequilibrium between the DR and DQ loci, in some cases it has been difficult to determine the specific locus or combination of class II loci involved. In some cases, the susceptibility gene may be one of the HLA-linked genes located near the class I or class II region, but not the HLA gene itself, and in other cases the susceptibility gene may be a non-HLA gene, such as TNF-α, which is nearby.

As might be predicted from the known function of the class I and class II gene products, almost all of the diseases associated with specific HLA alleles have an immunologic component to their pathogenesis. It should be stressed that even the strong HLA associations with disease (those associations with relative risk of $\geq$10) implicate normal, rather than defective, alleles. Most individuals who carry these susceptibility genes do not express the associated disease; in this way the particular HLA gene is permissive for disease but requires other environmental (e.g., the presence of specific antigens) or genetic factors for full penetrance. In each case studied, even in diseases with very strong HLA associations, the concordance of disease in monozygotic twins is higher than in HLA-identical dizygotic twins or other sibling pairs, indicating that non-HLA genes contribute to susceptibility and can significantly modify the risk attributable to HLA.

Another group of diseases is genetically linked to HLA, not because of the immunologic function of HLA alleles, but rather because they are caused by autosomal dominant or recessive abnormal alleles at loci that happen to reside in or near the HLA region. Examples of these are 21-hydroxylase deficiency (Chap. 321), hemochromatosis (Chap. 336), and spinocerebellar ataxia (Chap. 353).

CLASS I ASSOCIATIONS WITH DISEASE Although the associations of human disease with particular HLA alleles or haplotypes predominantly involve the class II region, there are also several prominent disease associations with class I alleles. These include the association of Behçet's disease (Chap. 307) with HLA-B51, psoriasis vulgaris (Chap. 47) with HLA-Cw6, and, most notably, the spondyloarthropathies (Chap. 305) with HLA-B27. Twenty-five HLA-B locus alleles, designated HLA-B*2701 to B*2725, encode the family of B27 class I molecules. All of the subtypes share a common B pocket in the peptide-binding groove, a deep, negatively charged pocket that shows a strong preference for binding the arginine side chain. In addition, B27 is among the most negatively charged of HLA class I heavy chains, and the overall preference is for positively charged peptides. HLA-B*2705 is the predominant subtype in Caucasians and most other non-Oriental populations, and this subtype is very highly associated with ankylosing spondylitis (AS) (Chap. 305), both in its idiopathic form and in association with chronic inflammatory bowel disease or psoriasis vulgaris. It is also associated with reactive arthritis (ReA) (Chap. 305), with other idiopathic forms of peripheral arthritis (undifferentiated spondyloarthropathy), and with recurrent acute anterior uveitis. B27 is found in 50 to 90% of individuals with these conditions, compared with a prevalence of ~7% in North American Caucasians. The prevalence of B27 in patients with idiopathic AS is 90%, and in AS complicated by iritis or aortic insufficiency it is close to 100%. The absolute risk of spondyloarthropathy in unselected B27+ individuals has been variously estimated at 2 to 13% and >20% if a B27+ first-degree relative is affected. The concordance rate of AS in identical twins is very high, at least 65%. It can be concluded that the B27 molecule itself is involved in disease pathogenesis, based on strong evidence from clinical epidemiology and on the occurrence of a spon-

dyloarthropathy-like disease in HLA-B27 transgenic rats. Both AS and ReA are associated with the B27 subtypes B*2702, -04, and -05, and anecdotal association has been reported for subtypes B*2701, -03, -07, -08, -10, and -11.

The association of B27 with these diseases may derive from the specificity of a particular peptide or family of peptides bound to B27 or through another mechanism that is independent of the peptide specificity of B27. The first alternative can be further subdivided into mechanisms that involve T cell recognition of B27-peptide complexes and those that do not. A variety of other roles for B27 in disease pathogenesis have been postulated, including molecular or antigenic mimicry between B27 and certain bacteria and reduced killing of intracellular bacteria in cells expressing B27. HLA-B27 has been shown to form heavy chain homodimers, utilizing the cysteine residue at position 67 of the B57 α chain. These homodimers are expressed on the surface of lymphocytes and monocytes from patients with AS, and receptors including KIR3DL1, KIR3DL2, and ILT4 are capable of binding to them. Whether these interactions contribute to disease susceptibility or pathogenesis is currently unknown.

CLASS II DISEASE ASSOCIATIONS As can be seen in Table 296-1, the majority of associations of HLA and disease are with class II alleles. Several diseases have complex HLA genetic associations.

Celiac Disease In the case of celiac disease (Chap. 275), it is probable that the HLA-DQ genes are the primary basis for the disease association. HLA-DQ genes present on both the celiac-associated DR3 and DR7 haplotypes include the DQB1*0201 gene, and further detailed studies have documented a specific class II $\alpha\beta$ dimer encoded by the DQA1*0501 and DQB1*0201 genes, which appears to account for the HLA genetic contribution to celiac disease susceptibility. This specific HLA association with celiac disease may have a straightforward explanation: peptides derived from the wheat gluten component gliaden are bound to the molecule encoded by DQA1*0501 and DQB1*0201 and presented to T cells. A gliaden-derived peptide that has been implicated in this immune activation binds the DQ class II dimer best when the peptide contains a glutamine to glutamic acid substitution. It has been proposed that tissue transglutaminase, an enzyme present at increased levels in the intestinal cells of celiac patients, converts glutamine to glutamic acid in gliadin, creating peptides that are capable of being bound by the DQ2 molecule and presented to T cells.

Pemphigus Vulgaris In the case of pemphigus vulgaris (Chap. 49), there are two HLA haplotypes associated with disease, DRB1*0402-DQB1*0302 and DRB1*1401-DQB1*0503. Peptides derived from epidermal autoantigens have been implicated that preferentially bind to the DRB1*0402-encoded molecule, suggesting that specific peptide binding by this disease-associated class II molecule is important in disease. However, there are no class II genes in common between the disease-associated DR4 and DR14 haplotypes, and there is no evidence for any interaction of the latter haplotype interacting with the epidermal peptides that bind the DRB1*0402-encoded molecule. Thus, the most likely interpretation is that each of these class II associations with pemphigus represents a different pathway to a comparable clinical outcome.

Juvenile Arthritis Pauciarticular juvenile arthritis (Chap. 301) is an autoimmune disease associated with genes at the DRB1 locus and also with genes at the DPB1 locus. Patients with both DPB1*0201 and a DRB1 susceptibility allele (usually DRB1*08 or -*05) have a higher relative risk than expected from the additive effect of those genes alone. In juvenile patients with rheumatoid factor–positive polyarticular disease, heterozygotes carrying both DRB1*0401 and -*0404 have a relative risk >100, reflecting an apparent synergy in individuals inheriting both of these susceptibility genes.

Type I Diabetes Mellitus There are several aspects of the genetics of type I diabetes (Chap. 323) that illustrate the complex nature of HLA associations with autoimmune diseases. First, type 1 (autoimmune) diabetes mellitus is associated with both DR3 and DR4 serotypes and

TABLE 296-1 *Significant HLA Class I and Class II Associations with Disease*[a]

	Marker	Gene	Strength of Association
SPONDYLOARTHROPATHIES

Congenital adrenal hyperplasia	B47	21·OH (Cyp21B)	+++
Narcolepsy	DR2		++++
Goodpasture's syndrome (anti-GBM)	DR2		++

[a] Various diseases associated with HLA genes are listed, with the HLA serotype or linked marker most frequently found related to disease. Genes are listed for cases where specific alleles have been identified as responsible for this association. The strength of association reflects the likelihood of disease in individuals with the marker compared to individuals who do not carry the marker; ++++, relative risk > 10; +++, relative risk > 5; ++, relative risk > 3; +, relative risk > 1.5.

[b] Strong negative association, i.e., genetic association with protection from diabetes.

their corresponding genes. The presence of both the DR3 and DR4 haplotypes in one individual confers the highest known genetic risk for type 1 diabetes, and individuals carrying either of these haplotypes also carry some increased risk. Specific class II genes on each haplotype have been thoroughly studied, and the strongest association is with DQB1*0302, a specific gene on the diabetes-associated DR4 haplotypes. Thus, all DR4 haplotypes that carry a DQB1*0302 gene are associated with type 1 diabetes, whereas related DR4 haplotypes that carry a different DQB1 gene are not. The primary class II determinant of susceptibility, therefore, is HLA-DQB1*0302. However, the relative risk associated with inheritance of this gene can be modified, depending on other HLA genes present either on the same or a second haplotype. For example, just as the presence of a second haplotype containing DR3 is associated with increased diabetes risk, the presence of a DR2-positive haplotype containing a DQB1*0602 gene is associated with decreased risk. This gene, DQB1*0602, is considered "protective" for type 1 diabetes. Even some DRB1 genes that can occur on the same haplotype as DQB1*0302 may modulate risk, so that individuals with the DR4 haplotype that contains DRB1*0403 are less susceptible to type 1 diabetes than individuals with other DR4-DQB1*0302 haplotypes.

Although the presence of a DR3 haplotype in combination with the DR4-DQB1*0302 haplotype is a very high risk combination for diabetes susceptibility, the specific gene on the DR3 haplotype that is responsible for this synergy is not yet identified. This is because the predominant HLA-DR3 haplotype in Caucasians has very tight linkage with other genes within the MHC, including HLA-A1, -B8, -Cw7, and -C4A, as discussed above. Thus, any of a large variety of genes within the HLA region on this DR3 haplotype may be the primary gene(s) responsible for contributing to diabetes susceptibility. An example that more directly implicates other genes linked to DR3 is the association between HLA genes and systemic lupus erythematosus (SLE) (Chap. 300). The C4A null alleles that are present on the HLA-DR3 haplotypes in SLE are also often present in patients without DR3, notably those with HLA-DR2. This implicates the presence of a C4A silent allele, which is a defective structural gene for the C4 complement component, rather than the expression of any particular class II gene, as a potential susceptibility gene within HLA associated with SLE.

HLA and Rheumatoid Arthritis The HLA genes associated with rheumatoid arthritis (RA) (Chap. 301) are DRB1*0401 and DRB1*0404. These genes encode a distinctive sequence of amino acids from codons 67 to 74 of the DRβ molecule: RA-associated class II molecules carry the sequence LeuLeuGluGlnArgArgAlaAla or LeuLeuGluGlnLysArgAlaAla in this region, while non-RA-associated genes carry one or more differences in this region. These residues form a portion of the molecule that lies in the middle of the α-helical portion of the DRB1-encoded class II molecule, termed the *shared epitope*.

These DR4-positive RA-associated alleles are most frequent among patients with more severe, erosive disease. The frequency of these DR4-positive alleles is lower among rheumatoid factor–negative patients with RA, as well as among patients with nonerosive forms of the disease. It is important to note that, although the frequency of these DRB1 susceptibility alleles in RA patients is high, the same genes are also prevalent in the unaffected population, and thus the absolute risk associated with these susceptibility alleles is low. The highest risk for susceptibility to RA comes in individuals who carry both a DRB1*0401 and DRB1*0404 gene. Some forms of RA are associated with other HLA genes, such as DRB1*01, -*1001, and -*1402, which also carry the shared epitope sequence, strongly suggesting that this part of the class II molecule contributes directly to disease pathogenesis.

MOLECULAR MECHANISMS FOR HLA-DISEASE ASSOCIATIONS As noted above, HLA molecules play a key role in the selection and establishment of the antigen-specific T cell repertoire and a major role in the subsequent activation of those T cells during the initiation of an immune response. Precise genetic polymorphisms characteristic of individual alleles dictate the specificity of these interactions and thereby instruct and guide antigen-specific immune events. These same genetically determined pathways are therefore implicated in disease pathogenesis when specific HLA genes are responsible for autoimmune disease susceptibility.

The fate of developing T cells within the thymus is determined by the affinity of interaction between T cell receptor and HLA molecules bearing self-peptides, and thus the particular HLA types of each individual control the precise specificity of the T cell repertoire (Chap. 295). The primary basis for HLA-associated disease susceptibility may well lie within this thymic maturation pathway. The positive selection of potentially autoreactive T cells, based on the presence of specific HLA susceptibility genes, may establish the threshold for disease risk in a particular individual.

At the time of onset of a subsequent immune response, the primary role of the HLA molecule is to bind peptide and present it to antigen-specific T cells. The HLA complex can therefore be viewed as encoding genetic determinants of precise immunologic activation events. Antigenic peptides that bind particular HLA molecules are capable of stimulating T cell immune responses; peptides that do not bind are not presented to T cells and are not immunogenic. This genetic control of the immune response is mediated by the polymorphic sites within the HLA antigen–binding groove that interact with the bound peptides. In autoimmune and immune-mediated diseases, it is likely that specific tissue antigens that are targets for pathogenic lymphocytes are complexed with the HLA molecules encoded by specific susceptibility alleles. In autoimmune diseases with an infectious etiology, it is likely that immune responses to peptides derived from the initiating pathogen are bound and presented by particular HLA molecules to activate T lymphocytes that play a triggering or contributory role in disease pathogenesis. The concept that early events in disease initiation are triggered by specific HLA-peptide complexes offers some prospects for therapeutic intervention, since it may be possible to design compounds that interfere with the formation or function of specific HLA-peptide–T cell receptor interactions.

When considering mechanisms of HLA associations with immune response and disease, it is well to remember that just as HLA genetics are complex, so are the mechanisms likely to be heterogeneous. Immune-mediated disease is a multistep process in which one of the HLA-associated functions is to establish a repertoire of potentially reactive T cells, while another HLA-associated function is to provide the essential peptide-binding specificity for T cell recognition. For diseases with multiple HLA genetic associations, it is possible that both of these interactions occur and synergize to advance an accelerated pathway of disease.

297 PRIMARY IMMUNE DEFICIENCY DISEASES

Max D. Cooper, Harry W. Schroeder, Jr.

Specific adaptive immune responses are mediated by developmentally independent, but functionally interacting, families of lymphocytes. T lymphocytes mediate cellular immunity, while B lymphocytes and their plasma cell progeny produce antibodies to provide humoral immunity. The activities of B and T cells and their products in host defense are closely integrated with innate immune functions of other cells of the reticuloendothelial system. Dendritic cells, Langerhans' cells in the skin, and macrophages play an important role in the trapping and presentation of antigens to T and B cells to initiate the immune response. Macrophages also become effector cells, especially when activated by cytokine products of lymphocytes. The scavenger activity of macrophages and polymorphonuclear leukocytes is directed and made specific by antibodies in concert with cytokines and the complement system. Natural killer (NK) cells, a population of granular lymphocytes with receptors specific for major histocompatibility complex (MHC) class I molecules, may spontaneously kill tumor and virus-infected cells, activities that are enhanced by the cytokine products of immune and inflammatory cells. Killing by NK cells can also be targeted by IgG antibodies for which NK cells have cell-surface receptors. The interaction of basophils and tissue mast cells with IgE antibodies in causation of immediate-type hypersensitivity is discussed in Chap. 298. Consideration of these interrelationships is an important part of the analysis of patients with suspected immune deficiency.

DIFFERENTIATION OF T AND B CELLS The functional deficits that occur in both congenital and acquired immunodeficiencies are usefully viewed as being caused by defects at various points along the differentiation pathways of immunocompetent cells. Lymphoid progenitors derived from hematopoietic stem cells may migrate to the thymus to begin T cell development or remain in the fetal liver or bone marrow where they enter the B and NK cell pathways of development (Fig. 297-1). Immature T and B cells then migrate through the circulation to the spleen, lymph nodes, intestine, and other peripheral lymphoid organs. In these sites, they may encounter antigens presented by dendritic cells or macrophages and respond with proliferation, differentiation, and mediation of immune responses. ***→Chap. 295 provides a general account of their roles in cellular and humoral immunity.***

Differentiation of T or B cells may be arrested at either the primary or secondary stages. Reflecting the complex cellular interactions involved in immune responses and the pivotal role played by T lymphocytes, immune deficiencies primarily involving T cells are usually also associated with abnormal B cell function.

CLINICAL DISEASE FEATURES COMMON TO IMMUNE DEFICIENCY Immunodeficiency syndromes, whether congenital, spontaneously acquired, or iatrogenic, are characterized by unusual susceptibility to infection and not infrequently to autoimmune disease and lymphoreticular malignancies. The types of infection often provide the first clue to the nature of the immunologic defect.

Patients with *defects in humoral immunity* have recurrent or chronic sinopulmonary infection, meningitis, and bacteremia, most commonly caused by pyogenic bacteria such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. These and other pyogenic organisms also cause frequent infections in individuals who have either neutropenia or a deficiency of the pivotal third component of complement (C3). The tripartite collaboration of antibody, complement, and phagocytes in host defense against pyogenic organisms makes it important to assess all three systems in individuals with unusual susceptibility to bacterial infections.

Antibody-deficient patients in whom cell-mediated immunity is intact have an interesting response to viral infections. The clinical course of primary infection with viruses such as varicella zoster or rubeola, unless complicated by bacterial infection, does not differ significantly from that of the normal host. However, multiple bouts of chickenpox and measles may occur. Such observations suggest that intact T cells may be sufficient for control of established viral infections, while antibodies play an important role in limiting the initial dissemination of virus and in providing long-lasting protection. Exceptions to this generalization are becoming more widely recognized. Agammaglobulinemic patients fail to clear hepatitis B virus from their circulation and

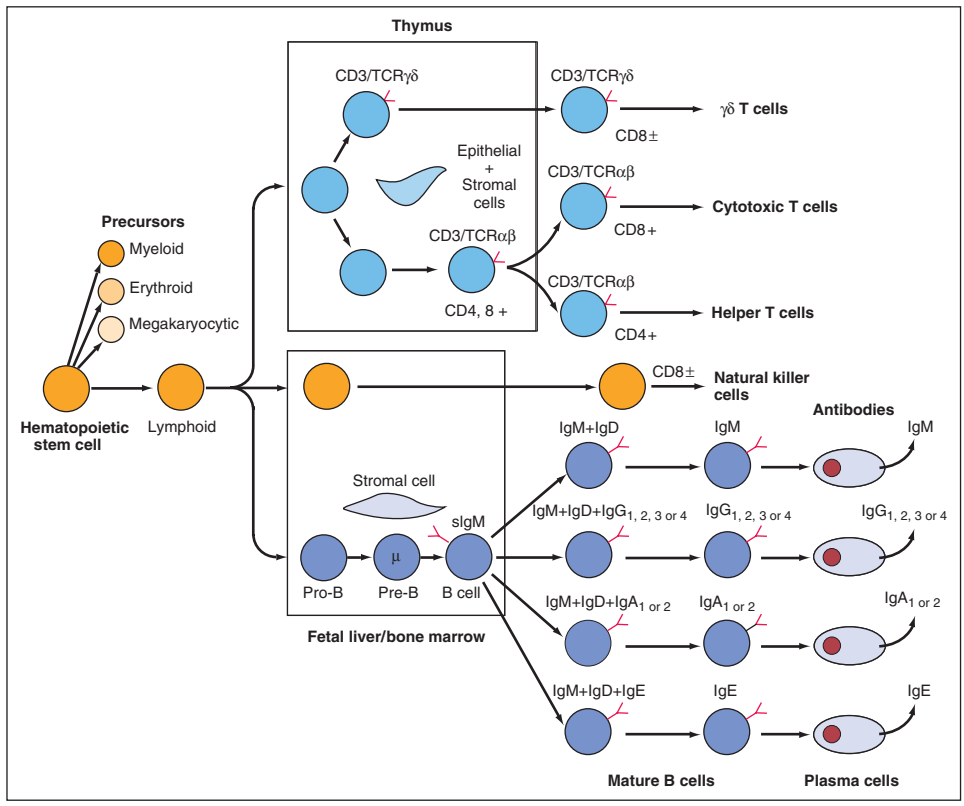

FIGURE 297-1 Hypothetical model outlining the differentiation of hematopoietic stem cells along T, B, and NK cell lineages. The antigen presenting dendritic cells, not shown here, are derived from both lymphoid and myeloid progenitors. Failure to develop T and B cells may result from defective stem cells or from inborn metabolic errors affecting both cell types. Rarely, other hematopoietic cell lines are also absent. Absence of either T or B cells suggests malfunction of central lymphoid tissues, including the thymus and the fetal liver–bone marrow complex. B cell deficiency may result from failure to generate pre-B cells from their stem cell precursors or from failure of pre-B cells to give rise to their B lymphocyte progeny. Similarly, differentiation may be arrested at several levels within the T cell lineage; arrests at the thymocyte level and failure to develop the helper subset have been observed in immunodeficient patients. Agammaglobulinemia and deficiencies of some T cell functions may occur despite the presence of normal numbers of B or T cells in the circulation. Failure of B lymphocytes to differentiate to plasma cells can be due to intrinsic cellular abnormalities or to faulty T cell regulation.

have a progressive, and often fatal, course. Poliomyelitis has occurred following live-virus vaccination in some patients. Chronic encephalitis, which may progress over a period of months to years, is a particular threat in congenitally agammaglobulinemic boys. Echoviruses and adenoviruses have been isolated from brain, spinal fluid, or other sites in such patients.

The occurrence of an unusually serious infection, for example, *H. influenzae* meningitis in an older child or adult, warrants consideration of humoral immune deficiency. Recurrent bacterial pneumonias also suggest this possibility. Chronic otitis media occurs frequently in patients with hypogammaglobulinemia and is significant because of its relative rarity in normal adults. Pansinusitis, although almost invariably present in immunoglobulin deficiency, is a less helpful finding because it is not rare in apparently normal people. Bacterial infections of the skin or urinary tract are less frequent problems in hypogammaglobulinemic patients. Infestation with the intestinal parasite *Giardia lamblia* is a frequent cause of diarrhea in antibody-deficient patients.

Abnormalities of cell-mediated immunity predispose to disseminated virus infections, particularly with latent viruses such as herpes simplex (Chap. 163), varicella zoster (Chap. 164), and cytomegalovirus (Chap. 166). In addition, patients so affected almost invariably develop mucocutaneous candidiasis and frequently acquire systemic fungal infections. Pneumonia caused by *Pneumocystis carinii* is also common (Chap. 191). Severe enteritis caused by *Cryptosporidium* infection may extend to the biliary tract to result in sclerosing cholangitis.

T cell deficiency is always accompanied by some abnormality of antibody responses (Fig. 297-1), although this may not be reflected by hypogammaglobulinemia. This explains in part why patients with primary T cell defects are also subject to overwhelming bacterial infection.

The most severe form of immune deficiency occurs in individuals who lack both cell-mediated and humoral immune functions. Individuals with severe combined immunodeficiency (SCID) are susceptible to the whole range of infectious agents including organisms not ordinarily considered pathogenic. Multiple infections with viruses, bacteria, and fungi occur, often simultaneously. Because donor lymphocytes cannot be rejected by these recipients, blood transfusions can produce fatal graft-versus-host disease.

EVALUATION OF IMMUNODEFICIENT PATIENTS A careful history and physical examination will usually indicate whether the major problem involves the antibody-complement-phagocyte system or cell-mediated immunity. A history of contact dermatitis due to poison ivy suggests intact cellular immunity. Persistent mucocutaneous candidiasis suggests deficient cell-mediated immunity. Lymphopenia and the absence of palpable lymph nodes may be important findings. However, patients with profound immunodeficiency may have diffuse lymphoid hyperplasia. Most immunodeficiencies may be diagnosed by thoughtful use of tests available in local or regional clinical laboratories. More precise evaluation of immunologic functions and treatment may require referral to specialized centers. Table 297-1 presents a résumé of widely available laboratory investigations.

Humoral Immunity With rare exceptions, deficiency of humoral immunity is accompanied by diminished serum concentration of one or more classes of immunoglobulin. Normal values vary with age, and adult concentrations of IgM (1.0 ± 0.4 g/L) are reached at about 1 year, of IgG (10.0 ± 3.0 g/L) at 5 to 6 years, and of IgA (2.5 ± 1.0 g/L) by puberty (Chap. 295). The wide range of values among normal adults creates difficulty in defining the lower limits of normal. Reasonable estimates for low values are below 0.4 g/L for IgM, 5 g/L for IgG, and 0.5 g/L for IgA. In the presence of borderline hypogammaglobulinemia, assessing the patient's capacity to produce specific antibodies becomes particularly important. Isohemagglutinins and "febrile agglutinins" are valuable standard assays, and measurements of pre- and postimmunization titers to tetanus toxoid, diphtheria toxoid, *H. influenzae* capsular polysaccharide, and *S. pneumoniae* serotypes provide a comprehensive assessment of humoral responsiveness.

TABLE 297-1 Laboratory Evaluation of Host Defense Status

Initial Screening Assays[a]
Complete blood count with differential smear
Serum immunoglobulin levels: IgM, IgG, IgA, IgD, IgE
Other Readily Available Assays
Quantification of blood mononuclear cell populations by immunofluorescence assays employing monoclonal antibody markers[b]
T cells: CD3, CD4, CD8, TCR$\alpha\beta$, TCR$\gamma\delta$
B cells: CD19, CD20, CD21, Ig(μ, δ, γ, α, κ, λ), Ig-associated molecules (α, β)
Activation markers: HLA-DR, CD25, CD80 (B cells), CD154 (T cells)
NK cells: CD16/CD56
Monocytes: CD15
T cell functional evaluation
1. Delayed hypersensitivity skin tests (PPD, *Candida*, histoplasmin, tetanus toxoid)
2. Proliferative response to mitogens (anti-CD3 antibody, phytohemagglutinin, concanavalin A) and allogeneic cells (mixed lymphocyte response)
3. Cytokine production
B cell functional evaluation
1. Natural or commonly acquired antibodies: isohemagglutinins; antibodies to common viruses (influenza, rubella, rubeola) and bacterial toxins (diphtheria, tetanus)
2. Response to immunization with protein (tetanus toxoid) and carbohydrate (pneumococcal vaccine, *H. influenzae B* vaccine) antigens
3. Quantitative IgG subclass determinations
Complement
1. CH_{50} assays (classic and alternative pathways)
2. C3, C4, and other components
Phagocyte function
1. Reduction of nitroblue tetrazolium
2. Chemotaxis assays
3. Bactericidal activity

[a] Together with a history and physical examination, these tests will identify more than 95% of patients with primary immunodeficiencies.

[b] The menu of monoclonal antibody markers may be expanded or contracted to focus on particular clinical questions.

Estimation of numbers of circulating B and T lymphocytes is of value in determining the pathogenesis of certain types of immune deficiency. B lymphocytes are identified by the presence of membrane-bound immunoglobulins, their associated α- and β-chain units, and other lineage-specific molecules on the B cell surface (Table 297-1), which can be identified and enumerated by specific monoclonal antibodies.

Since antibody deficiency may be mimicked clinically by deficiency of complement components, measurement of total hemolytic complement (CH_{50}) should be a part of the evaluation of host defense. Measurement of C3 alone is inadequate for screening, since deficiencies of both early and late complement components may predispose to bacterial infection (Chap. 295).

Cellular Immunity T lymphocytes may be enumerated by their expression of the TCR/CD3 complex of surface molecules (TCR; T cell receptor). The CD4 molecule serves as a marker for helper T cells, although macrophages also express this molecule in relatively low levels. Conversely, CD8$\alpha\beta$ heterodimers are expressed by cytotoxic T cells. CD8 is also expressed by some $\gamma\delta$ T cells and by NK cells as CD8$\alpha\alpha$ homodimeric molecules.

Normal levels of serum immunoglobulins and antibody responsiveness are reliable indices of intact helper T cell function. T lymphocyte function can be measured directly by delayed hypersensitivity skin testing using a variety of antigens to which the majority of older children and adults have been sensitized. A generally useful skin test antigen is a 1:5 dilution of tetanus toxoid injected intradermally, since almost all individuals will have been sensitized. Purified protein derivative (PPD), histoplasmin, mumps antigen, and extracts of *Candida* or *Trichophyton* also may be used.

T lymphocyte function may be estimated in vitro by the capacity of cells to proliferate in response to antigens to which the patient has been sensitized, to lymphocytes from an unrelated donor, to antibodies that cross-link the CD3/TCR complex, or to the T cell mitogens, such as phytohemagglutinin and concanavalin A. The response is usually quantified 3 days later by measurement of incorporation of radioactive thymidine into newly synthesized DNA. The production of cytokines (or interleukins) by activated T cells can be measured, as can the ability of T cells activated in mixed lymphocyte culture to lyse target cells. Finally, assays exist for detection of defects in T cell surface receptors and specific elements of their signal transduction pathways.

CLASSIFICATION *Primary immunodeficiencies* may be either congenital or manifested later in life and are currently classified according to mode of inheritance and whether the genetic defect affects T cells, B cells, or both (Table 297-2). The following discussion emphasizes three related concepts: (1) that immunodeficiencies are logically viewed as defects of cellular differentiation; (2) that these defects may involve either primary development of T or B cells or the antigen-dependent phase of their differentiation; and (3) that defects of B cell differentiation may in some instances reflect faulty T-B collaboration.

Secondary immunodeficiencies are those not caused by intrinsic

TABLE 297-2 *Primary Immunodeficiencies—Laboratory and Clinical Features*

	Lymphocytes			Cellular Immunity	Humoral Immunity: Serum Immunoglobulins				Antibody Responses	Common Infections
	B	T	NK		M	G	A	E		
Severe combined immunodeficiency (SCID)										
Adenosine deaminse (ADA) deficiency	−	−	+	−	↓	↓	↓	↓	−	Bacteria, viruses, fungi
Artemis deficiency (SCIDA)	−	−	+	−	↓	↓	↓	↓	−	Bacteria, viruses, fungi
CD45 deficiency	+	−	−	−	↓	↓	↓	↓	−	Bacteria, viruses, fungi
Interleukin receptor γ chain deficiency (X-linked SCID)	+	−	−	−	N	↓	↓	↓	−	Bacteria, viruses, fungi
Janus-associated kinase 3 (JAK3) deficiency	+	−	−	−	N	↓	↓	↓	−	Bacteria, viruses, fungi
Recombinase activating gene (RAG 1/2) deficiency	−	−	+	−	↓	↓	↓	↓	−	Bacteria, viruses, fungi
Reticular dysgenesis	−	−	−	−	↓	↓	↓	↓	−	Bacteria, viruses, fungi
TAP-1 or TAP-2 deficiency (MHC class I deficiency)	+	±	+	−	N	N	N	N	+	Bacteria, viruses, fungi
Primary T Cell Deficiency										
CD8 deficiency	+	±	+	±	N	N	N	N	+	Bacteria
DiGeorge syndrome	+	−	+	−	N	N	N	N	±	Bacteria, viruses, fungi
MHC class II deficiency	+	±	+	+	N	↓	↓	↓	±	Bacteria, viruses, fungi
Nude syndrome (wing helix nude deficiency)	+	−	+	−	N	N/↓	N/↓	N/↓	±	Bacteria, viruses, fungi
Purine nucleotide phosphorylase (PNP) deficiency	+	−	+	−	N	↓	↓	↓	±	Bacteria, viruses, fungi
T cell receptor deficiency ($CD3_\epsilon$ or CD3ϵ deficiency)	+	+	+	−	N	N	N	N	±	Bacteria, viruses, fungi
Zap70 tyrosine kinase deficiency	+	±	+	−	N	N/↓	N/↓	N/↓	±	Bacteria, viruses, fungi
Predominantly antibody deficiency										
IgG subclass deficiency	+	+	+	+	N	N/↓	N/↓	N/↓	±	Bacteria
Autosomal recessive agammaglobulinemia (λ5, Igβ, or BLNK deficiency)	−	+	+	+	↓	↓	↓	↓	−	Bacteria, *Giardia lamblia*
Common variable immune deficiency	+	+	+	+	N/↓	↓	↓	↓	−	Bacteria, *Giardia lamblia*
Selective IgA deficiency	+	+	+	+	N	N	↓	N	±	Bacteria, *Giardia lamblia*
X-linked agammaglobulinemia	−	+	+	+	↓	↓	↓	↓	−	Bacteria, *Giardia lamblia*
Hyper IgM syndrome

Interleukin 12 and interleukin 12 receptor deficiency	+	+	+	+	N	N	N	N	+	Mycobacteria, *Salmonella*
X-linked lymphoproliferative syndrome	+	+	+	+	N	N/↓	N/↓	N/↓	±	Epstein-Barr virus

Note: B, B cells; T, T cells; NK, natural killer lymphocytes; +, normal levels; −, reduced or absent levels; N, ↑, ↓, normal, elevated, or reduced serum immunoglobulins.

abnormalities in development or function of T and B cells. The best known of these is AIDS, which may follow infection with the human immunodeficiency virus (Chap. 173). Other examples are immune deficiency associated with malnutrition, protein-losing enteropathy, and intestinal lymphangiectasia. Also considered secondary are immunodeficiencies resulting from hypercatabolic states such as occur in myotonic dystrophy; immunodeficiency associated with lymphoreticular malignancy; and immunodeficiency resulting from treatment with x-rays, antilymphocyte antibodies, or immunosuppressive drugs.

Incidence As a group, the primary immunodeficiencies are relatively common. The most frequent, isolated IgA deficiency, occurs in approximately 1 in 600 individuals in Europe and North America. Common variable immunodeficiency, a related disorder characterized by pan-hypogammaglobulinemia, is the next most common disorder. Both of these immunodeficiency states often become clinically evident in young adults.

The more severe forms of primary immunodeficiency are relatively rare, have their onset early in life, and all too frequently result in death during childhood. However, patients with congenital hypogammaglobulinemia may lead relatively healthy lives with adequate antibody-replacement therapy. In a referral center for patients with immunodeficiency diseases, approximately two-thirds of the immunodeficient patients will be adults.

Severe Combined Immunodeficiency The SCID syndrome is characterized by gross functional impairment of both humoral and cell-mediated immunity and by susceptibility to devastating fungal, bacterial, and viral infections. Inherited either as an X-linked or autosomal recessive defect, affected infants rarely survive beyond 1 year without treatment.

The overall incidence of SCID is 1 in 100,000 to 1 in 1,000,000. The syndrome has been associated with a diversity of defects in development of immunocompetent cells, which are caused by mutations in genes whose products are necessary for the normal differentiation of T, B, and, sometimes, NK cells.

In one autosomal recessive form of SCID characterized by severe lymphopenia, the failure in T and B cell development is due to mutations in the *RAG-1* or *RAG-2* genes, the combined activities of which are needed for V(D)J recombination. A function-loss mutation in either the DNA-dependent tyrosine kinase or the *Artemis* genes may cause SCID, since they also encode essential enzymes for the V(D)J gene rearrangement process. About half of patients with autosomal recessive SCID are deficient in an enzyme involved in purine metabolism, adenosine deaminase (ADA), due to mutations in the *ADA* gene. The abortive lymphoid differentiation associated with ADA deficiency is due to intracellular accumulation of adenosine and deoxyadenosine nucleotides that trigger apoptosis of immature T and B lineage cells.

SCID may also occur with an X-linked inheritance pattern. Aborted thymocyte differentiation and an absence of peripheral T cells and NK cells is seen in X-linked SCID. B lymphocytes are present in normal numbers but are functionally defective. The defective gene encodes a common γ chain of the receptors for interleukin (IL) 2, -4, -7, -9, and -15, thus disrupting the action of this important set of lymphokines. The same T^- NK^-B^+ SCID phenotype seen in X-linked SCID can be inherited as an autosomal recessive disease due to mutations in the gene for JAK3 protein kinase deficiency. This enzyme associates with the common γ chain of the receptors for IL-2, -4, -7, -9, and -15 to serve as a key element in their signal transduction pathways.

Rx TREATMENT

The cellular defects in SCID patients logically rest with the pluripotent hematopoietic stem cells or their lymphoid progenitor progeny. Accordingly, the immunologic deficits in all of the different types of SCID patients have been repaired by transplantation of histocompatible bone marrow as a source of stem cells, thereby implying that the stromal microenvironments of these individuals are intact and capable of supporting T and B cell development. However, antibody deficiency requiring immunoglobulin replacement therapy may persist for years in the γc-deficient and JAK3-deficient patients, unless the defective B cells are eliminated prior to bone marrow transplantation to allow their replacement with normal B cells of donor origin. *Ex vivo* insertion of a γc transgene into bone marrow progenitors has successfully corrected the immune deficiency of X-linked SCID patients. Notably, however, chance insertion of the γc transgene near a tumor-suppressor gene was associated with development of a $\gamma\delta$ T cell lymphoproliferative disorder in two patients so treated. In ADA-deficient patients without histocompatible bone marrow donors, the administration of exogenous ADA (conjugated to polyethylene glycol to prolong its half-life) may improve immunologic function and clinical status. Hematopoietic stem cell gene therapy has also been used successfully in treating ADA-deficient SCID patients; myeloablative conditioning was required to clear a space in the bone marrow for the ADA transduced cells. Treatment of SCID patients should be performed in centers with a strong research interest in this problem. It is crucial that these patients be recognized and treated early. Live viral vaccines or blood transfusions must be avoided since they can cause fatal infections and graft-versus-host disease in SCID patients.

Primary T Cell Immunodeficiency Reflecting the diversity of T cell functions, abnormalities of T cell development may be responsible for a wide spectrum of immune deficiencies, including combined immunodeficiency, selective defects in cell-mediated immunity, and syndromes presenting as antibody deficiency. These defects may be acquired (Chap. 173) as well as congenital.

THE DIGEORGE SYNDROME This classic example of isolated T cell deficiency results from maldevelopment of thymic epithelial elements derived from the third and fourth pharyngeal pouches. The gene defect has been mapped to chromosome 22q11 in most patients with the DiGeorge syndrome, and to chromosome 10p in others. Defective development of organs dependent on cells of embryonic neural crest origin includes: congenital cardiac defects, particularly those involving the great vessels; hypocalcemic tetany, due to failure of parathyroid development; and absence of a normal thymus. Facial abnormalities may include abnormal ears, shortened philtrum, micrognathia, and hypertelorism. Serum immunoglobulin concentrations are frequently normal, but antibody responses, particularly of IgG and IgA isotypes, are usually impaired. T cell levels are reduced, whereas B cell levels are normal. Affected individuals usually have a small, histologically normal thymus located near the base of the tongue or in the neck, allowing most patients to develop functional T cells in numbers that may or may not be adequate for host defense.

THE NUDE SYNDROME The human disease counterpart to the *nude* mouse is caused by mutations of the *whn* (winged-helix-nude) gene that result in impairment of hair follicle and epithelial thymic development. The human *nude* phenotype is characterized by congenital baldness, nail dystrophy, and severe T cell immunodeficiency.

T CELL RECEPTOR DEFICIENCY Since the expression and function of antigen-specific TCRs is dependent on their signal transducing CD3γ, δ, ϵ, and ζ-η chains, defective genes for any of these receptor components can impair T cell development and function. Immunodeficiencies due to inherited CD3γ and CD3ϵ mutations have been identified. CD3γ mutations result in a selective deficit in CD8 T cells, whereas CD3ϵ mutations lead to a preferential reduction in CD4 T cells, thus implying differences in the signal transduction roles for each CD3 component.

MHC CLASS II DEFICIENCY Because T cells are required for B cell responses to most antigens, any gene defect (or acquired disorder) that interferes with T cell development and cell-mediated immunity will also compromise antibody production and humoral immunity. MHC class II deficiency results in one such immunodeficiency in that the TCR$\alpha\beta$ must see protein antigens as peptide fragments held within the α helical grooves of class II and class I molecules encoded by the MHC. Antigen-presenting cells in individuals with this relatively rare disorder fail to express the class II molecules DP, DQ, and DR on their

surface. Limited numbers of helper CD4 T cells are therefore generated in the thymus, and they fail to see antigen in the periphery. Affected individuals experience recurrent bronchopulmonary infections, chronic diarrhea, and severe viral infections that usually prove fatal before 4 years of age. The defect is caused by mutations in genes that encode essential transcriptional factors that bind to promoter elements for the MHC class II genes. The class II transactivator (*CIITA*) gene is mutated in one subgroup of MHC class II–deficient patients, whereas mutations in *RFX* genes encoding additional transcriptional factors for MHC class II genes are responsible for the defective development and function of CD4 T cells in other families: *RFXANK* in subgroup B, *RFX5* in subgroup C, and *RFXAP* in subgroup D.

ZAP70 TYROSINE KINASE DEFICIENCY Recurrent and opportunistic infections begin within the first year of life in individuals with a deficiency in ZAP70 tyrosine kinase, a pivotal component in the TCR/CD3 signal transduction cascade. The rare inheritance of mutations in both alleles of the *ZAP70* gene results in a selective deficiency of CD8 T cells and dysfunction of CD4 T cells, which are present in normal numbers. Severe immunodeficiency is the inevitable consequence.

PURINE NUCLEOSIDE PHOSPHORYLATION DEFICIENCY Function-loss mutations of the *purine nucleoside phosphorylase (PNP)* gene are associated with an often severe and selective deficiency of T lymphocyte function. This enzyme functions in the same purine salvage pathway as ADA; toxic effects of the PNP deficiency may result from the intracellular accumulation of deoxyguanosine triphosphate.

ATAXIA-TELANGIECTASIA Ataxia-telangiectasia (AT) is an autosomal recessive genetic disorder characterized by cerebellar ataxia, oculocutaneous telangiectasia, and immunodeficiency. The mutant *ATM* gene has sequence similarity to the phosphatidyl-inositol-3 kinases that are involved in signal transduction. The *ATM* gene belongs to a conserved family of genes that monitor DNA repair and coordinate DNA synthesis with cell division. The deleterious effects of the *ATM* gene are widespread. Truncal ataxia may become evident when walking begins and is progressive. Telangiectasia, primarily represented by dilated blood vessels in the ocular sclera, in a butterfly area of the face, and on the ears, is an early diagnostic feature. Immunodeficiency may be clinically manifest by recurrent and chronic sinopulmonary infection leading to bronchiectasis, although not all patients have overt immunodeficiency. Ovarian agenesis is a frequent occurrence. Persistence of very high serum levels of oncofetal proteins, including α fetoprotein and carcinoembryonic antigen, may be of diagnostic value. Frequent causes of death are chronic pulmonary disease and malignancy. Lymphomas are most common, although carcinomas also occur.

The immunologic abnormalities seem to be related to maldevelopment of the thymus. The markedly hypoplastic thymus is similar in appearance to an embryonic thymus. The peripheral T cell pool is reduced in size, especially in lymphoid tissue compartments. Cutaneous anergy and delayed rejection of skin grafts are common. Although B lymphocyte development is normal, most patients are deficient in serum IgE and IgA, and a smaller number have reduced serum levels of IgG, particularly of the IgG2, IgG4 subclasses.

The defect in DNA repair mechanisms in AT patients renders their cells highly susceptible to radiation-induced chromosomal damage and resultant tumor development. AT is a rare disorder, one in 10,000 to 100,000 incidence, but 1% of the population is heterozygous for an AT mutation. This is important because the heterozygous state also predisposes to enhanced cellular radiosensitivity and cancer, especially breast cancer in females (Chap. 353).

TREATMENT

Therapeutic options other than symptomatic treatment are limited for this group of patients. Live vaccines and blood transfusions containing viable T cells should be assiduously avoided. Exposure to x-irradiation should also be avoided in patients with AT. Therapeutic intervention in the form of an epithelial thymic transplant should repair the T cell deficiency in patients with the *nude* syndrome and in the most severe cases of the DiGeorge syndrome where T cells are absent. Treatment by bone marrow transplantation is sometimes successful after myeloablative conditioning in patients with PNP and MHC class II deficiencies. Preventive therapy for *P. carinii* in the form of trimethoprim-sulfamethoxazole should be considered. Immunoglobulin infusions are also recommended for those T cell–deficient individuals with severe antibody deficiency reflected by low serum levels of IgG.

Immunoglobulin Deficiency Syndromes

X-LINKED AGAMMAGLOBULINEMIA Males with this syndrome often begin to have recurrent bacterial infections in the first year of life when maternally derived immunoglobulins have disappeared. Although B cell progenitors are found in the bone marrow, affected individuals have very few immunoglobulin-bearing B lymphocytes in their circulation and lack primary and secondary lymphoid follicles. The developmental block is evident at the pre-B cell level (Fig. 297-1). Mutations of *Bruton's tyrosine kinase (Btk)* gene are responsible for X-linked agammaglobulinemia. B cells in heterozygous female carriers exclusively utilize the X chromosome with the normal *Btk* gene, while T cells and myeloid cells express either X chromosome. A variant disorder, *X-linked agammaglobulinemia with growth hormone deficiency*, has been associated with *Btk* mutations that result in truncated messages.

Agammaglobulinemia is a misnomer, since most of these patients synthesize some immunoglobulins. Within the same family, some affected males may have substantial levels of IgM, IgG, and IgA, while others are nearly agammaglobulinemic. Btk-deficient patients typically are very deficient in circulating B lymphocytes. The few B lymphocytes that escape the block in pre-B cell differentiation are impaired in their responsiveness to antigenic stimulation, making antibody replacement therapy essential in these patients.

Sinopulmonary bacterial infections constitute the most frequent clinical problem. *Mycoplasma* infections also cause arthritis in some of these patients. Chronic encephalitis of viral etiology, sometimes associated wtih dermatomyositis, can be a fatal complication. These complications are reduced by treatment with intravenous immunoglobulin.

AUTOSOMAL RECESSIVE AGAMMAGLOBULINEMIA This syndrome can result from mutations in a variety of genes whose products are required for B lineage differentiation. For example, signals induced via pre-B receptors are essential for pre-B cell development. Consequently, mutations in any of the genes coding pre-B receptor components—μ *heavy chain*, *surrogate light chain* (*VpreB* and $\lambda 5/14.1$), $Ig\alpha$, and $Ig\beta$—can block B lineage differentiation. Congenital absence of B cells, agammaglobulinemia, and recurrent bacterial infections have been seen in children with function-loss mutations in both alleles of the μ *heavy chain* gene or the $\lambda 5/14.1$ and $Ig\beta$ genes. Disruption of B cell development may also occur as a consequence of mutations in genes coding transcription factors for pre-B receptor genes or for key elements in the pre-B receptor signaling pathway. For example, mutations in the *BLNK* gene can cause agammaglobulinemia because this gene encodes a cytoplasmic adaptor protein that is essential for B cell development.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY This diagnosis is reserved for those rare instances in which normal physiologic hypogammaglobulinemia of infancy is unusually prolonged and severe. IgG levels normally drop to 3.0 to 4.0 g/L between 3 and 6 months of age as maternally derived IgG is catabolized. The IgG levels subsequently rise, reflecting the infants' increased synthetic capacity. Periodic immunologic assessment is needed to differentiate transient hypogammaglobulinemia from other forms of antibody deficiency. Antibody replacement therapy is recommended only in the face of severe or recurrent infections.

IgA DEFICIENCY An inability to produce antibodies of the IgA1 and IgA2 subclasses occurs in approximately 1 in 600 individuals of European origin, a much higher incidence than is seen for other primary immunodeficiencies. IgA deficiency is much less common in people of

Asian and African origin. In Japan, for example, the incidence is approximately 1 in 18,500. While the precise genetic basis for this difference in incidence is unknown, IgA deficiency is frequently associated with certain MHC haplotypes that are more common in Caucasians.

Individuals with isolated IgA deficiency may appear healthy or present with an increased number of respiratory infections of varying severity, and a few have progressive pulmonary disease leading to bronchiectasis. Chronic diarrheal diseases also occur. Reductions in the IgG2 and IgG4 subclasses are associated with the increased infections in some IgA-deficient individuals. The incidence of asthma and other atopic diseases among IgA-deficient patients is high. Conversely, the incidence of IgA deficiency among atopic children has been found to be more than 20 times that in the normal population. IgA deficiency is also significantly associated with arthritis (Chap. 301) and systemic lupus erythematosus (Chap. 300). IgA-deficient patients frequently produce autoantibodies. Some of them produce antibodies to IgA, which make them vulnerable to severe anaphylactic reactions when transfused with normal blood or blood products containing IgA.

An accurate picture of the clinical consequences of IgA deficiency requires lifelong study of affected individuals. Among 204 healthy young adults whose IgA deficiency was identified when they served as blood donors, 80% were found to experience episodes of infections, drug allergy, autoimmune disorders, or atopic disease during the next 20 years of their life. They had an increased susceptibility to pneumonia, recurrent episodes of respiratory infections, and a higher incidence of autoimmune diseases, including vitiligo, autoimmune thyroiditis, and possibly rheumatoid arthritis.

IgA deficiency is often familial. It can also occur in association with congenital intrauterine infections, such as toxoplasmosis, rubella, and cytomegalovirus infection, or following treatment with phenytoin, penicillamine, or other medications in genetically susceptible individuals. The pathogenesis of IgA deficiency, whether genetic or triggered by environmental insult, involves a block in B cell differentiation that may reflect defective interaction between T and B cells.

Treatment of IgA deficiency is essentially symptomatic. IgA cannot be effectively replaced by exogenous immunoglobulin or plasma, and use of either can increase the risk of development of antibodies to IgA. IgA-deficient patients in need of transfusion should be screened for the presence of antibodies to IgA and ideally should be given blood only from IgA-deficient donors. Immunoglobulin infusions may benefit the exceptional IgA-deficient person in whom IgG2 and IgG4 subclass deficiencies are associated with severe infections, but the risk of anaphylactic reactions to contaminating IgA must always be considered in treating these patients.

IgG SUBCLASS DEFICIENCIES Selective deficiencies in one or more of the four IgG subclasses are seen in some patients with repeated infections. The IgG subclass deficiency may easily go undetected when the total serum IgG level is measured, because IgG2, IgG3, and IgG4 together account for only 30 to 40% of the IgG antibodies. Even a deficiency in IgG1 may be masked by increases in the remaining IgG isotypes. However, the availability of subclass-specific monoclonal antibodies allows precise measurement of IgG subclass levels.

Homozygous deletions of genes encoding the constant region of the different γ chains are the basis for the IgG subclass deficiency in some individuals. For example, deletion of the $C_{\alpha 1}$, $C_{\gamma 2}$, $C_{\gamma 4}$, and C_{ϵ} genes in the heavy chain locus on both chromosomes 14 was responsible for one individual's inability to make IgA1, IgG2, IgG4, and IgE. Because other components of their immune system are intact, individuals with this and other patterns of C_H-gene deletions may not have unusual infections.

Most of the IgG subclass–deficient individuals with repeated infections appear to have regulatory defects that prevent normal B cell differentiation. The defect may extend to other isotypes. IgA deficiency may accompany IgG2 and IgG4 subclass deficiencies (see "IgA Deficiency," above); an inability to produce IgM antibodies to polysaccharide antigens often reflects a broader defect in antibody responsiveness. While patients with IgG subclass deficiency may benefit from administration of immunoglobulin, a thorough assessment of humoral immunity is needed to identify the relatively few who need this therapy.

COMMON VARIABLE IMMUNODEFICIENCY This diagnostic category includes a heterogeneous group, mostly adults, who have in common the clinical manifestations of deficient production of all the different classes of antibodies. The majority of these hypogammaglobulinemic patients have normal numbers of B lymphocytes that are clonally diverse but phenotypically immature. B lymphocytes in these patients are able to recognize antigens and can proliferate in response, but they largely fail to become memory B cells and mature plasma cells. This abortive differentiation pattern leads to the frequent occurrence of nodular B lymphocyte hyperplasia, resulting in splenomegaly and intestinal lymphoid hyperplasia, sometimes of massive proportion.

It is important to note that common variable immunodeficiency and IgA deficiency represent polar ends of a clinical spectrum due to the same underlying gene defect(s) in a large subset of these patients. The two disorders feature similar B cell differentiation arrests, differing only in the numbers of immunoglobulin classes involved. Over a period of years, IgA-deficient patients may progress to the pan-hypogammaglobulinemia phenotype characteristic of common variable immunodeficiency, and vice versa. Both disorders occur frequently within the same family, and the same MHC haplotypes are associated with both immunodeficiency patterns. Family studies suggest an underlying susceptibility gene in the MHC class III region for both disorders.

It is important to consider the diagnosis of common variable immunodeficiency in adults with chronic pulmonary infections, some of whom will present with bronchiectasis. Intestinal diseases—including chronic giardiasis, intestinal malabsorption, and atrophic gastritis with pernicious anemia—are common in this group of patients. Patients with common variable immunodeficiency may also present with signs and symptoms highly suggestive of lymphoid malignancy, including fever, weight loss, anemia, thrombocytopenia, splenomegaly, generalized lymphadenopathy, and lymphocytosis. Histologic examination of lymphoid tissues usually reveals germinal center hyperplasia that may be difficult to distinguish from nodular lymphoma (Chap. 97). Demonstration of a normal distribution of immunoglobulin isotypes and light chain classes for circulating and tissue B lymphocytes can serve to distinguish these patients from those having a monoclonal B cell malignancy with secondary hypogammaglobulinemia. The administration of intravenous immunoglobulin in adequate doses (see below) is an essential part of the prevention and treatment of all these complications.

X-LINKED IMMUNODEFICIENCY WITH HYPER IgM In this syndrome, typically the IgG and IgA levels are very low, while IgM levels may be very high, normal, or even low. The development of B lymphocytes bearing IgM and IgD and the absence of IgG and IgA B lymphocytes indicate a defect in isotype switching. The defective *CD40L* gene in these patients encodes a transiently expressed molecule on activated T cells that is the ligand for the CD40 molecule on dendritic (D) cells and B cells. Gene mutations that preclude normal CD40 ligand expression prevent normal T and B cell cooperation, germinal center formation, V-region diversification by somatic hypermutation, and isotype switching. T cell responses are also compromised in these CD40 ligand–deficient patients because their T cells are deprived of an important activation stimulus as a consequence of the defective T, D, and B cell interactions (Chap. 295). Consequently, these patients experience more severe infections than those occurring with other hypogammaglobulinemic states. In addition to recurrent bacterial infections, pneumonia may be caused by *P. carinii*, cytomegalovirus, *Aspergillus*, *Cryptosporidium*, and other unusual organisms. Enteritis due to cryptosporidial infection may extend into the biliary tract to result in a sclerosing cholangitis and hepatic cirrhosis. Neutropenia is frequent in affected males and increases their vulnerability to infections.

Immunodeficiency with hyper IgM is also seen in patients of both sexes who lack mutations in their *CD40L* gene. One such hyper IgM syndrome is caused by deficiency of activation-induced cytidine deaminase (AID). Patients with AID mutations make IgM antibodies of relatively low affinity because this nuclear enzyme is essential for immunoglobulin isotype switching and somatic hypermutation. The non-X-linked form of immunodeficiency with hyper IgM can also be caused by *CD40* mutation or by mutations of genes coding components of the CD40/CD40L signaling pathways. Impaired signaling through the nuclear factor–kappa B (NF-kB) pathway due to *I Kappa–B kinase gamma IKBKG* mutations can cause an X-linked hyper-IgM and anhidrotic ectodermal dysplasia (XHM-ED) syndrome with or without osteopetrosis and lymphedema.

TREATMENT

Replacement therapy with human immunoglobulin is the therapeutic cornerstone for antibody-deficient patients who have recurrent infections and who are deficient in IgG. Maintenance of serum IgG levels above 5.0 g/L will prevent most systemic infections in the patients. These serum levels can usually be achieved by intravenous administration of immunoglobulin, 400 to 500 mg/kg, at 3- to 4-week intervals. In patients with mild to moderate IgG deficiency (3.0 to 5.0 g/L) or isolated IgG subclass deficiencies, the decision to treat should be based on evaluation of clinical symptoms and antibody responses to antigenic challenge. Since immunoglobulin preparations are composed almost entirely of IgG antibodies, they are of no value for repairing deficiencies of immunoglobulins other than IgG. Infusions of immunoglobulin are also not benign. While HIV transmission has not been reported, previous epidemics of hepatitis C virus infections in hypogammaglobulinemic patients receiving contaminated immunoglobulin preparations have led to improved safety measures for current commercial preparations. Some antibody-deficient patients develop symptoms of diaphoresis, tachycardia, flank pain, and hypotension during immunoglobulin infusion. This reaction may be resolved by slowing the rate of immunoglobulin infusion. Thrombotic complications, including stroke, myocardial infarction, and pulmonary emboli, have also been reported to be associated with rapid immunoglobulin infusion. Serious anaphylactic reactions may occur as a consequence of antibodies produced by the patient against donor immunoglobulins, particularly IgA (Chap. 99). The potential for severe adverse reactions merits administration of the initial immunoglobulin infusion under medical supervision in a hospital or clinic setting.

A heightened index of suspicion of infection is essential for antibody-deficient patients. Identification of infectious agents in order to select appropriate antibiotic, antiparasitic, or antiviral therapy is also very important. Immunoglobulin infusions usually do not suffice to eliminate chronic sinopulmonary infections with *H. influenzae* and other microorganisms, and a prolonged course of antibiotic therapy may be required to treat these infections effectively and prevent progression to pulmonary fibrosis and bronchiectasis. Maintenance of good pulmonary toilet with regular postural drainage and chest percussion can be especially important in management of these patients. Infestation with *G. lamblia*, a common cause of chronic diarrhea in antibody-deficient patients, usually responds to therapy with metronidazole.

Cryptosporidial infections in CD40 ligand–deficient patients may respond to long-term treatment with amphotericin B and flucytosine. The neutropenia frequently associated with infections in these patients may or may not resolve with improvement of infections and antibody replacement therapy. Bone marrow transplantation following myeloablative pretransplantation therapy can be curative for boys with this devastating immunodeficiency. This treatment has a much greater chance of success when performed during childhood.

Miscellaneous Immunodeficiency Syndromes Infection with *Candida albicans* is the almost universal accompaniment of severe deficiencies in cell-mediated immunity. *Chronic mucocutaneous candidiasis* is different because superficial candidiasis is usually the only major manifestation of immunodeficiency in this syndrome. These patients rarely develop systemic infection with *Candida* or other fungal agents and are not unusually susceptible to virus or bacterial disease. No uniformity of immunologic defects has been identified in these patients, although defects of antibody formation have been detected occasionally. Humoral immunity, including ability to make specific anti-*Candida* antibodies, is usually normal. Many patients are anergic, some to a variety of antigens and some only to *Candida*. The syndrome is often congenital and may be associated with single or multiple endocrinopathies as well as iron deficiency. One well-defined genetic disorder, *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED) is caused by autoimmune regulator (*AIRE*) mutations. The AIRE transcription factor upregulates ectopic expression of many tissue-specific proteins in the thymus to promote the development of immunologic tolerance to self-antigens. Treatment of associated con-

TABLE 297-3 Primary Immunodeficiencies Associated with or Secondadry to Other Diseases[a]

- Chromosomal instability or defective repair
  - Bloom syndrome (*BLM* helicase)
  - DNA ligase IV deficiency
  - Fanconi anemia (multiple complementation groups)
  - ICF syndrome (*DNMT3B* DNA methyltransferase)
  - Nijmegen breakage syndrome (*Nibrin*)
  - Seckel syndrome
  - Xeroderma pigmentosum (multiple complementation groups)
- Chromosomal defects
  - Down syndrome (trisomy 21)
  - Turner syndrome (X chromosome monosomy)
  - Deletions or rings of chromosome 18 (18p- and 18q-)
- Immunodeficiency with generalized growth retardation
  - Schimke immuno-osseous dysplasia (*SMARCAL1*)
  - Dubowitz syndrome
  - Kyphomelic dysplasia with SCID
  - Mulibrey nannism (*TRIM37*)
  - Growth retardation, facial anomalies, and immunodeficiency
  - Progeria (Hutchinson-Gilford syndrome)
  - Thumb agenesis, short stature, and immunodeficiency
  - X-linked agammaglobulinemia with growth hormone deficiency (*BTK*)
- Immunodeficiency with dermatologic defects
  - Dyskeratosis congenita
    - Autosomal dominant (*TERC*)
    - Autosomal recessive
    - X-linked, Zinsser-Cole-Engman syndrome (*dyskerin*)
  - Ectrodactyly-ectodermal dysplasia-clefting syndrome
  - Erythroderma desquamative of Leiner
  - Griscelli syndrome, partial albinism (*RAB27A*)
  - Netherton syndrome (*SPINK5*)
  - Omenn syndrome (*RAG 1/2*)
  - Trichothiodystrophy, congenital ichthyosis (*ERCC2*/*XPD* or *ERCC3*/*XPB*)
- Hereditary metabolic defects
  - α-Mannosidosis (*MAN2B1*)
  - Acrodermatitis enteropathica, zinc deficiency type (*SLC39A4*)
  - Propionyl-CoA carboxylase, beta subunit, deficiency (*PCCB*)
  - Glycogen storage disease, type 1b (*G6PT1*)
  - Hyperzincemia with functional zinc depletion
  - Oroticaciduria I (*UMPS*)
  - Transcobalamin 2 deficiency (*TCN2*)
- Hypercatabolism of immunoglobulin
  - Familial hypercatabolism
  - Intestinal lymphangiectasia
- Other
  - Chédiak-Higashi syndrome (*CHS1*)
  - Cartilage-hair hypoplasia (endoribonuclease *RMRP*)
  - Chronic mucocutaneous candidiasis
  - Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED)
  - Hereditary or congenital hyposplenia or asplenia
  - Ivermark syndrome

[a] Mutant genes indicated in parentheses.

TABLE 297-4 *Genes or Genetic Loci Associated with Primary Immunodeficiencies*

Disorder	Gene or Locus	Chromosome
Severe combined immunodeficiency (SCID)		
Adenosine deaminase deficiency	*ADA*	20q13.11
Artemis deficiency	*ARTEMIS*	10p
CD45 deficiency	*CD45*	1q31-32
DNA-dependent protein kinase deficiency	*PRKDC*	8q11
Interleukin receptor γ chain deficiency	IL2RG	Xq13
Janus-associated kinase 3 deficiency	JAK3	19p13.1
Recombinase activating gene deficiency	*RAG1, RAG2*	11p13
Primary T cell immunodeficiency		
Antigen peptide transporter deficiency	*TAP1, TAP2*	6p21.3
CD8 deficiency	*CD8*	2p12
DiGeorge syndrome	*DGCR1*	22q11
	DGCR2	10p13
Nude syndrome	*WHN*	17q11-q12
T cell receptor deficiency:		
CD3γ	*CD3G*	7q35
CD3ϵ	CD3E	11q23
MHC class II deficiency:		
MHC class II transactivator (group A)	*CIITA*	16p13
Regulatory factor X, ankyrin-repeat containing (group B)	*RFXANK*	19p12
Regulatory factor X, 5 (group C)	*RFX5*	1q21.1-q21.3
Regulatory factor X-associated protein (group D)	*RFXAP*	13q14
Zeta-chain-associated protein kinase deficiency	*ZAP70*	2q12
Purine nucleotide phosphorylase deficiency	*NP*	14q13.1
Predominantly antibody deficiencies		
Activation-induced cytidine deaminase deficiency	*HIGM2*	12p13
CD40 deficiency	*HIGM3*	20 q12-q13.2
IgA deficiency/common variable immunodeficiency	*MHC*	6p21.3
Immunoglobulin-associated beta (Igβ) deficiency	*CD79B*	17q23
Immunoglobulin heavy chain deficiencies	*IGHG1*1	14q32.33
BLNK deficiency	*BLNK*	10q23.2
Surrogate light chain deficiency	*IGLL55*	22q11.21
X-linked agammaglobulinemia	*BTK*	Xq21.3-q22
X-linked hyper-IgM syndrome	*HIGM1*	Xq26
XHM with ectodermal dysplasia (XHM-ED)	*IKBKG*	Xq28
Other well-defined immunodeficiency syndromes		
Ataxia telangiectasia	*ATM*	11q22.3
Interferon γ receptor deficiency	*IFNGR1*	6q23-q24
	IFNGR2	21q22.1-22.2
Interleukin 12 deficiency	*IL12B*	5q31-q33
Interleukin 12 receptor deficiency	*IL12RB1*	19p13.1
Mannose binding lectin deficiency	*MBL2*	10q11.2-q21
Wiskott-Aldrich syndrome	*WAS*	Xp11.23-p11.22
X-linked lymphoproliferative syndrome	*SH2D1A/SAP*	Xq25

ditions may lead to improvement or even cure of *Candida* infection. In other patients, intensive treatment with amphotericin B coupled with surgical removal of infected nails has led to sustained improvement. Oral antifungal agents, such as fluconazole and itraconazole, may also be effective.

INTERFERON γ RECEPTOR DEFICIENCY This immunodeficiency is characterized by serious infections caused by bacille Calmette-Guérin vaccine and environmental non-tuberculous mycobacteria. Associated salmonella infections occur in a minority of the cases. This syndrome can be caused by mutations in the interferon γ receptor signal-transducing chain (*IFNGR2*). Two additional forms of this syndrome are caused by different types of mutations in the interferon γ receptor 1 (*IFNGR1*) gene that encodes the ligand binding chain of the interferon γ receptor. Null mutations in both *IFNGR1* alleles are responsible for a more severe autosomal recessive form. A less severe form, inherited in an autosomal dominant pattern, is caused by *IFNGR1* mutations in a small deletional hotspot that result in a truncated receptor chain lacking the cytoplasmic tail. Accumulation of the truncated receptor on the surface of macrophages compromises their response to interferon γ and the killing of ingested mycobacterium.

INTERLEUKIN 12 RECEPTOR DEFICIENCY Mutations in the gene coding the β_1 subunit of the IL-12 receptor can also result in disseminated mycobacterial infections attributable to bacille Calmette-Guérin and non-tuberculous mycobacteria, and in some cases non-typhi salmonella infections. Although the clinical manifestations are usually less severe than in patients with complete IFNGR1 deficiency, IL-12 receptor deficiency may predispose individuals to clinical tuberculosis as well. Deficient interferon γ production by the otherwise normal NK and T cells is seen in IL-12 receptor deficient patients, and therapeutic use of interferon γ may cure their mycobacterial infection.

IMMUNODEFICIENCY WITH THYMOMA The association of hypogammaglobulinemia with spindle cell thymoma usually occurs relatively late in adult life. Bacterial infections and severe diarrhea often reflect the antibody deficiency, whereas fungal and viral infections are infrequent complications. T cell numbers and cell-mediated immunity are usually intact, but these patients are very deficient in circulating B lymphocytes and pre-B cells in the bone marrow. They also frequently have eosinopenia and may develop erythroid aplasia. Complete bone marrow failure sometimes occurs. The relationship between the usually benign thymoma and apparent abnormalities of hematopoietic stem cells remains conjectural, and treatment is limited to immunoglobulin administration and symptomatic therapy.

WISKOTT-ALDRICH SYNDROME This X-linked disease characterized by eczema, thrombocytopenia, and repeated infections is caused by mutations in the *WASP* gene. The WASP protein is expressed in cells of all hematopoietic lineages. It may serve a cytoskeletal organizing role for signaling elements that are particularly important in platelets and T cells. The platelets are small and have a shortened half-life. Affected male infants often present with bleeding, and most do not survive childhood, dying of complications of bleeding, infection, or lymphoreticular malignancy. The immunologic defects include low serum concentrations of IgM, while IgA and IgG are normal and IgE is frequently increased. The number and class distribution of B lymphocytes are usually normal. Functionally, these patients are unable to make antibodies to polysaccharide antigens normally; responses to protein antigens may also be impaired late in the course of the disease. Most patients eventually acquire T cell deficiencies. Affected boys frequently become anergic, and their T cells do not respond normally to antigenic challenge. This results in vulnerability to overwhelming infections with herpes simplex virus and other infectious agents.

Transplantation of histocompatible bone marrow from a sibling donor following myeloablative therapy can correct both the hematologic and immunologic abnormalities. In patients lacking a suitable donor, intravenous immunoglobulin infusions or splenectomy may improve platelet counts and reduce the risk of serious hemorrhage. Because of the increased risk of pneumococcal bacteremia, splenectomized patients should receive prophylactic penicillin.

X-LINKED LYMPHOPROLIFERATIVE SYNDROME This disease involves a selective impairment in immune elimination of Epstein-Barr virus (EBV). A fulminant and fatal outcome is the consequence of EBV infection in approximately half of the affected males. Hypogammaglobulinemia is the outcome in 30%, and B cell malignancies are acquired in approximately 25% of EBV-infected patients. The disease may be manifested from early childhood onward, depending on the time of EBV infection. Carrier females handle EBV infections normally. Cytotoxic T cells and NK appear to be primarily responsible for control of EBV infec-

tion in normal persons. In males with the X-linked lymphoproliferative syndrome, this process is impaired as a consequence of mutations in a gene coding a T cell and NK cell signaling element called SH2D1A or SAP. Intravenous immunoglobulins should be administered to affected males who develop hypogammaglobulinemia. Bone marrow transplantation from an HLA-matched donor may be curative, especially in younger children with this syndrome. However, myeloablative chemotherapy is a necessary prerequisite to successful bone marrow transplantation, thereby increasing the risk of this procedure.

HYPER-IgE SYNDROME The hyper IgE syndrome (Chap. 55) is characterized by recurrent abscesses involving skin, lungs, and other organs and very high IgE levels. IgE levels may decline with time to reach normal levels in approximately 20% of affected adults. Staphylococcal infection is common to all patients, but most have infections with other pyogenic organisms as well. Abnormal neutrophil chemotaxis is an inconsistent finding, and diminished antibody responses to secondary immunization have been noted. Non-immunologic features include impaired shedding of the primary teeth, recurrent bone fractures, hyperextensible joints, and scoliosis. Males and females are affected in an inheritance pattern suggesting an autosomal dominant defect with variable penetrance, but the gene defect has not been identified. Prophylaxis with penicillinase-resistant penicillins or cephalosporins is highly recommended to prevent staphylococcal infections. Pneumatoceles, a frequent complication of pneumonias, may require surgical excision.

Metabolic Abnormalities Associated with Immunodeficiency The relation of deficiencies of the purine salvage enzymes adenosine deaminase and purine nucleoside phosphorylase to immunodeficiency was discussed earlier. The syndrome of *acrodermatitis enteropathica* includes severe desquamating skin lesions, intractable diarrhea, bizarre neurologic symptoms, variable combined immunodeficiency, and an often fatal outcome. This disease is apparently caused by an inborn error of metabolism resulting in malabsorption of dietary zinc and can be treated effectively by parenteral or large oral doses of zinc. Zinc deficiency might in part account for the immunodeficiency that accompanies severe malnutrition. Inherited *deficiency of transcobalamin II*, the serum carrier molecule responsible for transport of vitamin B_{12} to tissues, is associated with failure of immunoglobulin production as well as megaloblastic anemia, leukopenia, thrombocytopenia, and severe malabsorption. All abnormalities of this rare disorder are reversed by administration of vitamin B_{12}. Finally, primary immunodeficiencies are associated with or are secondary to a number of diverse diseases (Table 297-3).

CONCLUSION Defective genes have been identified for most of the primary immunodeficiency diseases that are currently recognized (Table 297-4). It can be anticipated that many different gene mutations will be identified in other individuals with increased susceptibility to infection. Identification of the mutant genes is the first step toward a better understanding of the pathogenesis of immunodeficiency disease and improved therapeutic strategies. Successful gene repair is the ultimate goal for these individuals.

298 ALLERGIES, ANAPHYLAXIS, AND SYSTEMIC MASTOCYTOSIS

K. Frank Austen

The term *atopic allergy* implies a familial tendency to manifest such conditions as asthma, rhinitis, urticaria, and eczematous dermatitis (atopic dermatitis) alone or in combination. However, individuals without an atopic background may also develop hypersensitivity reactions, particularly urticaria and anaphylaxis, associated with the same class of antibody, IgE, found in atopic individuals. Inasmuch as the mast cell is the key effector cell of the biologic response in allergic rhinitis, urticaria, anaphylaxis, and systemic mastocytosis, the introduction to these clinical problems will consider the developmental biology, activation pathway, product profile, and target tissues for this cell type.

The fixation of IgE to human mast cells and basophils, a process termed *sensitization*, prepares these cells for subsequent antigen-specific activation. The sensitization of the high-affinity Fc receptor for IgE, designated FcϵRI, also stabilizes the cellular expression of the receptor. FcϵRI is composed of one α, one β, and two disulfide-linked γ chains, which together cross the plasma membrane seven times. The α chain is responsible for IgE binding, and the β and γ chains provide for signal transduction that follows the aggregation of the sensitized tetrameric receptors by polymeric antigen. Signal transduction is initiated through the action of a *src* family–related tyrosine kinase, termed *Lyn*, that is constitutively associated with the β chain. Lyn transphosphorylates the canonical immunoreceptor tyrosine-based activation motifs (ITAMs) of the β and γ chains of the receptor, resulting in recruitment of more active Lyn to the β chain and of the Syk/zap-70 family tyrosine kinases. The phosphorylated tyrosines in the ITAMs function as binding sites for the tandem *src* homology two (SH2) domains within these kinases. Syk activates not only phospholipase Cγ but also phosphatidylinositol-3-kinase to provide phosphatidyl-3,4,5-triphosphate, which allows membrane targeting of the Tec family kinases (Btk and Itk) and their activation by Lyn. The phospholipase Cγ cleavage of the phospholipid membrane substrate provides inositol-1,4,5-triphosphate (IP_3) and 1,2-diacylglycerols (1,2-DAGs) so as to mobilize intracellular calcium and activate protein kinase C. The subsequent opening of calcium-regulated activated channels provides the sustained elevations of intracellular calcium required to recruit the mitogen-activated protein kinases, JNK and p38 (serine/threonine kinases), which provide cascades to augment arachidonic acid release and to mediate nuclear translocation of transcription factors for various cytokines. The calcium ion–dependent activation of phospholipases cleaves membrane phospholipids to generate lysophospholipids, which, like 1,2-DAG, are fusogenic and may facilitate the fusion of the secretory granule perigranular membrane with the cell membrane, a step that releases the membrane-free granules containing the preformed mediators of mast cell effects.

The secretory granule of the human mast cell has a crystalline struc-

ture, unlike mast cells of lower species. IgE-dependent cell activation results in solubilization and swelling of the granule contents within the first minute of receptor perturbation; this reaction is followed by the ordering of intermediate filaments about the swollen granule, movement of the granule toward the cell surface, and fusion of the perigranular membrane with that of other granules and with the plasmalemma to form extracellular channels for mediator release while maintaining cell viability.

In addition to exocytosis, aggregation of FcεRI initiates two other pathways for generation of bioactive products, namely, lipid mediators and cytokines. The biochemical steps involved in expression of such cytokines as tumor necrosis factor α (TNF-α), interleukin (IL) 6, IL-4, IL-5, IL-13, granulocyte-macrophage colony-stimulating factor (GM-CSF), and others have not been specifically defined for mast cells. Nonetheless, inhibition studies of cytokine production (IL-1β, TNF-α, and IL-6) in mouse mast cells with cyclosporine or FK506 reveal binding to the ligand-specific immunophilin and attenuation of the calcium ion– and calmodulin-dependent serine/threonine phosphatase, calcineurin.

Lipid mediator generation (Fig. 298-1) involves translocation of calcium ion–dependent cytosolic phospholipase A_2 to the outer nuclear membrane, with subsequent release of arachidonic acid for metabolic processing by the distinct prostanoid and leukotriene pathways. The constitutive prostaglandin endoperoxide synthase (PGHS-1/cyclooxygenase-1) and the de novo inducible PGHS-2 (cyclooxygenase-2) convert released arachidonic acid to the sequential intermediates, prostaglandins G_2 and H_2. The glutathione-dependent hematopoietic prostaglandin D_2 (PGD_2) synthase then converts PGH_2 to PGD_2, the predominant mast cell prostanoid.

For the leukotriene biosynthetic pathway, the released arachidonic acid is metabolized by 5-lipoxygenase (5-LO) in the presence of an integral nuclear membrane protein, the 5-LO activating protein (FLAP). The calcium ion–dependent translocation of 5-LO to the nuclear membrane converts the arachidonic acid to the sequential intermediates, 5-hydroperoxyeicosatetraenoic acid and leukotriene (LT) A_4. LTA_4 is conjugated with reduced glutathione by LTC_4 synthase, an integral nuclear membrane protein homologous to FLAP. Intracellular LTC_4 is released by a carrier-specific export step for extracellular conversion to LTD_4 and LTE_4 by sequential removal of glutamic acid and glycine. Alternatively, cytosolic LTA_4 hydrolase converts some LTA_4 to the dihydroxy leukotriene LTB_4, which also undergoes specific export. Two receptors for LTB_4, LTB_1R and LTB_2R, mediate chemotaxis of human neutrophils. Two receptors for the cysteinyl leukotrienes, $CysLT_1R$ and $CysLT_2R$, are present on smooth muscle of the airways and the microvasculature and on hematopoietic cells such as eosinophils and mast cells. Whereas $CysLT_1R$ has a preference for LTD_4 and is blocked by the receptor antagonists in clinical use, $CysLT_2R$ is equally responsive to LTC_4 and is unaffected by these antagonists. The lysophospholipid formed during release of arachidonic acid from 1-*O*-alkyl-2-acyl-*sn*-glyceryl-3-phosphorylcholine can be acetylated in the second position to form platelet-activating factor (PAF).

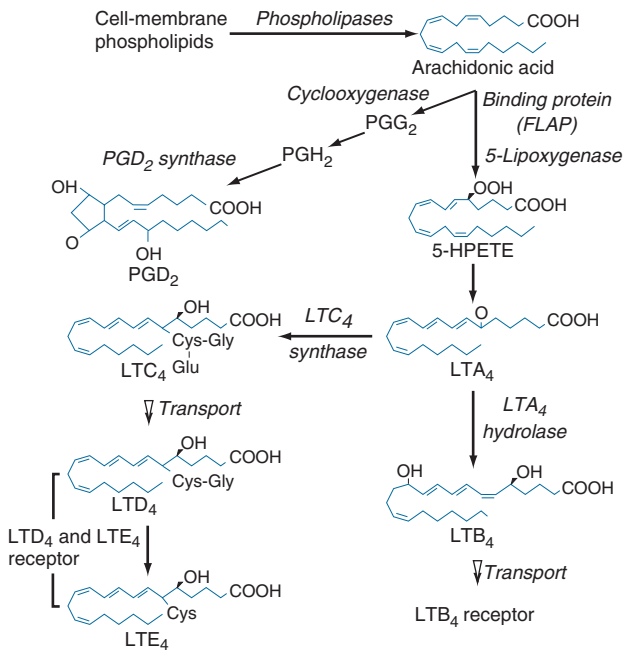

FIGURE 298-1 Pathways for biosynthesis and release of membrane-derived lipid mediators from mast cells. In the 5-lipoxygenase pathway leukotriene A_4 (LTA_4) is the intermediate from which the terminal-pathway enzymes generate the distinct final products, leukotriene C_4 (LTC_4) and leukotriene B_4 (LTB_4), which leave the cell by separate saturable transport systems. Gamma glutamyl transpeptidase and a dipeptidase then cleave glutamic acid and glycine from LTC_4 to form LTD_4 and LTE_4, respectively. The only mast cell product of the cyclooxygenase system is PGD_2.

Unlike most other cells of bone marrow origin, mast cells leave the marrow and circulate as committed progenitors lacking their definitive secretory granules and characteristic FcεRI. These committed progenitors express the receptor, c-*kit*, for stem cell factor (SCF), and unlike other lineages, they retain and increase its expression with maturation. The SCF interaction with c-*kit* is an absolute requirement for the development of constitutive tissue mast cells residing in skin and connective tissue sites and for the T cell–dependent comitogenesis providing mast cells to mucosal surfaces. Indeed, in clinical T cell deficiencies, mast cells are absent from the intestinal mucosa but are present in the submucosa. Based on the immunodetection of secretory granule neutral proteases, mast cells in the lung parenchyma and intestinal mucosa selectively express tryptase, and those in the intestinal and airway submucosa, skin, lymph nodes, and breast parenchyma express tryptase, chymase, and carboxypeptidase A (CPA). The secretory granules of mast cells selectively positive for tryptase exhibit closed scrolls with a periodicity suggestive of a crystalline structure by electron microscopy; whereas the secretory granules of mast cells with mutiple proteases are scroll-poor, with an amorphous or lattice-like appearance.

Mast cells are distributed at cutaneous and mucosal surfaces and in submucosal tissues about venules and could influence the entry of foreign substances by their rapid response capability (Fig. 298-2). Upon stimulus-specific activation and secretory granule exocytosis, histamine and acid hydrolases are solubilized, whereas the neutral proteases, which are cationic, remain largely complexed to the anionic proteoglycans, heparin and chrondroitin sulfate E, so as to function in concert. Histamine and the various lipid mediators (PGD_2, $LTC_4/D_4/E_4$, PAF) alter venular permeability, thereby allowing influx of plasma proteins such as complement and immunoglobulins, whereas LTB_4 mediates leukocyte–endothelial cell adhesion and subsequent directed migration (chemotaxis). The accumulation of leukocytes and plasma opsonins would facilitate defense of the microenvironment. The inflammatory response can also be detrimental, as in bronchial asthma, where the smooth-muscle constrictor activity of the cysteinyl leukotrienes is evident and much more potent than that of histamine.

The cellular component of the mast cell–mediated inflammatory response would be augmented and sustained by cytokines and chemokines of mast cell origin. IgE-dependent activation of human skin mast cells in situ elicits TNF-α production and release, which in turn induces endothelial cell responses favoring leukocyte adhesion. Similarly, activation of purified human lung mast cells or cord blood–derived cultured mast cells in vitro results in substantial production of proinflammatory (TNF-α) and immunomodulatory cytokines (IL-4, IL-5, IL-13) and chemokines. Bronchial biopsies of patients with bronchial asthma reveal that mast cells are immunohistochemically positive for IL-4 and IL-5, but that the predominant localization of IL-4, IL-5, and GM-CSF is to T cells, defined as T_H2 by this profile. IL-4 modulates the T cell phenotype to the T_H2 subtype, determines the isotype switch to IgE (as does IL-13), and upregulates FcεRI-mediated expression of cytokines by mast cells.

An immediate and late cellular phase of allergic inflammation can be induced in the skin, nose, or lung of some allergic humans with local allergen challenge. In the immediate phase of a local challenge, there is pruritus and watery discharge from the nose, bronchospasm and mucus secretion in the lungs, and a wheal-and-flare response with pruritus in the skin. The reduced nasal patency, reduced pulmonary function, or evident erythema with swelling at the skin site in a late-phase response at 6 to 8 h is associated with biopsy findings of infiltrating and activated T_H2 type T cells, eosinophils, basophils, and even some neutrophils. This allergic inflammation proceeding from early mast cell activation to late cellular infiltration has been used as an experimental surrogate of perennial rhinitis or bronchial asthma. However, in bronchial asthma there is a separate variable, intrinsic hyperreactivity of the airways.

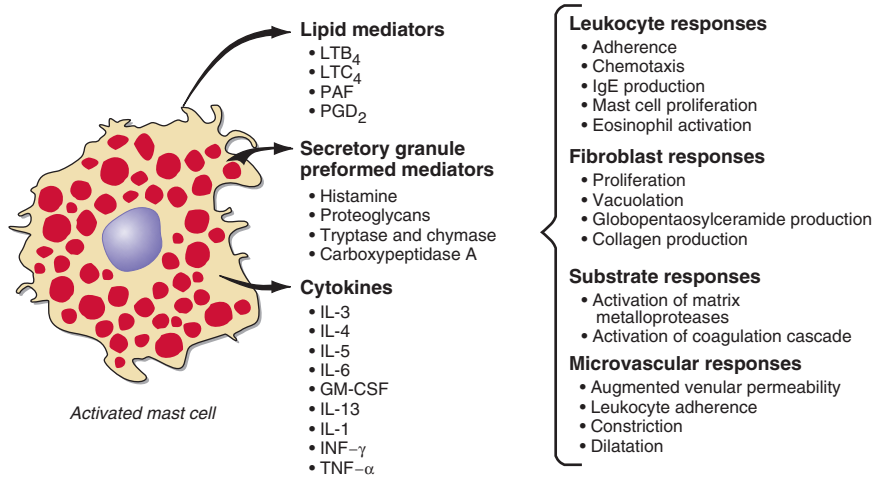

FIGURE 298-2 Bioactive mediators of three categories generated by IgE-dependent activation of murine mast cells can elicit common but sequential target cell effects leading to acute and sustained inflammatory responses. LT, leukotriene; PAF, platelet-activating factor; PGD_2, prostaglandin D_2; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; INF, interferon; TNF, tumor necrosis factor.

Consideration of the mechanism of immediate-type hypersensitivity diseases in the human has focused largely on the IgE-dependent recognition of otherwise nontoxic substances. A region of chromosome 5 (5q23-31) contains genes implicated in the control of IgE levels including IL-4 and IL-13, as well as IL-3 and IL-9 involved in reactive mast cell hyperplasia and IL-5 and GM-CSF central to eosinophil development and their enhanced tissue viability. Genes with linkage to the specific IgE response to particular allergens include those encoding the major histocompatibility complex (MHC) and certain chains of the T cell receptor (TCR-$\alpha\delta$). The complexity of atopy and the associated diseases includes susceptibility, severity, and therapeutic responses, each of which is among the separate variables modulated by both innate and adaptive immune stimuli.

The induction of allergic disease requires sensitization of a predisposed individual to specific allergen. This sensitization can occur anytime in life, although the greatest propensity for the development of allergic disease appears to occur in childhood and early adolescence. Exposure of a susceptible individual to an allergen results in processing of the allergen by antigen-presenting cells of the monocytic lineage located throughout the body at surfaces that contact the outside environment, such as the nose, lungs, eyes, skin, and intestine. These antigen-presenting cells process the allergen protein and present the epitope-bearing peptides via their MHC to particular T cell helper subsets. The T cell response depends both on cognate recognition through various ligand/receptor interactions and on the cytokine microenvironment, with IL-4 directing a T_H2 response and interferon (IFN)γ a T_H1 profile. T cells can potentially induce several responses to an allergen, including those typical of contact dermatitis, known as the T_H1 type response, and those mediated by IgE, known as the T_H2 allergic response. The T_H2 response is associated with activation of specific B cells that can also present allergens or that transform into plasma cells for antibody production. Synthesis and release into the serum of allergen-specific IgE by plasma cells result in sensitization of IgE Fc receptor–bearing cells including mast cells and basophils, which subsequently are capable of becoming activated upon exposure to the specific allergen. In certain diseases, including those associated with atopy, the monocyte and eosinophil populations can express a trimeric high-affinity receptor, FcϵRI, which lacks the β chain, and yet respond to its aggregation.

ANAPHYLAXIS

DEFINITION The life-threatening anaphylactic response of a sensitized human appears within minutes after administration of specific antigen and is manifested by respiratory distress, laryngeal edema, and/or intense bronchospasm, often followed by vascular collapse or by shock without antecedent respiratory difficulty. Cutaneous manifestations exemplified by pruritus and urticaria with or without angioedema are characteristic of such systemic anaphylactic reactions. Gastrointestinal manifestations include nausea, vomiting, crampy abdominal pain, and diarrhea.

PREDISPOSING FACTORS AND ETIOLOGY There is no convincing evidence that age, sex, race, occupation, or geographic location predisposes a human to anaphylaxis except through exposure to some immunogen. According to most studies, atopy does not predispose individuals to anaphylaxis from penicillin therapy or venom of a stinging insect but is a risk factor for allergens in food or latex.

The materials capable of eliciting the systemic anaphylactic reaction in humans include the following: heterologous proteins in the form of hormones (insulin, vasopressin, parathormone), enzymes (trypsin, chymotrypsin, penicillinase, streptokinase), pollen extracts (ragweed, grass, trees), nonpollen extracts (dust mites, dander of cats, dogs, horses, and laboratory animals), food (milk, eggs, seafood, nuts, grains, beans, gelatin in capsules), antiserum (antilymphocyte gamma globulin), occupation-related proteins (latex rubber products), and Hymenoptera venom (yellow jacket, yellow and baldfaced hornets, paper wasp, honey bee, imported fire ants); polysaccharides such as dextran and thiomerosal as a vaccine preservative; and most commonly drugs such as protamine and antibiotics (penicillins, cephalosporins, amphotericin B, nitrofurantoin, quinolones), local anesthetics (procaine, lidocaine), muscle relaxants (suxamethonium, gallamine, pancuronium), vitamins (thiamine, folic acid), diagnostic agents (sodium dehydrocholate, sulfobromophthalein), and occupation-related chemicals (ethylene oxide), which are considered to function as haptens that form immunogenic conjugates with host proteins. The conjugating hapten may be the parent compound, a nonenzymatically derived storage product, or a metabolite formed in the host.

PATHOPHYSIOLOGY AND MANIFESTATIONS Individuals differ in the time of appearance of symptoms and signs, but the hallmark of the anaphylactic reaction is the onset of some manifestation within seconds to minutes after introduction of the antigen, generally by injection or less commonly by ingestion. There may be upper or lower airway obstruction or both. Laryngeal edema may be experienced as a "lump" in the throat, hoarseness, or stridor, while bronchial obstruction is associated with a feeling of tightness in the chest and/or audible wheezing. Patients with bronchial asthma are predisposed to severe involvement of the lower airways. A characteristic feature is the eruption of well-circumscribed, discrete cutaneous wheals with erythematous, raised, serpiginous borders and blanched centers. These urticarial eruptions are intensely pruritic and may be localized or disseminated. They may coalesce to form giant hives, and they seldom persist beyond 48 h. A localized, nonpitting, deeper edematous cutaneous process, angioedema, may also be present. It may be asymptomatic or cause a burning or stinging sensation.

In fatal cases with clinical bronchial obstruction, the lungs show marked hyperinflation on gross and microscopic examination. The microscopic findings in the bronchi, however, are limited to luminal secretions, peribronchial congestion, submucosal edema, and eosinophilic infiltration, and the acute emphysema is attributed to intractable bronchospasm that subsides with death. The angioedema resulting in death by mechanical obstruction occurs in the epiglottis and larynx, but the process is also evident in the hypopharynx and to some extent in the trachea; on microscopic examination there is wide separation of the collagen fibers and the glandular elements; vascular congestion and eosinophilic infiltration are also present. Patients dying of vascular collapse without antecedent hypoxia from respiratory insufficiency have visceral congestion with a presumptive loss of intravascular blood volume. The associated electrocardiographic abnormalities, with or without infarction, noted in some patients may reflect a primary cardiac event or be secondary to a critical reduction in blood volume.

The angioedematous and urticarial manifestations of the anaphylactic syndrome have been attributed to release of endogenous histamine. A role for the cysteinyl leukotrienes in altering pulmonary mechanics by causing marked bronchiolar constriction seems likely. Vascular collapse without respiratory distress in response to experimental challenge with the sting of a hymenopteran was associated not only with marked and prolonged elevations in blood histamine but also with evidence of intravascular coagulation and kinin generation. The finding that patients with systemic mastocytosis and episodic hypotension proceeding to vascular collapse excrete large amounts of PGD_2 metabolites in addition to histamine suggests that PGD_2 is also of importance in the hypotensive anaphylactic reactions. The cysteinyl leukotrienes may be involved in the pathobiologic process in patients with myocardial ischemia without or with infarction.

DIAGNOSIS The diagnosis of an anaphylactic reaction depends largely on an accurate history revealing the onset of the appropriate symptoms and signs within minutes after the responsible material is encountered. When only a portion of the full syndrome is present, such as isolated urticaria, sudden bronchospasm in a patient with asthma, or vascular collapse after intravenous administration of an agent, it may be appropriate to consider a complement-mediated immune complex reaction, an idiosyncratic response to any of the nonsteroidal anti-inflammatory agents, or the direct effect of certain drugs or diagnostic agents on mast cells. Intravenous administration of a chemical mast cell–degranulating agent, including opiate derivatives and radiographic contrast media, may elicit generalized urticaria, angioedema, and a sensation of retrosternal oppression with or without clinically detectable bronchoconstriction or hypotension. Aspirin and other nonsteroidal anti-inflammatory agents such as indomethacin, aminopyrine, and mefenamic acid may precipitate a life-threatening episode of obstruction of upper or lower airways, especially in patients with asthma, that is clinically reminiscent of anaphylaxis but is not associated with a detectable IgE response. This syndrome, which is commonly associated with nasal polyposis, is due to inhibition of PGHS-1 with corresponding unregulated, amplified generation of the cysteinyl leukotrienes via the 5-LO/LTC_4 synthase pathway. In the transfusion anaphylactic reaction that occurs in patients with IgA deficiency, the responsible specificity resides in IgG or IgE anti-IgA; the mechanism of the reaction mediated by IgG anti-IgA is presumed to be complement activation with secondary mast cell participation.

The presence of specific IgE in the heart blood of patients dying of systemic anaphylaxis has been demonstrated at postmortem by passive transfer of the serum intradermally into a normal recipient, followed in 24 h by antigen challenge into the same site, with subsequent development of a wheal and flare, the *Prausnitz-Küstner reaction*. To avoid the hazards of transferring hepatitis or other infections to a recipient, it is preferable to use the serum to seek passive sensitization of a human leukocyte suspension enriched with basophils for subsequent antigen-induced histamine release. Furthermore, radioimmunoassays have demonstrated specific IgE antibodies in patients with anaphylactic reactions, but such approaches require purified antigens. Elevations of β-tryptase levels in serum implicate mast cell activation in an adverse systemic reaction and are particularly informative with episodes of hypotension during general anesthesia or when there has been a fatal outcome.

TREATMENT

Early recognition of an anaphylactic reaction is mandatory, since death occurs within minutes to hours after the first symptoms. Mild symptoms such as pruritus and urticaria can be controlled by administration of 0.3 to 0.5 mL of 1:1000 epinephrine subcutaneously or intramuscularly, with repeated doses as required at 20-min intervals for a severe reaction. If the antigenic material was injected into an extremity, the rate of absorption may be reduced by prompt application of a tourniquet proximal to the reaction site, administration of 0.2 mL of 1:1000 epinephrine into the site, and removal without compression of an insect stinger, if present. An intravenous infusion should be initiated to provide a route for administration of 2 to 10 mL epinephrine, diluted 1:100,000, at 5- to 10-min intervals, volume expanders such as normal saline, and vasopressor agents such as dopamine if intractable hypotension occurs. Replacement of intravascular volume due to postcapillary venular leakage may require several liters of saline. Epinephrine provides both α- and β-adrenergic effects, resulting in vasoconstriction, bronchial smooth-muscle relaxation, and attenuation of enhanced venular permeability. Beta blockers are relatively contraindicated in persons at risk for anaphylactic reactions, especially those sensitive to Hymenoptera venom or those undergoing immunotherapy for respiratory system allergy. When epinephrine fails to control the anaphylactic reaction, hypoxia due to airway obstruction or related to a cardiac arrhythmia, or both, must be considered. Oxygen via a nasal catheter or intermittent positive-pressure breathing of oxygen with inhaled or nebulized albuterol may be helpful, but either endotracheal intubation or a tracheostomy is mandatory for oxygen delivery if progressive hypoxia develops. Ancillary agents such as the antihistamine diphenhydramine, 50 to 100 mg intramuscularly or intravenously, and aminophylline, 0.25 to 0.5 g intravenously, are appropriate for urticaria-angioedema and bronchospasm, respectively. Intravenous glucocorticoids are not effective for the acute event but may alleviate later recurrence of bronchospasm, hypotension, or urticaria. Furthermore, in a syndrome termed *idiopathic anaphylaxis* with recurrent angioedema of the upper airways, glucocorticoid administration may be beneficial by reducing the frequency of attacks and/or the severity of episodes.

PREVENTION Prevention of anaphylaxis must take into account the sensitivity of the recipient, the dose and character of the diagnostic or therapeutic agent, and the effect of the route of administration on the rate of absorption. If there is a definite history of a past anaphylactic reaction, even though mild, it is advisable to select another agent or procedure. A knowledge of cross-reactivity among agents is critical since, for example, cephalosporins share a common β-lactam ring with the penicillins. A prick or scratch skin test should precede an intradermal skin test, since the latter has a higher risk of causing anaphylaxis. These tests should be performed before the administration of certain materials that are likely to elicit anaphylactic reactions, such as allergenic extracts, or when the nature of the past adverse reaction is unknown. With regard to penicillin, two-thirds of patients with a positive reaction history and positive skin tests to benzylpenicilloyl-polylysine (BPL) and/or the minor determinant mixture (MDM) of benzylpenicillin products experience allergic reactions with treatment, and these are almost uniformly of the anaphylactic type in those patients with minor determinant reactivity. Even patients without a history of previous clinical reactions have a 2 to 6% incidence of positive skin tests to the two test materials, and about 3 per 1000 with a negative history experience anaphylaxis with therapy, with a mortality of about 1 per 100,000. Skin testing for antibiotics should be performed

only on patients with a positive clinical history consistent with an IgE-mediated reaction and in imminent need of the antibiotic in question; skin testing is of no value for non-IgE-mediated eruptions. Desensitization with most antibiotics can proceed by the intravenous, subcutaneous, or oral route. Typically, graded quantities of the antibiotic are given by the selected route using double doses until a therapeutic dosage is achieved. Due to the risk of systemic anaphylaxis during the course of desensitization, such a procedure should be performed only in a setting in which resuscitation equipment is at hand and an intravenous line is in place. It is critical to give the therapeutic agent at regular intervals to prevent the reestablishment of a sensitized cell pool of large size.

A different form of protection involves the development of blocking antibody of the IgG class, which is protective against Hymenoptera venom–induced anaphylaxis by interacting with antigen so that less reaches the sensitized tissue mast cells; to be effective, this immunotherapy requires the use of specific or cross-reacting Hymenoptera venom. Because sensitization can be transient, the maximal risk for systemic anaphylactic reactions in persons with Hymenoptera sensitivity occurs in association with a currently positive skin test. Although there is only low-grade cross-reactivity between honey bee and yellow jacket venoms, there is a high degree of cross-reactivity between yellow jacket venom and the rest of the vespid venoms (yellow or bald-faced hornets and wasps). Prevention involves modification of outdoor activities to exclude bare feet, wearing perfumed toiletries, eating in areas attractive to insects, clipping hedges or grass, and hauling away trash or fallen fruit. As with each anaphylactic sensitivity, the individual should wear an informational bracelet and have immediate access to an unexpired epinephrine kit. The limitations of lifestyle and the psychological duress can be addressed by venom immunotherapy to achieve a venom-specific IgG titer. Although it has been recommended that venom therapy be continued indefinitely or until the skin and specific serum IgE tests are unremarkable, there is evidence that 5 years of treatment induces a state of resistance to sting reactions that is independent of serum levels of specific IgG or IgE. This contrasts with the definite relation of sting immunity to specific IgG earlier in the treatment regime. For children with a systemic reaction limited to skin, the likelihood of progression to more serious respiratory or vascular manifestations is low, and thus immunotherapy is not recommended.

URTICARIA AND ANGIOEDEMA

DEFINITION Urticaria and angioedema may appear separately or together as cutaneous manifestations of localized nonpitting edema; a similar process may occur at mucosal surfaces of the upper respiratory or gastrointestinal tract. *Urticaria* involves only the superficial portion of the dermis, presenting as well-circumscribed wheals with erythematous raised serpiginous borders with blanched centers that may coalesce to become giant wheals. *Angioedema* is a well-demarcated localized edema involving the deeper layers of the skin, including the subcutaneous tissue. Recurrent episodes of urticaria and/or angioedema of less than 6 weeks' duration are considered acute, whereas attacks persisting beyond this period are designated chronic.

PREDISPOSING FACTORS AND ETIOLOGY The occurrence of urticaria and angioedema is probably more frequent than usually described because of the evanescent, self-limited nature of such eruptions, which seldom require medical attention when limited to the skin. Although persons in any age group may experience acute or chronic urticaria and/or angioedema, these lesions increase in frequency after adolescence, with the highest incidence occurring in persons in the third decade of life; indeed, one survey of college students indicated that 15 to 20% had experienced a pruritic wheal reaction.

The classification of urticaria-angioedema presented in Table 298-1 focuses on the different mechanisms for eliciting clinical disease and can be useful for differential diagnosis; nonetheless, most cases of chronic urticaria are idiopathic. Urticaria and/or angioedema occurring during the appropriate season in patients with seasonal respiratory allergy or as a result of exposure to animals or molds is attributed to inhalation or physical contact with pollens, animal dander, and mold spores, respectively. However, urticaria and angioedema secondary to inhalation are relatively uncommon compared to urticaria and angioedema elicited by ingestion of fresh fruits, shellfish, fish, milk products, chocolate, legumes including peanuts, and various drugs that may elicit not only the anaphylactic syndrome with prominent gastrointestinal complaints but also chronic urticaria.

TABLE 298-1 Classification of Urticaria and/or Angioedema

1. IgE-dependent
   a. Specific antigen sensitivity (pollens, foods, drugs, fungi, molds, Hymenoptera venom, helminths)
   b. Physical: dermographism, cold, solar, cholinergic, vibratory, exercise-related
   c. Autoimmune
2. Bradykinin-mediated
   a. Hereditary angioedema: C1 inhibitor deficiency: null (type 1) and dysfunctional (type 2)
   b. Acquired angioedema: C1 inhibitor deficiency: anti-idiotype and anti-C1 inhibitor
   c. Angiotensin-converting enzyme inhibitors
3. Complement-mediated
   a. Necrotizing vasculitis
   b. Serum sickness
   c. Reactions to blood products
4. Nonimmunologic
   a. Direct mast cell–releasing agents (opiates, antibiotics, curare, D-tubocurarine, radiocontrast media)
   b. Agents that alter arachidonic acid metabolism (aspirin and nonsteroidal anti-inflammatory agents, azo dyes, and benzoates)
5. Idiopathic

Additional etiologies include physical stimuli such as cold, heat, solar rays, exercise, and mechanical irritation. The physical urticarias can be distinguished by the precipitating event and other aspects of the clinical presentation. *Dermographism*, which occurs in 1 to 4% of the population, is defined by the appearance of a linear wheal at the site of a brisk stroke with a firm object or by any configuration appropriate to the eliciting event. Dermographism has a prevalence that peaks in the second to third decades. It is not influenced by an atopic diathesis and has a duration generally of less than 5 years. *Pressure urticaria*, which often accompanies dermographism or chronic idiopathic urticaria, presents in response to a sustained stimulus such as a shoulder strap or belt, running (feet), or manual labor (hands). *Cholinergic urticaria* is distinctive in that the pruritic wheals are of small size (1 to 2 mm) and are surrounded by a large area of erythema; attacks are precipitated by fever, a hot bath or shower, or exercise and are presumptively attributed to a rise in core body temperature. *Exercise-related anaphylaxis* can be precipitated by exertion alone or can be dependent on prior food ingestion. The clinical presentation can be limited to erythema and pruritic urticaria but may progress to angioedema of the face, oropharynx, larynx, or intestine or to vascular collapse; it is distinguished from cholinergic urticaria by presenting with wheals of conventional size and by not occurring with fever or a hot bath. *Cold urticaria*, either acquired or hereditary, is local at body areas exposed to low ambient temperature or cold objects (ice cube) but can progress to vascular collapse with immersion in cold water (swimming). *Solar urticaria* is subdivided into three groups by the response to specific portions of the light spectrum. *Vibratory angioedema* may occur after years of occupational exposure or can be idiopathic; it may be accompanied by cholinergic urticaria. Other rare forms of physical allergy, always defined by stimulus-specific elicitation, include *local heat urticaria*, *aquagenic urticaria* from contact with water of any temperature (sometimes associated with polycythemia vera), and *contact urticaria* from direct interaction with some chemical substance.

Angioedema without urticaria due to generation of bradykinin occurs with C1 inhibitor (C1INH) deficiency that may be inborn as an autosomal dominant characteristic or may be acquired. The angiotensin-converting enzyme (ACE) inhibitors can provoke a similar clinical presentation in 0.1 to 0.5% of hypertensive patients due to attenuated degradation of bradykinin. The urticaria and angioedema associated with classic serum sickness or with hypocomplementemic cutaneous necrotizing angiitis are believed to be immune-complex diseases. The drug reactions to mast cell granule–releasing agents and to nonsteroidal anti-inflammatory drugs may be systemic, resembling anaphylaxis, or limited to cutaneous sites.

PATHOPHYSIOLOGY AND MANIFESTATIONS Urticarial eruptions are distinctly pruritic, involve any area of the body from the scalp to the soles of the feet, and appear in crops of 24- to 72-h duration, with old lesions fading as new ones appear. The most common sites for urticaria are the extremities and face, with angioedema often being periorbital and in the lips. Although self-limited in duration, angioedema of the upper respiratory tract may be life-threatening due to laryngeal obstruction, while gastrointestinal involvement may present with abdominal colic, with or without nausea and vomiting, and may precipitate unnecessary surgical intervention. No residual discoloration occurs with either urticaria or angioedema unless there is an underlying process leading to superimposed extravasation of erythrocytes.

The pathology of urticaria and angioedema is usually characterized by edema of the dermis in urticaria and of the subcutaneous tissue as well as the dermis in angioedema. Collagen bundles in affected areas are widely separated, and the venules are sometimes dilated. The perivenular infiltrate may consist of lymphocytes, eosinophils, and neutrophils that are present in varying combination and number throughout the dermis.

Perhaps the best-studied example of IgE- and mast cell–mediated urticaria and angioedema is *cold urticaria*. Cryoglobulins may be recognized, but not in the majority of patients. Immersion of an extremity in an ice bath precipitates angioedema of the distal portion with urticaria at the air interface within minutes of the challenge. Histologic studies reveal marked mast cell degranulation with associated edema of the dermis and subcutaneous tissues. The venous effluent of the cold-challenged and angioedematous extremity reveals a marked rise in plasma content of histamine, whereas the venous effluent of the contralateral normal extremity contains no increment of this mediator. Elevated levels of histamine have been found in the plasma of venous effluent and in the fluid of suction blisters at experimentally induced lesional sites in patients with dermographism, pressure urticaria, vibratory angioedema, light urticaria, and heat urticaria. By ultrastructural analysis, the pattern of mast cell degranulation in cold urticaria resembles an IgE-mediated response with solubilization of granule contents, fusion of the perigranular and cell membranes, and discharge of granule contents, whereas in a dermographic lesion there is an additional superimposed zonal (piecemeal) degranulation. Elevations of plasma histamine levels with biopsy-proven mast cell degranulation have also been demonstrated with systemic attacks of *cholinergic urticaria* and *exercise-related anaphylaxis* precipitated experimentally in subjects exercising on a treadmill while wearing a wet suit; however, only in cholinergic urticaria is there a concomitant decrease in pulmonary function.

Up to one-third of patients with chronic urticaria have autoantibodies to IgE or to the α chain of the FcϵRI. In these patients, autologous serum injected into their own skin can induce a wheal and flare involving mast cell activation, but the relationship of such antibodies to the clinical course remains to be defined. In vitro studies reveal that these autoantibodies can mediate basophil degranulation with enhancement by serum as a source of the anaphylatoxic fragment, C5a.

Hereditary angioedema is an autosomal dominant disease due to a deficiency of C1INH (type 1) in about 85% of patients and to a dysfunctional protein (type 2) in the remainder. In the acquired form there is excessive consumption of C1INH due either to immune complexes formed between anti-idiotypic antibody and monoclonal IgG presented by B cell lymphomas or to an autoantibody directed to C1INH. C1INH blocks the catalytic function of activated factor XII (Hageman factor) and of kallikrein, as well as the C1r/C1s components of C1. During clinical attacks of angioedema, C1INH-deficient patients have elevated plasma levels of bradykinin, particularly in the venous effluent of an involved extremity, and reduced levels of prekallikrein and high-molecular-weight kinnogen, from which bradykinin is cleaved. The parallel decline in the complement substrates, C4 and C2, reflect the action of activated C1 during such attacks. Mice with targeted disruption of the gene for C1INH exhibit a chronic increase in vascular permeability. The pathobiology is aggravated by administration of an ACE inhibitor (captopril) and is attenuated by breeding the C1INH null strain to a bradykinin 2 receptor (Bk2R) null strain. As ACE is also described as kininase II, the use of blockers results in impaired bradykinin degradation and explains the angioedema occurring idiosyncratically in hypertensive patients with a normal C1INH.

DIAGNOSIS The rapid onset and self-limited nature of urticarial and angioedematous eruptions are distinguishing features. Additional characteristics are the occurrence of the urticarial crops in various stages of evolution and the asymmetric distribution of the angioedema. Urticaria and/or angioedema involving IgE-dependent mechanisms are often appreciated by historic considerations implicating specific allergens or physical stimuli, by seasonal incidence, and by exposure to certain environments. Direct reproduction of the lesion with physical stimuli is particularly valuable because it so often establishes the cause of the lesion. The diagnosis of an environmental allergen based on the clinical history can be confirmed by skin testing or assay for allergen-specific IgE in serum. IgE-mediated urticaria and/or angioedema may or may not be associated with an elevation of total IgE or with peripheral eosinophilia. Fever, leukocytosis, and an elevated sedimentation rate are absent.

The classification of urticarial and angioedematous states noted in Table 298-1 in terms of possible mechanisms necessarily includes some differential diagnostic points. Hypocomplementemia is not observed in IgE-mediated mast cell disease and may reflect either an acquired abnormality generally attributed to the formation of immune complexes or a genetic deficiency of C1INH. Chronic recurrent urticaria, generally in females, associated with arthralgias, an elevated sedimentation rate, and normo- or hypocomplementemia suggests an underlying cutaneous necrotizing angiitis. Vasculitic urticaria typically persists longer than 72 h, whereas conventional urticaria often has a duration of less than 24 to 48 h. Confirmation depends on a biopsy that reveals cellular infiltration, nuclear debris, and fibrinoid necrosis of the venules. The same pathobiologic process accounts for the urticaria in association with such diseases as systemic lupus erythematosus or viral hepatitis with or without an associated arteritis. Serum sickness per se or a similar clinical entity due to drugs includes not only urticaria but also pyrexia, lymphadenopathy, myalgia, and arthralgia or arthritis. Urticarial reactions to blood products or intravenous administration of immunoglobulin are defined by the event and generally are not progressive unless the recipient is IgA-deficient in the former case or the reagent is aggregated in the latter.

The diagnosis of hereditary angioedema is suggested not only by family history but also by the lack of pruritus and of urticarial lesions, the prominence of recurrent gastrointestinal attacks of colic, and episodes of laryngeal edema. Laboratory diagnosis depends on demonstrating a deficiency of C1INH antigen (type 1) or a nonfunctional protein (type 2) by a catalytic inhibition assay. While levels of C1 are normal, its substrates, C4 and C2, are chronically depleted and fall further during attacks due to the activation of additional C1. The acquired forms of C1INH deficiency have the same clinical manifestations but differ in the lack of a familial element and exhibit a reduction of C1 function and C1q protein as well as C1INH, C4, and C2. Inborn and acquired C1INH deficiency and ACE inhibitor–elicited angioedema are associated with elevated levels of bradykinin.

Urticaria and angioedema must be differentiated from contact sensitivity, a vesicular eruption that progresses to chronic thickening of the skin with continued allergenic exposure. They must also be differentiated from atopic dermatitis, a condition that may present as erythema, edema, papules, vesiculation, and oozing proceeding to a subacute and chronic stage in which vesiculation is less marked or absent and scaling, fissuring, and lichenification predominate in a distribution that characteristically involves the flexor surfaces. In cutaneous mastocytosis, the reddish brown macules and papules, characteristic of urticaria pigmentosa, urticate with pruritus upon trauma; and in systemic mastocytosis, without or with urticaria pigmentosa, there is an episodic systemic flushing with or without urticaria but no angioedema.

TREATMENT

Identification of the etiologic factor(s) and their elimination provide the most satisfactory therapeutic program; this approach is feasible to varying degrees with IgE-mediated reactions to allergens or physical stimuli. For most forms of urticaria, H_1 antihistamines such as chlorpheniramine or diphenhydramine, and including the nonsedating class such as loratadine or cetirizine, are effective in attenuating both urtication and pruritus. Cyproheptadine and especially hydroxyzine have proven effective when H_1 antihistamines have been inadequate. Doxepin, a dibenzoxepin tricyclic compound with both H_1 and H_2 receptor antagonist activity, is yet another alternative. Terbutaline, an α-adrenergic agonist, or a $CysLT_1R$ antagonist may be added to the treatment regimen. Topical glucocorticoids are of no value, and systemic glucocorticoids are generally avoided in idiopathic, allergen-induced, or physical urticarias due to their long-term toxicity. Systemic glucocorticoids are useful in the management of patients with pressure urticaria, with vasculitic urticaria (especially with eosinophil prominence), with idiopathic angioedema with or without urticaria, or with chronic urticaria that responds poorly to conventional treatment. With persistent vasculitic urticaria, hydroxychloroquine or colchicine may be added to the regimen after hydroxyzine and before or along with systemic glucocorticoids.

The therapy of inborn C1INH deficiency has been simplified by the finding that attenuated androgens correct the biochemical defect and afford prophylactic protection; their efficacy is attributed to production by the normal gene of an amount of functional C1INH sufficient to control the spontaneous activation of C1. The antifibrinolytic agent ϵ-aminocaproic acid may be used for preoperative prophylaxis but is contraindicated in patients with thrombotic tendencies or ischemia due to arterial atherosclerosis. Infusion of isolated C1INH protein appears useful in prophylaxis and to ameliorate an attack.

SYSTEMIC MASTOCYTOSIS

DEFINITION *Systemic mastocytosis* is defined by mast cell hyperplasia that in most instances is indolent and nonneoplastic. The hyperplasia is generally recognized only in bone marrow and in the normal peripheral distribution sites of the cells, such as skin, gastrointestinal mucosa, liver, and spleen. Mastocytosis occurs at any age and has a slight preponderance in males. The prevalence of systemic mastocytosis is not known, a familial occurrence has not been established, and atopy is not increased.

CLASSIFICATION AND PATHOPHYSIOLOGY A recent consensus classification for mastocytosis recognizes cutaneous mastocytosis with variants and four systemic forms (Table 298-2). The form designated as *indolent systemic mastocytosis* (ISM) accounts for the majority of patients; it implies that there is no evidence of an associated hematologic disorder, liver disease, or lymphadenopathy and is not known to alter life expectancy. In *systemic mastocytosis associated with clonal hematologic non-mast cell lineage disease* (SM-AHNMD), the prognosis is determined by the nature of the associated disorder, which can range from dysmyelopoiesis to leukemia. In *aggressive systemic mastocytosis* (ASM), mast cell proliferation in parenchymal organs causing impaired liver function, hypersplenism, and/or malabsorption has a poor prognosis in the absence of a hematologic disorder; a subset of these patients have prominent eosinophilia with hepatosplenomegaly and lymphadenopathy. *Mast cell leukemia* is the rarest form of the disease and is invariably fatal at present; the peripheral blood contains circulating, metachromatically staining, atypical mast cells.

TABLE 298-2 Classification of Mastocytosis

Cutaneous mastocytosis (CM)
Urticaria pigmentosa (UP)/maculopapular cutaneous mastocytosis (MPCM)
Variants: plaque form, nodular form; telangiectasia macularis eruptive perstans (TMEP); diffuse cutaneous mastocytosis (DCM)
Solitary mastocytoma of skin
Indolent systemic mastocytosis (ISM)
Systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease (SM-AHNMD)
Aggressive systemic mastocytosis (ASM)
Variant: lymphadenopathic mastocytosis with eosinophilia
Mast cell leukemia (MCL)
Mast cell sarcoma (MCS)

Source: Modified from P Valent et al, in ES Jaffee et al (eds): *World Health Organization Classification of Tumors: Pathology and Genetics in Tumors of Hematopoietic and Lymphoid Tissues*, Lyon, IARC Press, 2001.

A point mutation of A to T at codon 816 that causes an aspartic acid to valine substitution is found in multiple cell lineages in patients with mastocytosis, indicating a somatic gain-in-function mutation. This substitution, as well as others at 816, is characteristic of adults with SM-AHNMD but is also detected in patients with ISM and cutaneous mastocytosis, as might be anticipated because mast cells at any site are of bone marrow lineage. In infants and children with cutaneous manifestations, namely, urticaria pigmentosa or bullous lesions, visceral involvement is usually lacking, and resolution is common because gain-in-function mutations are infrequent.

CLINICAL MANIFESTATIONS The clinical manifestations of systemic mastocytosis, distinct from a leukemic complication, are due to tissue occupancy by the mast cell mass, the tissue response to that mass, and the release of bioactive substances acting at both local and distal sites. The pharmacologically induced manifestations are pruritus, flushing, palpitations and vascular collapse, gastric distress, lower abdominal crampy pain, and recurrent headache. The increase in cell burden is evidenced by the lesions of urticaria pigmentosa at skin sites, but it also contributes to bone pain and malabsorption. The mast cell–mediated fibrotic changes are limited to liver, spleen, and bone marrow and presumably relate to the functional characteristics of mast cells developing at those sites, as opposed to those at sites without fibrosis, such as the gastrointestinal tissue or skin. Immunofluorescent analysis of bone marrow and skin lesions in ISM and of spleen, lymph node, and skin in ASM has revealed only one mast cell phenotype, namely, scroll-poor cells expressing tryptase, chymase, and CPA.

The cutaneous lesions of urticaria pigmentosa are reddish-brown macules or papules that respond to trauma with urtication and erythema (Darier's sign). The apparent incidence of these lesions is $\geq$90% in patients with ISM and $<$50% in those with SM-AHNMD or ASM. Approximately 1% of patients with ISM have skin lesions that appear as tan-brown macules with striking patchy erythema and associated telangiectasia (telangiectasia macularis eruptiva perstans). In the upper gastrointestinal tract, histamine-mediated hypersecretion is the most common problem, with resultant gastritis and peptic ulcer. In the lower intestinal tract, the occurrence of diarrhea and abdominal pain is attributed to increased motility due to mast cell mediators, and this can be aggravated by malabsorption with secondary nutritional insufficiency and osteomalacia. The periportal fibrosis associated with mast cell infiltration and a prominence of eosinophils may lead to portal hypertension and ascites. In some patients, flushing and recurrent vascular collapse are markedly aggravated by an idiosyncratic response to a minimal dosage of nonsteroidal anti-inflammatory agents. The

neuropsychiatric disturbances are clinically most evident as impaired recent memory, decreased attention span, and "migraine-like" headaches. Patients in every category of systemic mastocytosis may experience exacerbation of a specific clinical sign or symptom with alcohol ingestion, use of mast cell–interactive narcotics, or ingestion of nonsteroidal anti-inflammatory agents.

DIAGNOSIS Although the diagnosis of mastocytosis is generally suspected on the basis of the clinical history and physical findings, and can be supported by laboratory procedures, it can be established only by a tissue diagnosis. By recent convention, the diagnosis of systemic mastocytosis is facilitated by bone marrow biopsy to meet the criteria of one major plus one minor or three minor findings (Table 298-3). The bone marrow provides the major criterion by revealing aggregates of mast cells, often in paratrabecular and perivascular locations with lymphocytes and eosinophils, as well as the minor criteria of an abnormal mast cell morphology, an aberrant mast cell membrane immunophenotype, or a codon 816 mutation in any cell type. A serum total tryptase level and/or a 24-h urine collection for measurement of histamine, histamine metabolites, or metabolites of PGD_2 are useful common noninvasive approaches to consider before bone marrow biopsy. The α form of tryptase is elevated in more than one-half of patients with systemic mastocytosis and provides a minor criterion; the β form is increased in patients undergoing an anaphylactic reaction. Additional studies directed by the presentation include a bone scan or skeletal survey; contrast studies of the upper gastrointestinal tract with small-bowel follow-through, computed tomography scan, or endoscopy; and a neuropsychiatric evaluation, including an electroencephalogram.

The differential diagnosis requires the exclusion of other flushing disorders. The 24-h urine assessment of 5-hydroxy-indoleacetic acid and metanephrines should exclude a carcinoid tumor or a pheochromocytoma. Most patients with recurrent anaphylaxis, including the idiopathic group, present with angioedema and/or wheezing, which are not manifestations of systemic mastocytosis.

TREATMENT

The management of systemic mastocytosis uses a stepwise and symptom/sign–directed approach that includes an H_1 antihistamine for flushing and pruritus, an H_2 antihistamine or proton pump inhibitor for gastric acid hypersecretion, oral cromolyn sodium for diarrhea and abdominal pain, and aspirin for severe flushing with or without associated vascular collapse, despite use of H_1 and H_2 antihistamines, to block biosynthesis of PGD_2. Systemic glucocorticoids appear to alleviate the malabsorption. Headaches are generally managed with tricyclic antidepressants and other neurotransmitter-modifying agents. Ketotifen has been used to alleviate flushing in patients with gastric intolerance to nonsteroidal anti-inflammatory agents and in patients with bone pain or intractable headaches. The efficacy of IFN-α in ASM is controversial, and this may relate to dosage limitations due to side effects. Treatment with hydroxyurea to reduce the mast cell lineage progenitors may have merit in ASM. Chemotherapy is appropriate for the frank leukemias.

TABLE 298-3 Diagnostic Criteria for Systemic Mastocytosis[a]

Major:	Multifocal dense infiltrates of mast cells in bone marrow or other extracutaneous tissues with confirmation by immunodetection of tryptase or metachromasia
Minor:	Abnormal mast cell morphology with a spindle shape and/or multilobed or eccentric nucleus
	Aberrant mast cell surface phenotype with expression of CD25 and CD2 (IL-2 receptor) in addition to C117 (c-*kit*)
	Detection of codon 816 mutation in peripheral blood cells, bone marrow cells, or lesional tissue
	Total serum tryptase (mostly alpha) greater than 20 ng/mL

[a] Diagnosis requires either major and one minor or three minor criteria.

ALLERGIC RHINITIS

DEFINITION Allergic rhinitis is characterized by sneezing; rhinorrhea; obstruction of the nasal passages; conjunctival, nasal, and pharyngeal itching; and lacrimation, all occurring in a temporal relationship to allergen exposure. Although commonly seasonal due to elicitation by airborne pollens, it can be perennial in an environment of chronic exposure. The incidence of allergic rhinitis in North America is about 7%, with the peak occurring in childhood and adolescence.

PREDISPOSING FACTORS AND ETIOLOGY Allergic rhinitis generally presents in atopic individuals, i.e., in persons with a family history of a similar or related symptom complex and a personal history of collateral allergy expressed as eczematous dermatitis, urticaria, and/or asthma (Chap. 236). Up to 40% of patients with rhinitis manifest asthma, whereas ~70% of individuals with asthma experience rhinitis. Symptoms generally appear before the fourth decade of life and tend to diminish gradually with aging, although complete spontaneous remissions are uncommon. A relatively small number of weeds that depend on wind rather than insects for cross-pollination, as well as grasses and some trees, produce sufficient quantities of pollen suitable for wide distribution by air currents to elicit seasonal allergic rhinitis. The dates of pollination of these species generally vary little from year to year in a particular locale but may be quite different in another climate. In the temperate areas of North America, trees typically pollinate from March through May, grasses in June and early July, and ragweed from mid-August to early October. Molds, which are widespread in nature because they occur in soil or decaying organic matter, may propagate spores in a pattern dependent on climatic conditions. Perennial allergic rhinitis occurs in response to allergens that are present throughout the year, including desquamating epithelium in animal dander, cockroach-derived proteins, mold spores, or dust, which has mites such as *Dermatophagoides farinae* and *D. pteronyssinus*. Dust mites are scavengers of flecks of human skin and coat the digestate with mite-specific protein for excretion. In up to one-half of patients with perennial rhinitis, no clear-cut allergen can be demonstrated as causative. The ability of allergens to cause rhinitis rather than lower respiratory symptoms may be attributed to their large size, 10 to 100 μm, and retention within the nose.

PATHOPHYSIOLOGY AND MANIFESTATIONS Episodic rhinorrhea, sneezing, obstruction of the nasal passages with lacrimation, and pruritus of the conjunctiva, nasal mucosa, and oropharynx are the hallmarks of allergic rhinitis. The nasal mucosa is pale and boggy, the conjunctiva congested and edematous, and the pharynx is generally unremarkable. Swelling of the turbinates and mucous membranes with obstruction of the sinus ostia and eustachian tubes precipitates secondary infections of the sinuses and middle ear, respectively. Nasal polyps, representing mucosal protrusions containing edema fluid with variable numbers of eosinophils, can arise concurrently with infection within the nasopharynx or sinuses and increase obstructive symptoms.

The nose presents a large mucosal surface area through the folds of the turbinates and serves to adjust the temperature and moisture content of inhaled air and to filter out particulate materials above 10 μm in size by impingement in a mucous blanket; ciliary action moves the entrapped particles toward the pharynx. Entrapment of pollen and digestion of the outer coat by mucosal enzymes such as lysozymes release protein allergens generally of 10,000 to 40,000 molecular weight. The initial interaction occurs between the allergen and intraepithelial mast cells and then proceeds to involve deeper perivenular mast cells, both of which are sensitized with specific IgE. During the symptomatic season when the mucosae are already swollen and hyperemic, there is enhanced adverse reactivity to the seasonal pollen as well as to antigenically unrelated pollens for which there is underlying hypersensitivity due to improved penetration of the allergens. Biopsy specimens of nasal mucosa during seasonal rhinitis show submucosal edema with infiltration by eosinophils, along with some basophils and neutrophils.

The mucosal surface fluid contains IgA that is present because of its secretory piece and also IgE, which apparently arrives by diffusion

from plasma cells in proximity to mucosal surfaces. IgE fixes to mucosal and submucosal mast cells, and the intensity of the clinical response to inhaled allergens is quantitatively related to the naturally occurring pollen dose. In sensitive individuals, the introduction of allergen into the nose is associated with sneezing, "stuffiness," and discharge, and the fluid contains histamine, PGD_2, and leukotrienes. Thus the mast cells of the nasal mucosa and submucosa generate and release mediators through IgE-dependent reactions that are capable of producing tissue edema and eosinophilic infiltration.

DIAGNOSIS The diagnosis of seasonal allergic rhinitis depends largely on an accurate history of occurrence coincident with the pollination of the offending weeds, grasses, or trees. The continuous character of perennial allergic rhinitis due to contamination of the home or place of work makes historic analysis difficult, but there may be a variability in symptoms that can be related to exposure to animal dander, dust mite and/or cockroach allergens, or work-related allergens such as latex. Patients with perennial rhinitis commonly develop the problem in adult life, and manifest nasal congestion and a postnasal discharge, often associated with thickening of the sinus membranes demonstrated by radiography. The term *vasomotor rhinitis* designates a condition of enhanced reactivity of the nasopharynx in which a symptom complex resembling perennial allergic rhinitis occurs with nonspecific stimuli. Other entities to be excluded are structural abnormalities of the nasopharynx; exposure to irritants; upper respiratory infection; pregnancy with prominent nasal mucosal edema; prolonged topical use of α-adrenergic agents in the form of nose drops (rhinitis medicamentosa); and the use of certain therapeutic agents such as rauwolfia, β-adrenergic antagonists, or estrogens.

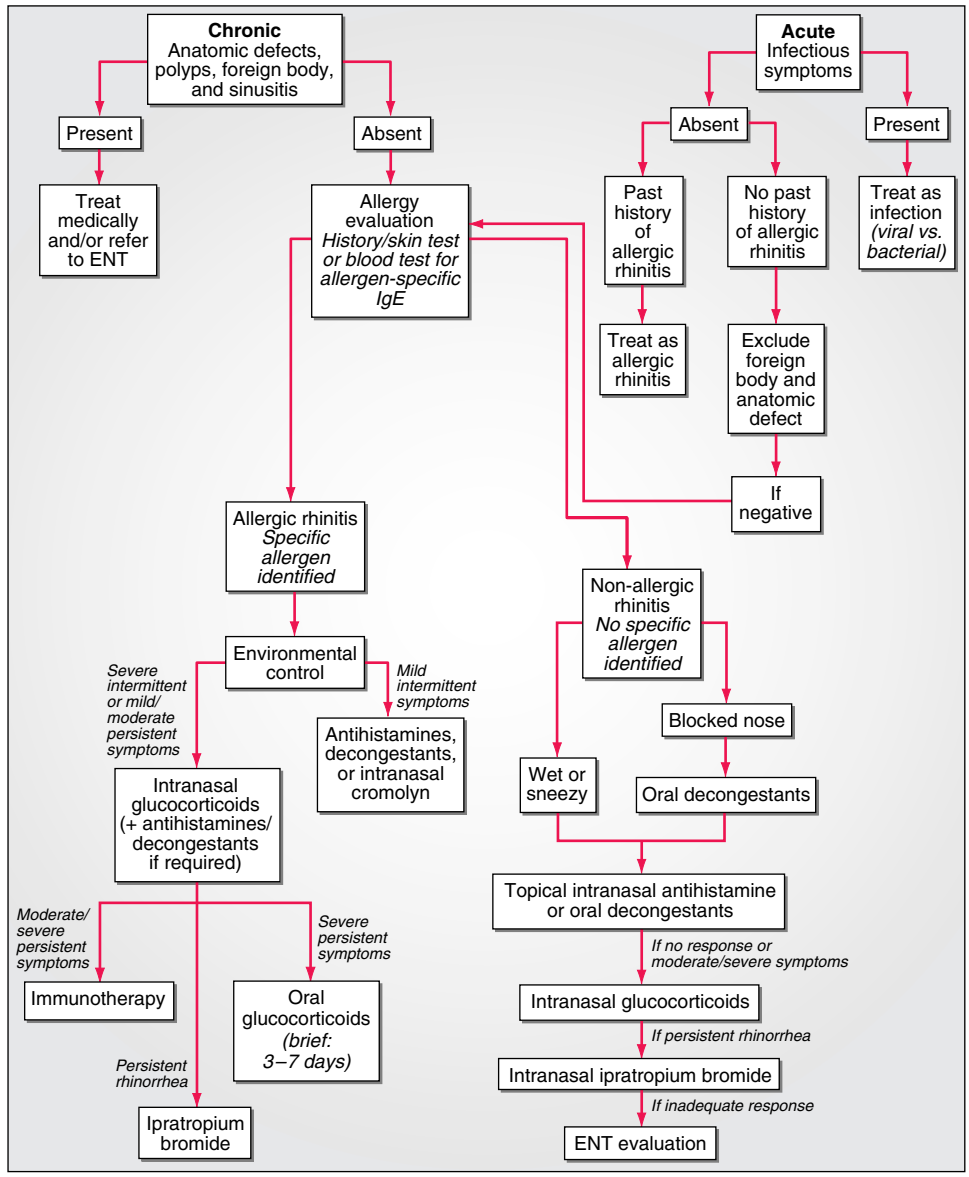

FIGURE 298-3 Algorithm for the diagnosis and management of rhinitis. ENT, ear, nose, and throat surgeon.

The nasal secretions of allergic patients are rich in eosinophils, and a modest peripheral eosinophilia is a common feature. Local or systemic neutrophilia implies infection. Total serum IgE is frequently elevated, but the demonstration of immunologic specificity for IgE is critical to an etiologic diagnosis. A skin test by the intracutaneous route (puncture or prick) with the allergens of interest provides a rapid and reliable approach to identifying allergen-specific IgE that has sensitized cutaneous mast cells. A positive intracutaneous skin test with 1:10 to 1:20 weight/volume of extract has a high predictive value for the presence of allergy. An intradermal test with a 1:500 to 1:1000 dilution of 0.05 mL may follow if indicated by history when the intracutaneous test is negative; but while more sensitive, it is less reliable due to the reactivity of some asymptomatic individuals at the test dose. Skin testing by the intracutaneous route for food allergens can be supportive of the clinical history. A double-blind, placebo-controlled challenge may document a food allergy, but such a procedure does bear the risk of an anaphylactic reaction. An elimination diet is safer but is tedious and less definitive. Food allergy is uncommon as a cause of allergic rhinitis.

Newer methodology for detecting total IgE, including the development of enzyme-linked immunosorbent assays (ELISA) employing anti-IgE bound to either a solid-phase or a liquid-phase particle, provides rapid and cost-effective determinations. Measurements of specific anti-IgE in serum are obtained by its binding to an allergen and quantitation by subsequent uptake of labeled anti-IgE. As compared to the skin test, the assay of specific IgE in serum is less sensitive but has high specificity.

PREVENTION Avoidance of exposure to the offending allergen is the most effective means of controlling allergic diseases; removal of pets from the home to avoid animal danders, utilization of air filtration devices to minimize the concentrations of airborne pollens, elimination of cockroach-derived proteins by chemical destruction of the pest and careful food storage, travel to nonpollinating areas during the critical periods, and even a change of domicile to eliminate a mold spore problem may be necessary. Control of dust mites by allergen avoidance includes use of plastic-lined covers for mattresses, pillows, and comforters, and elimination of carpets and drapes.

Rx TREATMENT

Although allergen avoidance is the most cost-effective means of managing allergic rhinitis, treatment with pharmacologic agents represents

the standard approach to seasonal or perennial allergic rhinitis. Oral antihistamines of the H_1 class are effective for nasopharyngeal itching, sneezing, and watery rhinorrhea and for such ocular manifestations as itching, tearing, and erythema, but they are not efficacious for the nasal congestion. The older antihistamines are sedating, and they induce psychomotor impairment, including reduced eye-hand coordination and impaired automobile driving skills. Their anticholinergic (muscarinic) effects include visual disturbance, urinary retention, and constipation. Because the newer H_1 antihistamines such as fexofenadine, loratadine, desloradine, cetirizine, and azelastine are less lipophilic and more H_1 selective, their ability to cross the blood-brain barrier is reduced, and thus their sedating and anticholinergic side effects are minimized. These newer antihistamines do not differ appreciably in efficacy for relief of coryza and/or sneezing. Antihistamines have little effect on congestion. Azelastine nasal spray may benefit individuals with nonallergic vasomotor rhinitis, but it has an adverse effect of dysgeusia (taste perversion) in some patients. α-Adrenergic agents such as phenylephrine or oximetazoline are generally used topically to alleviate nasal congestion and obstruction, but the duration of efficacy is limited because of rebound rhinitis and such systemic responses as hypertension. Oral α-adrenergic agonist decongestants containing pseudoephedrine are standard for the management of nasal congestion, generally in combination with an antihistamine. These pseudoephedrine combination products can cause insomnia and are precluded in patients with narrow angle glaucoma, urinary retention, severe hypertension, or marked coronary artery disease. Cromolyn sodium, a nasal spray, is essentially without side effects and is used prophylactically on a continuous basis during the season. The clinical efficacy of cromolyn sodium used prophylactically is less than that of second-generation oral antihistamines. Intranasal high-potency glucocorticoids are the most potent drugs available for the relief of established rhinitis, seasonal or perennial, and even vasomotor rhinitis; they provide efficacy with substantially reduced side effects as compared with this same class of agent administered orally. Their most frequent side effect is local irritation, with *Candida* overgrowth being a rare occurrence. The currently available intranasal glucocorticoids—beclomethasone, flunisolide, budesonide, fluticasone, and mometasone—are equally effective clinically, achieving up to 70% overall symptom relief with some variation in the time period for onset of benefit. Topical ipratropium is an anticholinergic agent effective in reducing rhinorrhea, including that in patients with perennial symptoms, and it can be additionally efficacious when combined with intranasal steroids. For systemic symptoms not related to the nasopharynx, such as allergic conjunctivitis, treatment may be local.

Immunotherapy, often termed *hyposensitization*, consists of repeated subcutaneous injections of gradually increasing concentrations of the allergen(s) considered to be specifically responsible for the symptom complex. Controlled studies of ragweed, grass, dust mite, and cat dander allergens administered for treatment of allergic rhinitis have demonstrated at least partial relief of symptoms and signs. The duration of such immunotherapy is 3 to 5 years, with discontinuation being based on minimal symptoms over two consecutive seasons of exposure. Clinical benefit appears related to the administration of a high dose of relevant allergen advancing from weekly to monthly intervals. Patients should remain at the treatment site for at least 20 min after allergen administration so that any anaphylactic consequence can be managed. Local reactions with erythema and induration are not uncommon and may persist for 1 to 3 days. Immunotherapy is contraindicated in patients with significant cardiovascular disease or unstable asthma and should be conducted with particular caution in any patient requiring β-adrenergic blocking therapy because of the difficulty in managing an anaphylactic complication. The response to immunotherapy is derived from a complex of cellular and humoral effects that likely includes a modulation in T cell cytokine production. Immunotherapy should be reserved for clearly documented seasonal or perennial rhinitis, clinically related to defined allergen exposure with confirmation by the presence of allergen-specific IgE. A sequence for the management of allergic or perennial rhinitis based on an allergen-specific diagnosis and stepwise management as required for symptom control would include the following: (1) identification of the offending allergen(s) by history with confirmation of the presence of allergen-specific IgE by skin test and/or serum assay; (2) avoidance of the offending allergen; and (3) medical management in a stepwise fashion (Fig. 298-3). Mild intermittent symptoms of allergic rhinitis are treated with oral antihistamines, intranasal antihistamines, or intranasal cromolyn prophylaxis. Moderate to more severe allergic rhinitis is managed with intranasal glucocorticoids plus oral antihistamines or antihistamine-decongestant combinations. Persistent allergic rhinitis requiring the daily use of intranasal glucocorticoids with add-on interventions such as oral antihistamines, decongestant combinations, or topical ipratropium merits consideration of allergen-specific immunotherapy. Even a brief course of oral prednisone can be indicated.

299 AUTOIMMUNITY AND AUTOIMMUNE DISEASES

Peter E. Lipsky, Betty Diamond

One of the classically accepted features of the immune system is the capacity to distinguish self from non-self. Although they are able to recognize and generate reactions to a vast array of foreign materials, most animals do not mount immune responses to self-antigens under ordinary circumstances and thus are tolerant to self. Whereas recognition of self plays an important role in shaping both the T cell and B cell repertoires of immune receptors and plays an essential role in the recognition of nominal antigen by T cells, the development of potentially harmful immune responses to self-antigens is, in general, precluded. Autoimmunity, therefore, represents the end result of the breakdown of one or more of the basic mechanisms regulating immune tolerance.

The essential feature of an autoimmune disease is that tissue injury is caused by the immunologic reaction of the organism with its own tissues. Autoimmunity, on the other hand, refers merely to the presence of antibodies or T lymphocytes that react with self-antigens and does not necessarily imply that the development of self-reactivity has pathogenic consequences.

Autoimmunity may be seen in normal individuals and in higher frequency in normal older people. In addition, autoreactivity may develop during various infectious conditions. The expression of autoimmunity may be self-limited, as occurs with many infectious processes, or persistent. When autoimmunity is induced by an inciting

event, such as infection or tissue damage from trauma or infarction, there may or may not be ensuing pathology. Even in the presence of organ pathology, it may be difficult to determine whether the damage is mediated by autoreactivity. Thus, the presence of self-reactivity may be either the cause or a consequence of an ongoing pathologic process.

MECHANISMS OF AUTOIMMUNITY Since Ehrlich first postulated the existence of mechanisms to prevent the generation of self-reactivity in 1900, ideas concerning the nature of this inhibition have developed in parallel with the progressive increase in understanding of the immune system. Burnet's clonal selection theory included the idea that interaction of lymphoid cells with their specific antigens during fetal or early postnatal life would lead to elimination of such "forbidden clones." This idea became untenable, however, when it was shown by a number of investigators that autoimmune diseases could be induced by simple immunization procedures, that autoantigen-binding cells could be demonstrated easily in the circulation of normal individuals, and that self-limited autoimmune phenomena frequently developed during infections. These observations indicated that clones of cells capable of responding to autoantigens were present in the repertoire of antigen-reactive cells in normal adults and suggested that mechanisms in addition to clonal deletion were responsible for preventing their activation.

Currently, three general processes are thought to be involved in the maintenance of selective unresponsiveness to autoantigens (Table 299-1): (1) sequestration of self-antigens, rendering them inaccessible to the immune system; (2) specific unresponsiveness (tolerance or anergy) of relevant T or B cells; and (3) limitation of potential reactivity by regulatory mechanisms.

Derangements of these normal processes may predispose to the development of autoimmunity (Table 299-2). In general, these abnormal responses relate to stimulation by exogenous agents, usually bacterial or viral, or endogenous abnormalities in the cells of the immune system. Microbial superantigens, such as staphylococcal protein A and staphylococcal enterotoxins, are substances that can stimulate a broad range of T and B cells based upon specific interactions with selected families of immune receptors irrespective of their antigen specificity. If autoantigen reactive T and/or B cells express these receptors, autoimmunity might develop. Alternatively, molecular mimicry or cross-reactivity between a microbial product and a self-antigen might lead to activation of autoreactive lymphocytes. One of the best examples of autoreactivity and autoimmune disease resulting from molecular mimicry is rheumatic fever, in which antibodies to the M protein of streptococci cross-react with myosin, laminin, and other matrix proteins. Deposition of these autoantibodies in the heart initiates an inflammatory response. Molecular mimicry between microbial proteins and host tissues has been reported in type 1 diabetes mellitus, rheumatoid arthritis, and multiple sclerosis. The capacity of nonspecific stimulation of the immune system to predispose to the development of autoimmunity has been explored in a number of models; one is provided by the effect of adjuvants on the production of autoimmunity. Autoantigens become much more immunogenic when administered with adjuvant. It is presumed that infectious agents may be able to overcome self-tolerance because they possess molecules, such as bacterial endotoxin, that have adjuvant-like effects on the immune system by stimulating cells through Toll-like receptors.

Endogenous derangements of the immune system may also contribute to the loss of immunologic tolerance to self-antigens and the development of autoimmunity (Table 299-2). Many autoantigens reside in immunologically privileged sites, such as the brain or the anterior chamber of the eye. These sites are characterized by the inability of engrafted tissue to elicit immune responses. Immunologic privilege results from a number of events, including the limited entry of proteins from those sites into lymphatics, the local production of immunosuppressive cytokines such as transforming growth factor (TGF) β, and the local expression of molecules such as Fas ligand that can induce apoptosis of activated T cells. Lymphoid cells remain in a state of immunologic ignorance (neither activated nor anergized) to proteins expressed uniquely in immunologically privileged sites. If the privileged site is damaged by trauma or inflammation, or if T cells are activated elsewhere, proteins expressed at this site can become the targets of immunologic assault. Such an event may occur in multiple sclerosis and sympathetic ophthalmia, in which antigens uniquely expressed in the brain and eye, respectively, become the target of activated T cells.

Alterations in antigen presentation may also contribute to autoimmunity. This may occur by epitope spreading, in which protein determinants (*epitopes*) not routinely seen by lymphocytes (*cryptic epitopes*) are recognized as a result of immunologic reactivity to associated molecules. For example, animals immunized with one protein component of a multimolecular complex may be induced to produce antibodies to the other components of the complex. Finally, inflammation, drug exposure, or normal senescence may cause a primary chemical alteration in proteins, resulting in the generation of immune responses that cross-react with normal self-proteins. Alterations in the availability and presentation of autoantigens may be important components of immunoreactivity in certain models of organ-specific autoimmune diseases. In addition, these factors may be relevant in understanding the pathogenesis of various drug-induced autoimmune conditions. However, the diversity of autoreactivity manifest in non-organ-specific systemic autoimmune diseases suggests that these conditions might result from a more general activation of the immune system rather than from an alteration in individual self-antigens.

A number of experimental models have suggested that intense stimulation of T lymphocytes can produce nonspecific signals that bypass the need for antigen-specific helper T cells and lead to polyclonal B cell activation with the formation of multiple autoantibodies. For example, antinuclear, antierythrocyte, and antilymphocyte antibodies are produced during the chronic graft-versus-host reaction. In addition, true autoimmune diseases, including autoimmune hemolytic anemia and immune complex–mediated glomerulonephritis, can also be induced in this manner. While it is clear that such diffuse activation of helper T cell activity can cause autoimmunity, nonspecific stimulation of B lymphocytes can also lead to the production of autoantibodies. Thus, the administration of polyclonal B cell activators, such as bac-

TABLE 299-3 *Mechanisms of Tissue Damage in Autoimmune Disease*

Effector	Mechanism	Target	Disease
Autoantibody	Blocking or inactivation	α Chain of the nicotinic acetylcholine receptor	Myasthenia gravis
		Phospholipid–β_2-glycoprotein 1 complex	Antiphospholipid syndrome
		Insulin receptor	Insulin-resistant diabetes mellitus
		Intrinsic factor	Pernicious anemia
	Stimulation	TSH receptor (LATS)	Graves' disease
		Proteinase-3 (ANCA)	Wegener's granulomatosis
		Epidermal cadherin$_1$ Desmoglein 3	Pemphigus vulgaris
	Complement activation	α_3 Chain of collagen IV	Goodpasture's syndrome
	Immune-complex formation	Double-strand DNA	Systemic lupus erythematosus
		Ig	Rheumatoid arthritis
	Opsonization	Platelet GpIIb:IIIa	Autoimmune thrombocytopenic purpura
		Rh antigens, I antigen	Autoimmune hemolytic anemia
	Antibody-dependent cellular cytotoxicity	Thyroid peroxidase, thyroglobulin	Hashimoto's thyroiditis
T cells	Cytokine production	?	Rheumatoid arthritis, multiple sclerosis, type 1 diabetes mellitus
	Cellular cytotoxicity	?	Type 1 diabetes mellitus

Note: ANCA, antineutrophil cytoplasmic antibody; LATS, long-acting thyroid stimulator; TSH, thyroid-stimulating hormone.

terial endotoxin, to normal mice leads to the production of a number of autoantibodies, including those directed to DNA and IgG (rheumatoid factor).

Primary alterations in the activity of T and/or B cells, cytokine imbalances, or defective immunoregulatory circuits may also contribute to the emergence of autoimmunity. For example, decreased apoptosis, as can be seen in animals with defects in Fas (CD95) or Fas ligand or in patients with related abnormalities, can be associated with the development of autoimmunity. Similarly, diminished production of tumor necrosis factor (TNF) and interleukin (IL) 10 has been reported to be associated with the development of autoimmunity.

Autoimmunity may also result from an abnormality of immunoregulatory mechanisms. Observations made in both human autoimmune disease and animal models suggest that defects in the generation and expression of regulatory T cell activity may allow for the production of autoimmunity. Administration of normal regulatory T cells or factors derived from them can prevent the development of autoimmune disease in rodent models of autoimmunity.

It should be apparent that no single mechanism can explain all the varied manifestations of autoimmunity. Furthermore, genetic evaluation has shown that a number of abnormalities often need to converge to induce an autoimmune disease. Additional factors that appear to be important determinants in the induction of autoimmunity include age, sex (many autoimmune diseases are far more common in women), genetic background, exposure to infectious agents, and environmental contacts. How all of these disparate factors affect the capacity to develop self-reactivity is currently being intensively investigated.

GENETIC CONSIDERATIONS Evidence in humans that there are susceptibility genes for autoimmunity comes from family studies and especially from studies of twins. Studies in type 1 diabetes mellitus, rheumatoid arthritis, multiple sclerosis, and systemic lupus erythematosus (SLE) have shown that approximately 15 to 30% of pairs of monozygotic twins show disease concordance, compared with <5% of dizygotic twins. The occurrence of different autoimmune diseases within the same family has suggested that certain susceptibility genes may predispose to a variety of autoimmune diseases. Genetic mapping has begun to identify chromosomal regions that predispose to specific autoimmune diseases. In addition to this evidence from humans, certain inbred mouse strains reproducibly develop specific spontaneous or experimentally induced autoimmune diseases, whereas others do not. These findings have led to an extensive search for genes that determine susceptibility to autoimmune disease.

The most consistent association for susceptibility to autoimmune disease has been with particular alleles of the major histocompatibility complex (MHC). It has been suggested that the association of MHC genotype with autoimmune disease relates to differences in the ability of different allelic variations of MHC molecules to present autoantigenic peptides to autoreactive T cells. An alternative hypothesis involves the role of MHC alleles in shaping the T cell receptor repertoire during T cell ontogeny in the thymus. Additionally, specific MHC gene products themselves may be the source of peptides that can be recognized by T cells. Cross-reactivity between such MHC peptides and peptides derived from proteins produced by common microbes may trigger autoimmunity by molecular mimicry. However, MHC genotype alone does not determine the development of autoimmunity. Identical twins are far more likely to develop the same autoimmune disease than MHC-identical nontwin siblings, suggesting that genetic factors other than the MHC also affect disease susceptibility. Recent studies of the genetics of type 1 diabetes, SLE, rheumatoid arthritis, and multiple sclerosis in humans and mice have shown that there are several independently segregating disease susceptibility loci in addition to the MHC.

There is evidence that several other genes are important in increasing susceptibility to autoimmune disease. In humans, inherited homozygous deficiency of the early proteins of the classic pathway of complement (C1, C4, or C2) is very strongly associated with the development of SLE. In mice and humans, abnormalities in the genes encoding proteins involved in the regulation of apoptosis, including Fas (CD95) and Fas ligand (CD95 ligand), are strongly associated with the development of autoimmunity. There is also evidence that inherited variation in the level of expression of certain cytokines, such as TNFα or IL-10, may also increase susceptibility to autoimmune disease.

A further important factor in disease susceptibility is the hormonal status of the patient. Many autoimmune diseases show a strong sex bias, which appears in most cases to relate to the hormonal status of women.

IMMUNOPATHOGENIC MECHANISMS IN AUTOIMMUNE DISEASES The mechanisms of tissue injury in autoimmune diseases can be divided into antibody-mediated and cell-mediated processes. Representative examples are listed in Table 299-3.

The pathogenicity of autoantibodies can be mediated through several mechanisms, including opsonization of soluble factors or cells, activation of an inflammatory cascade via the complement system, and interference with the physiologic function of soluble molecules or cells.

In autoimmune thrombocytopenic purpura, opsonization of platelets targets them for elimination by phagocytes. Likewise, in autoimmune hemolytic anemia, binding of immunoglobulin to red cell membranes leads to phagocytosis and lysis of the opsonized cell. Goodpasture's syndrome, a disease characterized by lung hemorrhage

and severe glomerulonephritis, represents an example of antibody binding leading to local activation of complement and neutrophil accumulation and activation. The autoantibody in this disease binds to the α_3 chain of type IV collagen in the basement membrane. In SLE, activation of the complement cascade at sites of immunoglobulin deposition in renal glomeruli is considered to be a major mechanism of renal damage.

Autoantibodies can also interfere with normal physiologic functions of cells or soluble factors. Autoantibodies against hormone receptors can lead to stimulation of cells or to inhibition of cell function through interference with receptor signaling. For example, long-acting thyroid stimulators, which are autoantibodies that bind to the receptor for thyroid-stimulating hormone, are present in Graves' disease and function as agonists, causing the thyroid to respond as if there were an excess of thyroid-stimulating hormone. Alternatively, antibodies to the insulin receptor can cause insulin-resistant diabetes mellitus through receptor blockade. In myasthenia gravis, autoantibodies to the acetylcholine receptor can be detected in 85 to 90% of patients and are responsible for muscle weakness. The exact location of the antigenic epitope, the valence and affinity of the antibody, and perhaps other characteristics determine whether activation or blockade results from antibody binding.

Antiphospholipid antibodies are associated with thromboembolic events in primary and secondary antiphospholipid syndrome and have also been associated with fetal wastage. The major antibody is directed to the phospholipid–β_2-glycoprotein I complex and appears to exert a procoagulant effect. In pemphigus vulgaris, autoantibodies bind to a component of the epidermal cell desmosome, desmoglein 3, and play a role in the induction of the disease. They exert their pathologic effect by disrupting cell-cell junctions through stimulation of the production of epithelial proteases, leading to blister formation. Cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA), found in Wegener's granulomatosis, is an antibody to an intracellular antigen, the 29-kDa serine protease (proteinase-3). In vitro experiments have shown that IgG anti-c-ANCA causes cellular activation and degranulation of primed neutrophils.

It is important to note that autoantibodies of a given specificity may cause disease only in genetically susceptible hosts, as has been shown in experimental models of myasthenia gravis. Finally, some autoantibodies seem to be markers for disease but have as yet no known pathogenic potential.

AUTOIMMUNE DISEASE Manifestations of autoimmunity are found in a large number of pathologic conditions. However, their presence does not necessarily imply that the pathologic process is an autoimmune disease. A number of attempts to establish formal criteria for the diagnosis of autoimmune diseases have been made, but none is universally accepted. One set of criteria is shown in Table 299-4; however, this should be viewed merely as a guide in consideration of the problem.

To classify a disease as autoimmune, it is necessary to demonstrate that the immune response to a self-antigen causes the observed pathology. Initially, the demonstration that antibodies against the affected tissue could be detected in the serum of patients suffering from various diseases was taken as evidence that these diseases had an autoimmune basis. However, such autoantibodies are also found when tissue damage is caused by trauma or infection, and the autoantibody is secondary to tissue damage. Thus, it is necessary to show that autoimmunity is pathogenic before classifying a disease as autoimmune.

If the autoantibodies are pathogenic, it may be possible to transfer disease to experimental animals by the administration of autoantibodies, with the subsequent development of pathology in the recipient similar to that seen in the patient from whom the antibodies were obtained. This has been shown, for example, in Graves' disease. Some autoimmune diseases can be transferred from mother to fetus and are observed in the newborn babies of diseased mothers. The symptoms of the disease in the newborn usually disappear as the levels of the maternal antibody decrease. An exception is congenital heart block, in which damage to the developing conducting system of the heart as a result of transfer of anti-Ro antibody from the mother results in permanent heart block.

TABLE 299-4 Human Autoimmune Disease: Presumptive Evidence for an Immunologic Pathogenesis

Major Criteria
1. Presence of autoantibodies or evidence of cellular reactivity to self
2. Documentation of relevant autoantibody or lymphocytic infiltrate in the pathologic lesion.
3. Demonstration that relevant autoantibody or T cells can cause tissue pathology
   a. Transplacental transmission
   b. Adaptive transfer into animals
   c. In vitro impact on cellular function

Supportive Evidence
1. Reasonable animal model
2. Beneficial effect from immunosuppressive agents
3. Association with other evidence of autoimmunity
4. No evidence of infection or other obvious cause

In most situations, the critical factors that determine when the development of autoimmunity results in autoimmune disease have not been delineated. The relationship of autoimmunity to the development of autoimmune disease may relate to the fine specificity of the antibodies or T cells or their specific effector capabilities. In many circumstances a mechanistic understanding of the pathogenic potential of autoantibodies has not been established. In some autoimmune diseases, biased production of cytokines by helper T (T_H) cells may play a role in pathogenesis. In this regard, T cells can differentiate into specialized effector cells that predominantly produce interferon γ (T_H1) or IL-4 (T_H2) (Chap. 295). The former facilitate macrophage activation and classic cell-mediated immunity, whereas the latter are thought to have regulatory functions and are involved in the resolution of normal immune responses and also the development of responses to a variety of parasites. In a number of autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis, type 1 diabetes mellitus, and Crohn's disease, there appears to be biased differentiation of T_H1 cells, with resultant organ damage.

ORGAN-SPECIFIC VERSUS SYSTEMIC AUTOIMMUNE DISEASES Autoimmune diseases form a spectrum, from those specifically affecting a single organ to systemic disorders with involvement of many organs (Table 299-5). Hashimoto's autoimmune thyroiditis is an example of an organ-specific autoimmune disease (Chap. 320). In this disorder, there is a specific lesion in the thyroid associated with infiltration of mono-

TABLE 299-5 Some Autoimmune Diseases

ORGAN SPECIFIC	
Graves' disease	Autoimmune hemolytic anemia
Hashimoto's thyroiditis	Autoimmune thrombocytopenic purpura
Autoimmune polyglandular syndrome	Pernicious anemia
Type 1 diabetes mellitus	Myasthenia gravis
Insulin-resistant diabetes mellitus	Multiple sclerosis
Immune-mediated infertility	Guillain-Barré syndrome
Autoimmune Addison's disease	Stiff-man syndrome
Pemphigus vulgaris	Acute rheumatic fever
Pemphigus foliaceus	Sympathetic ophthalmia
Dermatitis herpetiformis	Goodpasture's syndrome
Autoimmune alopecia	
Vitiligo	
ORGAN NONSPECIFIC (SYSTEMIC)	
Systemic lupus erythematosus	Wegener's granulomatosis
Rheumatoid arthritis	Antiphospholipid syndrome
Systemic necrotizing vasculitis	Sjögren's syndrome

nuclear cells and damage to follicular cells. Antibody to thyroid constituents can be demonstrated in nearly all cases. Other organ- or tissue-specific autoimmune disorders include pemphigus vulgaris, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, Goodpasture's syndrome, myasthenia gravis, and sympathetic ophthalmia. One important feature of some organ-specific auto-immune diseases is the tendency for overlap, such that an individual with one specific syndrome is more likely to develop a second syndrome. For example, there is a high incidence of pernicious anemia in individuals with autoimmune thyroiditis. More striking is the tendency for individuals with an organ-specific autoimmune disease to develop multiple other manifestations of autoimmunity without the development of associated organ pathology. Thus, as many as 50% of individuals with pernicious anemia have non-cross-reacting antibodies to thyroid constituents, whereas patients with myasthenia gravis may develop antinuclear antibodies, antithyroid antibodies, rheumatoid factor, antilymphocyte antibodies, and polyclonal hypergammaglobulinemia. Part of the explanation for this may relate to the genetic elements shared by individuals with these different diseases.

Systemic autoimmune diseases differ from organ-specific diseases in that pathologic lesions are found in multiple, diverse organs and tissues. The hallmark of these conditions is the demonstration of associated relevant autoimmune manifestations that are likely to be etiologic in the organ pathology. SLE represents the prototype of these disorders because of its abundance of autoimmune manifestations.

SLE is a disease of protean manifestations that characteristically involves the kidneys, joints, skin, serosal surfaces, blood vessels, and central nervous system (Chap. 300). The disease is associated with a vast array of autoantibodies whose production appears to be a part of a generalized hyperreactivity of the humoral immune system. Other features of SLE include generalized B cell hyperresponsiveness, polyclonal hypergammaglobulinemia, and increased titers of antibodies to commonly encountered viral antigens.

TREATMENT

Treatment of autoimmune diseases can focus on either suppressing the induction of autoimmunity, restoring normal regulatory mechanisms, or inhibiting the effector mechanisms. To eliminate autoreactive cells, immunosuppressive or ablative therapies are most commonly used. In recent years, cytokine blockade has been demonstrated to be effective in preventing immune activation in some diseases. New therapies are currently in clinical trials to target lymphoid cells more specifically, either by blocking a costimulatory signal needed for T or B cell activation, by eliminating the effector T cells or B cells, or by using autoantigen itself to induce tolerance. The major advance in inhibiting effector mechanisms has been the introduction of cytokine blockade, targeting at TNF or IL-1, that appears to limit organ damage in some diseases. Therapies that prevent target organ damage or support target organ function remain an important therapeutic approach to autoimmune disease.

300 SYSTEMIC LUPUS ERYTHEMATOSUS

Bevra Hannahs Hahn

DEFINITION AND PREVALENCE Systemic lupus erythematosus (SLE) is an autoimmune disease in which organs, tissues, and cells undergo damage mediated by tissue-binding autoantibodies and immune complexes. Ninety percent of patients are women of child-bearing years; people of both genders, all ages, and all ethnic groups are susceptible. Prevalence of SLE in the United States is 15 to 50 per 100,000; the highest prevalence among ethnic groups is in African Americans.

PATHOGENESIS AND ETIOLOGY SLE is caused by interactions between susceptibility genes and environmental factors, resulting in abnormal immune responses. The immune responses include hyperreactivity and hypersensitivity of T and B lymphocytes and ineffective regulation of antigen availability and of ongoing antibody responses. Hyperreactivity of T and B cells is indicated by increased surface expression of molecules such as HLA-D and CD40L, showing that cells are easily activated by antigens that induce first-activating signals and by molecules that drive cells to full activation via second signals. The end result of these abnormalities is sustained production of pathogenic autoantibodies and formation of immune complexes that bind target tissues, resulting in (1) sequestration and destruction of Ig-coated circulating cells; (2) fixation and cleaving of complement proteins; and (3) release of chemotaxins, vasoactive peptides, and destructive enzymes into tissues. Many autoantibodies in persons with SLE are directed against DNA/protein or RNA/protein complexes such as nucleosomes, some nucleolar RNA, and spliceosomal RNA (Table 300-1). During apoptosis these antigens migrate to cell surfaces, where they are enclosed in blebs, and membrane phospholipids change orientation so that antigenic portions are near the surface. Intracellular molecules altered during cell activation or damage migrate to the cell surface. All these antigens near or in cell surfaces probably activate the immune system to produce autoantibodies. In individuals with SLE, phagocytosis and removal of apoptotic cells and of immune complexes are impaired. Thus, in SLE, antigens are available; they are presented in locations recognized by the immune system; and the antigens, autoantibodies, and immune complexes persist for prolonged periods of time, allowing tissue damage to accumulate to the point of clinical illness.

SLE is a multigenic disease. It is likely that alleles of multiple normal genes each contribute a small amount to the abnormal immune responses; if enough variations accumulate, disease results. Some predisposing genes are located in the HLA region (particularly HLA class II DR and DQ genes, and HLA class III genes encoding C′2 and C′4). The relevant HLA DR/DQ genes increase risk for SLE by approximately twofold if one susceptibility haplotype is present and by four- to sixfold if two or more are present. Some proteins important in clearing apoptotic cells play a role in genetic susceptibility; for example, homozygous deficiencies of early components of complement Clq, C′2, and C′4 and certain alleles of mannose-binding ligand increase the risk for SLE. Clq deficiency confers the highest genetic risk known but is rare. There are at least five chromosomal regions independent of HLA that contain susceptibility genes. Within one of these regions on chromosome 1 are alleles encoding Fcγ receptors that bind subsets of IgG (IgG1, -2, or -3): African Americans inheriting one allele of FcγRIIA have a receptor that binds the Ig in immune complexes weakly; those persons have increased risk for lupus nephritis. Caucasians and Asians in some populations with alleles of FcγRIIIA that bind Ig weakly are predisposed to SLE. A region on chromosome 16 contains genes that predispose to SLE, rheumatoid arthritis, pso-

riasis, and Crohn's disease, suggesting the presence of "autoimmunity genes" that, when interacting with other genes, predispose to different autoimmune diseases. Thus, SLE is modified by multiple susceptibility genes, some of which interact. There are likely to be protective gene alleles as well. These gene combinations influence immune responses to the external and internal environment; when such responses are too high and/or too prolonged, autoimmunity results.

Female gender is permissive for SLE; females of many mammalian species make higher antibody responses than males. Women exposed to estrogen-containing oral contraceptives or hormone replacement have an increased risk of developing SLE (approximately twofold). Estradiol binds to receptors on T and B lymphocytes, increasing activation and survival of those cells, thus favoring prolonged immune responses.

Several environmental stimuli may influence SLE. Exposure to ultraviolet light causes SLE flares in approximately 70% of patients, possibly by increasing apoptosis in keratinocytes and other cells or by altering DNA and intracellular proteins to make them antigenic. It is likely that various infections that stimulate immune responses (antibodies and activated T lymphocytes) that cross-react with self or responses that, as they mature, develop the ability to recognize self can promote autoimmune responses that lead to SLE. The observation that children and adults with SLE are more likely to be infected by Epstein-Barr Virus (EBV) than age-, gender-, and ethnically matched controls without SLE is intriguing, because EBV activates B lymphocytes and also contains amino acid sequences that mimic sequences on human spliceosomes—a common autoantibody specificity in people with SLE. Thus, interplay between genetic susceptibility, gender, and environmental stimuli may result in autoimmunity.

TABLE 300-1 *Autoantibodies of SLE*

Antibody	Prevalence, %	Antigen Recognized	Clinical Utility
Antinuclear antibodies	98	Multiple nuclear	Best screening test; repeated negative tests make SLE unlikely
Anti-dsDNA	70	DNA (double-stranded)	High titers are SLE-specific and in some patients correlate with disease activity, nephritis, vasculitis
Anti-Sm	25	Protein complexed to 6 species of nuclear U1 RNA	Specific for SLE; no definite clinical correlations; most patients also have anti-RNP; more common in African Americans and Asians than Caucasians
Anti-RNP	40	Protein complexed to U1 RNAγ	Not specific for SLE; high titers associated with syndromes that have overlap features of several rheumatic syndromes including SLE; more common in African Americans than Caucasians
Anti-Ro (SS-A)	30	Protein complexed to hY RNA, primarily 60 kDa and 52 kDa	Not specific for SLE; associated with sicca syndrome, subacute cutaneous lupus, and neonatal lupus with congenital heart block; associated with decreased risk for nephritis
Anti-La (SS-B)	10	47-kDa protein complexed to hY RNA	Usually associated with anti-Ro; associated with decreased risk for nephritis
Antihistone	70	Histones associated with DNA (in nucleosome, chromatin)	More frequent in drug-induced lupus than in SLE
Antiphospholipid	50	Phospholipids, β_2 glycoprotein 1 cofactor, prothrombin	Three tests available—ELISAs for cardiolipin and B2G1, sensitive prothrombin time (DRVVT); predisposes to clotting, fetal loss, thrombocytopenia
Antierythrocyte	60	Erythrocyte membrane	Measured as direct Coombs' test; a small proportion develop overt hemolysis
Antiplatelet	30	Surface and altered cytoplasmic antigens in platelets	Associated with thrombocytopenia but sensitivity and specificity are not good; this is not a useful clinical test
Antineuronal	60	Neuronal and lymphocyte surface antigens	In some series a positive test in CSF correlate with active CNS lupus
Antiribosomal P	20	Protein in ribosomes	In some series a positive test in serum correlates with depression or psychosis due to CNS lupus

Note: ELISA, enzyme-linked immunosorbent assay; DRVVT, dilute Russell viper venom time; CSF, cerebrospinal fluid; CNS, central nervous system.

For maximal production of harmful autoantibodies, B cells require help from T cells, and those functions of T and B cells are normally downregulated by several mechanisms. In murine SLE models, many downregulating networks are abnormal, including generation of multiple types of regulatory and natural killer T cells and of humoral idiotypic downregulating networks.

PATHOLOGY In SLE, biopsies of affected skin show deposition of Ig at the dermal-epidermal junction (DEJ), injury to basal keratinocytes, and inflammation dominated by T lymphocytes in the DEJ and around blood vessels and dermal appendages. Clinically unaffected skin may also show Ig deposition at the DEJ. In renal biopsies, the pattern of injury is important in diagnosis and in selecting the best therapy. The World Health Organization (WHO) has classified lupus nephritis as grade I (no histologic changes), II (proliferative changes confined to the mesangium), III (proliferative changes in tufts of 10 to 50% of glomeruli; higher proportions of glomeruli affected suggest worse prognosis), IV [diffuse proliferative glomerulonephritis (DPGN) affecting >50% of glomeruli], V (predominantly membranous changes with various degrees of proliferation), and VI (end stage, scarred glomeruli). In addition, pathologists report the extent of inflammatory (potentially reversible) and chronic (irreversible scarring in glomeruli, renal tubules, and blood vessels) changes. In general, treatment for lupus nephritis is not recommended in patients with class I or II disease or with extensive irreversible changes. In contrast, aggressive immunosuppression is recommended for patients with class III, IV, or V inflammatory proliferative lesions because the majority of those individuals, if untreated, develop end-stage renal disease (ESRD) within 2 years. In children, a diagnosis of SLE can be established on the basis of renal histology without meeting additional diagnostic criteria (Table 300-2). Histologic abnormalities in blood vessels are not specific for SLE: leukocytoclastic vasculitis is most common (Chap. 306). Lymph node biopsies show nonspecific diffuse chronic inflammation.

DIAGNOSIS The diagnosis of SLE is based on characteristic clinical features and autoantibodies. Criteria for classification are listed in Table 300-2, and an algorithm for diagnosis and initial therapy is shown in Fig. 300-1. The criteria are intended for confirming the diagnosis of SLE in patients included in studies; the author uses them in individual patients for estimating the probability that a disease is SLE. Any combination of 4 or more of 11 criteria, well-documented at any time during a patient's history, makes it likely that the patient has SLE (specificity and sensitivity are ~95% and 75%, respectively). In many

TABLE 300-2 Classification Criteria for the Diagnosis of SLE[a]

Malar rash	Fixed erythema, flat or raised, over the malar eminences
Discoid rash	Erythematous circular raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur
Photosensitivity	Exposure to ultraviolet light causes rash
Oral ulcers	Includes oral and nasopharyngeal ulcers, observed by physician
Arthritis	Nonerosive arthritis of two or more peripheral joints, with tenderness, swelling, or effusion
Serositis	Pleuritis or pericarditis documented by ECG or rub or evidence of effusion
Renal disorder	Proteinuria >0.5 g/d or ≥3+, or cellular casts
Neurologic disorder	Seizures or psychosis without other causes
Hematologic disorder	Hemolytic anemia or leukopenia (<4000/μL) or lymphopenia (<1500/μL) or thrombocytopenia (<100,000/μL) in the absence of offending drugs
Immunologic disorder	Anti-dsDNA, anti-Sm, and/or anti-phospholipid
Antinuclear antibodies	An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time in the absence of drugs known to induce ANAs

[a] If ≥4 of these criteria, well documented, are present at any time in a patient's history, the diagnosis is likely to be SLE. Specificity is ~95%: sensitivity is ~75%.
Note: ECG, electrocardiography; dsDNA, double-stranded DNA; ANA, antinuclear antibodies.
Source: Criteria published by EM Tan et al: Arthritis Rheum 25:1271, 1982; updated by MC Hochberg, Arthritis Rheum 40:1725, 1997.

patients, additional criteria accrue over time. Antinuclear antibodies (ANA) are positive in >95% of patients during the course of disease; repeated negative tests suggest that the diagnosis is not SLE. High-titer IgG antibodies to double-stranded DNA and antibodies to the Sm antigen are both specific for SLE and, therefore, favor the diagnosis in the presence of compatible clinical manifestations. The presence in an individual of multiple autoantibodies without clinical symptoms should not be considered diagnostic for SLE, although such persons are at increased risk.

INTERPRETATION OF CLINICAL MANIFESTATIONS When a diagnosis of SLE is made, it is important to establish the severity and potential reversibility of the illness and estimate the possible consequences of various therapeutic interventions. In the following paragraphs, descriptions of some disease manifestations begin with relatively mild problems and progress to those more life-threatening.

Overview and Systemic Manifestations At its onset, SLE may involve one or several organ systems; over time, additional manifestations of disease may occur (Table 300-3). Most of the autoantibodies characteristic of each person are present at the time clinical manifestations appear (Tables 300-1 and 300-2). Severity of SLE varies from mild and intermittent to severe and fulminant. Most patients experience exacerbations interspersed with periods of relative quiescence; however, permanent complete remissions (absence of symptoms with no treatment) are rare. Systemic symptoms, particularly fatigue and myalgias/arthralgias, are present most of the time. Severe systemic illness requiring glucocorticoid therapy can occur with fever, prostration, weight loss, and anemia in addition to any other organ-targeted manifestations.

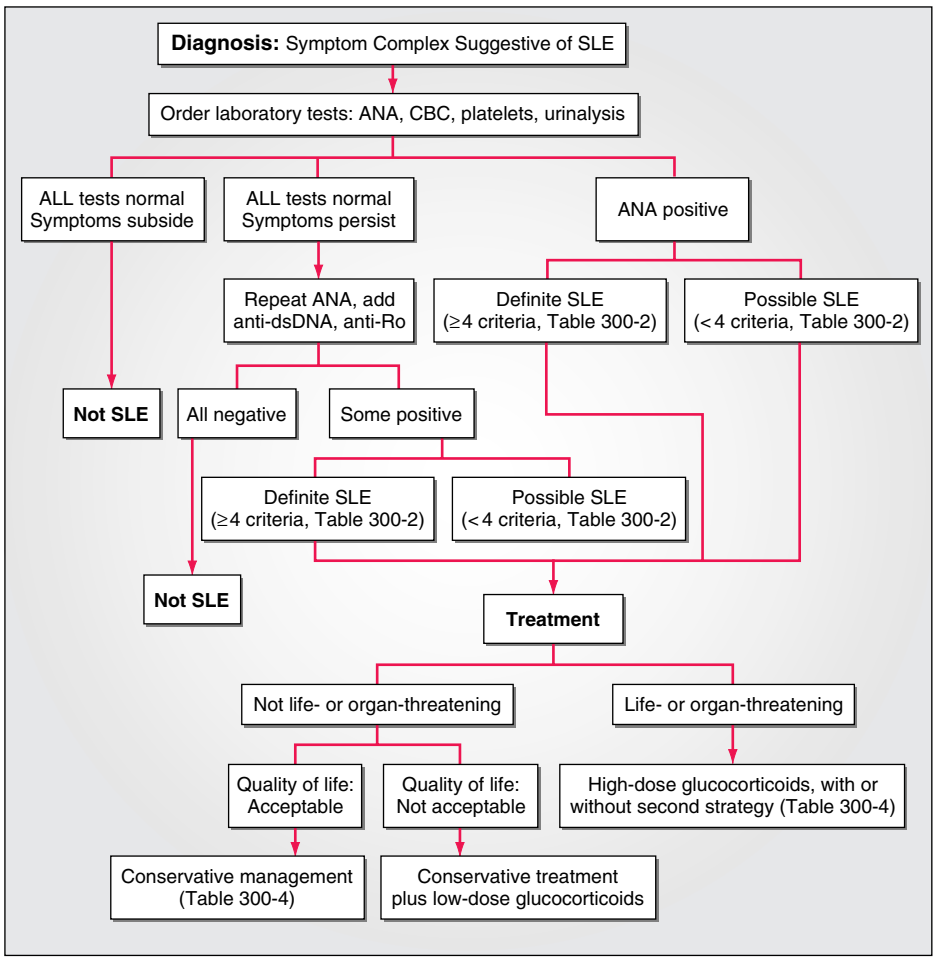

FIGURE 300-1 Algorithm for diagnosis and initial therapy of SLE. ANA, antinuclear antibodies; CBC, complete blood count.

Musculoskeletal Manifestations Most people with SLE have intermittent polyarthritis, varying from mild to disabling, characterized by soft tissue swelling and tenderness in joints, most commonly in hands, wrists, and knees. Presence of visible synovitis suggests active systemic disease. Joint deformities (hands and feet) develop in only 10%. Erosions on joint x-rays are rare; their presence suggests a non-lupus inflammatory arthropathy such as rheumatoid arthritis (Chap. 301). If pain persists in a single joint, such as knee, shoulder, or hip, a diagnosis of ischemic necrosis of bone should be considered, particularly if there are no other manifestations of active SLE. The prevalence of ischemic necrosis of bone is increased in SLE, especially in patients treated with systemic glucocorticoids. Myositis with clinical muscle weakness, elevated creatine kinase levels, and biopsy evidence of muscle necrosis and inflammation can occur, although most patients have myalgias without frank myositis. Glucocorticoid and, rarely, antimalarial therapies can also cause muscle weakness; these adverse effects must be distinguished from active disease.

Cutaneous Manifestations Lupus dermatitis can be classified as discoid lupus erythematosus (DLE), systemic rash, subacute cutaneous lupus erythematosus (SCLE), or "other." Discoid lesions are roughly circular with slightly raised, scaly hyperpigmented erythematous rims and depigmented, atrophic centers in which all dermal appendages are permanently destroyed. Lesions can be disfiguring, partic-

TABLE 300-3 Clinical Manifestations of SLE and Prevalence over the Entire Course of Disease[a]

Systemic: Fatigue, malaise, fever, anorexia, weight loss	95
Musculoskeletal	95
Arthralgias/myalgias	95
Nonerosive polyarthritis	60
Hand deformities	10
Myopathy/myositis	25/5

Vasculitis	5

[a] Numbers indicate percent of patients who have the manifestation sometime during the course of illness.

Note: TIA, transient ischemic attack; ARDS, acute respiratory distress syndrome.

ularly on the face and scalp. Treatment consists primarily of local glucocorticoids and systemic antimalarials. Only 5% of people with DLE have SLE (although half have positive ANA); however, among people with SLE, as many as 20% have DLE. The most common SLE rash is a photosensitive, slightly raised erythema, occasionally scaly, on the face (particularly the cheeks and nose—the "butterfly" rash), ears, chin, V region of the neck, upper back, and extensor surfaces of the arms. Worsening of this rash often accompanies flare of systemic disease. SCLE consists of scaly red patches similar to psoriasis or attacks of circular red-rimmed lesions. Patients with these manifestations are exquisitely photosensitive; most have antibodies to Ro (SS-A). Many other rashes are seen less frequently in SLE, including recurring urticaria, lichen planus–like dermatitis, bullae, and panniculitis ("lupus profundus"). Rashes of SLE can be minor or very severe; they may be the major disease manifestation. Small, painful ulcerations on the oral or nasal mucosa are common in SLE: the lesions resemble aphthous ulcers and usually indicate systemic disease activity.

Renal Manifestations Nephritis is usually the most serious manifestation of SLE, particularly since nephritis and infection are the leading causes of mortality in the first decade of disease. Since nephritis is asymptomatic in most lupus patients, urinalysis should be ordered in any person suspected of having SLE. The classification of lupus nephritis is primarily histologic (see "Pathology," above). Renal biopsy is useful in planning current and near-future therapies. Patients with dangerous proliferative forms of glomerular damage usually have microscopic hematuria and proteinuria (>500 mg per 24 h); approximately one-half develop nephrotic syndrome, and most develop hypertension. If DPGN is untreated, virtually all patients develop ESRD within 2 years of diagnosis. Therefore, aggressive immunosuppression is indicated (usually systemic glucocorticoids plus a cytotoxic drug), unless damage is irreversible. African-American individuals are more likely to develop ESRD than are Caucasians, even with the most current therapies. Overall in the United States, ~20% of individuals with DPGN die or develop ESRD within 10 years of diagnosis. Such individuals require aggressive control of SLE and of the complications of renal disease and of therapy. A small proportion of SLE patients with proteinuria (usually nephrotic) have membranous glomerular changes without proliferation on renal biopsy. Their outcome is better than for those with DPGN, but proteinuria is less likely to improve on lupus nephritis immunosuppressive therapies. Lupus nephritis tends to be an ongoing disease, with flares requiring re-treatment over many years. For most people with lupus nephritis, accelerated atherosclerosis becomes important after several years of disease; attention must be given to control of blood pressure, hyperlipidemia, and hyperglycemia.

Nervous System Manifestations There are many central nervous system (CNS) and peripheral nervous system manifestations of SLE; in some patients these are the major cause of morbidity and mortality. It is useful to approach this diagnostically by asking first whether the symptoms result from SLE or another condition (such as infection in immunosuppressed individuals). If symptoms are related to SLE, it should be determined whether they are caused by a diffuse process or vascular occlusive disease. The most common manifestation of diffuse CNS lupus is cognitive dysfunction, particularly difficulties with memory and reasoning. Headaches are also common; when excruciating, they often indicate SLE flare; when milder, they are difficult to distinguish from migraine or tension headaches. Seizures of any type may be caused by lupus; treatment often requires both anti-seizure and immunosuppressive therapies. Psychosis can be the dominant manifestation of SLE; it must be distinguished from glucocorticoid-induced psychosis. The latter usually occurs in the first weeks of glucocorticoid therapy, at doses of ≥40 mg of prednisone or equivalent; psychosis resolves over several days after glucocorticoids are decreased or stopped. Myelopathy is not rare and is often disabling; high-dose glucocorticoid therapy is recommended and should be started within hours or a few days of the onset of symptoms.

Vascular Occlusions The prevalence of transient ischemic attacks, strokes, and myocardial infarctions is increased in patients with SLE. These vascular events are increased in, but not exclusive to, SLE patients with antibodies to phospholipids (aPL). Ischemia in the brain can be caused by focal occlusion (either noninflammatory or associated with vasculitis) or by embolization from carotid artery plaque or from fibrinous vegetations of Libman-Sachs endocarditis. Appropriate tests for aPL (see below) and for sources of emboli should be ordered in such patients to estimate the need for, intensity of, and duration of anti-inflammatory and/or anticoagulant therapies. In SLE, myocardial infarctions are primarily manifestations of accelerated atherosclerosis. The increased risk for vascular events is as much as 50-fold in women

with SLE <45 years old compared to healthy women. Characteristics associated with increased risk for atherosclerosis include older age, hypertension, dyslipidemia, aPL, repeated high scores for disease activity, and high cumulative doses of glucocorticoids. When it is most likely that an event results from clotting, long-term anticoagulation is the therapy of choice. Two processes can occur at once—vasculitis plus bland vascular occlusions—in which case it is appropriate to treat with anticoagulation plus immunosuppression.

Pulmonary Manifestations The most common pulmonary manifestation of SLE is pleuritis with or without pleural effusion. This manifestation, when mild, may respond to treatment with nonsteroidal anti-inflammatory drugs (NSAIDs); when more severe, patients require a brief course of glucocorticoid therapy. Pulmonary infiltrates also occur as a manifestation of active SLE and are difficult to distinguish from infection on imaging studies. Life-threatening pulmonary manifestations include interstitial inflammation, leading to fibrosis, and intraalveolar hemorrhage; both of these probably require aggressive immunosuppressive and supportive treatments early after their onset.

Cardiac Manifestations Pericarditis is the most frequent cardiac manifestation; it usually responds to anti-inflammatory therapy and infrequently leads to tamponade. More serious cardiac manifestations are myocarditis and fibrinous endocarditis of Libman-Sachs. The endocardial involvement can lead to valvular insufficiencies, most commonly of the mitral or aortic valves, or to embolic events. It has not been proved that glucocorticoid or other immunosuppressive therapies lead to improvement of lupus myocarditis or endocarditis, but it is usual practice to administer a trial of high-dose steroids along with appropriate supportive therapy for heart failure, arrhythmia, or embolic events. As discussed above, patients with SLE are at increased risk for myocardial infarction, usually due to accelerated atherosclerosis.

Hematologic Manifestations The most frequent hematologic manifestation of SLE is anemia, usually normochromic normocytic, reflecting chronic illness. Hemolysis can be rapid in onset and severe, requiring high-dose glucocorticoid therapy, which is effective in most patients. Leukopenia is also common and almost always consists of lymphopenia, not granulocytopenia; this rarely predisposes to infections and by itself usually does not require therapy. Thrombocytopenia may be a recurring problem. If platelet counts are >40,000/μL and abnormal bleeding is absent, therapy may not be required. High-dose glucocorticoid therapy (e.g., 1 mg/kg per day of prednisone or equivalent) is usually effective for the first few episodes of severe thrombocytopenia. Recurring or prolonged hemolytic anemia or thrombocytopenia, or disease requiring an unacceptably high dose of daily glucocorticoids, should be treated with an additional strategy (see "Treatment," below).

Gastrointestinal Manifestations Nausea, sometimes with vomiting, and diarrhea can be manifestations of an SLE flare, as can diffuse abdominal pain caused by autoimmune peritonitis. Increases in serum AST and ALT are common when SLE is active. These manifestations usually improve promptly during systemic glucocorticoid therapy. Vasculitis involving the intestine may be life-threatening; perforations, ischemia, bleeding, and sepsis are frequent complications. Aggressive immunosuppressive therapy with high-dose glucocorticoids is recommended for short-term control; evidence of recurrence is an indication for additional therapies.

Ocular Manifestations Sicca syndrome (Sjögren's syndrome; Chap. 304) and nonspecific conjunctivitis are common in SLE and rarely threaten vision. In contrast, retinal vasculitis and optic neuritis are serious manifestations: blindness can develop over days to weeks. Aggressive immunosuppression is recommended, although there are no controlled trials to prove effectiveness. Complications of glucocorticoid therapy include cataracts (common) and glaucoma.

LABORATORY TESTS Laboratory tests serve (1) to establish or rule out the diagnosis; (2) to follow the course of disease, particularly to suggest that a flare is occurring or organ damage is developing; and (3) to identify adverse effects of therapies.

Tests for Autoantibodies (See Tables 300-1 and 300-2) Diagnostically, the most important autoantibodies to detect are ANA since the test is positive in >95% of patients, usually at the onset of symptoms. A few patients develop ANA within 1 year of symptom onset; repeated testing may then be useful. ANA-negative lupus exists but is very rare in adults and is usually associated with other autoantibodies (anti-Ro or anti-DNA). High-titer IgG antibodies to double-stranded DNA (dsDNA) (but not to single-stranded DNA) are specific for SLE. There is no international standardized test for ANA; variability between different service laboratories is high. Enzyme-linked immunosorbent assays (ELISA) and immunofluorescent reactions of sera with the dsDNA in the flagellate *Crithidia lucilliae* have ~60% sensitivity for SLE; identification of high-avidity anti-dsDNA in the Farr assay is not as sensitive but may correlate better with risk for nephritis. Titers of anti-dsDNA vary over time. In some patients, increase in quantities of anti-dsDNA herald a flare, particularly of nephritis or vasculitis. Antibodies to Sm are also specific for SLE and assist in diagnosis; anti-Sm antibodies do not usually correlate with disease activity or clinical manifestations. aPL are not specific for SLE, but their presence fulfills one classification criterion and they identify patients at increased risk for venous or arterial clotting, thrombocytopenia, and fetal loss. There are two widely accepted tests that measure different antibodies (anticardiolipin and the lupus anticoagulant): (1) ELISA for anticardiolipin (internationally standardized with good reproducibility) and (2) a sensitive phospholipid-based activated prothrombin time such as the dilute Russell venom viper test. Some centers also recommend measurement of antibodies to β_2 glycoprotein 1, a serum protein cofactor that is the target of most antibodies to cardiolipin and some lupus anticoagulants. High titers of IgG anticardiolipin (>50 IU) indicate high risk for a clinical episode of clotting. Quantities of aPL may vary markedly over time; repeated testing is justified if clinical manifestations of the antiphospholipid antibody syndrome (APS) appear. To make a diagnosis of APS, with or without SLE, requires the presence of clotting and/or repeated fetal losses plus at least two positive tests for aPL, at least 6 weeks apart.

An additional autoantibody test with predictive value (not used for diagnosis) detects anti-Ro, which indicates increased risk for neonatal lupus, sicca syndrome, and SCLE. Women with child-bearing potential and SLE should be screened for aPL and anti-Ro.

Standard Tests for Diagnosis Screening tests for complete blood count, platelet count, and urinalysis may detect abnormalities that contribute to the diagnosis and influence management decisions.

Tests for Following Disease Course It is useful to follow tests that indicate the status of organ involvement known to be present during SLE flares. These might include hemoglobin levels, platelet counts, urinalysis, and serum levels of creatinine or albumin. There is great interest in identification of additional markers of disease activity. Candidates include levels of anti-DNA antibodies, several components of complement (C′3 is most widely available), activated complement products, soluble interleukin (IL) 2, and urinary monocyte chemotactic protein 1. None are uniformly agreed upon as reliable indicators of response or flare. The physician should determine for each patient whether certain laboratory test changes predict flare. If so, altering therapy in response to these changes is acceptable to prevent flares. In addition, given the increased prevalence of atherosclerosis in SLE, it is advisable to follow the recommendations of the National Cholesterol Education Program for testing.

TREATMENT

There is no cure for SLE, and complete sustained remissions are rare. Therefore, the physician should plan to control acute, severe flares then develop maintenance strategies that suppress symptoms to an accept-

able level and prevent organ damage. Usually patients will endure some adverse effects of medications. Therapeutic choices depend on: (1) whether disease manifestations are life-threatening or likely to cause organ damage, justifying aggressive therapies; (2) whether manifestations are potentially reversible; and (3) the best approaches to preventing complications of disease and its treatments. Therapies, doses, and adverse effects are listed in (Table 300-4).

Conservative Therapies for Management of Non-Life-Threatening Disease Among patients with fatigue, pain, and autoantibodies of SLE, but without major organ involvement, management can be directed to suppression of symptoms. Analgesics and antimalarials are mainstays. NSAIDs are useful analgesics/anti-inflammatories, particularly for arthritis/arthralgias; however, SLE patients compared to the general population are at increased risk for NSAID-induced aseptic meningitis, elevated serum transaminases, hypertension, and renal dysfunction. Cyclooxygenase-2 specific inhibitors, compared to nonspecific

TABLE 300-4 *Medications for the Management of SLE*

Medication	*Dose Range*	*Drug Interactions*	*Serious or Common Adverse Effects*
NSAIDs, salicylates (Ecotrin[a] and St. Joseph's aspirin[a] approved by FDA for use in SLE)	Doses toward upper limit of recommended range usually required	A2R/ACE inhibitors, glucocorticoids, fluconazole, methotrexate, thiazides	NSAIDs: Higher incidence of aseptic meningitis, transaminitis, decreased renal function, vasculitis of skin Salicylates: ototoxicity, tinnitus Both: GI events and symptoms, allergic reactions, dermatitis, dizziness, acute renal failure, edema, hypertension
Topical glucocorticoids	Mid-potency for face; mid to high potency other areas	None known	Atrophy of skin, contact dermatitis, folliculitis, hypopigmentation, infection
Topical sunscreens	SPF 15 at least; 30+ preferred	None known	Contact dermatitis
Hydroxychloroquine[a] (quinacrine can be added or substituted)	200–400 mg qd (100 mg qd)	None known	Retinal damage, agranulocytosis, aplastic anemia, ataxia, cardiomyopathy, dizziness, myopathy, ototoxicity, peripheral neuropathy, pigmentation of skin, seizures, thrombocytopenia Quinacrine usually causes diffuse yellow skin coloration
DHEA (dehydroepiandrosterone)	200 mg qd	Unclear	Acne, menstrual irregularities, high serum levels of testosterone
Methotrexate (for dermatitis, arthritis)	10–25 mg once a week, with folic acid; decrease dose if CrCl $<$ 60 mL/min	Acitretin, leflunomide, NSAIDs and salicylates, penicillins, probenecid, sulfonamides, trimethoprim	Anemia, bone marrow suppression, leukopenia, thrombocytopenia, hepatotoxicity, nephrotoxicity, infections, neurotoxicity, pulmonary fibrosis, pneumonitis, severe dermatitis, seizures
Glucocorticoids, oral[a] (several specific brands are approved by FDA for use in SLE)	Prednisone, prednisolone: 0.5–1 mg/kg per day for severe SLE 0.07–0.3 mg/kg per day or qod for milder disease	A2R/ACE antagonists, antiarrhythmics class III, β_2 cyclosporine, NSAIDs and salicylates, phenothiazines, phenytoins, quinolones, rifampin, risperidone, thiazides, sulfonylureas, warfarin	Infection, VZV infection, hypertension, hyperglycemia, hypokalemia, acne, allergic reactions, anxiety, aseptic necrosis of bone, Cushingoid changes, CHF, fragile skin, insomnia, menstrual irregularities, mood swings, osteoporosis, psychosis
Methylprednisolone sodium succinate, intravenous[a] (approved for lupus nephritis)	For severe disease, 1 g IV qd $\times$ 3 days	As for oral glucocorticoids	As for oral glucocorticoids (if used repeatedly); anaphylaxis
Cyclophosphamide[b]		Allopurinol, bone marrow suppressants, colony-stimulating factors, doxorubicin, rituximab, succinylcholine, zidovudine	Infection, VZV infection, bone marrow suppression, leukopenia, anemia, thrombocytopenia, hemorrhagic cystitis (less with IV), carcinoma of the bladder, alopecia, nausea, diarrhea, malaise, malignancy, sterility
Intravenous	0.7–2.5 mg/kg q month $\times$ 6; consider mesna administration with dose		
Oral	1.5–3 mg/kg per day Decrease dose for CrCl $<$ 25 mL/min		
Mycophenolate mofetil[b] (approved for lupus nephritis)	2–3 g/d PO	Acyclovir, antacids, azathioprine, bile acid–binding resins, ganciclovir, iron salts, probenecid, oral contraceptives	Infection, leukopenia, anemia, thrombocytopenia, lymphoma, lymphoproliferative disorders, malignancy Alopecia, cough, diarrhea, fever, GI symptoms, headache, hypertension, hypercholesterolemia, hypokalemia, insomnia peripheral edema, transaminitis, tremor, rash
Azathioprine[b]	2–3 mg/kg per day PO; decrease frequency of dose if CrCl $<$ 50 mL/min	ACE inhibitors, allopurinol, bone marrow suppressants, interferons, mycophenolate mofetil, rituximab, warfarin, zidovudine	Infection, VZV infection, bone marrow suppression, leukopenia, anemia, thrombocytopenia, pancreatitis, hepatotoxicity, malignancy, alopecia, fever, flulike illness, GI symptoms

[a] Indicates medication is approved for use in SLE by the U.S. Food and Drug Administration.

[b] Indicates the medication has been used with glucocorticoids in the trials showing efficacy.

Note: NSAIDs, nonsteroidal anti-inflammatory drugs; FDA, U.S. Food and Drug Administration; A2R, angiotensin 2 receptor; ACE, angiotensin-converting enzyme; GI, gastrointestinal; SPF, sun protection factor; CrCl, creatinine clearance; VZV, varicella-zoster virus; CHF, congestive heart failure.

NSAIDs, are no safer in this regard, although they may cause fewer adverse gastrointestinal events (studies are not available in SLE). Antimalarials (hydroxychloroquine, chloroquine, and quinacrine) often reduce dermatitis, arthritis, and fatigue; a randomized placebo-controlled prospective trial has shown that hydroxychloroquine reduces the number of disease flares. Because of potential retinal toxicity, patients receiving antimalarials should undergo opthalmologic examinations at least annually. A recent placebo-controlled prospective trial suggests that administration of dehydroepiandrosterone may reduce disease activity. If quality of life is inadequate in spite of these conservative measures, treatment with low doses of systemic glucocorticoids may be necessary.

Life-Threatening SLE: Proliferative Forms of Lupus Nephritis The mainstay of treatment for any inflammatory life-threatening or organ-threatening manifestations of SLE is systemic glucocorticoids (0.5 to 2 mg/kg per day orally or 1000 mg of methylprednisolone sodium succinate intravenously daily for 3 days followed by 0.5–1 mg/kg of daily prednisone or equivalent). Evidence that glucocorticoid therapy is life-saving comes from retrospective studies from the predialysis era; survival is significantly better in people with DPGN treated with high-dose daily glucocorticoids (40 to 60 mg of prednisone daily for 4 to 6 months) versus lower doses. Currently, high doses are recommended for much shorter periods; recent trials of interventions for severe SLE employ 4 to 6 weeks of these doses. Thereafter, doses are tapered as rapidly as the clinical situation permits, usually to a maintenance dose varying from 5 to 10 mg of prednisone, prednisolone, or equivalent per day or 10 to 20 mg every other day. Most patients with an episode of severe lupus require many years of maintenance therapy with low-dose glucocorticoids, which can be increased to prevent or treat disease flares. However, frequent attempts to gradually reduce the glucocorticoid requirement are recommended because virtually everyone develops important adverse effects (Table 300-4). Prospective controlled trials in active lupus nephritis show that administration of high doses of glucocorticoids (1000 mg of methylprednisolone daily for 3 days) by intravenous routes compared to daily oral routes shortens the time to maximal improvement by a few weeks but does not result ultimately in better renal function. It has become standard practice to initiate therapy for active, potentially life-threatening SLE with high-dose intravenous glucocorticoid pulses, based on studies in lupus nephritis. This approach must be tempered by safety considerations, such as the presence of conditions adversely affected by glucocorticoids (infection, hyperglycemia, hypertension, osteoporosis, etc).

Cytotoxic drugs are another important class of drugs used to treat serious SLE. Almost all prospective controlled trials in SLE involving cytotoxic agents have been conducted in patients with lupus nephritis. The alkylating agent cyclophosphamide has become the standard drug used for controlling life-threatening active lupus nephritis, particularly in patients whose renal biopsies show WHO grades III, IV, and V proliferative or membranoproliferative forms of nephritis. All successful studies with cyclophosphamide have also used concomitant glucocorticoid therapy; cyclophosphamide responses begin 3 to 16 weeks after treatment is initiated, whereas glucocorticoid responses may begin within 24 h. Cyclophosphamide should be administered to patients whose severe lupus is likely to be reversible (Table 300-4); those with high serum creatinine levels [e.g., $\geq$265 μmol/L $\geq$3.0 mg/dL)] of many months duration and high chronicity scores on renal biopsy are not likely to respond. Prospective studies suggest that ESRD is significantly less frequent in patients treated with cyclophosphamide (intermittent intravenous or daily oral) compared to patients treated with glucocorticoids alone or azathioprine plus glucocorticoids. This benefit becomes measurable 5 years or more following initiation of therapy. Short-term results of any intervention (e.g., 1 to 2 years) are useful but may not adequately describe the overall utility of that approach. The recommended duration of cyclophosphamide therapy is controversial; one prospective controlled trial (from the U.S. National Institutes of Health) comparing 6 months of intermittent intravenous treatment (monthly doses) to 30 months of treatment (6 monthly doses followed by quarterly doses) showed fewer disease flares in the 30-month group. However, a recent prospective controlled trial suggests that similar good improvement occurs if 6 monthly doses of intravenous cyclophosphamide (500 mg/m^2) plus 2 quarterly doses are followed by daily azathioprine for 2 years; equally effective was intravenous cyclophosphamide, 500 mg total, every 2 weeks for six doses, followed by daily azathioprine. Approximately 90% of this group were Caucasian. Response of lupus nephritis to cyclophosphamide and glucocorticoids is better in Caucasian groups than in African Americans. Therefore, interpretation of studies using different therapeutic approaches must include considerations of ethnicity as well as duration of follow-up and differences in inclusion and exclusion criteria for entry. The adverse effects most likely to influence patient choice against the use of cyclophosphamide are a high rate of irreversible ovarian or testicular failure with increasing cumulative doses, nausea and malaise that often accompany each intravenous dose, alopecia, and frequent infections.

Since glucocorticoid-plus-cyclophosphamide therapy has many adverse effects and is often disliked by patients, there has been a search for other cytotoxic agents and for different approaches that are less toxic. Azathioprine (a purine antagonist) added to glucocorticoids probably reduces the number of SLE flares and the maintenance glucocorticoid requirement; however, this approach requires several months to be effective, and cyclophosphamide is effective in a higher proportion of patients. Daily oral azathioprine may have fewer adverse effects than daily oral cyclophosphamide; intermittent intravenous cyclophosphamide probably has fewer adverse effects than daily oral cyclophosphamide. Mycophenolate mofetil (a relatively lymphocyte-specific inhibitor of inosine monophosphate dehydrogenase) is an effective cytotoxic agent in some patients with severe SLE. A recent prospective study in Chinese patients with lupus nephritis comparing daily oral mycophenolate plus prednisolone for 12 months to daily oral cyclophosphamide plus prednisolone for 6 months followed by oral daily azathioprine plus prednisolone showed good improvement in ~80% of patients in both groups at 1 year of follow-up and fewer adverse effects with mycophenolate. Chlorambucil is an alkylating agent that can be substituted for cyclophosphamide; the risk of irreversible bone marrow suppression may be greater with this agent. Methotrexate (a folinic acid antagonist) may have a role in the treatment of arthritis and dermatitis but probably not in life-threatening disease. The role of leflunomide, a relatively lymphocyte-specific pyrimidine antagonist, is being studied in patients with SLE. Cyclosporine, which inhibits production of IL-2 and inhibits T lymphocyte functions, has not been studied in prospective controlled trials in SLE but is nonetheless used by some clinicians. Since it has potential nephrotoxicity, but no bone marrow toxicity, the author uses it (in doses of 3 to 5 mg/kg per day orally) in patients with steroid-resistant cytopenias of SLE or in steroid-resistant patients who have developed bone marrow suppression from standard cytotoxic agents.

Special Conditions in SLE that May Require Additional or Different Therapies

■ *PREGNANCY AND LUPUS* Fertility rates for men and women with SLE are probably normal. However, rate of fetal loss is increased (approximately two- to threefold) in women with SLE. Fetal demise is higher in mothers with high disease activity, antiphospholipid antibodies, and/or nephritis. Suppression of disease activity can be achieved by administration of systemic glucocorticoids. A placental enzyme 11-β-dehydrogenase 2 deactivates glucocorticoids; it is more effective in deactivating prednisone and prednisolone than the fluorinated glucocorticoids dexamethasone and betamethasone. Therefore, maternal SLE should be controlled with prednisone/prednisolone at the lowest effective doses for the shortest time required. Adverse effects of prenatal glucocorticoid exposure (primarily betamethasone) on offspring may include low birth weight, developmental abnormalities in the

CNS, and predeliction toward adult metabolic syndrome. In SLE patients with aPL (on at least two occasions) and prior fetal losses, treatment with heparin (standard or low-molecular-weight) plus low-dose aspirin has been shown in prospective controlled trials to increase significantly the proportion of live births. An additional potential problem for the fetus is the presence of antibodies to Ro, sometimes associated with neonatal lupus (rash and congenital heart block). The latter can be life-threatening; therefore the presence of anti-Ro requires vigilant monitoring of fetal heart rates with prompt intervention if distress occurs. Women with SLE usually tolerate pregnancy without disease flares. However, a small proportion develop severe flares requiring aggressive glucocorticoid therapy or early delivery. Poor maternal outcomes are highest in women with active nephritis or irreversible organ damage in kidneys, brain, or heart.

LUPUS AND APS Patients with SLE who have venous or arterial clotting, and/or repeated fetal losses, and at least two positive tests for aPL have APS and should be managed with long-term anticoagulation. A target INR of 3.0 is recommended, based on reduction of new clotting events in patients treated to this target INR compared to patients treated to lower INR levels, in retrospective analyses of cohorts with primary or secondary APS.

MICROVASCULAR THROMBOTIC CRISIS (THROMBOTIC THROMBOCYTOPENIC PURPURA, HEMOLYTIC UREMIC SYNDROME) This syndrome of hemolysis, thrombocytopenia, and microvascular thrombosis in kidneys, brain, and other tissues carries a high mortality rate and occurs most commonly in young individuals with lupus nephritis. The most useful laboratory tests are identification of schistocytes on peripheral blood smears and elevated serum levels of lactate dehydrogenase. Plasma exchange or extensive plasmapheresis is usually life-saving; there is no evidence that glucocorticoids or cytotoxic drugs are effective.

LUPUS DERMATITIS Patients with any form of lupus dermatitis should minimize exposure to ultraviolet light, employing appropriate clothing and sunscreens with a sun protection factor of at least 15. Topical glucocorticoids and antimalarials (such as hydroxychloroquine) are effective in reducing lesion severity in most patients and are relatively safe. Systemic treatment with retinoic acid is a useful strategy in patients with inadequate improvement on topical glucocorticoids and antimalarials; adverse effects are potentially severe (particularly fetal abnormalities). Extensive, pruritic, bullous, or ulcerating dermatitides usually improve promptly after institution of systemic glucocorticoids; tapering may be accompanied by flare of lesions, thus necessitating use of a second medication such as hydroxychloroquine, retinoids, or cytotoxic medications such as methotrexate or azathioprine. In therapy-resistant lupus dermatitis there are reports of success with topical tacrolimus or with systemic dapsone or thalidomide (the extreme danger of fetal deformities from thalidomide requires permission from and supervision by the supplier).

Preventive Therapies Prevention of complications of SLE and its therapy include providing appropriate vaccinations (the administration of influenza and pneumococcal vaccines has been studied in patients with SLE; flare rates are similar to those receiving placebo) and suppressing recurrent urinary tract infections. In addition, strategies to prevent osteoporosis should be initiated in most patients likely to require long-term glucocorticoid therapy and/or with other predisposing factors. Control of hypertension and appropriate prevention strategies for atherosclerosis, including monitoring and treatment of dyslipidemias, management of hyperglycemia, and obesity, are recommended.

Experimental Therapies Several new biologics and selective cytotoxic medications are in various phases of clinical trials in the United States. Most strategies target T or B lymphocytes, particularly those undergoing activation, rather than entire cell populations. These include LJP394 (may tolerize B cells making anti-DNA), antibodies to CD40L and CTLA4-Ig fusion protein (interrupt T/B second signals), antibody to complement C′5, and antibody to CD20 (depletes some B cells). Several studies have employed transplantation of hematopoietic stem cells for the treatment of severe and refractory SLE.

PATIENT OUTCOMES, PROGNOSIS, AND SURVIVAL Survival in patients with SLE is 90 to 95% at 2 years, 82 to 90% at 5 years, 71 to 80% at 10 years, and 63 to 75% at 20 years. Poor prognosis (approximately 50% mortality in 10 years) is associated with (at the time of diagnosis) high serum creatinine levels [>124 μmol/L (>1.4 mg/dL)], hypertension, nephrotic syndrome (24-h urine protein excretion >2.6 g), anemia [hemoglobin <124 g/L (<12.4 g/dL)], hypoalbuminemia, hypocomplementemia, and aPL. Prognosis is worse in African Americans than in Caucasians. Patients who require renal transplantation have a relatively high incidence of graft rejection (approximately twice that of patients with other causes of ESRD), but overall patient survival is comparable (85% at 2 years). Lupus nephritis occurs in 10% of transplanted kidneys. Disability in patients with SLE is common due primarily to chronic renal disease, fatigue, arthritis, and pain. As many as 25% of patients may experience remissions, sometimes for a few years, but these are rarely permanent. The leading causes of death in the first decade of disease are systemic disease activity, renal failure, and infections; subsequently, thromboembolic events become increasingly frequent causes of mortality.

DRUG-INDUCED LUPUS This is a syndrome of positive ANA associated with symptoms such as fever, malaise, arthritis or intense arthralgias/myalgias, serositis, and/or rash. The syndrome appears during therapy with certain medications and biologic agents, is predominant in Caucasians, has less female predilection than SLE, rarely involves kidneys or brain, is rarely associated with anti-dsDNA, is commonly associated with antibodies to histones, and usually resolves over several weeks after discontinuation of the offending medication. The list of substances that can induce lupus-like disease is long. Among the most frequent are the anti-arrhythmics procaineamide, disopyramide, propafenone; the antihypertensives hydralazine, several angiotensin-converting enzyme inhibitors and beta-blockers; the antithyroid propylthiouracil; the antipsychotics chlorpromazine and lithium; the anticonvulsants carbamazepine and phenytoin; the antibiotics isoniazid, minocycline, and macrodantin; the antirheumatic sulfasalazine; the diuretic hydrochlorothiazide; the antihyperlipidemics lovastatin and simvastatin; and the biologics interferons and tumor necrosis factor inhibitors. ANA usually appears before symptoms; however, many of the medications mentioned above induce ANA in patients who never develop symptoms of drug-induced lupus. It is appropriate to test for ANA at the first hint of relevant symptoms and to use test results to help decide whether to withdraw the suspect agent.

301 RHEUMATOID ARTHRITIS

Peter E. Lipsky

Rheumatoid arthritis (RA) is a chronic multisystem disease of unknown cause. Although there are a variety of systemic manifestations, the characteristic feature of RA is persistent inflammatory synovitis, usually involving peripheral joints in a symmetric distribution. The potential of the synovial inflammation to cause cartilage damage and bone erosions and subsequent changes in joint integrity is the hallmark of the disease. Despite its destructive potential, the course of RA can be quite variable. Some patients may experience only a mild oligoarticular illness of brief duration with minimal joint damage, whereas others will have a relentless progressive polyarthritis with marked functional impairment.

EPIDEMIOLOGY AND GENETICS The prevalence of RA is approximately 0.8% of the population (range 0.3 to 2.1%); women are affected approximately three times more often than men. The prevalence increases with age, and sex differences diminish in the older age group. RA is seen throughout the world and affects all races. However, the incidence and severity seem to be less in rural sub-Saharan Africa and in Caribbean blacks. The onset is most frequent during the fourth and fifth decades of life, with 80% of all patients developing the disease between the ages of 35 and 50. The incidence of RA is more than six times greater in 60- to 64-year-old women compared to 18- to 29-year-old women. Recent data indicate that the incidence of RA may be diminishing.

Family studies indicate a genetic predisposition. For example, severe RA is found at approximately four times the expected rate in first-degree relatives of individuals with disease associated with the presence of the autoantibody, rheumatoid factor; approximately 10% of patients with RA will have an affected first-degree relative. Moreover, monozygotic twins are at least four times more likely to be concordant for RA than dizygotic twins, who have a similar risk of developing RA as nontwin siblings. Only 15 to 20% of monozygotic twins are concordant for RA, however, implying that factors other than genetics play an important etiopathogenic role. Of note, the highest risk for concordance of RA is noted in twins who have two HLA-DRB1 alleles known to be associated with RA. The class II major histocompatibility complex allele HLA-DR4 (DRβ1*0401) and related alleles are known to be major genetic risk factors for RA. Early studies showed that as many as 70% of patients with classic or definite RA express HLA-DR4 compared with 28% of control individuals. An association with HLA-DR4 has been noted in many populations, including North American and European whites, Chippewa Indians, Japanese, and native populations in India, Mexico, South America, and southern China. In a number of groups, including Israeli Jews, Asian Indians, and Yakima Indians of North America, however, there is no association between the development of RA and HLA-DR4. In these individuals, there is an association between RA and the closely related HLA-DR1 (DRβ1*0101) in the former two groups and HLA-Dw16 (DRβ1*1402) in the latter. It has been estimated that the risk of developing RA in a person with DRβ1*0401 or the closely related DRβ1*0404 is 1 in 35 and 1 in 20, respectively, whereas the presence of both alleles puts persons at an even greater risk. In certain groups of patients, there does not appear to be a clear association between HLA-DR4–related epitopes and RA. Thus, nearly 75% of African-American RA patients do not have this genetic element. Moreover, there is an association with HLA-DR10 (DRβ1*1001) in Spanish and Italian patients, with HLA-DR9 (DRβ1*0901) in Chileans, and with HLA-DR3 (DRβ1*0301) in Arab populations.

Additional genes in the HLA-D complex may also convey altered susceptibility to RA. Certain HLA-DR alleles, including HLA-DR5 (DRβ1*1101), HLA-DR2 (DRβ1*1501), HLA-DR3 (DRβ1*0301), and HLA-DR7 (DRβ1*0701), may protect against the development of RA in that they tend to be found at lower frequency in RA patients than in controls. Moreover, the HLA-DQ alleles, DQβ1*0301 and DQβ1*0302, that are in linkage disequilibrium with HLA-DR4 and DQβ1*0501, have also been associated with RA. This has raised the possibility that HLA-DQ alleles may represent the actual RA susceptibility genes, whereas specific HLA-DR alleles may convey protection. In this model, the complement of HLA-DR and DQ alleles determines RA susceptibility. Disease manifestations have also been associated with HLA phenotype. Thus, early aggressive disease and extraarticular manifestations are more frequent in patients with DRβ1*0401 or DRβ1*0404, and more slowly progressive disease in those with DRβ1*0101. The presence of both DRβ1*0401 and DRβ1*0404 appears to increase the risk for both aggressive articular and extraarticular disease. It has been estimated that HLA genes contribute only a portion of the genetic susceptibility to RA. Thus genes outside the HLA complex also contribute. These include genes controlling the expression of the antigen receptor on T cells and both immunoglobulin heavy and light chains. Moreover, polymorphisms in the tumor necrosis factor (TNF) and the interleukin (IL) 10 genes are also associated with RA, as is a region on chromosome 3 (3q13). In addition, a number of other genetic regions appear to confer risk for RA.

Genetic risk factors do not fully account for the incidence of RA, suggesting that environmental factors also play a role in the etiology of the disease. This is emphasized by epidemiologic studies in Africa that have indicated that climate and urbanization have a major impact on the incidence and severity of RA in groups of similar genetic background.

ETIOLOGY The cause of RA remains unknown. It has been suggested that RA might be a manifestation of the response to an infectious agent in a genetically susceptible host. Because of the worldwide distribution of RA, it has been hypothesized that if an infectious agent is involved, the organism must be ubiquitous. A number of possible causative agents have been suggested, including *Mycoplasma*, Epstein-Barr virus (EBV), cytomegalovirus, parvovirus, and rubella virus, but convincing evidence that these or other infectious agents cause RA has not emerged. The process by which an infectious agent might cause chronic inflammatory arthritis with a characteristic distribution also remains a matter of controversy. One possibility is that there is persistent infection of articular structures or retention of microbial products in the synovial tissues that generates a chronic inflammatory response. Alternatively, the microorganism or response to the microorganism might induce an immune response to components of the joint by altering its integrity and revealing antigenic peptides. In this regard, reactivity to type II collagen and heat shock proteins has been demonstrated. Another possibility is that the infecting microorganism might prime the host to cross-reactive determinants expressed within the joint as a result of "molecular mimicry." Recent evidence of similarity between products of certain gram-negative bacteria and EBV and the HLA-DR4 molecule itself has supported this possibility. Finally, products of infecting microorganisms, such as superantigens, might induce the disease. Superantigens are proteins with the capacity to bind to HLA-DR molecules and particular V_β segments of the heterodimeric T cell receptor and stimulate specific T cells expressing the V_β gene products (Chap. 295). The role of superantigens in the etiology of RA remains speculative. Of all the potential environmental triggers, the only one clearly associated with the development of RA is cigarette smoking.

PATHOLOGY AND PATHOGENESIS Microvascular injury and an increase in the number of synovial lining cells appear to be the earliest lesions in rheumatoid synovitis. The nature of the insult causing this response is not known. Subsequently, an increased number of synovial lining cells is seen along with perivascular infiltration with mononuclear cells. Before the onset of clinical symptoms, the perivascular infiltrate is predominantly composed of myeloid cells, whereas in symptomatic arthritis, T cells can also be found, although their number does not appear to correlate with symptoms. As the process continues, the syn-

ovium becomes edematous and protrudes into the joint cavity as villous projections.

Light-microscopic examination discloses a characteristic constellation of features, which include hyperplasia and hypertrophy of the synovial lining cells; focal or segmental vascular changes, including microvascular injury, thrombosis, and neovascularization; edema; and infiltration with mononuclear cells, often collected into aggregates around small blood vessels (Fig. 301-1). The endothelial cells of the rheumatoid synovium have the appearance of high endothelial venules of lymphoid organs and have been altered by cytokine exposure to facilitate entry of cells into tissue. Rheumatoid synovial endothelial cells express increased amounts of various adhesion molecules involved in this process. Although this pathologic picture is typical of RA, it can also be seen in a variety of other chronic inflammatory arthritides. The mononuclear cell collections are variable in composition and size. The predominant infiltrating cell is the T lymphocyte. CD4+ T cells predominate over CD8+ T cells and are frequently found in close proximity to HLA-DR+ macrophages and dendritic cells. Increased numbers of a separate population of T cells expressing the $\gamma\delta$ form of the T cell receptor have also been found in the synovium, although they remain a minor population there and their role in RA has not been delineated. The major population of T cells in the rheumatoid synovium is composed of CD4+ memory T cells that form the majority of cells aggregated around postcapillary venules. Scattered throughout the tissue are CD8+ T cells. Both populations express the early activation antigen, CD69. Besides the accumulation of T cells, rheumatoid synovitis is also characterized by the infiltration of variable numbers of B cells and antibody-producing plasma cells. In advanced disease, structures similar to germinal centers of secondary lymphoid organs may be observed in the synovium. Both polyclonal immunoglobulin and the autoantibody rheumatoid factor are produced within the synovial tissue, which leads to the local formation of immune complexes. Antibodies to synovial tissue components may also contribute to inflammation. Increased numbers of activated mast cells are also found in the rheumatoid synovium. Local release of the contents of their granules may contribute to inflammation. Finally, the synovial fibroblasts in RA manifest evidence of activation in that they produce a number of enzymes such as collagenase and cathepsins that can degrade components of the articular matrix. These activated fibroblasts are particularly prominent in the lining layer and at the interface with bone and cartilage. Osteoclasts are also prominent at sites of bone erosion. Activated mesenchymal stromal cells, similar to those found in normal bone marrow, can also be found in the rheumatoid synovium.

The rheumatoid synovium is characterized by the presence of a number of secreted products of activated lymphocytes, macrophages, and fibroblasts. The local production of these cytokines and chemokines appears to account for many of the pathologic and clinical manifestations of RA. These effector molecules include those that are derived from T lymphocytes, those originating from activated myeloid cells, and those secreted by other cell types in the synovium, such as fibroblasts and endothelial cells. The activity of these chemokines and cytokines appears to account for many of the features of rheumatoid synovitis, including the synovial tissue inflammation, synovial fluid inflammation, synovial proliferation, and cartilage and bone damage, as well as the systemic manifestations of RA. In addition to the production of effector molecules that propagate the inflammatory process, local factors are produced that tend to slow the inflammation, including specific inhibitors of cytokine action and additional cytokines, such as transforming growth factor (TGF-β), which inhibits many of the features of rheumatoid synovitis including T cell activation and proliferation, B cell differentiation, and migration of cells into the inflammatory site.

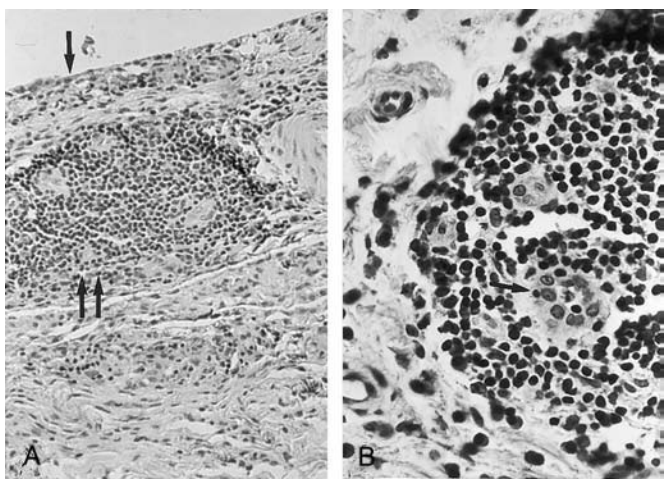

FIGURE 301-1 Histology of rheumatoid synovitis. *A.* The characteristic features of rheumatoid inflammation with hyperplasia of the lining layer (*arrow*) and mononuclear infiltrates in the sublining layer (*double arrow*). *B.* A higher magnification of the largely CD4+ T cell infiltrate around postcapillary venules (*arrow*).

These findings have suggested that the propagation of RA is an immunologically mediated event, although the original initiating stimulus has not been characterized. One view is that the inflammatory process in the tissue is driven by the CD4+ T cells infiltrating the synovium. Evidence for this includes (1) the predominance of CD4+ T cells in the synovium; (2) the increase in soluble IL-2 receptors, a product of activated T cells, in blood and synovial fluid of patients with active RA; and (3) amelioration of the disease by removal of T cells by thoracic duct drainage or peripheral lymphapheresis or suppression of their proliferation or function by drugs, such as cyclosporine, leflunomide, or nondepleting monoclonal antibodies to CD4, or inhibitors of T cell activation, such as the T cell co-stimulation competitor, CTLA-4·Ig. In addition, the association of RA with certain HLA-DR or -DQ alleles, whose only known functions are to shape the repertoire of CD4+ T cells during ontogeny in the thymus and bind and present antigenic peptides to CD4+ T cells in the periphery, strongly implies a role for CD4+ T cells in the pathogenesis of the disease. Finally, patients with established RA who become infected with HIV have also been noted to improve, although this has not been a uniform finding. Within the rheumatoid synovium, the CD4+ T cells differentiate predominantly into T_H1-like effector cells producing the proinflammatory cytokine interferon (IFN) γ and appear to be deficient in differentiation into T_H2-like effector cells capable of producing the anti-inflammatory cytokine IL-4. As a result of the ongoing secretion of IFN-γ without the regulatory influences of IL-4, macrophages are activated to produce the proinflammatory cytokines IL-1 and TNF and also increase expression of HLA molecules. Direct contact between activated T cells and myeloid cells may also lead to the production of proinflammatory cytokines by the latter. Moreover, T lymphocytes express surface molecules such as CD154 (CD40 ligand) and also produce a variety of cytokines that promote B cell proliferation and differentiation into antibody-forming cells and therefore may also promote local B cell stimulation. The resultant production of immunoglobulin and rheumatoid factor can lead to immune-complex formation with consequent complement activation and exacerbation of the inflammatory process by the production of the anaphylatoxins, C3a and C5a, and the chemotactic factor C5a. In addition, antibodies may be produced to other self-antigens than can contribute to disease pathogenesis. The tissue inflammation is reminiscent of chronic inflammatory responses to persistent microorganisms, although it has become clear that the number of T cells producing cytokines such as IFN-γ is less than is found in typical delayed-type hypersensitivity reactions, perhaps owing to the large amount of reactive oxygen species produced locally in the synovium that can dampen T cell function. It remains unclear whether the persistent T cell activity represents a response to a persistent exogenous antigen or to altered autoantigens such as collagen, immunoglobulin, or one of the heat shock proteins, or perhaps both. Alternatively, it could represent persistent responsiveness to activated autologous cells such as might occur as a result

of EBV infection or persistent response to a foreign antigen or superantigen in the synovial tissue. Finally, rheumatoid inflammation could reflect persistent stimulation of T cells by synovial-derived antigens that cross-react with determinants introduced during antecedent exposure to foreign antigens or infectious microorganisms. The important contribution of B lymphocytes to the chronic inflammatory process has been emphasized by the observation that treatment with a monoclonal antibody to the B cell marker, CD20, caused prompt depletion of B lymphocytes and an amelioration of signs and symptoms of inflammation.

Overriding the chronic inflammation in the synovial tissue is an acute inflammatory process in the synovial fluid. The exudative synovial fluid contains more polymorphonuclear leukocytes than mononuclear cells. A number of mechanisms play a role in stimulating the exudation of synovial fluid. Locally produced antibodies to tissue components and immune complexes can activate complement and generate anaphylatoxins and chemotactic factors. Local production of chemokines and cytokines with chemotactic activity as well as inflammatory mediators such as leukotriene B_4 and products of complement activation can attract neutrophils. Moreover, many of these same agents can also stimulate the endothelial cells of postcapillary venules to become more efficient at binding circulating cells. The net result is the enhanced migration of polymorphonuclear leukocytes into the synovial site. In addition, vasoactive mediators such as histamine produced by the mast cells that infiltrate the rheumatoid synovium may also facilitate the exudation of inflammatory cells into the synovial fluid. Finally, the vasodilatory effects of locally produced prostaglandin E_2 may also facilitate entry of inflammatory cells into the inflammatory site. Once in the synovial fluid, the polymorphonuclear leukocytes can ingest immune complexes, with the resultant production of reactive oxygen metabolites and other inflammatory mediators, further adding to the inflammatory milieu. Locally produced cytokines and chemokines can additionally stimulate polymorphonuclear leukocytes. The production of large amounts of cyclooxygenase and lipoxygenase pathway products of arachidonic acid metabolism by cells in the synovial fluid and tissue further accentuates the signs and symptoms of inflammation.

The precise mechanism by which bone and cartilage destruction occurs has not been completely resolved. Although the synovial fluid contains a number of enzymes potentially able to degrade cartilage, the majority of destruction occurs in juxtaposition to the inflamed synovium, or pannus, that spreads to cover the articular cartilage. This vascular granulation tissue is composed of proliferating fibroblasts, small blood vessels, and a variable number of mononuclear cells and produces a large amount of degradative enzymes, including collagenase and stromelysin, that may facilitate tissue damage. The cytokines IL-1 and TNF play an important role by stimulating the cells of the pannus to produce collagenase and other neutral proteases. These same two cytokines also activate chondrocytes in situ, stimulating them to produce proteolytic enzymes that can degrade cartilage locally and also inhibiting synthesis of new matrix molecules. Finally, these two cytokines may contribute to the local demineralization of bone by activating osteoclasts that accumulate at the site of local bone resorption. Prostaglandin E_2 produced by fibroblasts and macrophages may also contribute to bone demineralization. The common final pathway of bone erosion is likely to involve the activation of osteoclasts that are present in large numbers at these sites. Systemic manifestations of RA can be accounted for by release of inflammatory effector molecules from the synovium. These include IL-1, TNF, and IL-6, which account for many of the manifestations of active RA, including malaise, fatigue, and elevated levels of serum acute-phase reactants. The importance of TNF in producing these manifestations is emphasized by the prompt amelioration of symptoms following administration of a monoclonal antibody to TNF or a soluble TNF receptor Ig construct to patients with RA. In addition, immune complexes produced within the synovium and entering the circulation may account for other features of the disease, such as systemic vasculitis.

As shown in Fig. 301-2, the pathology of RA evolves over the duration of this chronic disease. The earliest event appears to be a nonspecific inflammatory response initiated by an unknown stimulus and characterized by accumulation of macrophages and other mononuclear cells within the sublining layer of the synovium. The activity of these cells is demonstrated by the increased appearance of macrophage-derived cytokines, including TNF, IL-1β, and IL-6. Subsequently, activation and differentiation of memory CD4+ T cells is induced, presumably in response to antigenic peptides displayed by a variety of antigen-presenting cells in the synovial tissue. The activated memory T cells are capable of producing cytokines, especially IFN-γ, which amplify and perpetuate the inflammation. The presence of activated T cells expressing CD154 (CD40 ligand) can induce polyclonal B cell stimulation and differentiation of memory B cells and plasma cells that produce autoantibodies locally. The cascade of cytokines produced in the synovium activates a variety of cells in the synovium, bone, and cartilage to produce effector molecules that can cause tissue damage characteristic of chronic inflammation. It is important to emphasize that there is no current way to predict the progress from one stage of inflammation to the next, and once established, each can influence the other. Important features of this model include the following: (1) the major pathologic events vary with time in this chronic disease; (2) the time required to progress from one step to the next may vary in different patients, and the events, once established, may persist simultaneously; (3) once established, the major pathogenic events operative in an individual patient, may vary at different times; (4) the process is chronic and reiterative, with successive events stimulating progressive amplification of inflammation; and (5) once memory T cells and B cells have been generated, anti-inflammatory and anti-cytokine therapy may be capable of suppressing disease manifestations but not preventing recrudescence of disease activity once therapy is discontinued. These considerations have important implications with regard to appropriate treatment.

CLINICAL MANIFESTATIONS ■ Onset Characteristically, RA is a chronic polyarthritis. In approximately two-thirds of patients, it begins insidiously with fatigue, anorexia, generalized weakness, and vague musculoskeletal symptoms until the appearance of synovitis becomes apparent. This prodrome may persist for weeks or months and defy diagnosis. Specific symptoms usually appear gradually as several joints, especially those of the hands, wrists, knees, and feet, become affected in a symmetric fashion. In approximately 10% of individuals, the onset is more acute, with a rapid development of polyarthritis, often accompanied by constitutional symptoms, including fever, lymphadenopathy, and splenomegaly. In approximately one-third of patients, symptoms may initially be confined to one or a few joints. Although the pattern of joint involvement may remain asymmetric in a few patients, a symmetric pattern is more typical.

Signs and Symptoms of Articular Disease Pain, swelling, and tenderness may initially be poorly localized to the joints. Pain in affected joints, aggravated by movement, is the most common manifestation of established RA. It corresponds in pattern to the joint involvement but does not always correlate with the degree of apparent inflammation. Generalized stiffness is frequent and is usually greatest after periods of inactivity. Morning stiffness of greater than 1-h duration is an almost invariable feature of inflammatory arthritis and may serve to distinguish it from various noninflammatory joint disorders. Notably, however, the presence of morning stiffness may not reliably distinguish between chronic inflammatory and noninflammatory arthritides, as it is also found frequently in the latter. The majority of patients will experience constitutional symptoms such as weakness, easy fatigability, anorexia, and weight loss. Although fever to 40°C occurs on occasion, temperature elevation in excess of 38°C is unusual and suggests the presence of an intercurrent problem such as infection.

Clinically, synovial inflammation causes swelling, tenderness, and limitation of motion. Initially, impairment in physical function is caused by pain and inflammation, and disability owing to this is a frequent early feature of aggressive RA. Warmth is usually evident on

examination, especially of large joints such as the knee, but erythema is infrequent. Pain originates predominantly from the joint capsule, which is abundantly supplied with pain fibers and is markedly sensitive to stretching or distention. Joint swelling results from accumulation of synovial fluid, hypertrophy of the synovium, and thickening of the joint capsule. Initially, motion is limited by pain. The inflamed joint is usually held in flexion to maximize joint volume and minimize distention of the capsule. Later, fibrous or bony ankylosis or soft tissue contractures lead to fixed deformities.

Although inflammation can affect any diarthrodial joint, RA most often causes symmetric arthritis with characteristic involvement of certain specific joints such as the proximal interphalangeal and metacarpophalangeal joints. The distal interphalangeal joints are rarely involved. Synovitis of the wrist joints is a nearly uniform feature of RA and may lead to limitation of motion, deformity, and median nerve entrapment (carpal tunnel syndrome). Synovitis of the elbow joint often leads to flexion contractures that may develop early in the disease. The knee joint is commonly involved with synovial hypertrophy, chronic effusion, and frequently ligamentous laxity. Pain and swelling behind the knee may be caused by extension of inflamed synovium into the popliteal space (Baker's cyst). Arthritis in the forefoot, ankles, and subtalar joints can produce severe pain with ambulation as well as a number of deformities. Axial involvement is usually limited to the upper cervical spine. Involvement of the lumbar spine is not seen, and lower back pain cannot be ascribed to rheumatoid inflammation. On occasion, inflammation from the synovial joints and bursae of the upper cervical spine leads to atlantoaxial subluxation. This usually presents as pain in the occiput but on rare occasions may lead to compression of the spinal cord.

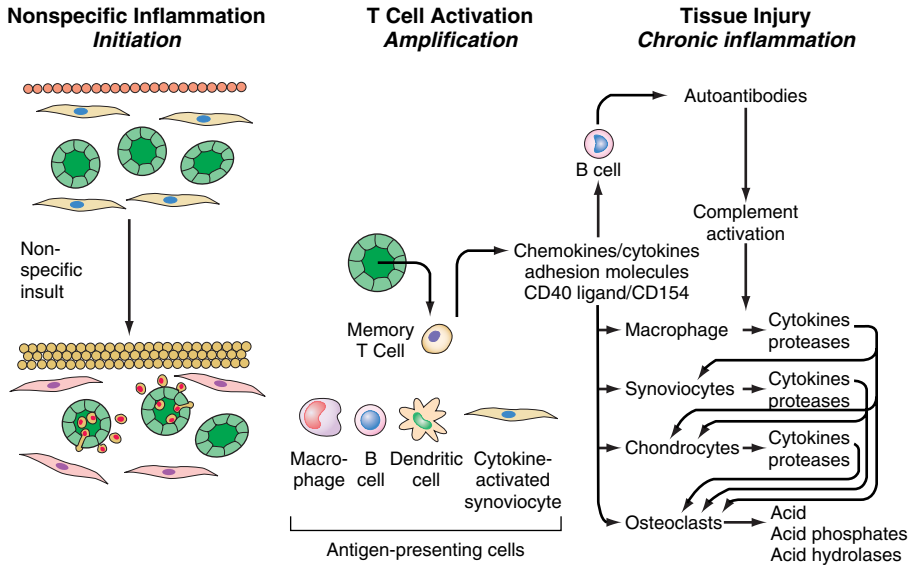

FIGURE 301-2 The progression of rheumatoid synovitis. This figure depicts the evolution of the pathogenic mechanisms and ultimate pathologic changes involved in the development of rheumatoid synovitis. The stages of rheumatoid arthritis are proposed to be an initiation phase of nonspecific inflammation, followed by an amplification phase resulting from T cell activation, and finally a stage of chronic inflammation with tissue injury. A variety of stimuli may initiate the initial phase of nonspecific inflammation, which may last for a protracted period of time with no or moderate symptoms. When activation of memory T cells in response to a variety of peptides presented by antigen-presenting cells occurs in genetically susceptible individuals, amplification of inflammation occurs with the promotion of local rheumatoid factor production and enhanced capacity to mediate tissue damage.

With persistent inflammation, a variety of characteristic joint changes develop. These can be attributed to a number of pathologic events, including laxity of supporting soft tissue structures; damage or weakening of ligaments, tendons, and the joint capsule; cartilage degradation; muscle imbalance; and unopposed physical forces associated with the use of affected joints. Characteristic changes of the hand include (1) radial deviation at the wrist with ulnar deviation of the digits, often with palmar subluxation of the proximal phalanges ("Z" deformity); (2) hyperextension of the proximal interphalangeal joints, with compensatory flexion of the distal interphalangeal joints (swan-neck deformity); (3) flexion contracture of the proximal interphalangeal joints and extension of the distal interphalangeal joints (boutonnière deformity); and (4) hyperextension of the first interphalangeal joint and flexion of the first metacarpophalangeal joint with a consequent loss of thumb mobility and pinch. Typical joint changes may also develop in the feet, including eversion at the hindfoot (subtalar joint), plantar subluxation of the metatarsal heads, widening of the forefoot, hallux valgus, and lateral deviation and dorsal subluxation of the toes. Later in the disease, disability is more related to structural damage to articular structures.

Extraarticular Manifestations RA is a systemic disease with a variety of extraarticular manifestations. Although these occur frequently, not all of them have clinical significance. However, on occasion, they may be the major evidence of disease activity and source of morbidity and require management per se. As a rule, these manifestations occur in individuals with high titers of autoantibodies to the Fc component of immunoglobulin G (rheumatoid factors).

Rheumatoid nodules develop in 20 to 30% of persons with RA. They are usually found on periarticular structures, extensor surfaces, or other areas subjected to mechanical pressure, but they can develop elsewhere, including the pleura and meninges. Common locations include the olecranon bursa, the proximal ulna, the Achilles tendon, and the occiput. Nodules vary in size and consistency and are rarely symptomatic, but on occasion they break down as a result of trauma or become infected. They are found almost invariably in individuals with circulating rheumatoid factor. Histologically, rheumatoid nodules consist of a central zone of necrotic material including collagen fibrils, noncollagenous filaments, and cellular debris; a midzone of palisading macrophages that express HLA-DR antigens; and an outer zone of granulation tissue. Examination of early nodules has suggested that the initial event may be a focal vasculitis. In some patients, treatment with methotrexate can increase the number of nodules dramatically.

Clinical weakness and atrophy of skeletal muscle are common. Muscle atrophy may be evident within weeks of the onset of RA and is usually most apparent in musculature approximating affected joints. Muscle biopsy may show type II fiber atrophy and muscle fiber necrosis with or without a mononuclear cell infiltrate.

Rheumatoid vasculitis (Chap. 306), which can affect nearly any organ system, is seen in patients with severe RA and high titers of circulating rheumatoid factor. Rheumatoid vasculitis is very uncommon in African Americans. In its most aggressive form, rheumatoid vasculitis can cause polyneuropathy and mononeuritis multiplex, cutaneous ulceration and dermal necrosis, digital gangrene, and visceral infarction. While such widespread vasculitis is very rare, more limited forms are not uncommon, especially in white patients with high titers of rheumatoid factor. Neurovascular disease presenting either as a mild distal sensory neuropathy or as mononeuritis multiplex may be the only sign of vasculitis. Cutaneous vasculitis usually presents as crops of small brown spots in the nail beds, nail folds, and digital pulp. Larger ischemic ulcers, especially in the lower extremity, may also develop. Myocardial infarction secondary to rheumatoid vasculitis has been reported, as has vasculitic involvement of lungs, bowel, liver, spleen, pancreas, lymph nodes, and testes. Renal vasculitis is rare.

Pleuropulmonary manifestations, which are more commonly observed in men, include pleural disease, interstitial fibrosis, pleuropulmonary nodules, pneumonitis, and arteritis. Evidence of pleuritis is found commonly at autopsy, but symptomatic disease during life is

infrequent. Typically, the pleural fluid contains very low levels of glucose in the absence of infection. Pleural fluid complement is also low compared with the serum level when these are related to the total protein concentration. Pulmonary fibrosis can produce impairment of the diffusing capacity of the lung. Pulmonary nodules may appear singly or in clusters. When they appear in individuals with pneumoconiosis, a diffuse nodular fibrotic process (Caplan's syndrome) may develop. On occasion, pulmonary nodules may cavitate and produce a pneumothorax or bronchopleural fistula. Rarely, pulmonary hypertension secondary to obliteration of the pulmonary vasculature occurs. In addition to pleuropulmonary disease, upper airway obstruction from cricoarytenoid arthritis or laryngeal nodules may develop.

Clinically apparent heart disease attributed to the rheumatoid process is rare, but evidence of asymptomatic pericarditis is found at autopsy in 50% of cases. Pericardial fluid has a low glucose level and is frequently associated with the occurrence of pleural effusion. Although pericarditis is usually asymptomatic, on rare occasions death has occurred from tamponade. Chronic constrictive pericarditis may also occur.

RA tends to spare the central nervous system directly, although vasculitis can cause peripheral neuropathy. *Neurologic manifestations* may also result from atlantoaxial or midcervical spine subluxations. Nerve entrapment secondary to proliferative synovitis or joint deformities may produce neuropathies of median, ulnar, radial (interosseous branch), or anterior tibial nerves.

The rheumatoid process involves the *eye* in fewer than 1% of patients. Affected individuals usually have long-standing disease and nodules. The two principal manifestations are episcleritis, which is usually mild and transient, and scleritis, which involves the deeper layers of the eye and is a more serious inflammatory condition. Histologically, the lesion is similar to a rheumatoid nodule and may result in thinning and perforation of the globe (scleromalacia perforans). From 15 to 20% of persons with RA may develop Sjögren's syndrome with attendant keratoconjunctivitis sicca.

Felty's syndrome consists of chronic RA, splenomegaly, neutropenia, and, on occasion, anemia and thrombocytopenia. It is most common in individuals with long-standing disease. These patients frequently have high titers of rheumatoid factor, subcutaneous nodules, and other manifestations of systemic rheumatoid disease. Felty's syndrome is very uncommon in African Americans. It may develop after joint inflammation has regressed. Circulating immune complexes are often present, and evidence of complement consumption may be seen. The leukopenia is a selective neutropenia with polymorphonuclear leukocyte counts of <1500 cells/μL and sometimes <1000 cell/μL. Bone marrow examination usually reveals moderate hypercellularity with a paucity of mature neutrophils. However, the bone marrow may be normal, hyperactive, or hypoactive; maturation arrest may be seen. Hypersplenism has been proposed as one of the causes of leukopenia, but splenomegaly is not invariably found and splenectomy does not always correct the abnormality. Excessive margination of granulocytes caused by antibodies to these cells, complement activation, or binding of immune complexes may contribute to granulocytopenia. Patients with Felty's syndrome have increased frequency of infections usually associated with neutropenia. The cause of the increased susceptibility to infection is related to the defective function of polymorphonuclear leukocytes as well as the decreased number of cells.

Osteoporosis secondary to rheumatoid involvement is common and may be aggravated by glucocorticoid therapy. Glucocorticoid treatment may cause significant loss of bone mass, especially early in the course of therapy, even when low doses are employed. Osteopenia in RA involves both juxtaarticular bone and long bones distant from involved joints. RA is associated with a modest decrease in mean bone mass and a moderate increase in the risk of fracture. Bone mass appears to be adversely affected by functional impairment and active inflammation, especially early in the course of the disease.

RA is associated with an increased incidence of lymphoma, especially large B cell lymphoma. Notably, this is particularly observed in those with persistent inflammatory disease.

RA in the Elderly The incidence of RA continues to increase past age 60. It has been suggested that elderly-onset RA might have a poorer prognosis, as manifested by more persistent disease activity, more frequent radiographically evident deterioration, more frequent systemic involvement, and more rapid functional decline. Aggressive disease is largely restricted to those patients with high titers of rheumatoid factor. By contrast, elderly patients who develop RA without elevated titers of rheumatoid factor (seronegative disease) generally have less severe, often self-limited disease.

LABORATORY FINDINGS No tests are specific for diagnosing RA. However, rheumatoid factors, which are autoantibodies reactive with the Fc portion of IgG, are found in more than two-thirds of adults with the disease. Widely utilized tests largely detect IgM rheumatoid factors. The presence of rheumatoid factor is not specific for RA. Rheumatoid factor is found in 5% of healthy persons. The frequency of rheumatoid factor in the general population increases with age, and 10 to 20% of individuals over 65 years old have a positive test. In addition, a number of conditions besides RA are associated with the presence of rheumatoid factor. These include systemic lupus erythematosus, Sjögren's syndrome, chronic liver disease, sarcoidosis, interstitial pulmonary fibrosis, infectious mononucleosis, hepatitis B, tuberculosis, leprosy, syphilis, subacute bacterial endocarditis, visceral leishmaniasis, schistosomiasis, and malaria. In addition, rheumatoid factor may appear transiently in normal individuals after vaccination or transfusion and may also be found in relatives of individuals with RA.

The presence of rheumatoid factor does not establish the diagnosis of RA as the predictive value of the presence of rheumatoid factor in determining a diagnosis of RA is poor. Thus fewer than one-third of unselected patients with a positive test for rheumatoid factor will be found to have RA. Therefore, the rheumatoid factor test is not useful as a screening procedure. However, the presence of rheumatoid factor can be of prognostic significance because patients with high titers tend to have more severe and progressive disease with extraarticular manifestations. Rheumatoid factor is uniformly found in patients with nodules or vasculitis. In summary, a test for the presence of rheumatoid factor can be employed to confirm a diagnosis in individuals with a suggestive clinical presentation and, if present in high titer, to designate patients at risk for severe systemic disease. A number of additional autoantibodies may be found in patients with RA, including antibodies to filaggrin, citrullinated proteins, calpastatin, components of the spliceosome (RA-33), and an unknown antigen, Sa. Some of these may be useful in diagnosis in that they may occur early in the disease before rheumatoid factor is present or may be associated with aggressive disease.

Normochromic, normocytic anemia is frequently present in active RA. It is thought to reflect ineffective erythropoiesis; large stores of iron are found in the bone marrow. In general, anemia and thrombocytosis correlate with disease activity. The white blood cell count is usually normal, but a mild leukocytosis may be present. Leukopenia may also exist without the full-blown picture of Felty's syndrome. Eosinophilia, when present, usually reflects severe systemic disease.

The erythrocyte sedimentation rate is increased in nearly all patients with active RA. The levels of a variety of other acute-phase reactants including ceruloplasmin and C-reactive protein are also elevated, and generally such elevations correlate with disease activity and the likelihood of progressive joint damage.

Synovial fluid analysis confirms the presence of inflammatory arthritis, although none of the findings is specific. The fluid is usually turbid, with reduced viscosity, increased protein content, and a slightly decreased or normal glucose concentration. The white cell count varies between 5 and 50,000/μL; polymorphonuclear leukocytes predominate. A synovial fluid white blood cell count $>2000/\mu$L with more than 75% polymorphonuclear leukocytes is highly characteristic of inflammatory arthritis, although not diagnostic of RA. Total hemolytic complement, C3, and C4 are markedly diminished in synovial fluid

relative to total protein concentration as a result of activation of the classic complement pathway by locally produced immune complexes.

RADIOGRAPHIC EVALUATION Early in the disease, radiographic evaluations of the affected joints are usually not helpful in establishing a diagnosis. They reveal only that which is apparent from physical examination, namely, evidence of soft tissue swelling and joint effusion. As the disease progresses, abnormalities become more pronounced, but none of the radiographic findings is diagnostic of RA. The diagnosis, however, is supported by a characteristic pattern of abnormalities, including the tendency toward symmetric involvement. Juxtaarticular osteopenia may become apparent within weeks of onset. Loss of articular cartilage and bone erosions develop after months of sustained activity. The primary value of radiography is to determine the extent of cartilage destruction and bone erosion produced by the disease, particularly when one is attempting to estimate the aggressive nature of the disease, monitoring the impact of therapy with disease-modifying drugs, or determining the need for surgical intervention. Other means of imaging bones and joints, including ^{99m}Tc bisphosphonate bone scanning and magnetic resonance imaging, may be capable of detecting early inflammatory changes that are not apparent from standard radiography but are rarely necessary in the routine evaluation of patients with RA.

CLINICAL COURSE AND PROGNOSIS The course of RA is quite variable and difficult to predict in an individual patient. Most patients experience persistent but fluctuating disease activity, accompanied by a variable degree of joint abnormalities and functional impairment. After 10 to 12 years, <20% of patients will have no evidence of disability or joint abnormalities. Within 10 years, ~50% of patients will have work disability. A number of features are correlated with a greater likelihood of developing joint abnormalities or disabilities. These include the presence of >20 inflamed joints, a markedly elevated erythrocyte sedimentation rate, radiographic evidence of bone erosions, the presence of rheumatoid nodules, high titers of serum rheumatoid factor, the presence of functional disability, persistent inflammation, advanced age at onset, the presence of comorbid conditions, low socioeconomic status or educational level, or the presence of HLA-DRβ1*0401 or -DRβ*0404. The presence of one or more of these implies the presence of more aggressive disease with a greater likelihood of developing progressive joint abnormalities and disability. Persistent elevation of the erythrocyte sedimentation rate, disability, and pain on longitudinal follow-up are good predictors of work disability. Patients who lack these features have more indolent disease with a slower progression to joint abnormalities and disability. The pattern of disease onset does not appear to predict the development of disabilities. Approximately 15% of patients with RA will have a short-lived inflammatory process that remits without major disability. These individuals tend to lack the aforementioned features associated with more aggressive disease.

Several features of patients with RA appear to have prognostic significance. Remissions of disease activity are most likely to occur during the first year. White females tend to have more persistent synovitis and more progressively erosive disease than males. Persons who present with high titers of rheumatoid factor, C-reactive protein, and haptoglobin also have a worse prognosis, as do individuals with subcutaneous nodules or radiographic evidence of erosions at the time of initial evaluation. Sustained disease activity of more than 1 year's duration portends a poor outcome, and persistent elevation of acute-phase reactants appears to correlate strongly with radiographic progression. A large proportion of inflamed joints manifest erosions within 2 years, whereas the subsequent course of erosions is highly variable; however, in general, radiographic damage appears to progress at a constant rate in patients with RA. Foot joints are affected more frequently than hand joints. Despite the decrease in the rate of progressive joint damage with time, functional disability, which develops early in the course of the disease, continues to worsen at the same rate, although the most rapid rate of functional loss occurs within the first 2 years of disease.

The median life expectancy of persons with RA is shortened by 3 to 7 years. Of the 2.5-fold increase in mortality rate, RA itself is a contributing feature in 15 to 30%. The increased mortality rate seems to be limited to patients with more severe articular disease and can be attributed largely to infection and gastrointestinal bleeding. Recent evidence has also shown an important role of cardiovascular disease in the increased mortality of RA patients, and this appears to diminish with effective anti-inflammatory therapy. Drug therapy may also play a role in the increased mortality rate seen in individuals with RA. Factors correlated with early death include disability, disease duration or severity, glucocorticoid use, age at onset, and low socioeconomic or educational status.

DIAGNOSIS The mean delay from disease onset to diagnosis is 9 months. This is often related to the nonspecific nature of initial symptoms. The diagnosis of RA is easily made in persons with typical established disease. In a majority of patients, the disease assumes its characteristic clinical features within 1 to 2 years of onset. The typical picture of bilateral symmetric inflammatory polyarthritis involving small and large joints in both the upper and lower extremities with sparing of the axial skeleton except the cervical spine suggests the diagnosis. Constitutional features indicative of the inflammatory nature of the disease, such as morning stiffness, support the diagnosis. Demonstration of subcutaneous nodules is a helpful diagnostic feature. Additionally, the presence of rheumatoid factor, inflammatory synovial fluid with increased numbers of polymorphonuclear leukocytes, and radiographic findings of juxtaarticular bone demineralization and erosions of the affected joints substantiate the diagnosis.

The diagnosis is somewhat more difficult early in the course when only constitutional symptoms or intermittent arthralgias or arthritis in an asymmetric distribution may be present. A period of observation may be necessary before the diagnosis can be established. A definitive diagnosis of RA depends predominantly on characteristic clinical features and the exclusion of other inflammatory processes. The isolated finding of a positive test for rheumatoid factor or an elevated erythrocyte sedimentation rate, especially in an older person with joint pains, should not itself be used as evidence of RA.

In 1987, the American College of Rheumatology developed revised criteria for the classification of RA (Table 301-1). These criteria demonstrate a sensitivity of 91 to 94% and a specificity of 89% when used

TABLE 301-1 *The 1987 Revised Criteria for the Classification of RA*

1. Guidelines for classification
   a. Four of seven criteria are required to classify a patient as having rheumatoid arthritis (RA).
   b. Patients with two or more clinical diagnoses are not excluded.
2. Criteria[a]
   a. Morning stiffness: Stiffness in and around the joints lasting 1 h before maximal improvement.
   b. Arthritis of three or more joint areas: At least three joint areas, observed by a physician simultaneously, have soft tissue swelling or joint effusions, not just bony overgrowth. The 14 possible joint areas involved are right or left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints.
   c. Arthritis of hand joints: Arthritis of wrist, metacarpophalangeal joint, or proximal interphalangeal joint.
   d. Symmetric arthritis: Simultaneous involvement of the same joint areas on both sides of the body.
   e. Rheumatoid nodules: Subcutaneous nodules over bony prominences, extensor surfaces, or juxtaarticular regions observed by a physician.
   f. Serum rheumatoid factor: Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in less than 5% of normal control subjects.
   g. Radiographic changes: Typical changes of RA on posteroanterior hand and wrist radiographs that must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints.

[a] Criteria a–d must be present for at least 6 weeks. Criteria b–e must be observed by a physician.

Source: From FC Arnett et al: Arthritis Rheum 31:315, 1988.

to classify patients with RA compared with control subjects with rheumatic diseases other than RA. Although these criteria were developed as a means of disease classification for investigational purposes, they can be useful as guidelines for establishing the diagnosis. Failure to meet these criteria, however, especially during the early stages of the disease, does not exclude the diagnosis. Indeed, these criteria do not effectively differentiate patients with new-onset RA from those with a variety of other forms of early inflammatory arthritis. Moreover, in patients with early arthritis, the criteria do not discriminate effectively between patients who subsequently develop persistent, disabling, or erosive disease and those who do not.

TREATMENT

General Principles The goals of therapy of RA are (1) relief of pain, (2) reduction of inflammation, (3) protection of articular structures, (4) maintenance of function, and (5) control of systemic involvement. Since the etiology of RA is unknown, the pathogenesis is not completely delineated, and the mechanisms of action of some of the therapeutic agents employed are uncertain, therapy remains somewhat empirical. None of the therapeutic interventions is curative, and therefore all must be viewed as palliative, aimed at relieving the signs and symptoms of the disease. The various therapies employed are directed at nonspecific suppression of the inflammatory or immunologic process in the hope of ameliorating symptoms and preventing progressive damage to articular structures.

Management of patients with RA involves an interdisciplinary approach, which attempts to deal with the various problems that these individuals encounter with functional as well as psychosocial interactions. A variety of physical therapy modalities may be useful in decreasing the symptoms of RA. Rest ameliorates symptoms and can be an important component of the total therapeutic program. In addition, splinting to reduce unwanted motion of inflamed joints may be useful. Exercise directed at maintaining muscle strength and joint mobility without exacerbating joint inflammation is also an important aspect of the therapeutic regimen. A variety of orthotic and assistive devices can be helpful in supporting and aligning deformed joints to reduce pain and improve function. Education of the patient and family is an important component of the therapeutic plan to help those involved become aware of the potential impact of the disease and make appropriate accommodations in life-style to maximize satisfaction and minimize stress on joints.

Medical management of RA involves five general approaches. The first is the use of aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), and simple analgesics to control the symptoms and signs of the local inflammatory process. These agents are rapidly effective at mitigating signs and symptoms, but they appear to exert minimal effect on the progression of the disease. Recently, specific inhibitors of the isoform of cyclooxygenase (COX) that is upregulated at inflammatory sites (COX-2) have been developed. COX inhibitors (known as Coxibs), which selectively inhibit COX-2 and not COX-1, have been shown to be as effective as classic NSAIDs, which inhibit both isoforms of COX, but to cause significantly less gastroduodenal ulceration. The second line of therapy involves use of low-dose oral glucocorticoids. Although low-dose glucocorticoids have been widely used to suppress signs and symptoms of inflammation, recent evidence suggests that they may also retard the development and progression of bone erosions. Intraarticular glucocorticoids can often provide transient symptomatic relief when systemic medical therapy has failed to resolve inflammation. The third line of agents includes a variety of agents that have been classified as the disease-modifying or slow-acting antirheumatic drugs. These agents appear to have the capacity to decrease elevated levels of acute-phase reactants in treated patients and, therefore, are thought to modify the inflammatory component of RA and thus its destructive capacity. Recently, combinations of disease-modifying antirheumatic drugs (DMARDs) have shown promise in controlling the signs and symptoms of RA. A fourth group of agents are the cytokine-neutralizing agents, which have been shown to have a major impact on the signs and symptoms of RA and also to slow progressive damage to articular structures. A fifth group of agents are the immunosuppressive and cytotoxic drugs that have been shown to ameliorate the disease process in some patients. Additional approaches have been employed in an attempt to control the signs and symptoms of RA. Substituting omega-3 fatty acids such as eicosapentaenoic acid found in certain fish oils for dietary omega-6 essential fatty acids found in meat has also been shown to provide symptomatic improvement in patients with RA. A variety of nontraditional approaches have also been claimed to be effective in treating RA, including diets, plant and animal extracts, vaccines, hormones, and topical preparations of various sorts. Many of these are costly, and none has been shown to be effective. However, belief in their efficacy ensures their continued use by some patients.

Drugs ■ *NONSTEROIDAL ANTI-INFLAMMATORY DRUGS* Besides aspirin, many NSAIDs are available to treat RA. As a result of the capacity of these agents to block the activity of the COX enzymes and therefore the production of prostaglandins, prostacyclin, and thromboxanes, they have analgesic, anti-inflammatory, and antipyretic properties. In addition, the agents may exert other anti-inflammatory effects. These agents are all associated with a wide spectrum of toxic side effects. Some, such as gastric irritation, azotemia, platelet dysfunction, and exacerbation of allergic rhinitis and asthma, are related to the inhibition of cyclooxygenase activity, whereas a variety of others, such as rash, liver function abnormalities, and bone marrow depression, may not be. None of the NSAIDs has been shown to be more effective than aspirin in the treatment of RA. However, these nonaspirin drugs are associated with a lower incidence of gastrointestinal intolerance. None of the newer NSAIDs appears to show significant therapeutic advantages over the other available agents. In addition, there is no consistent advantage of any of these newer agents over the others with respect to the incidence or severity of toxic manifestations. Recent evidence indicates that two separate enzymes, COX-1 and -2, are responsible for the initial metabolism of arachidonic acid into various inflammatory mediators. The former is constitutively present in many cells and tissues, including the stomach and the platelet, whereas the latter is specifically induced in response to inflammatory stimuli and is absent from the normal stomach and platelet. Inhibition of COX-2 accounts for the anti-inflammatory effects of NSAIDs, whereas inhibition of COX-1 induces much of the mechanism-based toxicity. As the currently available NSAIDs inhibit both enzymes, therapeutic benefit and toxicity are intertwined. Coxibs have been approved for the treatment of RA. Clinical trials have shown that Coxibs suppress the signs and symptoms of RA as effectively as classic COX-nonspecific NSAIDs but are associated with a significantly reduced incidence of gastroduodenal ulceration and appear to reduce the incidence of gastrointestinal bleeding, perforations, and obstruction to a variable degree compared with classic NSAIDs. However, the use of Coxibs is associated with sodium retention, hypertension, and peripheral edema in a fraction of patients, and the use of some Coxibs may be associated with an increased frequency of myocardial infarction. This suggests that Coxibs might be considered instead of classic COX-nonspecific NSAIDs, especially in persons with increased risk of NSAID-induced major upper gastrointestinal side effects, including persons over 65, those with a history of peptic ulcer disease, persons receiving glucocorticoids or anticoagulants, or those requiring high doses of NSAIDs.

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS Clinical experience has delineated a number of agents that appear to have the capacity to alter the course of RA. This group of agents includes methotrexate, gold compounds, D-penicillamine, the antimalarials, and sulfasalazine. Despite having no chemical or pharmacologic similarities, in practice these agents share a number of characteristics. They exert minimal direct

nonspecific anti-inflammatory or analgesic effects, and therefore NSAIDs must be continued during their administration, except in a few cases when true remissions are induced with them. The appearance of benefit from DMARD therapy is usually delayed for weeks or months. As many as two-thirds of patients develop some clinical improvement as a result of therapy with any of these agents, although the induction of true remissions is unusual. In addition to clinical improvement, there is frequently an improvement in serologic evidence of disease activity, and titers of rheumatoid factor and C-reactive protein and the erythrocyte sedimentation rate frequently decline. Moreover, emerging evidence suggests that DMARDs actually retard the development of bone erosions or facilitate their healing. Furthermore, developing evidence suggests that early aggressive treatment with DMARDs may be effective at slowing the appearance of bone erosions.

Which DMARD should be the drug of first choice remains controversial, and trials have failed to demonstrate a consistent advantage of one over the other. Despite this, methotrexate has emerged as the DMARD of choice because of its relatively rapid onset of action, its capacity to effect sustained improvement with ongoing therapy, and the higher level of patient retention on therapy. Each of the DMARDs is associated with considerable toxicity, and therefore careful patient monitoring is necessary. Toxicity of the various agents also becomes important in determining the drug of first choice. Of note, failure to respond or development of toxicity to one DMARD does not preclude responsiveness to another. Thus, a similar percentage of RA patients who have failed to respond to one DMARD will respond to another when it is given as the second disease-modifying drug.

No characteristic features of patients have emerged that predict responsiveness to a DMARD. Moreover, the indications for the initiation of therapy with one of these agents are not well defined. Recently, evidence has emerged that the initiation of DMARD therapy early in the course of RA clearly has a major impact on the development of bone erosions and the progression to disability. It is now felt that DMARD therapy should be begun as soon as the diagnosis of RA is established, especially in those with any evidence of aggressive disease with a poor prognosis.

The folic acid antagonist methotrexate, given in an intermittent low dose (7.5 to 30 mg once weekly), is currently a frequently utilized DMARD. Most rheumatologists recommend use of methotrexate as the initial DMARD, especially in individuals with evidence of aggressive RA. Recent trials have documented the efficacy of methotrexate and have indicated that its onset of action is more rapid than other DMARDs, and patients tend to remain on therapy with methotrexate longer than they remain on other DMARDs because of better clinical responses and less toxicity. Long-term trials have indicated that methotrexate does not induce remission but rather suppresses symptoms while it is being administered. Maximal improvement is observed after 6 months of therapy, with little additional improvement thereafter. Major toxicity includes gastrointestinal upset, oral ulceration, and liver function abnormalities that appear to be dose-related and reversible and hepatic fibrosis that can be quite insidious, requiring liver biopsy for detection in its early stages. Drug-induced pneumonitis has also been reported. Liver biopsy is recommended for individuals with persistent or repetitive liver function abnormalities. Concurrent administration of folic acid or folinic acid may diminish the frequency of some side effects without diminishing effectiveness.

Glucocorticoid Therapy Systemic glucocorticoid therapy can provide effective symptomatic therapy in patients with RA. Low-dose ($<$7.5 mg/d) prednisone has been advocated as useful additive therapy to control symptoms. Moreover, recent evidence suggests that low-dose glucocorticoid therapy may retard the progression of bone erosions. Monthly pulses with high-dose glucocorticoids may be useful in some patients and may hasten the response when therapy with a DMARD is initiated.

Anti-Cytokine Agents Recently, biologic agents that bind and neutralize TNF have become available. One of these is a TNF type II receptor fused to IgG1 (etanercept), the second is a chimeric mouse/human monoclonal antibody to TNF (infliximab), and the third is a fully human antibody to TNF (adalimumab). Clinical trials have shown that parenteral administration of any of these TNF neutralizing agents is remarkably effective at controlling signs and symptoms of RA in patients who have failed DMARD therapy, as well as in DMARD naïve patients. Repetitive therapy with these agents is effective with or without concomitant methotrexate. These agents not only are effective in persistently controlling signs and symptoms of RA in a majority of patients, but they have also been shown to slow the rate of progression of joint damage assessed radiographically and to improve disability. Side effects include the potential for an increased risk of serious infections. Particularly notable is the capacity of TNF blockade to increase the risk of developing reactivation of dormant tuberculosis. It is prudent to carry out tuberculin skin testing and, if necessary, further evaluation with chest radiographs before beginning therapy with an anti-TNF agent to limit the chance of inciting reactivation of tuberculosis. TNF-neutralizing therapy can also induce the development of anti-DNA antibodies, but rarely is there associated evidence of signs and symptoms of systemic lupus erythematosus. Other side effects include infusion or injection site reactions and rarely the development of demyelinating central nervous system disease. Although these side effects are uncommon, their occurrence mandates that TNF-neutralizing therapy be supervised by physicians with experience in their use.

Anakinra is a recombinant IL-1 receptor antagonist that competitively blocks the binding of IL-1β and IL-1α to the IL-1 receptor and thereby inhibits the activity of these two related proinflammatory cytokines. Anakinra has been shown to improve the signs and symptoms of RA, to decrease disability, and to slow progression of articular damage associated radiographically. It can be given as monotherapy or in combination with methotrexate. The major side effects are injection site reactions.

Immunosuppressive Therapy The immunosuppressive drugs azathioprine, leflunomide, cyclosporine, and cyclophosphamide have been shown to be effective in the treatment of RA and to exert therapeutic effects similar to those of the DMARDs. However, these agents appear to be no more effective than the DMARDs. Moreover, they cause a variety of toxic side effects, and cyclophosphamide appears to predispose the patient to the development of malignant neoplasms. Therefore, these drugs have been reserved for patients who have clearly failed therapy with DMARDs and anti-cytokine therapy. On occasion, extraarticular disease such as rheumatoid vasculitis may require cytotoxic immunosuppressive therapy.

Leflunomide is metabolized to an active metabolite that acts to inhibit dihydroorotate dehydrogenase, an essential enzyme in the pyrimidine biosynthetic pathway. Its predominant action is to inhibit the proliferation of T lymphocytes. Leflunomide has been shown to control the signs and symptoms of RA and to slow the progression of joint damage as effectively as methotrexate. Leflunomide can be given alone or with methotrexate and is the most frequently employed immunosuppressive agent used to treat patients with RA. It is used as monotherapy in patients who have had adverse reactions to methotrexate or inadequate responses to it. The major side effect is the associated increase in liver function enzymes that occurs in 5% of patients receiving leflunomide alone and in $>$50% of individuals taking leflunomide with methotrexate.

Surgery Surgery plays a role in the management of patients with severely damaged joints. Although arthroplasties and total joint replacements can be done on a number of joints, the most successful procedures are carried out on hips, knees, and shoulders. Realistic goals of these procedures are relief of pain and reduction of disability. Reconstructive hand surgery may lead to cosmetic improvement and some functional benefit. Open or arthroscopic synovectomy may be useful in some patients with persistent monarthritis, especially of the knee.

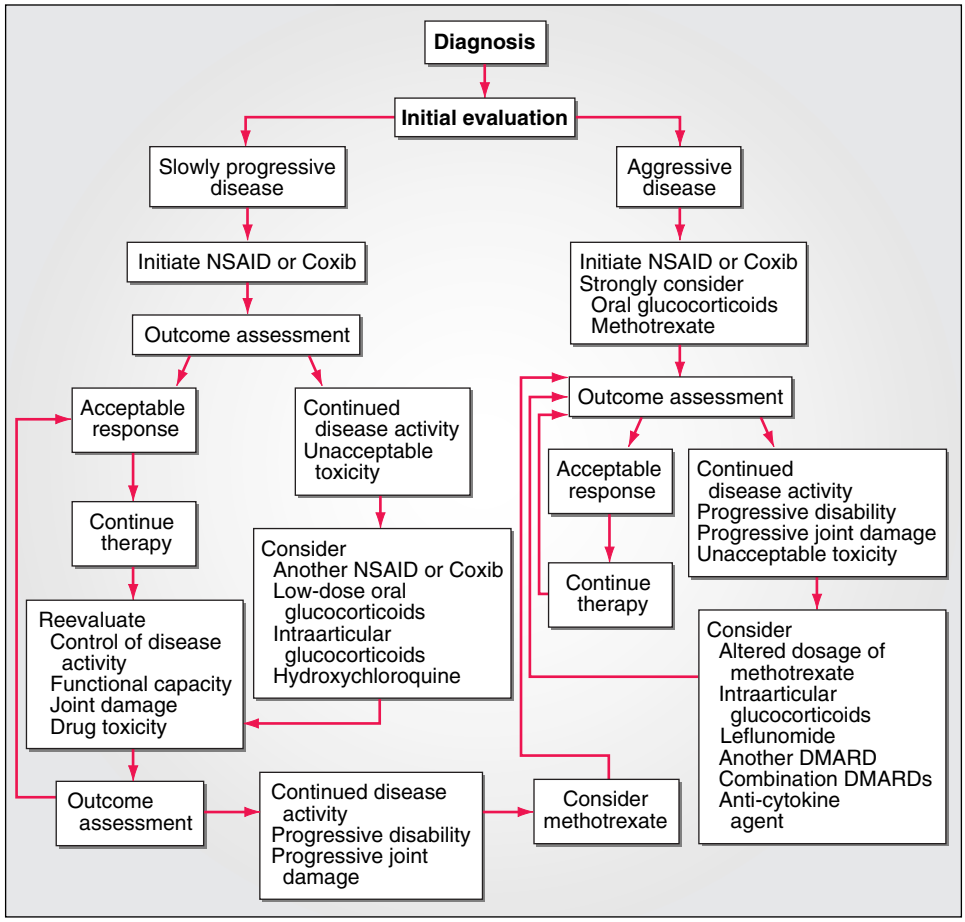

FIGURE 301-3 Algorithm for the medical management of rheumatoid arthritis. NSAID, nonsteroidal anti-inflammatory drug; Coxib, COX-2 inhibitors; DMARD, disease-modifying antirheumatic drug.

Although synovectomy may offer short-term relief of symptoms, it does not appear to retard bone destruction or alter the natural history of the disease. In addition, early tenosynovectomy of the wrist may prevent tendon rupture.

APPROACH TO THE PATIENT

An approach to the medical management of patients with RA is depicted in Fig. 301-3. The principles underlying care of these patients reflect the variability of the disease, the frequent persistent nature of the inflammation and its potential to cause disability, the relationship between sustained inflammation and bone erosions, and the need to reevaluate the patient frequently for symptomatic response to therapy, progression of disability and joint damage, and side effects of treatment. At the onset of disease it is difficult to predict the natural history of an individual patient's illness. Therefore, the usual approach is to attempt to alleviate the patient's symptoms with NSAIDs or Coxibs. Some patients may have mild disease that requires no additional therapy. However, if the patient has any evidence of aggressive disease, as described above, initiation of DMARD therapy should be considered as early as feasible. In RA patients there appears to be a window of opportunity early in the course of the disease, during which initiation of aggressive therapy can have a major impact on subsequent damage to articular structures and disability.

At some time during most patients' course, the possibility of initiating DMARD therapy and/or low-dose oral glucocorticoids is entertained. With aggressive disease this might occur sooner, often within 1 to 3 months of diagnosis, whereas in patients with more indolent disease, smoldering activity may not require such therapy for many years. The development of bone erosions or radiographic evidence of cartilage loss is clear-cut evidence of the destructive potential of the inflammatory process and indicates the need for DMARD therapy. The other indications as outlined above, including persistent pain, joint swelling, or functional impairment, are much more subjective, however. As persistent inflammation, involvement of multiple joints, elevated levels of acute-phase reactants, and rheumatoid factor titers correlate with the development of disability and/or bony erosions, some have advocated the use of these prognostic indicators of aggressive disease in the decision to employ DMARDs early in the course of RA. The decision to begin use of a DMARD and/or low-dose oral glucocorticoids requires experience and clinical judgment as well as the ability to assess joint swelling and functional activity and the patient's pain tolerance and expectation of therapy accurately. In this setting, the fully informed patient must play an active role in the decision to begin DMARD and/or low-dose oral glucocorticoid therapy, after careful review of the therapeutic and toxic potential of the various drugs. If DMARD therapy, usually methotrexate, fails to control signs and symptoms of RA, a decision to add or switch to an anti-cytokine agent is considered. These are quite potent at controlling signs and symptoms of RA, slowing damage to articular structures, and limiting disability but are very expensive and associated with serious adverse events. The decision to employ these agents requires considerable experience, judgment, and the agreement of a fully informed patient.

If a patient responds to a DMARD, therapy is continued with careful monitoring to avoid toxicity. All DMARDs provide a suppressive effect and therefore require prolonged administration. Even with successful therapy, local injection of glucocorticoids may be necessary to diminish inflammation that may persist in a limited number of joints. In addition, NSAIDs or Coxibs may be necessary to mitigate symptoms. Even after inflammation has totally resolved, symptoms from loss of cartilage and supervening degenerative joint disease or altered joint function may require additional treatment. Surgery may also be necessary to relieve pain or diminish the functional impairment secondary to alterations in joint function. Recently an alternative approach to treat patients with RA has been suggested. This involves the initiation of therapy with multiple agents early in the course of disease in an attempt to control inflammation, followed by maintenance on one or more agents as necessary to control disease activity.

302 RHEUMATIC FEVER

Edward L. Kaplan

In many parts of the world, especially in industrialized countries, acute rheumatic fever (ARF) is less common than it was during the early and mid-years of the twentieth century. In the late 1940s, patients with rheumatic fever (RF) and rheumatic heart disease accounted for more than half of schoolchildren recognized to have cardiovascular problems in the United States. During World War II, there were >20,000 cases of ARF in U.S. Navy personnel alone. The incidence of RF has declined remarkably in the industrialized countries of the world, where the disease has become rare. However, in many developing countries, which account for almost two-thirds of the world's population, streptococcal infections, RF, and rheumatic heart disease remain a very significant public health problem. The magnitude of the problem in these countries today is similar to that in North America 60 years ago.

The decreased incidence of ARF and the low prevalence of rheumatic heart disease in industrialized countries have led many physicians and public health authorities to the incorrect conclusion that these conditions are no longer a problem. However, starting in the 1980s, unexpected scattered outbreaks of ARF among both adults and children in North America have confirmed the capacity for this potentially serious illness to reappear and pose significant public health problems. As an example, >600 cases of ARF were seen in middle-class populations in Salt Lake City, Utah, between 1985 and the end of 2002. The disease continues to be a major public health problem in many developing countries of the world. Neither antimicrobial agents nor other public health measures have been totally effective in the control of RF in the industrialized or industrializing world.

EPIDEMIOLOGY The epidemiology of ARF is identical to that of group A streptococcal upper respiratory tract infections (Chap. 121). As is the case for streptococcal sore throat, ARF most often occurs in children; the peak age-related incidence is between 5 and 15 years. Most initial attacks in adults take place at the end of the second and beginning of the third decades of life. Rarely, initial attacks occur as late as the fourth decade, and recurrent attacks have been documented as late as the fifth decade.

Epidemiologic risk factors classically associated with individual attacks and especially with outbreaks of ARF include lower standards of living, especially crowding; the disease has been more common among socially and economically disadvantaged populations. However, the outbreaks in the United States in the late 1980s and early 1990s cannot be explained entirely by these factors. The large Utah outbreak of >600 cases during 17 years has affected primarily middle-class patients with ready access to medical care. Therefore, one can conclude that the organism itself as well as the degree of host/herd immunity to the prevalent M-types in an affected community are equally important risk factors.

Studies have shown that ~3% of individuals with untreated group A streptococcal pharyngitis will develop RF. The epidemiology of RF is also influenced by the serotypes of group A streptococci present in a population. The concept of "rheumatogenecity" of specific strains is largely based upon epidemiologic evidence associating certain serotypes with RF (serotypes 1, 3, 5, 6, 18, etc.). Mucoid isolates are frequently associated with virulence and with RF.

PATHOGENESIS More than half a century ago the pioneering studies of Lancefield differentiated β-hemolytic streptococci into serologic groups (Chap. 121). This ultimately led to the association of infection by the group A organism of the pharynx and tonsils (not of the skin) and the subsequent development of ARF. However, the mechanism(s) responsible for the development of RF after an infection remains incompletely defined. Historically, approaches to understanding the pathogenesis of RF have been grouped into three major categories: (1) direct infection by the group A streptococcus, (2) a toxic effect of streptococcal extracellular products on the host tissues, and (3) an abnormal or dysfunctional immune response to one or more as yet unidentified somatic or extracellular antigens produced by all (or perhaps only by some) group A streptococci ("antigenic mimicry.")

There is insufficient evidence to support direct infection of the heart as the inciting event. Additionally, while toxins such as streptolysin O and others have been postulated to have a pathogenetic role, there is relatively little convincing evidence of this at the present time. Major efforts have focused on an abnormal immune response by the human host to one or more group A streptococcal antigens.

The hypothesis of "antigenic mimicry" between human and group A streptococcal antigens has been studied extensively and has concentrated on two interactions. The first is the similarity between the group-specific carbohydrate of the group A streptococcus and the glycoprotein of heart valves; the second involves the molecular similarity among the streptococcal cell membrane, streptococcal M protein sarcolemma, and other moieties of the human myocardial cell. Investigators have studied tissue-specific antigens as well as major histocompatibility antigens in an attempt to define the pathogenesis.

The possibility of a predisposing genetic influence in some individuals is one of the most tantalizing of the incompletely understood factors that might contribute to susceptibility to RF. The precise genetic factors influencing the attack rate have never been adequately defined. Observations have been described that support the concept that this nonsuppurative sequel to a group A streptococcal upper respiratory tract infection results from an abnormal immune response by the human host. Thus, differences in immune responses to streptococcal antigens have been reported. Further, new data suggest that a unique surface marker on non-T lymphocytes in patients with RF and rheumatic heart disease may be associated with individuals who are susceptible to developing RF after a streptococcal infection because of abnormal immune responses; conclusive proof gained by prospective studies is not yet available.

DIAGNOSIS There is no specific laboratory test that can establish a diagnosis of RF. The diagnosis, therefore, is a clinical one but requires supporting evidence from the clinical microbiology and clinical immunology laboratories. Because of the variety of signs and symptoms associated with the RF syndrome, in 1944 Jones first proposed criteria to assist the clinician in standardizing the diagnosis of RF. The most recent modification of the *Jones criteria* (Updated Jones Criteria) was published in 1992 by a Special Writing Group of the American Heart Association (Table 302-1). A recent consideration of the Jones criteria by the American Heart Association has basically not resulted in change.

TABLE 302-1 *The Jones Criteria for Rheumatic Fever, Updated 1992*

Major Criteria	*Minor Criteria*
Carditis	Clinical
Migratory polyarthritis	Fever
Sydenham's chorea	Arthralgia
Subcutaneous nodules	Laboratory
Erythema marginatum	Elevated acute phase reactants
	Prolonged PR interval

plus

Supporting evidence of a recent group A streptococcal infection (e.g., positive throat culture or rapid antigen detection test; and/or elevated or increasing streptococcal antibody test)

Source: Modified from the Special Writing Group of the American Heart Association: JAMA 268:2069, 1992.

There are five criteria termed *major* because they are most commonly found in patients with RF: carditis, migratory polyarthritis, Sydenham's chorea, subcutaneous nodules, and erythema marginatum.

The *carditis* of ARF is a pancarditis involving the pericardium, myocardium, and endocardium. In most published series, between 40 and 60% of patients with ARF have evidence of carditis, which is characterized by one or more of the following: sinus tachycardia, the murmur of mitral regurgitation, an S_3 gallop, a pericardial friction rub, and cardiomegaly. The introduction of echocardiography has assisted in the identification of subtle abnormalities of the mitral valve, and these may be present in an additional 20% of patients who do not have an audible heart murmur. A prolonged PR interval and evidence of heart failure may be present as well, but these are nonspecific and may be found in a number of other diseases. Among the more controversial aspects of diagnosing RF has been the several reports of significant valvular (particularly of the mitral valve) involvement in the absence of audible murmurs. Although there are suggestions in the literature that echocardiographic criteria be included with the Jones criteria, the long-term follow-ups remain inadequate at the present time.

Healing of the rheumatic valvulitis may cause fibrous thickening and adhesion, resulting in the most serious complication of RF, i.e., valvular stenosis and/or regurgitation (Chap. 219). The mitral valve is involved most frequently, followed by the aortic valve. However, isolated aortic valve disease as a consequence of ARF is quite rare. In patients with aortic valve disease due to RF, the mitral valve is almost always simultaneously affected. Even minor degrees of rheumatic valvular involvement can lead to susceptibilities to infective endocarditis (Chap. 109). Although rheumatic pericarditis can cause a serous effusion, fibrin deposits, and even pericardial calcification, it does not lead to constrictive pericarditis.

A *migratory polyarthritis* is present in as many as 75% of cases, most often affecting the ankles, wrists, knees, and elbows over a period of days. It usually does not affect the small joints of the hands or feet and seldom involves the hip joints. Since salicylates and other anti-inflammatory drugs usually cause prompt resolution of joint symptoms, it is important that the clinician *not* prescribe these medications until it is determined whether the arthritis is migratory. The arthritis of ARF is extremely painful. Pain can be controlled with codeine or similar analgesics until the diagnosis is established. The difference between arthralgia (subjective joint pain) and arthritis (joint pain and swelling) must be understood. Too often, arthralgia is used (incorrectly) as a major criterion. An inflammatory reactive arthritis associated with streptococcal pharyngitis is often confused with the arthritis or arthralgias of ARF. Currently, several antibiotics have been promoted to be used in a <10-day course of therapy. The data at the present time are inconclusive as regards short-course therapy, and most recommendations at the present time recommend a full 10-day course of antibiotics orally for treatment of streptococcal pharyngitis.

Sydenham's chorea occurs in <10% of patients with RF. The latent period between the onset of the initiating streptococcal infection and the onset of Sydenham's chorea may be as long as several months. While differing from the other manifestations, this central nervous system disorder is a part of the RF complex and should be managed as such. Many patients who appear to have only chorea may present several decades later with evidence of typical rheumatic valvular disease. There is no definitive laboratory test for establishing a diagnosis of Sydenham's chorea, and the diagnosis is one of exclusion. Patients with Sydenham's chorea should be given secondary prophylaxis for prevention of recurrent attacks, even if they do not appear to have rheumatic heart disease.

Subcutaneous nodules and *erythema marginatum* are rare major manifestations, usually present in <10% of cases. Subcutaneous nodules are found over extensor surfaces of joints, are seen most often in patients with long-standing rheumatic heart disease, and are extremely rare in patients experiencing an initial attack. Erythema marginatum is an uncommon manifestation. It is an evanescent macular eruption with rounded borders—usually concentrated on the trunk.

The *minor criteria* (Table 302-1) are nonspecific and may be present in many clinical conditions.

To fulfill the Jones criteria, either two major criteria, or one major criterion and two minor criteria, *plus* evidence of an antecedent streptococcal infection are required. The latter may be provided by recovery of the organism on culture or by evidence of an immune response to one of the commonly measured group A streptococcal antibodies (e.g., anti-streptolysin O, anti-deoxyribonuclease B). Since the accurate diagnosis of RF has future medical and financial implications, the clinician is obligated to evaluate any patient completely until the suspected diagnosis is either established or excluded.

Both the clinical microbiology and the clinical immunology laboratories have important roles in confirming the diagnosis of RF. An attempt should be made to recover the organism from a throat culture, although group A streptococci can be recovered from the upper respiratory tract of only 25 to 40% of patients at the time the diagnosis is made. If a rapid antigen detection test is used but is negative, a confirmatory throat culture must be performed. It is helpful to obtain two or three cultures from the throat at the time the diagnosis is suspected, but before initiating antibiotic therapy, in order to confirm the presence of the organism.

At least 80% of patients with ARF have an elevated anti-streptolysin O titer at presentation. If one employs two additional streptococcal antibody tests such as the anti-DNAse B or anti-hyaluronidase test, the percentage of patients who show evidence of a preceding group A streptococcal infection will rise to >95%. While an initially elevated titer is convincing, being able to demonstrate a rise in titer from the acute to the convalescent phase is a more reliable means of documenting the recent infection. If three antibody tests are done and there is no evidence of a preceding infection, the diagnosis must be seriously reconsidered.

TREATMENT

There are two necessary therapeutic approaches to patients with ARF: anti-streptococcal antibiotic therapy and therapy for the clinical manifestations of the disease. At the time of diagnosis, *all* patients with ARF should be treated as if they have a group A streptococcal infection, whether or not the organism is recovered by culture. In addition to the relatively large percentage of such patients who may have a negative throat culture at the time of diagnosis, others may have only a few organisms present in the throat. Conventional antibiotic treatment should be started immediately: a complete 10-day course in adults of either oral penicillin V (500 mg twice daily) or erythromycin (250 mg four times daily) for those with penicillin allergy. Many choose intramuscular benzathine penicillin G (a single intramuscular injection of 1.2 million units) for the treatment of the presumed streptococcal infection; this will also serve as the first dose of secondary prophylaxis for the prevention of recolonization of the upper respiratory tract in the future. Intramuscular benzathine penicillin G has been reported to result in a transient elevation of the erythrocyte sedi-

mentation rate, which can prove confusing in the acute phase of the disease.

Following the initial anti-streptococcal therapy, secondary prophylaxis should be initiated to prevent subsequent infection of the upper respiratory tract with group A streptococci. Recommendations of the American Heart Association and of the World Health Organization are for intramuscular injection of 1.2 million units of benzathine penicillin G every 4 weeks or for oral penicillin V (250 mg twice daily) or oral sulfadiazine (1.0 g daily). Recent studies have shown that in those individuals who are at high risk for recurrence of RF, intramuscular benzathine penicillin G given every 3 weeks is more effective in reducing the risk of recurrence. Since it is known that the risk of recurrence of RF is highest during the first 5 years after the attack, secondary prophylaxis is always given for at least this period. After that the decision to continue or discontinue secondary prophylaxis is dependent upon whether the patient has documented rheumatic heart disease and whether the patient is at high risk of exposure to streptococci (e.g., students, school teachers, medical and military personnel). Many believe that those with documented recurrences and/or documented rheumatic valvular heart disease should receive secondary prophylaxis for life. The duration of prophylaxis is often individualized for specific patients.

Medical therapy for the manifestations of RF depends on the clinical status of the patient. For adult patients with the arthritis of RF, salicylates in doses escalating to 2 g four times daily are very effective and will result in marked clinical improvement, often within 12 h. When this prompt relief does not occur, one should reexamine the original diagnosis. Salicylates may be given for 4 to 6 weeks and gradually tapered so as to prevent a rebound. The erythrocyte sedimentation rate is one method for determining the rate of taper for salicylates. Usually this requires at least 2 weeks. There are no conclusive data to support using nonsteroidal anti-inflammatory drugs for ARF. There is no indication for the use of steroids (usually prednisone) solely for the treatment of the arthritis of RF.

Most experienced physicians believe that there is a role for steroids in patients with severe carditis accompanied by congestive heart failure. However, neither salicylates nor glucocorticoids influence the future development of valvular heart disease. In adults, prednisone can be started in doses as high as 30 mg four times daily in especially severe cases, and, as the patient improves, salicylates can be added during the tapering of the steroid dose; this may require 4 to 6 weeks.

In the presence of congestive heart failure, conventional medical measures (Chap. 216) are indicated. In the past, patients with ARF were kept at complete bed rest for months. This is inappropriate unless there is a specific reason such as persistent active carditis or severe heart failure. Patients with arthritis will begin to feel better very soon after anti-inflammatory therapy with salicylates is begun. They may be released from bed rest but should not resume full activity until signs of inflammatory process have abated and the acute-phase reactants have returned to normal.

303 SYSTEMIC SCLEROSIS (SCLERODERMA) AND RELATED DISORDERS

Bruce C. Gilliland

DEFINITION Systemic sclerosis (SSc) is a chronic multisystem disorder of unknown etiology characterized clinically by thickening of the skin caused by accumulation of connective tissue and by structural and functional abnormalities of visceral organs, including the gastrointestinal tract, lungs, heart, and kidneys. Classification of SSc and scleroderma-like disorders is shown in Table 303-1. Vascular damage, immune activation, and excessive synthesis and deposition of extracellular matrix are prominent features of SSc. The degree and rate of skin and internal organ involvement vary among patients. Two subsets, however, can be identified, even though there is some overlap (Table 303-2). One subset is referred to as *diffuse cutaneous scleroderma* and is characterized by the rapid development of symmetric skin thickening of proximal and distal extremities, face, and trunk. These patients are at greater risk for developing kidney and other visceral disease early in their course. The other subset is *limited cutaneous scleroderma*, which is defined by symmetric skin thickening limited to distal extremities and face. This subset frequently has features of the *CREST syndrome*, standing for *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia. The prognosis in limited cutaneous scleroderma is better except for those patients who, after many years, develop pulmonary arterial hypertension or biliary cirrhosis. Involvement of visceral organs may also occur in the absence of any skin involvement, which is referred to as *systemic sclerosis sine scleroderma*. Survival is determined by the severity of visceral disease, especially involving the lungs, heart, and/or kidneys.

TABLE 303-1 Classification of Scleroderma/Systemic Sclerosis and Scleroderma-Like Disorders

Systemic sclerosis
Limited cutaneous disease
Diffuse cutaneous disease
Sine scleroderma
Undifferentiated connective tissue disease
Overlap syndromes
Localized scleroderma
Morphea
Linear scleroderma
En coup de sabre
Chemically induced scleroderma-like disorders
Toxic-oil syndrome
Vinyl chloride–induced disease
Bleomycin-induced fibrosis
Pentazocine-induced fibrosis
Epoxy- and aromatic hydrocarbons–induced fibrosis
Eosinophilia-myalgia syndrome
Other scleroderma-like disorders
Scleredema adultorum of Buschke
Scleromyxedema
Chronic graft-vs.-host disease
Eosinophilic fasciitis
Digital sclerosis in diabetes
Primary amyloidosis and amyloidosis associated with multiple myeloma

TABLE 303-2 *Subsets of Systemic Sclerosis*

	Diffuse	*Limited*[a]
Skin involvement	Distal and proximal extremities, face, trunk	Distal to elbows, face
Raynaud's phenomenon	Onset within 1 year or at time of skin changes	May precede skin disease by years
Organ involvement	Pulmonary (interstitial fibrosis); renal (renovascular hypertensive crisis); gastrointestinal; cardiac	Gastrointestinal; pulmonary arterial hypertension after 10–15 years of disease in <10% of patients; biliary cirrhosis
Nail fold capillaries	Dilatation and dropout	Dilatation without significant dropout
Antinuclear antibodies	Anti-topoisomerase 1	Anticentromere

[a] Also referred to as CREST (*c*alcinosis, *R*aynaud's, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasia).

Preliminary criteria for the classification of systemic sclerosis were developed by the American Rheumatism Association (now called the American College of Rheumatology) for the purpose of uniformity in clinical studies. A major criterion was the presence of sclerodermatous involvement proximal to the digits, affecting proximal portions of the extremities, face, neck, or trunk usually in a bilateral and symmetrical pattern. Sclerodactyly was almost always present. This single major criterion was present in 91% if SSc patients and in less than 1% of comparison disorders. Minor criteria were sclerodactyly, digital pitting scars or tissue loss of the volar pads of the fingertips, and bibasilar pulmonary fibrosis. The diagnosis of SSc was based on the presence of the major criterion or two or more minor criteria. The sensitivity of these criteria was 97%, and the specificity 98%. These criteria are not, however, applicable to clinical practice as some patients with limited cutaneous SSc do not meet these criteria. These patients may have esophageal and/or bowel dysmotility or pulmonary arterial hypertension without pulmonary fibrosis. Scleroderma can also occur in a localized form limited to the skin, subcutaneous tissue, and muscle and without systemic involvement. Localized scleroderma occurs most often in children and young women but can affect any age group. The two localized forms are *morphea*, which occurs as single or multiple plaques of skin induration, and *linear scleroderma*, which involves an extremity or the face. Linear scleroderma of one side of the forehead and scalp produces a disfiguration referred to as *en coup de sabre* because it resembles a wound from a sword. It may be associated with hemiatrophy of the same side of the face.

SSc also occurs in association with features of other connective tissue diseases. The term *overlap syndrome* has been used to describe such patients. Undifferentiated connective tissue disease has been suggested as a designation for patients who do not have diagnostic criteria for any one connective tissue disease. *Mixed connective tissue disease* (MCTD), a syndrome involving features of systemic lupus erythematosus (SLE), SSc, polymyositis, and rheumatoid arthritis and very high titers of circulating antibody to nuclear ribonucleoprotein (RNP) antigen, will be discussed later in the chapter. *Eosinophilic fasciitis* and the *eosinophilia-myalgia syndrome* (EMS) associated with contaminated L-tryptophan ingestion (Chap. 369) are scleroderma-like illnesses and will also be discussed in this chapter.

EPIDEMIOLOGY SSc has a worldwide distribution and affects all races. The onset of disease is unusual in childhood and young men. The incidence increases with age, peaking in the third to fifth decade. Women overall are affected approximately three times as often as men and even more often during the mid to late childbearing years (≥8:1). African Americans are affected approximately twice as frequently, have a lower age of onset, and more often have diffuse cutaneous involvement and pulmonary fibrosis than Caucasians. Hispanics and Native Americans may also have more severe disease than Caucasians. The annual incidence has been estimated to be 19 cases per million population. The reported prevalence of SSc is between 19 and 75 per 100,000 persons. An exceptionally high prevalence of SSc (469 per 100,000 persons) has been noted in the Choctaw Native Americans in Oklahoma—the highest found to date in any ethnic group. Both incidence and prevalence may be underestimated because patients with early and atypical disease may be overlooked in surveys. Genetic factors play a role in the susceptibility and expression of SSc. Familial aggregation for SSc has been reported in ~1.5% of SSc families. SSc in a first-degree relative is a very strong relative risk factor for SSc. There is also an increased incidence of other autoimmune diseases, including SLE and rheumatoid arthritis, as well as antinuclear antibodies in first-degree relatives of SSc patients. In a recent study, the rate of concordance of SSc in monozygotic twins was only 4.7%, the same as in dizygotic twins. The concordance for the presence of antinuclear antibodies was significantly greater in monozygotic twins (90%) than in dizygotic twins (40%). SSc-associated serum autoantibodies (see Laboratory Findings below) were found only in twins with SSc. The finding of antinuclear antibodies in spouses of SSc patients suggests that environmental factors are also involved in the development of antinuclear antibodies. Studies have not shown a strong association between human leukocyte antigens (HLA) and susceptibility to SSc. C4A null alleles (C4AQ0) and HLA-DQA2 have been reported by some investigators to be markers for disease susceptibility. In a recent study, the frequency of HLA-DQA1*0501 was increased in Caucasian men with SSc over healthy controls from the same geographic area. No one HLA type has been shown to be associated with disease susceptibility in all ethnic groups. A more consistent relationship has been found between certain HLA types and the occurrence of specific autoantibodies in SSc patients. Anticentromere antibodies have been shown to be associated with HLA-DRβ1*0101 and -DQβ1*0501 in Caucasians, African Americans, and Hispanics. Antitopoisomerase 1 antibodies, on the other hand, are associated most frequently with HLA-DRβ1*1101, *1104 and -DQβ1*0301 in Caucasians and African Americans, -DRβ1*1502 in Japanese, and -DRβ1*1602 in Chocktaw Native Americans.

Stronger evidence for a genetic role in SSc comes from studies of the Chocktaw Native Americans in Oklahoma who have a very high incidence of SSc. Affected individuals have in common diffuse cutaneous disease, pulmonary fibrosis, and antitopoisomerase antibodies. These autoantibodies are associated with the haplotype DQ 7, DR2 (DRβ1*1602) in this population of Native Americans. The association is stronger for the presence of antitopoisomerase antibodies than for the presence of SSc, as many individuals with autoantibodies do not have SSc. The extracellular fibrillin-1 matrix gene, FBN1, has also been found to be strongly associated with SSc in Chocktaw Native Americans. Not all SSc-affected individuals express the gene, and vice versa. The majority of Chocktaws were shown to produce autoantibodies to recombinant fibrillin-1 proteins. Of interest is that a tandem duplication of the murine gene, *fbn1*, in the tight-skin mouse (murine model of SSc) is thought to be responsible for the tight-skin mouse phenotype.

Infectious agents may play a role in the pathogenesis of SSc in the genetically susceptible individual. Latent cytomegalovirus (CMV) infection has been implicated in the vascular injury of SSc either by direct vascular injury or by immune-mediated mechanisms involving molecular mimicry in which viral and host proteins share similar amino acid sequences. Sera from SSc patients were shown to have antibodies that recognized an epitope contained within human CMV late protein UL94. This epitope is similar to a protein expressed in human endothelial cells. Incubation of SSc serum containing this antibody with endothelial cells was shown to induce apoptosis of endothelial cells, which is a feature of the vascular pathology observed in SSc. Parvovirus B19 has also been implicated in the development of SSc. In one study parvovirus B19 was detected in the bone marrow of >50% of SSc patients, compared to none in normal controls. Also, the frequency of anti-parvovirus B19 antibody was shown to be in-

creased in SSc patients. The actual role of this virus or other microorganisms in the pathogenesis of SSc awaits further studies.

Several environmental factors have been associated with the development of SSc and scleroderma-like illnesses. SSc appears to be more common in coal and gold miners, especially in those with more extensive exposure, suggesting that silica dust may be a predisposing factor. Workers exposed to polyvinyl chloride may develop Raynaud's phenomenon, acroosteolysis, scleroderma-like skin lesions, pulmonary fibrosis, and nail fold capillary abnormalities similar to those observed in SSc. These workers may also develop hepatic fibrosis and angiosarcoma. The observation that individuals exposed to similar amounts of polyvinyl chloride do not develop the same degree of disease suggests that a genetic factor may determine susceptibility and disease severity. The development of scleroderma has also been associated with exposure to epoxy resins and aromatic hydrocarbons such as benzine, toluene, and trichloroethylene. In 1981, in Spain, a multisystem disease resembling scleroderma occurred following the ingestion of aniline-adulterated cooking oil (rapeseed oil). Approximately 20,000 people were affected. The patients initially developed interstitial pneumonitis, eosinophilia, arthralgias, arthritis, and myositis, followed subsequently by joint contractures, skin thickening, Raynaud's phenomenon, pulmonary hypertension, sicca syndrome, and resorption of the distal fingertips. Extensive sclerosis of the dermis and subcutaneous tissue has been noted in patients receiving pentazocine, a nonnarcotic analgesic agent. Bleomycin, an anticancer agent, produces fibrotic skin nodules, linear hyperpigmentation, alopecia, Raynaud's phenomenon, gangrene of fingers, and pulmonary fibrosis affecting mainly the lower lobes. Scleroderma and other connective tissue diseases have been reported in women who have had silicone breast implants. Recent studies have not shown that women with these implants carry an increased risk for developing scleroderma or other connective tissue diseases. Localized fibrosis, however, can occur around the implant. While environmental factors or undefined infectious agents may be of etiologic significance, the cause of SSc remains unknown.

PATHOGENESIS The outstanding feature of SSc is overproduction and accumulation of collagen and other extracellular matrix proteins, including fibronectin, tenascin, fibrillin-1, and glycosaminoglycans, in skin and other organs. The disease process involves immunologic mechanisms, vascular endothelial cell activation and/or injury, and activation of fibroblasts resulting in production of excessive collagen (Fig. 303-1).

An early event in SSc that precedes fibrosis is vascular injury involving small arteries, arterioles, and capillaries in the skin, gastrointestinal tract, kidneys, heart, and lungs. Raynaud's phenomenon, the initial symptom of SSc in the majority of patients, is a clinical expression of the abnormal regulation of blood flow resulting from vascular injury. Injury to endothelial cells and basal lamina occurs early and is followed by proliferation of the intima and smooth-muscle cells, with deposition of matrix and perivascular fibrosis leading to narrowing of the lumen and eventual obliteration of the vessel. As vascular damage progresses, the microvascular bed in the skin and other sites is diminished, producing a state of chronic ischemia. Vascular abnormalities can be observed in the nail folds by wide-field microscopy, which shows drop-out of capillaries with dilatation and tortuosity of remaining ones. In the skin, remaining capillaries may proliferate and dilate to become visible telangiectasia. Endothelial cell damage is reflected in elevated levels of factor VIII/von Willebrand factor in the sera of some patients with SSc.

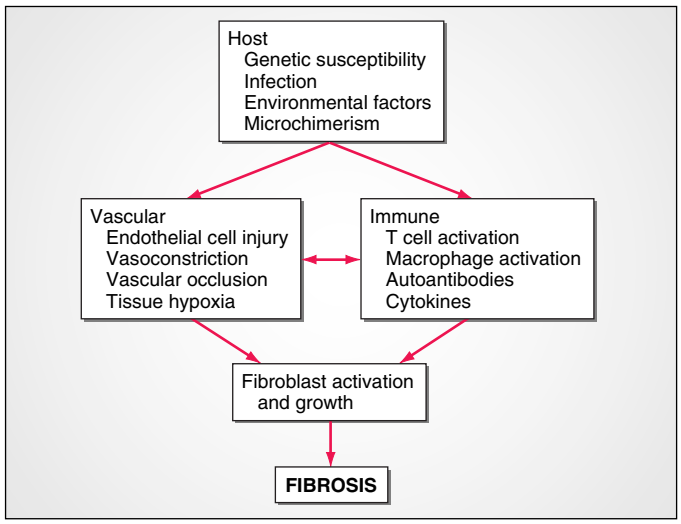

FIGURE 303-1 Algorithm for the multifactorial pathogenic mechanisms of systemic sclerosis.

Several mechanisms for endothelial injury or activation have been proposed in SSc. Any or all of these mechanisms may be involved in a given patient; some evidence for each exists. A cytotoxic factor for endothelium has been identified in some patients that degrades the basal lamina, releasing fragments of type IV collagen and laminin. This factor, a type IV collagenase, is secreted by activated T cells and is referred to as *granzyme 1* because of its location in cytolytic T cells. Type IV collagen and laminin fragments may stimulate an immune response to the basal lamina. Both antibodies and cell-mediated immunity to type IV collagen and laminin have been observed in some SSc patients and may be involved in endothelial injury or may be an epiphenomenon. Anti-endothelial cell antibodies (AECA) may be another mechanism for microvascular damage. In 25% of SSc patients, AECA have been shown to mediate antibody-dependent cell cytotoxicity against human endothelial cells. Circulating AECA in general have been reported in the sera of SSc patients in amounts ranging from 21 to 85%. This wide variation reflects patient selection, type of assay, and the source of endothelium. These antibodies are not specific for SSc and are found in other connective tissue diseases. The frequency of AECA is higher in patients with diffuse cutaneous SSc. They have also been shown to be associated with digital infarcts, pulmonary hypertension, and impaired alveolocapillary diffusion. Studies have shown that AECA initiate programmed cell death (apoptosis) of endothelial cells, which may be an important event in the pathogenesis of SSc. These antibodies also induce expression of vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), E-selectin, and P-selectin on endothelial cells in SSc and stimulate the production of chemoattractants [interleukin (IL) 1, IL-8, monocyte chemotactic protein (MCP)], leading to the binding of T and B cells, natural killer cells, and monocytes to the endothelium and their migration into the perivascular tissue. Elevated serum levels of VCAM-1, ICAM-1, and P-selectin are observed in early stages of SSc.

The injury to the endothelium leads to a state favoring vasoconstriction and tissue ischemia. The damaged endothelium produces decreased amounts of prostacylin, which is an important vasodilator and inhibitor of platelet aggregation. Platelets are activated on binding to the damaged endothelium and release thromboxane, a potent vasoconstrictor. Activated platelets also release platelet-derived growth factor (PDGF), which is chemotactic and mitogenic for both smooth-muscle cells and fibroblasts, and transforming growth factor (TGF) β, which stimulates fibroblast collagen synthesis. These and other cytokines stimulate intimal fibrosis and, with their passage through the injured endothelium, may produce adventitial and perivascular fibrosis. Endothelin-1, a vasoconstricting factor released from endothelial cells on cold exposure, is also increased in SSc patients. In addition, it stimulates fibroblasts and smooth-muscle cells. The vasoconstriction action of endothelin-1 is normally opposed by endothelium-derived relaxation factor (EDRF, nitric oxide), also secreted by endothelial cells. The normal compensatory increase in EDRF is not seen in some patients with SSc, suggesting impairment of its synthesis. An increased α_2 adrenergic–mediated vasoconstriction has been demonstrated in SSc dermal arterioles. A deficiency of vasodilatory neuropeptides resulting from sensory system nerve damage may also produce a

condition favoring vasoconstriction. Vasoconstriction itself also contributes to endothelial damage through a mechanism of reperfusion injury. Following hypoxic endothelial injury from vasoconstriction, reperfusion can lead to release of oxygen free radicals, causing further tissue damage.

Existing evidence indicates that cell-mediated immunity plays a central role in the development of fibrosis in SSc. T cells, macrophages, endothelial cells, and other cells along with cytokines and growth factors interact in a complex manner to stimulate fibrosis. The vascular endothelium has been proposed as a target for cell-mediated immunity. Laminin and type IV collagen, components of the subendothelial basement membrane, induce in vitro transformation of lymphocytes from SSc patients. In the early stages of SSc, a mononuclear cell infiltrate consisting predominantly of activated helper-inducer T cells (T_H2 type) surrounds small blood vessels in the dermis. Subsequently, mononuclear cell infiltrates are found in macroscopically normal-appearing skin adjacent to areas of fibrosis. T cell hyperactivity is reflected by increased serum levels of CD4+ T cells. The ratio of CD4+ to CD8+ T cells is also increased. Elevated circulating levels of IL-2, a product of activated T cells, and IL-2 receptors have been shown to be associated with active fibrosis. In addition, serum levels of IL-4 are increased in SSc patients. IL-4, a product of activated T cells, stimulates fibroblast chemotaxis and proliferation and collagen production. In a recent study, CD8+ T cells isolated from bronchoalveolar lavage fluid from SSc patients made IL-4 and/or IL-5 mRNA. SSc patients with these type 2 cytokines were more likely to have alveolitis and a lower forced vital capacity. Although larger studies are needed, the findings suggest that these cytokines are involved in the pathogenesis of interstitial pulmonary fibrosis. Another cytokine, interferon γ, is produced by activated T cells (T_H1 type) and stimulates macrophages but inhibits collagen synthesis by fibroblasts. Reduced serum levels of interferon γ are found in some SSc patients. In vitro stimulation of T cells from SSc patients did not show an increased production of interferon γ compared to normal individuals, suggesting an inability in SSc patients to suppress fibrosis normally.

Macrophages are present in increased numbers in the infiltrates of SSc lesions, including the pulmonary alveoli. Activated macrophages secrete several important products involved in the pathogenesis of SSc including IL-1, IL-6, tumor necrosis factor (TNF) α, TGF-β, and PDGF. IL-1 has been shown to stimulate fibroblast proliferation and collagen synthesis. The important role for IL-6 may be in stimulating the local release of tissue inhibitor of metalloproteinase (TIMP) by fibroblasts and thereby limiting the breakdown of collagen. The role of TGF-β and PDGF secreted by macrophages and other cells is discussed below. In addition to the above cytokines, macrophages secrete *fibronectin*, a large matrix protein that is increased in SSc lesions. Fibronectin is also secreted by fibroblasts. Fibronectin interacts with collagen in the SSc lesions where it binds fibroblasts and mononuclear cells through receptors called *integrins*. Fibronectin functions as a chemoattractant and mitogen for fibroblasts.

Additional support for involvement of cell-mediated immunity in the pathogenesis of SSc is the appearance of scleroderma-like lesions in patients with graft-versus-host disease (GVHD) after bone marrow transplantation and in a murine model of chronic GVHD, conditions known to be associated with activated T cells. GVHD and SSc are both associated with progressive skin induration, joint contractures, and gastrointestinal and pulmonary involvement and are frequently accompanied by Sjögren's syndrome. Antinuclear antibodies are present in both diseases. Raynaud's phenomenon and kidney involvement are infrequent in GVHD.

Mast cells may also be involved in the development of fibrosis. Increased numbers of mast cells are found in the dermis in both involved and uninvolved skin. Mast cell degranulation has been noted in skin that subsequently became fibrosed. Interaction with T cells may be one mechanism for mast cell degranulation resulting in release of tryptase that stimulates fibroblast collagen synthesis. Release of histamine from mast cells may also contribute to edema observed in early disease.

Fibroblast growth and synthesis of collagen, fibronectin, and glycosaminoglycans are increased in SSc. The number of α-smooth muscle actin-positive fibroblasts is greatly increased in SSc lesions. Fibroblasts from SSc appear to have aberrant regulation of growth compared with fibroblasts from normal persons. When fibroblasts from affected SSc skin are removed and cultured in vitro, they continue to produce excessive quantities of collagen. The collagen is biochemically normal, and the proportion of type I to type III is the same as in normal skin. Fibroblasts from SSc patients appear to be in a state of permanent activation, due in part to autocrine and paracrine stimulation by TGF-β and connective tissue growth factor (CTGF). These activated cells are thought to represent an expanded subpopulation of fibroblasts that inherently express increased matrix genes. Studies have revealed a subpopulation of SSc fibroblasts that produces two to three times more collagen than other cells from the same tissue. Fibroblasts with a high-collagen-producing phenotype may be clonally selected by cytokines or other immune stimuli. Another explanation for the subpopulation of high-collagen-producing fibroblasts is that fibroblasts with low-collagen-producing phenotype may be selectively removed by apoptosis. Fibroblasts expressing elevated levels of mRNA for types I and III collagen have been demonstrated by in situ hybridization, particularly around dermal blood vessels in affected SSc skin. Collagen deposition is also initially perivascular in other organs including myocardium, muscle, and kidney. A small number of fibroblasts express increased levels of mRNA for types VI and VII collagen. Type VII collagen is normally found at the dermal-epidermal basement membrane zone and is the major component of anchoring fibrils that act to stabilize the attachment of the basement membrane to the underlying dermis. In SSc patients, type VII collagen is found throughout the dermis and may account for the indurated, tightly bound skin in this disease. PDGF receptors are expressed on SSc fibroblasts not only from affected areas but also from macroscopically normal-appearing skin. Fibroblasts from normal persons lack expression of these receptors. TGF-β has been shown to upregulate the expression of these receptors in SSc fibroblasts but not in normal cells and, in conjunction with PDGF, stimulates SSc fibroblast proliferation. Macrophages and fibroblasts are capable of secreting PDGF and TGF-β, and activated T cells release TGF-β. TGF-β also induces the synthesis of CTGF by fibroblasts, which further stimulates fibroblast proliferation and extracellular matrix proteins including collagen synthesis. CTGF mRNA and protein expression in SSc tissue are increased, and serum levels of CTGF have been found to be elevated in SSc and correlate with the degree of dermal and pulmonary fibrosis.

TGF-β is considered to play an essential role in mediating fibrosis in SSc. TGF-β stimulates fibroblast proliferation and synthesis of extracellular matrix proteins as well as CTGF, which in turn is a profibrotic cytokine. TGF-β is synthesized by fibroblasts and by endothelial cells, keratinocytes, and inflammatory cells that also express TGF-β receptors. SSc fibroblasts have been shown to have increased expression of TGF-β receptors, rendering these cells more responsive to TGF-β. TGF-β transmits its signal from the cell surface to the nucleus of fibroblasts through intracellular transcription factor proteins referred to as *Smads*. When the TGF-β receptor is engaged by TGF-β, Smad proteins 2, 3, and 4 are activated and assemble into multimeric complexes, which are translocated to the nucleus where they activate target genes for matrix synthesis. This pathway is controlled by Smad proteins 6 and 7, inhibitory proteins of the Smad family, which block Smad-dependent signal transduction. A recent study showed reduced Smad 7 protein levels in involved SSc skin, suggesting that an abnormality in regulation of intracellular signaling may lead to excessive fibroblast activation. The importance of TGF-β in fibrosis is further supported by studies in several animal models of fibrosis in which antibodies to TGF-β reduced or prevented fibrosis.

Recent studies have suggested that microchimerism may be involved in the pathogenesis of SSc. Microchimerism in SSc is of interest because of the clinical similarities between SSc and GVHD after

allogeneic bone marrow transplantation. Also relevant are the predilection for women in SSc and the increased incidence of SSc in women after the childbearing years. Fetal progenitor cells can persist in the serum of normal women for many years after childbirth. Microchimerism can also occur in nulligravid women and in men with SSc as non-host cells may come from blood transfusion, engraftment of cells from a twin, or from maternal cells in utero. Two-directional traffic of cells occurs during pregnancy. Compared to normal controls, both the quantity and frequency of immune fetal cells have been found to be increased in the serum of SSc patients. The mechanism by which microchimerism is involved in the pathogenesis is not known, but it is conceivable that these small numbers of non-host cells alter immune regulation, leading to autoimmunity.

Chromosomal abnormalities have been noted in >90% of SSc patients. These acquired abnormalities include chromatid breaks, acentric fragments, and ring chromosomes and are found in ~30% of mitotic cells. A chromosomal breakage factor has been found in the serum of SSc patients and their first-degree relatives. The significance of these chromosomal abnormalities is unknown.

PATHOLOGY ■ Skin In the skin, a thin epidermis overlies compact bundles of collagen that lie parallel to the epidermis. Fingerlike projections of collagen extend from the dermis into the subcutaneous tissue and bind the skin to the underlying tissue. Dermal appendages are atrophied, and rete pegs are lost. In early stages of disease, a mononuclear cell infiltrate of predominantly T cells surrounds small dermal blood vessels. Increased numbers of T cells, monocytes, plasma cells, and mast cells are found, particularly in the lower dermis of involved skin.

Gastrointestinal Tract In the lower two-thirds of the esophagus, the histologic findings consist of a thin mucosa and increased collagen in the lamina propria, submucosa, and serosa. The degree of fibrosis is less than in the skin. Atrophy of the muscularis in the esophagus and throughout the involved portions of the gastrointestinal tract is more prominent than the amount of fibrotic replacement of muscle. Ulceration of the mucosa is often present and may be due to either SSc or superimposed peptic esophagitis. Chronic esophageal reflux can lead to metaplasia of the lower esophagus (Barrett's esophagus), which is a premalignant lesion. Striated muscles in the upper third of the esophagus are relatively spared. Similar changes may be found throughout the gastrointestinal tract, especially in the second and third portions of the duodenum, in the jejunum, and in the large intestine. Atrophy of the muscularis of the large intestine may lead to the development of large-mouth diverticula. In the later stages of the disease, the involved portions of the gastrointestinal tract become dilated. Infiltration of lymphocytes and plasma cells in the lamina propria is also present.

Lung With pulmonary involvement, diffuse interstitial fibrosis, thickening of the alveolar membrane, and peribronchial and pleural fibrosis are observed. Bronchiolar epithelial proliferation accompanies the pulmonary fibrosis. Rupture of septa produces small cysts and areas of bullous emphysema. Small pulmonary arteries and arterioles show intimal thickening, fragmentation of the elastica, and muscular hypertrophy; this may occur without interstitial pulmonary fibrosis and produce pulmonary hypertension, particularly in a subset of patients with limited cutaneous SSc.

Musculoskeletal System The synovium in patients with arthritis is similar to that seen in early rheumatoid arthritis and shows edema with infiltration of lymphocytes and plasma cells. A characteristic finding is a thick layer of fibrin overlying and within the synovium. Later in the disease the synovium may become fibrotic. Fibrinous deposits appear on the surfaces of tendon sheaths and in the overlying fascia and may lead to audible creaking over moving tendons.

Histologic features of primary myopathy consist of interstitial and perivascular lymphocytic infiltrations, degeneration of muscle fibers, and interstitial fibrosis. Arterioles may be thickened, and capillaries may be decreased in number. Pathologic and electrophysiologic findings of polymyositis in proximal muscles are present in the few patients who are considered to have the overlap syndrome of SSc and polymyositis.

Heart Cardiac involvement consists of degeneration of myocardial fibers and irregular areas of interstitial fibrosis that are most prominent around blood vessels. Intermittent spasm of blood vessels may result in contraction band necrosis, similar to changes observed in myocardial infarction in patients with atherosclerotic coronary artery disease. Fibrosis also involves the conduction system, leading to atrioventricular conduction defects and arrhythmias. The wall of smaller coronary arteries may be thickened. Fibrinous pericarditis and pericardial effusions are found in some patients.

Kidney Renal involvement is found in over half the patients and consists of intimal hyperplasia of the interlobular arteries; fibrinoid necrosis of the afferent arterioles, including the glomerular tuft; and thickening of the glomerular basement membrane. Small cortical infarctions and glomerulosclerosis may be present. The renal pathologic change is often indistinguishable from that observed in malignant hypertension. Renal vascular lesions, however, may be present in the absence of hypertension. Immunofluorescence studies of kidney have shown IgM, complement components, and fibrinogen in the walls of affected vessels. Angiographic renal studies in patients with SSc may show constriction of the interlobular arteries, a finding that simulates the vasospasm of the digital arteries observed in Raynaud's phenomenon. Cold-induced Raynaud's phenomenon has been shown to decrease renal blood flow.

Other Organs Primary liver involvement is not common. Primary biliary cirrhosis occurs in some patients, particularly in those with the limited cutaneous form of SSc. Fibrosis of the thyroid gland may develop in the presence or absence of autoimmune thyroiditis.

Thickening of the periodontal membrane with replacement of the lamina dura is demonstrated radiographically as widening of the periodontal space and may cause gingivitis and loosening of the teeth. The decreased oral aperture and mucosal dryness make eating and oral hygiene difficult.

CLINICAL MANIFESTATIONS (See Table 303-3) ■ **Raynaud's Phenomenon** SSc usually begins insidiously; the first symptoms are frequently Raynaud's phenomenon and puffy fingers. Some 95% of patients will experience Raynaud's phenomenon, which is defined as episodic vasoconstriction of small arteries and arterioles of fingers, toes, and sometimes the tip of the nose and earlobes. Episodes are brought on by cold exposure, vibration, or emotional stress. Patients experience pallor and/or cyanosis followed by rubor on rewarming. Pallor and/or cyanosis are usually associated with coldness and numbness of fingers and/or toes, and rubor with pain and tingling. Not all patients appreciate the three color phases. A history of digit pallor appears to be the most reliable symptom for the presence of Raynaud's phenomenon.

TABLE 303-3 *Clinical Features of Systemic Sclerosis*

Clinical Feature	% Patients during Course of Disease: Limited[a]	Diffuse[a]
Raynaud's phenomenon	95–100	90–95
Skin thickening	98[b]	100

[a] Limited cutaneous and diffuse cutaneous subsets of SSc.
[b] 2% or fewer of patients have SSc sine scleroderma.

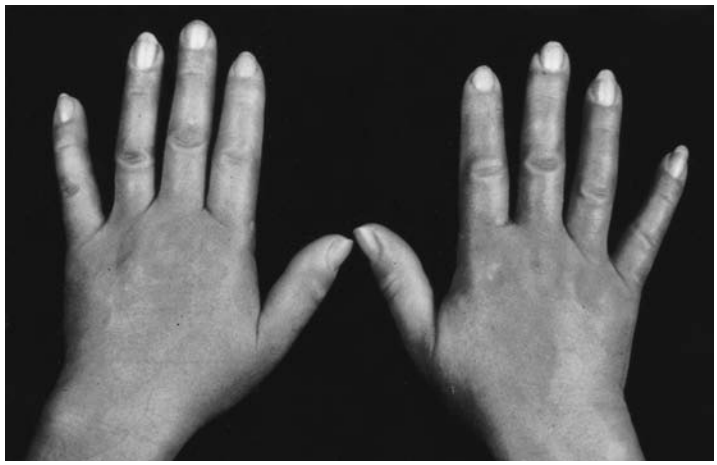

FIGURE 303-2 Swollen hands and fingers in early systemic sclerosis. Swelling may also involve forearms, distal lower extremities, and face. Edematous phase may last weeks to months or even longer.

Raynaud's phenomenon may precede skin changes by several months or even years in those patients who subsequently develop the limited cutaneous form of SSc. In diffuse cutaneous SSc, skin changes are seen typically within a year of the onset of Raynaud's phenomenon. After 2 or more years of Raynaud's phenomenon, few patients who have this as their only symptom will subsequently develop SSc.

Skin Features In early disease, fingers and hands are swollen (Fig. 303-2). Swelling may also involve forearms, feet, lower legs, and face. However, lower extremities are relatively spared. This edematous phase may last for a few weeks, months, or even longer. The edema may be pitting or nonpitting and accompanied by erythema. The skin changes begin distally in the extremities and advance proximally. The skin gradually becomes firm, thickened, and eventually tightly bound to underlying subcutaneous tissue (indurative phase). In patients with diffuse cutaneous scleroderma, skin changes will become generalized, involving initially the extremities, followed by the face and trunk over a period of time, varying from months to a few years. In some patients, the skin changes may develop gradually over several years. Rapid progression of these changes over a 1- to 3-year period is associated with a greater risk of visceral disease, particularly of the lungs, heart, or kidneys. Also in diffuse cutaneous SSc, the skin changes usually peak in 3 to 5 years and then slowly improve. On the other hand, patients with limited cutaneous scleroderma will usually have a more gradual progression of skin changes, which are restricted to fingers or distal extremity and face and may continue to worsen. In both subsets of SSc, skin thickening is usually greater in the distal extremity. After many years of disease, the skin may soften and return to normal thickness or become thin and atrophic.

In the extremities, the taut skin over fingers gradually limits full extension, and flexion contractures develop (Fig. 303-3). Ulcers may appear on the volar pads of the fingertips and over bony prominences such as elbows, malleoli, and the extensor surface of the proximal interphalangeal joints of the hands. These ulcers may become secondarily infected. The volar pads of the fingertips develop pitting scars and lose soft tissue. In some instances, resorption of the terminal phalanges occurs. Skin over the extremities, face, and trunk may become darkly pigmented, even without exposure to the sun. Hyperpigmentation of the skin may occur over superficial blood vessels and tendons. Areas of hypopigmentation may also develop, similar to vitiligo, involving the eyebrows, scalp, and trunk. The sparing of pigment around hair follicles gives the skin a "salt-and-pepper" appearance. Other patients may develop a diffuse tanning of the skin. The skin loses hair, oil, and sweat glands and so becomes dry and coarse. Vaginal dryness occurs and may cause dyspareunia.

In some patients, particularly those with the limited cutaneous form of disease, calcific deposits develop in intracutaneous and subcutaneous tissue. The sites commonly involved are periarticular tissue, digital pads, olecranon and prepatellar bursae, and skin along the extensor surface of the forearms. The overlying skin may break down, with drainage of calcific material. Involvement of the face results in thinning of the lips, loss of skin wrinkles and facial expression, as well as microstomia, which may make eating and dental hygiene difficult (Fig. 303-4). The nose takes on a pinched or beaklike appearance. Wrinkles appear around the mouth perpendicular to the lips. Small telangiectatic mats may appear on the fingers, face, lips, tongue, and buccal mucosa after several years. They are seen more frequently in patients with limited cutaneous SSc but are also observed in patients with long-standing diffuse cutaneous SSc. The capillary beds of nail folds of the fingers may show enlargement of capillaries with little or no capillary loss, usually indicative of limited cutaneous scleroderma. In diffuse cutaneous scleroderma, there is disorganization of the capillary beds with dilated capillaries interspersed with areas where capillaries have disappeared (Fig. 303-5). These capillary changes, which are observed by wide-angle microscopy or with an ophthalmoscope used as a magnifier, are not found in patients who have only Raynaud's phenomenon.

Musculoskeletal Features More than half the patients with SSc complain of pain, swelling, and stiffness of the fingers and knees. A symmetric polyarthritis resembling rheumatoid arthritis may be seen. In more advanced stages of the disease, leathery crepitation can be palpated over moving joints, especially the knee. Extensive fibrotic thickening of the tendon sheaths in the wrist can produce a carpal tunnel syndrome. Muscle weakness is usually present in patients with severe skin involvement and, in most cases, is due to disuse atrophy. There is a distinctive histologic myopathy that accompanies SSc that is not associated with muscle enzyme abnormalities. A few patients develop a myositis characterized by proximal muscle weakness and muscle enzyme elevations that are identical to polymyositis (overlap syndrome). In addition to terminal phalanges, resorption of bone may involve ribs, clavicle, and angle of mandible.

Gastrointestinal Features The majority of patients from both subsets of SSc have gastrointestinal involvement. Symptoms attributable to esophageal involvement are present in >50% of patients and include epigastric fullness, burning pain in the epigastric or retrosternal regions, and regurgitation of gastric contents. These symptoms, most noticeable when the patient is lying flat or bending over, are due to the reduced tone of the gastroesophageal sphincter and to dilatation of the distal esophagus. Peptic esophagitis frequently occurs and may lead to strictures and narrowing of the lower esophagus. However, it seldom results in bleeding. Barrett's metaplasia may develop, but transition to adenocarcinoma is uncommon. Dysphagia, particularly of solid foods, may occur independent of other esophageal symptoms and is caused by loss of esophageal motility due to neuromuscular dys-

FIGURE 303-3 Flexion deformities of the fingers and sclerodactlyly. The skin over the fingers and hands is taunt and indurated. There is shortening and bony resorption of distal phalanges of the second and third fingers. Ulcers may develop over the distal phalanges and dorsal surfaces of the metacarpal phalangeal and proximal interphalangeal joints.

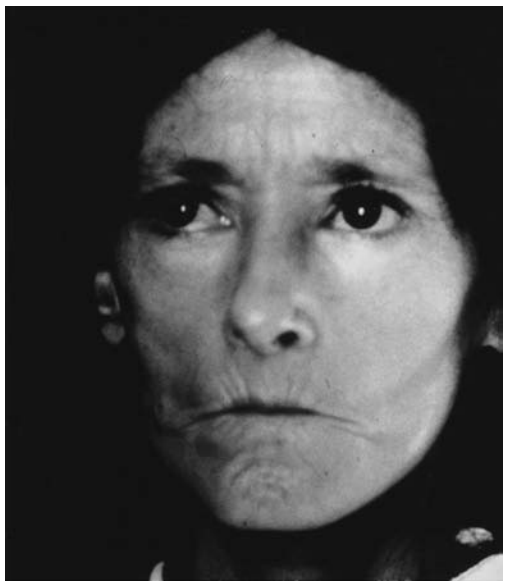

FIGURE 303-4 Skin over cheeks and forehead is tight and shiny with loss of wrinkles and facial expression. There are furrows around the mouth perpendicular to the lips and the lips are thin. The nose has a pinched appearance.

function. Manometry or cineradiography reveals decreased amplitude or disappearance of peristaltic waves in the lower two-thirds of the esophagus. Raynaud's phenomenon in the absence of a connective tissue disease is also associated with esophageal dysmotility. Later in the course of the illness, dilatation and atony of the lower portion of the esophagus as well as reflux are seen. With gastric involvement, barium studies show dilatation, atony, and delayed gastric emptying. Patients may complain of early satiety. Gastric outlet obstruction can also occur.

Hypomotility of the small intestine produces symptoms of bloating and abdominal pain and may suggest an intestinal obstruction or paralytic ileus (pseudoobstruction). Malabsorption syndrome with weight loss, diarrhea, and anemia is due to bacterial overgrowth in the atonic intestine or possibly to obliteration of lymphatics by fibrosis. Roentgenographic features of the second and third portions of the duodenum and of the jejunum include dilatation, loss of the usual feathery pattern, and delayed disappearance of barium. Pneumatosis intestinalis occasionally occurs and appears as radiolucent cysts or linear streaks within the wall of the small intestine. Benign pneumoperitoneum may result from the rupture of these cysts. Involvement of the large intestine may cause chronic constipation and fecal impaction with episodes of bowel obstruction. A segment of atonic bowel may act as a fulcrum for intussuception to occur. Barium studies of the large intestine may show dilatation, atony, and large-mouth diverticula. Laxity of the anal sphincter may cause incontinence or rarely anal prolapse. Some patients may have gastrointestinal features of SSc with little or no cutaneous or other organ involvement, referred to as *SSc sine scleroderma*. Vascular ectasia may develop in the stomach and intestine and can be the source of gastrointestinal bleeding. These dilated submucosal capillaries in the stomach appear on endoscopy as broad stripes—hence the term *watermelon stomach*.

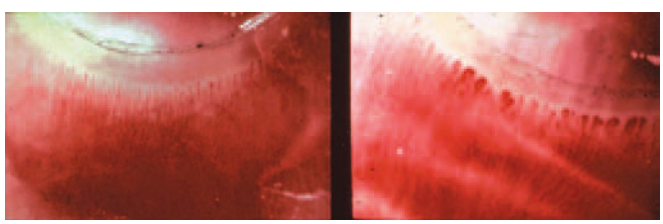

FIGURE 303-5 Nail fold capillaries in normal person (*left panel*) and in scleroderma patient (*right panel*). Capillary loops are found just proximal to the cuticle using a wide angle microscope, a dermatoscope, or an opthalmoscope serving as a magnifier. Immersion oil is placed over the nail fold to reduce reflection of light. *Left panel*: Capillary loops are small and well organized being parallel to each other and perpendicular to the nail. *Right panel*: Enlarged dilated capillary loops are interspersed with areas where capillaries have disappeared.

Pulmonary Features Pulmonary involvement occurs in at least two-thirds of SSc patients and is now the leading cause of death in SSc, replacing renal disease, which can usually be treated effectively. The most common symptom is exertional dyspnea, often accompanied by a dry, nonproductive cough. Bilateral basilar rales may be present. In the majority of patients, symptoms usually correlate with radiologic evidence of pulmonary fibrosis and with restrictive lung disease on pulmonary function tests.

Pulmonary function tests are frequently abnormal and show a reduction in vital capacity and decreased lung compliance. Impairment of gas exchange is reflected by a low diffusing capacity and low P_{O_2} with exercise. These abnormalities may be present even when the chest radiograph is normal. Chest film may show a pattern of linear densities, mottling, and honeycombing involving most prominently the lower two-thirds of the lung. Early interstitial pulmonary disease can be detected by high-resolution computed tomography (HRCT) and bronchoalveolar lavage (BAL). Active inflammatory alveolitis gives a "ground glass" appearance on HRCT. The recovery by BAL of increased numbers of cells, mostly alveolar macrophages accompanied by neutrophils or eosinophils, is evidence for alveolitis.

Both interstitial fibrosis and vascular lesions are found in the lungs of patients with SSc. Interstitial pulmonary fibrosis may be the predominant lesion in patients with diffuse or limited cutaneous SSc. Patients with diffuse cutaneous involvement who have antitopoisomerase 1 antibodies are particularly at risk of developing severe pulmonary fibrosis. In the absence of significant interstitial fibrosis, a severe form of pulmonary arterial hypertension may develop after many years of disease in a subset of patients with limited cutaneous SSc. Fewer than 10% of patients will develop this complication, which is caused by narrowing and obliteration of pulmonary arteries and arterioles by intimal fibrosis and medial hypertrophy. Pulmonary hypertension is manifested initially by exertional dyspnea and eventually by the appearance of right-sided heart failure. Pulmonary artery pressure can be measured noninvasively by two-dimensional echocardiography. The prognosis is extremely poor with the development of pulmonary hypertension; the mean duration of survival is ~2 years.

A less common pulmonary problem is aspiration pneumonia resulting from gastric reflux due to lower esophageal atony. Restriction of chest movement caused by extensive fibrotic skin involvement of the thorax rarely occurs. Superimposed bacterial or viral infection can be a serious complication in patients with pulmonary fibrosis. An increased frequency of alveolar cell and bronchogenic carcinoma is seen in patients with pulmonary fibrosis.

Cardiac Features Primary cardiac involvement in SSc includes pericarditis with or without effusions, heart failure, and varying degrees of heart block or arrhythmias. The majority of patients with diffuse cutaneous SSc have cardiac abnormalities. Cardiomyopathy attributable to myocardial fibrosis appears in <10% of patients and involves primarily those patients with diffuse cutaneous scleroderma. Radionuclide studies have shown abnormalities of left ventricular function due to myocardial fibrosis. Cold-induced vasospasm of the hands produces defects in myocardial thallium perfusion. The characteristic pathologic feature of contraction band necrosis results from cardiac muscle damage caused by intermittent vasospasm of coronary vessels. Patients may experience angina pectoris even though coronary angiograms are normal. Patients can also develop left ventricular failure secondary to systemic hypertension or cor pulmonale secondary to pulmonary arterial hypertension.

Renal Features Renal failure was the leading cause of death in SSc until the advent of effective treatment. Significant renal disease occurs

mostly in those patients with diffuse cutaneous scleroderma. A high risk of renal crisis is present in those patients who have rapidly progressive widespread skin thickening in their first 2 to 3 years of disease. Renal crisis is characterized by malignant hypertension, which can progress rapidly to renal failure. These patients manifest hypertensive encephalopathy, severe headache, retinopathy, seizures, and left ventricular failure. Hematuria and proteinuria are followed by oliguria and renal failure. The mechanism for the hypertensive crisis is activation of the renin-angiotensin system. Before the advent of effective antihypertensive drugs, the majority of these patients died within 6 months. A small number of patients may develop renal crises in the absence of hypertension. Renal failure can also develop insidiously later in the course of disease in the setting of mild to moderate hypertension and proteinuria. In these patients or those with clinically unrecognized renal disease, reduction of renal plasma flow secondary to heart failure or volume depletion resulting from overdiuresis may precipitate renal crisis. An indicator of impending renal failure is microangiopathic anemia, which may occur in a normotensive patient. The presence of a large chronic pericardial effusion may also herald subsequent renal failure.

Other Features Symptoms of dry eyes and/or dry mouth are frequently present in patients with SSc. Lip biopsy may show lymphocytic infiltration of minor salivary glands characteristic of Sjögren's syndrome or intraglandular or periglandular fibrosis secondary to SSc. Antibodies to SS-A (Ro) and/or SS-B (La) are found in those patients with lip biopsies consistent with Sjögren's syndrome (overlap syndrome-SSc and Sjögren's syndrome) and not in those with salivary gland fibrosis.

Hypothyroidism occurs in a significant number of patients and may be associated with high levels of antithyroid antibodies. Fibrosis of the thyroid gland may be present but also occurs in the absence of autoimmune thyroiditis. Other manifestations of SSc include trigeminal neuralgia and male impotence secondary to decreased penile tumescence. These men have normal serum levels of testosterone and gonadotropins. Pathogenesis of this abnormality has been considered to be caused by vascular and/or autonomic nervous system abnormalities. Biliary cirrhosis is occasionally observed in patients with limited cutaneous SSc.

LABORATORY FINDINGS The erythrocyte sedimentation rate may be elevated. Hypoproliferative anemia related to chronic inflammation is the most common cause of anemia in SSc. Anemia may also be caused by iron deficiency secondary to gastrointestinal bleeding. Bacterial overgrowth due to atony of the small bowel may lead to vitamin B_{12} and/or folic acid–deficiency anemia. Microangiopathic hemolytic anemia is most often associated with renal involvement and is caused by the presence of intravascular fibrin in renal arterioles. Polyclonal hypergammaglobulinemia, consisting mostly of IgG, is found in approximately half the patients. Rheumatoid factor, in low titer, is present in 25% of patients. Cryoglobulins may be present in the serum. Antinuclear antibodies detected by using a cultured human laryngeal carcinoma cell line (HEp-2) substrate are present in 95% of patients (Table 303-4). Antinuclear antibodies that have a high specificity for SSc are antitopoisomerase 1 (Scl-70), antinucleolar, and anticentromere. Antitopoisomerase 1, originally called anti-Scl-70, recognizes the nuclear enzyme DNA topoisomerase 1, a nuclear enzyme involved in the unwinding of DNA for replication and RNA transcription. These antibodies are found in ~20% of all SSc patients and in ~40% of those with diffuse cutaneous SSc. They are associated with diffuse cutaneous involvement, interstitial pulmonary disease, and renal and other visceral organ involvement. A very high frequency of these antibodies has been reported in Choctaw Native Americans in association with diffuse cutaneous SSc. They are seldom present in other disorders or in conjunction with anticentromere antibodies. Anticentromere antibodies react with protein antigens located in the kinetochore region of chromosomes and are present in 40 to 80% of patients with limited cutaneous scleroderma or CREST syndrome. Anticentromere antibodies are found in only about 2 to 5% of patients with diffuse cutaneous scleroderma and rarely in other connective tissue diseases. They are found occasionally in patients with only Raynaud's phenomenon and may indicate subsequent development of limited cutaneous disease. Antinucleolar antibodies are relatively specific for SSc and are present in ~20 to 30% of patients. Several antinucleolar antibodies have been associated with SSc: Anti-RNA polymerases I, II, and III are found in patients with diffuse cutaneous SSc who have a higher prevalence of renal and cardiac involvement. Anti-Th RNP has been found in patients with limited cutaneous SSc, and anti-PM-Scl, formerly referred to as anti-PM1, along with anti-Ku, may be found in a subset of patients with overlapping features of limited cutaneous SSc and polymyositis. Anti-U_3 RNP (anti-fibrillarin) is also highly specific for SSc and may be associated with skeletal muscle disease, bowel involvement, and pulmonary arterial hypertension. Anti-U_1 RNP is found in ~5 to 10% of SSc patients and in 95 to 100% of those patients with the overlap syndrome of MCTD. The titers in MCTD are usually high (see below). Anti-SS-A (Ro) and/or anti-SS-B (La) are present in those patients with overlap syndrome of SSc and Sjögren's syndrome.

TABLE 303-4 *Autoantibodies in Systemic Sclerosis*

Autoantibody	Clinical Association	Percent[a]
Anti-topoisomerase 1	Diffuse cutaneous SSc	40
Anticentromere	Limited cutaneous SSc	60–80
Anti-RNA polymerase I, II, III	Diffuse cutaneous SSc	5–40
Anti-Th RNP	Limited cutaneous SSc	14
Anti-U_1 RNP	Limited cutaneous SSc	5–10
	Mixed connective tissue disease	95–100
Anti-U_3 RNP[b]	Diffuse and limited cutaneous SSc, skeletal myopathy, pulmonary arterial hypertension	5
Anti-PM/Scl	Overlap (SSc, polymyositis)	25

[a] Approximate percentages for the predominant clinical association.
[b] Anti-fibrillarin.

DIAGNOSIS The diagnosis of SSc presents no difficulty in the presence of Raynaud's phenomenon, with typical skin lesions and visceral involvement. Although Raynaud's phenomenon may be the first symptom of SSc, most patients with Raynaud's phenomenon alone do not develop a connective tissue disease. Other causes of Raynaud's phenomenon include thoracic outlet (scalenus anticus and cervical rib) syndromes, shoulder-hand syndrome, trauma (jackhammer or vibratory machine operators), previous cold injury, vinyl chloride exposure, and circulating cryoglobulins or cold agglutinins. Linear scleroderma and morphea are localized forms of scleroderma that can usually be distinguished clinically. In early disease, SSc may initially be confused with rheumatoid arthritis, SLE, or polymyositis when articular or muscle involvement is prominent. SSc without cutaneous involvement should be considered in patients with unexplained pulmonary fibrosis, pulmonary hypertension, cardiomyopathies, heart block, dysphagia, or malabsorption syndrome. Several conditions have scleroderma-like features but lack the visceral involvement. Scleredema (scleredema adultorum of Buschke) occurs predominantly in children and is characterized by painless edematous induration involving the face, scalp, neck, trunk, and proximal portions of the extremities. Involvement of the hands and feet usually does not occur. Scleredema may be associated with previous streptococcal infection and is usually self-limited, resolving in 6 to 12 months. Histology reveals accumulation of mucopolysaccharides in the dermis and skeletal muscle. A rare entity, scleromyxedema is manifested by yellowish or pale red papules in association with diffuse skin thickening that may involve the face and hands. Acid mucopolysaccharide deposits are found in the dermis. Monoclonal IgG may be detected in some of these patients. Patients with insulin-dependent diabetes mellitus may develop digital sclerosis and contractures (prayer hand deformity). Primary amyloidosis and

amyloidosis associated with multiple myeloma may involve the skin of the extremities and face diffusely to give the appearance of scleroderma. Biopsy will clearly differentiate these entities.

COURSE AND PROGNOSIS The course of SSc is quite variable. Until the disease differentiates into recognizable subsets, prognosis in early disease is difficult to predict. Patients with limited cutaneous scleroderma, especially those with anticentromere antibodies, have a good prognosis, with the notable exception of those few patients, <10%, who after ≥10 to 20 years develop pulmonary arterial hypertension. Malabsorption syndrome and primary biliary cirrhosis are the causes of morbidity and mortality in some patients with limited cutaneous disease. On the other hand, the prognosis is generally worse in patients with diffuse cutaneous disease, particularly when the onset occurs at an older age. In addition, males have a worse prognosis. Renal and other visceral organ disease may develop early in the course of those patients with rapidly progressive generalized skin thickening. Death occurs most often from pulmonary, cardiac, and renal involvement. With the advent of effective therapy for renal crisis along with renal dialysis for those patients with renal failure, survival has greatly improved. In patients with diffuse cutaneous disease, the 5-year cumulative survival rate is ~70% and the 10-year is ~55%. In limited cutaneous disease the 5-year is ~90% and the 10-year is ~75%.

Skin may spontaneously soften after years of disease. Softening occurs in the reverse order of original skin involvement, beginning with the trunk and followed by the proximal and then the distal extremities. Sclerodactyly and flexion contractures may persist. Skin thickness may eventually approach normal; however, the skin may be atrophic.

TREATMENT

Even though SSc cannot be cured, treatment of involved organ systems can relieve symptoms and improve function. The doctor-patient relationship is extremely important in caring for patients with this chronic debilitating illness. Once the diagnosis of SSc has been made, the patient and family should be instructed about this disorder. The patient will need repeated explanations and reassurances throughout his or her illness. Depending on the severity of illness, the patient will require monitoring of blood pressure, blood counts, urinalysis, and monitoring of renal and pulmonary function on a regular basis.

Effectiveness of drug therapy in SSc is difficult to evaluate because of the variable course and severity of disease especially within its subsets. Controlled drug studies have been difficult to achieve because of this variability and the relative few number of SSc patients. Several drugs with antifibrotic, immunosuppressive, or both properties have been tried in the treatment of SSc without any consistent or prolonged benefit. These drugs have included D-penicillamine, colchicine, IFN-γ, IFN-α, and recombinant human relaxin. In the past, high-dose D-penicillamine (750–1000 mg/d) has been used in patients with early diffuse cutaneous SSc, but a recent study showed no benefit of high versus low doses of this drug (see below). The rationale for using D-penicillamine was that it interfered with inter- and intramolecular cross-linking of collagen and was also thought to be immunosuppressive. Several earlier uncontrolled studies with D-penicillamine showed a reduction in skin thickening and prevention of significant internal organ involvement when compared to historic controls. Five-year cumulative survival rates of 80% had been reported in D-penicillamine–treated patients. A recent study did not show an advantage of high-dose D-penicillamine treatment in SSc. The results of a 2-year double-blind randomized study comparing high-dose D-penicillamine (750–1000 mg/d) with low-dose D-penicillamine (125 mg every other day) in patients with early diffuse cutaneous SSc did not show a significant difference between the groups as to the degree of skin thickening, occurrence of renal crises, other organ involvement and mortality. The majority of adverse or toxic effects occurred in the high dosage group. This study, however, did not compare patients on low-dose D-penicillamine versus placebo. It is possible that this drug in low dose might have some beneficial effect in SSc. Its therapeutic value, however, in SSc remains in question. Open uncontrolled trials with colchicine showed skin improvement, but other studies were negative. Randomized controlled multicenter trials with recombinant human IFN-γ demonstrated modest improvement in skin sclerosis. Worsening of Raynaud's phenomenon and development of renal crisis as well as influenza-like symptoms were noted in patients treated with recombinant human IFN-γ, and follow-up studies have not been done. IFN-α in a controlled trial showed no benefit. In a randomized, double-blind, placebo-controlled trial, recombinant human relaxin given by continuous subcutaneous infusion for 24 weeks was associated with reduced skin thickening and improved mobility in patients with moderate to severe diffuse cutaneous scleroderma. A subsequent follow-up, however, did not demonstrate any significant benefit. It is unlikely that further studies with this agent will be done.

Several immunosuppressive agents have been tried in SSc. The rationale for using these agents is based on the cellular and humoral immunologic abnormalities that have been demonstrated in SSc. The results of immunosuppressive therapy have been disappointing and, as of now, no agent has been clearly shown in a controlled prospective study to fully suppress or reverse the disease process of SSc. A controlled randomized, double-blind trial with chlorambucil versus control was negative. Earlier reports of benefit with azathioprine have not been confirmed in controlled studies. Cyclosporine was shown to decrease skin induration without improvement in pulmonary or cardiac manifestations. Concern regarding nephrotoxicity has limited its use in SSc. Randomized controlled trials of methotrexate in early diffuse cutaneous SSc have shown mixed results, with one study showing improvement and others showing marginal, if any, clinical benefit. Extracorporeal photopheresis employing ultraviolet A irradiation after the patient has received oral 6-methoxypsoralen has been tried in SSc with the initial report showing skin improvement. The methodology of this study has been challenged and other studies did not show efficacy. Treatment with 5-fluorouracil led to some skin improvement but caused significant gastrointestinal toxicity. Several uncontrolled studies using cyclophosphamide in treating early sclerodermal interstitial lung disease have shown improvement or stabilization of pulmonary function. Improvement of skin induration was also noted in some patients. A controlled study in patients with early and active alveolitis is currently in progress. Because of the poor prognosis in SSc patients who have a rapid onset of diffuse cutaneous disease and early visceral organ involvement (pulmonary, cardiac, or renal), clinical trials are in progress using high-dose immunosuppressive therapy followed by autologous stem cell transplantation. The rationale is that high doses of an immunosuppressive drug such as cyclophosphamide may reverse or modify the disease course. The autologous stem cell transplantation permits the rapid reconstitution of hematopoiesis. Initial results of a multicenter study involving 19 patients with poor prognoses showed improvement of skin and disability scores exceeding those reported with other therapies. Internal organ function was the same or slightly worse following treatment. Four patients had progressive or nonresponsive disease. Two patients died of treatment complications and one of progressive SSc. The role of high-dose immunosuppressive therapy in SSc needs further evaluation in prospective controlled studies before its clinical efficacy can be determined. This treatment is at present experimental.

Several other agents including minocyline, thalidomide and etanercept have been reported to improve skin involvement in small uncontrolled studies. Randomized controlled studies will need to be performed to know whether these agents are effective.

Antiplatelet therapy may play a role in the treatment of SSc, since the biologic products of platelets affect blood vessels. Low doses of aspirin block the formation of thromboxane A_2, a powerful vasoconstrictor and platelet aggregator. In addition, dipyridamole, 200 to 400 mg in divided daily doses, also decreases platelet adhesion to damaged vessel walls. While these drugs have a reasonable therapeutic rationale, a 2-year double-blind study did not show any benefit from their use.

Glucocorticoids are not effective in improving or preventing skin induration and the progression of SSc. They can be beneficial in certain situations. Short courses of low-dose prednisone (10 mg/d or less) may decrease edema associated with the edematous phase of early skin involvement and may also be useful in relieving joint and tendon pain. Higher doses of a glucocorticoid such as prednisone 20–30 mg/d are indicated in only those patients with inflammatory myositis, pericarditis, and possibly in patients with early active alveolitis. The dose should be reduced as soon as possible to the lowest effective dose, which in some patients may require the addition of a steroid-sparing agent such as methotrexate or azathioprine. Glucocorticoids should not be used for the indolent primary form of muscle disease of SSc (see Musculoskeletal System, above). Glucocorticoids have been associated with the development of renal crisis. A retrospective case-control study in patients with early diffuse cutaneous SSc showed a significant association between prior high-dose glucocorticoids (prednisone $\geq$ 15 mg/d) and the development of scleroderma renal crisis. For this reason, glucocorticoids should be used cautiously in SSc.

The management of Raynaud's phenomenon is directed at control of vasospasm. Patients should be advised to dress warmly and wear mittens and socks, not to smoke, to remove causes of external stress, and to avoid drugs such as amphetamine and ergotamine. Cold drafts should be avoided. Air-conditioned rooms in warm climates can also be a problem for patients with Raynaud's phenomenon. Beta-blocking drugs may make Raynaud's phenomenon worse. Warmth of the central body induces peripheral vasodilatation. Drugs that block sympathetic vasoconstriction, such as reserpine, α-methyldopa, phenoxybenzamine, and prazosin, may be useful in the treatment of Raynaud's phenomenon, but their side effects often curtail extended use. The calcium channel blockers nifedipine, diltiazem, and the longer acting amlodipine can be effective in alleviating Raynaud's phenomenon, but side effects of light-headedness and palpitations may limit their use. The sustained-release form of nifedipine is better tolerated; the dose is 30 mg/d up to 60 or 90 mg/d as required to control symptoms. Nitroglycerin paste, applied to an affected digit, may improve local blood flow. Sildenafil, a phosphodiesterase inhibitor used primarily for erectile dysfunction, is a vasodilator and may be helpful in treating Raynaud's phenomenon. In a 12-week pilot study, losartan (50 mg/d), a specific nonpeptide angiotensen II type 1 receptor antagonist, reduced the severity and frequency of Raynaud's phenomenon episodes. Ketanserin (40 mg TID), an oral serotonin antagonist, has also been shown to be effective. Selective serotonin reuptake inhibitors (e.g., fluoxetine, 20 mg/d) may be beneficial in some patients. These drugs decrease platelet 5-hydroxytryptamine, which is thought to play a role in the pathogenesis of Raynaud's phenomenon. Studies with intravenous iloprost, a prostacyclin analogue, have shown a decrease in frequency and severity of Raynaud's phenomenon and healing of digital ulcers in some patients. Iloprost is still not available in the United States for general use. Intravenous alprostadil, a prostaglandin, can be effective in treating severe Raynaud's phenomenon with digital ulcers. Intravenous epoprostenol and oral Bosentan, an endothelin-1 receptor antagonist, used in the treatment of pulmonary hypertension, also improves Raynaud's phenomenon. Pentoxifylline (400 mg TID) may also improve perfusion by increasing the deformability of the red cell plasma membranes. Techniques of biofeedback have also been used with variable success for teaching patients to control the temperature of their hands. Stellate ganglion blockage may be useful in temporarily alleviating severe ischemic pain in the fingers. Surgical cervical sympathectomy usually provides only temporary improvement, and it, along with other forms of therapy, does not prevent progression of the vascular lesion. Digital sympathectomy can be effective in some patients. The response to any therapy for Raynaud's phenomenon is limited by the degree of existing structural narrowing of digital arteries. In patients with severe Raynaud's phenomenon and refractory digital ulcers, distal ulnar artery occlusion should be considered. A positive Allen test is suggestive, and the diagnosis is confirmed by angiography. When ulnar artery occlusion is present, revascularization and a digital sympathectomy may be beneficial. Gangrene of distal digits may occur and require surgical amputation.

Skin care is very important in SSc. Dryness of the skin may be reduced by avoiding frequent use of detergent soaps and by regularly applying hydrophilic ointments and bath oils. Regular exercise helps to maintain flexibility of extremities and pliability of skin. Massaging the skin several times a day may also be beneficial. Fingertip ulcerations can be protected by applying a guard or cage over the end of the finger. The use of an occlusive dressing, such as the hydrocolloid duoDERM or other membranes, over a noninfected ulcer may promote healing and protect the finger. Skin ulcers should be kept clean by soaking or by surgical or chemical debridement. Sympatholytic drugs or local nitroglycerin paste applied to or adjacent to the ulcer may be beneficial in promoting healing. Infected ulcers can usually be treated with topical antibiotics but may require systemic antibiotics, especially when there is a question of underlying osteomyelitis. The development of calcinosis cannot be prevented, nor can deposits be dissolved. Warfarin has been reported to reduce calcinosis in a few patients.

In patients experiencing dry mouth, frequent sips of water help to relieve symptoms. Pilocarpine hydrochloride tablets may increase salivary secretions in some patients. Patients with dry eyes should use artificial tears regularly.

Patients with reflux esophagitis are treated with small, frequent meals, antacids between meals, and elevation of the head of the bed. Patients should be advised not to lie down for a few hours after a meal and to avoid coffee, tea, alcohol, peppermint, and chocolate, which reduce the pressure of the lower esophageal sphincter. Fatty foods and late-evening snacks should be avoided. Cimetidine, ranitidine, or other newer H_2 blockers may be beneficial. Gastric acid (proton) pump inhibitors are more effective in treating erosive esophagitis than are H_2 blockers. Metoclopramide does not significantly improve esophageal motility; it increases lower esophageal sphincter tone and promotes gastric emptying and can be of help in some patients. The dose is 10 mg given 15–20 min before each meal up to 4 times a day. Nifedipine and, to a lesser extent, diltiazem reduce lower esophageal sphincter tone resulting in esophageal reflux. Patients with dysphagia should be instructed to chew their food thoroughly and wash it down with fluids. Malabsorption syndrome due to duodenal hypomotility and bacterial overgrowth causes bloating and diarrhea, which may improve with intermittent use of appropriate antibiotics. Antibiotics are rotated every 2 weeks. Commonly used antibiotics are metronidazole, vancomycin, erythromycin, ciprofloxacin, neomycin, and tetracycline. Patients with severe debilitating malabsorption may benefit from parenteral hyperalimentation. Patients with chronic intestinal pseudoobstruction might respond to octreotide. Stool softeners and mild laxatives are usually adequate for treating constipation caused by hypomotility of the colon.

Articular symptoms are treated with nonsteroidal anti-inflammatory agents. Low-dose prednisone ($\leq$10 mg/d) may improve symptoms in those not responding to these agents. Physical therapy may help to reduce the loss of joint mobility that occurs in SSc.

In patients with diffuse cutaneous SSc, the early recognition of alveolitis as previously described (see "Pulmonary Features") may allow treatment that might slow or prevent the development of pulmonary fibrosis. Cyclophosphamide has been reported in uncontrolled studies to be beneficial, and a controlled study is presently being done. The role of glucocorticoids in preventing progression of interstitial lung disease is not clear but may be of benefit in early disease. *N* acetylcysteine has been used as an antioxidant to reduce lung damage in patients with respiratory distress syndromes and may help in SSc lung disease. Pulmonary fibrosis is not reversible, and therefore treatment is directed at symptoms or complications. Pulmonary infection requires prompt treatment with antibiotics. Hypoxia necessitates giving low concentrations of oxygen. Patients should receive polyvalent pneumoccal vaccine (Pneumovax) and yearly influenza immunizations.

For patients with limited cutaneous SSc who develop isolated pul-

monary arterial hypertension, treatment is limited. The usual treatment is supplemental oxygen, anticoagulation, and the administration of a vasodilator. A calcium channel blocker such as nifedipine lowers pulmonary arterial resistance and improves cardiac function, but in most patients this is only for a short period of time. Few patients survive more than 5 years. Heart-lung or single-lung transplantation may be a therapeutic option only in those patients without other significant systemic involvement. Intravenous epoprostenol (prostacyclin) is now given to treat SSc-associated pulmonary hypertension. Epoprostenol is infused continuously via a central line with a portable pump. Improvement in symptoms of right heart failure and exercise tolerance occurred. Also hemodynamic tests showed a decrease in the pulmonary vascular resistance and pulmonary artery pressure both in the short term and in a few patients after 1 or 2 years. Bosentan, an orally administered endothelin-1 receptor antagonist, has been shown to improve exercise capacity and cardiopulmonary hemodynamics in patients with pulmonary arterial hypertension, both primary and secondary to SSc. In some treated SSc patients, Raynaud's phenomenon also improved.

Recognition of early signs of renal hypertensive crisis is important in order to preserve renal function and prevent hypertensive encephalopathy. Renal involvement is often accompanied by hypertension and mild to moderate proteinuria. An occasional patient may be normotensive. Antihypertensive agents are often effective in lowering blood pressure and stabilizing or reversing renal failure. These drugs include propranolol, clonidine, and minoxidil. Particularly effective are the angiotensin-converting enzyme inhibitors, which include captopril, enalapril, and lisinopril. Dialysis may be required in patients with progressive renal failure. Some patients, however, have a slow return of renal function after several months and may no longer require dialysis. Patients are usually not candidates for kidney transplantation because of the other systemic manifestations of SSc.

Patients with cardiac failure require careful monitoring of digitalis and diuretic administration. Noninflammatory pericardial effusions may also improve with diuretics. Care should be taken to avoid overdiuresis, which may lead to decreased renal blood flow, decreased cardiac output, and renal failure.

MIXED CONNECTIVE TISSUE DISEASE

MCTD is an overlap syndrome characterized by combinations of clinical features of SLE (Chap. 300), SSc, polymyositis (Chap. 370), and rheumatoid arthritis (Chap. 301) and the presence of very high titers of circulating autoantibodies to nuclear RNP antigen. This antibody in high titer, now referred to as *anti-U_1 RNP*, has been a justification for considering MCTD as a distinct clinical entity. MCTD has been challenged as a distinct disorder by those who consider it as a subset of SLE or scleroderma. Others prefer to classify MCTD as an undifferentiated connective tissue disease. MCTD occurs worldwide and in all races. The peak onset of disease is in the second and third decades, but MCTD is seen in children and the elderly. Women are predominantly affected. The pathogenic mechanisms in MCTD reflect the disorders making up this syndrome.

Clinical Features The presenting symptoms of MCTD are most often Raynaud's phenomenon, puffy hands, arthralgias, myalgias, and fatigue. Occasionally, patients may present with the acute onset of high fever, polymyositis, arthritis, and neurologic features such as trigeminal neuralgia and aseptic meningitis. The various features of the connective tissue disorders making up MCTD develop over months and years.

The fingers as well as the entire hand may be puffy, followed later by sclerodactyly. Sclerodermal changes are usually limited to the distal extremities and sometimes the face but spare the trunk. Telangiectasia and calcinosis may develop. Some patients have mucocutaneous features of SLE including a classic malar rash, photosensitivity, discoid lesions, alopecia, and painful oral ulcerations. An erythematous rash over the knuckles, elbows, and knees and heliotropic eyelids, typical of dermatomyositis, are uncommon.

Joint pain, stiffness, and swelling involving the peripheral joints occur frequently. Deformities of the hands similar to those of rheumatoid arthritis may develop but usually without bony erosions. A destructive polyarthritis is occasionally observed. Myalgias are a frequent symptom. Some patients develop typical symptoms of polymyositis with proximal muscle weakness, abnormal electromyographic findings, elevated levels of muscle enzymes, and inflammatory changes on muscle biopsy.

Approximately 85% of patients have pulmonary involvement, which is often asymptomatic. Diffusing capacity for carbon monoxide may be the only abnormality. Pleurisy commonly occurs but is seldom associated with large pleural effusions. Some patients develop interstitial lung disease. Pulmonary arterial hypertension is the most common cause of death in MCTD.

Approximately 25% of patients develop renal disease. Membranous glomerulonephritis is most common and usually mild but can cause nephrotic syndrome. Diffuse proliferative glomerulonephritis is unusual in MCTD, perhaps because of the protective role believed to be played by the high titers of anti-U_1 RNP. Renal crisis secondary to malignant renovasculature hypertension, as occurs in scleroderma, is seen in a few patients.

Gastrointestinal involvement is seen in ~70% of patients. The most common manifestations are esophageal dysmotility, lower esophageal sphincter laxity, and gastroesophageal reflux. Bowel manifestations mimic those of scleroderma bowel disease.

Pericarditis occurs in 30% of patients. Other cardiac features include myocarditis, arrhythmia, conduction disturbances, and mitral valve prolapse. Other clinical features of MCTD include trigeminal neuropathy, peripheral neuropathy, aseptic meningitis, lymphadenopathy, and Sjögren's syndrome. The majority of patients have developed, or will develop within 5 years of presentation, diagnostic clinical criteria for one of the overlapping connective tissue diseases, most often SLE or SSc.

Laboratory Findings Anemia of chronic inflammation is seen in the majority of patients. A positive direct Coombs' test is found in many patients, but hemolytic anemia is unusual. Leukopenia, thrombocytopenia, or both are present in some patients. Hypergammaglobulinemia is common, and rheumatoid factor is present in 50% of patients.

All patients, by definition of MCTD, have antibodies to U_1 RNP. The specificity of this antibody is to the 70-kDa protein complexed to small nuclear RNA. The anti-U_1 RNP antibodies are associated with HLA-DR4 but not with -DR2 and -DR3 as found in SLE. Molecular mimicry has been demonstrated between U_1 RNP and retroviral antigens by some laboratories.

TREATMENT

The treatment of MCTD is essentially the same as would be indicated for the respective connective tissue diseases defining this syndrome. More than half the patients have a favorable course. The 10-year survival rate overall is ~80% but varies depending on the connective tissue disease that may eventually develop.

EOSINOPHILIC FASCIITIS

Eosinophilic fasciitis is a scleroderma-like syndrome of unknown cause characterized by inflammation followed later by sclerosis of the dermis, subcutis, and deep fascia. The disease affects adults and often occurs after strenuous physical activity. Patients do not have Raynaud's phenomenon or internal organ involvement. Several immunologic abnormalities have been associated with eosinophilic fasciitis and include aplastic anemia, myelodysplastic syndrome, and thrombocytopenia. Patients usually have the abrupt onset of symmetric tenderness and swelling of the extremities, rapidly followed by induration of the skin and subcutaneous tissue. The skin takes on a cobblestone or puckered appearance. Carpal tunnel syndrome appears early in the course, and flexion contractures develop later. A low-grade myositis

is often present, but creatinine kinase levels are usually normal. A marked eosinophilia is found in the early stage of disease and subsequently decreases. Increased levels of polyclonal IgG and immune complexes are often present in the serum. A full-thickness biopsy consisting of skin, fascia, and superficial muscle shows perivascular infiltration of histiocytes, eosinophils, lymphocytes, and plasma cells. Biopsies later in the course show sclerosis. Spontaneous improvement and occasionally complete remission may occur after 2 to 5 years of disease. Some patients have persistent disease, while others are left with flexion contractures. Administration of glucocorticoids may provide symptomatic improvement and will decrease the eosinophilia. Improvement has been reported with the use of the H_2 blocker cimetidine.

EOSINOPHILIA-MYALGIA SYNDROME

In 1989, reports of patients with scleroderma-like skin changes, myalgias, and eosinophilia dramatically increased. Most, but not all, of these cases were associated with ingestion of L-tryptophan manufactured by a single Japanese company. Batches of L-tryptophan implicated in EMS were found to contain trace amounts of a contaminant identified as a dimer of L-tryptophan that appeared in 1988 after changes were made in the method of manufacturing this drug. It is not clear whether this chemical contaminant is the etiologic agent or whether another unidentified substance is responsible. ***L-Tryptophan products were taken off the market in 1990***. The onset of EMS can be either abrupt or insidious. In the early phases of the disease, clinical manifestations include low-grade fever, fatigue, dyspnea, cough, arthralgias/arthritis, evanescent erythematous rashes, muscle cramping, and severe myalgias. Pulmonary infiltrates may be present. Over the next 2 to 3 months, scleroderma-like skin changes appear. Some patients develop a peripheral neuropathy, which may persist. An ascending polyneuropathy may lead to paralysis and respiratory failure requiring ventilatory assistance. Cognitive dysfunction with impairment of memory and concentration has been recognized in this syndrome. Myocarditis and cardiac arrhythmias occur in some patients, and a few patients develop pulmonary hypertension. Approximately a third of patients have features of eosinophilic fasciitis. EMS most closely resembles toxic oil syndrome; however, Raynaud's phenomenon does not occur, and there is a lower prevalence of pulmonary hypertension and thromboembolic disease. The peripheral eosinophil count is $>1000/\mu L$ in most patients. The histologic findings on biopsy of skin, fascia, and superficial muscle are similar to those found in eosinophilic fasciitis. The clinical features of EMS may persist after L-tryptophan has been discontinued. EMS may run a chronic course, and response to therapy has been variable. Treatment has included glucocorticoids, antimalarial drugs, immunosuppressive drugs, and plasmapheresis. Prednisone was beneficial during the acute inflammatory phase of the disease in the majority of patients and resulted in resolution of pulmonary infiltrates, peripheral edema, and eosinophilia. In the later phase of the illness, no treatment was found to be of particular value. The pathogenesis of this disease is not known. A follow-up of patients 2 years after their onset of illness showed that most symptoms and physical findings had resolved or improved except for cognitive dysfunction, which became worse in approximately one-third of the patients, and peripheral neuropathy, which remained unchanged (Chap. 370).

304 SJÖGREN'S SYNDROME

Haralampos M. Moutsopoulos

DEFINITION

Sjögren's syndrome is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands resulting in xerostomia and dry eyes. Approximately one-third of patients present with systemic manifestations. A small but significant number of patients may develop malignant lymphoma. The disease can be seen alone (primary Sjögren's syndrome) or in association with other autoimmune rheumatic diseases (secondary Sjögren's syndrome) (Table 304-1).

INCIDENCE AND PREVALENCE

The disease affects predominantly middle-age women (female-to-male ratio 9:1), although it occurs in all ages, including childhood. The prevalence of primary Sjögren's syndrome is approximately 0.5 to 1.0%. In addition, 30% of patients with autoimmune rheumatic diseases suffer from secondary Sjögren's syndrome.

PATHOGENESIS

Sjögren's syndrome is characterized by lymphocytic infiltration of the exocrine glands and B lymphocyte hyperreactivity, as illustrated by circulating autoantibodies. In one-fourth of the patients, it is accompanied by an oligomonoclonal B cell process, which is characterized by cryoprecipitable monoclonal immunoglobulins with rheumatoid factor activity.

Sera of patients with Sjögren's syndrome often contain a number of autoantibodies directed against non-organ-specific antigens such as immunoglobulins (rheumatoid factors) and extractable nuclear and cytoplasmic antigens (Ro/SS-A, La/SS-B). Ro/SS-A autoantigen consists of two polypeptides (52 and 60 kDa) in conjunction with cytoplasmic RNAs, whereas the 48-kDa La/SS-B protein is bound to RNA III polymerase transcripts. Autoantibodies to Ro/SS-A and La/SS-B antigens are usually detected at the time of diagnosis and are associated with earlier disease onset, longer disease duration, salivary gland enlargement, severity of lymphocytic infiltration of minor salivary glands, and certain extraglandular manifestations. Antibodies to α-fodrin (120 kDa), a salivary gland–specific protein, have been found

Myositis	1

in sera of patients with Sjögren's syndrome. The major infiltrating cells in the affected exocrine glands are activated B and T lymphocytes. Macrophages and natural killer cells are rarely detected. In chronic lesions, a small but persistent number of dendritic cells are apparent in lymphoid follicle–like formations. In contrast to the infiltrating lymphocytes, the glandular epithelial cells undergo apoptotic death. Ductal and acinar epithelial cells appear to play a significant role in the initiation and perpetuation of the autoimmune injury since they inappropriately produce proinflammatory cytokines and lympho-attractant chemokines and express on their surface nuclear autoantigens. Further, they express class II major histocompatibility complex (MHC) and co-stimulatory molecules and are able to provide the second signal for lymphocyte activation. Redistribution of the water-channel protein aquaporin-5 from the apical membranes to the cytoplasm of acinar epithelial cells has also been observed.

Immunogenetic studies have demonstrated that HLA-B8, -DR3, and -DRw52 are prevalent in patients with primary Sjögren's syndrome as compared with the normal control population. Molecular analysis of HLA class II genes has revealed that patients with Sjögren's syndrome, regardless of their ethnic origin, are highly associated with the HLA DQA1*0501 allele.

CLINICAL MANIFESTATIONS

The majority of Sjögren's syndrome patients have symptoms related to diminished lacrimal and salivary gland function. In most patients, the primary syndrome runs a slow and benign course. The initial manifestations can be mucosal dryness or nonspecific, and 8 to 10 years elapse from the initial symptoms to full-blown development of the disease.

The principal oral symptom of Sjögren's syndrome is dryness (xerostomia). Patients complain of difficulty in swallowing dry food, inability to speak continuously, a burning sensation, increase in dental caries, and problems in wearing complete dentures. Physical examination shows a dry, erythematous, sticky oral mucosa. There is atrophy of the filiform papillae on the dorsum of the tongue, and saliva from the major glands is either not expressible or cloudy. Enlargement of the parotid or other major salivary glands occurs in two-thirds of patients with primary Sjögren's syndrome but is uncommon in those with the secondary syndrome. Diagnostic tests include sialometry, sialog-

TABLE 304-5 *Revised International Classification Criteria for Sjögren's Syndrome*[a,b,c]

I. Ocular symptoms: a positive response to at least one of three validated questions.
   1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
   2. Do you have a recurrent sensation of sand or gravel in the eyes?
   3. Do you use tear substitutes more than three times a day?

II. Oral symptoms: a positive response to at least one of three validated questions.
   1. Have you had a daily feeling of dry mouth for more than 3 months?
   2. Have you had recurrent or persistently swollen salivary glands as an adult?
   3. Do you frequently drink liquids to aid in swallowing dry foods?

III. Ocular signs: objective evidence of ocular involvement defined as a positive result to at least one of the following two tests:
   1. Shirmer's I test, performed without anesthesia (≤5 mm in 5 min)
   2. Rose Bengal score or other ocular dye score (≥4 according to van Bijsterveld's scoring system)

IV. Histopathology: In minor salivary glands focal lymphocytic sialoadenitis, with a focus score ≥ 1.

V. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result to at least one of the following diagnostic tests:
   1. Unstimulated whole salivary flow (≤1.5 mL in 15 min)
   2. Parotid sialography
   3. Salivary scintigraphy

VI. Antibodies in the serum to Ro/SS-A or La/SS-B antigens, or both

[a] Exclusion criteria: Past head and neck radiation treatment, hepatitis C infection, AIDS, preexisting lymphoma, sarcoidosis, graft versus host disease, use of anticholinergic drugs.

[b] Primary Sjögren's syndrome: any four of the six items, as long as item IV (histopathology) or VI (serology) is positive, or any three of the four objective criteria items (items III, IV, V, VI).

[c] In patients with a potentially associated disease (e.g., another well-defined connective tissue disease), the presence of item I or item II plus any two from among items III, IV, and V may be considered as indicative of secondary Sjögren's syndrome.

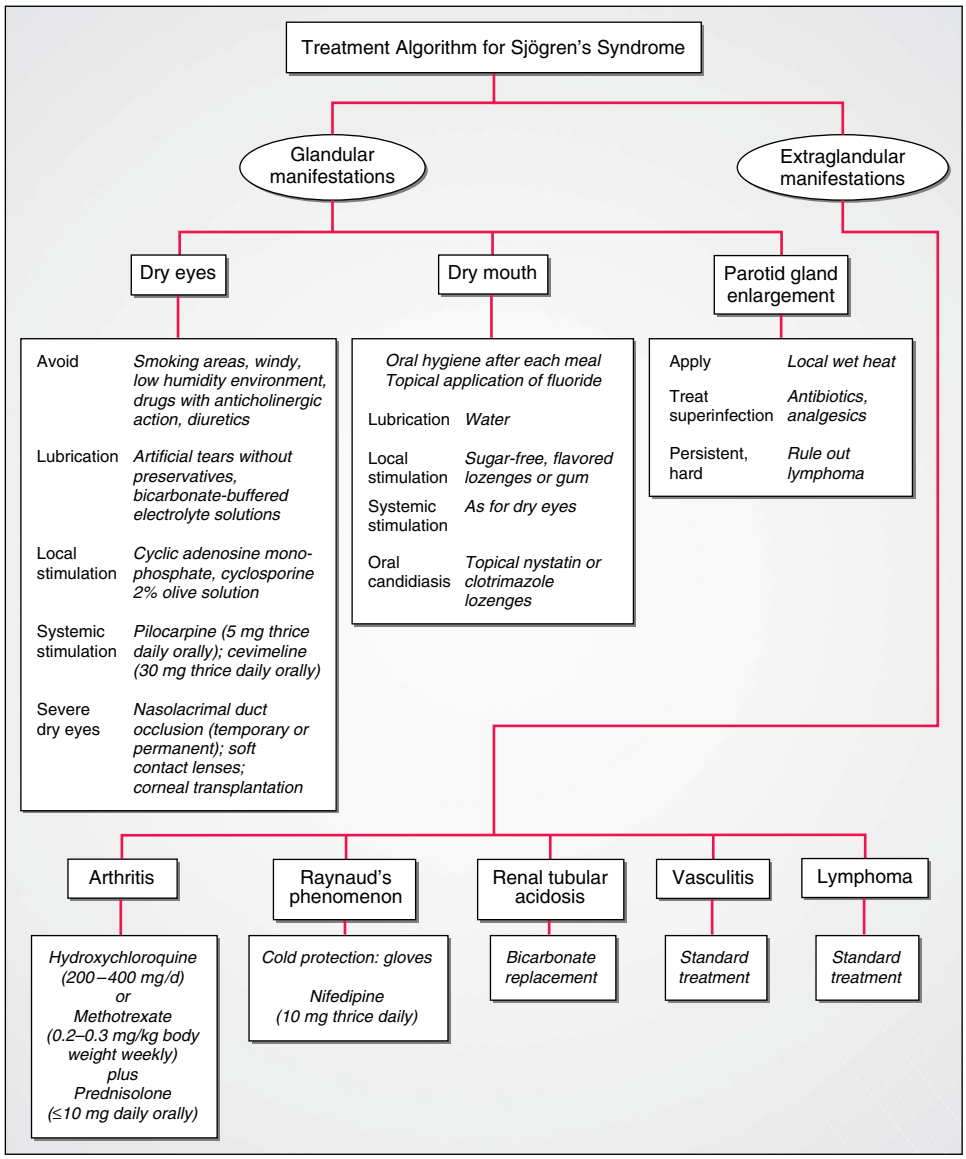

FIGURE 304-1 Treatment algorithm for Sjögren's syndrome.

raphy, and scintigraphy. The labial minor salivary gland biopsy permits histopathologic confirmation of the focal lymphocytic infiltrates.

Ocular involvement is the other major manifestation of Sjögren's syndrome. Patients usually complain of a sandy or gritty feeling under the eyelids. Other symptoms include burning, accumulation of thick strands at the inner canthi, decreased tearing, redness, itching, eye fatigue, and increased photosensitivity. These symptoms are attributed to the destruction of corneal and bulbar conjunctival epithelium, defined as *keratoconjunctivitis sicca*. Diagnostic evaluation of keratoconjunctivitis sicca includes measurement of tear flow by Schirmer's I test and tear composition as assessed by the tear breakup time or tear lysozyme content. Slit-lamp examination of the cornea and conjunctiva after rose Bengal staining reveals punctate corneal ulcerations and attached filaments of corneal epithelium.

Involvement of other exocrine glands occurs less frequently and includes a decrease in mucous gland secretions of the upper and lower respiratory tree, resulting in dry nose, throat, and trachea (xerotrachea), and diminished secretion of the exocrine glands of the gastrointestinal tract, leading to esophageal mucosal atrophy, atrophic gastritis, and subclinical pancreatitis. Dyspareunia due to dryness of the external genitalia and dry skin may also occur.

Extraglandular (systemic) manifestations are seen in one-third of patients with Sjögren's syndrome (Table 304-2), while they are very rare in patients with Sjögren's syndrome associated with rheumatoid arthritis. These patients complain more often of easy fatigability, low-grade fever, Raynaud's phenomenon, myalgias, and arthralgias. Most patients with primary Sjögren's syndrome experience at least one episode of nonerosive arthritis during the course of their disease. Manifestations of pulmonary involvement are frequent but rarely important clinically. Dry cough is the major manifestation that is attributed to small airway disease. Renal involvement includes interstitial nephritis, clinically manifested by hyposthenuria and renal tubular dysfunction with or without acidosis. Untreated acidosis may lead to nephrocalcinosis. Glomerulonephritis is a rare finding that occurs in patients with mixed cryoglobulinemia, or systemic lupus erythematosus overlapping with Sjögren's syndrome. Vasculitis affects small and medium-sized vessels. The most common clinical features are purpura, recurrent urticaria, skin ulcerations, glomerulonephritis, and mononeuritis multiplex. Sensorineural hearing loss was found in one-half of patients with Sjögren's syndrome and correlated with the presence of anticardiolipin antibodies.

It has been suggested that primary Sjögren's syndrome with vasculitis may also present with multifocal, recurrent, and progressive nervous system disease, such as hemiparesis, transverse myelopathy, hemisensory deficits, seizures, and movement disorders. Aseptic meningitis and multiple sclerosis have also been reported in these patients.

Lymphoma is a well-known manifestation of Sjögren's syndrome that usually presents later in the illness. Persistent parotid gland enlargement, purpura, leukopenia, cryoglobulinemia, and low C4 complement levels are manifestations suggesting the development of lymphoma. Most lymphomas are extranodal, marginal zone B cell, and low grade. Usually the low-grade lymphomas are detected incidentally upon evaluating the labial biopsy.

The affected lymph nodes are usually peripheral. Survival is decreased in patients with B symptoms, lymph node mass >7 cm in diameter, and high or intermediate histologic grade.

Routine laboratory tests reveal mild normochromic, normocytic anemia. An elevated erythrocyte sedimentation rate is found in approximately 70% of patients.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of primary Sjögren's syndrome is obtained if the patient presents with eye and/or mouth dryness, the eye tests disclose keratoconjunctivitis sicca, the mouth evaluation reveals the classic manifestations of the syndrome, and the patient's serum reacts with Ro/SS-A and/or La/SS-B autoantigens. Labial biopsy is needed when the diagnosis is uncertain or to rule out conditions that may cause dry mouth or eyes or parotid gland enlargement (Tables 304-3, 304-4). Validated diagnostic criteria have been established by a European study and have now been further improved by a European-American study group (Table 304-5).

TREATMENT

Treatment of Sjögren's syndrome is aimed at symptomatic relief and limiting the damaging local effects of chronic xerostomia and keratoconjunctivitis sicca by substituting or simulating the missing secretions (Fig. 304-1).

To replace deficient tears, there are several readily available ophthalmic preparations (Tearisol; Liquifilm; 0.5% methylcellulose; Hypo Tears). If corneal ulcerations are present, eye patching and boric acid ointments are recommended. Certain drugs that may increase lacrimal and salivary hypofunction such as diuretics, antihypertensive drugs, and antidepressants should be avoided.

For xerostomia the best replacement is water. Propionic acid gels may be used to treat vaginal dryness. To stimulate secretions, pilocarpine (5 mg thrice daily) or cevimeline (30 mg thrice daily) administered orally appears to improve sicca manifestations and both are well tolerated. Hydroxychloroquine (200 mg) is helpful for arthralgias.

Patients with renal tubular acidosis should receive sodium bicarbonate orally (0.5 to 2.0 mmol/kg in four divided doses). Glucocorticoids (1 mg/kg per day) and/or immunosuppressive agents (e.g., cyclophosphamide) are indicated only for the treatment of systemic vasculitis.

305 THE SPONDYLOARTHRITIDES

Joel D. Taurog

The spondyloarthritides are a group of disorders that share certain clinical features and an association with the HLA-B27 allele. These disorders include ankylosing spondylitis, reactive arthritis, psoriatic arthritis and spondylitis, enteropathic arthritis and spondylitis, juvenile-onset spondyloarthritis, and undifferentiated spondyloarthritis. The similarities in clinical manifestations and genetic predisposition suggest that these disorders share pathogenic mechanisms.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is an inflammatory disorder of unknown cause that primarily affects the axial skeleton; peripheral joints and extraarticular structures may also be involved. The disease usually begins in the second or third decade; the male to female prevalence is approximately 3:1. Older names include *Marie-Strümpell disease* or *Bechterew's disease*.

EPIDEMIOLOGY AS shows a striking correlation with the histocompatibility antigen HLA-B27 and occurs worldwide roughly in proportion to the prevalence of this antigen (Chap. 296). In North American Caucasians, the general prevalence of B27 is 7%, whereas >90% of patients with AS have inherited this antigen. The association with B27 is independent of disease severity.

In population surveys, 1 to 6% of adults inheriting B27 have been found to have AS. In contrast, in families of patients with AS, the prevalence is 10 to 30% among adult first-degree relatives inheriting B27. The concordance rate in identical twins is approximately 65%. It is currently believed that susceptibility to AS is determined almost entirely by genetic factors, with B27 comprising about one-third of the genetic component.

PATHOLOGY The enthesis, the site of ligamentous attachment to bone, is thought to be the primary site of pathology in AS, particularly in the lesions around the pelvis and spine. Enthesitis is associated with prominent edema of the adjacent bone marrow and is often characterized by erosive lesions that eventually undergo ossification.

Sacroiliitis is usually one of the earliest manifestations of AS, with features of both enthesitis and synovitis. The early lesions consist of subchondral granulation tissue, infiltrates of lymphocytes and macrophages in ligamentous and periosteal zones, and subchondral bone marrow edema. Synovitis follows and may progress to pannus formation with islands of new bone formation. The eroded joint margins are gradually replaced by fibrocartilage regeneration and then by ossification. Ultimately, the joint may be totally obliterated.

In the spine, early in the process there is inflammatory granulation tissue at the junction of the annulus fibrosus of the disk cartilage and the margin of vertebral bone. The outer annular fibers are eroded and eventually replaced by bone, forming the beginning of a bony syndesmophyte, which then grows by continued enchondral ossification, ultimately bridging the adjacent vertebral bodies. Ascending progression of this process leads to the "bamboo spine" observed radiographically. Other lesions in the spine include diffuse osteoporosis, erosion of vertebral bodies at the disk margin, "squaring" of vertebrae, and inflammation and destruction of the disk-bone border. Inflammatory arthritis of the apophyseal joints is common, with erosion of cartilage by pannus, often followed by bony ankylosis.

Bone mineral density is significantly diminished in the spine and proximal femur early in the course of the disease, before the advent of significant immobilization.

Peripheral arthritis in AS can show synovial hyperplasia, lymphoid infiltration, and pannus formation, but the process lacks the exuberant synovial villi, fibrin deposits, ulcers, and accumulations of plasma cells seen in rheumatoid arthritis (RA) (Chap. 301). Central cartilaginous erosions caused by proliferation of subchondral granulation tissue are common in AS but rare in RA.

PATHOGENESIS The pathogenesis of AS is incompletely understood but is almost certainly immune mediated. The dramatic response of all aspects of the disease to therapeutic blockade of tumor necrosis factor α (TNF-α) indicates that this cytokine plays a central role in the immunopathogenesis of AS. The inflamed sacroiliac joint is infiltrated with CD4+ and CD8+ T cells and macrophages and shows high levels of TNF-α. No specific event or exogenous agent that triggers the onset of disease has been identified, although overlapping features with reactive arthritis and inflammatory bowel disease (IBD) suggest that enteric bacteria may play a role. Elevated serum titers of antibodies to certain enteric bacteria are common in AS patients, but no role for these antibodies in the pathogenesis of AS has been identified. Evidence that B27 plays a direct role is provided by the finding that rats transgenic for B27 spontaneously develop spondylitis, along with colitis, peripheral arthritis, and other lesions characteristic of the spondyloarthritides.

Some evidence has accumulated for autoimmunity to the cartilage proteoglycan aggrecan. Sharing of proteoglycan antigenic epitopes may be a possible explanation for the distribution of pathologic sites in AS.

CLINICAL MANIFESTATIONS The symptoms of the disease are usually first noticed in late adolescence or early adulthood; the median age in western countries is 23. In 5% of patients, symptoms begin after age 40.

The initial symptom is usually dull pain, insidious in onset, felt deep in the lower lumbar or gluteal region, accompanied by low-back morning stiffness of up to a few hours' duration that improves with activity and returns following periods of inactivity. Within a few months of onset, the pain has usually become persistent and bilateral. Nocturnal exacerbation of pain that forces the patient to rise and move around may be frequent.

In some patients, bony tenderness (presumably reflecting enthesitis) may accompany back pain or stiffness, while in others it may be the predominant complaint. Common sites include the costosternal junctions, spinous processes, iliac crests, greater trochanters, ischial tuberosities, tibial tubercles, and heels. Occasionally, bony chest pain is the presenting complaint. Arthritis in the hips and shoulders ("root" joints) occurs in 25 to 35% of patients, in many cases early in the disease course. Arthritis of peripheral joints other than the hips and shoulders, usually asymmetric, occurs in up to 30% of patients and can occur at any stage of the disease. Neck pain and stiffness from involvement of the cervical spine are usually relatively late manifestations. Occasional patients, particularly in the older age group, present with predominantly constitutional symptoms such as fatigue, anorexia, fever, weight loss, or night sweats.

AS often has a juvenile onset in developing countries. In these individuals, peripheral arthritis and enthesitis usually predominate, with axial symptoms supervening in late adolescence.

Initially, physical findings mirror the inflammatory process. The most specific findings involve loss of spinal mobility, with limitation of anterior and lateral flexion and extension of the lumbar spine and of chest expansion. Limitation of motion is usually out of proportion to the degree of bony ankylosis, reflecting muscle spasm secondary to pain and inflammation. Pain in the sacroiliac joints may be elicited either with direct pressure or with maneuvers that stress the joints. In addition, there is commonly tenderness upon palpation at the sites of symptomatic bony tenderness and paraspinous muscle spasm.

The Schober test is a useful measure of lumbar spine flexion. The patient stands erect, with heels together, and marks are made directly over the spine 5 cm below and 10 cm above the lumbosacral junction (identified by a horizontal line between the posterosuperior iliac spines.) The patient then bends forward maximally, and the distance between the two marks is measured. The distance between the two marks increases by $\geq$5 cm in the case of normal mobility and by $<$4 cm in the case of decreased mobility. Chest expansion is measured as the difference between maximal inspiration and maximal forced expiration in the fourth intercostal space in males or just below the breasts in females. Normal chest expansion is $\geq$5 cm.

Limitation or pain with motion of the hips or shoulders is usually present if either of these joints is involved. It should be emphasized that early in the course of mild cases, symptoms may be subtle and nonspecific, and the physical examination may be completely normal.

The course of the disease is extremely variable, ranging from the individual with mild stiffness and radiographically equivocal sacroiliitis to the patient with a totally fused spine and severe bilateral hip arthritis, possibly accompanied by severe peripheral arthritis and extraarticular manifestations. Pain tends to be persistent early in the disease and then becomes intermittent, with alternating exacerbations and quiescent periods. In a typical severe untreated case with progression of the spondylitis to syndesmophyte formation, the patient's posture undergoes characteristic changes, with obliterated lumbar lordosis, buttock atrophy, and accentuated thoracic kyphosis. There may be a forward stoop of the neck or flexion contractures at the hips, compensated by flexion at the knees. The progression of the disease may be followed by measuring the patient's height, chest expansion, Schober test, and occiput-to-wall distance. Occasional individuals are encountered with advanced physical findings who report having never had significant symptoms.

In some but not all studies, onset of the disease in adolescence correlates with a worse prognosis. Early severe hip involvement is an indication of progressive disease. The disease in women tends to progress less frequently to total spinal ankylosis, although there is some evidence for an increased prevalence of isolated cervical ankylosis and peripheral arthritis in women. In industrialized countries, peripheral arthritis (distal to hips and shoulders) occurs overall in about 25% of patients, usually as a late manifestation, whereas in developing countries, the prevalence is much higher, with onset typically early in the disease course. Pregnancy has no consistent effect on AS, with symptoms improving, remaining the same, or deteriorating in about one-third of pregnant patients, respectively.

The most serious complication of the spinal disease is spinal fracture, which can occur with even minor trauma to the rigid, osteoporotic spine. The cervical spine is most commonly involved. These fractures are often displaced and cause spinal cord injury.

The most common extraarticular manifestation is acute anterior uveitis, which occurs in 30% of patients and can antedate the spondylitis. Attacks are typically unilateral, causing pain, photophobia, and increased lacrimation. These tend to recur, often in the opposite eye. Cataracts and secondary glaucoma are not uncommon sequelae. Up to 60% of patients have inflammation in the colon or ileum. This is usually asymptomatic, but in 5 to 10% of patients with AS, frank IBD will develop. Aortic insufficiency, sometimes producing symptoms of congestive heart failure, occurs in a few percent of patients, occasionally early in the course of the spinal disease but usually after prolonged disease. Third-degree heart block may occur alone or together with aortic insufficiency. Subclinical pulmonary lesions and cardiac dysfunction may be relatively common. Cauda equina syndrome and slowly progressive upper pulmonary lobe fibrosis are rare complications of long-standing AS. Retroperitoneal fibrosis is a rare associated condition. Prostatitis has been reported to have an increased prevalence in men with AS. Amyloidosis is rare (Chap. 310).

Several validated measures of disease activity and functional outcome have recently been developed for AS. Despite the persistence of the disease, most patients remain gainfully employed. The effect of AS on survival is controversial. Some, but not all, studies have suggested that AS shortens life span, compared with the general population. Mortality attributable to AS is largely the result of spinal trauma, aortic insufficiency, respiratory failure, amyloid nephropathy, or complications of therapy such as upper gastrointestinal hemorrhage.

LABORATORY FINDINGS No laboratory test is diagnostic of AS. In most ethnic groups, B27 is present in approximately 90% of patients with AS. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often, but not always, elevated. Mild anemia may be present. Patients with severe disease may show an elevated alkaline phosphatase level. Elevated serum IgA levels are common. Rheumatoid factor and antinuclear antibodies are largely absent unless caused by a coexistent disease. Synovial fluid from peripheral joints in AS is nonspecifically inflammatory. In cases with restriction of chest wall motion, decreased vital capacity and increased functional residual capacity are common, but airflow measurements are normal and ventilatory function is usually well maintained.

RADIOGRAPHIC FINDINGS Radiographically demonstrable sacroiliitis is usually present in AS. The earliest changes by standard radiography are blurring of the cortical margins of the subchondral bone, followed by erosions and sclerosis. Progression of the erosions leads to "pseudowidening" of the joint space; as fibrous and then bony ankylosis supervene, the joints may become obliterated. The changes and progression of the lesions are usually symmetric.

In the lumbar spine, progression of the disease leads to straightening, caused by loss of lordosis, and reactive sclerosis, caused by osteitis of the anterior corners of the vertebral bodies with subsequent erosion, leading to "squaring" of the vertebral bodies. Progressive ossification leads to eventual formation of marginal syndesmophytes, visible on plain films as bony bridges connecting successive vertebral bodies anteriorly and laterally.

In mild cases, years may elapse before unequivocal sacroiliac abnormalities are evident on plain radiographs. Computed tomography

(CT) and magnetic resonance imaging (MRI) can detect abnormalities reliably at an earlier stage than plain radiography. MRI is highly sensitive and specific for identifying early intraarticular inflammation, cartilage changes, and underlying bone marrow edema in sacroiliitis (Fig. 305-1). In suspected cases in which conventional radiography does not reveal definite sacroiliac abnormalities or is undesirable (e.g., in young women or children), dynamic MRI is the procedure of choice for establishing a diagnosis of sacroiliitis.

Reduced bone mineral density can be detected by dual-energy x-ray absorptiometry of the femoral neck and the lumbar spine. Falsely elevated readings related to spinal ossification can be avoided by using a lateral projection of the L3 vertebral body.

DIAGNOSIS It is important to establish the diagnosis of early AS before the development of irreversible deformity. Modified New York criteria (1984) are widely used for diagnosis. These consist of the following: (1) a history of inflammatory back pain (see below); (2) limitation of motion of the lumbar spine in both the sagittal and frontal planes; (3) limited chest expansion, relative to standard values for age and sex; and (4) definite radiographic sacroiliitis. The presence of radiographic sacroiliitis plus any one of the other three criteria is sufficient for a diagnosis of definite AS. The use of MRI to demonstrate sacroiliitis significantly increases the sensitivity of these criteria (Fig. 305-1).

The presence of B27 is neither necessary nor sufficient for the diagnosis, but the B27 test can be helpful in patients with suggestive clinical findings who have not yet developed radiographic sacroiliitis. Moreover, the absence of B27 in a typical case of AS significantly increases the probability of coexistent IBD.

AS must be differentiated from numerous other causes of low-back pain, some of which are far more common than AS. The inflammatory back pain of AS is usually distinguished by the following five features: (1) age of onset below 40, (2) insidious onset, (3) duration >3 months before medical attention is sought, (4) morning stiffness, and (5) improvement with exercise or activity. The most common causes of back pain other than AS are primarily mechanical or degenerative rather than inflammatory and do not show these features. Less common metabolic, infectious, and malignant causes of back pain must also be differentiated from AS. Ochronosis can produce a phenotype that is clinically and radiographically similar to AS.

Marked calcification and ossification of paraspinous ligaments occur in *diffuse idiopathic skeletal hyperostosis* (DISH). Ligamentous calcification and ossification are usually most prominent in the anterior spinal ligament and give the appearance of "flowing wax" on the anterior bodies of the vertebrae. Intervertebral disk spaces are preserved, and sacroiliac and apophyseal joints appear normal, helping to differentiate DISH from spondylosis and from AS, respectively.

DISH occurs in the middle-aged and elderly. Patients are frequently asymptomatic but may have stiffness. Radiographic changes are generally much more dramatic than symptoms.

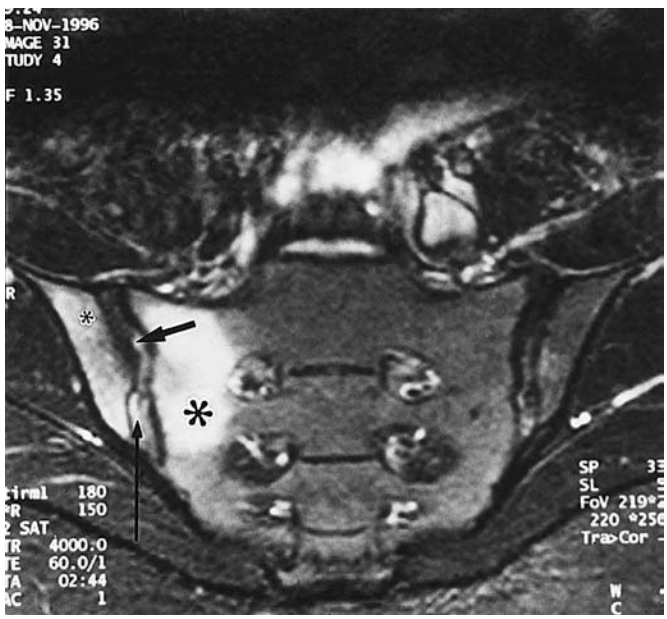

FIGURE 305-1 Early sacroiliitis of ankylosing spondylitis. Magnetic resonance imaging of the sacroiliac joints of a 23-year-old woman with progressive right-sided inflammatory back pain of 6 months' duration. Conventional radiographs were normal. A fat-suppressed image employing a short tau inversion recovery (STIR) sequence shows acute sacroiliitis on the right side, with edema in the juxtaarticular bone marrow (*asterisks*), in the region of the synovium and joint capsule (*thin arrow*), and in the region of the interosseous ligaments (*thick arrow*). Early chronic changes, including cortical erosions and joint space widening, were evident in the right sacroiliac joint in T1-, contrast-enhanced T1-, and T2*-weighted images (not shown). The patient subsequently developed radiographically evident bilateral sacroiliitis, fulfilling the criteria for ankylosing spondylitis. *(Photo provided by Dr. Jürgen Braun; previously published in Zeitschrift für Rheumatologie 58:61, 1999. TREATMENT

The publication in 2000 of dramatic responses to anti-TNF-α therapy heralded a revolution in the management of AS and other spondyloarthritides. Patients with AS treated with either infliximab (chimeric human/mouse anti-TNF-α monoclonal antibody) or etanercept (soluble p75 TNF-α receptor–IgG fusion protein) have shown rapid, profound, and sustained reductions in all clinical and laboratory measures of disease activity. Patients with long-standing disease and even complete spinal ankylosis have shown striking improvement in both objective and subjective indicators of disease activity and function, including morning stiffness, pain, spinal mobility, peripheral joint swelling, CRP, and ESR. MRI studies indicate substantial resolution of bone marrow edema, enthesitis, and joint effusions in the sacroiliac joints, spine, and peripheral joints. Overall, 10 studies published from 2000 to 2002 (9 with infliximab, 1 with etanercept; 7 open label, 3 randomized controlled trials; duration 8 to 54 weeks) have reported a median 60% reduction in the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), the most commonly used measure of disease activity (range 45 to 93%, vs. 3 to 10% in the three placebo groups). At present, it is not definitely known whether this therapy will halt the progression of the disease, but it seems likely to do so. Whether this therapy can reverse ankylosis or other damage is less clear but also not improbable.

The administration of these agents to AS patients has been similar to that in RA. Infliximab is given as an intravenous infusion, typically at a dose of 5 mg per kg body weight, and then repeated 2 weeks later, again 6 weeks later, and then at 8-week intervals. Etanercept is given in a dose of 25 mg by subcutaneous injection twice weekly.

Although these potent immunosuppressive agents have so far been remarkably safe, six types of side effects have been seen: (1) serious infections, including disseminated tuberculosis; (2) hematologic disorders such as pancytopenia; (3) demyelinating disorders; (4) exacerbation of congestive heart failure; (5) systemic lupus erythematosus–related autoantibodies and clinical features; and (6) hypersensitivity infusion or injection site reactions. Increased incidence of malignancy is of theoretical concern.

Although serious complications have been uncommon, neither the incidence of side effects nor the long-term effects of these agents are yet known. Moreover, the currently available anti-TNF-α agents are quite expensive. Thus, uncertainty remains as to which patients with AS and other spondyloarthritides should be given this form of therapy. Previously, the mainstay of treatment for AS was nonsteroidal anti-inflammatory drug (NSAID) therapy with drugs such as indomethacin or more recently COX-2 inhibitors, combined with exercise programs designed to maintain posture and range of motion. Sulfasalazine, in doses of 2 to 3 g/d, and methotrexate, in doses of 10 to 25 mg/wk, have been shown to be of modest benefit, primarily for peripheral arthritis. No therapeutic role for gold or oral glucocorticoids has been documented in AS. Recent studies suggest potential benefit in AS from three diverse agents: the bisphosphonate pamidronate, at

a dose of 60 mg given monthly by intravenous infusion; thalidomide, 200 mg/d, perhaps also acting through inhibition of TNF-α; and the α-emitting isotope ^{224}Ra, at a dose of 1 MBq given weekly by intravenous infusion.[1]

AS is a chronic progressive disease with a significant impact on productivity and quality of life. Although there are patients with mild AS whose pain is well controlled with NSAID therapy and whose disease shows little radiographic progression, many, if not most, patients have axial pain, stiffness, and disease progression despite conventional therapy. Thus, should anti-TNF-α agents, or similarly potent biologicals, prove reasonably safe and continuously effective, it can be predicted that eventually these agents will become standard therapy for most patients with AS.

The most common indication for surgery in patients with AS is severe hip joint arthritis, the pain and stiffness of which are usually dramatically relieved by total hip arthroplasty. A small number of patients may benefit from surgical correction of extreme flexion deformities of the spine or of atlantoaxial subluxation.

Attacks of uveitis are usually managed effectively with local glucocorticoid administration in conjunction with mydriatic agents, although systemic glucocorticoids or even immunosuppressive drugs may be required in some cases. The response of uveitis to anti-TNF-α therapy has not been as predictable as that of other features of AS. Coexistent cardiac disease may require pacemaker implantation and/or aortic valve replacement. Management of osteoporosis of the axial skeleton is at present similar to that used for primary osteoporosis, since data specific for AS are not available.

REACTIVE ARTHRITIS

Reactive arthritis (ReA) refers to acute nonpurulent arthritis complicating an infection elsewhere in the body. In recent years, the term has been used primarily to refer to spondyloarthritides following enteric or urogenital infections and occurring predominantly in individuals with the histocompatibility antigen HLA-B27. In the setting of HIV infection, the association with B27 is not necessarily found. →***Other forms of reactive and infection-related arthritis not associated with B27 and showing a different spectrum of clinical features, such as rheumatic fever or Lyme disease, are discussed in Chaps. 302 and 157.***

HISTORIC BACKGROUND The association of acute arthritis with episodes of diarrhea or urethritis has been recognized for centuries. A large number of cases during World Wars I and II focused attention on the triad of arthritis, urethritis, and conjunctivitis, which became known as *Reiter's syndrome*, often occurring with additional mucocutaneous lesions. This eponym is now of historic interest only.

The identification of bacterial species capable of triggering the clinical syndrome and the finding that up to 85% of the patients possess the B27 antigen have led to the unifying concept of ReA as a clinical syndrome triggered by specific etiologic agents in a genetically susceptible host. A similar spectrum of clinical manifestations can be triggered by enteric infection with any of several *Shigella*, *Salmonella*, *Yersinia*, and *Campylobacter* species; by genital infection with *Chlamydia trachomatis*; and possibly by other agents as well. The triad of arthritis, urethritis, and conjunctivitis represents one part of the spectrum of the clinical manifestations of ReA, particularly that induced by *Shigella* or *Chlamydia*. For the purposes of this chapter, the use of the term *ReA* will be restricted to those cases of spondyloarthritis in which there is at least presumptive evidence for a related antecedent infection. Patients with clinical features of ReA who lack evidence of an antecedent infection will be considered to have *undifferentiated spondyloarthritis*, discussed below.

[1]Azathioprine, methotrexate, sulfasalazine, infliximab, etanercept, pamidronate, thalidomide, and ^{224}Ra have not been approved for this purpose by the U.S. Food and Drug Administration at the time of publication.

EPIDEMIOLOGY Outside the setting of HIV infection, ReA occurs predominantly in individuals who have inherited the B27 gene; in most series in which *Shigella*, *Yersinia*, or *Chlamydia* are the triggering infectious agents, 60 to 85% of patients are B27 positive. The prevalence of B27 tends to be much lower ($\leq$50%) in ReA triggered by *Salmonella* and even lower for *Campylobacter*. The disease is most common in individuals 18 to 40 years of age, but it can occur both in children over 5 years of age and in older adults.

The sex ratio in ReA following enteric infection is nearly 1:1, whereas venereally acquired ReA occurs predominantly in men. The overall prevalence and incidence of ReA are difficult to assess because of the variable prevalence of the triggering infections and genetic susceptibility factors in different populations. The spondyloarthritides were previously almost unknown in sub-Saharan Africa, where $<$1% of the population carries B27. However, ReA and other peripheral spondyloarthritides have now become the most common rheumatic diseases in Africans in the wake of the AIDS epidemic, with no association to B27. Spondyloarthritis in Africans with HIV infection usually occurs in individuals with stage I disease (as classified by the World Health Organization). It is often the first manifestation of infection and often remits with disease progression. In contrast, western Caucasian patients with HIV and spondyloarthritis are predominantly B27 positive, and the arthritis flares as AIDS advances.

PATHOLOGY Synovial histology is similar to that of other inflammatory arthropathies. Enthesitis shows increased vascularity and macrophage infiltration of fibrocartilage. Microscopic histopathologic evidence of inflammation has occasionally been noted in the colon and ileum of patients with postvenereal ReA, but much less commonly than in postenteric ReA. The skin lesions of keratoderma blenorrhagica, which is associated mainly with venereally acquired ReA, are histologically indistinguishable from psoriatic lesions.

ETIOLOGY AND PATHOGENESIS Of the four *Shigella* species *S. sonnei*, *S. boydii*, *S. flexneri*, and *S. dysenteriae*, *S. flexneri* has most often been implicated in cases of ReA, both sporadic and epidemic. *S. sonnei*, although responsible for the majority of cases of shigellosis in the United States, has only rarely been implicated in cases of ReA.

Other bacteria identified definitively as triggers of ReA include several *Salmonella* spp., *Y. enterocolitica*, *C. jejuni*, and *C. trachomatis*. There is evidence implicating several other microorganisms, including *Y. pseudotuberculosis*, *Clostridium difficile*, and *Ureaplasma urealyticum*. There are also numerous isolated reports of acute arthritis preceded by other bacterial, viral, or parasitic infections, but whether the microorganisms involved are actual triggers of ReA remains to be determined.

It has not been determined whether ReA occurs by the same pathogenic mechanism following infection with each of these microorganisms, nor has the mechanism been fully elucidated in the case of any one of the known bacterial triggers. Most, if not all, of the triggering organisms produce lipopolysaccharide (LPS) and share a capacity to attack mucosal surfaces, to invade host cells, and to survive intracellularly. Antigens from *Chlamydia*, *Yersinia*, *Salmonella*, and *Shigella* have been shown to be present in the synovium and/or synovial fluid leukocytes of patients with ReA for long periods following the acute attack. In ReA triggered by *Y. enterocolitica*, bacterial LPS and heat shock protein antigens have been found in peripheral blood cells years after the triggering infection. In the case of *C. trachomatis*, synovial persistence of microbial DNA and RNA suggests the presence of viable organisms, despite uniform failure to culture the organism from these specimens. ReA, at least in some cases, thus may be a form of chronic infection, rather than solely "reactive." T cells that specifically respond to antigens of the inciting organism have been found in inflamed synovium but not in peripheral blood of patients with ReA. These T cells are predominantly CD4+, but CD8+ B27-restricted bacteria-specific cytolytic T cells have also been isolated in *Yersinia*- and *C. trachomatis*-induced ReA. A unique conserved T cell antigen receptor sequence has been identified in B27-restricted synovial T cells in ReA. Unlike the synovial CD4 T cells in RA, which are predomi-

nantly of the T_H1 phenotype, those in ReA also show a T_H2 phenotype. It is likely that antigen-specific T cells play an important role in the pathogenesis of ReA, but the mechanisms remain to be determined.

The role of HLA-B27 in ReA also remains to be determined. The presence of HLA-B27 significantly prolongs the intracellular survival of *Y. enterocolitica* and *S. enteritidis* in human and mouse cell lines. Prolonged intracellular bacterial survival, promoted by B27, other factors, or both, may permit trafficking of infected leukocytes from the site of primary infection to joints, where a T cell response to persistent bacterial antigens may then promote arthritis.

CLINICAL FEATURES The clinical manifestations of ReA constitute a spectrum that ranges from an isolated, transient monarthritis to severe multisystem disease. Usually, a careful history will elicit evidence of an antecedent infection 1 to 4 weeks before onset of symptoms of the reactive disease. However, in a sizable minority, no clinical or laboratory evidence of an antecedent infection can be found. In many cases of presumed venereally acquired reactive disease, there is a history of a recent new sexual partner, even in the absence of laboratory evidence of infection.

Constitutional symptoms are common, including fatigue, malaise, fever, and weight loss. The musculoskeletal symptoms are usually acute in onset. Arthritis is usually asymmetric and additive, with involvement of new joints occurring over a period of a few days to 1 to 2 weeks. The joints of the lower extremities, especially the knee, ankle, and subtalar, metatarsophalangeal, and toe interphalangeal joints, are the most common sites of involvement, but the wrist and fingers can be involved as well. The arthritis is usually quite painful, and tense joint effusions are not uncommon, especially in the knee. Patients often cannot walk without support. Dactylitis, or "sausage digit," a diffuse swelling of a solitary finger or toe, is a distinctive feature of ReA and other peripheral spondyloarthritides but can be seen in polyarticular gout and sarcoidosis. Tendinitis and fasciitis are particularly characteristic lesions, producing pain at multiple insertion sites (entheses), especially the Achilles insertion, the plantar fascia, and sites along the axial skeleton. Spinal and low-back pain are quite common and may be caused by insertional inflammation, muscle spasm, acute sacroiliitis, or, presumably, arthritis in intervertebral articulations.

Urogenital lesions may occur throughout the course of the disease. In males, urethritis may be marked or relatively asymptomatic and may be either an accompaniment of the triggering infection or a result of the reactive phase of the disease. Prostatitis is also common. Similarly, in females, cervicitis or salpingitis may be caused either by the infectious trigger or by the sterile reactive process.

Ocular disease is common, ranging from transient, asymptomatic conjunctivitis to an aggressive anterior uveitis that occasionally proves refractory to treatment and may result in blindness.

Mucocutaneous lesions are frequent. Oral ulcers tend to be superficial, transient, and often asymptomatic. The characteristic skin lesions, *keratoderma blenorrhagica*, consist of vesicles that become hyperkeratotic, ultimately forming a crust before disappearing. They are most common on the palms and soles but may occur elsewhere as well. In patients with HIV infection, these lesions are often extremely severe and extensive, to the point of dominating the clinical picture (Chap. 173). Lesions on the glans penis, termed *circinate balanitis*, are common; these consist of vesicles that quickly rupture to form painless superficial erosions, which in circumcised individuals can form crusts similar to those of keratoderma blenorrhagica. Nail changes are common and consist of onycholysis, distal yellowish discoloration, and/or heaped-up hyperkeratosis.

Less frequent or rare manifestations of ReA include cardiac conduction defects, aortic insufficiency, central or peripheral nervous system lesions, and pleuropulmonary infiltrates.

Long-term follow-up studies suggest that some joint symptoms persist in 30 to 60% of patients with ReA. Recurrences of the acute syndrome are common, and as many as 25% of patients either become unable to work or are forced to change occupations because of persistent joint symptoms. Chronic heel pain is often particularly distressing. Some aspects of AS are also common sequelae. In most studies, HLA-B27-positive patients have shown a worse outcome than B27-negative patients. The extent to which the long-term prognosis varies with different inciting agents is not known. However, patients with *Yersinia*-induced arthritis appear to have less chronic disease than those whose initial episode follows epidemic shigellosis.

LABORATORY AND RADIOGRAPHIC FINDINGS The ESR is usually elevated during the acute phase of the disease. Mild anemia may be present, and acute-phase reactants tend to be increased. Synovial fluid is nonspecifically inflammatory. In most ethnic groups, 50 to 85% of the patients are B27 positive, although the prevalence of B27 can be much lower in cases triggered by *Campylobacter* or *Salmonella* infections. It is unusual for the triggering infection to persist at the site of primary mucosal infection through the time of onset of the reactive disease, but it may occasionally be possible to culture the organism, e.g., in the case of *Yersinia*- or *Chlamydia*-induced disease. Serologic evidence of a recent infection may be present, such as a marked elevation of antibodies to *Yersinia*, *Salmonella*, or *Chlamydia*.

In early or mild disease, radiographic changes may be absent or confined to juxtaarticular osteoporosis. With long-standing persistent disease, marginal erosions and loss of joint space can be seen in affected joints. Periostitis with reactive new bone formation is characteristic of the disease, as it is with all the spondyloarthritides. Spurs at the insertion of the plantar fascia are common.

Sacroiliitis and spondylitis may be seen as late sequelae. The sacroiliitis is more commonly asymmetric than in AS, and the spondylitis, rather than ascending symmetrically from the lower lumbar segments, can begin anywhere along the lumbar spine. The syndesmophytes may be coarse and nonmarginal, arising from the middle of a vertebral body, a pattern rarely seen in primary AS. Progression to spinal fusion is uncommon.

DIAGNOSIS ReA is a clinical diagnosis, there being no definitively diagnostic laboratory test or radiographic finding. The diagnosis should be entertained in any patient with an acute inflammatory, asymmetric, additive arthritis or tendinitis. The evaluation should include questioning regarding possible triggering events such as an episode of diarrhea or dysuria. On physical examination, attention must be paid to the distribution of the joint and tendon involvement and to possible sites of extraarticular involvement, such as the eyes, mucous membranes, skin, nails, and genitalia. Synovial fluid analysis may be helpful in excluding septic or crystal-induced arthritis. Culture, serology, or molecular methods may help to identify a triggering infection.

Although typing for B27 is not needed to secure the diagnosis in clear-cut cases, it may have prognostic significance in terms of severity, chronicity, and the propensity for spondylitis and uveitis. Furthermore, it can be helpful diagnostically in atypical cases, a positive test increasing and a negative test decreasing the probability of ReA. HIV testing is often indicated and may be necessary in order to select appropriate therapy.

It is important to differentiate ReA from disseminated gonococcal disease (Chap. 128), both of which can be venereally acquired and associated with urethritis. Unlike ReA, gonococcal arthritis and tenosynovitis tend to involve both upper and lower extremities equally, to lack back symptoms, and to be associated with characteristic vesicular skin lesions. A positive gonococcal culture from the urethra or cervix does not exclude a diagnosis of ReA; however, culturing gonococci from blood, skin lesion, or synovium establishes the diagnosis of disseminated gonococcal disease. Polymerase chain reaction (PCR) assay for *Neisseria gonorrheae* and *C. trachomatis* may be helpful. Occasionally, only a therapeutic trial of antibiotics can distinguish the two.

ReA shares many features in common with psoriatic arthropathy. However, psoriatic arthritis is usually gradual in onset; the arthritis tends to affect primarily the upper extremities; there is less associated

periarthritis; and there are usually no associated mouth ulcers, urethritis, or bowel symptoms.

TREATMENT

Most patients with ReA are benefitted to some degree by NSAIDs, although rarely are symptoms of the acute arthritis completely ameliorated, and some patients fail to respond at all. Indomethacin, 75 to 150 mg/d in divided doses, is the initial treatment of choice. Other NSAIDs may be tried, with phenylbutazone, 100 mg tid or qid, being the NSAID of last resort, to be used only in severe, refractory cases because of its potentially serious side effects. There are no published data on the use of selective COX-2 inhibitors, but these may be tried in patients who do not tolerate conventional NSAIDs.

Several controlled trials have failed to demonstrate any benefit for antibiotic therapy in ReA. However, prompt, appropriate antibiotic treatment of acute chlamydial urethritis may prevent subsequent ReA.

Multicenter trials have suggested that sulfasalazine, up to 3 g/d in divided doses, may be beneficial to patients with persistent ReA.[1] Patients with persistent disease may respond to azathioprine, 1 to 2 mg/kg per day, or to methotrexate, 7.5 to 15 mg per week. Although no trials of anti-TNF-α in ReA have been reported, anecdotal evidence supports the use of these agents in severe chronic cases, although lack of response has also been observed.

Tendinitis and other enthesitic lesions may benefit from intralesional glucocorticoids. Uveitis may require aggressive treatment with glucocorticoids to prevent serious sequelae. Skin lesions ordinarily require only symptomatic treatment. In patients with HIV infection and ReA, many of whom have severe skin lesions, the skin lesions in particular respond to anti-retroviral therapy. Cardiac complications are managed conventionally; management of neurologic complications is symptomatic.

Comprehensive management includes counseling of patients in the avoidance of sexually transmitted disease and exposure to enteropathogens, as well as appropriate use of physical therapy, vocational counseling, and continued surveillance for long-term complications such as ankylosing spondylitis.

PSORIATIC ARTHRITIS

Psoriatic arthritis (PsA) refers to an inflammatory arthritis that characteristically occurs in individuals with psoriasis.

HISTORIC BACKGROUND The association between arthritis and psoriasis was noted in the nineteenth century. In the 1960s, on the basis of epidemiologic and clinical studies, it became clear that unlike RA the arthritis associated with psoriasis was usually seronegative, often involved the distal interphalangeal (DIP) joints of the fingers and the spine and sacroiliac joints, had distinctive radiographic features, and showed considerable familial aggregation. In the 1970s, PsA was included in the broader category of the spondyloarthritides because of features similar to those of AS and ReA.

EPIDEMIOLOGY A recent consensus has emerged that, among individuals with psoriasis, the prevalence of PsA is about 5 to 10%, but figures as high as 30% continue to be reported. In Caucasian populations, psoriasis is estimated to have a prevalence of 1 to 3%. Psoriasis and PsA are less common in other races in the absence of HIV infection. First-degree relatives of PsA patients have an elevated risk for psoriasis, for PsA itself, and for other forms of spondyloarthritis. Of patients with psoriasis, 30% have an affected first-degree relative. In monozygotic twins, the concordance for psoriasis is $\geq$65%, and for PsA $\geq$30%. A variety of HLA associations have been found. HLA-Cw6 is highly associated with psoriasis, particularly familial juvenile onset (type I) psoriasis. HLA-B27 is highly associated with psoriatic spondylitis (see below). HLA-DR7, -DQ3, and -B57 are associated with PsA because of linkage disequilibrium with Cw6. Other associations include HLA-B13, -B37, -B38, -B39, and DR4. The MIC-A-A9 allele at the HLA-B-linked MIC-A locus has also recently been reported associated with PsA, as have certain killer immunoglobulin-like receptor (KIR) alleles. The complex inheritance patterns of psoriasis and PsA suggest that several unlinked allelic loci are required for susceptibility. However, only the MHC has shown consistent linkage from study to study.

PATHOLOGY The inflamed synovium in PsA resembles that of RA, although with somewhat less hyperplasia and cellularity than in RA, and somewhat greater vascularity. Some studies have indicated a higher tendency to synovial fibrosis in PsA. Unlike RA, PsA shows prominent enthesitis, with histology similar to that of the other spondyloarthritides.

PATHOGENESIS PsA is almost certainly immune mediated, although the mechanism is as yet not well understood. PsA synovium shows infiltration with T cells, B cells, and macrophages, and upregulation of leukocyte homing receptors. CD8+ T cells are more frequent in PsA. Cytokine production in the synovium in PsA resembles that in psoriatic skin lesions and in RA synovium, having predominantly a T_H1 pattern. Interleukin (IL) 2, interferon γ, TNF-α, and IL-1β, -6, -8, -10, -12, -13, and -15 are found in PsA synovium or synovial fluid. Differences between PsA and RA in this regard are primarily quantitative, not qualitative.

CLINICAL FEATURES In 60 to 70% of cases, psoriasis precedes joint disease. In 15 to 20%, the two manifestations appear within 1 year of each other. In about 15 to 20% of cases, the arthritis precedes the onset of psoriasis and can present a diagnostic challenge. The frequency in men and women is almost equal, although the frequency of disease patterns differs somewhat in the two sexes. The disease can begin in childhood or late in life, but typically begins in the fourth or fifth decade, at an average age of 37 years.

The spectrum of arthropathy associated with psoriasis is quite broad. Several classification schemes have been proposed, but the most widely accepted is that of Wright and Moll, who described five patterns: (1) arthritis of the DIP joints; (2) asymmetric oligoarthritis; (3) symmetric polyarthritis similar to RA; (4) axial involvement (spine and sacroiliac joints); and (5) arthritis mutilans, a highly destructive form of disease. These patterns are not fixed, and in many patients the pattern that persists chronically differs from that of the initial presentation.

Nail changes in the fingers or toes occur in 90% of patients with PsA, compared with 40% of psoriatic patients without arthritis, and pustular psoriasis is said to be associated with more severe arthritis. Several articular features distinguish PsA from other joint disorders. Dactylitis occurs in >30%; enthesitis and tenosynovitis are also common, and are probably present in most patients, although often not appreciated on physical examination. Shortening of digits because of underlying osteolysis is particularly characteristic of PsA, and there is a much greater tendency than in RA for both fibrous and bony ankylosis of small joints. Rapid ankylosis of one or more PIP joints early in the course of disease is not uncommon. Back and neck pain and stiffness are also common in PsA.

Arthropathy confined to the DIP joints predominates in about 15% of cases. Accompanying nail changes in the affected digits are almost always present. These joints are also often affected in the other patterns of PsA. Approximately 30% of patients have asymmetric oligoarthritis. This pattern commonly involves a knee or another large joint with a few small joints in the fingers or toes, often with dactylitis. Symmetric polyarthritis occurs in about 40% of PsA patients. It may be indistinguishable from RA in terms of the joints involved, but other features characteristic of PsA are usually also present. In general, peripheral joints in PsA tend to be somewhat less tender than in RA, although signs of inflammation are usually present. Almost any peripheral joint can be involved. Axial arthropathy without peripheral involvement is found in about 5% of PsA patients. It may be indistin-

guishable from idiopathic AS, although more neck involvement and less thoracolumbar spinal involvement is characteristic, and nail changes are not found in idiopathic AS. About 5% of PsA patients have arthritis mutilans, in which there can be widespread shortening of digits ("telescoping"), sometimes coexisting with ankylosis and contractures in other digits.

Six patterns of nail involvement are identified: pitting, horizontal ridging, onycholysis, yellowish discoloration of the nail margins, dystrophic hyperkeratosis, and combinations of these findings. Other extraarticular manifestations of the spondyloarthritides are common. Eye involvement, either conjunctivitis or uveitis, is reported in 7 to 33% of PsA patients. Unlike the uveitis associated with AS, the uveitis in PsA shows more tendency to be bilateral, chronic, and/or posterior. Aortic valve insufficiency has been found in <4% of patients, usually after long-standing disease.

Widely varying estimates of clinical outcome have been reported in PsA. At its worst, severe PsA with arthritis mutilans is at least as crippling and ultimately fatal as severe RA. Unlike RA, however, many patients with PsA experience temporary remissions. Overall, erosive disease develops in the majority of patients, progressive disease with deformity and disability is common, and in some large published series mortality was found to be significantly increased compared with the general population.

The psoriasis and associated arthropathy seen in individuals infected with HIV both tend to be severe and can occur in populations with very little psoriasis in noninfected individuals. Severe enthesopathy, dactylitis, and rapidly progressive joint destruction are seen, but axial involvement is very rare. This condition is prevented by or responds well to anti-retroviral therapy.

LABORATORY AND RADIOGRAPHIC FINDINGS There are no diagnostic laboratory tests for PsA. ESR and CRP are often, but not always, elevated. A small percentage of patients may have low titers of rheumatoid factor or antinuclear antibodies. Uric acid may be elevated in the presence of extensive psoriasis. HLA-B27 is found in 50 to 70% of patients with axial disease, but in ≤15 to 20% in patients with only peripheral joint involvement.

The peripheral and axial arthropathies in PsA show a number of radiographic features that distinguish them from RA and AS, respectively. Characteristics of peripheral PsA include DIP involvement, including the classic "pencil-in-cup" deformity; marginal erosions with adjacent bony proliferation ("whiskering"); small joint ankylosis; osteolysis of phalangeal and metacarpal bone, with telescoping of digits; and periostitis and proliferative new bone at sites of enthesitis. Characteristics of axial PsA include asymmetric sacroiliitis; compared with idiopathic AS, less zygoapophyseal joint arthritis, fewer and less symmetric and delicate syndesmophytes; fluffy hyperperiostosis on anterior vertebral bodies; severe cervical spine involvement, with a tendency to atlantoaxial subluxation but relative sparing of the thoracolumbar spine; and paravertebral ossification. Ultrasound and MRI both readily demonstrate enthesitis and tendon sheath effusions that can be difficult to assess on physical examination.

DIAGNOSIS The diagnosis of PsA is primarily clinical and can be challenging when the arthritis precedes psoriasis, the psoriasis is undiagnosed or obscure, or the joint involvement closely resembles another form of arthritis. A high index of suspicion is needed in any patient with an undiagnosed inflammatory arthropathy. The history should include inquiry about psoriasis in the patient and family members. Patients should be asked to disrobe for the physical examination, and psoriasiform lesions should be sought in the scalp, ears, umbilicus, and gluteal folds in addition to more accessible sites, and the finger and toe nails should be carefully examined. Axial symptoms or signs, dactylitis, enthesitis, ankylosis, the pattern of joint involvement, and characteristic radiographic changes can be helpful clues. The differential diagnosis of isolated DIP involvement is short. Osteoarthritis (Heberden's nodes) is usually not inflammatory; gout involving more than one DIP joint often involves other sites and is accompanied by tophi; the very rare entity multicentric reticulohistiocytosis involves other joints and has characteristic small pearly periungual skin nodules; and the uncommon entity inflammatory osteoarthritis, like the others, lacks the nail changes of PsA. Radiography can be helpful in all of these cases and in distinguishing between psoriatic spondylitis and idiopathic AS. A history of trauma to an affected joint preceding the onset of arthritis is said to occur more frequently in PsA than in other types of arthritis, perhaps reflecting the Koebner phenomenon in which psoriatic skin lesions can arise at sites of the skin trauma.

TREATMENT

Ideally, coordinated therapy is directed at both the skin and joints in PsA. As described above for AS, use of the anti-TNF-α agents promises to revolutionize the treatment of PsA. Prompt and dramatic resolution of both arthritis and skin lesions has been observed in at least five trials of etanercept and infliximab. Many of the responding patients had long-standing disease that was resistant to all previous therapy, as well as extensive skin disease. Although the effect on disease progression has not yet been reported, the clinical response is even more dramatic than in RA, in which both etanercept and infliximab have been shown to halt the progression of joint erosions.

Other treatment for PsA has been based on drugs that have efficacy in RA and/or in psoriasis. Although methotrexate in doses of 15 to 25 mg/wk and sulfasalazine (usually given in doses of 2 to 3 g/d) have each been found to have clinical efficacy in controlled trials, neither effectively halts progression of erosive joint disease. Other agents with efficacy in psoriasis reported to benefit PsA are cyclosporine, retinoic acid derivatives, and psoralen plus ultraviolet light (PUVA). There is controversy regarding the efficacy in PsA of gold and antimalarials, which have been widely used in RA. The new antirheumatic agent leflunomide is currently being evaluated.

All of these treatments require careful monitoring. Use of immunosuppressive therapy, including anti-TNF-α agents, methotrexate, and cyclosporine, is largely contraindicated in HIV-associated PsA.

In one large prospective series, 7% of patients with PsA required musculoskeletal surgery beginning at a mean of 13 years' disease duration. Indications for surgery are similar to those in RA, although there is an impression that outcomes in PsA may be less satisfactory.

SAPHO SYNDROME

The syndrome of synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) is characterized by a variety of skin and musculoskeletal manifestations. Dermatologic manifestations include palmoplantar pustulosis, acne conglobata, acne fulminans, and hidradenitis suppurativa. The main musculoskeletal findings are sternoclavicular and spinal hyperostosis, chronic recurrent foci of sterile osteomyelitis, and occasionally peripheral arthritis. Cases with one or a few manifestations are probably the rule. Granulomas may be present on bone biopsy. The ESR is usually elevated, sometimes dramatically. In some series, B27 is present in about 30% of the cases. Either bone scan or CT scan is helpful diagnostically. Therapy has been inadequate, with high dose NSAIDs, including phenylbutazone, providing the most relief from bone pain. Response to pamidronate and to anti-TNF-α therapy has been observed anecdotally.

UNDIFFERENTIATED AND JUVENILE-ONSET SPONDYLOARTHRITIS

Many patients, usually young adults, present with some features of one or more of the spondyloarthritides discussed above but lack criteria for these diagnoses. For example, a patient may present with inflammatory synovitis of one knee, Achilles tendinitis, and dactylitis of one digit, or sacroiliitis in the absence of other criteria for AS. Such patients are said to have undifferentiated spondyloarthritis, or simply spondyloarthritis, as defined by the European Spondyloarthropathy Study Group (ESSG criteria, Fig. 305-2). Some of these patients may

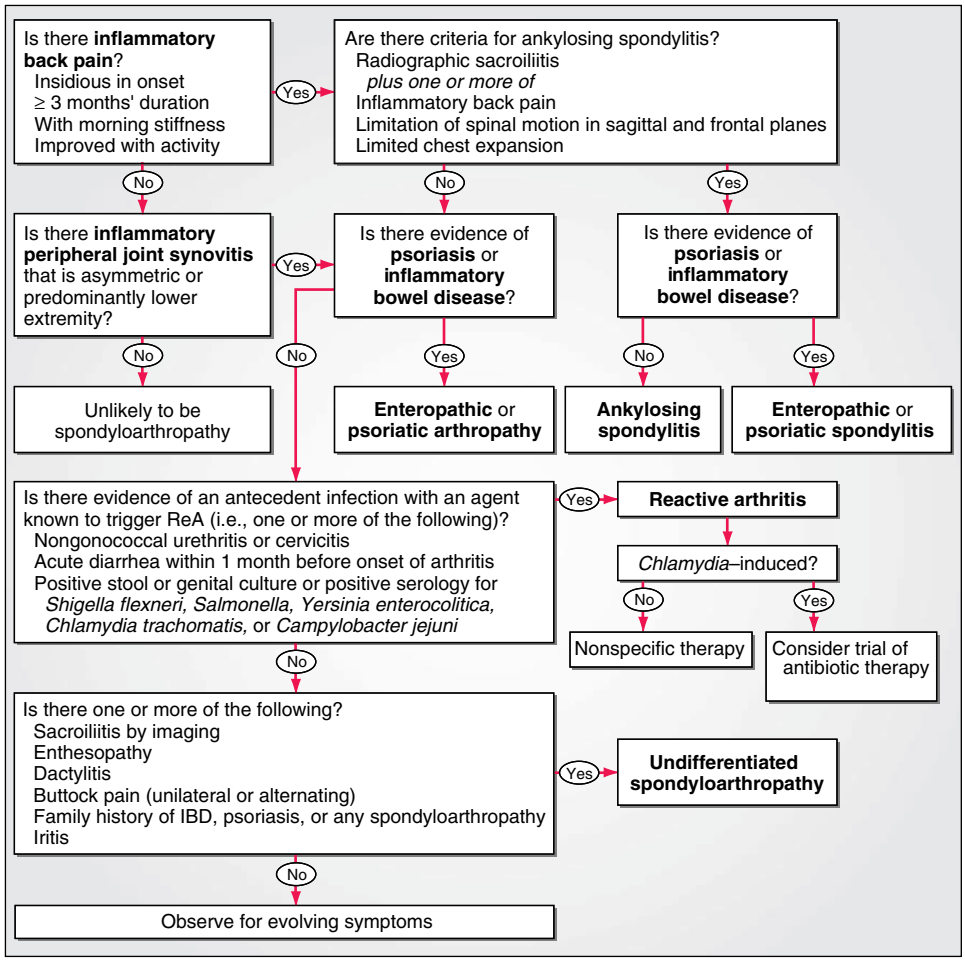

FIGURE 305-2 Algorithm for diagnosis of the spondyloarthritides, adapted from the European Spondyloarthropathy Study Group criteria. If a diagnosis of psoriatic arthropathy, reactive arthritis, or undifferentiated spondyloarthritis is made on the basis of peripheral arthropathy, then HIV infection needs to be considered.

have ReA in which the triggering infection remains clinically silent. In some other cases, the patient subsequently develops IBD or psoriasis or the process eventually meets criteria for AS. Approximately half the patients with undifferentiated spondyloarthritis are HLA-B27 positive, and thus the absence of B27 is not useful in establishing or excluding the diagnosis. In familial cases, which are almost always B27 positive, there is often eventual progression to AS.

In juvenile-onset spondyloarthritis, which begins between ages 7 and 16, most commonly in boys (60 to 80%), an asymmetric, predominantly lower extremity oligoarthritis and enthesitis without extraarticular features is the typical mode of presentation. The prevalence of B27 in this condition, which has been termed the seronegative, enthesopathy, arthropathy (SEA) syndrome, is approximately 80%. Many, but not all, of these patients go on to develop AS in late adolescence or adulthood.

Management of undifferentiated spondyloarthritis is similar to that of the other spondyloarthritides. Response to anti-TNF-α therapy has been documented, and this therapy is indicated in severe, persistent cases not responsive to other treatment. Current pediatric textbooks and journals should be consulted for information on management of juvenile-onset spondyloarthritis. An algorithm for the diagnosis of the spondyloarthritides in adults is presented in Fig. 305-2.

ENTEROPATHIC ARTHRITIS

HISTORIC BACKGROUND A relationship between arthritis and IBD was observed in the 1930s. The relationship was further defined by the epidemiologic studies in the 1950s and '60s and included in the concept of the spondyloarthritides in the 1970s.

EPIDEMIOLOGY Both of the common forms of IBD, ulcerative colitis (UC) and Crohn's disease (CD) (Chap. 276), are associated with spondyloarthritis. UC and CD both have an estimated prevalence of 0.05 to 0.1%, and the incidence of each is thought to have increased in recent decades. AS and peripheral arthritis are both associated with UC and with CD. Wide variations have been reported in the estimated frequencies of these associations. In three recent European series encompassing almost 2000 patients with IBD for a median 5 to 10 years, overall, AS was diagnosed in 2%, inflammatory back pain in 9%, enthesopathy in 7%, and peripheral arthritis in 10%, with somewhat higher frequencies found in CD than in UC. The combined total frequency of spondyloarthritis was 19%. These figures are somewhat lower than earlier estimates. Asymptomatic radiographic sacroiliitis was found in an additional 5%.

The prevalence of UC or CD in patients with AS is thought to be 5 to 10%. However, investigation of unselected spondyloarthritis patients by ileocolonoscopy has revealed that from one-third to two-thirds of patients with AS have subclinical intestinal inflammation that is evident either macroscopically or histologically. These lesions have also been found in patients with undifferentiated spondyloarthritis or ReA (both enterically and urogenitally acquired).

Both UC and CD have a tendency to familial aggregation, more so for CD. HLA associations have been weak and inconsistent. HLA-B27 is found in about 70% of patients with IBD and AS, but in ≤15% of patients with IBD and peripheral arthritis or IBD alone. Certain alleles of the *NOD2/CARD15* gene on chromosome 16 have recently been found in up to half of patients with CD. It appears that these alleles are not associated with the spondyloarthritides, either occurring alone or in association with CD, but the data are not yet conclusive.

PATHOLOGY Available data for IBD-associated peripheral arthritis suggest a nonspecific inflammatory synovitis, although one study found granulomas associated with CD. Association with arthropathy does not affect the gut histology of UC or CD (Chap. 276). The subclinical inflammatory lesions in the colon and distal ileum associated with spondyloarthritis have been classified as either acute or chronic. The former resemble acute bacterial enteritis, with largely intact architecture and neutrophilic infiltration in the lamina propria. The latter resemble the lesions of CD, with distortion of villi and crypts, aphthoid ulceration, and mononuclear cell infiltration in the lamina propria.

PATHOGENESIS Both IBD and the spondyloarthropathies are immune mediated, but the specific pathogenic mechanisms are poorly understood, and the connection between the two is obscure. IBD is a common phenotype in a number of rodent lines with transgenic overexpression or targeted deletion of genes involved in immune processes. Arthritis is an accompanying prominent feature in two of these IBD models, HLA-B27 transgenic rats and mice with constitutive overexpression of TNF-α, and immune dysregulation is prominent in both. Several lines of evidence indicate trafficking of leukocytes between the gut and the joint. Mucosal leukocytes from IBD patients have been

shown to bind avidly to synovial vasculature through several different adhesion molecules, and T cells with identical antigen receptor sequences have been isolated from both the gut and the synovium in the same patient. Macrophages expressing CD163 are prominent in the inflammatory lesions of both gut and synovium in the spondyloarthritides.

CLINICAL FEATURES AS associated with IBD is clinically indistinguishable from idiopathic AS. It runs a course independent of the bowel disease, and in many patients it precedes the onset of IBD, sometimes by many years. In contrast, peripheral arthritis has generally been reported to parallel the activity of the bowel disease, although it not infrequently begins before onset of overt bowel disease. A recent large study classified the peripheral arthritis of IBD patients into two types. Type 1 involved fewer than five joints, was associated with acute self-limited attacks, and often coincided with relapses of IBD. Type 2 involved five or more joints, tended to be symmetric, and ran a chronic course independent of IBD. The patterns of joint involvement were similar in UC and CD. Type 1 arthritis involved primarily the knee and ankle, whereas type 2 involved these joints but also tended to involve joints in the hand and upper extremity. This dichotomy has yet to be confirmed, but both types are characteristic of the spectrum of peripheral arthritis previously described in IBD. In general, erosions and deformities are infrequent in IBD-associated peripheral arthritis, and joint surgery is rarely required. Dactylitis and enthesopathy are occasionally found. In addition to the ~20% of IBD patients with spondyloarthritis, a comparable percentage have arthralgias or fibromyalgia symptoms.

Other extraintestinal manifestations of IBD are seen in addition to arthropathy, including uveitis, pyoderma gangrenosum, erythema nodosum, and finger clubbing, all somewhat more common in CD than UC. The uveitis shares the features described above for PsA-associated uveitis.

LABORATORY AND RADIOGRAPHIC FINDINGS Laboratory findings reflect the inflammatory and metabolic manifestations of IBD. Joint fluid is usually at least mildly inflammatory. Of patients with AS and IBD, about 70% carry the HLA-B27 gene, compared with >90% of patients with AS alone and 50 to 70% of those with AS and psoriasis. Hence, definite or probable AS in a B27-negative individual in the absence of psoriasis should prompt a search for occult IBD. Radiographic changes in the axial skeleton are the same as in uncomplicated AS. Erosions are uncommon in peripheral arthritis but may occur, particularly in the metatarsophalangeal joints. Isolated destructive hip disease has been described.

DIAGNOSIS Diarrhea and arthritis are both common conditions that can coexist for a variety of reasons. When etiopathogenically related, reactive arthritis and IBD-associated arthritis are the most common causes. Rare causes include celiac disease, blind loop syndromes, and Whipple's disease. In most cases, diagnosis depends upon investigation of the bowel disease.

℞ TREATMENT

As with the spondyloarthritides, treatment of CD is being revolutionized by therapy with infliximab, particularly in patients with fistulas or refractory disease. Recent anecdotal evidence suggests that associated arthritis responds promptly to infliximab. It is of interest that the spondyloarthritides respond to both infliximab and etanercept, whereas only infliximab has efficacy in CD and neither agent is effective in UC. Other treatment for IBD, including sulfasalazine and related drugs, systemic glucocorticoids, and immunosuppressive drugs, are also usually of benefit for associated peripheral arthritis. NSAIDs are generally helpful and well tolerated, but they can precipitate flares of IBD.

WHIPPLE'S DISEASE

Whipple's disease (Chap. 275) is a rare chronic bacterial infection, mostly of middle-aged Caucasian men, caused by *Tropheryma whippelii*. At least 75% of affected individuals develop an oligo- or polyarthritis. The joint manifestations usually precede other symptoms of the disease by 5 years or more; they are particularly important because antibiotic therapy is curative, whereas the untreated disease is fatal. Large and small peripheral joints and sacroiliac joints may be involved. The arthritis is abrupt in onset, migratory, usually lasts hours to a few days and then resolves completely. Chronic polyarthritis and joint space loss, visible on x-ray, can occur but are not typical. Eventually, prolonged diarrhea, malabsorption, and weight loss occur. Other manifestations of systemic disease include fever, edema, serositis, endocarditis, pneumonia, hypotension, lymphadenopathy, hyperpigmentation, subcutaneous nodules, clubbing, and uveitis. Central nervous system involvement eventually develops in 80% of untreated patients, with cognitive changes, headache, diplopia, and papilledema, and may be appreciated by abnormalities on MRI. Oculomasticatory and oculo-facial-skeletal myorhythmia, accompanied by supranuclear vertical gaze palsy, are said to be pathognomonic. Laboratory abnormalities include anemia and changes from malabsorption. There may be a weak association with HLA-B27. Synovial fluid is usually inflammatory. Radiography rarely shows joint erosions but may show sacroiliitis. Abdominal CT may reveal lymphadenopathy. Foamy macrophages containing PAS-staining bacterial remnants can be seen in biopsies of small intestine, synovium, lymph node, and other tissues. Diagnosis is established by PCR amplification of the 16S ribosomal gene sequences of *T. whippelii* in biopsied tissue. The organism has recently been isolated, and serologic tests may become available. The syndrome responds best to therapy with penicillin (or ceftriaxone) and streptomycin for 2 weeks followed by trimethoprim-sulfamethoxazole for 1 to 2 years. Monitoring for central nervous system relapse is critical.

306 THE VASCULITIS SYNDROMES

Michael C. Sneller, Carol A. Langford, Anthony S. Fauci

DEFINITION *Vasculitis* is a clinicopathologic process characterized by inflammation of and damage to blood vessels. The vessel lumen is usually compromised, and this is associated with ischemia of the tissues supplied by the involved vessel. A broad and heterogeneous group of syndromes may result from this process, since any type, size, and location of blood vessel may be involved. Vasculitis and its consequences may be the primary or sole manifestation of a disease; alternatively, vasculitis may be a secondary component of another primary disease. Vasculitis may be confined to a single organ, such as the skin, or it may simultaneously involve several organ systems.

CLASSIFICATION A major feature of the vasculitic syndromes as a group is the fact that there is a great deal of heterogeneity at the same time as there is considerable overlap among them. This heterogeneity and overlap in addition to a lack of understanding of the pathogenesis of these syndromes have been major impediments to the development of a coherent classification system for these diseases. Table 306-1 lists the major vasculitis syndromes. The distinguishing and overlapping features of these syndromes are discussed below.

PATHOPHYSIOLOGY AND PATHOGENESIS Generally, most of the vasculitic syndromes are assumed to be mediated at least in part by immunopathogenic mechanisms that occur in response to certain antigenic stimuli (Table 306-2). However, evidence supporting this hypothesis is for the most part indirect and may reflect epiphenomena as opposed to true causality. Furthermore, it is unknown why some individuals might develop vasculitis in response to certain antigenic stimuli, whereas others do not. It is likely that a number of factors are involved in the ultimate expression of a vasculitic syndrome. These include the genetic predisposition, environmental exposures, and the regulatory mechanisms associated with immune response to certain antigens.

Pathogenic Immune-Complex Formation Vasculitis is generally considered within the broader category of *immune-complex diseases* that include serum sickness and certain of the connective tissue diseases, of which systemic lupus erythematosus (Chap. 300) is the prototype. Although deposition of immune complexes in vessel walls is the most widely accepted pathogenic mechanism of vasculitis, the causal role of immune complexes has not been clearly established in most of the vasculitic syndromes. Circulating immune complexes need not result in deposition of the complexes in blood vessels with ensuing vasculitis, and many patients with active vasculitis do not have demonstrable circulating or deposited immune complexes. The actual antigen contained in the immune complex has only rarely been identified in vasculitic syndromes. In this regard, hepatitis B antigen has been identified in both the circulating and deposited immune complexes in a subset of patients with systemic vasculitis, most notably in polyarteritis nodosa (see below). The syndrome of essential mixed cryoglobulinemia is strongly associated with hepatitis C virus infection; hepatitis C virions and hepatitis C virus antigen-antibody complexes have been identified in the cryoprecipitates of these patients (see below).

TABLE 306-1 Vasculitis Syndromes

Primary Vasculitis Syndromes	Secondary Vasculitis Syndromes
Wegener's granulomatosis	Drug-induced vasculitis
Churg-Strauss syndrome	Serum sickness
Polyarteritis nodosa	Vasculitis associated with other primary diseases

Source: Adapted from Sneller and Fauci.

The mechanisms of tissue damage in immune complex–mediated vasculitis resemble those described for serum sickness. In this model, antigen-antibody complexes are formed in antigen excess and are deposited in vessel walls whose permeability has been increased by vasoactive amines such as histamine, bradykinin, and leukotrienes released from platelets or from mast cells as a result of IgE-triggered mechanisms. The deposition of complexes results in activation of complement components, particularly C5a, which is strongly chemotactic for neutrophils. These cells then infiltrate the vessel wall, phagocytose the immune complexes, and release their intracytoplasmic enzymes, which damage the vessel wall. As the process becomes subacute or chronic, mononuclear cells infiltrate the vessel wall. The common denominator of the resulting syndrome is compromise of the vessel lumen with ischemic changes in the tissues supplied by the involved vessel. Several variables may explain why only certain types of immune complexes cause vasculitis and why only certain vessels are affected in individual patients. These include the ability of the reticuloendothelial system to clear circulating complexes from the blood, the size and physicochemical properties of immune complexes, the relative degree of turbulence of blood flow, the intravascular hydrostatic pressure in different vessels, and the preexisting integrity of the vessel endothelium.

Antineutrophil Cytoplasmic Antibodies (ANCA) ANCA are antibodies directed against certain proteins in the cytoplasmic granules of neutrophils and monocytes. These autoantibodies are present in a high percentage of patients with certain systemic vasculitis syndromes, particularly Wegener's granulomatosis and microscopic polyangiitis, and in patients with necrotizing and crescentic glomerulonephritis. There are two major categories of ANCA based on different targets for the antibodies. The terminology of *cytoplasmic ANCA* (c-ANCA) refers to the diffuse, granular cytoplasmic staining pattern observed by immunofluorescence microscopy when serum antibodies bind to indicator neutrophils. Proteinase-3, the 29-kDa neutral serine proteinase present in neutrophil azurophilic granules, is the major c-ANCA antigen. More than 90% of patients with typical active Wegener's granulomatosis have detectable antibodies to proteinase-3 (see below). The terminology of *perinuclear ANCA* (p-ANCA) refers to the more localized perinuclear or nuclear staining pattern of the indicator neutrophils. The major target for p-ANCA is the enzyme myeloperoxidase; other targets that can produce a p-ANCA pattern of staining include elastase, cathepsin G, lactoferrin, lysozyme, and bactericidal/permeability-increasing protein. However, only antibodies to myeloperoxi-

dase have been convincingly associated with vasculitis. Antimyeloperoxidase antibodies have been reported to occur in variable percentages of patients with microscopic polyangiitis, Churg-Strauss syndrome, crescentic glomerulonephritis, Goodpasture's syndrome, and Wegener's granulomatosis (see below). A p-ANCA pattern of staining that is not due to antimyeloperoxidase antibodies has been associated with nonvasculitic entities such as rheumatic and nonrheumatic autoimmune diseases, inflammatory bowel disease, certain drugs, and infections such as endocarditis and bacterial airway infections in patients with cystic fibrosis.

It is unclear why patients with these vasculitis syndromes develop antibodies to myeloperoxidase or proteinase-3, whereas such antibodies are rare in other inflammatory diseases and autoimmune diseases. There are a number of in vitro observations that suggest possible mechanisms whereby these antibodies can contribute to the pathogenesis of the vasculitis syndromes. Proteinase-3 and myeloperoxidase reside in the azurophilic granules and lysosomes of resting neutrophils and monocytes, where they are apparently inaccessible to serum antibodies. However, when neutrophils or monocytes are primed by tumor necrosis factor (TNF) α or interleukin (IL) 1, proteinase-3 and myeloperoxidase translocate to the cell membrane where they can interact with extracellular ANCA. The neutrophils then degranulate and produce reactive oxygen species that can cause tissue damage. Furthermore, ANCA-activated neutrophils can adhere to and kill endothelial cells in vitro. Activation of neutrophils and monocytes by ANCA also induces the release of proinflammatory cytokines such as IL-1 and IL-8. Recent adoptive transfer experiments in genetically engineered mice provide further evidence for a direct pathogenic role of ANCA in vivo. In contradiction, however, a number of clinical and laboratory observations argue against a primary pathogenic role for ANCA. Patients may have active Wegener's granulomatosis in the absence of ANCA; the absolute height of the antibody titers does not correlate well with disease activity; and patients with Wegener's granulomatosis in remission may continue to have high antiproteinase-3 (c-ANCA) titers for years (see below). Thus, the role of these autoantibodies in the pathogenesis of systemic vasculitis remains unclear.

Pathogenic T Lymphocyte Responses and Granuloma Formation In addition to the classic immune complex–mediated mechanisms of vasculitis as well as ANCA, other immunopathogenic mechanisms may be involved in damage to vessels. The most prominent of these are delayed hypersensitivity and cell-mediated immune injury as reflected in the histopathologic feature of granulomatous vasculitis. However, immune complexes themselves may induce granulomatous responses. Vascular endothelial cells can express HLA class II molecules following activation by cytokines such as interferon (IFN) γ. This allows these cells to participate in immunologic reactions such as interaction with CD4+ T lymphocytes in a manner similar to antigen-presenting macrophages. Endothelial cells can secrete IL-1, which may activate T lymphocytes and initiate or propagate in situ immunologic processes within the blood vessel. In addition, IL-1 and TNF-α are potent inducers of endothelial-leukocyte adhesion molecule 1 (ELAM-1) and vascular cell adhesion molecule 1 (VCAM-1), which may enhance the adhesion of leukocytes to endothelial cells in the blood vessel wall. Other mechanisms such as direct cellular cytotoxicity, antibody directed against vessel components, or antibody-dependent cellular cytotoxicity have been suggested in certain types of vessel damage. However, there is no convincing evidence to support their causal contribution to the pathogenesis of any of the recognized vasculitic syndromes.

APPROACH TO THE PATIENT

The diagnosis of vasculitis is often considered in any patient with an unexplained systemic illness. However, there are certain clinical abnormalities that when present alone or in combination should suggest a diagnosis of vasculitis. These include palpable purpura, pulmonary infiltrates and microscopic hematuria, chronic inflammatory sinusitis, mononeuritis multiplex, unexplained ischemic events, and glomerulonephritis with evidence of multisystem disease. A number of nonvasculitic diseases may also produce some or all of these abnormalities. Thus, the first step in the workup of a patient with suspected vasculitis is to exclude other diseases that produce clinical manifestations that can mimic vasculitis (Table 306-3). It is particularly important to exclude infectious diseases with features that overlap those of vasculitis, especially if the patient's clinical condition is deteriorating rapidly and empirical immunosuppressive treatment is being contemplated.

Once diseases that mimic vasculitis have been excluded, the workup should follow a series of progressive steps that establish the diagnosis of vasculitis and determine, where possible, the category of the vasculitis syndrome (Fig. 306-1). This approach is of considerable importance since several of the vasculitis syndromes require aggressive therapy with glucocorticoids and cytotoxic agents, while other syndromes usually resolve spontaneously and require symptomatic treatment only. The definitive diagnosis of vasculitis is made upon biopsy of involved tissue. The yield of "blind" biopsies of organs with no subjective or objective evidence of involvement is very low and should be avoided. When syndromes such as polyarteritis nodosa, Takayasu's arteritis, or isolated central nervous system vasculitis are suspected, angiogram of organs with suspected involvement should be performed. However, angiograms should not be performed routinely when patients present with localized cutaneous vasculitis with no clinical indication of visceral involvement.

The constellation of clinical, laboratory, biopsy, and radiographic findings usually allows proper categorization to a specific syndrome, and therapy where appropriate should be initiated according to this information (see individual syndromes below). If an offending antigen that precipitates the vasculitis is recognized, the antigen should be removed where possible. If the vasculitis is associated with an underlying disease such as an infection, neoplasm, or connective tissue disease, the underlying disease should be treated. If the syndrome does not resolve following removal of an offending antigen or treatment of an underlying disease, or if there is no recognizable underlying disease, treatment should be initiated according to the category of the vasculitis syndrome.

TABLE 306-3 Conditions That Can Mimic Vasculitis

Infectious diseases
Bacterial endocarditis
Disseminated gonococcal infection
Pulmonary histoplasmosis
Coccidioidomycosis
Syphilis
Lyme disease
Rocky Mountain spotted fever
Whipple's disease
Coagulopathies/thrombotic microangiopathies
Antiphospholipid antibody syndrome
Thrombotic thrombocytopenic purpura
Neoplasms
Atrial myxoma
Lymphoma
Carcinomatosis
Drug toxicity
Cocaine
Amphetamines
Ergot alkaloids
Methysergide
Arsenic
Sarcoidosis
Atheroembolic disease
Goodpasture's syndrome
Amyloidosis
Migraine
Cryofibrinogenemia

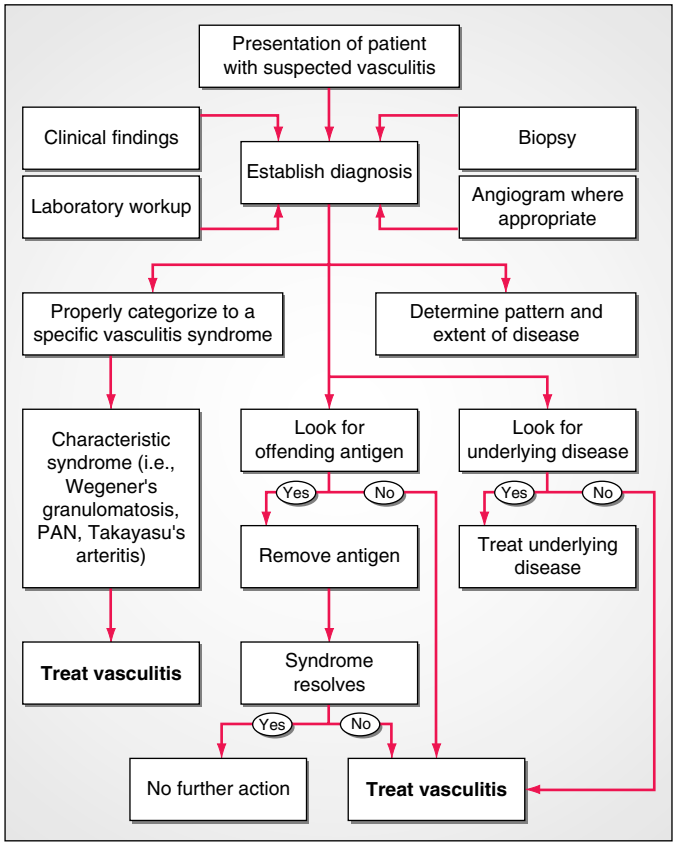

FIGURE 306-1 Algorithm for the approach to a patient with suspected diagnosis of vasculitis.

Treatment options will be considered under the individual syndromes (see below), and general principles of therapy will be considered at the end of the chapter.

WEGENER'S GRANULOMATOSIS

DEFINITION *Wegener's granulomatosis* is a distinct clinicopathologic entity characterized by granulomatous vasculitis of the upper and lower respiratory tracts together with glomerulonephritis. In addition, variable degrees of disseminated vasculitis involving both small arteries and veins may occur.

INCIDENCE AND PREVALENCE Wegener's granulomatosis is an uncommon disease with an estimated prevalence of 3 per 100,000. It is extremely rare in blacks compared with whites; the male-to-female ratio is 1:1. The disease can be seen at any age; approximately 15% of patients are <19 years of age, but only rarely does the disease occur before adolescence; the mean age of onset is approximately 40 years.

PATHOLOGY AND PATHOGENESIS The histopathologic hallmarks of Wegener's granulomatosis are necrotizing vasculitis of small arteries and veins together with granuloma formation, which may be either intravascular or extravascular (Fig. 306-2). Lung involvement typically appears as multiple, bilateral, nodular cavitary infiltrates (Fig. 306-3), which on biopsy almost invariably reveal the typical necrotizing granulomatous vasculitis. Upper airway lesions, particularly those in the sinuses and nasopharynx, typically reveal inflammation, necrosis, and granuloma formation, with or without vasculitis.

In its earliest form, renal involvement is characterized by a focal and segmental glomerulitis that may evolve into a rapidly progressive crescentic glomerulonephritis. Granuloma formation is only rarely seen on renal biopsy. In contrast to other forms of glomerulonephritis, evidence of immune complex deposition is not found in the renal lesion of Wegener's granulomatosis. In addition to the classic triad of disease of the upper and lower respiratory tracts and kidney, virtually any organ can be involved with vasculitis, granuloma, or both.

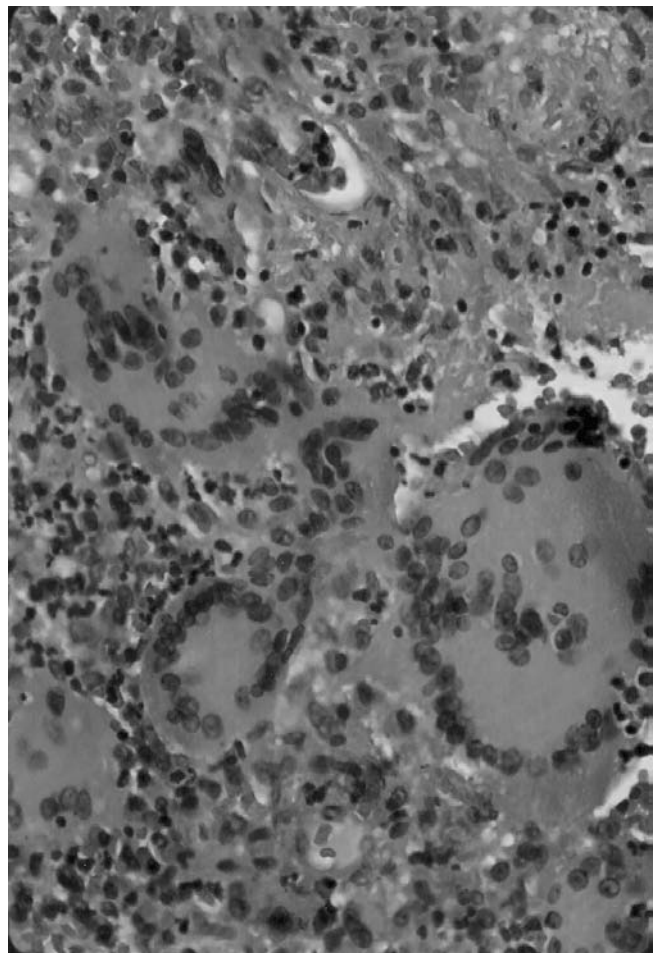

FIGURE 306-2 Lung biopsy in a patient with Wegener's granulomatosis. Biopsy revealed necrotizing vasculitis with granuloma formation. This section demonstrates several well-formed multinucleated giant cells in an area of granulomatous inflammation.

The immunopathogenesis of this disease is unclear, although the involvement of upper airways and lungs with granulomatous vasculitis suggests an aberrant cell-mediated immune response to an exogenous or even endogenous antigen that enters through or resides in the upper airway. Chronic nasal carriage of *Staphylococcus aureus* has been reported to be associated with a higher relapse rate of Wegener's gran-

FIGURE 306-3 Computed tomography scan of a patient with Wegener's granulomatosis. The patient developed multiple, bilateral, and cavitary infiltrates.

ulomatosis; however, there is no evidence for a role of this organism in the pathogenesis of the disease.

Peripheral blood mononuclear cells obtained from patients with Wegener's granulomatosis manifest increased secretion of IFN-γ but not of IL-4, IL-5, or IL-10 compared to normal controls. In addition, TNF-α production from peripheral blood mononuclear cells and CD4+ T cells is elevated. Furthermore, monocytes from patients with Wegener's granulomatosis produce increased amounts of IL-12. These findings indicate an unbalanced T_H1-type T-cell cytokine pattern in this disease that may have pathogenic and perhaps ultimately therapeutic implications.

A high percentage of patients with Wegener's granulomatosis develop ANCA and these autoantibodies may play a role in the pathogenesis of this disease (see above).

CLINICAL AND LABORATORY MANIFESTATIONS Involvement of the upper airways occurs in 95% of patients with Wegener's granulomatosis. Patients often present with severe upper respiratory tract findings such as paranasal sinus pain and drainage and purulent or bloody nasal discharge, with or without nasal mucosal ulceration (Table 306-4). Nasal septal perforation may follow, leading to saddle nose deformity. Serous otitis media may occur as a result of eustachian tube blockage. Subglottic tracheal stenosis resulting from active disease or scarring occurs in approximately 16% of patients and may result in severe airway obstruction.

Pulmonary involvement may be manifested as asymptomatic infiltrates or may be clinically expressed as cough, hemoptysis, dyspnea, and chest discomfort. It is present in 85 to 90% of patients. Endobronchial disease, either in its active form or as a result of fibrous scarring, may lead to obstruction with atelectasis.

Eye involvement (52% of patients) may range from a mild conjunctivitis to dacryocystitis, episcleritis, scleritis, granulomatous sclerouveitis, ciliary vessel vasculitis, and retroorbital mass lesions leading to proptosis.

Skin lesions (46% of patients) appear as papules, vesicles, palpable purpura, ulcers, or subcutaneous nodules; biopsy reveals vasculitis, granuloma, or both. Cardiac involvement (8% of patients) manifests as pericarditis, coronary vasculitis, or, rarely, cardiomyopathy. Nervous system manifestations (23% of patients) include cranial neuritis, mononeuritis multiplex, or, rarely, cerebral vasculitis and/or granuloma.

Renal disease (77% of patients) generally dominates the clinical picture and, if left untreated, accounts directly or indirectly for most of the mortality in this disease. Although it may smolder in some cases as a mild glomerulitis with proteinuria, hematuria, and red blood cell casts, it is clear that once clinically detectable renal functional impairment occurs, rapidly progressive renal failure usually ensues unless appropriate treatment is instituted.

While the disease is active, most patients have nonspecific symptoms and signs such as malaise, weakness, arthralgias, anorexia, and weight loss. Fever may indicate activity of the underlying disease but more often reflects secondary infection, usually of the upper airway.

Characteristic laboratory findings include a markedly elevated erythrocyte sedimentation rate (ESR), mild anemia and leukocytosis, mild hypergammaglobulinemia (particularly of the IgA class), and mildly elevated rheumatoid factor. Thrombocytosis may be seen as an acute-phase reactant. Approximately 90% of patients with active Wegener's granulomatosis have a positive antiproteinase-3 ANCA. However, in the absence of active disease, the sensitivity drops to approximately 60 to 70%. A small percentage of patients with Wegener's granulomatosis may have antimyeloperoxidase rather than antiproteinase-3 antibodies.

TABLE 306-4 *Wegener's Granulomatosis: Frequency of Clinical Manifestations in 158 Patients Studied at the National Institutes of Health*

Manifestation	Percent at Disease Onset	Percent Throughout Course of Disease
Kidney		
Glomerulonephritis	18	77
Ear/nose/throat	73	92
Sinusitis	51	85
Nasal disease	36	68
Otitis media	25	44
Hearing loss	14	42
Subglottic stenosis	1	16
Ear pain	9	14
Oral lesions	3	10
Lung	45	85
Pulmonary infiltrates	25	66
Pulmonary nodules	24	58
Hemoptysis	12	30
Pleuritis	10	28
Eyes		
Conjunctivitis	5	18
Dacryocystitis	1	18
Scleritis	6	16
Proptosis	2	15
Eye pain	3	11
Visual loss	0	8
Retinal lesions	0	4

Source: Hoffman et al.

DIAGNOSIS The diagnosis of Wegener's granulomatosis is made by the demonstration of necrotizing granulomatous vasculitis on tissue biopsy in a patient with compatible clinical features. Pulmonary tissue offers the highest diagnostic yield, almost invariably revealing granulomatous vasculitis. Biopsy of upper airway tissue usually reveals granulomatous inflammation with necrosis but may not show vasculitis. Renal biopsy can confirm the presence of pauci-immune glomerulonephritis.

The specificity of a positive antiproteinase-3 ANCA for Wegener's granulomatosis is very high, especially if active glomerulonephritis is present. However, the presence of ANCA should be adjunctive and, with very rare exceptions, should not substitute for a tissue diagnosis. False-positive ANCA titers have been reported in certain infectious and neoplastic diseases.

In its typical presentation, the clinicopathologic complex of Wegener's granulomatosis usually provides ready differentiation from other disorders. However, if all the typical features are not present at once, it needs to be differentiated from the other vasculitides, Goodpasture's syndrome (Chap. 264), tumors of the upper airway or lung, and infectious diseases such as histoplasmosis (Chap. 183), mucocutaneous leishmaniasis (Chap. 196), and rhinoscleroma (Chap. 27) as well as noninfectious granulomatous diseases.

Of particular note is the differentiation from *midline granuloma* and *upper airway neoplasms*, which are part of the spectrum of *midline destructive diseases*. These diseases lead to extreme tissue destruction and mutilation localized to the midline upper airway structures including the sinuses; erosion through the skin of the face commonly occurs, a feature that is extremely rare in Wegener's granulomatosis. Although blood vessels may be involved in the intense inflammatory reaction and necrosis, primary vasculitis is seen rarely. When systemic involvement occurs, it usually declares itself as a neoplastic process.

In this regard, it is likely that midline granuloma is part of the spectrum of *angiocentric immunoproliferative lesions*. The latter are considered to represent a spectrum of postthymic T cell proliferative lesions and should be treated as such (Chap. 97). The term *idiopathic* has been applied to midline granuloma when extensive diagnostic workup including multiple biopsies has failed to reveal anything other than inflammation and necrosis. Under these circumstances, it is possible that the tumor cells were masked by the intensive inflammatory response. Such cases have responded to local irradiation with 50 Gy (5000 rad). Upper airway lesions should never be irradiated in Wegener's granulomatosis.

Wegener's granulomatosis must also be differentiated from *lymphomatoid granulomatosis*, which is an Epstein-Barr virus–positive B cell proliferation that is associated with an exuberant T cell reaction. Lymphomatoid granulomatosis is characterized by lung, skin, central nervous system, and kidney involvement in which atypical lymphocytoid and plasmacytoid cells infiltrate nonlymphoid tissue in an angioinvasive manner. In this regard, it clearly differs from Wegener's granulomatosis in that it is not an inflammatory vasculitis in the classic sense but an infiltration of vessels with atypical mononuclear cells; granuloma may be present in involved tissues. Up to 50% of patients may develop a true malignant lymphoma.

TREATMENT

Wegener's granulomatosis was formerly universally fatal, usually within a few months after the onset of clinically apparent renal disease. Glucocorticoids alone led to some symptomatic improvement, with little effect on the ultimate course of the disease. It has been well established that the most effective therapy in this disease is cyclophosphamide given in doses of 2 mg/kg per day orally together with glucocorticoids. The leukocyte count should be monitored closely during therapy, and the dosage of cyclophosphamide should be adjusted in order to maintain the count above 3000/μL, which generally maintains the neutrophil count at approximately 1500/μL. With this approach, clinical remission can usually be induced and maintained without causing severe leukopenia with its associated risk of infection. As it was originally studied, cyclophosphamide was continued for 1 year following the induction of complete remission and gradually tapered and discontinued thereafter.

At the initiation of therapy, glucocorticoids should be administered together with cyclophosphamide. This can be given as prednisone, 1 mg/kg per day initially (for the first month of therapy) as a daily regimen, with gradual conversion to an alternate-day schedule followed by tapering and discontinuation after approximately 6 months.

Using the above regimen, the prognosis of this disease is excellent; marked improvement is seen in >90% of patients, and complete remissions are achieved in 75% of patients. A number of patients who developed irreversible renal failure but who achieved subsequent remission on appropriate therapy have undergone successful renal transplantation.

Despite the dramatic remissions induced by the therapeutic regimen described above, long-term follow-up of patients has revealed that approximately 50% of remissions are later associated with one or more relapses. Reinduction of remission is almost always achieved; however, a high percentage of patients ultimately have some degree of morbidity from irreversible features of their disease, such as varying degrees of renal insufficiency, hearing loss, tracheal stenosis, saddle nose deformity, and chronically impaired sinus function. The determination of relapse should be based on objective evidence of disease activity taking care to rule out other features that may have a similar appearance such as infection, medication toxicity, or chronic disease sequelae. The ANCA titer can be misleading. Many patients who achieve remission continue to have elevated titers for years. In addition, one study found that >40% of patients who were in remission and had a fourfold increase in ANCA titer did not have a relapse in disease. Patients who relapse may not do so until many months or years after the rise in ANCA titer. Thus, a rise in ANCA titer by itself is not a harbinger of immediate disease relapse and should not lead to reinstitution or increase in immunosuppressive therapy. However, such a finding should prompt the clinician to examine the patient carefully for any objective evidence of active disease and to monitor that patient closely.

Certain types of morbidity are related to toxic side effects of treatment. Glucocorticoid-related side effects can include diabetes mellitus, cataracts, life-threatening infectious disease complications, serious osteoporosis, and severe cushingoid features. The risk of such toxicities can be reduced with the use of an alternate-day glucocorticoid regimen as outlined in the preceding regimen. Cyclophosphamide-related toxicities are more frequent and severe. Cystitis to varying degrees occurs in at least 30% of patients, bladder cancer in 6%, myelodysplasia in 2%, and there is a high risk of permanent infertility in both men and women.

Some reports have indicated therapeutic success with less frequent and severe toxic side effects using intermittent boluses of intravenous cyclophosphamide (1 g/m^2 per month) in place of daily administration. However, we and others have found an increased rate of relapse with bolus intravenous cyclophosphamide. We therefore strongly recommend that the drug be given as daily oral therapy.

In patients with immediately life-threatening disease, such as rapidly progressive glomerulonephritis, a regimen of daily cyclophosphamide and glucocorticoids is clearly the treatment of choice to induce remission. However, after patients have achieved remission, consideration can be given to stopping cyclophosphamide and beginning methotrexate or azathioprine for remission maintenance. This approach is aimed at lessening the toxicity associated with chronic cyclophosphamide therapy. Methotrexate is administered orally starting at a dosage of 0.3 mg/kg as a single weekly dose, not to exceed 15 mg/week. If the treatment is well tolerated after 1 to 2 weeks, the dosage should be increased by 2.5 mg weekly up to a dosage of 20 to 25 mg/week and maintained at that level. This regimen is given for 2 years past remission, after which time it is tapered by 2.5 mg each month until discontinuation. To lessen toxicity, methotrexate is often given together with folic acid, 1 mg daily, or folinic acid, 5 to 10 mg once a week 24 h following methotrexate. Azathioprine, 2 mg/kg per day, has also proven effective in some patients in maintaining remission following induction with daily cyclophosphamide. There have been no studies to date comparing methotrexate to azathioprine for remission maintenance. In the absence of such data, the choice of agent is often based on toxicity profile, as methotrexate cannot be given to patients with renal insufficiency or chronic liver disease.

For selected patients whose disease is not immediately life threatening or in those patients who have experienced significant cyclophosphamide toxicity, methotrexate together with glucocorticoids given at the dosages described above may be considered as an alternative for initial therapy.

Although certain reports have indicated that trimethoprim-sulfamethoxazole (TMP-SMX) may be of benefit in the treatment of Wegener's granulomatosis, there are no firm data to substantiate this, particularly in patients with serious renal and pulmonary disease. In a study examining the effect of trimethoprim-sulfamethoxazole on relapse, decreased relapses were shown only with regard to upper airway disease, and no differences in major organ relapses were observed. Trimethoprim-sulfamethoxazole alone should never be used to treat active Wegener's granulomatosis outside of the upper airway.

Not all manifestations of Wegener's granulomatosis require or respond to cytotoxic therapy. In managing non-major organ disease, such as that isolated to the sinus, joints, or skin, the risks of treatment should be carefully weighed against the benefits. Given the potential toxicities of this agent, treatment with cyclophosphamide is rarely if ever justified for the treatment of isolated sinus disease in Wegener's granulomatosis. Although patients with non-major organ disease may be effectively treated without cytotoxic therapy, these individuals must be monitored closely for the development of disease activity affecting

the lungs, kidneys, or other major organs. Subglottic tracheal stenosis and endobronchial stenosis are examples of disease manifestations that do not typically respond to systemic immunosuppressive treatment.

CHURG-STRAUSS SYNDROME

DEFINITION Churg-Strauss syndrome, also referred to as *allergic angiitis and granulomatosis*, was described in 1951 by Churg and Strauss and is characterized by asthma, peripheral and tissue eosinophilia, extravascular granuloma formation, and vasculitis of multiple organ systems.

INCIDENCE AND PREVALENCE Churg-Strauss syndrome is an uncommon disease with an estimated annual incidence of 1 to 3 per million. The disease can occur at any age with the possible exception of infants. The mean age of onset is 48 years, with a female-to-male ratio of 1.2:1.

PATHOLOGY AND PATHOGENESIS The necrotizing vasculitis of Churg-Strauss syndrome involves small and medium-sized muscular arteries, capillaries, veins, and venules. A characteristic histopathologic feature of Churg-Strauss syndrome are granulomatous reactions that may be present in the tissues or even within the walls of the vessels themselves. These are usually associated with infiltration of the tissues with eosinophils. This process can occur in any organ in the body; lung involvement is predominant, with skin, cardiovascular system, kidney, peripheral nervous system, and gastrointestinal tract also commonly involved. Although the precise pathogenesis of this disease is uncertain, its strong association with asthma and its clinicopathologic manifestations, including eosinophilia, granuloma, and vasculitis, point to aberrant immunologic phenomena.

CLINICAL AND LABORATORY MANIFESTATIONS Patients with Churg-Strauss syndrome often exhibit nonspecific manifestations such as fever, malaise, anorexia, and weight loss, which are characteristic of a multisystem disease. The pulmonary findings in Churg-Strauss syndrome clearly dominate the clinical picture with severe asthmatic attacks and the presence of pulmonary infiltrates. Mononeuritis multiplex is the second most common manifestation and occurs in up to 72% of patients. Allergic rhinitis and sinusitis develop in up to 61% of patients and are often observed early in the course of disease. Clinically recognizable heart disease occurs in approximately 14% of patients and is an important cause of mortality. Skin lesions occur in approximately 51% of patients and include purpura in addition to cutaneous and subcutaneous nodules. The renal disease in Churg-Strauss syndrome is less common and generally less severe than that of Wegener's granulomatosis and microscopic polyangiitis.

The characteristic laboratory finding in virtually all patients with Churg-Strauss syndrome is a striking eosinophilia, which reaches levels >1000 cells/μL in $>80\%$ of patients. Evidence of inflammation as evidenced by elevated ESR, fibrinogen, or α_2-globulins can be found in 81% of patients. The other laboratory findings reflect the organ systems involved. Approximately 48% of patients with Churg-Strauss syndrome have circulating ANCA that is usually antimyeloperoxidase.

DIAGNOSIS Although the diagnosis of Churg-Strauss syndrome is optimally made by biopsy in a patient with the characteristic clinical manifestations (see above), histologic confirmation can be challenging as the pathognomonic features often do not occur simultaneously. In order to be diagnosed with Churg-Strauss syndrome, a patient should have evidence of asthma, peripheral blood eosinophilia, and clinical features consistent with vasculitis.

TREATMENT

The prognosis of untreated Churg-Strauss syndrome is poor, with a reported 5-year survival of 25%. With treatment, prognosis is favorable, with one study finding a 78-month actuarial survival rate of 72%. Myocardial involvement is the most frequent cause of death and is responsible for 39% of patient mortality. Glucocorticoids alone appear to be effective in many patients. Dosage tapering is often limited by asthma, and many patients require low-dose prednisone for persistent asthma many years after clinical recovery from vasculitis. In glucocorticoid failure or in patients who present with fulminant multisystem disease, the treatment of choice is a combined regimen of daily cyclophosphamide and prednisone (see "Wegener's Granulomatosis" for a detailed description of this therapeutic regimen).

POLYARTERITIS NODOSA

DEFINITION *Polyarteritis nodosa* (PAN), also referred to as *classic PAN*, was described in 1866 by Kussmaul and Maier. It is a multisystem, necrotizing vasculitis of small and medium-sized muscular arteries in which involvement of the renal and visceral arteries is characteristic. PAN does not involve pulmonary arteries, although bronchial vessels may be involved; granulomas, significant eosinophilia, and an allergic diathesis are not observed.

INCIDENCE AND PREVALENCE It is difficult to establish an accurate incidence of PAN because previous reports have included PAN and microscopic polyangiitis as well as other related vasculitides. PAN as currently defined, is felt to be a very uncommon disease.

PATHOLOGY AND PATHOGENESIS The vascular lesion in PAN is a necrotizing inflammation of small and medium-sized muscular arteries. The lesions are segmental and tend to involve bifurcations and branchings of arteries. They may spread circumferentially to involve adjacent veins. However, involvement of venules is not seen in PAN and, if present, suggests microscopic polyangiitis (see below). In the acute stages of disease, polymorphonuclear neutrophils infiltrate all layers of the vessel wall and perivascular areas, which results in intimal proliferation and degeneration of the vessel wall. Mononuclear cells infiltrate the area as the lesions progress to the subacute and chronic stages. Fibrinoid necrosis of the vessels ensues with compromise of the lumen, thrombosis, infarction of the tissues supplied by the involved vessel, and, in some cases, hemorrhage. As the lesions heal, there is collagen deposition, which may lead to further occlusion of the vessel lumen. Aneurysmal dilatations up to 1 cm in size along the involved arteries are characteristic of PAN. Granulomas and substantial eosinophilia with eosinophilic tissue infiltrations are not characteristically found and suggest Churg-Strauss syndrome (see above).

Multiple organ systems are involved, and the clinicopathologic findings reflect the degree and location of vessel involvement and the resulting ischemic changes. As mentioned above, pulmonary arteries are not involved in PAN, and bronchial artery involvement is uncommon. The pathology in the kidney in classic PAN is that of arteritis without glomerulonephritis. In patients with significant hypertension, typical pathologic features of glomerulosclerosis may be seen alone or superimposed on lesions of glomerulonephritis. In addition, pathologic sequelae of hypertension may be found elsewhere in the body.

The presence of hepatitis B antigenemia in approximately 10 to 30% of patients with systemic vasculitis, particularly of the PAN type, together with the isolation of circulating immune complexes composed of hepatitis B antigen and immunoglobulin, and the demonstration by immunofluorescence of hepatitis B antigen, IgM, and complement in the blood vessel walls, strongly suggest the role of immunologic phenomena in the pathogenesis of this disease. Hairy cell leukemia can be associated with PAN; the pathogenic mechanisms of this association are unclear.

CLINICAL AND LABORATORY MANIFESTATIONS Nonspecific signs and symptoms are the hallmarks of PAN. Fever, weight loss, and malaise are present in over one-half of cases. Patients usually present with vague symptoms such as weakness, malaise, headache, abdominal pain, and myalgias that can rapidly progress to a fulminant illness. Specific complaints related to the vascular involvement within a particular organ system may also dominate the presenting clinical picture as well as the entire course of the illness (Table 306-5). In PAN, renal involvement most commonly manifests as hypertension, renal insufficiency, or hemorrhage due to microaneurysms.

TABLE 306-5 *Clinical Manifestations Related to Organ System Involvement in Classic Polyarteritis Nodosa*

Organ System	Percent Incidence	Clinical Manifestations
Renal	60	Renal failure, hypertension
Musculoskeletal	64	Arthritis, arthralgia, myalgia
Peripheral nervous system	51	Peripheral neuropathy, mononeuritis multiplex
Gastrointestinal tract	44	Abdominal pain, nausea and vomiting, bleeding, bowel infarction and perforation, cholecystitis, hepatic infarction, pancreatic infarction
Skin	43	Rash, purpura, nodules, cutaneous infarcts, livedo reticularis, Raynaud's phenomenon
Cardiac	36	Congestive heart failure, myocardial infarction, pericarditis
Genitourinary	25	Testicular, ovarian, or epididymal pain
Central nervous system	23	Cerebral vascular accident, altered mental status, seizure

Source: From TR Cupps, AS Fauci: *The Vasculitides*. Philadelphia, Saunders, 1981.

There are no diagnostic serologic tests for PAN. In >75% of patients, the leukocyte count is elevated with a predominance of neutrophils. Eosinophilia is seen only rarely and, when present at high levels, suggests the diagnosis of Churg-Strauss syndrome. The anemia of chronic disease may be seen, and an elevated ESR is almost always present. Other common laboratory findings reflect the particular organ involved. Hypergammaglobulinemia may be present, and up to 30% of patients have a positive test for hepatitis B surface antigen. Antibodies against myeloperoxidase or proteinase-3 (ANCA) are rarely found in patients with PAN.

DIAGNOSIS The diagnosis of PAN is based on the demonstration of characteristic findings of vasculitis on biopsy material of involved organs. In the absence of easily accessible tissue for biopsy, the angiographic demonstration of involved vessels, particularly in the form of aneurysms of small and medium-sized arteries in the renal, hepatic, and visceral vasculature, is sufficient to make the diagnosis. Aneurysms of vessels are not pathognomonic of PAN; furthermore, aneurysms need not always be present, and angiographic findings may be limited to stenotic segments and obliteration of vessels. Biopsy of symptomatic organs such as nodular skin lesions, painful testes, and nerve/muscle provides the highest diagnostic yields.

TREATMENT

The prognosis of untreated PAN is extremely poor, with a reported 5-year survival rate between 10 and 20%. Death usually results from gastrointestinal complications, particularly bowel infarcts and perforation, and cardiovascular causes. Intractable hypertension often compounds dysfunction in other organ systems, such as the kidneys, heart, and central nervous system, leading to additional late morbidity and mortality in PAN. With the introduction of treatment, survival rate has increased substantially. Favorable therapeutic results have been reported in PAN with the combination of prednisone and cyclophosphamide (see "Wegener's Granulomatosis" for a detailed description of this therapeutic regimen). In less severe cases of PAN, glucocorticoids alone have resulted in disease remission. Favorable results have also been reported in the treatment of PAN related to hepatitis B virus with IFN-α in combination with glucocorticoids and plasma exchange. Careful attention to the treatment of hypertension can lessen the acute and late morbidity and mortality associated with renal, cardiac, and central nervous system complications of PAN. Following successful treatment, relapse of PAN has been estimated to occur in only 10% of patients.

MICROSCOPIC POLYANGIITIS

DEFINITION The term *microscopic polyarteritis* was introduced into the literature by Davson in 1948 in recognition of the presence of glomerulonephritis in patients with PAN. In 1992, the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis adopted the term *microscopic polyangiitis* to connote a necrotizing vasculitis with few or no immune complexes affecting small vessels (capillaries, venules, or arterioles). Glomerulonephritis is very common in microscopic polyangiitis, and pulmonary capillaritis often occurs. The absence of granulomatous inflammation in microscopic polyangiitis is said to differentiate it from Wegener's granulomatosis.

INCIDENCE AND PREVALENCE The incidence of microscopic polyangiitis has not yet been reliably established due to its previous inclusion as part of PAN. The mean age of onset is approximately 57 years of age, and males are slightly more frequently affected than females.

PATHOLOGY AND PATHOGENESIS The vascular lesion in microscopic polyangiitis is histologically similar to that in PAN. Unlike PAN, the vasculitis seen in microscopic polyangiitis has a predilection to involve capillaries and venules in addition to small and medium-sized arteries. Immunohistochemical staining reveals a paucity of immunoglobulin deposition in the vascular lesion of microscopic polyangiitis, suggesting that immune complex formation does not play a role in the pathogenesis of this syndrome. The renal lesion seen in microscopic polyangiitis is identical to that of Wegener's granulomatosis. Like Wegener's granulomatosis, microscopic polyangiitis is highly associated with the presence of ANCA, which may play a role in pathogenesis of this syndrome (see above).

CLINICAL AND LABORATORY MANIFESTATIONS Because of its predilection to involve the small vessels, microscopic polyangiitis and Wegener's granulomatosis share similar clinical features. Disease onset may be gradual with initial symptoms of fever, weight loss, and musculoskeletal pain; however, it is often acute. Glomerulonephritis occurs in at least 79% of patients and can be rapidly progressive, leading to renal failure. Hemoptysis may be the first symptom of alveolar hemorrhage, which occurs in 12% of patients. Other manifestations include mononeuritis multiplex and gastrointestinal tract and cutaneous vasculitis. Upper airways disease and pulmonary nodules are not typically found in microscopic polyangiitis and, if present, suggest Wegener's granulomatosis.

Features of inflammation may be seen, including an elevated ESR, anemia, leukocytosis, and thrombocytosis. ANCA are present in 75% of patients with microscopic polyangiitis, with antimyeloperoxidase antibodies being the predominant ANCA associated with this disease.

DIAGNOSIS The diagnosis is based on histologic evidence of vasculitis or pauci-immune glomerulonephritis in a patient with compatible clinical features of multisystem disease. Although microscopic polyangiitis is strongly ANCA-associated, no studies have as yet established the sensitivity and specificity of ANCA in this disease.

TREATMENT

The 5-year survival rate for patients with treated microscopic polyangiitis is 74% with disease-related mortality occurring from alveolar hemorrhage or gastrointestinal, cardiac, or renal disease. To date there has been limited disease-specific information on the treatment of microscopic polyangiitis. Available data together with a predilection for this disease to affect the small vessels support a therapeutic approach similar to that used in Wegener's granulomatosis. Patients with immediately life-threatening disease should be treated with the combination of prednisone and daily cyclophosphamide (see "Wegener's Granulomatosis" for a detailed description of this therapeutic regimen). Disease relapse has been observed in at least 34% of patients. Treatment for such relapses would be similar to that used at the time of initial presentation and based upon site and severity of disease.

GIANT CELL ARTERITIS

DEFINITION *Giant cell arteritis*, also referred to as *cranial arteritis* or *temporal arteritis*, is an inflammation of medium- and large-sized ar-

teries. It characteristically involves one or more branches of the carotid artery, particularly the temporal artery. However, it is a systemic disease that can involve arteries in multiple locations.

INCIDENCE AND PREVALENCE Giant cell arteritis occurs almost exclusively in individuals >50 years. It is more common in women than in men and is rare in blacks. The incidence of giant cell arteritis varies widely in different studies and in different geographic regions. A high incidence has been found in Scandinavia and in regions of the United States with large Scandinavian populations, compared to a lower incidence in southern Europe. The annual incidence rates in individuals ≥50 years range from 6.9 to 32.8 per 100,000 population. Familial aggregation has been reported, as has an association with HLA-DR4. In addition, genetic linkage studies have demonstrated an association of temporal arteritis with alleles at the HLA-DRB1 locus, particularly HLA-DRB1*04 variants. The disease is closely associated with *polymyalgia rheumatica*, which is more common than giant cell arteritis. In Olmsted County, Minnesota, the annual incidence of polymyalgia rheumatica in individuals ≥50 years is 58.7 per 100,000 population.

PATHOLOGY AND PATHOGENESIS Although the temporal artery is most frequently involved in this disease, patients often have a systemic vasculitis of multiple medium- and large-sized arteries, which may go undetected. Histopathologically, the disease is a panarteritis with inflammatory mononuclear cell infiltrates within the vessel wall with frequent giant cell formation. There is proliferation of the intima and fragmentation of the internal elastic lamina. Pathophysiologic findings in organs result from the ischemia related to the involved vessels. Distinct cytokine patterns as well as T lymphocytes expressing specific antigen receptors have been described, suggesting the involvement of immunopathogenic mechanisms in temporal arteritis. IL-6 and IL-1β expression have been detected in a majority of circulating monocytes of patients with temporal arteritis and polymyalgia rheumatica. T cells recruited to vasculitic lesions in patients with temporal arteritis produce predominantly IL-2 and IFN-γ, and the latter has been suggested to be involved in the progression to overt arteritis. Sequence analysis of the T cell receptor of tissue-infiltrating T cells in lesions of temporal arteritis indicates restricted clonal expansion, suggesting that an antigen residing in the arterial wall is recognized by a small fraction of T cells.

CLINICAL AND LABORATORY MANIFESTATIONS The disease is characterized clinically by the complex of fever, anemia, high ESR, and headaches in a patient over the age of 50 years. Other manifestations include malaise, fatigue, anorexia, weight loss, sweats, and arthralgias. The polymyalgia rheumatica syndrome is characterized by stiffness, aching, and pain in the muscles of the neck, shoulders, lower back, hips, and thighs.

In patients with involvement of the temporal artery, headache is the predominant symptom and may be associated with a tender, thickened, or nodular artery, which may pulsate early in the disease but may become occluded later. Scalp pain and claudication of the jaw and tongue may occur. A well-recognized and dreaded complication of giant cell arteritis, particularly in untreated patients, is ischemic optic neuropathy, which may lead to serious visual symptoms, even sudden blindness in some patients. However, most patients have complaints relating to the head or eyes before visual loss. Attention to such symptoms with institution of appropriate therapy (see below) will usually avoid this complication. Claudication of the extremities, strokes, myocardial infarctions, and infarctions of visceral organs have been reported. Of note, giant cell arteritis is associated with an increased risk of aortic aneurysm, which is usually a late complication and may lead to dissection and death.

Characteristic laboratory findings in addition to the elevated ESR include a normochromic or slightly hypochromic anemia. Liver function abnormalities are common, particularly increased alkaline phosphatase levels. Increased levels of IgG and complement have been reported. Levels of enzymes indicative of muscle damage such as serum creatine kinase are not elevated.

DIAGNOSIS The diagnosis of giant cell arteritis and its associated clinicopathologic syndrome can often be suggested clinically by the demonstration of the complex of fever, anemia, and high ESR with or without symptoms of polymyalgia rheumatica in a patient >50 years. The diagnosis is confirmed by biopsy of the temporal artery. Since involvement of the vessel may be segmental, positive yield is increased by obtaining a biopsy segment of 3 to 5 cm together with serial sectioning of biopsy specimens. Ultrasonography of the temporal artery has been reported to be helpful in diagnosis. A temporal artery biopsy should be obtained as quickly as possible in the setting of ocular signs and symptoms, and under these circumstances therapy should not be delayed pending a biopsy. In this regard, it has been reported that temporal artery biopsies may show vasculitis even after more than 14 days of glucocorticoid therapy. A dramatic clinical response to a trial of glucocorticoid therapy can further support the diagnosis.

Rx TREATMENT

Disease-related mortality from giant cell arteritis is very uncommon with fatalities occurring from cerebrovascular events, myocardial infarction, or aortic aneurysms. The goals of treatment are to reduce symptoms and, most importantly, to prevent visual loss. Giant cell arteritis and its associated symptoms are exquisitely sensitive to glucocorticoid therapy. Treatment should begin with prednisone, 40 to 60 mg/d for approximately 1 month, followed by a gradual tapering. When ocular signs and symptoms occur, it is important that therapy be initiated or adjusted to control them. Although the optimal duration of glucocorticoid therapy has not been established, most series have found that patients require treatment for ≥2 years. The ESR can serve as a useful indicator of inflammatory disease activity in monitoring and tapering therapy and can be used to judge the pace of the tapering schedule. However, minor increases in the ESR can occur as glucocorticoids are being tapered and do not necessarily reflect an exacerbation of arteritis, particularly if the patient remains symptom-free. Under these circumstances, the tapering should continue with caution. Glucocorticoid toxicity occurs in 35 to 65% of patients and represents an important cause of patient morbidity. The use of weekly methotrexate as a glucocorticoid-sparing agent has been examined in two randomized placebo-controlled trials that reached conflicting conclusions.

TAKAYASU'S ARTERITIS

DEFINITION *Takayasu's arteritis* is an inflammatory and stenotic disease of medium- and large-sized arteries characterized by a strong predilection for the aortic arch and its branches. For this reason, it is often referred to as the *aortic arch syndrome*.

INCIDENCE AND PREVALENCE Takayasu's arteritis is an uncommon disease with an estimated annual incidence rate of 1.2 to 2.6 cases per million. It is most prevalent in adolescent girls and young women. Although it is more common in Asia, it is neither racially nor geographically restricted.

PATHOLOGY AND PATHOGENESIS The disease involves medium- and large-sized arteries, with a strong predilection for the aortic arch and its branches; the pulmonary artery may also be involved. The most commonly affected arteries seen by angiography are listed in Table 306-6. The involvement of the major branches of the aorta is much more marked at their origin than distally. The disease is a panarteritis with inflammatory mononuclear cell infiltrates and occasionally giant cells. There are marked intimal proliferation and fibrosis, scarring and vascularization of the media, and disruption and degeneration of the elastic lamina. Narrowing of the lumen occurs with or without thrombosis. The vasa vasorum are frequently involved. Pathologic changes in various organs reflect the compromise of blood flow through the involved vessels.

Immunopathogenic mechanisms, the precise nature of which is uncertain, are suspected in this disease. As with several of the vasculitis

TABLE 306-6 *Frequency of Arteriographic Abnormalities and Potential Clinical Manifestations of Arterial Involvement in Takayasu's Arteritis*

Artery	Percent of Arteriographic Abnormalities	Potential Clinical Manifestations
Subclavian	93	Arm claudication, Raynaud's phenomenon
Common carotid	58	Visual changes, syncope, transient ischemic attacks, stroke
Abdominal aorta[a]	47	Abdominal pain, nausea, vomiting
Renal	38	Hypertension, renal failure
Aortic arch or root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Visual changes, dizziness
Coeliac axis[a]	18	Abdominal pain, nausea, vomiting
Superior mesenteric[a]	18	Abdominal pain, nausea, vomiting
Iliac	17	Leg claudication
Pulmonary	10–40	Atypical chest pain, dyspnea
Coronary	<10	Chest pain, myocardial infarction

[a] Arteriographic lesions at these locations are usually asymptomatic but may potentially cause these symptoms.
Source: Kerr et al.

syndromes, circulating immune complexes have been demonstrated, but their pathogenic significance is unclear.

CLINICAL AND LABORATORY MANIFESTATIONS Takayasu's arteritis is a systemic disease with generalized as well as vascular symptoms. The generalized symptoms include malaise, fever, night sweats, arthralgias, anorexia, and weight loss, which may occur months before vessel involvement is apparent. These symptoms may merge into those related to vascular compromise and organ ischemia. Pulses are commonly absent in the involved vessels, particularly the subclavian artery. The frequency of arteriographic abnormalities and the potentially associated clinical manifestations are listed in Table 306-6. Hypertension occurs in 32 to 93% of patients and contributes to renal, cardiac, and cerebral injury.

Characteristic laboratory findings include an elevated ESR, mild anemia, and elevated immunoglobulin levels.

DIAGNOSIS The diagnosis of Takayasu's arteritis should be suspected strongly in a young woman who develops a decrease or absence of peripheral pulses, discrepancies in blood pressure, and arterial bruits. The diagnosis is confirmed by the characteristic pattern on arteriography, which includes irregular vessel walls, stenosis, poststenotic dilatation, aneurysm formation, occlusion, and evidence of increased collateral circulation. Complete aortic arteriography should be obtained, unless this is renally contraindicated, in order to fully delineate the distribution and degree of arterial disease. Histopathologic demonstration of inflamed vessels adds confirmatory data; however, tissue is rarely readily available for examination.

TREATMENT

The long-term outcome of patients with Takayasu's arteritis has varied widely between studies. Although two North American reports found overall survival to be ≥94%, or the 5-year mortality rate from other studies has ranged from 0 to 35%. Disease-related mortality most often occurs from congestive heart failure, cerebrovascular events, myocardial infarction, aneurysm rupture, or renal failure. Even in the absence of life-threatening disease Takayasu's arteritis can be associated with significant morbidity. The course of the disease is variable, and although spontaneous remissions may occur, Takayasu's arteritis is most often chronic and relapsing. Although glucocorticoid therapy in doses of 40 to 60 mg prednisone per day alleviates symptoms, there are no convincing studies that indicate that they increase survival. The combination of glucocorticoid therapy for acute signs and symptoms and an aggressive surgical and/or angioplastic approach to stenosed vessels has markedly improved outcome and decreased morbidity by lessening the risk of stroke, correcting hypertension due to renal artery stenosis, and improving blood flow to ischemic viscera and limbs. Unless it is urgently required, surgical correction of stenosed arteries should be undertaken only when the vascular inflammatory process is well controlled with medical therapy. In individuals who are refractory to or unable to taper glucocorticoids, methotrexate in doses up to 25 mg per week has yielded encouraging results.

HENOCH-SCHÖNLEIN PURPURA

DEFINITION *Henoch-Schönlein purpura*, also referred to as *anaphylactoid purpura*, is a distinct systemic vasculitis syndrome that is characterized by palpable purpura (most commonly distributed over the buttocks and lower extremities), arthralgias, gastrointestinal signs and symptoms, and glomerulonephritis. It is a small-vessel vasculitis.

INCIDENCE AND PREVALENCE Henoch-Schönlein purpura is usually seen in children; most patients range in age from 4 to 7 years; however, the disease may also be seen in infants and adults. It is not a rare disease; in one series it accounted for between 5 and 24 admissions per year at a pediatric hospital. The male-to-female ratio is 1.5:1. A seasonal variation with a peak incidence in spring has been noted.

PATHOLOGY AND PATHOGENESIS The presumptive pathogenic mechanism for Henoch-Schönlein purpura is immune-complex deposition. A number of inciting antigens have been suggested including upper respiratory tract infections, various drugs, foods, insect bites, and immunizations. IgA is the antibody class most often seen in the immune complexes and has been demonstrated in the renal biopsies of these patients.

CLINICAL AND LABORATORY MANIFESTATIONS In pediatric patients, palpable purpura is seen in virtually all patients; most patients develop polyarthralgias in the absence of frank arthritis. Gastrointestinal involvement, which is seen in almost 70% of pediatric patients, is characterized by colicky abdominal pain usually associated with nausea, vomiting, diarrhea, or constipation and is frequently accompanied by the passage of blood and mucus per rectum; bowel intussusception may occur. Renal involvement occurs in 10 to 50% of patients and is usually characterized by mild glomerulonephritis leading to proteinuria and microscopic hematuria, with red blood cell casts in the majority of patients (Chap. 264); it usually resolves spontaneously without therapy. Rarely, a progressive glomerulonephritis will develop. In adults, presenting symptoms are most frequently related to the skin and joints, while initial complaints related to the gut are less common. Although certain studies have found that renal disease is more frequent and more severe in adults, this has not been a consistent finding. However, the course of renal disease in adults may be more insidious and thus requires close follow-up. Myocardial involvement can occur in adults but is rare in children.

Laboratory studies generally show a mild leukocytosis, a normal platelet count, and occasionally eosinophilia. Serum complement components are normal, and IgA levels are elevated in about one-half of patients.

DIAGNOSIS The diagnosis of Henoch-Schönlein purpura is based on clinical signs and symptoms. Skin biopsy specimen can be useful in confirming leukocytoclastic vasculitis with IgA and C3 deposition by immunofluorescence. Renal biopsy is rarely needed for diagnosis but may provide prognostic information in some patients.

TREATMENT

The prognosis of Henoch-Schönlein purpura is excellent. Mortality is exceedingly rare, and 1 to 5% of children progress to end-stage renal disease. Most patients recover completely, and some do not require therapy. Treatment is similar for adults and children. When glucocorticoid therapy is required, prednisone, in doses of 1 mg/kg per day and tapered according to clinical response, has been shown to be useful in decreasing tissue edema, arthralgias, and abdominal discomfort; however, it has not proven beneficial in the treatment of skin or renal disease and does not appear to shorten the duration of active disease

or lessen the chance of recurrence. Patients with rapidly progressive glomerulonephritis have been anecdotally reported to benefit from intensive plasma exchange combined with cytotoxic drugs. Disease recurrences have been reported in 10 to 40% of patients.

IDIOPATHIC CUTANEOUS VASCULITIS

DEFINITION The term *cutaneous vasculitis* is defined broadly as inflammation of the blood vessels of the dermis. Due to its heterogeneity, cutaneous vasculitis has been described by a variety of terms including *hypersensitivity vasculitis* and *cutaneous leukocytoclastic angiitis*. However, cutaneous vasculitis is not one specific disease but a manifestation that can be seen in a variety of settings. In >70% of cases, cutaneous vasculitis occurs either as part of a primary systemic vasculitis or as a secondary vasculitis related to an inciting agent or an underlying disease (see "Secondary Vasculitis"). In the remaining 30% of cases, cutaneous vasculitis occurs idiopathically.

INCIDENCE AND PREVALENCE Cutaneous vasculitis represents the most commonly encountered vasculitis in clinical practice. The exact incidence of idiopathic cutaneous vasculitis has not been determined due to the predilection for cutaneous vasculitis to be associated with an underlying process and the variability of its clinical course.

PATHOLOGY AND PATHOGENESIS The typical histopathologic feature of cutaneous vasculitis is the presence of vasculitis of small vessels. Postcapillary venules are the most commonly involved vessels; capillaries and arterioles may be involved less frequently. This vasculitis is characterized by a *leukocytoclasis*, a term that refers to the nuclear debris remaining from the neutrophils that have infiltrated in and around the vessels during the acute stages. In the subacute or chronic stages, mononuclear cells predominate; in certain subgroups, eosinophilic infiltration is seen. Erythrocytes often extravasate from the involved vessels, leading to palpable purpura.

CLINICAL AND LABORATORY MANIFESTATIONS The hallmark of idiopathic cutaneous vasculitis is the predominance of skin involvement. Skin lesions may appear typically as palpable purpura; however, other cutaneous manifestations of the vasculitis may occur, including macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. The skin lesions may be pruritic or even quite painful, with a burning or stinging sensation. Lesions most commonly occur in the lower extremities in ambulatory patients or in the sacral area in bedridden patients due to the effects of hydrostatic forces on the postcapillary venules. Edema may accompany certain lesions, and hyperpigmentation often occurs in areas of recurrent or chronic lesions.

There are no specific laboratory tests diagnostic of idiopathic cutaneous vasculitis. A mild leukocytosis with or without eosinophilia is characteristic, as is an elevated ESR. Laboratory studies should be aimed towards ruling out features to suggest an underlying disease or a systemic vasculitis.

DIAGNOSIS The diagnosis of cutaneous vasculitis is made by the demonstration of vasculitis on biopsy. An important diagnostic principle in patients with cutaneous vasculitis is to search for an etiology of the vasculitis—be it an exogenous agent, such as a drug or an infection, or an endogenous condition, such as an underlying disease (Fig. 306-1). In addition, a careful physical and laboratory examination should be performed to rule out the possibility of systemic vasculitis. This should start with the least invasive diagnostic approach and proceed to the more invasive only if clinically indicated.

Rx TREATMENT

When an antigenic stimulus is recognized as the precipitating factor in the cutaneous vasculitis, it should be removed; if this is a microbe, appropriate antimicrobial therapy should be instituted. If the vasculitis is associated with another underlying disease, treatment of the latter often results in resolution of the former. In situations where disease is apparently self-limited, no therapy, except possibly symptomatic therapy, is indicated. When cutaneous vasculitis persists and when there is no evidence of an inciting agent, an associated disease, or an underlying systemic vasculitis, the decision to treat should be based on weighing the balance between the degree of symptoms and the risk of treatment. Some cases of idiopathic cutaneous vasculitis resolve spontaneously, while others remit and relapse. In those patients with persistent vasculitis, a variety of therapeutic regimens have been tried with variable results. In general, the treatment of idiopathic cutaneous vasculitis has not been satisfactory. Fortunately, since the disease is generally limited to the skin, this lack of consistent response to therapy usually does not lead to a life-threatening situation. Glucocorticoids are often used in the treatment of idiopathic cutaneous vasculitis. Therapy is usually instituted as prednisone, 1 mg/kg per day, with rapid tapering where possible, either directly to discontinuation or by conversion to an alternate-day regimen followed by ultimate discontinuation. In cases that prove refractory to glucocorticoids, a trial of a cytotoxic agent may be indicated. Patients with chronic vasculitis isolated to cutaneous venules rarely respond dramatically to any therapeutic regimen, and cytotoxic agents should be used only as a last resort in these patients. Methotrexate and azathioprine have been used in such situations in anecdotal reports. Although cyclophosphamide is the most effective therapy for the systemic vasculitides, it should almost never be used for idiopathic cutaneous vasculitis because of the potential toxicity. Other agents with which there have been anecdotal reports of success include dapsone, colchicine, and nonsteroidal anti-inflammatory agents.

ESSENTIAL MIXED CRYOGLOBULINEMIA

DEFINITION Cryoglobulins are cold-precipitable monoclonal or polyclonal immunoglobulins. Cryoglobulinemia may be associated with a systemic vasculitis characterized by palpable purpura, arthralgias, weakness, neuropathy, and glomerulonephitis. Although this can be observed in association with a variety of underlying disorders including multiple myeloma, lymphoproliferative disorders, connective tissue diseases, infection, and liver disease, in many instances it appeared to be idiopathic. Because of the apparent absence of an underlying disease and the presence of cryoprecipitate containing oligoclonal/polyclonal immunoglobulins, this entity was referred to as *essential mixed cryoglobulinemia*. Since the discovery of hepatitis C, it has been established that in the vast majority of patients, essential mixed cryoglobulinemia is related to an aberrant immune response to chronic hepatitis C infection.

INCIDENCE AND PREVALENCE The incidence of essential mixed cryoglobulinemia has not been established. It has been estimated, however, that 5% of patients with chronic hepatitis C will develop the syndrome of essential mixed cryoglobulinemia.

PATHOLOGY AND PATHOGENESIS Skin biopsies in essential mixed cryoglobulinemia reveal an inflammatory infiltrate surrounding and involving blood vessel walls, with fibrinoid necrosis, endothelial cell hyperplasia, and hemorrhage. Deposition of immunoglobulin and complement is common. Abnormalities of uninvolved skin including basement membrane alterations and deposits in vessel walls may be found. Membranoproliferative glomerulonephritis is responsible for 80% of all renal lesions in essential mixed cryoglobulinemia.

The association between hepatitis C and essential mixed cryoglobulinemia has been supported by the high frequency of documented hepatitis C infection, the presence of hepatitis C RNA and anti–hepatitis C antibodies in serum cryoprecipitates, evidence of hepatitis C antigens in vasculitic skin lesions, and the effectiveness of antiviral therapy (see below). Current evidence suggest that in the majority of cases, essential mixed cryoglobulinemia occurs when an aberrant immune response to hepatitis C infection leads to the formation of immune complexes consisting of hepatitis C antigens, polyclonal hepatitis C–specific IgG, and monoclonal IgM rheumatoid factor. The deposition of these immune complexes in blood vessel walls triggers an inflammatory cascade that results in the clinical syndrome of essential mixed cryoglobulinemia.

CLINICAL AND LABORATORY MANIFESTATIONS The most common clinical manifestations of essential mixed cryoglobulinemia are cutaneous vasculitis, arthritis, peripheral neuropathy, and glomerulonephritis. Renal disease develops in 10 to 30% of patients. Life-threatening rapidly progressive glomerulonephritis or vasculitis of the central nervous system, gastrointestinal tract, or heart occurs infrequently.

The presence of circulating cryoprecipitates is the fundamental finding in essential mixed cryoglobulinemia. Rheumatoid factor is almost always found and may be a useful clue to the disease when cryoglobulins are not detected. Hypocomplementemia occurs in 90% of patients. An elevated ESR and anemia occur frequently. Evidence for hepatitis C infection must be sought in all patients by testing for hepatitis C antibodies and hepatitis C RNA.

TREATMENT

Acute mortality from essential mixed cryoglobulinemia is uncommon, but the presence of glomerulonephritis is a poor prognostic sign for overall outcome. In such patients, 15% progress to end-stage renal disease with 40% later experiencing fatal cardiovascular disease, infection, or liver failure. As indicated above, the majority of cases are associated with hepatitis C infection. In such patients, treatment with IFN-α and ribavirin (Chap. 285) can prove beneficial. Clinical improvement with IFN-α and ribavirin is dependent on the virologic response. Patients who clear hepatitis C from the blood have objective improvement in their vasculitis along with significant reductions in levels of circulating cryoglobulins, IgM, and rheumatoid factor. However, substantial portions of patients with hepatitis C do not have a sustained virologic response to such therapy, and the vasculitis typically relapses with the return of viremia. While transient improvement can be observed with glucocorticoids, a complete response is seen in only 7% of patients. Plasmapheresis and cytotoxic agents have been used in anecdotal reports. These observations have not been confirmed, and such therapies carry significant risks.

BEHÇET'S SYNDROME

Behçet's Syndrome is a clinicopathologic entity characterized by recurrent episodes of oral and genital ulcers, iritis, and cutaneous lesions. The underlying pathologic process is a leukocytoclastic venulitis, although vessels of any size and in any organ can be involved. →***This disorder is described in detail in Chap. 307.***

ISOLATED VASCULITIS OF THE CENTRAL NERVOUS SYSTEM

Isolated vasculitis of the central nervous system is an uncommon clinicopathologic entity characterized by vasculitis restricted to the vessels of the central nervous system without other apparent systemic vasculitis. Although the arteriole is most commonly affected, vessels of any size can be involved. The inflammatory process is usually composed of mononuclear cell infiltrates with or without granuloma formation.

Patients may present with severe headaches, altered mental function, and focal neurologic defects. Systemic symptoms are generally absent. Devastating neurologic abnormalities may occur depending on the extent of vessel involvement. The diagnosis is generally made by demonstration of characteristic vessel abnormalities on angiography (Fig. 306-4) and confirmed by biopsy of the brain parenchyma and leptomeninges. In the absence of a brain biopsy, care should be taken not to misinterpret as true primary vasculitis angiographic abnormalities that might actually be related to another cause. The differential diagnosis includes infection, atherosclerosis, emboli, connective tissue disease, sarcoidosis, malignancy, vasospasm, and drug-associated causes. The prognosis of this disease is poor; however, some reports indicate that glucocorticoid therapy, alone or together with cyclophosphamide administered as described above, has induced sustained clinical remissions in a small number of patients.

COGAN'S SYNDROME

Cogan's syndrome is characterized by interstitial keratitis together with vestibuloauditory symptoms. It may be associated with a systemic vasculitis, particularly aortitis with involvement of the aortic valve. Glucocorticoids are the mainstay of treatment. Initiation of treatment as early as possible after the onset of hearing loss improves the likelihood of a favorable outcome.

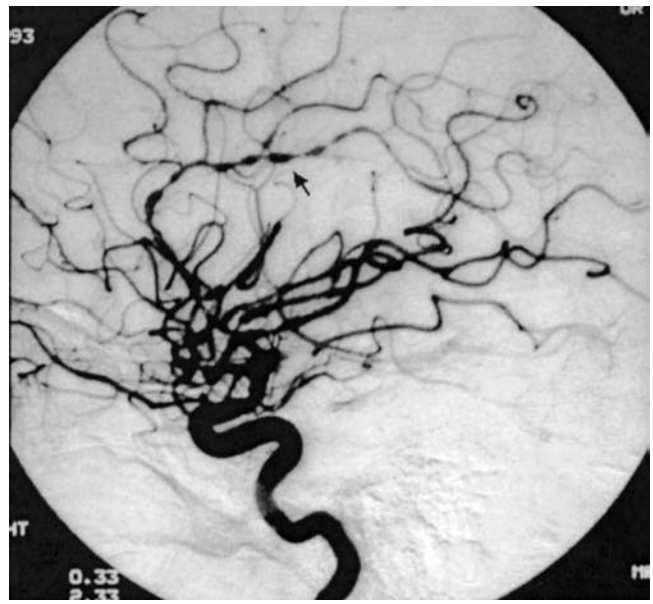

FIGURE 306-4 Cerebral angiogram from a 32-year-old male with central nervous system vasculitis. Dramatic beading (*arrow*) typical of vasculitis is seen.

KAWASAKI DISEASE

Kawasaki disease, also referred to as *mucocutaneous lymph node syndrome,* is an acute, febrile, multisystem disease of children. Some 80% of cases occur prior to the age of 5, with the peak incidence occurring at ≤2 years. It is characterized by nonsuppurative cervical adenitis and changes in the skin and mucous membranes such as edema; congested conjunctivae; erythema of the oral cavity, lips, and palms; and desquamation of the skin of the fingertips. Although the disease is generally benign and self-limited, it is associated with coronary artery aneurysms in approximately 25% of cases, with an overall case-fatality rate of 0.5 to 2.8%. These complications usually occur between the third and fourth weeks of illness during the convalescent stage. Vasculitis of the coronary arteries is seen in almost all the fatal cases that have been autopsied. There is typical intimal proliferation and infiltration of the vessel wall with mononuclear cells. Beadlike aneurysms and thromboses may be seen along the artery. Other manifestations include pericarditis, myocarditis, myocardial ischemia and infarction, and cardiomegaly.

Apart from the up to 2.8% of patients who develop fatal complications, the prognosis of this disease for uneventful recovery is excellent. High-dose intravenous γ globulin (2 g/kg as a single infusion over 10 h) together with aspirin (100 mg/kg per day for 14 days followed by 3 to 5 mg/kg per day for several weeks) have been shown to be effective in reducing the prevalence of coronary artery abnormalities when administered early in the course of the disease.

POLYANGIITIS OVERLAP SYNDROMES

Some patients with systemic vasculitis manifest clinicopathologic characteristics that do not fit precisely into any specific disease but have overlapping features of different vasculitides. Active systemic vasculitis in such settings has the same potential for causing irreversible organ system damage as when it occurs in one of the defined syndromes listed in Table 306-1. The diagnostic and therapeutic considerations as well as the prognosis for these patients depend on the sites and severity of active vasculitis. Patients with vasculitis that could potentially cause irreversible damage to a major organ system should be treated as described under "Wegener's granulomatosis."

SECONDARY VASCULITIS

Drug-Induced Vasculitis Vasculitis associated with drug reactions usually presents as palpable purpura that may be generalized or limited to the lower extremities or other dependent areas; however, urticarial lesions, ulcers, and hemorrhagic blisters may also occur (Chap. 50). Signs and symptoms may be limited to the skin, although systemic manifestations such as fever, malaise, and polyarthralgias may occur. Although the skin is the predominant organ involved, systemic vasculitis may result from drug reactions. Drugs that have been implicated in vasculitis include allopurinol, thiazides, gold, sulfonamides, phenytoin, and penicillin (Chap. 50).

An increasing number of drugs have been reported to cause vasculitis associated with antimyeloperoxidase ANCA. Of these, the best evidence of causality exists for hydralazine and propylthiouracil. The clinical manifestations in ANCA-positive drug-induced vasculitis can range from cutaneous lesions to glomerulonephritis and pulmonary hemorrhage. Outside of drug discontinuation, treatment should be based on the severity of the vasculitis. Patients with immediately life-threatening small-vessel vasculitis should initially be treated with glucocorticoids and cyclophosphamide as described for Wegener's granulomatosis. Following clinical improvement, consideration may be given for tapering such agents along a more rapid schedule.

Serum Sickness and Serum Sickness–Like Reactions These reactions are characterized by the occurrence of fever, urticaria, polyarthralgias, and lymphadenopathy 7 to 10 days after primary exposure and 2 to 4 days after secondary exposure to a heterologous protein (classic serum sickness) or a nonprotein drug such as penicillin or sulfa (serum sickness–like reaction). Most of the manifestations are not due to a vasculitis; however, occasional patients will have typical cutaneous venulitis that may progress rarely to a systemic vasculitis.

Vasculitis Associated with Other Underlying Primary Diseases Certain *infections* may directly trigger an inflammatory vasculitic process. For example, rickettsias can invade and proliferate in the endothelial cells of small blood vessels causing a vasculitis (Chap. 158). In addition, the inflammatory response around blood vessels associated with certain systemic fungal diseases such as histoplasmosis (Chap. 183) may mimic a primary vasculitic process. A leukocytoclastic vasculitis predominantly involving the skin with occasional involvement of other organ systems may be a minor component of many other infections. These include *subacute bacterial endocarditis*, *Epstein-Barr virus infection*, *HIV infection*, as well as a number of other infections.

Vasculitis can be associated with certain *malignancies*, particularly lymphoid or reticuloendothelial neoplasms. Leukocytoclastic venulitis confined to the skin is the most common finding; however, widespread systemic vasculitis may occur. Of particular note is the association of *hairy cell leukemia* (Chap. 97) with PAN.

A number of *connective tissue diseases* have vasculitis as a secondary manifestation of the underlying primary process. Foremost among these are *systemic lupus erythematosus* (Chap. 300), *rheumatoid arthritis* (Chap. 301), *inflammatory myositis* (Chap. 370), *relapsing polychondritis* (Chap. 308), and *Sjögren's syndrome* (Chap. 304). The most common form of vasculitis in these conditions is the small-vessel venulitis isolated to the skin. However, certain patients may develop a fulminant systemic necrotizing vasculitis.

Secondary vasculitis has also been observed in association with *ulcerative colitis*, *congenital deficiencies of various complement components*, *retroperitoneal fibrosis*, *primary biliary cirrhosis*, α_1-antitrypsin deficiency, and *intestinal bypass surgery*.

PRINCIPLES OF TREATMENT

Once a diagnosis of vasculitis has been established, a decision regarding therapeutic strategy must be made (Fig. 306-1). The vasculitis syndromes represent a wide spectrum of diseases with varying degrees of severity. Since the potential toxic side effects of certain therapeutic regimens may be substantial, the risk-versus-benefit ratio of any therapeutic approach should be weighed carefully. Specific therapeutic regimens are discussed above for the individual vasculitis syndromes; however, certain general principles regarding therapy should be considered. On the one hand, glucocorticoids and/or cytotoxic therapy should be instituted immediately in diseases where irreversible organ system dysfunction and high morbidity and mortality have been clearly established. Wegener's granulomatosis is the prototype of a severe systemic vasculitis requiring such a therapeutic approach (see above). On the other hand, when feasible, aggressive therapy should be avoided for vasculitic manifestations that rarely result in irreversible organ system dysfunction and that usually do not respond to such therapy. For example, idiopathic cutaneous vasculitis usually resolves with symptomatic treatment, and prolonged courses of glucocorticoids uncommonly result in clinical benefit. Cytotoxic agents have not proved to be beneficial in idiopathic cutaneous vasculitis, and their toxic side effects generally outweigh any potential beneficial effects. Glucocorticoids should be initiated in those systemic vasculitides that cannot be specifically categorized or for which there is no established standard therapy; cytotoxic therapy should be added in these diseases only if an adequate response does not result or if remission can only be achieved and maintained with an unacceptably toxic regimen of glucocorticoids. When remission is achieved, one should continually attempt to taper glucocorticoids to an alternate-day regimen and discontinue when possible. When using cytotoxic regimens, one should base the choice of agent upon the available therapeutic data supporting efficacy in that disease, the site and severity of organ involvement, and the toxicity profile of the drug.

Physicians should be thoroughly aware of the toxic side effects of therapeutic agents employed (Table 306-7). Many of the side effects of glucocorticoid therapy are markedly decreased in frequency and duration in patients on alternate-day regimens compared to daily regimens. When cyclophosphamide is administered chronically in doses of 2 mg/kg per day for substantial periods of time (one to several years), the incidence of cystitis is at least 30% and the incidence of bladder cancer is at least 6%. Bladder cancer can occur several years after discontinuation of cyclophosphamide therapy; therefore, monitoring for bladder cancer should continue indefinitely in patients who have received prolonged courses of daily cyclophosphamide. Instructing the patient to take cyclophosphamide all at once in the morning with a large amount of fluid throughout the day in order to maintain

a dilute urine can reduce the risk of bladder injury. Significant alopecia is unusual in the chronically administered, low-dose regimen. Permanent infertility can occur in both men and women. Bone marrow suppression is an important toxicity of cyclophosphamide and can be observed during glucocorticoid tapering or over time, even after periods of stable measurements. Monitoring of the complete blood count every 1 to 2 weeks for as long as the patient receives cyclophosphamide can effectively prevent cytopenias. When the white blood count (WBC) is maintained at $>3000/\mu L$, and the patient is not receiving daily glucocorticoids, the incidence of life-threatening opportunistic infections is low. However, the WBC is not an accurate predictor of risk of all opportunistic infections; and infections with *Pneumocystis carinii* and certain fungi can be seen in the face of WBCs that are within normal limits, particularly in patients receiving glucocorticoids. All vasculitis patients who are not allergic to sulfa and who are receiving daily glucocorticoids in combination with a cytotoxic drug should receive trimethoprim-sulfamethoxazole as prophylaxis against *P. carinii* infection.

Finally, it should be emphasized that each patient is unique and requires individual decision-making. The above outline should serve as a framework to guide therapeutic approaches; however, flexibility should be practiced in order to provide maximal therapeutic efficacy with minimal toxic side effects in each patient.

307 BEHÇET'S SYNDROME

Haralampos M. Moutsopoulos

DEFINITION

Behçet's syndrome is a multisystem disorder presenting with recurrent oral and genital ulcerations as well as ocular involvement. Internationally agreed diagnostic criteria have been proposed (Table 307-1).

PREVALENCE, PATHOGENESIS, AND PATHOLOGY

The syndrome affects young males and females from the Mediterranean region, the Middle East, and the Far East, suggesting a link with the ancient Silk Route. Males and females are affected equally, but males often have more severe disease. Blacks are not affected.

The etiology and pathogenesis of this syndrome remain obscure; vasculitis is the main pathologic lesion with a tendency to venous thrombus formation, and circulating autoantibodies to human oral mucous membranes are found in approximately 50% of the patients. In endemic areas the syndrome is associated with HLA-B5 (B51) alloantigen, and approximately 1 in 10 patients has an affected relative.

CLINICAL FEATURES

The recurrent aphthous ulcerations are a sine qua non for the diagnosis. The ulcers are usually painful, shallow or deep with a central yellowish necrotic base, appear singly or in crops, and are located anywhere in the oral cavity. The ulcers persist for 1 to 2 weeks and subside without leaving scars. The genital ulcers are less common, more specific, do not affect the glans penis or urethra, and produce scrotal scars.

Skin involvement includes folliculitis, erythema nodosum, an acne-like exanthem, and infrequently vasculitis. Nonspecific skin inflammatory reactivity to any scratches or intradermal saline injection (pathergy test) is a common and specific manifestation.

TABLE 307-1 Diagnostic Criteria of Behçet's Disease

Recurrent oral ulceration plus two of the following:
Recurrent genital ulceration
Eye lesions
Skin lesions
Pathergy test

Eye involvement with scarring, bilateral panuveitis is the most dreaded complication, since it occasionally progresses rapidly to blindness. The eye disease is usually present at the onset but may also develop within the first few years. In addition to iritis, posterior uveitis, retinal vessel occlusions, and optic neuritis can be seen in some patients with the syndrome. Hypopyon uveitis, a specific but rare manifestation, is a layer of inflammatory cells visible because of the effects of gravity; it usually indicates severe retinal vascular disease.

The arthritis of Behçet's syndrome is not deforming and affects the knees and ankles.

Superficial or deep peripheral vein thrombosis is seen in one-fourth of the patients. Pulmonary emboli are a rare complication. The superior vena cava is obstructed occasionally, producing a dramatic clinical picture. Arterial involvement occurs infrequently and presents with aortitis or peripheral arterial aneurysm and arterial thrombosis. Pulmonary artery vasculitis presenting with dyspnea, cough, chest pain, hemoptysis, and infiltrates on chest roentgenograms has been reported recently in 5% of patients.

Neurologic involvement (5 to 10%) appears mainly in the parenchymal form (80%); it is associated with brain stem involvement and has a serious prognosis. Dural sinus thrombi (20%) are associated with headache and increased intracranial pressure.

Gastrointestinal involvement consists of mucosal ulcerations of the gut.

Laboratory findings are mainly nonspecific indices of inflammation, such as leukocytosis and elevated erythrocyte sedimentation rate, as well as C-reactive protein levels; antibodies to the human oral mucosa are also found.

TREATMENT

The severity of the syndrome usually abates with time. Apart from the patients with parenchymal neurologic involvement, the life expectancy seems to be normal, and the only serious complication is blindness.

Mucous membrane involvement may respond to topical glucocorticoids in the form of mouthwash or paste. In more serious cases thalidomide (100 mg/d) is effective. Thrombophlebitis is treated with aspirin, 325 mg/d. Colchicine or interferon α can be beneficial for the mucocutaneous manifestations of the syndrome. Uveitis and central nervous system involvement require systemic glucocorticoid therapy (prednisone, 1 mg/kg per day) and azathioprine, 2 to 3 mg/kg per day,

or cyclosporine, 5 to 10 mg/kg per day. Preliminary data suggest that anti-tumor necrosis factor block may be an alternative therapeutic modality for panuveitis. Early initiation of azathioprine tends to favorably affect the long-term prognosis of Behçet's syndrome.

308 RELAPSING POLYCHONDRITIS

Bruce C. Gilliland

Relapsing polychondritis is an uncommon inflammatory disorder of unknown cause characterized by an episodic and generally progressive course affecting predominantly the cartilage of the ears, nose, and laryngotracheobronchial tree. Other manifestations include scleritis, neurosensory hearing loss, polyarthritis, cardiac abnormalities, skin lesions, and glomerulonephritis. The peak age of onset is between the ages of 40 to 50 years, but relapsing polychondritis may affect children and the elderly. It is found in all races, and both sexes are equally affected. No familial tendency is apparent. A significantly higher frequency of HLA-DR4 has been found in patients with relapsing polychondritis than in normal individuals. A predominant subtype allele(s) of HLA-DR4 was not found. Approximately 30% of patients with relapsing polychondritis will have another rheumatologic disorder, the most frequent being systemic vasculitis, followed by rheumatoid arthritis, systemic lupus erythematosus (SLE), Sjögren's syndrome, or ankylosing spondylitis. Nonrheumatic disorders associated with relapsing polychondritis include inflammatory bowel disease, primary biliary cirrhosis, and myelodysplastic syndrome (Table 308-1).

Diagnostic criteria were suggested over 20 years ago by McAdam et al. and modified by Damiani and Levine a few years later. These criteria continue to be generally used in clinical practice. McAdam et al. proposed the following: (1) recurrent chondritis of both auricles; (2) nonerosive inflammatory arthritis; (3) chondritis of nasal cartilage; (4) inflammation of ocular structures including conjunctivitis, keratitis, scleritis/episcleritis, and/or uveitis; (5) chondritis of the laryngeal and/or tracheal cartilages; and (6) cochlear and/or vestibular damage manifested by neurosensory hearing loss, tinnitus, and/or vertigo. The diagnosis is certain when three or more of these features are present along with a positive biopsy from the ear, nasal, or respiratory cartilage. Damiani and Levine later suggested that the diagnosis could be made when one or more of the above features and a positive biopsy were present, when two or more separate sites of cartilage inflammation were present that responded to glucocorticoids or dapsone, or when three or more of the above features were present. A biopsy is not necessary in most patients with clinically evident disease.

PATHOLOGY AND PATHOPHYSIOLOGY The earliest abnormality of hyaline and elastic cartilage noted histologically is a focal or diffuse loss of basophilic staining indicating depletion of proteoglycan from the cartilage matrix. Inflammatory infiltrates are found adjacent to involved cartilage and consist predominantly of mononuclear cells and occasional plasma cells. In acute disease, polymorphonuclear white cells may also be present. Destruction of cartilage begins at the outer edges and advances centrally. There is lacunar breakdown and loss of chondrocytes. Degenerating cartilage is replaced by granulation tissue and later by fibrosis and focal areas of calcification. Small loci of cartilage regeneration may be present. Immunofluorescence studies have shown immunoglobulins and complement at sites of involvement. Extracellular granular material observed in the degenerating cartilage matrix by electron microscopy has been interpreted to be enzymes, immunoglobulins, or proteoglycans.

Immunologic mechanisms play a role in the pathogenesis of relapsing polychondritis. Immunoglobulin and complement deposits are found at sites of inflammation. In addition, antibodies to type II collagen and to matrilin-1 and immune complexes are detected in the sera of some patients. The possibility that an immune response to type II collagen may be important in the pathogenesis is supported experimentally by the occurrence of auricular chondritis in rats immunized with type II collagen. Antibodies to type II collagen are found in the sera of these animals, and immune deposits are detected at sites of ear inflammation. Humoral immune responses to type IX and type XI collagen, matrilin-1, and cartilage oligomeric matrix protein have been demonstrated in some patients. In a study, rats immunized with matrilin-1 were found to develop severe inspiratory stridor and swelling of the nasal septum. The rats had severe inflammation with erosions of the involved cartilage, which was characterized by increased numbers of CD 4+ and CD 8+ T cells in the lesions. The cartilage of the joints and ear pinna was not involved. All had IgG antibodies to matrilin-1. Matrilin-1 is a noncollagenous protein present in the extracellular matrix in cartilage. It is present in high concentrations in the trachea and is also present in the nasal septum but not in articular cartilage. A subsequent study demonstrated serum anti-matrilin-1 antibodies in approximately 13% of patients with relapsing polychondritis; approximately 70 of these patients had respiratory symptoms. Cell-mediated immunity may also be operative in causing tissue injury, since lymphocyte transformation can be demonstrated when lymphocytes of patients are exposed to cartilage extracts. T cells specific for type II collagen have been found in some patients, and CD 4+ T cells have been observed at sites of cartilage inflammation. The accumulating data strongly suggest that both humoral and cell-mediated immunity play an important role in the pathogenesis of relapsing polychondritis.

Dissolution of cartilage matrix can be induced by the intravenous injection of crude papain, a proteolytic enzyme, into young rabbits, which results in collapse of their normally rigid ears within 4 h. Reconstitution of the matrix occurs in about 7 days. In relapsing polychondritis, loss of cartilage matrix also most likely results from action of proteolytic enzymes released from chondrocytes, polymorphonuclear white cells, and monocytes that have been activated by inflammatory mediators.

CLINICAL MANIFESTATIONS The onset of relapsing polychondritis is frequently abrupt with the appearance of one or two sites of cartilagenous inflammation. Fever, fatigue, and weight loss occur and may precede the clinical signs of relapsing polychondritis by several weeks. Relapsing polychondritis may go unrecognized for several months or even years in patients who only initially manifest intermittent joint pain and/or swelling, or who have unexplained eye inflammation, hearing loss, valvular heart disease, or pulmonary symptoms. The pattern of cartilagenous involvement and the frequency of episodes vary widely among patients.

TABLE 308-1 Disorders Associated with Relapsing Polychondritis[a]

Saddle nose deformity	20	30
Ocular deformities	20	50
Respiratory disease	25	50
Arthritis	35	50
Aortic regurgitation	—	5
Vasculitis	3	10

Source: Modified from Isaak et al.

Auricular chondritis is the most frequent presenting manifestation of relapsing polychondritis in 40% of patients and eventually affects about 85% of patients (Table 308-2). One or both ears are involved, either sequentially or simultaneously. Patients experience the sudden onset of pain, tenderness, and swelling of the cartilaginous portion of the ear (Fig. 308-1). Earlobes are spared because they do not contain cartilage. The overlying skin has a beefy red or violaceous color. Prolonged or recurrent episodes result in a flabby or droopy ear as a sequela of cartilage destruction. Swelling may close off the eustachian tube (causing otitis media) or the external auditory meatus, either of which can impair hearing. Inflammation of the internal auditory artery or its cochlear branch produces hearing loss, vertigo, ataxia, nausea, and vomiting. Vertigo is almost always accompanied by hearing loss. The cartilage of the nose becomes inflamed during the first or subsequent attacks. Approximately 50% of patients will eventually have nose involvement. Patients may experience nasal stuffiness, rhinorrhea, and epistaxis. The bridge of the nose becomes red, swollen, and tender and may collapse, producing a saddle deformity (Fig. 308-2). In some patients, the saddle deformity develops insidiously without overt inflammation. Saddle nose is observed more frequently in younger patients, especially in women.

Arthritis is the presenting manifestation in relapsing polychondritis in approximately one-third of patients and may be present for several months before other features appear. Eventually, more than half the patients will have arthritis. The arthritis is usually asymmetric and oligo- or polyarticular, and involves both large and small peripheral joints. An episode of arthritis lasts from a few days to several weeks and resolves spontaneously without residual joint deformity. Attacks of arthritis may not be temporally related to other manifestations of relapsing polychondritis. The joints are warm, tender, and swollen. Joint fluid has been reported to be noninflammatory. In addition to peripheral joints, inflammation may involve the costochondral, sternomanubrial, and sternoclavicular cartilages. Destruction of these cartilages may result in a pectus excavatum deformity or even a flail anterior chest wall. Relapsing polychondritis may occur in patients with preexisting rheumatoid arthritis, Reiter's syndrome, psoriatic arthritis, or ankylosing spondylitis.

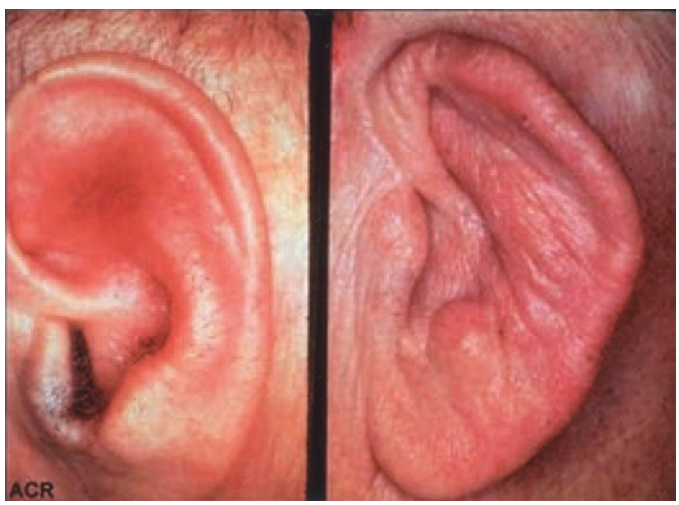

FIGURE 308-1 *Left*. The pinna is erythematous, swollen, and tender. Not shown is the ear lobule that is spared as there is no underlying cartilage. *Right*. The pinna is thickened and deformed. The destruction of the underlying cartilage results in a floppy ear. *(Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, © 1991, 1995, 1997, 1998, 1999. Used by permission of the American College of Rheumatology.)*

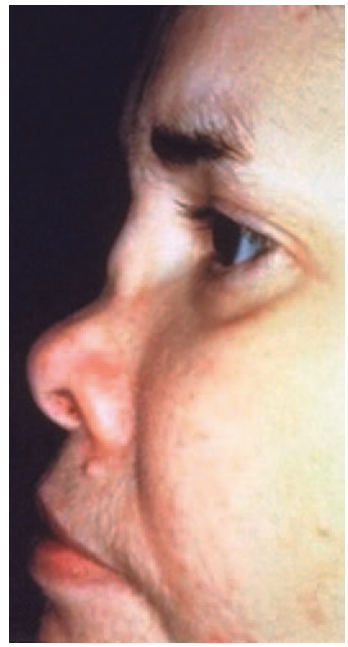

FIGURE 308-2 Saddle nose results from destruction and collapse of the nasal cartilage. *(Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, © 1991, 1995, 1997, 1998, 1999. Used by permission of the American College of Rheumatology.)*

Eye manifestations occur in more than half of patients and include conjunctivitis, episcleritis, scleritis, iritis, and keratitis. Eye involvement is seldom the presenting feature. Ulceration and perforation of the cornea may occur and cause blindness. Other manifestations include eyelid and periorbital edema, proptosis, cataracts, optic neuritis, extraocular muscle palsies, retinal vasculitis, and renal vein occlusion.

Laryngotracheobronchial involvement occurs in ~50% of patients. Symptoms include hoarseness, a nonproductive cough, and tenderness over the larynx and proximal trachea. Mucosal edema, strictures, and/or collapse of laryngeal or tracheal cartilage may cause stridor and life-threatening airway obstruction necessitating tracheostomy. Collapse of cartilage in bronchi leads to pneumonia and, when extensive, to respiratory insufficiency.

Aortic regurgitation occurs in about 5% of patients and is due to progressive dilation of the aortic ring or to destruction of the valve cusps. Mitral and other heart valves are less often affected. Other cardiac manifestations include pericarditis, myocarditis, and conduction abnormalities. Aneurysms of the proximal, thoracic, or abdominal aorta may occur even in the absence of active chondritis and occasionally rupture.

Systemic vasculitis may occur in association with relapsing polychondritis. Vasculitides include leukocytoclastic vasculitis, polyarteritis, temporal arteritis, and Takayasu's arteritis (Chap. 306). Neurologic abnormalities usually occur as a result of underlying vasculitis, manifesting as seizures, strokes, ataxia, and peripheral and cranial nerve neuropathies. Cranial nerves II, III, VI, and VII are most often involved. Approximately 25% of patients have skin lesions, none of which is characteristic for relapsing polychondritis, that reflect associated vasculitis. These include purpura, erythema nodosum, erythema multiforme, angioedema/urticaria, livedo reticularis, and panniculitis. Segmental necrotizing glomerulonephritis with crescent formation has been noted in some patients, usually in association with microscopic polyangiitis, but may occur in the absence of systemic vasculitis.

The course of disease is highly variable, with episodes lasting from a few days to several weeks and then subsiding spontaneously. Attacks may recur at intervals varying from weeks to months. In other patients, the disease has a chronic, smoldering course. In a few patients, the disease may be limited to one or two episodes of cartilage inflammation. In one study, the 5-year estimated survival rate was 74% and the 10-year survival rate 55%. In contrast to earlier series, only about half the deaths could be attributed to relapsing polychondritis or complications of treatment. Pulmonary complications accounted for only 10% of all fatalities. In general, patients with more widespread disease have a worse prognosis.

LABORATORY FINDINGS Mild leukocytosis and normocytic, normochromic anemia are often present. Eosinophilia is observed in 10% of patients. The erythrocyte sedimentation rate and C-reactive protein are usually elevated. Rheumatoid factor and antinuclear antibody tests are occasionally positive in low titers. Antibodies to type II collagen are present in fewer than half the patients and are specific. Circulating immune complexes may be detected, especially in patients with early active disease. Elevated levels of γ globulin may be present. Antineutrophil cytoplasmic antibodies (ANCA), either cytoplasmic (C-ANCA) or perinuclear (P-ANCA), are found in some patients with active disease. The upper and lower airways can be evaluated by imaging techniques such as linear tomography, laryngotracheography, and computed tomography, and by bronchoscopy. Magnetic resonance imaging (MRI) is helpful in evaluation of the larynx and trachea. Bronchography is performed to demonstrate bronchial narrowing. Intrathoracic airway obstruction can also be evaluated by inspiratory-expiratory flow studies. The chest film may show narrowing of the trachea and/or the main bronchi, widening of the ascending or descending aorta due to an aneurysm, and cardiomegaly when aortic insufficiency is present. MRI can be used in assessing aortic aneurysmal dilatation. Radiographs may show calcification at previous sites of cartilage damage involving ear, nose, larynx, or trachea.

DIAGNOSIS Diagnosis is based on recognition of the typical clinical features. Biopsies of the involved cartilage from the ear, nose, or respiratory tract will confirm the diagnosis but are only necessary when clinical features are not typical. Patients with Wegener's granulomatosis may have a saddle nose and pulmonary involvement but can be distinguished by the absence of auricular involvement and the presence of granulomatous lesions in the tracheobronchial tree. Patients with Cogan's syndrome have interstitial keratitis and vestibular and auditory abnormalities, but this syndrome does not involve the respiratory tract or ears. Reiter's syndrome may initially resemble relapsing polychondritis because of oligoarticular arthritis and eye involvement, but it is distinguished in time by the appearance of urethritis and typical mucocutaneous lesions and the absence of nose or ear cartilage involvement. Rheumatoid arthritis may initially suggest relapsing polychondritis because of arthritis and eye inflammation. The arthritis in rheumatoid arthritis, however, is erosive and symmetric. In addition, rheumatoid factor titers are usually high compared with those in relapsing polychondritis. Bacterial infection of the pinna may be mistaken for relapsing polychondritis but differs by usually involving only one ear, including the earlobe. Auricular cartilage may also be damaged by trauma or frostbite.

Relapsing polychondritis may develop in patients with a variety of autoimmune disorders, including SLE, rheumatoid arthritis, Sjögren's syndrome, and vasculitis. In most cases, these disorders antedate the appearance of polychondritis, usually by months or years. It is likely that these patients have an immunologic abnormality that predisposes them to development of this group of autoimmune disorders.

TREATMENT

In patients with active chondritis, prednisone, 40 to 60 mg/d, is often effective in suppressing disease activity; it is tapered gradually once disease is controlled. In some patients, prednisone can be stopped, while in others low doses in the range of 10 to 15 mg/d are required for continued suppression of disease. Dapsone instead of prednisone has been effective in suppressing inflammation in some patients. Immunosuppressive drugs such as methotrexate, cyclophosphamide, azathioprine, or cyclosporine should be reserved for patients who fail to respond to prednisone or who require high doses for control of disease activity. Patients with significant ocular inflammation often require intraocular steroids as well as high doses of prednisone. Heart valve replacement or repair of an aortic aneurysm may be necessary. In patients with early subglottic disease, intralesional injection of glutocorticoids may be beneficial. When obstruction is severe, tracheostomy is required. Stents may be necessary in patients with tracheobronchial collapse.

309 SARCOIDOSIS

Ronald G. Crystal

DEFINITION Sarcoidosis is a chronic, multisystem disorder of unknown cause characterized in affected organs by an accumulation of T lymphocytes and mononuclear phagocytes, noncaseating epithelioid granulomas, and derangements of the normal tissue architecture. Although there are usually skin anergy and depressed cellular immune processes in the blood, sarcoidosis is characterized at the sites of disease by exaggerated T helper 1 (T_H1) lymphocyte immune processes. All parts of the body can be involved, but the organ most frequently affected is the lung. Involvement of the skin, eye, liver, and lymph nodes is also common. The disease is often acute or subacute and self-limiting, but in many individuals it is chronic, waxing and waning over many years.

ETIOLOGY The cause of sarcoidosis is unknown. Various infectious and noninfectious agents have been implicated, but there is no proof that any specific agent is responsible. However, all available evidence is consistent with the concept that the disease results from an exaggerated cellular immune response (acquired, inherited, or both) to a limited class of persistent antigens or self-antigens.

INCIDENCE AND PREVALENCE Sarcoidosis is a relatively common disease affecting individuals of both sexes and almost all ages, races, and geographic locations. Females appear to be slightly more susceptible than males. Cases of sarcoidosis have been described in all of the major races, and the disease is found throughout the world. It has been suggested that sarcoidosis is more common in certain geographic areas such as the southeastern part of the United States, but when case-matched controls have been used, these geographic differences are less convincing. There is a remarkable diversity of the prevalence of sarcoidosis among certain ethnic and racial groups, with a range of <1 to 64 per 100,000 worldwide. The prevalence of sarcoidosis is from 10 to 40 per 100,000 in the United States and Europe. In the United States, most patients are black, with a ratio of blacks to whites ranging

from 10:1 to 17:1. In Europe, however, the disease affects mostly whites. Furthermore, while the prevalence per 100,000 in Sweden is 64, in France it is 10, in Poland 3, yet for Irish females living in London it is 200. In contrast, the disease is very rare among Inuit, Canadian Indians, New Zealand Maoris, and Southeast Asians.

Most patients present with sarcoidosis between the ages of 20 and 40, but the disease can occur in children and in the elderly. Several hundred kindred groups with familial sarcoidosis have been described, and the disease has been observed in twins, more commonly in monozygotic than in dizygotic pairs. There have also been several instances of husband-wife pairs identified, and geographic foci of sarcoidosis among unrelated individuals living closely within a community, arguing for some environmental factors in the pathogenesis of the disease. Although the disease is believed to result from exaggerated cellular immune responses to a limited class of antigens, no clear patterns in any HLA locus have emerged. Unlike many diseases in which the lung is involved, sarcoidosis favors nonsmokers.

PATHOPHYSIOLOGY AND IMMUNOPATHOGENESIS The first manifestation of the disease is an accumulation of mononuclear inflammatory cells, mostly CD4+ T_H1 lymphocytes and mononuclear phagocytes, in affected organs. This inflammatory process is followed by the formation of granulomas, aggregates of macrophages and their progeny, epithelioid cells, and multinucleated giant cells. The typical sarcoid granuloma is a compact structure composed of an aggregate of mononuclear phagocytes surrounded by a rim of CD4+ T lymphocytes and, to a far lesser extent, B lymphocytes. The overall structure is relatively discrete and is interspersed with fine collagen fibrils, presumably remnants of the underlying connective tissue matrix. The giant cells within the granuloma can be of the Langhans' or foreign-body variety and often contain inclusions such as Schaumann bodies (conchlike structures), asteroid bodies (stellate-like structures), and residual bodies (refractile calcium-containing inclusions).

Together the accumulated T cells, mononuclear phagocytes, and granulomas represent the active disease. Other than the fact that they take up space and thus their bulk modifies the local architecture, for all except late-stage cases, there is no evidence that the mononuclear inflammatory cells dispersed in the tissue or in the granuloma injure the affected organ by releasing mediators that damage the normal parenchymal cells or the extracellular matrix. Rather, organ dysfunction in sarcoidosis results mostly from the accumulated inflammatory cells distorting the architecture of the affected tissue; if a sufficient number of structures vital to the function of the tissue are involved, the disease becomes clinically apparent in that organ. Thus, while autopsy series show that, to some extent, sarcoidosis involves most organs in the majority of patients, the disease manifests clinically only in organs where it affects function (such as the lung and eye) or in organs where it is readily observed (such as the skin or, by x-ray, the hilar nodes). For example, in the lung, the inflammatory cells and granulomas distort the walls of the alveoli, bronchi, and blood vessels (Fig. 309-1*A*), thus altering the intimate relationships between air and blood necessary for normal gas exchange. When a sufficient amount of pulmonary tissue is involved, it is sensed by the individual as dyspnea. In contrast, most individuals with sarcoidosis have granulomatous mononuclear cell inflammation in the liver but usually do not have symptoms or significant functional derangements referable to that organ, likely because the disease process does not modify the local structures sufficiently to affect function.

If the disease is suppressed, either spontaneously or with therapy, the mononuclear inflammation is reduced in intensity and the number of granulomas is reduced. The granulomas resolve either by dispersion of the cells or by centripetal proliferation of fibroblasts from the periphery of the granuloma inward, to form a small scar. In chronic cases,

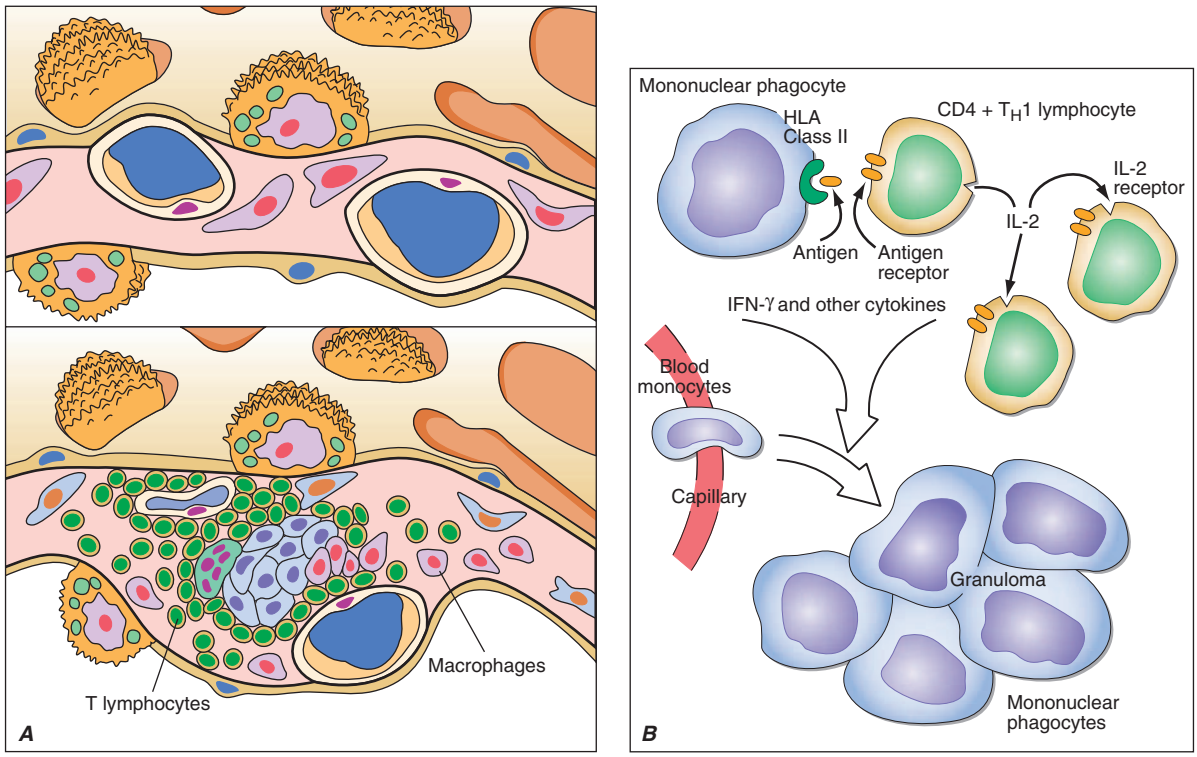

FIGURE 309-1 Pathogenesis of sarcoidosis. *A*. Histologic abnormalities. Normal alveoli (*top*) and alveoli in active sarcoidosis (*bottom*). The latter are distorted by the accumulated CD4+ T_H1 lymphocytes, alveolar macrophages, and macrophages aggregated into granulomas. There is mild damage to alveolar epithelial and endothelial cells. *B*. The exaggerated processes of T_H1 lymphocytes in affected organs result in the accumulation of these cells along with macrophages and macrophages aggregated into granulomas. The trigger for the T_H1 lymphocytes is unknown. It may be a limited class of antigens or self-antigens presented in the context of class II HLA surface molecules by mononuclear phagocytes to the T_H1 lymphocyte. The antigen class II HLA complex is identified by the T cell antigen receptor, and the T cell is activated. Consequent to this process the immune response is exaggerated and skewed to produce activated T_H1 lymphocytes that release IL-2, which drives the accumulation of more T lymphocytes. The activated T_H1 lymphocytes also release interferon γ (INF-γ). Together with cytokines such as IL-12, macrophage inflammatory protein 1α and granulocyte-macrophage colony-stimulating factor released in the local milieu, there is recruitment and activation of blood monocytes and subsequent granuloma formation.

the mononuclear cell inflammation persists for years. If the intensity of the inflammation is sufficiently high for a sufficiently long period, the derangements to the affected tissues result in extensive damage, the development of fibrosis, and permanent loss of organ function.

The available evidence suggests that active sarcoidosis results from an exaggerated cellular immune response to a variety of antigens or self-antigens, in which the process of T lymphocyte triggering, proliferation, and activation is skewed in the direction of CD4+ T_H1 lymphocyte processes (Fig. 309-1*B*). The result is an exaggerated T_H1 T lymphocyte response and thus the accumulation of large numbers of activated T_H1 cells in the affected organs. Since the activated T_H1 lymphocyte releases mediators that attract and activate mononuclear phagocytes, it is likely that the process of granuloma formation is a secondary phenomenon that is a consequence of the exaggerated T_H1 cell process. In this context, the current hypotheses of the cause of sarcoidosis, not mutually exclusive, include the following: (1) The disease is caused by a class of persistent antigens, nonself or self, that trigger only the T_H1 cell arm of the immune response; (2) the disease results from an inadequate suppressor arm of the immune response, such that T_H1 cell processes cannot be shut down in a normal fashion; or (3) the disease results from inherited (and/or acquired) differences in immune response genes, such that the response to a variety of antigens is an exaggerated, T_H1 cell process.

Independent of the inciting agent(s) or the reason why there is an exaggerated T_H1 cell response, there is a general understanding of the processes responsible for the maintenance of the inflammation and the development of the granuloma. The T_H1 lymphocytes accumulate at the sites of disease, at least in part, because they proliferate in these sites at an exaggerated rate. This T cell proliferation is maintained by the spontaneous release of interleukin (IL) 2, the T cell growth factor, by activated T_H1 cells in the local milieu. In this regard, sarcoidosis is a remarkable example of compartmentalization of the immune system and a dramatic illustration of why disease activity of sarcoidosis cannot be assessed by evaluating the immune system only in the blood. Whereas the T_H1 cells in the involved organs are releasing IL-2 and proliferating at an enhanced rate, the T cells in other sites, such as blood, are quiescent. Furthermore, while there is a marked enhancement of the number of T_H1 cells at the sites of disease, the numbers of T_H1 cells in the blood are normal or slightly reduced. In the involved organs, the ratio of CD4+ to CD8+ T cells may be as high as 10:1 compared to the ratio of 2:1 found in normal tissues or in the blood of affected individuals.

In addition to driving other T_H1 cells in the affected organs to proliferate, the T_H1 cells at the sites of disease are activated and release mediators that both recruit and activate mononuclear phagocytes. The activated T_H1 cells accomplish this by releasing a variety of mediators (lymphokines) including proteins capable of recruiting blood monocytes to the local milieu of the activated T cells and interferon γ, a protein that, among its many actions, activates mononuclear phagocytes. Together with cytokines such as IL-12 and others released locally, these mediators recruit blood monocytes to the affected organs and activate them, providing the building blocks for the formation of the granuloma.

In addition to these exaggerated cellular immune processes, active sarcoidosis is also characterized by hyperglobulinemia. Included among the immunoglobulins are antibodies against a variety of infectious agents as well as IgM anti-T cell antibodies. However, there is no evidence that any of these antibodies plays a role in the pathogenesis of the disease, and they are thought to result from the nonspecific polyclonal stimulation of B cells by the activated T cells at the site of disease.

If the damage in the affected organs is sufficiently extensive that the remaining parenchymal cells cannot reestablish the normal tissue architecture, the usual result is fibrosis, the proliferation of mesenchymal cells, and deposition of their connective tissue products. There is convincing evidence that the fibroblast proliferation is directed by tissue macrophages spontaneously releasing growth signals for fibroblasts, including platelet-derived growth factor, fibronectin, and insulin-like growth factor 1. It is not known, however, why this fibrotic process occurs only in a relatively small proportion of individuals with sarcoidosis.

CLINICAL MANIFESTATIONS Sarcoidosis is a systemic disease, and thus the clinical manifestations may be generalized or focused on one or more organs. However, because the lung is almost always involved, most patients have symptoms referable to the respiratory system. Independent of the site, the clinical manifestations of the disease relate directly to the exaggerated T_H1 lymphocyte–mononuclear phagocyte granulomatous inflammatory process itself or to the sequelae resulting from the permanent damage caused by this process.

Sarcoidosis is occasionally discovered in a completely asymptomatic individual, but more commonly it presents abruptly over 1 to 2 weeks or the affected individual develops symptoms insidiously over several months. Independent of the mode of presentation, ~75% of all cases present in individuals younger than 40 years.

The asymptomatic form is usually detected by a routine examination, such as a chest film. In the United States, this form represents about 10 to 20% of all cases, but in countries where chest films are mandatory in preemployment screening programs, the proportion of asymptomatic patients is higher.

So-called acute or subacute sarcoidosis develops abruptly over a period of a few weeks and represents 20 to 40% of all cases. These individuals usually have constitutional symptoms such as fever, fatigue, malaise, anorexia, or weight loss. These symptoms are usually mild, but in ~25% of the acute cases the constitutional complaints are extensive. Many patients have respiratory symptoms, including cough, dyspnea, a vague retrosternal chest discomfort, and/or polyarthritis. Two syndromes have been identified in the acute group. *Löfgren's syndrome*, frequent in Scandinavian, Irish, and Puerto Rican females, includes the complex of erythema nodosum (Fig. 309-2) and x-ray findings of bilateral hilar adenopathy, often accompanied by joint symptoms, including arthritis at the ankles, knees, wrists, or elbows. The *Heerfordt-Waldenström syndrome* describes individuals with fever, parotid enlargement, anterior uveitis, and facial nerve palsy.

The insidious form of sarcoidosis develops over months and is usually associated with respiratory complaints without constitutional symptoms. In the United States, 40 to 70% of all patients with sarcoidosis patients are in this category. About 10% of these individuals have symptoms referable to organs other than the lung. It is the individuals who present with the insidious form of sarcoidosis who most commonly go on to develop chronic sarcoidosis, with permanent damage to the lung and other organs.

FIGURE 309-2 Erythema nodosum is a panniculitis characterized by tender deep-seated nodules and plaques usually located on the lower extremities.

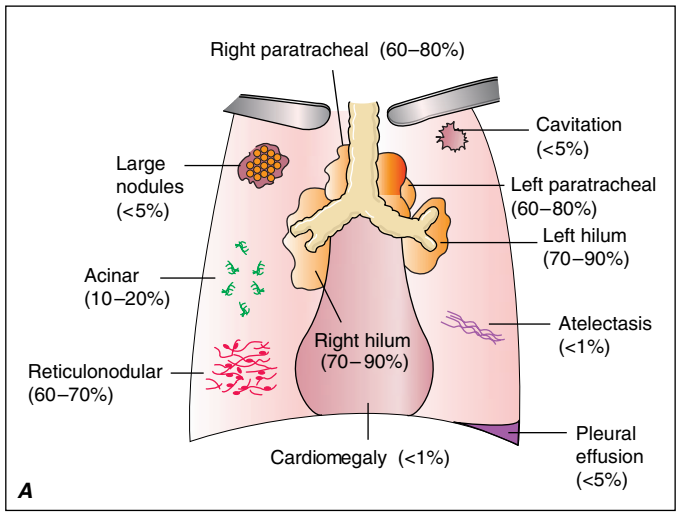
Despite the fact that sarcoidosis is a systemic disease and some evidence of inflammation can be detected in most organs in the majority of patients, sarcoidosis is important clinically because of the pulmonary abnormalities and, to a lesser extent, lymph node, skin, liver, and eye involvement. Far less commonly, other organs are involved significantly.

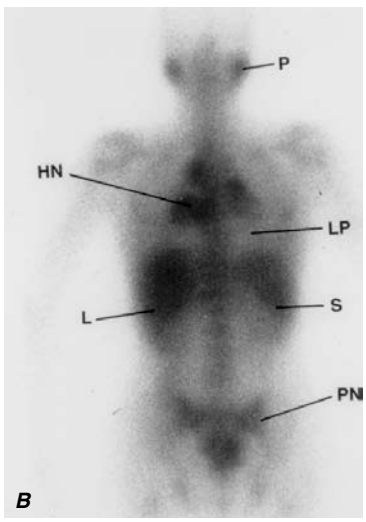
Lung Of individuals with sarcoidosis, 90% have abnormal findings on chest x-ray at some time during their course (Fig. 309-3*A*). Overall, ~50% develop permanent pulmonary abnormalities, and 5 to 15% have progressive fibrosis of the lung parenchyma. Sarcoidosis of the lung is primarily an interstitial lung disease (Chap. 243) in which the inflammatory process involves the alveoli, small bronchi, and small blood vessels. These individuals typically have symptoms of dyspnea, particularly with exercise, and a dry cough. In acute and subacute cases, physical examination usually reveals dry rales. Hemoptysis is rare, as is production of sputum. Occasionally, the large airways are involved to a degree sufficient to cause dysfunction. Distal atelectasis can result from endobronchial sarcoidosis or from external compression from enlarged intrathoracic nodes. Rarely, wheezing is heard, incorrectly suggesting asthma. Large-vessel pulmonary granulomatous arteritis is common, but it rarely causes major problems. If it dominates the pulmonary lesions, it is sometimes called *necrotizing sarcoidal granulomatosis*. The pleura is involved in 1 to 5% of cases, almost always manifesting as a unilateral pleural effusion with characteristics of an exudate containing lymphocytes. The effusions usually clear within a few weeks, but chronic pleural thickening can result. Pneumothorax or hydropneumothorax is observed in sarcoid but is very rare.

Lymph Nodes Lymphadenopathy is very common in sarcoidosis. Intrathoracic nodes are enlarged in 75 to 90% of all patients; usually this involves the hilar nodes, but the paratracheal nodes are commonly involved ((Fig. 309-3*A*). Less frequently, there is enlargement of subcarinal, anterior mediastinal, or posterior mediastinal nodes. Peripheral lymphadenopathy is very common, particularly involving the cervical, axillary, epitrochlear, and inguinal nodes. The nodes in the retroperitoneal area and in the mesenteric chain also can enlarge. All these nodes are nonadherent, with a firm, rubbery texture. Palpation causes no pain. Unlike nodes in tuberculosis, the nodes do not ulcerate. The lymphadenopathy rarely causes a problem for the affected individual; however, if it is massive, it can be disfiguring and can impinge on other organs and lead to functional impairment.

Skin Sarcoidosis involves the skin in ~25% of patients. The most common lesions are erythema nodosum (Fig. 309-2), plaques, maculopapular eruptions, subcutaneous nodules, and lupus pernio (Fig. 309-4). Erythema nodosum, comprising bilateral, tender red nodules on the anterior surface of the legs, is not specific for sarcoidosis but is common, particularly in acute sarcoidosis, in combination with systemic symptoms and polyarthralgias. Treatment is not required, since the lesions resolve spontaneously in 2 to 4 weeks. Erythema nodosum is much more common among patients with sarcoidosis in Europe than in the United States. Skin plaques associated with sarcoidosis are purple, indolent lesions, often raised, and usually occur on the face, buttocks, and extremities. The maculopapular eruptions occur on the face around the eyes and nose, on the back, and on the extremities. These are elevated lesions <1 cm in diameter with a flat, waxy top. Subcutaneous nodules are most common on the trunk and extremities. Lupus pernio is characterized by indurated blue-purple, swollen, shiny lesions on the nose, cheeks, lips, ears, fingers, and knees. The lesions on the tip of the nose cause a bulbous appearance, sometimes associated with varicosities. The nasal mucosa is usually involved, and underlying bone can be destroyed. Sarcoidosis can also involve old surgical scars and tattoos. Although it may be disfiguring, cutaneous sarcoidosis rarely causes major problems. Clubbing of the fingers is occasionally observed in sarcoidosis, usually in association with extensive pulmonary fibrosis.

Eye Eye involvement occurs in ~25% of patients with sarcoidosis, and it can cause blindness. The usual lesions involve the uveal tract, iris, ciliary body, and choroid. Of those patients with eye involvement, ~75% have anterior uveitis and 25 to 35% have posterior uveitis. There is blurred vision, tearing, and photophobia. The uveitis can develop rapidly and may clear spontaneously over a 6- to 12-month period. It also can develop insidiously and be chronic. The uveitis often occurs in association with retinal vasculitis. Conjunctival involvement is also common, usually with small, yellow nodules. When the lacrimal gland is involved, a keratoconjunctivitis sicca syndrome, with dry, sore eyes, can result.





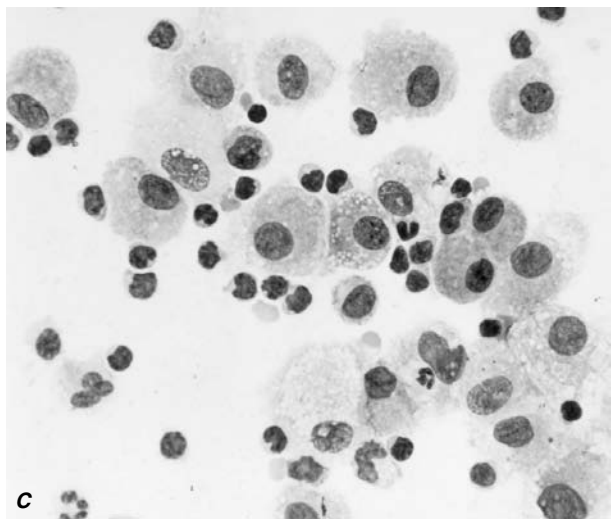


FIGURE 309-3 Common laboratory findings of sarcoidosis. *A*. Schematic view of the abnormal findings on the chest x-ray. Shown are changes observed with the average frequency of occurrence. *B*. Typical gallium-67 scan of an individual with active sarcoidosis. The isotope has accumulated in the lung parenchyma (LP), liver (L), spleen (S), parotid (P), hilar nodes (HN), and pelvic nodes (PN). *C*. Cells recovered by bronchoalveolar lavage of an individual with active pulmonary sarcoidosis. The lavage analysis reflects the inflammation in the tissue. Shown are alveolar macrophages (*large cells*) and lymphocytes (*small cells*). The cell population is dominated by the T_H1 subset of CD4+ lymphocytes, in contrast to normal individuals, in whom lymphocytes represent <20% of the cell population.

A

B

FIGURE 309-4 Sarcoid. *A*. Infiltrated papules and plaques of variable color are seen in a typical paranasal and periorbital location. *B*. Infiltrated, hyperpigmented, and erythematous coalescent papules and plaques on the upper area.

Upper Respiratory Tract The nasal mucosa is involved in up to 20% of patients, usually presenting with nasal stuffiness. Any of the structures of the mouth can be involved, particularly the tonsils but also the tongue. Sarcoidosis involves the larynx in ~5% of patients. The epiglottis and areas around the true vocal cords are usually involved, but the cords themselves are not. These individuals are usually hoarse, and they have dyspnea, wheezing, and stridor; complete obstruction can occur.

Bone Marrow and Spleen Sarcoidosis of the marrow is reported in 15 to 40% of patients, but it rarely causes hematologic abnormalities other than a mild anemia, neutropenia, eosinophilia, and occasionally, thrombocytopenia. Although splenomegaly occurs in only 5 to 10% of patients, celiac angiography or splenic biopsy reveals involvement in 50 to 60% of patients. The presentation and complications of splenomegaly in sarcoidosis are similar to those of splenomegaly in general.

Liver Although liver biopsy reveals liver involvement in 60 to 90% of patients, liver dysfunction is usually not important clinically. Sarcoidosis generally involves the periportal areas. Isolated granulomatous hepatitis can occur. Approximately 20 to 30% have hepatomegaly and/or biochemical evidence of liver involvement. Usually these changes reflect a cholestatic pattern and include an elevated alkaline phosphatase level; the bilirubin and aminotransferase levels are only mildly elevated, and jaundice is rare. Rarely, portal hypertension can develop, as can intrahepatic cholestasis with cirrhosis. There are several reports of the development of sarcoidosis in association of the treatment of chronic hepatitis C with interferon α.

Kidney Clinically apparent primary renal involvement in sarcoidosis is rare, although tubular, glomerular, and renal artery diseases have been reported. More commonly, but still in only 1 to 2% of all patients, there is a disorder of calcium metabolism with hypercalciuria, with or without hypercalcemia. If chronic, nephrocalcinosis and nephrolithiasis can result. It is believed that the calcium abnormalities are associated with enhanced calcium absorption in the gut, which is related to an abnormally high level of circulating 1,25-dihydroxyvitamin D produced by mononuclear phagocytes in the granulomas.

Nervous System All components of the nervous system can be involved in sarcoidosis. Neurologic findings are observed in about 5% of patients. Seventh nerve involvement with unilateral facial paralysis is most common. It occurs suddenly and is usually transient. Other common manifestations of neurosarcoid include optic nerve dysfunction, papilledema, palate dysfunction, hearing abnormalities, hypothalamic and pituitary abnormalities, chronic meningitis, and, occasionally, space-occupying lesions. Psychiatric disturbances have been described, and seizures can occur. Rarely, multiple lesions occur that mimic multiple sclerosis, spinal cord abnormalities, and peripheral neuropathy.

Musculoskeletal System The bones, joints, and/or muscles can be involved in sarcoidosis. Bone lesions are observed in 3 to 13% of patients and include variable-sized cysts in areas of expanded bone, with well-defined, round, punched-out lesions or lattice-like changes, often at the ends of the affected bones. The lesions are cortical, with the periostium preserved. Hand and foot bones are the common sites, but most bones can be involved. Occasionally, the bone lesions are tender and painful. Dactylitis with soft tissue swelling can be present over the affected digit. Joint involvement is more common, with an incidence of 25 to 50% in known cases of sarcoidosis. Arthralgias and frank arthritis occur mostly in large joints; they can be migratory and are usually transient, but they can be chronic and result in deformities. Although muscle biopsy frequently demonstrates granulomatous inflammation, muscle dysfunction is rare. However, nodules, polymyositis, and chronic myopathy have been described.

Heart Approximately 5% of patients have significant heart involvement, with clinical evidence of cardiac dysfunction. Left ventricular wall involvement is common. Arrhythmias are frequent, and serious conduction disturbances, including complete heart block, can occur. Sudden death has been associated with cardiac sarcoid. Papillary muscle dysfunction, pericarditis, and congestive heart failure are also observed. Cor pulmonale secondary to chronic pulmonary fibrosis may occur but is uncommon.

Endocrine and Reproductive System The hypothalamic-pituitary axis is the part of the endocrine system most commonly involved; this condition usually presents as diabetes insipidus. Anterior pituitary dysfunction is also seen, manifesting as a deficiency in one or more pituitary hormones. Complete hypopituitarism is rare. Much less frequently, sarcoidosis can cause primary dysfunction of other endocrine glands. Adrenal cortical involvement resulting in Addison's syndrome has been described. The reproductive organs may be involved, but infertility is rare. Pregnancy is not affected by sarcoidosis, and women with sarcoidosis who become pregnant usually improve during pregnancy. However, the disease may flare post partum; presumably this variation results from fluctuations in endogenous glucocorticoid production.

Exocrine Glands Parotid enlargement is a classic feature of sarcoidosis, but clinically apparent parotid involvement occurs in <10% of patients. Bilateral involvement is the rule. The gland is usually nontender, firm, and smooth. Xerostomia can occur; other exocrine glands are affected only rarely.

Gastrointestinal Tract Although sarcoidosis involvement of the gastrointestinal tract is found occasionally at autopsy, it rarely has clinical importance. Occasionally, patients have esophageal or gastric symptoms. Rarely, the peritoneum is involved with accompanying ascites.

Sarcoid can present as an isolated pancreatic lesion mimicking pancreatic carcinoma.

COMPLICATIONS The respiratory tract abnormalities cause most of the morbidity and mortality associated with sarcoidosis. The major problems are those characteristic of interstitial lung disease (Chap. 243), particularly dyspnea and insufficient oxygen delivery to vital organs. Respiratory failure with carbon dioxide retention is rare. In some patients, lung destruction results in formation of bullae that may harbor mycetomas, which are usually aspergillomas; erosion into the parenchyma can result in massive bleeding. The most common complications apart from the lung are associated with the eye; however, with therapy, blindness is rare. Complications of other organs include a gamut of abnormalities. The most serious are central nervous system (CNS) lesions or cardiac involvement leading to congestive heart failure or sudden death.

LABORATORY ABNORMALITIES Common abnormalities in the blood include lymphocytopenia, an occasional mild eosinophilia, an increased erythrocyte sedimentation rate, hyperglobulinemia, and an elevated level of angiotensin-converting enzyme (ACE). False-positive tests for rheumatoid factor or antinuclear antibodies can be observed. Hypercalcemia is rare. Other serum abnormalities relate to involvement of specific organs such as liver, kidney, or endocrine glands.

Because the lung is involved so commonly, the routine chest film is almost always abnormal (Fig. 309-3*A*). The three classic x-ray patterns of pulmonary sarcoidosis are type I—bilateral hilar adenopathy with no parenchymal abnormalities; type II—bilateral hilar adenopathy with diffuse parenchymal changes; and type III—diffuse parenchymal changes without hilar adenopathy. The type III pattern is sometimes split into two categories, with films that show fibrosis and upper lobe retraction classified separately. Although patients with type I x-ray patterns tend to have the acute or subacute, reversible form of the disease while those with types II and III often have the chronic, progressive disease, these patterns do not represent consecutive "stages" of sarcoidosis. Thus, except for epidemiologic purposes, this x-ray categorization is mostly of historic interest. The hilar adenopathy is almost always bilateral, but unilateral node enlargement can be seen. Nodes are also common in the paratracheal region. The diffuse parenchymal changes are typically reticulonodular infiltrates, but an acinar pattern is observed occasionally. Large nodules, similar to those of metastatic disease, are unusual but can occur. When there is massive fibrosis, the hila are pulled upward and there are conglomerate masses in the midlung zones. Some of the unusual chest x-ray findings in sarcoidosis include "egg shell" calcification of hilar nodes, pleural effusions, cavitation, atelectasis, pulmonary hypertension, pneumothorax, and cardiomegaly. Computed tomography of the chest is rarely helpful for either diagnosis or prognosis but can identify early fibrosis. A "ground-glass" appearance is often associated with an active alveolitis but more likely results from the granulomas.

The lung function abnormalities of sarcoidosis are typical for interstitial lung disease (Chap. 243) and include decreased lung volumes and diffusing capacity with a normal or supernormal ratio of the forced expiratory volume in 1 s to the forced vital capacity. Occasionally there is evidence of airflow limitation. There is usually mild hypoxemia and a mild, compensated hypocarbia.

The gallium-67 lung scan is usually abnormal, showing a pattern of diffuse uptake. If present, enlarged nodes are detected in these scans, as is inflammation in a variety of extrathoracic sites that usually have no clinical importance (Fig. 309-3*B*). Bronchoalveolar lavage typically demonstrates an increased proportion of lymphocytes, most of which are members of the activated T_H1 subset of CD4+ T lymphocytes (Fig. 309-3*C*). The remaining cells are mostly alveolar macrophages. In patients with significant fibrosis, a few neutrophils are also found. Eosinophils are rare.

The other laboratory features of sarcoidosis depend on the specific organ involved.

DIAGNOSIS For a typical case, the diagnosis of sarcoidosis is made by a combination of clinical, radiographic, and histologic findings (Fig. 309-5*A*). In a young adult with constitutional complaints, respiratory symptoms, erythema nodosum, blurred vision, and bilateral hilar adenopathy, the diagnosis is almost always sarcoidosis. Commonly, however, the findings are more subtle. Because sarcoidosis can occur in almost any place in the body, like tuberculosis or syphilis, it can be confused with many other disorders. In this context, the differential diagnosis of sarcoidosis must cover a wide range. However, it is confused most commonly with neoplastic diseases such as lymphoma or with disorders also characterized by a mononuclear cell granulomatous inflammatory process, such as the mycobacterial and fungal disorders.

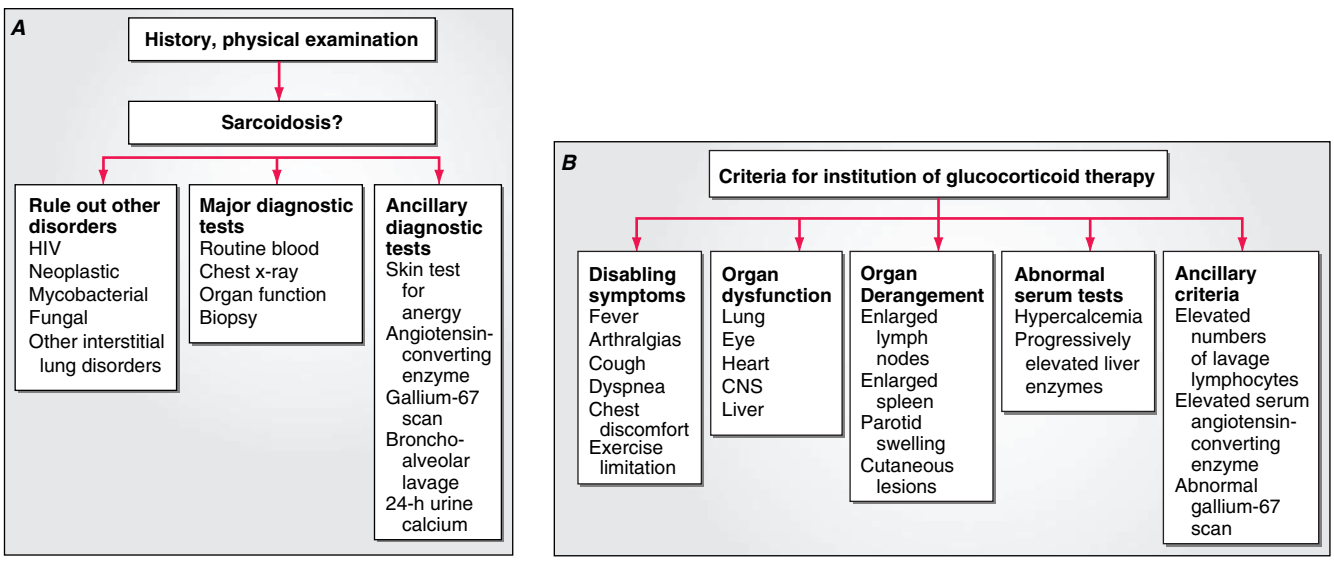

FIGURE 309-5 Diagnostic and therapeutic algorithms relevant to sarcoidosis. *A*. Diagnosis of sarcoidosis. If the history and physical examination suggest sarcoidosis, the diagnosis is made by a combination of history, physical examination, and diagnostic test. No tests are definitive for sarcoidosis; the diagnosis is made by a combination of findings. The major diagnostic tests carry the most weight, with biopsy and histologic assessment of the relevant organ the most important. Assessment of function of the organ systems that appear to be affected help with diagnosis and decisions about therapy. *B*. Therapy of sarcoidosis. Once the definitive diagnosis is made, the decision to not treat or to institute treatment with glucocorticoids is based on the presence or absence of disabling symptoms, organ dysfunction, organ derangement, and results of various tests of disease activity. Any organ can be threatened by sarcoidosis, but lung, eye, heart, liver, and central nervous system are at greatest risk. The disease can wax and wane, and periodic assessments at 3- to 6-month intervals are used to reevaluate decisions regarding therapy.

The presence of skin anergy is typical but not diagnostic of sarcoidosis. Individuals with sarcoidosis who develop active tuberculosis react strongly to skin tests with purified protein derivative. The Kveim-Siltzbach skin test, the intradermal injection of a heat-treated suspension of a sarcoidosis spleen extract which is biopsied 4 to 6 weeks later, yields sarcoidosis-like lesions in 70 to 80% of individuals with sarcoidosis, with <5% false-positive results. The Kveim-Siltzbach material is no longer available, and with the use of the transbronchial biopsy to obtain lung parenchyma for diagnostic purposes, the Kveim-Siltzbach test is only of historic interest.

No blood findings are diagnostic of the disease. Serum levels of ACE are elevated in approximately two-thirds of patients with sarcoidosis. Approximately 5% of all positive tests are not sarcoidosis and are seen in a variety of disorders, including asbestosis, silicosis, berylliosis, fungal infection, granulomatous hepatitis, hypersensitivity pneumonitis, leprosy, lymphoma, and tuberculosis. Hypercalcemia or an elevated 24-h urine calcium level is consistent with the diagnosis but is not specific.

The chest x-ray cannot be used as the sole criterion for the diagnosis of sarcoidosis. While the finding of bilateral hilar adenopathy is the hallmark of this disease, a similar pattern is occasionally observed in lymphoma, tuberculosis, coccidioidomycosis, brucellosis, and bronchogenic carcinoma.

The pattern of the gallium-67 scan is not diagnostic for sarcoidosis, nor is the finding of an increased proportion of lymphocytes among the cells recovered by bronchoalveolar lavage. However, the typical patterns of these tests (Fig. 309-3*B* and *C*) put the diagnosis in the general category of granulomatous lung disorders.

Whether or not the presentation is "classic," biopsy evidence of a mononuclear cell granulomatous inflammatory process is mandatory to make a definitive diagnosis of sarcoidosis. Because the lung is involved so frequently, it is the most common site to be biopsied, usually through a fiberoptic bronchoscope. Less common, but acceptable, sites for biopsy are the hilar nodes (by mediastinoscopy), the skin, conjunctiva, or lip. Rarely, the spleen, intraabdominal nodes, muscle, parotid or other salivary glands, upper respiratory tract, or the heart is biopsied for diagnostic purposes. At any of these sites, the findings must include the typical noncaseating granulomas. However, although histologic evidence is mandatory for a definitive diagnosis of sarcoidosis, the histologic findings are not sufficiently specific to make the diagnosis by themselves, since noncaseating granulomas are found in a number of other diseases, including infections and malignancy. Furthermore, although the liver or scalene nodes often reveal "positive" biopsies in cases of sarcoidosis, noncaseating granulomas from other causes are so frequent in these sites that they are not considered acceptable sites for establishing the diagnosis. Thus the definitive diagnosis of sarcoidosis is based on the biopsy in the context of the history, physical examination, blood tests, x-ray, lung function, and, if available, gallium-67 scan and bronchoalveolar lavage. Patients with HIV infection commonly have lymphocytopenia, chest x-ray abnormalities, positive gallium-67 chest scans, and increased proportions of lavage lymphocytes (early in the course of the disease), and they can have lung granulomas; thus, serologic testing for HIV infection should always be done in individuals suspected of having sarcoidosis.

PROGNOSIS Overall, the prognosis in sarcoidosis is good. Most individuals who present with the acute disease are left with no significant sequelae. Approximately half of all patients have some permanent organ dysfunction, but for most this is mild, stable, and progresses rarely. In ~15 to 20% of patients, the disease remains active or recurs intermittently. Death is attributable directly to the disease in ~10% of all those affected.

TREATMENT

The therapy of choice for sarcoidosis is glucocorticoids (Fig. 309-5*B*). Methotrexate is usually the second-line medication. Various other drugs have been used in refractory cases, including indomethacin, oxyphenbutazone, chloroquine, hydroxychloroquine, thalidomide, infliximab, etanercept, pentoxifylline, tacrolimus, *p*-aminobenzoate, allopurinol, levamisole, azothioprine, and cyclophosphamide; but there is no evidence, apart from anecdotal, uncontrolled reports, to support their efficacy. Cyclosporine is ineffective for the pulmonary manifestations of the disease; anecdotal reports suggest that it may be useful in extrathoracic sarcoid not responding to glucocorticoids.

The major problem in treating sarcoidosis is in deciding when to treat. Because the disease clears spontaneously in ~50% of patients, and because the permanent organ derangements often do not improve with glucocorticoid treatment, there is controversy among clinicians as to the criteria for treatment. However, there is no question that glucocorticoids effectively suppress the activated T_H1 lymphocyte processes occurring at the sites of disease. Thus, the major problem in making decisions concerning therapy in sarcoidosis is to determine the extent and activity of the inflammatory process in the organs at greatest risk, such as the lung, eye, heart, and CNS.

For the lung, this is based on a combination of history, physical findings, chest x-ray, and pulmonary function tests. Centers that see large numbers of these individuals sometimes use criteria based on gallium-67 lung scans and bronchoalveolar lavage findings to help define active disease. Computed tomography is not usually helpful in treatment decisions. The serum level of ACE has been suggested as a criterion for disease activity, but it is not specific for the lung. Unless the respiratory impairment is devastating, active pulmonary sarcoidosis is observed usually without therapy for 2 to 3 months; if the inflammation does not subside spontaneously, therapy is instituted. For the eye, decisions concerning therapy are based on slit-lamp examination and tests for visual acuity. For the heart and CNS, decisions are based on an estimate of the severity of the involvement; patients with minor dysfunction are usually observed, while patients with significant cardiac or neurologic abnormalities are treated. Usually, it is not necessary to treat the systemic symptoms, but occasionally the extent of the fevers, fatigue, and/or weight loss necessitate therapy.

The usual therapy for sarcoidosis is prednisone, 1 mg/kg, for 4 to 6 weeks, followed by a slow taper over 2 to 3 months. This regimen is repeated if the disease again becomes active. Alternate-day therapy is used by some clinicians, but there is no evidence that it is as effective. High-dose bolus intravenous glucocorticoids are used occasionally but are probably not as effective as oral therapy. There is no evidence that inhaled glucocorticoids are efficacious. Mild ocular disease responds usually to local therapy, but suppression of the uveitis often requires systemic glucocorticoids. Methotrexate, 5 to 15 mg/week in a single oral dose, is often used when glucocorticoids are contraindicated or in refractory cases, but there is a cumulative risk for side effects, paricularly hepatotoxicity. There is often a 6-month time lag before improvement is seen with methotrexate. Lung transplant, usually unilateral, is reserved for end-stage disease. The presence of mycetomas is usually a contraindication for transplant. There is a 30 to 80% incidence of recurrence of sarcoid in the transplanted lung, but it is rarely significant.

310 AMYLOIDOSIS

Jean D. Sipe, Alan S. Cohen

DEFINITION AND CLASSIFICATION *Amyloidosis* results from a sequence of changes in protein folding that leads to the deposition of insoluble amyloid fibrils, mainly in the extracellular spaces of organs and tissues. Depending upon the biochemical nature of the amyloid precursor protein, amyloid fibrils can be deposited locally or may involve virtually every organ system of the body. Amyloid fibril deposition may have no apparent clinical consequences or may be associated with severe pathophysiologic changes. Named by Virchow in 1854 on the basis of color after staining with iodine and sulfuric acid, all amyloid fibrils share an identical secondary structure, the β-pleated sheet conformation, and a unique ultrastructure. All amyloid deposits contain the pentraxin serum amyloid P (SAP) and glycosaminoglycans. Abnormal protein folding and assembly can also result in protein deposition (e.g., in brain or kidney) that lacks the classic fibrillar morphology of amyloid and the presence of SAP.

The amyloidoses are classified according to the identity of the fibril-forming protein (Table 310-1). *Systemic amyloidoses* are neoplastic, inflammatory, genetic, or iatrogenic in origin, while *localized amyloidoses* or *organ-limited amyloidoses* are associated with aging and diabetes and occur in isolated organs without evidence of systemic involvement.

Despite their biochemical and clinical differences, the various amyloidoses share common pathophysiologic features: (1) an amyloidogenic precursor in appropriate concentration; (2) appropriate host genetic background; (3) abnormalities in proteolysis of fibril precursors and nascent amyloid fibrils; and (4) alterations in extracellular matrix constituents such as glycosaminoglycans and Apo E. The guidelines for nomenclature and classification of amyloid and amyloidosis were updated in 2001 by the Nomenclature Committee of the International Society of Amyloidosis (Table 310-1). Amyloid deposits should be classified using the capital letter A as the first letter of designation followed by the protein designation without any open space; for example, AL for amyloidosis involving immunoglobulin light chains.

TABLE 310-1 *Amyloid Fibril Proteins and Their Precursors*

Amyloid Protein	Precursor	Systemic (S) or Localized (L)	Syndrome or Involved Tissues
AL	Immunoglobulin light chain	S, L	Primary Myeloma-associated
AH	Immunoglobulin heavy chain	S, L	Primary Myeloma-associated
ATTR	Transthyretin	S	Familial Senile systemic
		L?	Tenosynovium
Aβ_2M	β_2-microglobulin	S	Hemodialysis
		L?	Joints
AA	(Apo)serum AA	S	Secondary, reactive
AApoAI	Apolipoprotein AI	S	Familial
		L	Aortic
AApoAII	Apolipoprotein AII	S	Familial
AGel	Gelsolin	S	Familial
ALys	Lysozyme	S	Familial
AFib	Fibrinogen α-chain	S	Familial
ACys	Cystatin C	S	Familial
ABri[a]	ABriPP	L, S?	Familial dementia, British
ADan[a]	*ADanPP*	*L*	*Familial dementia, Danish*
Aβ	Aβ protein precursor (AβPP)	L	Alzheimer's disease, aging
APrP	Prion protein	L	Spongiform encephalopathies
ACal	(Pro)calcitonin	L	C-cell thyroid tumors
AIAPP	Islet amyloid polypeptide	L	Islets of Langerhans Insulinomas
AANF	Atrial natriuretic factor	L	Cardiac atria
APro	Prolactin	L	Aging pituitary Prolactinomas
AIns	Insulin	L	Iatrogenic
AMed	Lactadherin	L	Senile aortic, media
AKer	Kerato-epithelin	L	Cornea; familial
A(tbn)[b]	*tbn*[b]	*L*	*Pindborg tumors*
ALac	*Lactoferrin*	*L*	*Cornea; familial*

[a] ADan is coming from the same gene as ABri and has identical N-terminal sequence. It will be a matter of further discussion whether ADan should be included in the nomenclature as a separate protein (see text)
[b] To be named.
Note: Proteins in italics are preliminary.

ETIOLOGY AND PATHOGENESIS OF THE SYSTEMIC AMYLOIDOSES

Light Chain Amyloidosis (AL) The most common form of systemic amyloidosis seen in current clinical practice is AL (primary idiopathic amyloidosis, or that associated with multiple myeloma) resulting from fibril formation by fragments of monoclonal antibody light chains in primary amyloidosis and in some cases of multiple myeloma (Chap. 98). Fewer than 20% of patients with AL have myeloma. The rest have other monoclonal gammopathies, light chain disease, or even agammaglobulinemia (producing light chains, but not intact immunoglobulin). About 15 to 20% of patients with myeloma have amyloidosis. A monoclonal population of bone marrow plasma cells is present and consistently produces either small lambda or kappa fragments or immunoglobulins that are processed (cleaved) in an abnormal fashion by macrophage enzymes to produce the partially degraded light chains responsible for AL amyloidosis. Lambda chain class predominates over kappa in AL by a 2:1 ratio, whereas in multiple myeloma and normal immunoglobulin synthesis, the reverse is true. Indeed, almost all lambda VI family chains have been associated with amyloid. The primary structure of each amyloid-forming light chain is unique, reflecting the features of the B cell clone that produced it. Also, nonfibrillar deposition diseases have been described. There are three forms of human light chain–associated renal and systemic diseases: AL amyloidosis, cast nephropathy, and light chain deposition disease. Rarely, heavy chain amyloid deposition (AH) has been reported.

Amyloid A Amyloidosis (AA) AA amyloidosis (secondary, reactive, or acquired amyloidosis) occurs most frequently as a complication of chronic inflammatory disease. Effective treatment of the underlying inflammatory condition has reduced incidence in developed countries. In the past in the United States, tuberculosis (Chap. 150), osteomyelitis (Chap. 111), and leprosy (Chap. 151) were the most common precipitating diseases, and they remain so in developing countries. During inflammation, the cytokines interleukin (IL) 1, IL-6, and tumor necrosis factor (TNF) stimulate hepatic synthesis of serum amyloid A, the AA fibril precursor. Thus, effective treatment of the underlying inflammatory disorder blocks the stimulus for precursor synthesis. Familial deposition of the AA protein occurs in patients with the hereditary periodic fever syndromes familial Mediterranean fever (FMF), TNF receptor–associated periodic syndrome (TRAPS), Muckle-Wells syndrome (MWS), and familial cold uticaria (FCU) (Chap. 279). Colchicine treatment effectively blocks attacks of FMF and reduces the incidence of AA amyloidosis in association with FMF. FMF is an autosomal recessive disorder subdivided into phenotype I, with irregularly occurring fever and abdominal, chest, or joint pain, preceding or accompanying renal amyloid; and phenotype

II, in which renal amyloidosis is the first or only manifestation of the disease (Chap. 279). FMF is caused by mutations (17 identified to date) in the gene designated *MEFV* that encodes a 781-amino-acid protein named *pyrin* that appears to be a transcription factor. There is a strong correlation between the M694V mutation in MEFV and development of amyloidosis. TRAPS is an autosomal dominant disorder characterized by mutations in the TNF receptor that lead to defective shedding of the receptor and thus an impediment to the return to homeostasis. Remarkably, AA amyloidosis is not seen as a complication of the hyper IgD periodic fever syndrome (HIDS) that is associated with mutations in the mevalonate kinase gene.

Heredofamilial Amyloidoses There are a number of types of familial amyloidosis that are dominantly transmitted in association with a mutation that enhances protein misfolding and fibril formation. The protein precursors and the amyloidoses are: transthyretin (ATTR), apolipoprotein AI (AApoAI), apolipoprotein AII (AApoAII), cystatin C (ACys), gelsolin (AGel), fibrinogen alpha chain (AFib), and lysozyme (ALys). The mutant proteins, although present from birth, are associated with a delayed onset of disease symptoms, usually after three to seven decades of life. The familial amyloidoses present as neuropathy, nephropathy, cardiomyopathy, hepatomegaly, visceral pathology, lattice corneal dystrophy, and dementia. The familial amyloidoses are less commonly seen in clinical practice than AL amyloidosis, but the overlap in clinical symptoms and organ involvement makes the chemical identification of the fibril-forming protein imperative.

ATTR The most frequently occurring form of familial amyloidosis involves transthyretin (TTR), a 14-kDa protein originally described as prealbumin, that transports thyroxine and retinol-binding protein in the blood. The first mutation to be identified in Portuguese families and in families of Swedish origin was a single amino acid substitution, methionine for valine at position 30 (V30M). To date, more than 80 TTR variants have been defined, most of which are amyloidogenic. Variant TTR gene carriers exhibit clinically heterogeneous amyloidoses according to the nature of the amino acid substitution. Patients with the V30M mutation are symptomatic in the third to fifth decades of life with progressive polyneuropathy, postural hypotension, and little myocardial infiltration. Patients with the T60A mutation are symptomatic at an older age than V30M patients and exhibit peripheral and autonomic peripheral neuropathies and progressive myocardial amyloid infiltration. Nearly 4% of the African-American population carries the V122I allele that is associated with infiltrative cardiomyopathy and carpal tunnel syndrome. The disease is late in onset, and recognition requires a high degree of clinical suspicion.

AApoAI Deposition of apolipoprotein AI variants (G26R, W50R, L60R, L75P, L90P, L174S, and deletion mutations) can be associated with peripheral neuropathy that is clinically similar to the type of familial amyloidosis that is caused by variants of TTR. In some kindreds, the clinical presentation is kidney or liver failure without neurologic symptoms.

AApoAII A variant of apolipoprotein AII with an extension of the coding region that results in a 25% larger molecule than the wild-type protein is associated with a familial amyloidosis with involvement of kidney glomeruli.

AGel Two mutations, D187N and D187Y, within the actin-binding region of gelsolin lead to deposition of a 71-residue fragment encompassing the mutation in blood vessels and basement membrane. AGel has been reported primarily in Finland, but also in Denmark, Japan, the Netherlands, and the United States. Clinical manifestations of lattice corneal dystrophy and cranial neuropathy are followed by peripheral neuropathy, dystrophic skin changes, and involvement of other organs.

ALys Hereditary nonneuropathic systemic amyloidosis has been described in English and French families in which lysozyme is the major fibril protein. Three mutations have been described—I56T, W64R, and D67H. Clinical manifestations include visceral involvement and, in some kindreds, nephropathy.

AFib Hereditary nonneuropathic renal amyloidosis has been described in families with one of three mutations in the fibrinogen A α chains, R524L, E526V, or R554L.

Aβ_2M In long-term hemodialysis, amyloidosis is now well recognized as a serious bone and joint complication. β_2-microglobulin is the major constituent of the amyloid fibrils, and formation of advanced glycation end products of β_2-microglobulin has been implicated in the pathogenesis of Aβ_2M.

ETIOLOGY AND PATHOGENESIS OF THE LOCALIZED AMYLOIDOSES ■ Polypeptide Hormone–Derived Amyloidosis Amyloid deposits are common in polypeptide hormone–producing tissues and tumors. Calcitonin is deposited in the hereditary amyloid syndrome, medullary carcinoma of the thyroid (ACal) (Chap. 320). Prolactin is commonly deposited in the aging pituitary (APro). In AIAPP, islet amyloid polypeptide, also referred to as amylin, is deposited as amyloid fibrils in 90% of individuals with type 2 diabetes (Chap. 323), in endocrine tumors (Chap. 329), and in insulinoma (Chap. 329). AIAPP is thought to play an important role in the beta cell failure associated with type 2 diabetes. Human insulin does not naturally form amyloid fibrils, although fibrils of porcine insulin, AIns, are sometimes found as subcutaneous nodules at sites of insulin injection in diabetic individuals. The form of amyloid that occurs in Pindborg tumors, odontogenic tumors, has been identified as a fragment of a protein of unknown function (FLJ20513) and is thus designated as an amyloid to be named *A*(*tbn*) (Table 310-1).

Localized Corneal Amyloid AKer (kerato-epithelin) is deposited as a corneal amyloid fibril protein in association with mutations in the *BIGH3* gene. Lactoferrin, without significant size truncation, is apparently deposited as corneal amyloid with trichiasis.

Localized Cardiovascular Amyloid Localized deposits of AApoAI in atheromatous plaques, AMed (derived from medin, a fragment of aortic smooth muscle cell–derived lactoadherin) in the aortic media and AANF (atrial natriuretic factor–derived amyloid) in cardiac atria, were initially thought to be clinically insignificant but are now being viewed as potentially pathogenic.

Amyloidosis Associated with Alzheimer's Disease A novel protein, β-amyloid protein (Aβ), is the major fibril protein in the amyloid deposits of the cerebrovascular walls and the cores of the neuritic plaques of Alzheimer's disease (AD) patients and also in individuals with Down's syndrome (Chap. 57). The intracellular neurofibrillary tangles (ATau) are composed of paired helical filaments arranged in a twisted conformation and have as their major component an abnormally phosphorylated τ-protein, a microtubule-associated protein. Aβ varies in length from 39 to 43 amino acids and is derived from a large transmembrane glycoprotein called amyloid β-precursor protein (AβPP). Mutations in AβPP are associated with familial AD and also with a different type of amyloidosis, hereditary cerebral hemorrhage with amyloidosis (Dutch type). Other forms of familial AD are associated with mutations in genes that encode presenilin proteins. Familial dementias have also been found to be associated with deposition of a newly characterized amyloid fibril protein in families of British and Danish origin (Table 310-1). The 40-amino-acid residue fibril protein is composed of the 22 C-terminal amino acids of the wild-type protein and a 12-amino-acid extension that is due to a mutation in the stop codon.

Prion Diseases Prions are a unique class of infectious proteins associated with a group of neurodegenerative diseases, the transmissible spongiform encephalopathies. In humans, these diseases include kuru, Creutzfeldt-Jakob disease, Gerstmann-Straussler-Scheinker syndrome, and fatal familial insomnia (Chap. 363); in animals, scrapie and bovine spongiform encephalopathy (mad cow disease). PrP^{Sc} is a pathogenic, transmissible spongiform encephalopathy–specific form of the host-encoded prion protein (PrP); PrP^{Sc} differs from PrP in that it contains a high amount of β-pleated sheet structure and is insoluble and resis-

tant to proteolytic enzymes. PrP^{Sc} deposits either consist of or can be readily converted to amyloid fibrils. APrP is similar to Aβ and ATTR in that both familial and sporadic forms occur. In addition, infectious prion diseases have resulted from the transmission of PrP^{Sc} by ritualistic cannibalism, corneal transplantation, treatment with cadaveric human growth hormone, and a variety of neurosurgical procedures. It has been suggested that the earlier onset familial forms of amyloidosis are due to accelerated fibril formation from mutant precursors, whereas in sporadic cases, amyloid fibrils are formed more slowly from normal precursor molecules. The mutant PrP molecules are nearer the thermodynamic threshold for transition to the amyloidogenic PrP^{Sc} conformation than are the normal. The transition from normal to amyloidogenic PrP^{Sc} is essentially irreversible but very slow. The disease progresses because, once formed, amyloidogenic PrP^{Sc} can seed the conversion of normal molecules into an amyloidogenic form.

Localized Deposition of Systemic Amyloid Proteins The AL and ATTR forms of amyloidosis are usually systemic but are also observed in localized deposits. For example, AL is found in skin, lung, and other sites of the body. Cardiac amyloidosis involving wild-type TTR is considered to be localized but in some cases also to have a systemic component with predominant cardiac involvement, i.e., senile systemic amyloidosis.

CLINICAL MANIFESTATIONS The clinical manifestations of amyloidosis are varied and depend entirely on the biochemical nature of the fibril protein (Table 310-2). Proteinuria is often the first symptom associated with systemic amyloidosis, particularly of the AA and AL type; peripheral neuropathies are associated with familial amyloidoses, and dementia and cognitive dysfunction with amyloid deposits in brain. Organ enlargement, especially of the liver, kidney, spleen, and heart, may be prominent in the case of AL and AA amyloidosis; however, this does not occur in familial amyloidosis, AD, or PrP diseases.

Kidney Renal involvement may consist of mild proteinuria or frank nephrosis (Chaps. 40 and 261). In some cases, the urinary sediment may show a few red blood cells. The renal lesion is usually not reversible and in time leads to progressive azotemia and death. The prognosis does not appear to be related to the degree of the proteinuria; when azotemia finally develops, the prognosis is grave. Treatment by peritoneal dialysis or hemodialysis or kidney transplantation improves the prognosis considerably (Chaps. 262 and 263). Hypertension is rare, except in long-standing amyloidosis. Renal tubular acidosis or renal vein thrombosis may occur. Localized accumulation of amyloid may be noted in the ureter, bladder, or other parts of the genitourinary tract.

TABLE 310-2 *Clinical Presentation of Systemic Amyloidosis*

Disease	*Symptoms*
AL (primary)	Monoclonal immunoglobulin in urine or serum plus any of the following: Unexplained nephrotic syndrome Hepatomegaly Carpal tunnel syndrome Macroglossia Malabsorption or unexplained diarrhea or constipation Peripheral neuropathy Cardiomyopathy
AA (secondary)	Chronic infection (osteomyelitis, tuberculosis) or chronic inflammation (rheumatoid arthritis, granulomatous ileitis) plus development of any of the following: Proteinuria Hepatomegaly Unexplained gastrointestinal disease
Hereditary amyloidosis	Family history of neuropathy plus any of the following: Early sensorimotor disassociation Vitreous opacities Renal disease Autonomic nervous system symptoms Cardiovascular disease Gastrointestinal disease No family history of neuropathy but Idiopathic cardiomyopathy Idiopathic renal disease

Heart Cardiac amyloidosis can present as intractable heart failure (Chap. 216). Electrocardiographic abnormalities include a low-voltage QRS complex and abnormalities in atrioventricular and intraventricular conduction, often resulting in varying degrees of heart block (Chap. 210). Owing to their propensity to develop conduction defects and arrhythmias, patients with cardiac amyloidosis appear to be especially sensitive to digitalis, and this drug should be used with caution.

With respect to systemic amyloidoses, cardiac amyloidosis is common in primary (AL) and heredofamilial amyloidosis and very rare in the secondary (AA) form. With respect to localized amyloidosis, cardiac amyloidosis of the wild type or nonvariant TTR type is common after 80 years of age; also AANF may be present in the atria and AMed in the aortic media. In systemic amyloidosis, cardiac manifestations consist primarily of congestive failure and cardiomegaly (with or without murmurs) and a variety of arrhythmias and are comparable in AL and the familial amyloidoses, the predominant forms with cardiomyopathy (Chap. 221). Although these manifestations predominantly reflect diffuse myocardial amyloid, the endocardium, valves, and pericardium may also be involved. Pericarditis with effusion is rare, although the differential diagnosis of constrictive pericarditis versus restrictive cardiomyopathy frequently arises. Echocardiography has demonstrated symmetric thickening of the left ventricular wall, hypokinesia and decreased systolic contraction and thickening of the interventricular septum and left ventricular posterior wall, and left ventricular cavities of small to normal size (Chap. 211). Two-dimensional echocardiography produces the characteristic findings of thickened right and left ventricles, a normal left ventricular cavity, and, especially, a diffuse hyperrefractile "granular sparkling" appearance. Hearts that are heavily infiltrated with amyloid may or may not show an enlarged silhouette. Fluoroscopy usually shows decreased mobility of the ventricular wall; angiographic studies usually demonstrate thickened ventricular wall, decreased ventricular mobility, and absence of rapid ventricular filling in early diastole.

Liver While hepatic involvement is common except in heredofamilial amyloidosis of the TTR type, liver function abnormalities are minimal and occur late in the disease (Chap. 290). Portal hypertension occurs but is uncommon. Intrahepatic cholestasis has been noted in about 5% of patients with AL (primary) amyloidosis. Hepatomegaly is common, and AL hepatic amyloid is usually accompanied by the nephrotic syndrome and congestive heart failure with poor prognosis. Amyloidosis of the spleen characteristically is not associated with leukopenia and anemia.

Skin Involvement of the skin is one of the most characteristic manifestations of primary (AL) amyloidosis (Chap. 48). Other forms of amyloidosis such as lichen amyloidosis are thought to involve forms of keratin. In AL amyloidosis, the usually nonpruritic lesions may consist of slightly raised, waxy papules or plaques that are usually clustered in the folds of the axillae, anal, or inguinal regions; the face and neck; or mucosal areas such as ear or tongue. Periorbital ecchymoses ("black eye" or "raccoon syndrome") have been reported.

Gastrointestinal Tract Gastrointestinal symptoms are common in all systemic types of amyloidosis either from direct involvement of the gastrointestinal tract at any level or from infiltration of the autonomic nervous system with amyloid (Chap. 271). Symptoms include obstruction, ulceration, malabsorption, hemorrhage, protein loss, and diarrhea (Chap. 275). Infiltration of the tongue is characteristic of primary amyloidosis (AL) or amyloidosis accompanying multiple myeloma and occasionally leads to macroglossia. When not enlarged, the tongue

may become stiffened and firm to palpation. Gastrointestinal bleeding may occur from any of a number of sites, notably the esophagus, stomach, or large intestine, and may be severe. Amyloid infiltration of the esophagus may lead to an incompetent or nonrelaxing lower esophageal sphincter, nonspecific motility disorders of the esophageal body, or rarely achalasia. Small-bowel lesions may lead to clinical and x-ray changes of obstruction. A malabsorption syndrome is common. Amyloidosis (AA or secondary) may also develop in association with other entities involving the gastrointestinal tract, especially tuberculosis (Chap. 150), granulomatous enteritis (Chap. 276), lymphoma (Chap. 97), and Whipple's disease (Chap. 275); differentiation of these conditions, which give rise to secondary amyloidosis, from diffuse primary amyloidosis of the small bowel may be difficult. Similarly, amyloidosis of the stomach may closely mimic gastric carcinoma, with obstruction, achlorhydria, and the radiologic appearance of tumor masses.

Nervous System Neurologic manifestations, especially prominent in the heredofamilial amyloidoses, may include peripheral neuropathy, postural hypotension, inability to sweat, Adies's pupil, hoarseness, and sphincter incompetence (Chaps. 22 and 364). The cranial nerves are generally spared, except in the Finnish hereditary amyloidosis (AGel). Carpal tunnel syndrome may be caused by several amyloidoses, especially primary (AL) and chronic hemodialysis ($A\beta_2M$) amyloid. Peripheral neuropathy is frequent in the former type. $A\beta$ amyloid occurs in the central nervous system as a component of senile plaques and in blood vessels ("congophilic angiopathy") (Chap. 351). The protein concentration in the cerebrospinal fluid may be increased. Infiltrates of the cornea or vitreous body may be present in hereditary amyloid syndromes and give rise to a bilateral scalloping appearance of the pupil.

Endocrine Amyloid may infiltrate the thyroid or other endocrine glands but rarely causes endocrine dysfunction. Local amyloid deposits almost invariably accompany medullary carcinoma of the thyroid (Chap. 320). Amyloid is often found in the adrenal gland, pituitary gland, and pancreas. Pancreatic islet amyloid as a complication of type 2 diabetes is especially prominent and is caused by the islet amyloid polypeptide (IAPP, amylin). Clinical dysfunction is present when there is significant replacement of the gland by amyloid (Chap. 323).

Joints and Muscles Amyloid can directly, although rarely, involve articular structures by its presence in the synovial membrane and synovial fluid or in the articular cartilage. In these cases it is almost always of the AL type and associated with multiple myeloma (Chap. 98). Amyloid arthritis can mimic a number of the rheumatic diseases because it can present as a symmetric arthritis of small joints with nodules, morning stiffness, and fatigue (Chap. 311). The synovial fluid usually has a low white blood cell count, a good to fair mucin clot, a predominance of mononuclear cells, and no crystals. Studies of surgical specimens suggest a significant incidence of amyloid in cartilage, capsule, and synovium in osteoarthritis (Chap. 312). Amyloid infiltration of muscle may lead to a pseudomyopathy. Shoulder muscle infiltration can produce the "shoulder pad" sign. Amyloid is found in muscle inclusion body disease, where $A\beta$ and/or PrP have been identified.

Deposition of β_2-microglobulin as amyloid fibrils in the musculoskeletal systems is a serious complication of long-term hemodialysis. $A\beta_2M$ presents as the carpal tunnel syndrome, cystic bone lesions, and even destructive spondyloarthropathy. Carpal tunnel syndrome is also associated with AL and ATTR (Chap. 262).

Respiratory System The nasal sinuses, larynx, and trachea may be involved by accumulation of AL amyloid, which blocks the ducts, in the case of the sinuses, or the air passages. Amyloidosis of the lung

TABLE 310-4 *Symptoms, Diagnosis, and Treatment of Systemic Amyloidosis*

AL (Primary)	*AA (Secondary)*	*Familial Amyloidosis*
SYMPTOMS		
Unexplained nephropathy, cardiomyopathy, neuropathy Hepatomegaly syndrome Macroglossia Malabsorption or unexplained diarrhea or constipation Any of the above *plus* monoclonal immunoglobulin in urine	Proteinuria Hepatomegaly and/or splenomegaly *plus* Chronic infection (osteomyelitis, tuberculosis) or chronic inflammation (rheumatoid arthritis, granulomatous ileitis)	Family history of peripheral neuropathy, nephropathy *plus* any of following: Carpal tunnel syndrome Vitreous opacities Renal disease Autonomic nervous system symptoms Cardiovascular disease Gastrointestinal disease Sensorimotor disassociation
LABORATORY DIAGNOSIS		
Serum, urine immunofixation electrophoresis Bone marrow biopsy with kappa and lambda light chain immunohistochemistry	Elevated serum amyloid A (SAA) Positive immunohistochemical staining for AA protein in tissue specimen	Identification of protein variant in serum DNA-based test for mutant gene
TREATMENT OPTIONS		
Depending upon cardiac involvement or stage of disease Cyclic oral melphalan and prednisolone High dose IV melphalan with stem cell rescue	Aggressive treatment underlying inflammatory condition (monitor SAA) Surgical excision infection (bone resection, cholecystectemy) Colchicine for prevention and treatment of AA amyloidosis in FMF	Organ transplantation (liver) (ATTR)

Note: FMF, familial Mediterranean fever.

involves the bronchi and alveolar septa diffusely. The lower respiratory tract is affected most frequently in primary (AL) amyloidosis and in the disease associated with dysproteinemia. Pulmonary symptoms attributable to amyloid are present in about 30% of cases. Amyloid may be localized in the bronchi or pulmonary parenchyma and may resemble a neoplasm. In these cases, local excision should be attempted and, when successful, may be followed by prolonged remissions.

Hematopoietic System Hematologic changes may include fibrinogenopenia, increased fibrinolysis, and selective deficiency of clotting factors (Chap. 53). Deficient factor X seems to be due to nonspecific calcium-dependent binding to the polyanionic amyloid fibrils. Splenectomy in the patient with such a factor X deficiency can relieve the deficiency and the associated bleeding disorder, since factor X has been shown to bind to the large masses of splenic amyloid. Endothelial damage together with the clotting abnormalities lead to a propensity toward abnormal bleeding.

DIAGNOSIS Amyloid fibrils are identified in biopsy or necropsy tissue sections (Table 310-3). The systemic amyloidoses offer a choice of biopsy sites; abdominal fat aspirates or renal or rectal biopsies are often performed. Microscopically, amyloid deposits stain pink with the hematoxylin-eosin stain and show metachromasia with crystal violet. The widely used and useful Congo red stain imparts a unique green birefringence when stained tissue sections are viewed using the polarizing microscope (Fig. 310-1). Fluorescent dyes such as thioflavin are sensitive screening stains for amyloid deposits in brain and other tissues; however, specificity should be confirmed. After amyloid has been identified by staining, it should be chemically classified by genomic DNA and protein studies and by immunohistochemistry. In the case of heredofamilial amyloidosis, the presence of mutant TTR (or gelsolin, Apo AI, etc.) establishes the specific diagnosis of the disease. Isoelectric focusing is used as a simple screening test for variant transthyretins associated with familial TTR amyloidosis. In order to establish the relationship of immunoglobulin-related amyloid to multiple myeloma, electrophoretic and immunoelectrophoretic studies on serum and urine should be performed when the biopsy reveals amyloid deposition. Most of these patients will have only relatively small paraprotein components, and only a few will have frank multiple myeloma. If AL and familial amyloidosis have been ruled out, AA amyloidosis should be suspected in patients with renal amyloid and a chronic inflammatory condition (Table 310-4).

PROGNOSIS Generalized amyloidosis is usually a slowly progressive disease that leads to death if untreated. The average survival in most large series of AL amyloid is ~12 months and in familial amyloidosis is ~7 to 15 years. A number of individuals with amyloid have been followed 5 to 10 years and longer. The course of amyloidosis is difficult to document, because dating the time of origin of the disease is rarely possible. When amyloidosis deops in patients with rheumatoid arthritis, it seldom becomes evident when the arthritis is of less than 2 years' duration. When amyloidosis develops in patients with multiple myeloma, manifestations leading to initial hospitalization are more apt to be related to amyloid disease than to myeloma. In these cases, prognosis is very poor, and life expectancy is usually less than 6 months.

TREATMENT

Rational therapy should be directed at (1) reducing precursor production, (2) inhibiting the extracellular deposition of amyloid fibrils, and (3) promoting lysis or mobilization of existing amyloid deposits. There are new specific therapies for the various amyloidoses. In certain of the heredofamilial amyloidoses, genetic counseling is an important aspect of treatment, and the removal of the site of synthesis of the mutant protein by liver transplantation has proven remarkably successful. Liver transplantation has been carried out since 1990 for ATTR patients in Sweden, the United States, Portugal, Spain, and other countries. It appears that disease progression is halted and that there is some improvement in autonomic nervous system function. The utilization of chronic hemodialysis and of kidney transplantation has clearly improved the prognosis of renal amyloid.

In the case of AL amyloid, the fact that immunoglobulin light chain is made by plasma cells has led to the use of alkylating agents. However, these agents are toxic and not very effective. The most effective form of treatment currently is stem cell transplantation and immunosuppressive drugs (melphalan). Several long-term remissions have been reported, but serious complications, even death, can occur. A novel anthracycline, iododoxorubicin (IDOX), has been shown to bind to AL amyloid (similar to Congo red) in vivo and promote amyloid resorption. A subset of AL patients responds transiently to this experimental agent; and it is thought that IDOX may prove useful in combination with other forms of treatment. Cardiac tranplantation in selected cases of AL or heredofamilial amyloidosis has its advocates and has been successful.

Colchicine has been shown to be effective in preventing acute attacks and amyloidosis in patients with FMF (Chap. 279). Several clinical trials are in progress for AD.

The major causes of death are heart disease and renal failure. Sudden death, presumably due to arrhythmias, is common. Occasionally,

gastrointestinal hemorrhage, respiratory failure, intractable heart failure, and superimposed infections are the terminal events.

311 APPROACH TO ARTICULAR AND MUSCULOSKELETAL DISORDERS

John J. Cush, Peter E. Lipsky

Musculoskeletal complaints account for more than 315 million outpatient visits per year. Recent surveys by the Centers for Disease Control and Prevention suggest that 33% (69.9 million) of the U.S. population is affected by arthritis or joint disorders. Many of these are self-limited conditions requiring minimal evaluation and only symptomatic therapy and reassurance. However, in some patients, musculoskeletal symptoms may herald a more serious condition that requires further evaluation or additional laboratory testing to confirm the suspected diagnosis or document the extent and nature of the pathologic process. The initial goal of the clinician is to formulate a differential diagnosis that leads to an accurate diagnosis and timely therapy, while avoiding excessive diagnostic testing and unnecessary treatment (Table 311-1). There are several urgent conditions that must be diagnosed promptly to avoid significant morbid or mortal sequelae. These "red flag" diagnoses include septic arthritis, acute crystal-induced arthritis (e.g., gout), and fracture. Each of these may be suspected by an acute onset with a monoarticular or focal presenting complaint (see below).

Individuals with musculoskeletal complaints should be evaluated in a uniform, logical manner with a thorough history, a comprehensive physical examination, and, if appropriate, laboratory testing. The goals of the initial encounter are to determine whether the musculoskeletal complaint is (1) *articular* or *nonarticular* in origin, (2) *inflammatory* or *noninflammatory* in nature, (3) *acute* or *chronic* in duration, and (4) *localized* or *widespread* (*systemic*) in distribution.

With such an approach and an understanding of the pathophysiologic processes that underlie musculoskeletal complaints, an adequate diagnosis can be made in the vast majority of individuals. However, some patients will not fit immediately into an established diagnostic category. Many musculoskeletal disorders resemble each other at the outset, and some may take weeks or months to evolve into a readily recognizable diagnostic entity. This consideration should temper the desire to establish a definitive diagnosis at the first encounter.

ARTICULAR VERSUS NONARTICULAR The musculoskeletal evaluation must discriminate the anatomic site(s) of origin of the patient's complaint. For example, ankle pain can result from a variety of pathologic conditions involving disparate anatomic structures, including gonococcal arthritis, calcaneal fracture, Achilles tendinitis, cellulitis, and peripheral neuropathy. Distinguishing between articular and nonarticular conditions requires a careful and detailed examination. Articular structures include the synovium, synovial fluid, articular cartilage, intraarticular ligaments, joint capsule, and juxtaarticular bone. Nonarticular (or periarticular) structures, such as supportive extraarticular ligaments, tendons, bursae, muscle, fascia, bone, nerve, and overlying skin, may be involved in the pathologic process. Articular disorders may be characterized by deep or diffuse pain, limited range of motion on active and passive movement, swelling (caused by synovial proliferation, effusion, or bony enlargement), crepitation, instability, "locking," or deformity. By contrast, nonarticular disorders tend to be painful on active but not passive range of motion, demonstrate point or focal tenderness in regions distinct from articular structures, and have physical findings remote from the joint capsule. Moreover, nonarticular disorders seldom demonstrate crepitus, instability, or deformity.

TABLE 311-1 Evaluation of Patients with Musculoskeletal Complaints

Goals
Accurate diagnosis
Timely provision of therapy
Avoidance of unnecessary diagnostic testing
Approach
Anatomic localization of complaint (articular vs. nonarticular)
Determination of the nature of the pathologic process (inflammatory vs. noninflammatory)
Determination of the extent of involvement (monarticular, polyarticular, focal, widespread)
Determination of chronology (acute vs. chronic)
Formulation of a differential diagnosis

INFLAMMATORY VERSUS NONINFLAMMATORY DISORDERS In the course of a musculoskeletal evaluation, the examiner should elicit symptoms and signs that will narrow or establish the diagnosis. A primary objective is to identify the nature of the underlying pathologic process. Musculoskeletal disorders are generally classified as inflammatory or noninflammatory. Inflammatory disorders may be infectious (infection with *Neisseria gonorrhoea* or *Mycobacterium tuberculosis*), crystal-induced (gout, pseudogout), immune-related [rheumatoid arthritis (RA), systemic lupus erythematosus (SLE)], reactive (rheumatic fever, Reiter's syndrome), or idiopathic. Inflammatory disorders may be identified by the presence of all or some of the four cardinal signs of inflammation (erythema, warmth, pain, or swelling), systemic symptoms (prolonged morning stiffness, fatigue, fever, weight loss), or laboratory evidence of inflammation [elevated erythrocyte sedimentation rate (ESR) or C-reactive protein, thrombocytosis, anemia of chronic disease, or hypoalbuminemia]. Articular stiffness commonly accompanies chronic musculoskeletal disorders. However, the chronology and magnitude of stiffness may be diagnostically important. Morning stiffness related to inflammatory disorders (such as RA) is precipitated by prolonged rest, is often several hours in duration, and may improve with activity and anti-inflammatory medications. By contrast, intermittent stiffness associated with noninflammatory conditions (such as osteoarthritis) is precipitated by brief periods of rest, usually lasts <60 min, and is exacerbated by activity. Fatigue may accompany inflammation (as seen in RA and polymyalgia rheumatica) and can also be a feature of fibromyalgia (a noninflammatory disorder), anemia, cardiac failure, endocrinopathy, poor nutrition, poor sleep, or psychiatric disorders. Noninflammatory disorders may related to trauma (rotator cuff tear), ineffective repair (osteoarthritis), neoplasm (pigmented villonodular synovitis), or pain amplification (fibromyalgia). Noninflammatory disorders are often characterized by pain without swelling or

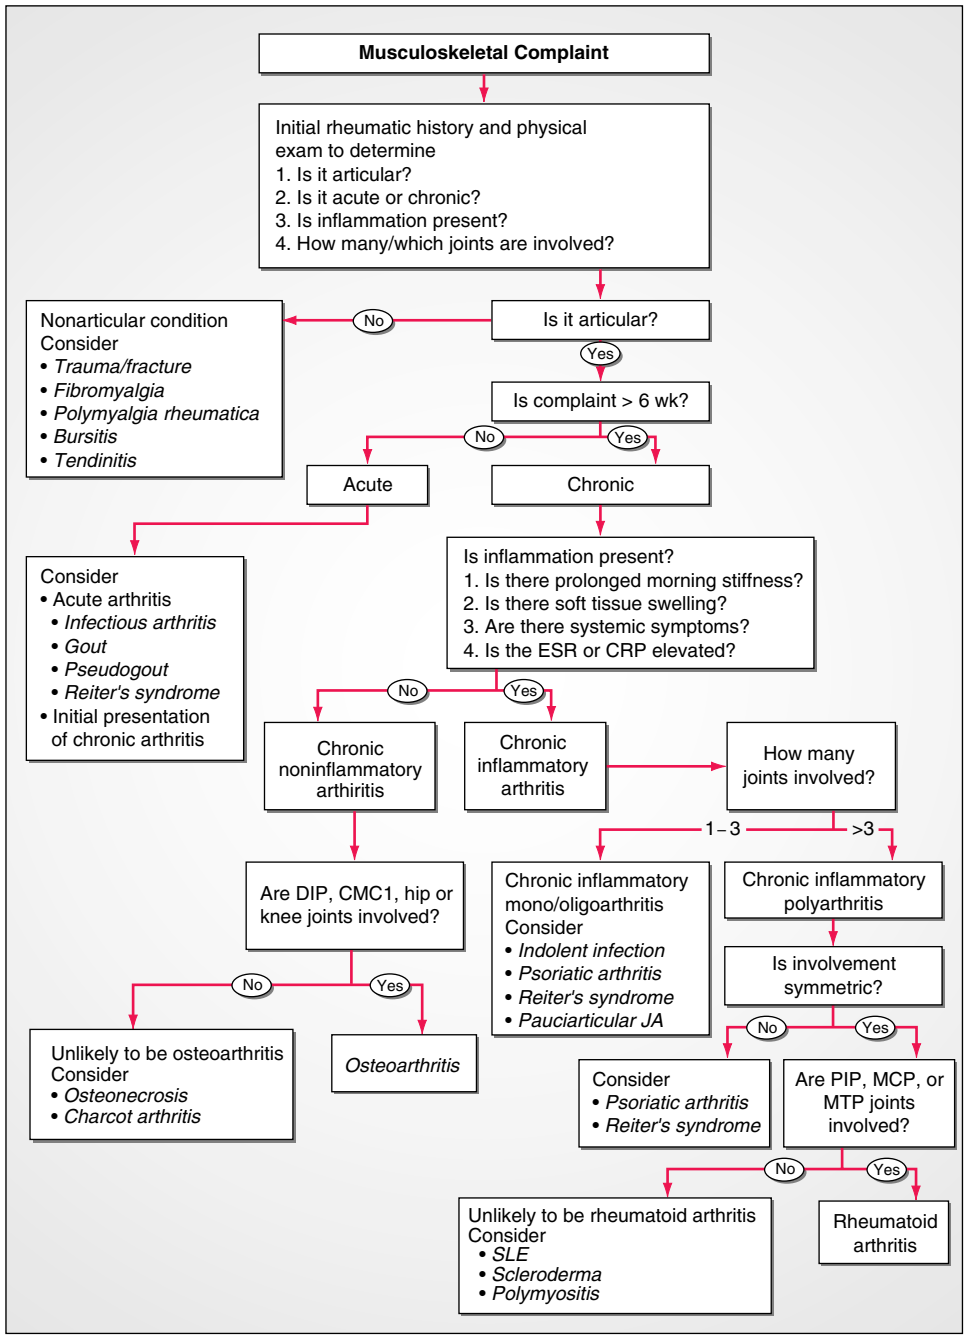

FIGURE 311-1 Algorithm for the diagnosis of musculoskeletal complaints. An approach to formulating a differential diagnosis (shown in italics). (ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; DIP, distal interphalangeal; CMC, carpometacarpal; PIP, proximal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PMR, polymyalgia rheumatica; SLE, systemic lupus erythematosus; JA, juvenile arthritis.)

warmth, absence of inflammatory or systemic features, minimal or absent morning stiffness, and normal (for age) or negative laboratory investigations.

Identification of the nature of the underlying process and the site of the complaint will enable the examiner to narrow the diagnostic considerations and to assess the need for immediate diagnostic or therapeutic intervention, or for continued observation. Figure 311-1 presents a logical approach to the evaluation of patients with musculoskeletal complaints.

CLINICAL HISTORY Additional historic features may be helpful in establishing the nature and extent of the pathologic process and may provide important clues to the diagnosis. Aspects of the patient profile, including age, sex, race, and family history, can provide important information. Certain diagnoses are more frequent in different *age* groups (Fig. 311-2). SLE, rheumatic fever, and Reiter's syndrome occur more frequently in the young, whereas fibromyalgia is most frequent in middle age and osteoarthritis and polymyalgia rheumatica are more prevalent among the elderly. Diagnostic clustering is also evident when *sex* and *race* are considered. Gout and the spondyloarthropathies (e.g., ankylosing spondylitis, Reiter's syndrome) are more common in men, whereas RA and fibromyalgia are more frequent in women. *Racial predilections* are noted with certain disorders. Thus, polymyalgia rheumatica, giant cell arteritis, and Wegener's granulomatosis commonly affect whites, whereas sarcoidosis and SLE more commonly affects African Americans. *Familial aggregation* may be seen in disorders such as ankylosing spondylitis, gout, RA, and Heberden's nodes of osteoarthritis.

The chronology of the complaint is an important diagnostic feature and can be divided into the *onset*, *evolution*, and *duration*. The onset of disorders such as septic arthritis or gout tends to be abrupt, whereas osteoarthritis, RA, and fibromyalgia may have more indolent presentations. The evolution of patients' complaints may also provide useful information. Disorders should be classified as either chronic (osteoarthritis), intermittent (gout), migratory (rheumatic fever, gonococcal or viral arthritis), or additive (RA, Reiter's syndrome). Musculoskeletal disorders are typically classified as acute or chronic based upon a disease duration that is either less than or greater than 6 weeks, respectively. Acute arthropathies tend to be infectious, crystal-induced, or reactive. Chronic arthritides often include noninflammatory and immunologic disorders such as osteoarthritis or RA, respectively. The duration of patients' complaints may alter the diagnostic considerations. For example, the musculoskeletal signs and symptoms of hepatitis B virus infection may be identical with those of early RA at the onset but rarely persist beyond 3 weeks.

The *number* and *distribution* of involved articulations should be noted. Articular disorders are classified based on the number of joints involved, as either *monarticular* (one joint), *oligoarticular* or *pauciarticular* (two to four joints), or *polyarticular* (more than 4 joints). Nonarticular disorders may be classified as either focal or widespread. Complaints secondary to trauma and gout are typically focal or monarticular, whereas others, such as polymyositis, RA, and fibromyalgia, are more diffuse or polyarticular in their presentation. Joint involvement in RA tends to be symmetric, whereas the spondyloarthropathies and gout are often asymmetric. The upper extremities are frequently involved in RA, whereas lower extremity arthritis is characteristic of Reiter's syndrome and gout at their onset. Involvement of the axial skeleton is common in osteoarthritis and ankylosing spondylitis but is infrequent in RA, with the notable exception of the cervical spine.

The clinical history should also identify *precipitating events*, such

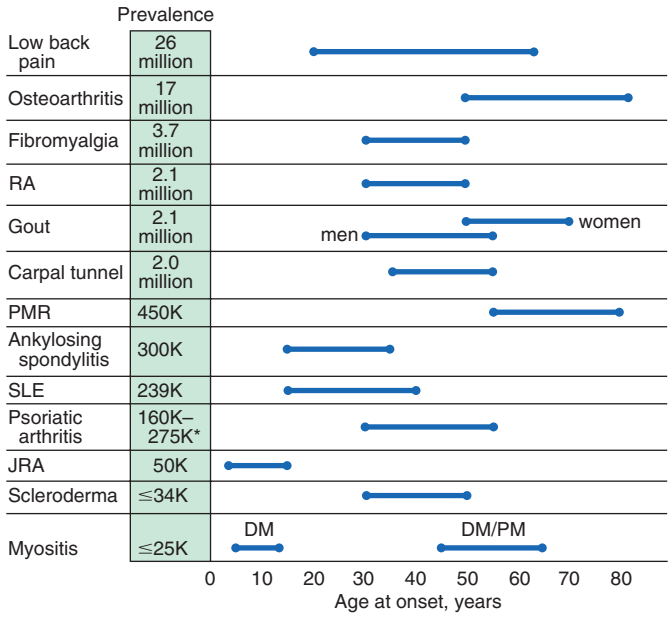

FIGURE 311-2 Age at onset for common rheumatic conditions; ranked by prevalance estimates in the United States in 1998. *Estimates vary. (RA, rheumatoid arthritis; PMR, polymyalgia rheumatica; SLE, systemic lupus erythematosus; JRA, juvenile rheumatoid arthritis; DM, dermatomyositis; PM, polymyositis.)

as trauma, drug administration (Table 311-2), or antecedent or intercurrent illnesses, that may have contributed to the patient's complaint. Lastly, a thorough *rheumatic review of systems* may disclose associated features outside the musculoskeletal system and provide useful diagnostic information. A variety of musculoskeletal disorders may be associated with systemic features such as fever (SLE, infection), rash (SLE, Reiter's syndrome, dermatomyositis), myalgias, weakness (polymyositis, polymyalgia rheumatica), or morning stiffness (inflammatory arthritis). In addition, some conditions are associated with involvement of other organ systems including the eyes (Behçet's disease, sarcoidosis, Reiter's syndrome), gastrointestinal tract (scleroderma, inflammatory bowel disease), genitourinary tract (Reiter's syndrome, gonococcemia), or the nervous system (Lyme disease, vasculitis).

PHYSICAL EXAMINATION The goal of the physical examination is to ascertain the structures involved, the nature of the underlying pathology, the extent and functional consequences of the process, and the presence of systemic or extraarticular manifestations. A knowledge of topographic anatomy is necessary to identify the primary site(s) of involvement and differentiate articular from nonarticular disorders. The musculoskeletal examination depends largely on careful inspection, palpation, and a variety of specific physical maneuvers to elicit diagnostic signs (Table 311-3). Although most articulations of the appendicular skeleton can be examined in this manner, adequate inspection and palpation are not possible for many axial (e.g., zygapophyseal) and inaccessible (e.g., sacroiliac or hip) joints. For such joints, there is a greater reliance upon specific maneuvers and imaging for assessment.

Examination of involved and uninvolved joints will determine whether *pain*, *warmth*, *erythema*, or *swelling* is present. The locale and level of pain elicited by palpation or movement should be quantified. For example, the number of tender joints on palpation or the patients' report of pain intensity (on a scale of 1 to 10) may be noted. The examination should distinguish true articular swelling caused by synovial effusion or synovial proliferation from nonarticular or periarticular involvement, which usually extends beyond the normal joint margins or full extent of the synovial space. Synovial effusion can be distinguished from synovial hypertrophy or bony hypertrophy by palpation or specific maneuvers. For example, small to moderate knee effusions may be identified by the "bulge sign" or "ballottement of the patellae." Bursal effusions (e.g., effusions of the olecranon or prepatellar bursa) overlie bony prominences and are fluctuant with sharply defined borders. Joint *stability* can be assessed by palpation and by the application of manual stress. *Subluxation* or *dislocation*, which may be secondary to traumatic, mechanical, or inflammatory causes, can be assessed by inspection and palpation. Joint *volume* can be assessed by palpation. Distention of the articular capsule usually causes pain. The patient will attempt to minimize the pain by maintaining the joint in the position of least intraarticular pressure and greatest volume, usually partial flexion. For this reason, inflammatory effusions may give rise to flexion contractures. Clinically, this may be detected as obvious swelling, voluntary or fixed flexion deformities, or diminished range of motion—especially on extension, when joint volumes are decreased. Active and passive *range of motion* should be assessed in all planes, with contralateral comparison. Serial evaluations of joint

TABLE 311-2 Drug-Induced Musculoskeletal Conditions

Arthralgias
Quinidine, amphotericin B, cimetidine, quinolones, chronic acyclovir, interferon, IL-2, nicardipine, vaccines, rifabutin

Myalgias/myopathy
Glucocorticoids, penicillamine, hydroxychloroquine, AZT, lovastatin, simvastatin, pravastatin, clofibrate, interferon, IL-2, alcohol, cocaine, taxol, docetaxel, colchicine, quinolones

Gout
Diuretics, aspirin, cytotoxics, cyclosporine, alcohol, moonshine, ethambutol

Drug-induced lupus
Hydralazine, procainamide, quinidine, phenytoin, methyldopa, isoniazid, chlorpromazine, lithium, penicillamine, tetracycline, infliximab

Osteonecrosis
Glucocorticoids, alcohol, radiation

Osteopenia
Glucocorticoids, chronic heparin, phenytoin, methotrexate

Scleroderma
Vinyl chloride, bleomycin, pentazocine, organic solvents, carbidopa, tryptophan, rapeseed oil

Vasculitis
Allopurinol, amphetamines, cocaine, thiazides, penicillamine, propylthiouracil

Note: IL-2, interleukin 2.

TABLE 311-3 Glossary of Musculoskeletal Terms

Crepitus
A palpable (less commonly audible) vibratory or crackling sensation elicited with joint motion; fine joint crepitus is common and often insignificant in large joints; coarse joint crepitus indicates advanced cartilaginous and degenerative changes (as in osteoarthritis).

Subluxation
Alteration of joint alignment such that articulating surfaces incompletely approximate each other

Dislocation
Abnormal displacement of articulating surfaces such that the surfaces are not in contact

Range of motion
For diarthrodial joints, the arc of measurable movement through which the joint moves in a single plane

Contracture
Loss of full movement resulting from a fixed resistance due either to tonic spasm of muscle (reversible) or to fibrosis of periarticular structures (permanent)

Deformity
Abnormal shape or size of a structure; may result from bony hypertrophy, malalignment of articulating structures, or damage to periarticular supportive structures

Enthesitis
Inflammation of the entheses (tendinous or ligamentous insertions on bone)

Epicondylitis
Infection or inflammation involving an epicondyle

motion may be recorded with a goniometer to quantify the arc of movement. Each joint should be passively manipulated through its full range of motion (including, as appropriate, flexion, extension, rotation, abduction, adduction, lateral bending, inversion, eversion, supination, pronation, and medial or lateral deviation, or bending). Limitation of motion is frequently caused by effusion, pain, deformity, or contracture. If passive motion exceeds active motion, a periarticular process (e.g., tendon rupture or myopathy) should be considered. *Contractures* may reflect antecedent synovial inflammation or trauma. Joint *crepitus* may be felt during palpation or maneuvers and may be prominent or coarse in osteoarthritis. Joint *deformity* usually indicates a long-standing or aggressive pathologic process. Deformities may result from ligamentous destruction, soft tissue contracture, bony enlargement, ankylosis, erosive disease, or subluxation. Examination of the musculature will document strength, atrophy, pain, or spasm. Muscle weakness should be characterized as proximal or distal. Muscle strength is graded on a 5-point scale: 0 for no movement; 1 for trace movement or twitch; 2 for movement with gravity eliminated; 3 for movement against gravity only; 4 for movement against gravity and resistance; and 5 for normal strength. The examiner should assess carefully for nonarticular or periarticular involvement, especially when articular complaints are not supported by objective findings referable to the joint capsule. The identification of musculoskeletal pain of soft tissue origin (nonarticular pain) will prevent unwarranted and often expensive additional evaluations. Specific maneuvers may reveal nonarticular abnormalities, such as a carpal tunnel syndrome (which can be identified by Tinel's or Phalen's sign). Other examples of soft tissue abnormalities include olecranon bursitis, epicondylitis (e.g., tennis elbow), enthesitis (e.g., Achilles tendinitis), and trigger points associated with fibromyalgia.

LABORATORY INVESTIGATIONS The vast majority of musculoskeletal disorders can be easily diagnosed by a complete history and physical examination. An additional objective of the initial encounter is to determine whether additional investigations or immediate therapy are required. A number of features indicate the need for additional evaluation. Monarticular conditions require additional evaluation, as do traumatic or inflammatory conditions and conditions accompanied by neurologic changes or systemic manifestations of serious disease. Finally, individuals with chronic symptoms (>6 weeks), especially when there has been a lack of response to symptomatic measures, are candidates for additional evaluation. The extent and nature of the additional investigation should be dictated by the clinical features and suspected pathologic process. Laboratory tests should be used to confirm a specific clinical diagnosis and not be used as a tool to screen or evaluate patients with vague rheumatic complaints. Indiscriminate use of broad batteries of diagnostic tests and radiographic procedures is rarely useful or cost-effective means to establish a diagnosis.

Besides a complete blood count, including a white blood cell (WBC) and differential count, the routine evaluation should include a determination of an acute-phase reactant such as the ESR or C-reactive protein, which can be useful in discriminating inflammatory from noninflammatory musculoskeletal disorders. Both are inexpensive and easily obtained and may be elevated with infections, inflammatory arthritis, autoimmune disorders, neoplasia, pregnancy, and advanced age. Serum uric acid determinations are useful only when gout has been diagnosed and therapy contemplated.

Serologic tests for rheumatoid factor, antinuclear antibodies (ANA), complement levels, Lyme and antineutrophil cytoplasmic antibodies, or antistreptolysin O titer should be carried out only when there is clinical evidence to suggest a relevant associated diagnosis, as these have poor predictive value when used for screening, especially when the pretest probability is low. Although, 4 to 5% of a healthy population will have positive tests for rheumatoid factor and ANA, only 1% and 0.4% of the population will have RA or SLE, respectively. IgM rheumatoid factor (autoantibodies against the Fc portion of IgG) is found in 80% of patients with RA and may also be seen in low titers in patients with chronic infections (*tuberculosis*, leprosy); other autoimmune diseases (SLE, Sjögren's syndrome); and chronic pulmonary, hepatic, or renal diseases. ANAs are found in nearly all patients with SLE and may also be seen in patients with other autoimmune diseases (polymyositis, scleroderma, antiphospholipid syndrome), drug-induced lupus (resulting from hydralazine, procainamide, or quinidine), chronic hepatitic, or renal disorders. The interpretation of a positive ANA may depend on the magnitude of the titer and the pattern observed under immunofluorescence microscopy. Diffuse and speckled patterns are least specific, whereas a peripheral, or rim, pattern is highly specific and suggestive of autoantibodies against double-stranded (native) DNA. This pattern is seen only in patients with SLE.

Aspiration and analysis of synovial fluid are always indicated in acute monarthritis or when an infectious or crystal-induced arthropathy is suspected. Synovial fluid analysis may be crucial in distinguishing between noninflammatory and inflammatory processes. This distinction can be made on the basis of the appearance, viscosity, and cell count of the synovial fluid. Tests for synovial fluid glucose, protein, lactate dehydrogenase, lactic acid, or autoantibodies are not recommended as they are insensitive or have little discriminatory value. Normal synovial fluid is clear or a pale straw color and is viscous, primarily because of the high levels of hyaluronate. Noninflammatory synovial fluid is clear, viscous, and amber-colored, with a white blood cell count of $<2000/\mu L$ and a predominance of mononuclear cells. The viscosity of synovial fluid is assessed by expressing fluid from the syringe one drop at a time. Normally there is a stringing effect, with a long tail behind each synovial drop. Effusions caused by osteoarthritis or trauma usually have normal viscosity. Inflammatory fluid is turbid and yellow, with an increased white cell count (2000 to $50{,}000/\mu L$) and a polymorphonuclear leukocyte predominance. Inflammatory fluid has reduced viscosity, diminished hyaluronate, and little or no tail following each drop of synovial fluid. Such effusions are found in RA, gout, other inflammatory arthritides, and septic arthritis. Infectious fluid is opaque, and purulent, with a white cell count usually $>50{,}000/\mu L$, a predominance of polymorphonuclear leukocytes (>75%), and low viscosity. Such effusions are typical of septic arthritis, but they occur rarely with sterile inflammatory arthritides such as RA or gout. In addition, hemorrhagic synovial fluid may be seen with trauma, hemarthrosis, or neuropathic arthritis. An algorithm for synovial fluid aspiration and analysis is shown in Fig. 311-3. Synovial fluid should be analyzed immediately for appearance, viscosity, and cell count. Cellularity and the presence of crystals may be assessed by either light or polarizing microscopy. Monosodium urate crystals, seen in gouty effusions, are long, needle-shaped, negatively birefringent, and usually intracellular, whereas calcium pyrophosphate dihydrate crystals, found in chondrocalcinosis and pseudogout, are usually short, rhomboid-shaped, positively birefringent crystals. Whenever infection is suspected, synovial fluid should be Gram-stained and cultured appropriately. If gonococcal arthritis is suspected, immediate plating of the fluid on appropriate culture medium is indicated. Synovial fluid from patients with chronic monarthritis should also be cultured for *M. tuberculosis* and fungi. Last, it should be noted that crystal-induced arthritis and infection occasionally occur together in the same joint.

DIAGNOSTIC IMAGING IN JOINT DISEASES Conventional radiography has been a valuable tool in the diagnosis and staging of articular disorders. Plain x-rays are most appropriate when there is a history of trauma, suspected chronic infection, progressive disability, or monarticular involvement; when therapeutic alterations are considered; or when a baseline assessment is desired for what appears to be a chronic process. However, in most inflammatory disorders, early radiography is rarely helpful in establishing a diagnosis and may only reveal soft tissue swelling or juxtaarticular demineralization. As the disease progresses, calcification (of soft tissues, cartilage, or bone), joint space narrowing, erosions, bony ankylosis, new bone formation (sclerosis, osteophytes,

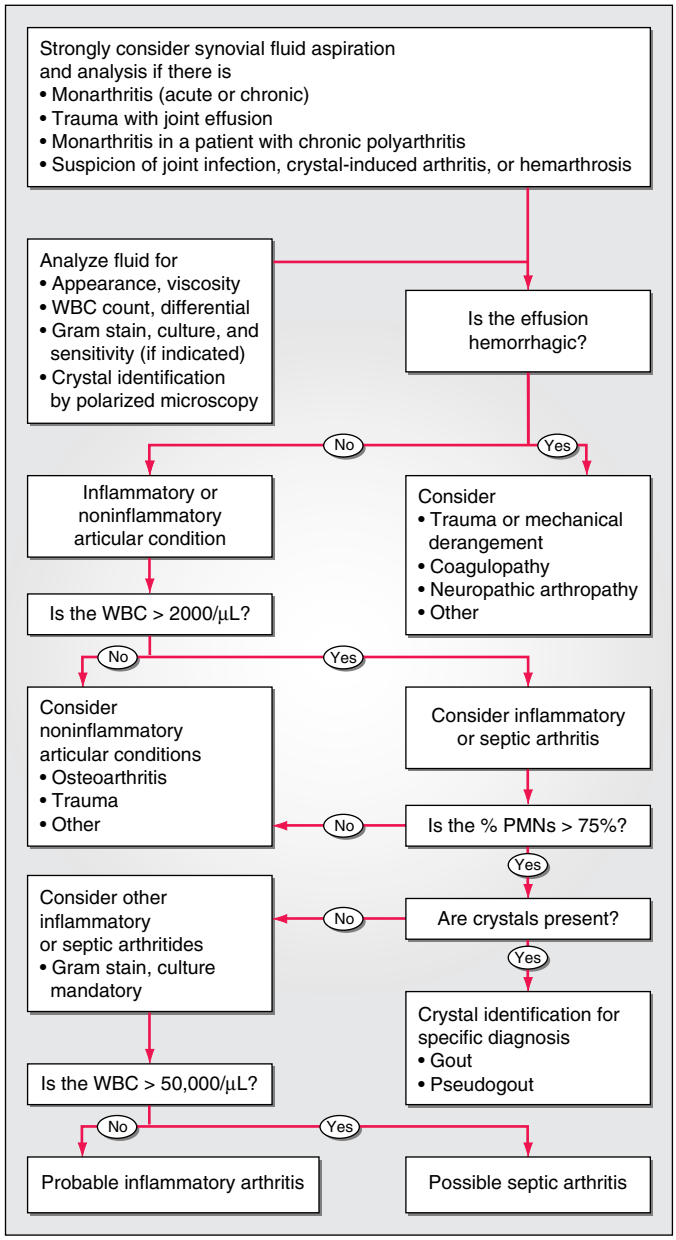

FIGURE 311-3 Algorithmic approach to the use and interpretation of synovial fluid aspiration and analysis. [WBC, white blood cell (count); PMNs, polymorphonuclear (leukocytes).]

or periostitis), or subchondral cysts may develop and suggest specific clinical entities. Consultation with a radiologist will help define proper imaging modality, technique, and positioning and prevent the need for further studies.

Additional imaging techniques may possess greater diagnostic sensitivity and facilitate early diagnosis in a limited number of articular disorders and in selected circumstances and are indicated when conventional radiography is not adequate (Table 311-4). *Ultrasonography* is useful in the detection of soft tissue abnormalities that cannot be fully appreciated by clinical examination. Although inexpensive and easily performed, in only a limited number of circumstances is it the preferred method of evaluation. The foremost application of ultrasound is in the diagnosis of synovial (Baker's) cysts, although rotator cuff tears and various tendon injuries may be evaluated with ultrasound by an experienced operator. *Radionuclide scintigraphy* provides useful information regarding the metabolic status of bone and, along with radiography, is well suited for total-body assessment of the extent and distribution of musculoskeletal involvement. Radionuclide imaging is a very sensitive, but poorly specific, means of detecting inflammatory or metabolic alterations in bone or periarticular soft tissue structures. The limited tissue contrast resolution of scintigraphy may obscure the distinction between a bony or periarticular process and may necessitate the additional use of other imaging modalities. Scintigraphy, using ^{99m}Tc, ^{67}Ga, or ^{111}In-labeled WBCs has been applied to a variety of articular disorders with variable success (Table 311-4). [^{99m}Tc] pertechnate or diphosphate scintigraphy may be useful in identifying infection, neoplasia, inflammation, increased blood flow, bone remodeling, heterotopic bone formation, or avascular necrosis (Fig. 311-4). The poor specificity of ^{99m}Tc scanning has limited its use to investigational and serial assessments of joint or bone involvement, inflammatory or infectious processes, and surveys for bone metastases. ^{67}Ga binds to serum and cellular transferrin and lactoferrin and is preferentially taken up by neutrophils, macrophages, bacteria, and tumor tissue (e.g., lymphoma) and is useful in the identification of infection and malignancies. Scanning with ^{111}In-labeled WBCs has been used to detect both infectious and inflammatory arthritis. Although both have been used with success, ^{111}In-labeled WBC scanning is superior to ^{67}Ga in the early diagnosis of osteomyelitis and infected prosthetic joints. Prior treatment with antibiotics may reduce the diagnostic sensitivity of both ^{67}Ga and ^{111}In-labeled WBC scintigraphy.

Computed tomography (CT) provides rapid reconstruction of sagittal, coronal, and axial images and spatial relationships among anatomic structures. It has proved to be most useful in the assessment of the axial skeleton because of its ability to visualize in the axial plane. Articulations previously considered difficult to visualize using conventional radiography, such as the zygapophyseal, sacroiliac, sternoclavicular, and hip joints, can be effectively evaluated using CT. CT has been demonstrated to be useful in the diagnosis of low back pain syndromes, sacroiliitis, osteoid osteoma, tarsal coalition, osteomyelitis, intraarticular osteochondral fragments, and advanced osteonecrosis. Helical or spiral CT (with or without contrast angiography) is a novel technique that is rapid, cost effective, and sensitive in diagnosing pulmonary embolism or obscure fractures, often in the setting of initially equivocal findings. High-resolution CT can be advocated in the evaluation of suspected or established infiltrative lung disease (e.g., scleroderma or rheumatoid lung).

Magnetic resonance imaging (MRI) has significantly advanced the ability to image musculoskeletal structures. MRI has the advantages of providing multiplanar images with fine anatomic detail and contrast resolution (Fig. 311-5). Other advantages are the lack of ionizing radiation and adverse effects and the superior ability to visualize bone marrow and soft tissue periarticular structures, which have led to the increased use of this modality. The advantages of MRI are counterbalanced by high cost and long procedural time, factors that have limited its use in the evaluation of musculoskeletal disorders. MRI should be used only when it will provide necessary information that cannot be obtained by less expensive and noninvasive means.

MRI can image fascia, vessels, nerve, muscle, cartilage, ligaments, tendons, pannus, synovial effusions, and bone marrow. Visualization of particular structures can be enhanced by altering the pulse sequence to produce either T1- or T2-weighted spin echo, gradient echo, or inversion recovery [including short tau inversion recovery (STIR)] images. Because of its sensitivity to changes in marrow fat, MRI is a sensitive but nonspecific means of detecting osteonecrosis and osteomyelitis (Fig. 311-5). Because of its enhanced soft tissue resolution, MRI is more sensitive than arthrography or CT in the diagnosis of soft tissue injuries (e.g., meniscal and rotator cuff tears); intraarticular derangements; and spinal cord damage, subluxation, or synovitis.

RHEUMATOLOGIC EVALUATION OF THE ELDERLY The incidence of rheumatic diseases rises with age, and so ~58% of those >65 will have joint complaints. Musculoskeletal disorders in elderly patients are often not diagnosed because the signs and symptoms may be insidious, chronic, or overshadowed by comorbidities. These difficulties are compounded by the diminished reliability of laboratory testing in the elderly, who

TABLE 311-4 *Diagnostic Imaging Techniques for Musculoskeletal Disorders*

Method	Imaging Time, h	Cost[a]	Current Indications

[a] Relative cost for imaging study. [b] Results depend on operator.

often manifest nonpathologic abnormal results. For example, the ESR may be misleadingly elevated, and low-titer positive tests for rheumatoid factor and ANAs may be seen in up to 15% of elderly patients. Although nearly all rheumatic disorders afflict the elderly, certain diseases and drug-induced disorders (Table 311-2) are more common in this age group. The elderly should be approached in the same manner as other patients with musculoskeletal complaints, but with additional inquiries to exclude common geriatric musculoskeletal disorders. An emphasis on identifying the rheumatic consequences of intercurrent medical conditions and therapies is extremely important. Osteoarthritis, osteoporosis, gout, pseudogout, polymyalgia rheumatica, vasculitis, drug-induced lupus erythematosus, and chronic salicylate toxicity are all more common in the elderly than in other individuals. The physical examination should identify the nature of the musculoskeletal complaint as well as coexisting diseases that may influence diagnosis and choice of treatment.

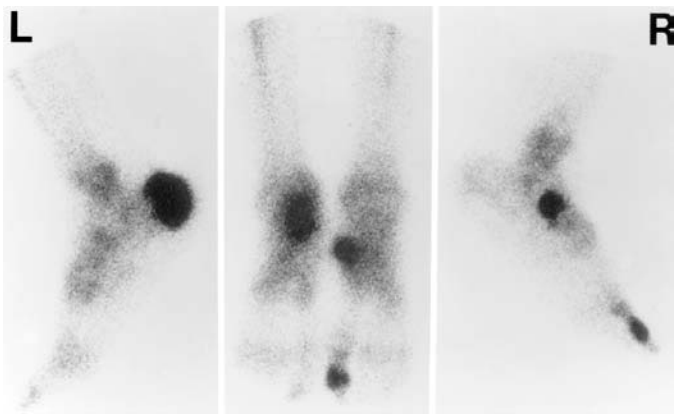

FIGURE 311-4 [^{99m}Tc]diphosphonate scintigraphy of the feet of a 33-year-old black male with Reiter's syndrome, manifested by sacroiliitis, urethritis, uveitis, asymmetric oligoarthritis, and enthesitis. This bone scan demonstrates increased uptake indicative of enthesitis involving the insertions of the left Achilles tendon, plantar aponeurosis, and right tibialis posterior tendon as well as arthritis of the right first interphalangeal joint.

APPROACH TO REGIONAL RHEUMATIC COMPLAINTS

Although all patients should be evaluated in a logical and thorough manner, many cases with focal musculoskeletal complaints are caused by commonly encountered disorders that exhibit a predictable pattern of onset, evolution, and localization; they can often be diagnosed immediately on the basis of limited historic information and selected maneuvers or tests. Although nearly every joint could be approached in this manner, the evaluation of four common involved anatomical regions—the hand, shoulder, hip, and knee—are reviewed here.

Hand Pain Focal or unilateral hand pain may result from trauma, overuse, infection, or a reactive or crystal-induced arthritis. By contrast, bilateral hand complaints suggest a degenerative (e.g., osteoarthritis), systemic, or inflammatory/immune (e.g., RA) etiology. The distribution or pattern of joint involvement is highly suggestive of certain disorders (Fig. 311-6). Thus, osteoarthritis (or degenerative arthritis) may manifest as distal interphalangeal (DIP) and proximal interphalangeal (PIP) joint pain with bony hypertrophy sufficient to produce Heberden's and Bouchard's nodes, respectively. Pain, with or without bony swell-

FIGURE 311-5 Superior sensitivity of magnetic resonance imaging in the diagnosis of osteonecrosis of the femoral head. A 45-year-old woman receiving high-dose glucocorticoids developed right hip pain. Conventional x-rays (*top*) demonstrated only mild sclerosis of the right femoral head. T1-weighted MRI (*bottom*) demonstrated low-density signal in the right femoral head, diagnostic of osteonecrosis.

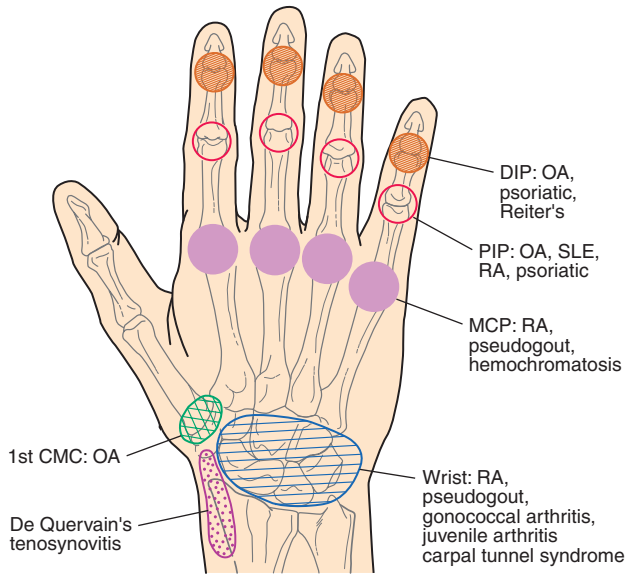

FIGURE 311-6 Sites of hand or wrist involvement and their potential disease associations. (DIP, distal interphalangeal; OA, osteoarthritis; PIP, proximal interphalangeal; SLE, systemic lupus erythematosus; RA, rheumatoid arthritis; MCP, metacarpophalangeal; CMC, carpometacarpal.) *(From JJ Cush, AF Kavanaugh: Rheumatology: Diagnosis and Therapeutics. Baltimore, Lippincott Williams & Wilkins, 1999; with permission.)*

ing, involving the base of the thumb (first carpometacarpal joint) is also highly suggestive of osteoarthritis. By contrast, RA tends to involve the PIP, metacarpophalangeal, intercarpal, and carpometacarpal joints (wrist) with pain, prolonged stiffness, and palpable synovial tissue hypertrophy. Psoriatic arthritis may also involve the DIP and PIP joints and the carpus with inflammatory pain, stiffness, and synovitis. Moreover, the diagnosis of psoriatic arthritis can be suggested by nail pitting or onycholysis. Soft tissue swelling may also be noted over the dorsum of the hand and wrist and may suggest an inflammatory extensor tendon tenosynovitis possibly caused by gonococcal infection, gout, or inflammatory arthritis. The diagnosis of tenosynovitis may be suggested by local warmth and edema and is confirmed when pain is induced by maintaining the wrist in a fixed, neutral position and flexing the digits distal to the metacarpophalangeal joints to stretch the extensor tendon sheaths.

Focal wrist pain localized to the radial aspect may be caused by DeQuervains tenosynovitis resulting from inflammation of the tendon sheath(s) involving the abductor pollicis longus or extensor pollicis brevis (Fig. 311-6). This commonly results from overuse or follows pregnancy and may be diagnosed with Finkelstein's test. A positive result is present when local wrist pain is induced after the thumb is flexed across the palm and placed inside a clenched fist and the patient actively deviates the hand downward with ulnar deviation at the wrist. Carpal tunnel syndrome is another common disorder of the upper extremity and results from compression of the median nerve within the carpal tunnel. Manifestations include paresthesia in the thumb, second, third, and radial half of the fourth finger and, at times, atrophy of thenar musculature. Carpal tunnel syndrome is commonly associated with pregnancy, edema, trauma, osteoarthritis, inflammatory arthritis, and infiltrative disorders (e.g., amyloidosis). The diagnosis is suggested by a positive Tinel's or Phalen's sign. With each test, paresthesia in a median nerve distribution is induced or increased by either "thumping" the volar aspect of the wrist (Tinel's sign) or pressing the extensor surfaces of both flexed wrists against each other (Phalen's sign).

Shoulder Pain During the evaluation of shoulder disorders, the examiner should carefully note any history of trauma, infection, inflammatory disease, occupational hazards, or previous cervical disease. In addition, the patient should be questioned as to the activities or movement(s) that elicit shoulder pain. Shoulder pain is frequently referred from the cervical spine but may also be referred from intrathoracic lesions (e.g., a Pancoast tumor) or from gall bladder, hepatic, or diaphragmatic disease. The shoulder should be put through its full range of motion both actively and passively (with examiner assistance): forward flexion, extension, abduction, adduction, and rotation. Manual inspection of the periarticular structures will often provide important diagnostic information. The examiner should apply direct manual pressure over the subacromial bursa that lies lateral to and immediately beneath the acromion. Subacromial bursitis is a frequent cause of shoulder pain. Anterior to the subacromial bursa, the bicipital tendon traverses the bicipital groove. This tendon is best identified by palpating it in its groove as the patient rotates the humerus internally and externally. Direct pressure over the tendon may reveal pain indicative of bicipital tendinitis. Palpation of the acromioclavicular joint may disclose local pain, bony hypertrophy, or, uncommonly, synovial swelling. Whereas osteoarthritis and RA commonly affect the acromioclavicular joint, osteoarthritis seldom involves the glenohumeral joint, unless there is a traumatic or occupational cause. The glenohumeral joint is best palpated anteriorly by placing the thumb over the humeral head (just medial and inferior to the coracoid process) and having the patient rotate the humerus internally and externally. Pain localized to this region is indicative of glenohumeral pathology. Synovial effusion or tissue is seldom palpable but, if present, may suggest infection, RA, or an acute tear of the rotator cuff.

Rotator cuff tendinitis or tear is a very common cause of shoulder pain. The rotator cuff is formed by the tendons of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. Rotator cuff tendinitis is suggested by pain on active abduction (but not passive abduction), pain over the lateral deltoid muscle, night pain, and evidence of the impingement sign. This maneuver is performed by the examiner raising the patient's arm into forced flexion while stabilizing and preventing rotation of the scapula. A positive sign is present if pain develops before 180° of forward flexion. A complete tear of the rotator cuff is more common in the elderly and often results from trauma; it may manifest in the same manner as tendinitis but is less common. The diagnosis is also suggested by the drop arm test in which the patient is unable to maintain his or her arm outstretched once it is passively abducted. If the patient is unable to hold the arm up once 90° of abduction is reached, the test is positive. Tendinitis or tear of the rotator cuff can be confirmed by MRI or arthrography.

Knee Pain A careful history should delineate the chronology of the knee complaint and whether there are predisposing conditions, trauma, or medications that might underlie the complaint. For example, patellofemoral disease (e.g., osteoarthritis) may cause anterior knee pain that worsens with climbing stairs. Observation of the patient's gait is also important. The knee should be carefully inspected in the upright (weight-bearing) and prone positions for swelling, erythema, contusion, laceration, or malalignment. The most common form of malalignment in the knee is *genu varum* (bowlegs) and *genu valgum* (knock knees). Bony swelling of the knee joint commonly results from hypertrophic osseous changes seen with disorders such as osteoarthritis and neuropathic arthropathy. Swelling caused by hypertrophy of intrasynovial structures (i.e., synovium or synovial effusion) may manifest as a fluctuant, ballotable, or soft tissue enlargement in the suprapatellar pouch (superior reflection of the synovial cavity) or lateral and medial to the patella. Synovial effusions may also be detected by balloting the patella downward toward the femoral groove or by eliciting a "bulge sign." With the the knee extended the examiner should manually compress, or "milk," synovial fluid down from the suprapatellar pouch and lateral to the patellae. The application of manual pressure lateral to the patella may cause an observable shift in synovial fluid (bulge) to the medial aspect. The examiner should note that this maneuver is only effective in detecting small to moderate effusions (<100 mL). Inflammatory disorders such as RA, gout, and Reiter's syndrome may involve the knee joint and produce significant pain, stiffness, swelling, or warmth. A popliteal or *Baker's cyst* is best palpated with

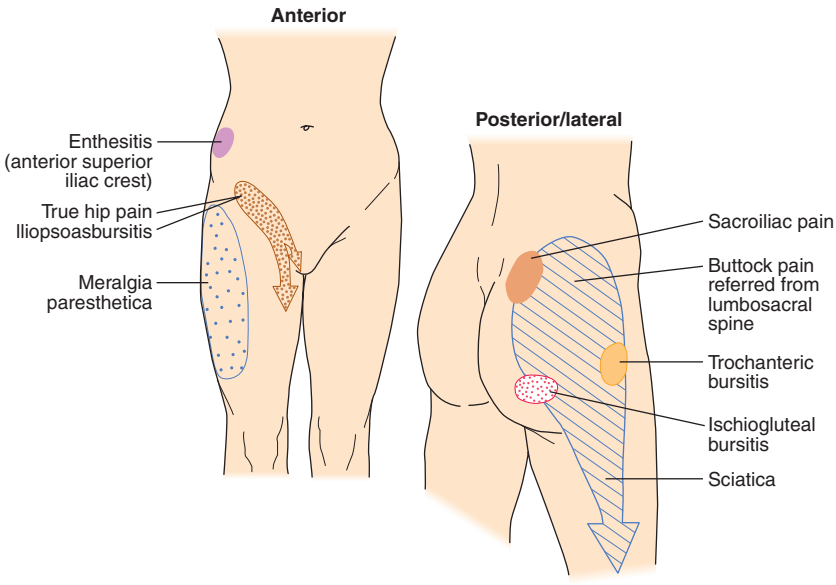

FIGURE 311-7 Origins of hip pain. *(From JJ Cush, AF Kavanaugh: Rheumatology: Diagnosis and Therapeutics. Baltimore, Lippincott Williams & Wilkins, 1999; with permission.)*

the knee partially flexed and is best seen with the patient standing and knees fully extended to visualize popliteal swelling or fullness from a posterior view.

Anserine bursitis is an often missed periarticular cause of knee pain in adults. The pes anserine bursa underlies the semimembranosus tendon and may become inflamed and painful following trauma, overuse, or inflammation. It is often tender in patients with fibromyalgia. Anserine bursitis manifests primarily as point tenderness inferior and medial to the patella and overlies the medial tibial plateau. Swelling and erythema may not be present. Other forms of bursitis may also present as knee pain. The prepatellar bursa is superficial and is located over the inferior portion of the patella. The infrapatellar bursa is deeper and lies beneath the patellar ligament before its insertion on the tibial tubercle.

Internal derangement of the knee may result from trauma or degenerative processes. Damage to the meniscal cartilage (medial or lateral) frequently presents as chronic or intermittent knee pain. Such an injury should be suspected when there is a history of trauma or athletic activity and when the patient relates symptoms of "locking," clicking, or "giving way" of the joint. Pain may be detected during direct palpation over the medial or lateral joint line. The diagnosis may also be suggested by ipsilateral joint line pain when the knee is stressed laterally or medially. A positive McMurray test may indicated a meniscal tear. To perform this test, the knee is first flexed at 90°, and the leg is then extended while simultaneously the lower extremity is torqued medially or laterally. A painful click during inward rotation may indicate a lateral meniscus tear, and pain during outward rotation may indicate a tear in the medial meniscus. Lastly, damage to the cruciate ligaments should be suspected with acute onset of pain, possibly with swelling, a history of trauma, or a synovial fluid aspirate that is grossly bloody. Examination of the cruciate ligaments is best accomplished by eliciting a drawer sign. With the patient recumbent, the knee should be partially flexed and the foot stabilized on the examining surface. The examiner should manually attempt to displace the tibia anteriorly or posteriorly with respect to the femur. If anterior movement is detected, then anterior cruciate ligament damage is likely. Conversely, significant posterior movement may indicate posterior cruciate damage. Contralateral comparison will assist the examiner in detecting significant anterior or posterior movement.

Hip Pain The hip is best evaluated by observing the patient's gait and assessing range of motion. The vast majority of patients reporting "hip pain" localize their pain unilaterally to the posterior or gluteal musculature (Fig. 311-7). Such pain may or may not be associated with low back pain and tends to radiate down the posterolateral aspect of the thigh. This presentation frequently results from degenerative arthritis of the lumbosacral spine and commonly follows a dermatomal distribution with involvement of nerve roots between L5 and S1. Some individuals instead localize their "hip pain" laterally to the area overlying the trochanteric bursa. Because of the depth of this bursa, swelling and warmth are usually absent. Diagnosis of trochanteric bursitis can be confirmed by inducing point tenderness over the trochanteric bursa. Range of movement may be limited by pain. Pain in the hip joint is less common and tends to be located anteriorly, over the inguinal ligament; it may radiate medially to the groin or along the anteromedial thigh. Uncommonly, iliopsoas bursitis may mimic true hip joint pain. Diagnosis of iliopsoas bursitis may be suggested by a history of trauma or inflammatory arthritis. Pain associated with an iliopsoas bursitis is localized to the groin or anterior thigh and tends to worsen with hyperextension of the hip; many patients prefer to flex and externally rotate the hip to reduce the pain from a distended bursa.

312 OSTEOARTHRITIS

Kenneth D. Brandt

Osteoarthritis (OA), also erroneously called degenerative joint disease, represents failure of the diarthrodial (movable, synovial-lined) joint. In idiopathic (primary) OA, the most common form of the disease, no predisposing factor is apparent. Secondary OA is pathologically indistinguishable from idiopathic OA but is attributable to an underlying cause (Table 312-1).

EPIDEMIOLOGY AND RISK FACTORS OA is the most common joint disease of humans. Among the elderly, knee OA is the leading cause of chronic disability in developed countries; some 100,000 people in the United States are unable to walk independently from bed to bathroom because of OA of the knee or hip.

In those <55 years, the joint distribution of OA in men and women is similar; in older individuals, hip OA is more common in men, while OA of interphalangeal joints and the thumb base is more common in women. Similarly, radiographic evidence of knee OA, and especially of *symptomatic* knee OA, is more common in women than in men (Table 312-2).

Racial differences exist in both the prevalence of OA and the pattern of joint involvement. The Chinese in Hong Kong have a lower incidence of hip OA than whites; OA is more frequent in Native Americans than in whites. Interphalangeal joint OA and especially hip OA are much less common in South African blacks than in whites in the same population. Whether these differences are genetic or due to

TABLE 312-1 Classification of Osteoarthritis

I. Idiopathic
  A. Localized OA
    1. Hands: Heberden's and Bouchard's nodes (nodal), erosive interphalangeal arthritis (nonnodal), 1st carpometacarpal joint
    2. Feet: hallux valgus, hallux rigidus, contracted toes (hammer/cock-up toes), talonavicular
    3. Knee:
      a. Medial compartment
      b. Lateral compartment
      c. Patellofemoral compartment
    4. Hip:
      a. Eccentric (superior)
      b. Concentric (axial, medial)
      c. Diffuse (coxae senilis)
    5. Spine:
      a. Apophyseal joints
      b. Intervertebral joints (disks)
      c. Spondylosis (osteophytes)
      d. Ligamentous (hyperostosis, Forestier's disease, diffuse idiopathic skeletal hyperstosis)
    6. Other single sites, e.g., glenohumoral, acromioclavicular, tibiotalar, sacroiliac, temporomandibular
  B. Generalized includes 3 or more of the areas listed above (Kellgren-Moore)
II. Secondary
  A. Trauma
    1. Acute
    2. Chronic (occupational, sports)
  B. Congenital or developmental
    1. Localized diseases: Legg-Calvé-Perthes, congenital hip dislocation, slipped epiphysis
    2. Mechanical factors: unequal lower extremity length, valgus/varus deformity, hypermobility syndromes
    3. Bone dysplasias: epiphyseal dysplasia, spondyloepiphyseal dysplasia, osteonychondystrophy
  C. Metabolic
    1. Ochronosis (alkaptonuria)
    2. Hemochromatosis
    3. Wilson's disease
    4. Gaucher's disease
  D. Endocrine

differences in joint usage related to life-style or occupation is unknown.

In some cases, the relation of heredity to OA is less ambiguous. Thus, the mother and sister of a woman with distal interphalangeal (DIP) joint OA (Heberden's nodes) are, respectively, two to three times as likely to exhibit OA in these joints as the mother and sister of an unaffected woman. Association analyses have identified several candidate genes encoding structural proteins of the extracellular matrix of cartilage and bone and implicated in regulation of bone density. However, no mutation has been identified in the common primary (i.e., idiopathic) form of OA. Most of the mutations identified are associated with relatively rare syndromes, a feature of which can be classified as secondary OA. Mutations in COL2A1 genes, for example, have been associated with clinical phenotypes ranging from mild spondyloepiphyseal dysplasia to severe generalized OA, with onset at an early age. It is likely that classifications of "common OA" will eventually be developed based on causative gene defect rather than on variable clinical phenotypes. This could permit the development of tests permitting the diagnosis of molecular defects and, ideally, prophylactic therapy.

Age is the most powerful risk factor for OA. In a radiographic survey of women <45 years, only 2% had OA; between the ages of 45 and 64 years, however, the prevalence was 30%, and for those >65 years it was 68%. In males, the figures were similar, but somewhat lower, in the older age groups.

Major trauma and repetitive joint use are also important risk factors for OA. Anterior cruciate ligament insufficiency or meniscus damage (and meniscectomy) may lead to knee OA. Although damage to the articular cartilage may occur at the time of injury or subsequently, with use of the affected joint, even normal cartilage will degenerate if the joint is unstable. A person with a trimalleolar fracture will almost certainly develop ankle OA. The pattern of joint involvement in OA is influenced by prior vocational or avocational overload. Thus, although ankle OA is common in ballet dancers, elbow OA in baseball pitchers, and metacarpophalangeal joint OA in prize fighters, OA is not very common at any of these sites in the general population.

Given the growing participation of the population of the United States in cardiovascular fitness programs, it is important to note that, if major trauma is excluded, there are no convincing data to support an association between specific nonprofessional athletic activities and arthritis. Neither long-distance running nor jogging has been shown to cause OA. This apparent lack of association may, however, be due to the lack of good long-term studies, the difficulty in retrospective assessment of activities, and selection bias, i.e., early discontinuation of the activity by those incurring joint damage. In contrast, vocational activities, such as those performed by jackhammer operators, cotton mill and shipyard workers, and coal miners, may lead to OA in the joints exposed to repetitive occupational use. Men whose jobs required knee bending and at least moderate physical demands had a higher rate of radiographic evidence of knee OA, and more severe radiographic changes, than men whose jobs required neither.

Obesity is a risk factor for both knee and hand OA. For those in the highest quintile for body mass index at baseline examination, the relative risk for developing knee OA in the ensuing 36 years was 1.5 for men and 2.1 for women. For *severe* knee OA, the relative risk rose to 1.9 for men and 3.2 for women, suggesting that obesity plays an even larger role in the etiology of the most serious cases of knee OA. Obese subjects who have not yet developed OA can reduce their risk: A weight loss of only 5 kg was associated with a 50% reduction in the odds of developing symptomatic knee OA.

The correlation between the pathologic severity of OA and symptoms is poor. Many people with radiographic changes of advanced OA have no symptoms. The risk factors for *pain and disability* in affected individuals are poorly understood. Disability in subjects with knee OA is more strongly associated with quadriceps muscle weakness than with joint pain or radiographic severity. For the same degree of path-

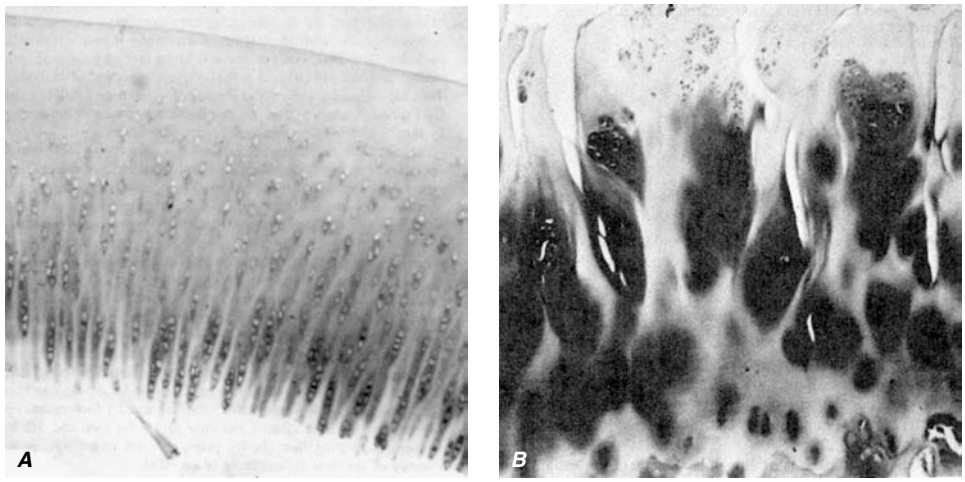

FIGURE 312-1 *A*. Normal articular cartilage. Note the intact surface and even distribution of chondrocytes. Mitotic figures are not present in normal adult articular cartilage. *B*. Osteoarthritic cartilage. Note the disruption of surface integrity, with vertical fissures (fibrillation) and irregular distribution of cells. Many of the chondrocytes have replicated and exist in clusters. Stained with safranin-O, which binds to the sulfated glycosaminoglycan chains of proteoglycans. Note patchy areas of diminished staining (pale extracellular matrix) due to proteoglycan depletion.

ologic severity, women are more likely to be symptomatic than men, those on welfare more likely than those who are working, and those who are divorced more likely than those who are married. For patients who had poor social support, periodic phone calls from a trained lay interviewer were as effective as a nonsteroidal anti-inflammatory drug (NSAID) in reducing joint pain, emphasizing the importance of psychosocial factors as determinants of pain.

PATHOLOGY Although the cardinal pathologic feature of OA is a progressive loss of articular cartilage, OA is not a disease of only the cartilage but a disease of an *organ*, the synovial joint, in which all of the tissues are affected: subchondral bone, synovium, meniscus, ligaments, and supporting neuromuscular apparatus as well as the cartilage.

The most striking morphologic changes in OA are usually seen in load-bearing areas of the articular cartilage. In the early stages the cartilage is thicker than normal, but with progression of OA the joint surface thins, the cartilage softens, the integrity of the surface is breached, and vertical clefts develop (fibrillation) (Fig. 312-1). Deep cartilage ulcers, extending to bone, may appear. Areas of fibrocartilaginous repair may develop, but these are inferior to pristine hyaline articular cartilage in their ability to withstand mechanical stress. All of the cartilage is metabolically active and the chondrocytes replicate, forming clusters (clones). Later, however, the cartilage becomes hypocellular.

Remodeling and hypertrophy of bone are major features of OA. Appositional bone growth occurs in the subchondral region, leading to the bony "sclerosis" seen radiographically. The abraded bone under a cartilage ulcer may take on the appearance of ivory (eburnation). Growth of cartilage and bone at the joint margins leads to osteophytes (spurs), which alter the contour of the joint and may restrict movement. A patchy chronic synovitis and thickening of the joint capsule may further restrict movement. Periarticular muscle wasting is common and may play a major role in symptoms and, as indicated above, in disability.

PATHOGENESIS The main load on articular cartilage—the major target tissue in OA—is generated by the contraction of the muscles that stabilize or move the joint. Although cartilage is an excellent shock absorber in terms of its bulk properties, at most sites it is only 1 to 2 mm thick—too thin to serve as the sole shock-absorbing structure in the joint. Additional protective mechanisms are provided by the subchondral bone and periarticular muscles.

Articular cartilage serves two essential functions within the joint, both of which are mechanical. First, it provides a remarkably smooth bearing surface, so that the bones glide effortlessly over each other with joint movement. With synovial fluid as lubricant, the coefficient of friction for cartilage rubbed against cartilage, even under physiologic loading, is 15 times lower than that of two ice cubes passed across each other! Second, articular cartilage prevents the concentration of stresses so the bones do not shatter when the joint is loaded.

OA develops in either of two settings: (1) the biomaterial properties of the articular cartilage and subchondral bone are normal, but excessive loading of the joint causes the tissues to fail; or (2) the applied load is reasonable, but the material properties of the cartilage or bone are inferior.

Although articular cartilage is highly resistant to wear under conditions of repeated oscillation, repetitive impact loading soon leads to joint failure. This fact accounts for the high prevalence of OA at specific sites related to vocational or avocational overloading. In general, the earliest changes occur at the sites in the joint that are subject to the greatest compressive loads. Some cases of so-called idiopathic OA of the hip may be due to subtle congenital or developmental defects, such as congenital subluxation/dislocation, acetabular dysplasia, Legg-Calvé-Perthes disease, or slipped capital femoral epiphysis, which increase joint congruity and concentrate the dynamic load.

Clinical conditions that reduce the ability of the cartilage or subchondral bone to deform are associated with development of OA. In ochronosis, for example, accumulation of homogentisic acid polymers leads to stiffening of the cartilage; in osteopetrosis, stiffness of the subchondral trabeculae occurs. In both conditions, severe generalized OA is usually apparent by the age of 40 years. If the subchondral bone is stiffened experimentally, repetitive impact loading soon leads to breakdown of the overlying cartilage. Conversely, osteoporosis, in which the bone is abnormally soft, may protect against OA.

The Extracellular Matrix of Normal Articular Cartilage Articular cartilage is composed of two major macromolecular species: proteoglycans (PGs), which are responsible for the compressive stiffness of the tissue and its ability to withstand load, and collagen, which provides tensile strength and resistance to shear. Although lysomal proteases (cathepsins) have been demonstrated within the cells and matrix of normal articular cartilage, their low pH optimum makes it likely that the proteoglycanase activity of these enzymes will be confined to intracellular sites or the immediate pericellular area. However, cartilage also contains a family of matrix metalloproteinases (MMPs), including stromelysin, collagenase, and gelatinase, which can degrade all the components of the extracellular matrix at neutral pH. Each is secreted by the chondrocyte as a latent proenzyme that must be activated by proteolytic cleavage of its N-terminal sequence. The level of MMP activity in the cartilage at any given time represents the balance between activation of the proenzyme and inhibition of the active enzyme by tissue inhibitors. Much of the total tissue pool of aggrecan, the major PG in articular cartilage, is degraded by a proteinase, which cleaves the protein core of the molecule at a site distinct from the cleavage site of the MMP. The enzyme responsible for this cleavage is referred to as *aggrecanase*.

The turnover of normal cartilage is affected through a degradative cascade; the driving force appears to be interleukin (IL) 1, a cytokine produced by mononuclear cells (including synovial lining cells) and synthesized by chondrocytes. IL-1 stimulates the synthesis and secretion of the latent MMPs and of tissue plasminogen activator. Plasminogen, the substrate for the latter enzyme, may be synthesized by the chondrocyte or may enter the cartilage from the synovial fluid. Both

plasminogen and stromelysin may play a role in activation of the latent MMPs. In addition to its catabolic effect on cartilage, IL-1 suppresses PG synthesis by the chondrocyte, inhibiting matrix repair (see below). The major proteinases involved in degradation of matrix of human articular cartilage appear to be collagenase-3 (MMP-13) and aggrecanase-1 (ADAMTS4). Control of MMP-13 activity appears to be exerted via transcriptional activation by cytokines and activation of the pro-form at the cell surface. The transcriptional activity is mediated primarily through the p38 mitogen-activated protein kinase pathway, but also involves nuclear factor kappa B. Interest currently exists in the inhibition of cartilage matrix degradation by therapeutic agents that block the p38-dependant transcriptional activity of MMP-13 expression or control extracellular activation of the secreted form of ADAMTS4.

The balance of the system lies with inhibitors of matrix degrading enzymes, e.g., tissue inhibitor of metalloproteinase (TIMP) and plasminogen activator inhibitor-1 (PAI-1), which are synthesized by the chondrocyte and limit the degradative activity of MMPs and plasminogen activator, respectively. If TIMP or PAI-1 is destroyed or present in concentrations that are insufficient relative to those of active enzymes, stromelysin and plasmin are free to act on matrix substrates. Stromelysin can degrade the protein core of the PG and activate latent collagenase. Conversion of latent stromelysin to an active, highly destructive protease by plasmin provides a second mechanism for matrix degradation.

Polypeptide mediators, e.g., insulin-like growth factor-1 (IGF-1) and transforming growth factor β (TGF-β), stimulate biosynthesis of PGs. They regulate matrix metabolism in normal cartilage and may play a role in matrix repair in OA. These growth factors modulate catabolic as well as anabolic pathways of chondrocyte metabolism; by down-regulating chondrocyte receptors for IL-1, they may decrease PG degradation. In addition to its responsiveness to cytokines and a variety of other biologic mediators, chondrocyte metabolism in normal cartilage can be modulated directly by mechanical loading. Whereas static loading inhibits synthesis of PGs and protein, loads of relatively brief duration may stimulate matrix biosynthesis.

Pathophysiology of Cartilage Changes in OA Most investigators feel that the primary changes in OA begin in the cartilage. A change in the arrangement and size of the collagen fibers is apparent. Biochemical data are consistent with the presence of a defect in the collagen network of the matrix, perhaps due to disruption of the "glue" that binds adjacent fibers. This is among the earliest matrix changes observed and appears to be irreversible.

Although "wear" may be a factor in the loss of cartilage, strong evidence supports the concept that MMPs account for much of the loss of cartilage matrix in OA. Whether their synthesis and secretion are stimulated by IL-1 or by other factors (e.g., mechanical stimuli), MMPs, plasmin, and cathepsins all appear to be involved in the breakdown of articular cartilage in OA. TIMP and PAI-1 may work to stabilize the system, at least temporarily, while growth factors such as IGF-1 and TGF-β are implicated in repair processes that may heal the lesion or, at least, stabilize the process. A stoichiometric imbalance exists between the levels of active enzyme and the level of TIMP, which may be only modestly increased.

Nitric oxide (NO) may play a significant role in articular cartilage damage in OA insofar as NO stimulates synthesis of MMPs by chondrocytes. Chondrocytes are a major source of NO, the synthesis of which is stimulated by IL-1 and tumor necrosis factor and by shear stress. In an experimental model of OA, treatment with a selective inhibitor of inducible NO synthase reduced the severity of cartilage damage.

The chondrocytes in OA cartilage undergo active cell division and are very active metabolically, producing increased quantities of DNA, RNA collagen, PG, and noncollagenous proteins. For this reason, it is inaccurate to call OA *degenerative* joint disease. Prior to cartilage loss and PG depletion, this marked biosynthetic activity may lead to an increase in PG concentration, which may be associated with thickening of the cartilage and a stage of homeostasis referred to as *compensated OA*. These mechanisms may maintain the joint in a reasonably functional state for years. The repair tissue, however, often does not hold up as well under mechanical stresses as does normal hyaline cartilage and eventually, at least in some cases, the rate of PG synthesis falls and "end-stage" OA develops, with full-thickness loss of cartilage.

Traumatic joint injury is a risk factor for secondary OA (Table 312-1). Mechanical injury to articular cartilage in vitro results in swelling, alteration in biomechanical properties, cell death, changes in biosynthesis of matrix macromolecules, loss of PGs, degradation of collagen, and an increase in MMP gene expression.

The extent to which the above changes are due to direct mechanical damage versus cell-mediated degradation is unclear. Injury may result in increased responsiveness of the chondrocyte to stimulation by cytokines. On the other hand, it may facilitate diffusion of cytokines into the matrix. In contrast to knee cartilage, glycosaminoglycan loss from ankle cartilage is not increased after mechanical injury of the tissue and exposure to cytokines. Chondrocytes in articular cartilage from some joints may react differently to cytokines, mechanical forces, and growth factors than to those in other joints, perhaps accounting for the lower incidence of OA in some joints than in others, e.g., ankle vs. knee.

CLINICAL FEATURES The joint pain of OA is often described as a deep ache localized to the involved joint. Typically, it is aggravated by joint use and relieved by rest but, as the disease progresses, it may become persistent. Nocturnal pain, interfering with sleep, is seen particularly in advanced OA of the hip and may be enervating. Stiffness of the involved joint after a period of inactivity (e.g., a night's sleep or automobile ride) may be prominent but usually lasts $<$20 min. Systemic manifestations are not a feature of primary OA.

Because articular cartilage is aneural, the joint pain in OA must arise from other structures (Table 312-3). In some cases it may be due to stretching of nerve endings in the periosteum covering osteophytes; in others, to microfractures in subchondral bone or medullary hypertension caused by distortion of blood flow by thickened subchondral trabeculae. Joint instability, leading to stretching of the joint capsule, and muscle spasm may also be sources of pain.

In some patients with OA, joint pain may be due to synovitis. In advanced OA, histologic evidence of synovial inflammation may be as marked as that in synovium of a patient with rheumatoid arthritis (Chap. 301). Synovitis in OA may be due to phagocytosis of shards of cartilage and bone from the abraded joint surface (wear particles), release from the cartilage of soluble matrix macromolecules, or crystals of calcium pyrophosphate or hydroxyapatite. In other cases, immune complexes, containing antigens derived from cartilage matrix, may be sequestered in collagenous tissues of the joint, leading to low-grade chronic synovitis. In contrast, in the earlier stages of OA, synovial inflammation may be absent, suggesting that the joint pain is due to one of the other factors mentioned above.

Physical examination of the OA joint may reveal localized tenderness and bony or soft tissue swelling. Bony crepitus (the sensation of bone rubbing against bone, evoked by joint movement) is characteristic. Synovial effusions, if present, are usually not large. Palpation may reveal some warmth over the joint. Periarticular muscle atrophy may be due to disuse or reflex inhibition of muscle contraction. In the

TABLE 312-3 *Causes of Joint Pain and Patients with OA*

Source	*Mechanism*
Synovium	Inflammation
Subchondral bone	Medullary hypertension, microfractures
Osteophyte	Stretching of periosteal nerve endings
Ligaments	Stretch
Capsule	Inflammation, distention
Muscle	Spasm

advanced stages of OA, there may be gross deformity, bony hypertrophy, subluxation, and marked loss of joint motion. The notion that OA is inexorably progressive, however, is incorrect. In many patients, the disease stabilizes; in some, regression of joint pain and even of radiographic changes occur.

Although the diagnosis of OA is often straightforward, because of the high prevalence of radiographic changes of OA in asymptomatic individuals, it is important to ensure that joint pain in a patient with radiographic evidence of OA is not due to some other cause, such as soft tissue rheumatism (e.g., anserine bursitis at the knee, trochanteric bursitis at the hip), radiculopathy, referral of pain from another joint (25% of patients with hip disease have pain referred to the knee), entrapment neuropathy, vascular disease (claudication), or some other type of arthritis (e.g., crystal-induced synovitis, septic arthritis). It is usually not difficult to differentiate OA from a systemic rheumatic disease, such as rheumatoid arthritis, because joint involvement in the latter disease is usually symmetric and polyarticular, with arthritis in wrists and metacarpophalangeal joints (sites not usually involved in OA), and constitutional features, such as prolonged morning stiffness, fatigue, weight loss, or fever, may be seen.

LABORATORY AND RADIOGRAPHIC FINDINGS The diagnosis of OA is usually based on clinical and radiographic features. In the early stages, the radiograph may be normal but joint space narrowing becomes evident as articular cartilage is lost. Other characteristic findings include subchondral bone sclerosis, subchondral cysts, and osteophytosis. A change in the contour of the joint, due to bony remodeling, and subluxation may be seen. Although tibiofemoral joint space narrowing has been considered to be a radiographic surrogate for articular cartilage thinning, joint space narrowing alone does not accurately indicate the status of the articular cartilage in patients with early OA who do not have radiographic evidence of bony changes (e.g., subchondral sclerosis or cysts, osteophytes). Similarly, osteophytosis alone, in the absence of other radiographic features of OA, may be due to aging rather than OA. As indicated above, there is often great disparity between the severity of radiographic findings, severity of symptoms, and functional ability in OA; while >90% of persons over age 40 have some radiographic changes of OA in weight-bearing joints, only 30% are symptomatic.

No laboratory studies are diagnostic for OA, but laboratory testing may help identify an underlying causes of secondary OA. Because primary OA is not systemic, the erythrocyte sedimentation rate, serum chemistry determinations, blood counts, and urinalysis are normal. Synovial fluid analysis reveals mild leukocytosis (<2000 white blood cells per microliter), with a predominance of mononuclear cells. Synovial fluid analysis is of particular value in excluding other conditions, such as calcium pyrophosphate dihydrate deposition disease (Chap. 313), gout (Chap. 313) or septic arthritis (Chap. 314).

Prior to the appearance of radiographic changes, the ability to clinically diagnose OA without an invasive procedure (e.g., arthroscopy) is limited. Magnetic resonance imaging and ultrasonography have not been sufficiently validated to justify their routine clinical use for diagnosis of OA or monitoring disease progression.

OA AT SPECIFIC JOINT SITES ■ Interphalangeal Joints Heberden's nodes (bony enlargement of the DIP joint) are the most common form of idiopathic OA (Fig. 312-2). A similar process at the proximal interphalangeal joints leads to Bouchard's nodes. Often, these nodes develop gradually, with little or no discomfort, and usually do not interfere significantly with function. However, they may present acutely with pain, redness, and swelling, sometimes triggered by minor trauma. Gelatinous dorsal cysts may develop at the insertion of the digital extensor tendon into the base of the distal phalanx.

EROSIVE OA In erosive OA, DIP and/or proximal interphalangeal joints of the hand are most prominently affected. Erosive OA is more destructive than typical nodal OA; x-ray evidence of collapse of the subchondral plate is characteristic, and bony ankylosis may occur. Deformity and functional impairment may be severe. The synovium is much more extensively infiltrated with mononuclear cells than in other forms of OA.

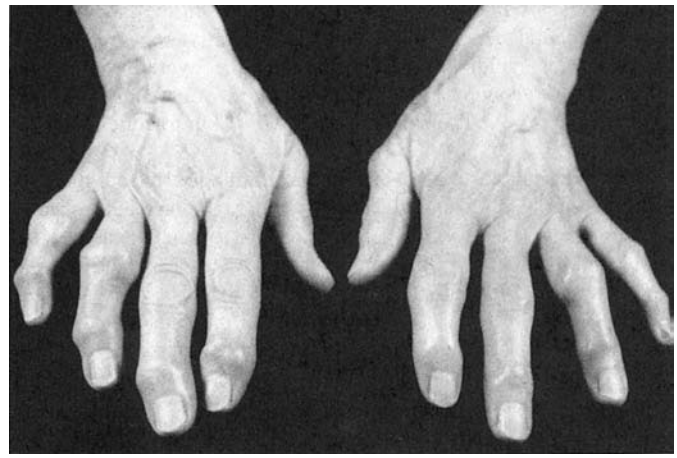

FIGURE 312-2 Nodal osteoarthritis. Note bony enlargement of distal and proximal interphalangeal joints (Heberden's nodes and Bouchard's nodes, respectively). *(Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, 1991, 1995. Reproduced with permission of the American College of Rheumatology.)*

GENERALIZED OA Generalized OA is characterized by involvement of three or more joints or groups of joints (DIP and proximal interphalangeal joints are counted as one group each). Heberden's and Bouchard's nodes are prominent. "Flare-ups" of inflammation may be marked by soft tissue swelling, redness, and warmth. The erthryocyte sedimentation rate may be elevated, but serum rheumatoid factor tests are negative.

Thumb Base The second most frequent area of involvement in OA is the thumb base. Swelling, tenderness, and crepitus on movement of the joint and loss of motion and strength are common. Osteophytes may lead to a "squared" appearance (Fig. 312-3). Pain with pinch leads to adduction of the thumb and contracture of the first web space, often resulting in compensatory hyperextension of the first metacarpophalangeal joint and swan-neck deformity of the thumb.

Hip Congenital or developmental defects of the hip (e.g., acetabular dysplasia, Legg-Calvé-Perthes disease, slipped capital epiphysis) can lead to OA. Pain from hip OA is generally referred to the inguinal area but may be referred to the buttock or proximal thigh. Less commonly, hip OA presents as knee pain. Pain can be evoked by putting the involved hip through its range of motion. Flexion may be painless initially, but internal rotation will exacerbate pain. Loss of internal rotation occurs early, followed by loss of extension, adduction, and flexion due to capsular fibrosis and/or buttressing osteophytes.

Knee OA of the knee may involve the medial or lateral femorotibial compartment and/or the patellofemoral compartment. Palpation may

FIGURE 312-3 Osteoarthritis of the first carpometacarpal joint. Note the squared appearance of the thumb base, due to bony enlargement and remodeling of the joint.

reveal bony hypertrophy (osteophytes) and tenderness. Effusions, if present, are generally small. Joint movement commonly elicits bony crepitus. OA in the medial compartment may result in a varus (bowleg) deformity; OA in the lateral compartment may produce a valgus (knock-knee) deformity. A positive "shrug" sign (pain with manual compression of the patella against the femur during quadriceps contraction) may be a sign of patellofemoral OA.

Chondromalacia patellae, which is also characterized by anterior knee pain and a positive shrug sign, is a syndrome of patellofemoral pain in teenagers and young adults. It is more common in females. It may be caused by a variety of factors (e.g., abnormal quadriceps angle, patella alta, trauma). Although exploration of the knee may reveal softening and fibrillation of cartilage on the posterior aspect of the patella, this change is usually not progressive; chondromalacia patellae is usually not a precursor of OA. In most cases, analgesics or NSAIDs and physical therapy are effective; in some, pain may be relieved by surgical correction of patellar malalignment.

Spine OA of the spine can involve the apophyseal joints, intervertebral disks, and paraspinous ligaments. *Spondylosis* refers to degenerative disk disease. The diagnosis of spinal OA should be reserved for patients with involvement of the apophyseal joints, and not only disk degeneration. Symptoms of spinal OA include localized pain and stiffness. Nerve root compression by an osteophyte blocking a neural foramen, prolapse of a degenerated disk, or subluxation of an apophyseal joint may cause radicular pain and motor weakness.

Marked calcification and ossification of paraspinous ligaments occur in diffuse idiopathic skeletal hyperostosis (DISH), which must be distinguished from OA. Although DISH is often categorized as a variant of OA, the diarthrodial joints are not involved. In radiographs, ligamentous calcification and ossification in the anterior spinal ligaments give the appearance of "flowing wax" on the anterior vertebral bodies. However, a radiolucency may be seen between the newly deposited bone and the vertebral body, differentiating DISH from the marginal osteophytes in spondylosis. Intervertebral disk spaces are preserved, and sacroiliac and apophyseal joints appear normal, helping to differentiate DISH from spondylosis and from ankylosing spondylitis, respectively. DISH occurs in the middle-aged and elderly and is more common in men than in women. Patients are frequently asymptomatic but may have musculoskeletal stiffness. The radiographic changes are generally much more severe than might be predicted from the mild symptoms.

TREATMENT

Treatment of OA is aimed at reducing pain, maintaining mobility, and minimizing disability. The vigor of the therapeutic intervention should be dictated by the severity of the condition in the individual patient. For those with only mild disease, reassurance, instruction in joint protection, and an occasional analgesic may be all that is required; for those with more severe OA, especially of knee or hip, a comprehensive program comprising a spectrum of nonpharmacologic measures supplemented by an analgesic and/or NSAID is appropriate.

Nonpharmacologic Measures ■ *REDUCTION OF JOINT LOADING* OA may be caused or aggravated by poor body mechanics. Correction of poor posture and a support for excessive lumbar lordosis can be helpful. Excessive loading of the involved joint should be avoided. Patients with knee or hip OA should avoid prolonged standing, kneeling, and squatting. Obese patients should be counseled to lose weight. In patients with medial compartment knee OA, a wedged insole may decrease joint pain.

Rest periods during the day may be of benefit, but complete immobilization of the painful joint is rarely indicated, except in cases of hand OA. For DIP joint OA that is so painful that it interferes with hand function, a custom-molded thermoplastic splint that blocks flexion can reduce pain, improve overall hand function, and reduce muscle spasm. Splinting can also be very effective for trapeziometacarpal joint and pantrapezial OA. Rigid immobilization is not an acceptable long-term option for pain in the proximal interphalangeal joints, however, because it limits hand function and can result in shortening of the collateral ligaments. In patients with unilateral OA of the hip or knee, a cane, held in the contralateral hand, may reduce joint pain by reducing the joint contact forces. Bilateral disease may necessitate use of crutches or a walker.

PATELLAR TAPING OA of the patellofemoral compartment can cause severe pain, especially with kneeling, squatting, or climbing stairs. Medial taping of the patella can significantly reduce pain in such cases. The taping procedure is simple and inexpensive and patients can learn to apply their own tape after minimal instruction. The prompt relief of symptoms that may be achieved by taping may be maintained by isometric exercises to strengthen the vastus medialis obliquus component of the quadriceps muscle, facilitating realignment of the patella on a long-term basis.

WEDGED INSOLES/ORTHOSES In patients with medial compartment knee OA, pain severity has been shown to be related to the magnitude of the external adduction moment (a measure of the varus torque on the knee during gait). Wedged insoles may be useful in conservative treatment of OA of the medial tibial femoral compartment. Their use may change the spatial position of the lower limb so that the mechanical axis becomes more nearly vertical and the calcaneal axis is shifted to a valgus position with respect to the tibiotalar joint, reducing excessive loading on the medial compartment of the knee and strain on the lateral collateral ligament. Use of lateral wedged insoles may result in a significant decrease in NSAID consumption by patients with knee OA. A polypropylene mesh insole is practical, inexpensive, and washable and may last about 2 years, i.e., approximately twice as long as a leather insole.

THERMAL MODALITIES Application of heat to the OA joint may reduce pain and stiffness. A variety of modalities are available; often, the least expensive and most convenient is a hot shower or bath. Occasionally, better analgesia may be obtained with ice than with heat.

EXERCISE Those who exercise regularly live longer and are healthier than those who are sedentary. Because OA of weight-bearing joints limits physical activity and the amount of exercise that an individual can perform, persons with this condition are at increased risk for hypertension, obesity, diabetes, and cardiovascular disease, i.e., diseases related to their inactivity. Only 24% of individuals with arthritis report a level of physical activity sufficient to achieve health; 75% do nothing or are not sufficiently active. Arthritis is *the* major reason that elderly individuals are not active or limit their activity and is a greater factor in limiting activity than heart disease, hypertension, blindness, or diabetes. Studies of cardiovascular health have shown that the aerobic capacity (cardiovascular fitness) of men with severe knee OA is >30% lower than that of controls who do not have OA. Even at slow speed, individuals with knee OA expend more energy (measured as oxygen consumption) in walking than age- and sex-matched controls.

Disability in patients with OA may have more to do with their ability to remain active and physically fit and maintain normal body weight than with pathologic changes in the OA joint. Even if we cannot cure OA, we can cure inactivity. Men in their forties who were not performing sufficient physical activity and had low scores on a treadmill test were found to have remarkably higher death rates than those who were fit. However, among those who were not fit at the outset but who *became* fit, the risk of mortality decreased by 44%.

The amount of *aerobic conditioning* (e.g., walking, cycling, aquatic exercise) necessary for cardiovascular fitness is not so great that it cannot be achieved by people with OA. Patients with OA of lower extremity joints who are able to perform moderate to vigorous exercise at least 3 days per week (i.e., 70 to 85% of maximal heart rate)—an intensity that permits an individual to talk while exercising continuously for 20 to 60 min—improve their fitness and health without exacerbating their joint pain or increasing their need for analgesic drugs. Persons with OA who exercise consistently at this level report de-

creases in joint pain and disability while improving their cardiovascular muscular fitness (strength and endurance). They also report improvement in function and quality of life and exhibit improved gait and walking speed. Patients with hip or knee OA can participate safely in conditioning exercises to improve fitness and health without increasing their joint pain or need for analgesics or NSAIDs.

Disuse of the OA joint because of pain will lead to muscle atrophy. Because periarticular muscles play a major role in protecting the articular cartilage from stress, strengthening exercises are important. In patients with knee OA, strengthening of the periarticular muscles may result, within weeks, in a decrease in joint pain as great as that seen with NSAIDs. Most of the information available about the benefits of *therapeutic exercise* relates to strength training. However, the benefits of therapeutic exercise go far beyond muscle strengthening. In studies that employed 4 to 10 instructional sessions followed by self-directed home exercise in which patients initially exercised up to 5 days per week, with recommendations to decrease the frequency over the next 6 months to 2 days per week, compliance was excellent. The results showed that pain, anxiety, and depression decreased, while lower extremity strength, endurance, proprioception, and functional status improved and disability was reduced. With fairly minimal intervention and self-directed exercise, patients with OA can achieve and maintain important gains.

PATIENT EDUCATION For effective management of many patients with OA, encouragement, reassurance, advice about exercise, and recommendation of measures to unload the arthritic joint (such as a cane and proper footwear) may be all that is required. Patient education programs offer benefits beyond those that can be achieved with an NSAID in symptomatic treatment of patients with OA. Patient education interventions provide an additive benefit 20 to 30% as great as that of NSAID treatment alone. Relevant education for the patient with OA is not education about joint anatomy or the definition of an osteophyte but is education in *self-management* that emphasizes the central role of the patient in managing the disease; furthermore, it teaches the skills required to permit patients to manage medically and emotionally and to maintain their role in society.

A variety of self-management programs have been developed for patients with OA, such as the Arthritis Self-Management Program that is sponsored in the United States by the Arthritis Foundation. Participation in a structured community-based education intervention, led by trained lay leaders, can result in significant decreases in pain, disability, and depression. Patients who participate in such programs report greater performance of self-management behaviors, e.g., taking their medication properly, communicating with their healthcare providers. Furthermore, the benefits may endure for years, even with no reinforcement of the intervention.

TIDAL IRRIGATION OF THE KNEE Copious irrigation of the OA knee through a large-bore needle, flushing out fibrin, cartilage shards, and other debris, has been reported to provide months of comfort for some patient whose joint pain has been refractory to analgesics, NSAIDs, and intraarticular glucocorticoid injections. However, results of a randomized controlled trial of patients with knee OA that included a sham-irrigation procedure led to the conclusion that the bulk of the benefit from this procedure is attributable to the placebo effect.

ARTHROSCOPIC DEBRIDEMENT AND LAVAGE Arthroscopic surgery can be helpful in alleviating knee pain and improving function in the subgroup of patients with knee OA in whom loose bodies, flaps of cartilage, or disruption of the meniscus (e.g., a bucket handle tear) cause mechanical symptoms, such as locking, giving way of the limb, or catching. Although arthroscopic debridement, e.g., smoothing of the surface of fibrillated articular cartilage or meniscus, trimming of osteophytes, and removal of inflamed synovium, is employed widely in patients with symptomatic knee OA who do not have mechanical symptoms, but who have not benefited from pharmacologic therapy, this therapeutic modality appears to be of no greater symptomatic benefit than placebo in such patients.

Pharmacologic Therapy ■ *NSAIDs AND ACETAMINOPHEN (N-ACETYL-p-AMINOPHENOL, APAP)* Drug therapy for OA today is palliative; no pharmacologic agent has been shown to prevent, delay the progression of, or reverse the pathologic changes of OA in humans. Although claims have been made that some NSAIDs slow the rate of cartilage damage, adequately controlled clinical trials in humans with OA to support this view are lacking.

In management of OA pain, pharmacologic agents should be used as adjuncts to nonpharmacologic measures, such as those described above. The latter are the *keystone* of OA treatment. Although NSAIDs often decrease joint pain and improve mobility in OA, the magnitude of improvement is generally modest—on average, about 30% reduction in pain and 15% improvement in function. Many patients taking a full therapeutic dose of NSAIDs continue to experience a significant level of residual joint pain. On the other hand, low (i.e., analgesic) doses of NSAIDs may be as effective as anti-inflammatory doses; 30 to 40% of patients with OA may find APAP—an analgesic recommended for treatment of mild-moderate pain—as effective as an NSAID. Even in patients with clinical signs of joint inflammation (synovial effusion, tenderness), relief of joint pain by APAP may be as effective as that achieved with an NSAID. Nonetheless, if simple analgesics are inadequate, it is reasonable to prescribe an NSAID for the patient with OA.

However, concern over the use of NSAIDs in OA has grown in recent years because of the adverse effects of these agents, especially those related to the gastrointestinal tract. Those at greatest risk for OA, i.e., the elderly, appear to be at greater risk than younger individuals for gastrointestinal symptoms, ulceration, hemorrhage, and death as a result of NSAID use. The annual rate of hospitalization for peptic ulcer disease among elderly current NSAID users was 16 per 1000, i.e., four times greater than that for persons not taking an NSAID. Among people age ≥65, as many as 30% of all hospitalizations and deaths related to peptic ulcer disease have been attributed to NSAID use. Risk factors for hemorrhage and other ulcer complications associated with NSAID use include, in addition to age, a history of peptic ulcer disease or of upper gastrointestinal bleeding, concomitant use of glucocorticoids or anticoagulants, and, possibly, smoking and alcohol consumption (Table 312-4).

SELECTIVE COX-2 INHIBITORS In patients who carry risk factors for an NSAID-associated gastrointestinal catastrophe, a cyclooxygenase (COX)-2 selective NSAID may be preferable to even a low dose of a nonselective COX inhibitor. In contrast to the nonselective NSAIDs, all of which inhibit COX-1 as well as COX-2, selective COX-2 inhibitors, e.g., celecoxib, rofecoxib, valdecoxib, are now available. These exhibit no greater efficacy than nonselective NSAIDs, but endoscopic studies show that they are associated with a lower incidence of gastroduodenal ulcer than nonselective NSAIDs. Of additional advantage with respect to the issue of upper gastrointestinal bleeding, selective COX-2 inhibitors do not have a clinically significant effect on platelet aggregation or bleeding time.

Results of two large-size gastrointestinal safety studies, the CLASS trial and VIGOR study, have been published (Table 312-5). Both were designed to ascertain whether treatment with celecoxib or rofecoxib, respectively, resulted in a lower incidence of clinically important NSAID-associated ulcers and ulcer complications than that seen with

TABLE 312-4 Risk Factors for Upper Gastrointestinal Adverse Events in Patients Taking NSAIDs

Increasing age	History of upper gastrointestinal bleeding
Comorbidity (poor or fair general health)	Anticoagulation
Oral glucocorticoids	Combination NSAID therapy
History of peptic ulcer	Increasing NSAID dose

Note: NSAID, nonsteroidal anti-inflammatory drug.

nonselective NSAIDs. In the VIGOR trial, a clear reduction in the incidence of upper gastrointestinal events was apparent in the rofecoxib treatment arm, in comparison with the naproxen arm. The risk of all clinical upper gastrointestinal events was reduced by some 54% ($p < .01$), of complicated upper gastrointestinal events by 57% ($p = .005$), and of any gastrointestinal bleeding by 62% ($p < .01$). In the CLASS study, the annualized incidence rates of ulcer complications (the primary outcome measure) with celecoxib was not significantly different from that and with the comparator nonselective NSAIDs after 6 months of treatment, although the difference for ulcer complications combined with symptomatic ulcers was significant (2.08% vs 3.54%, respectively, $p = .02$). Although a significant reduction in ulcer complications was seen with celecoxib, use of low-dose aspirin for cardiovascular prophylaxis appeared to mitigate the gastroprotective effect of celecoxib. (Although only 22% of subjects in the CLASS study were taking low-dose aspirin, as many as 60% of patients with OA >60 years old may do so in clinical practice.) Furthermore, the superiority of celecoxib observed among nonaspirin users during the first 6 months was not sustained in patients treated for 12 months.

TABLE 312-5 *Comparison of Study Designs for Rofecoxib (VIGOR) and Celecoxib (CLASS) Gastrointestinal (GI)*

	Trial	
Parameter	*VIGOR*	*CLASS*
Number of subjects	8076	7982
Mean age	~58 years	~60 years; ~38% >65 years
Underlying disease	Rheumatoid arthritis	Osteoarthritis 73%, rheumatoid arthritis 27%
Duration of follow-up	Median, 9 months Maximum, 13 months	Median, 9 months Maximum, 13 months
Type of analysis	Intention to treat (includes events within 14 days of last dose of study drug)	Excludes events on day 0–2 and >6 months
Dose of Coxib	Rofecoxib, 50 mg/d	Celecoxib, 400 mg/d
Comparator NSAID	Naproxen, 1000 mg/d	Ibuprofen, 2400 mg/d or diclofenac, 150 mg/d
Low-dose aspirin	Not permitted	22%
Concurrent steroid use	56%	30%
Primary end point	Clinical upper GI events	Complicated ulcers
Secondary end point	Complicated upper GI events	Symptomatic + complicated ulcers

Note: NSAID, nonsteroidal anti-inflammatory drug.
Source: Derived from VIGOR: Bombardier C et al: N Engl J Med 343:1520, 2000, with permission; CLASS: Silverstein F et al: JAMA 284:1247, 2000.

Unexpectedly, the incidence of myocardial infarction (MI) in the VIGOR study was fourfold greater among patients treated with rofecoxib than with naproxen. Although (1) the absolute number of MIs was small; (2) the study was not powered to compare the effects of the two treatments on MI; (3) the comparability of the treatment groups with respect to the prevalence of risk factors for MI (e.g., obesity, smoking, hypercholesterolemia, diabetes mellitus) was unknown; (4) the dose of rofecoxib was two to four times greater than that used for treatment of OA; and (5) the trial was conducted in patients with rheumatoid arthritis, in which the incidence of MI is about twice as great as that in OA. The rofecoxib label contains a caveat about use of this drug in patients predisposed to ischemic heart disease.

GLUCOCORTICOID INJECTION Systemic glucocorticoids have no place in the treatment of OA. However, intra- or periarticular injection of a depot glucocorticoid preparation may provide marked symptomatic relief for weeks to months. Because studies in animal models have suggested that glucocorticoids may produce cartilage damage, and frequent injections of large amounts of steroids have been associated with joint breakdown in humans, the injection should generally not be repeated in a given joint more often than every 4 to 6 months.

INTRAARTICULAR INJECTION OF HYALURONAN Intraarticular injection of hyaluronan has been approved for treatment of patients with knee OA who have failed a program of nonpharmacologic therapy and simple analgesics. Because the duration of benefit following treatment may exceed by many months the synovial half-life of exogenous hyaluronan, the mechanism of action is unclear. However, the placebo response to intraarticular injection of hyaluronan is often large and sustained. For example, the pivotal clinical trial of Hyalgan failed to demonstrate superiority of oral naproxen, 500 mg bid, over intraarticular injections of saline. Furthermore, intraarticular injection of a preparation of the high-molecular-weight hylan (Synvisc) which had been denatured to eliminate its viscoelasticity, was no less efficacious than injection of the intact hylan or non-cross-linked lower molecular weight hyaluronan. Consistent with this observation, no difference in efficacy was observed in a randomized placebo-controlled trial of Synvisc, a lower molecular weight hyaluronan formulation, and placebo.

OPIOIDS Health professionals and patients hold concerns about tolerance and physical and psychological dependence, and many physicians hesitate to prescribe opioids for patients with nonmalignant chronic pain because of concerns about legal action by governmental regulatory authorities. However, the prevalence of narcotic abuse among older people is low: <1% of patients attending methadone maintenance programs are ≥60 years.

For acute flares of OA pain, when APAP or an NSAID does not provide adequate pain relief or is not well tolerated, a weak opioid, e.g., oral codeine, deserves consideration. Because codeine, when taken alone in a dose of 60 mg, is no more effective than 650 mg of aspirin or APAP, it is used in combination with these drugs to treat moderate or moderately severe OA pain.

Opioids may also be useful for chronic OA pain. The major problem associated with the use of chronic opioid therapy for OA pain is the side effects of these agents, e.g., nausea, vomiting, constipation, urinary retention, mental confusion, drowsiness, and respiratory depression. In the elderly, the central nervous system effects of opioids (e.g., dizziness) may have particularly serious consequences. Prescription of either codeine or propoxyphene may increase the risk of hip fracture by 60%. Concurrent use of these opioids and a psychotropic drug (e.g., sedative, antidepressant, antipsychotic) carries a fracture risk 2.6 times as high as that in nonusers of either drug class.

Tramadol hydrochloride is a centrally acting analgesic with a dual mechanism of action: the molecule is a μ-opioid agonist and also inhibits reuptake of norepinephrine and serotonin. Although the affinity of binding to the μ-opioid regimen is some 6000 times lower than that of morphine, the opioid and nonopioid activities are synergistic. In contrast to NSAIDs, tramadol does not inhibit prostaglandin synthesis and has no adverse effects on the gastric mucosa, kidney, or platelet. It is a useful adjunct in patients with OA in whom APAP or a low dose of NSAID is ineffective or contraindications exist to the use of an NSAID. Improvement with tramadol, 200 to 400 mg/d, is comparable to that with ibuprofen, 1200 to 2400 mg/d, in patients with chronic joint pain. Because development of tolerance or dependence appears to be uncommon with long-term administration, tramadol has not been scheduled as a controlled substance. In general, its efficacy and adverse event profile are comparable to those of APAP/codeine. The latter, however, is considerably less expensive.

The frequency and severity of side effects of tramadol may be reduced considerably if treatment is initiated at a very low dose (e.g., 25 mg/d), which can then be increased gradually every few days. However, this "start low, go slow" approach limits the usefulness of the drug in management of acute pain. Because it inhibits the reuptake of serotonin and norepinephrine, tramadol should not generally be given to patients receiving a tricyclic antidepressant, selective serotonin reuptake inhibitor, or monoamine oxidase inhibitor. These combina-

tions have been reported to cause convulsions. Even in the absence of concomitant therapy with the above agents, however, seizures may occasionally occur in some patients taking tramadol.

A combination of tramadol and APAP in a 37.5 mg/325 mg tablet (ULTRACET) has recently become available. It has a more rapid onset of action than tramadol alone and longer duration of action than APAP alone. In subjects with an acute flare of hip or knee OA, who received 1 or 2 tablets of tramadol/APAP qid for 10 days in addition to their usual NSAID therapy, tramadol/APAP was significantly superior to placebo with respect to improvement in joint pain and global assessment by subjects and physicians. However, treatment-related adverse events (e.g., nausea, dizziness, vomiting) were reported in nearly 25% of the tramadol/APAP group, but in only 8% of the placebo group. Furthermore, the above figures may understate the true incidence of adverse events with this formulation, because subjects were excluded from the study if they had previously failed tramadol therapy or had discontinued tramadol because of an adverse event.

RUBEFACIENTS/CAPSAICIN Because use of systemic analgesics and NSAIDs is often accompanied by adverse effects and older individuals with OA often require medication for comorbid conditions (e.g., hypertension, heart disease, diabetes mellitus) and are at increased the risk of serious drug interactions with NSAIDs, topical therapy for management of OA has appeal.

Application of topical irritants to painful joints and muscles and the local heat provided by rubefacients may be beneficial. However, although topical medications are widely used in the United States as over-the-counter preparations, they are not often prescribed for OA in this country, chiefly because evidence of their efficacy is limited. Except for formulations of salicylate, topical NSAIDs have not been approved for use in the United States. It is unclear whether the benefit attributed to their use is mediated through a pharmacologic action, placebo effect, or their action as a rubefacient. Capsaicin cream, which depletes local sensory nerve endings of substance P, may reduce joint pain and tenderness when applied topically by patients with hand or knee OA, even when used as monotherapy, i.e., without NSAIDs or systemic analgesics.

Glucosamine, Chondroitin Sulfate Glucosamine and chondroitin sulfate have recently enjoyed striking popularity for treatment of OA. They are sold widely in pharmacies, supermarkets, and health food stores but are not approved for use in OA by the U.S. Food and Drug Administration. Several studies have shown glucosamine to be superior to placebo and comparable to NSAIDs with respect to efficacy in patients with knee OA, and to have a better safety profile than NSAIDs. However, the efficacy of neither glucosamine nor chondroitin sulfate has been examined in large, well-designed placebo-controlled trials. In a meta-analysis of randomized, double-blind, placebo-controlled studies of glucosamine and chondroitin sulfate, moderate symptomatic benefit was demonstrated for both agents, relative to placebo. In studies of chondroitin sulfate, symptomatic improvement was apparent as long as 12 months after the onset of treatment. However, when only high-quality or large-size trials were considered, the effect sizes for glucosamine and chondroitin sulfate were diminished, i.e., the better the study design, the smaller the therapeutic benefit. In three recent randomized, double-blind trials in which the manufacturer did not have access to the raw data and was not involved in data analysis, glucosamine was no more effective than placebo.

The question arises whether glucosamine is "chondroprotective." Results of two recent randomized clinical trials have led to the suggestion that glucosamine not only improves joint pain in patients with knee OA, but protects against articular cartilage damage, based upon analyses of changes in joint space width in the standing anteroposterior (AP) knee radiograph. However, concern has been expressed about the interpretation of the results of these studies because of limitations of the radiographic methods employed. A multicenter study supported by the National Institutes of Health, the Glucosamine Chondroitin Arthritis Intervention Trial (GAIT), is in progress which is comparing glucosamine, chondroitin sulfate, the combination, and celecoxib with placebo in patients with knee OA. Although the primary outcome measure is joint pain after 6 months of treatment, approximately 50% of the subjects will be maintained on treatment for 2 years and radiographs obtained at baseline will be compared with those obtained after 1 year and 2 years of treatment.

Orthopedic Surgery Joint replacement surgery should be reserved for patients with advanced OA in whom aggressive medical management has failed. In such cases total joint arthroplasty may be remarkably effective in relieving pain and increasing mobility. Osteotomy, which is surgically more conservative than arthroplasty, can eliminate the concentration of peak dynamic loads and may provide effective pain relief in patients with hip or knee OA. It is of greatest benefit when the disease is only moderately advanced.

Cartilage Regeneration Chondroplasty (abrasion arthroplasty) has enjoyed some popularity as treatment for OA, but well-controlled studies of its efficacy are lacking and the fibrocartilage that resurfaces the abraded bone is inferior to normal hyaline cartilage in its ability to withstand mechanical loads. In one study, knee pain and function were not related to the extent of cartilage regeneration 2 years later in patients who had undergone tibial osteotomy for medial compartment knee OA. Autologous chondrocyte transplantation and attempts at cartilage repair using mesenchymal stem cells and autologous osteochondral plugs are currently being used experimentally for repair of focal chondral defects, but have not been proved to be effective in treatment of OA.

A Rational Approach to the Nonsurgical Management of OA Nonpharmacologic management, as described above, is the foundation of treatment of OA pain and is as important, or more important, than drug treatment, which plays an adjunctive or complementary role in management of this disease. Figure 312-4 provides an algorithm that might be applied to treatment of a newly diagnosed patient with knee OA. The progressive levels of treatment are associated with increasing cost, decreasing convenience for the patient, and increasing risk of side effects. The scheme should not be interpreted dogmatically as a fixed progression of steps. Treatment of OA must be individualized, and the treatment program flexible. For example, in some patients it may be reasonable to institute patellar taping or to prescribe a wedged insole on the initial visit, or an intraarticular glucocorticoid injection on a later visit. Maintaining regular contact with the patient, e.g., via periodic telephone calls, may reduce joint pain to a level beyond that which can be achieved with an NSAID alone and this, or some surrogate measure, warrants incorporation into the treatment program.

It is reasonable to prescribe APAP initially, in a dose up to 4000 mg/d, because of its low cost, excellent safety profile, and the fact that it is as efficacious as NSAIDs in many patients with OA when an analgesic is required for treatment of OA pain. If this does not control joint symptoms within a reasonable period of time, a *low dose* of NSAID (e.g., ibuprofen, 1200 mg/d; naproxen, 500 mg/d) may be substituted for, or added to, the APAP. In patients with significant risk factors for a serious upper gastrointestinal adverse event, if a nonselective NSAID is used, even in a low dose, it is reasonable to recommend coadministration of a gastroprotective agent, such as misoprostol or a proton pump inhibitor, which have been shown by endoscopy to be effective in treating and preventing NSAID gastropathy. Because the risk of an NSAID-associated gastrointestinal catastrophe is dose-dependent, the lowest effective dose of NSAID should be employed. Salsalate and other nonacetylated salicylates, which have only minimal effect on prostaglandin synthase, are as effective as other NSAIDs and have a lower rate of serious gastrointestinal side effects. However, ototoxicity and central nervous system toxicity may limit their use.

When NSAIDs are required, they may be prescribed on an "as needed" basis, rather than in a fixed daily dose; pain control has been shown to be comparable and the risk of toxicity will be reduced. Once treatment with an NSAID or simple analgesic is initiated, the need for

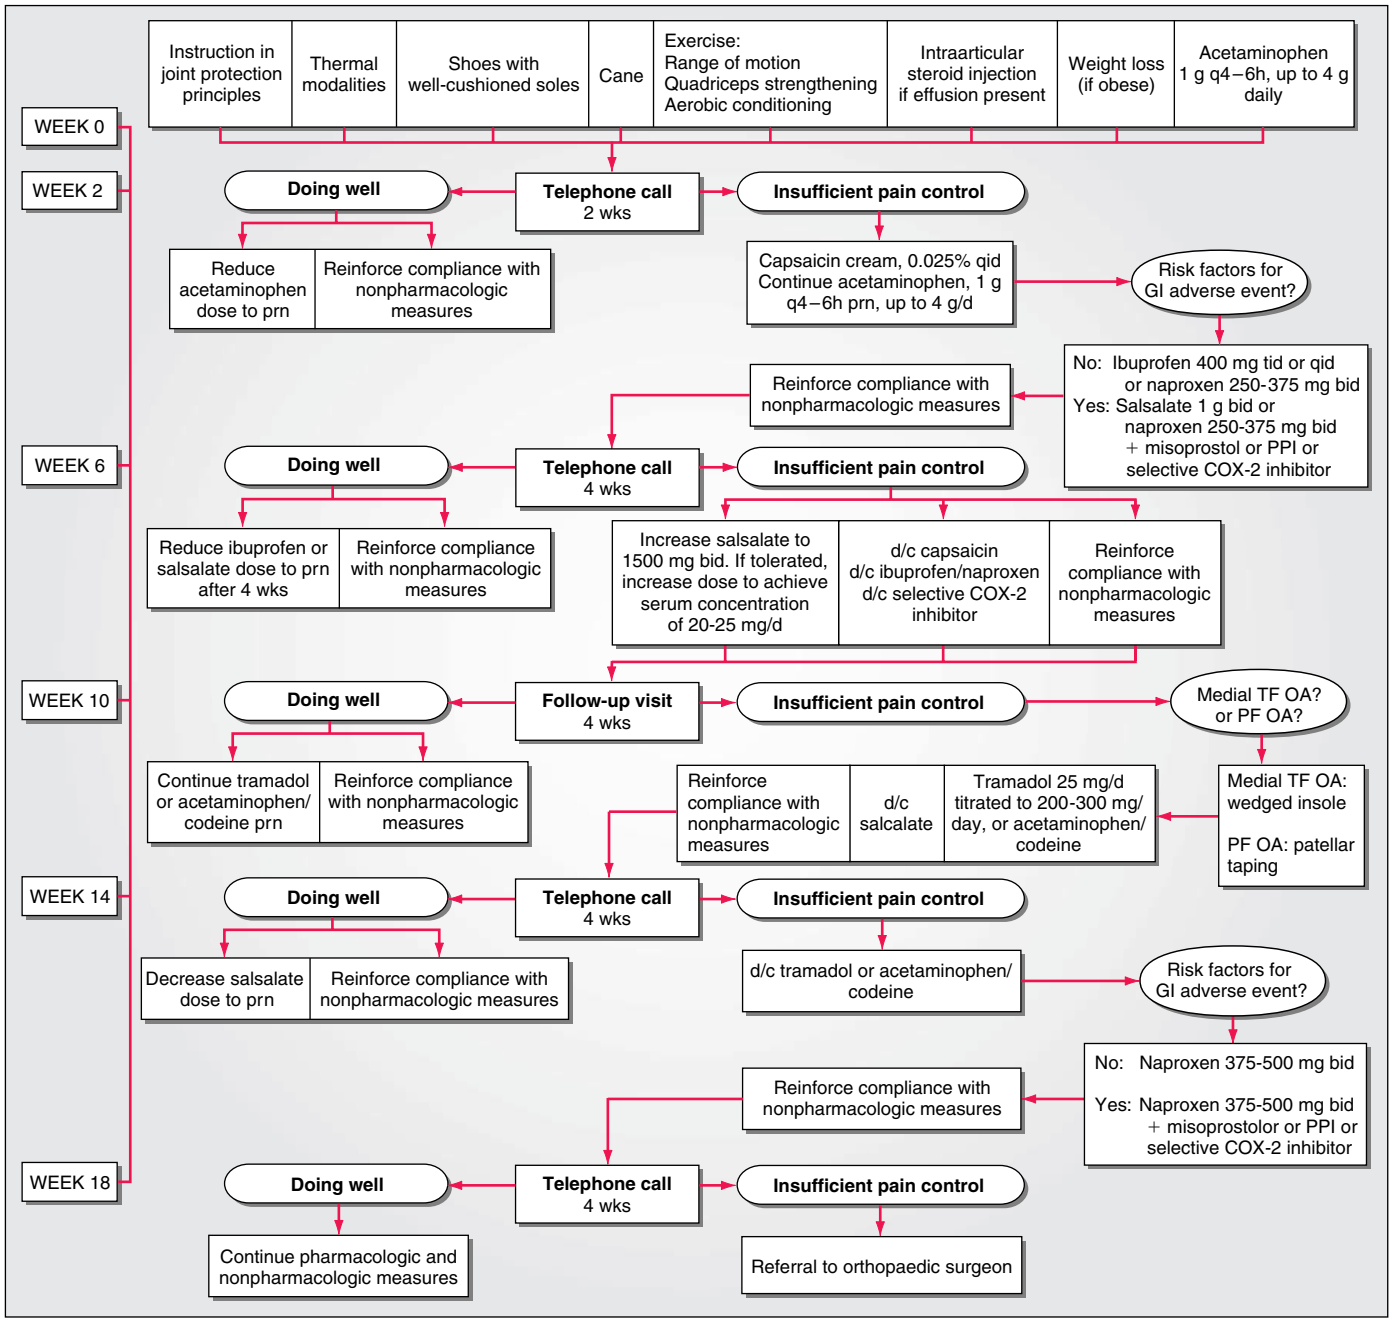

FIGURE 312-4 Algorithm for management of a newly diagnosed patient with knee OA. continuation of that treatment requires ongoing assessment. For many patients with OA, it will be possible eventually to reduce the dose of drug or to use the agent only intermittently during exacerbations of joint pain.

313 GOUT AND OTHER CRYSTAL ARTHROPATHIES

Antonio J. Reginato

"GOUT" CRYSTALLOGRAPHY AND ARTHRITIS The use of polarizing microscopy during synovial fluid analysis and the application of other crystallographic techniques, such as electron microscopy, energy-dispersive elemental analysis, and x-ray diffraction, have established the role of different microcrystals, including monosodium urate (MSU), calcium pyrophosphate dihydrate (CPPD), calcium hydroxyapatite (HA), and calcium oxalate (CaOx), in inducing acute or chronic arthritis or periarthritis. In spite of differences in crystal morphology, chemistry, and physical properties, the clinical events that result from deposition of MSU, CPPD, HA, and CaOx may be indistinguishable (Table 313-1). Prior to the use of crystallographic techniques in rheumatology, much of what was considered to be MSU gouty arthritis in fact was not. Simkin has suggested that the generic term *gout* be used to describe the whole group of crystal-induced arthritides (MSU gout, CPPD gout, HA gout, and CaOx gout). This concept further emphasizes the identical clinical presentations of these entities (Table 313-1) and the need to perform synovial fluid analysis to distinguish the type of crystal involved. In the setting of acute articular or periarticular inflammation, aspiration and analysis of effusions are most important to assess the possibility of infection and to identify the type of crystals present. Polarization microscopy alone can identify most typical crystals and allow diagnosis. HA, however, is an exception. Apart from the identification of specific microcrystalline materials or organisms, synovial fluid characteristics are nonspecific, and synovial fluid can be inflammatory or noninflammatory.

MONOSODIUM URATE GOUT MSU gout is a metabolic disease most often affecting middle-aged to elderly men and postmenopausal women. It is typically associated with an increased uric acid pool, hyperuricemia, episodic acute and chronic arthritis, and deposition of MSU crystals in connective tissue tophi and kidneys (Chap. 338).

Acute and Chronic Arthritis Acute arthritis is the most frequent early clinical manifestation of MSU gout. Usually, only one joint is affected initially, but polyarticular acute gout is also seen in male hypertensive patients with ethanol abuse as well as in postmenopausal women. The metatarsophalangeal joint of the first toe is often involved, but tarsal joints, ankles, and knees are also commonly affected. In elderly patients, finger joints may be inflamed. Inflamed Heberden's or Bouchard's nodes may be a first manifestation of gouty arthritis. The first episode of acute gouty arthritis frequently begins at night with dramatic joint pain and swelling. Joints rapidly become warm, red, and tender, and the clinical appearance often mimics a cellulitis. Early attacks tend to subside spontaneously within 3 to 10 days, and most of the patients do not have residual symptoms until the next episode. Several events may precipitate acute gouty arthritis: dietary excess, trauma, surgery, excessive ethanol ingestion, adrenocorticotropic hormone (ACTH) and glucocorticoid withdrawal, hypouricemic therapy, and serious medical illnesses such as myocardial infarction and stroke.

After many acute mono- or oligoarticular attacks, a proportion of gouty patients may present with a chronic nonsymmetric synovitis, causing potential confusion with rheumatoid arthritis (Chap. 301). Less commonly, chronic gouty arthritis will be the only manifestation and, more rarely, the disease will manifest as inflamed or noninflamed periarticular tophaceous deposits in the absence of chronic synovitis (Table 313-1). Women represent only 5 to 17% of all patients with gout. Premenopausal gout is a rare occurrence and accounts for only about 17% of all women with gout; it is seen mostly in individuals with a strong family history of gout. A few kindreds of precocious gout in young females caused by decreased renal urate clearance and renal insufficiency have been described. Most women with gouty arthritis are postmenopausal and elderly, have arterial hypertension causing mild renal insufficiency, and are usually receiving diuretics. Also, most of these patients have underlying degenerative joint disease, and inflamed tophaceous deposits may be seen on Heberden's and Bouchard's nodes.

TABLE 313-1 Musculoskeletal Manifestations of Crystal-Induced Arthritis

Acute mono- or polyarthritis	Destructive arthropathies
Bursitis	Pseudo-rheumatoid arthritis
Tendinitis	Pseudo-ankylosing spondylitis
Enthesitis	Spinal stenosis
Tophaceous deposits	Crown dens syndrome
Peculiar type of osteoarthritis	Carpal tunnel syndrome
Synovial osteochondromatosis	Tendon rupture

LABORATORY DIAGNOSIS Even if the clinical appearance strongly suggests gout, the diagnosis should be confirmed by needle aspiration of acutely or chronically inflamed joints or tophaceous deposits. Acute septic arthritis, several of the other crystalline-associated arthropathies, palindromic rheumatism, and psoriatic arthritis may present with similar clinical features. During acute gouty attacks, strongly birefringent needle-shaped MSU crystals with negative elongation are largely intracellular (Fig. 313-1). Synovial fluid cell counts are elevated from 2000 to 60,000/μL. Effusions appear cloudy due to leukocytes, and large amounts of crystals occasionally produce a thick pasty or chalky joint fluid. Bacterial infection can coexist with urate crystals in synovial fluid; if there is any suspicion of septic arthritis, joint fluid must also be cultured. MSU crystals can often be demonstrated in the first metatarsophalangeal joint and in knees not acutely involved with gout. Arthrocentesis of these joints is a useful technique to establish the diagnosis of gout between attacks. Serum uric acid levels can be normal or low at the time of the acute attack, since lowering of uric acid with hypouricemic therapy or other medications limits the value of serum uric acid determinations for the diagnosis of gout. Despite these limitations, serum uric acid is almost always elevated at some time and can be used to follow the course of hypouricemic therapy. A 24-h urine collection for uric acid is valuable in assessing the risk of stones, in elucidating overproduction or underexcretion of uric acid, and in deciding which hypouricemic regimen to use (Chap. 338). Excretion of >800 mg of uric acid per 24 h on a regular diet suggests that causes of overproduction of purine should be considered. Urinalysis, blood urea nitrogen, serum creatinine, white blood cell (WBC) count, and serum lipids should be obtained because of possible pathologic sequelae of gout and other associated diseases requiring treatment.

RADIOGRAPHIC FEATURES Cystic changes, well-defined erosions described as punched-out lytic lesions with overhanging bony edges [Martel's sign, or G sign (G for gout)], associated with soft tissue calcified masses are characteristic radiographic features of chronic tophaceous gout. However, similar radiographic signs can also be observed in erosive osteoarthritis, destructive apatite arthropathies, and rheumatoid arthritis.

TREATMENT

Acute Gouty Arthritis The mainstay of treatment during an acute attack is the administration of an anti-inflammatory drug such as colchicine, nonsteroidal anti-inflammatory drugs (NSAIDs), or glucocorticoids depending on the age of the patient and comorbid conditions. Both colchicine and NSAIDs may be quite toxic in the elderly, particularly in the presence of renal insufficiency and gastrointestinal disorders. In elderly patients, one may favor the use of intraarticular glucocorticoid injections for attacks involving one or two larger joints or ice pack applications along with lower oral doses of colchicine for gouty synovitis affecting small joints. Colchicine given orally is a traditional and effective treatment, if used early in the attack, in at least 85% of patients. One tablet (0.6 mg) is given every hour until relief of symptoms or gastrointestinal toxicity occurs, or a total of four to eight tablets may be given in accordance with the age of the patient. The drug

must be stopped promptly at the first sign of loose stools, and symptomatic treatment must be given for the diarrhea. Intravenous colchicine is sometimes used and can reduce, though not eliminate, the gastrointestinal side effects. Intravenous colchicine is most reliable for pre- or postoperative prophylaxis in 1- to 2-mg doses when patients cannot take medications orally. Life-threatening colchicine toxicity and sudden death have been described with the administration of >4 mg/d intravenously. The intravenous dose for acute gouty arthritis is 1 to 2 mg given slowly through an established venous line over 10 min in a soluset, and two additional doses of 1 mg each may be given at 6-h intervals, but the total dose should never exceed 4 mg. NSAIDs are affective in ~90% of patients, and the resolution of signs and symptoms usually occurs in 5 to 7 days. The most effective drugs are those with a short half-life and include indomethacin, 25 to 50 mg tid, ibuprofen, 800 mg tid, or diclofenac, 50 mg tid. Cyclooxigenase-2 highly selective inhibitors are probably equally effective but with less short-term gastrointestinal toxicity. Oral glucocorticoids such as prednisone, 30 to 50 mg/d as the initial dose and tapered over 5 to 7 days, a single intravenous dose of methylprednisolone, 7 mg of betametasone, or 20 to 40 mg of intraarticular triamcinolone acetonide have been equally effective. ACTH as an intramuscular injection of 40 to 80 IU in a single dose or every 12 h for 1 to 2 days is effective in patients with acute polyarticular refractory gout or with a contraindication for using colchicine or NSAIDs.

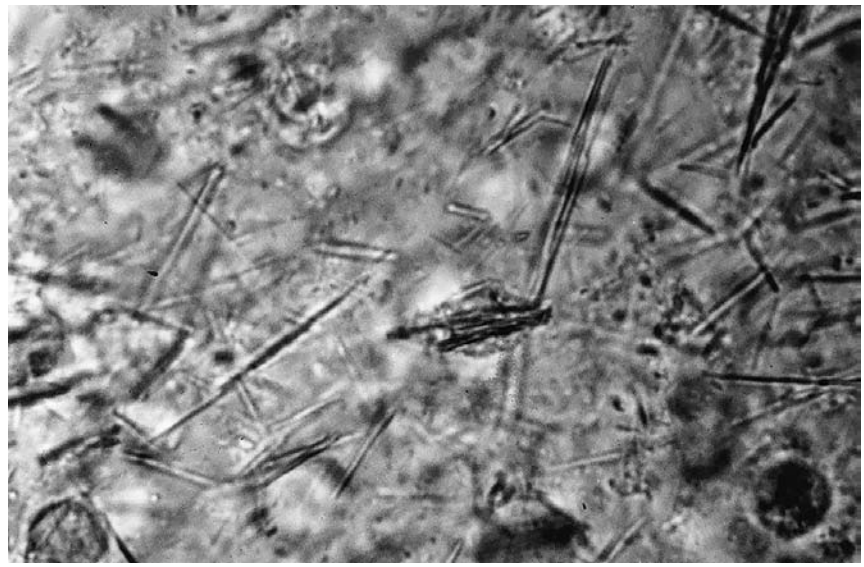

FIGURE 313-1 Extracellular and intracellular monosodium urate crystals, as seen in a fresh preparation of synovial fluid, illustrate needle- and rod-shaped strongly negative birefringent crystals (compensated polarized light microscopy; 400×).

Hypouricemic Therapy Attempts to normalize serum uric acid to <300 μmol/L (5.0 mg/dL) to prevent recurrent gouty attacks and eliminate tophaceous deposits entail a commitment to long-term hypouricemic regimens and medications that generally are required for life. Hypouricemic therapy should be considered when the hyperuricemia cannot be corrected by simple means (control of body weight, low-purine diet, increase in liquid ingestion, limitation of ethanol intake, and avoidance of diuretic use). The decision to initiate hypouricemic therapy is usually made taking into consideration the number of acute attacks, family history of gout, presence of MSU tophaceous deposits, uric acid excretion >800 mg per 24 hours, presence of uric acid stones, and risk for acute uric acid nephropathy during chemotherapy for myeloproliferative disorders. Uricosuric agents, such as probenecid, can be used in patients with good renal function who underexcrete uric acid, with <600 mg in a 24-hour urine sample. Urine volume must be maintained by ingestion of 1500 mL of water every day. Probenecid can be started at a dosage of 200 mg twice daily and increased gradually as needed up to 2 g in order to maintain a serum uric acid level <300 μmol/L (5 mg/dL). Probenecid is the drug of choice to treat elderly patients with hypertension and thiazide dependence; however, probenecid is not effective with a renal creatinine clearance <1 mL/s. These patients may require allopurinol or benzbromarone (not available in the United States), which is another uricosuric drug that is effective in patients with renal failure and who are receiving diuretics. Allopurinol is the best drug to lower serum urate in overproducers, stone formers, and patients with advanced renal failure. It can be given in a single morning dose, 300 mg initially and increasing up to 800 mg if needed. In most patients, it is not necessary to start at a lower dose; however, in patients with renal failure, the dosage should be adjusted depending on the serum creatinine concentration in order to minimize side effects. Patients with frequent acute attacks may require lower initial doses to prevent exacerbations. Toxicity of allopurinol has been recognized increasingly in patients with renal failure who use thiazide diuretics and in those patients allergic to penicillin and ampicillin. The most serious side effects include skin rash with progression to life-threatening toxic epidermal necrolysis, systemic vasculitis, bone marrow suppression, granulomatous hepatitis, and renal failure. Urate-lowering drugs should not be initiated during acute attacks. This is especially important in patients who have refractory acute arthritis or who had a flare-up previously with hypouricemic drugs. Colchicine prophylaxis in doses of 0.6 mg one to two times daily is usually continued, along with hypouricemic therapy, until the patient is normouricemic and without gouty attacks for 3 months. However, prophylactic colchicine treatment may be necessary as long as tophi are present. Recombinant urate oxidase uricase can be used in the short-term prophylaxis and treatment of chemotherapy-associated hyperuricemia in patients with lymphoproliferative and myeloproliferative disorders.

CPPD DEPOSITION DISEASE ■ Pathogenesis The deposition of CPPD crystals in articular tissues is most common in the elderly, affecting 10 to 15% of persons 65 to 75 years old and 30 to 60% of those >85 years old. In most cases this process is asymptomatic, and the cause of CPPD deposition is uncertain. Because >80% of patients are more than 60 years old and 70% have preexisting joint damage from other conditions, it is likely that biochemical changes in aging cartilage favor crystal nucleation. Examples of such chemical alterations include the following. There is an increased production of inorganic pyrophosphate and decreased levels of pyrophosphatases in cartilage extracts from patients with CPPD arthritis. This condition, which increases inorganic pyrophosphate and promotes CPPD crystal formation, may also inhibit hydroxyapatite formation. The increase in pyrophosphate production appears to be related to enhanced activity of ATP pyrophosphohydrolase and 5′-nucleotidase, which catalyze the reaction of ATP to adenosine and pyrophosphate. This pyrophosphate could combine with calcium to form CPPD crystals in matrix vesicles or on collagen fibers. There is a diminution in the levels of cartilage glycosaminoglycans that normally inhibit and regulate crystal nucleation. These deficiencies may lead to increased crystal deposition. In vitro studies have demonstrated that transforming growth factor β1 and epidermal growth factor both stimulate the production of pyrophosphate by articular cartilage and thus may contribute to the deposition of CPPD crystals. The release of CPPD crystals into the joint space is followed by the phagocytosis of these crystals by neutrophils, which respond by releasing inflammatory substances. In addition, neutrophils release a glycopeptide that is chemotactic for other neutrophils, thus augmenting the inflammatory events. The same substance is present in MSU gout.

A minority of patients with CPPD arthropathy have metabolic abnormalities or hereditary CPPD disease (Table 313-2). These associations suggest that a variety of different metabolic products may enhance CPPD deposition. Included among these conditions are the

[a] Mutations in the ANKH gene.

"four H's" of hyperparathyroidism, hemochromatosis, hypophosphatasia, and hypomagnesemia. Hemochromatosis and hyperparathyroidism are good examples. Ferrous ions and hypercalcemia may either directly alter cartilage or inhibit inorganic pyrophosphatases, leading to enhanced susceptibility to CPPD deposition. The presence of CPPD arthritis in individuals <50 years old should lead to consideration of these metabolic disorders and inherited forms of disease, including those identified in a variety of ethnic groups (Table 313-2). Genomic DNA studies performed on five different kindreds have shown a possible location of the genetic defects on chromosome 8q in one, and on chromosome 5p in the other four in a region that expresses the gene of a membrance pyrophosphate channel (*ANK* gene). A defective gene described in the *ank/ank* mice causes elevation of the intracellular pyrophosphate and reduction of the extracellular pyrophosphate and promotes apatite deposition. Mutations described in the human *ANK* gene in four kindreds with CPPD arthritis might increase extracellular pyrophosphate and induce CPPD crystal formation (Fig. 313-2). Identification of these genes will help elucidate the pathogenesis of both the familial and the more common sporadic form of the disease. Investigation should include inquiry for evidence of familial aggregation and evaluation of serum calcium, phosphorus, alkaline phosphatase, magnesium, serum ferritin, and transferritin saturation.

Clinical Manifestations CPPD arthropathy may be asymptomatic, acute, subacute, or chronic or cause acute synovitis superimposed on chronically involved joints. Acute CPPD arthritis was originally termed *pseudogout* by McCarty and coworkers because of its striking similarity to MSU gout. Other clinical manifestations of CPPD deposition include (1) induction or enhancement of peculiar forms of osteoarthritis; (2) induction of severe destructive disease that may radiographically mimic neuropathic arthritis; (3) production of symmetric proliferative synovitis, clinically similar to rheumatoid arthritis and frequently seen in familial forms with early onset; (4) intervertebral disk and ligament calcification with restriction of spine mobility, mimicking ankylosing spondylitis (also seen in hereditary forms); and (5) rarely spinal stenosis (most commonly seen in the elderly) (Table 313-1).

The knee is the joint most frequently affected in CPPD arthropathy.

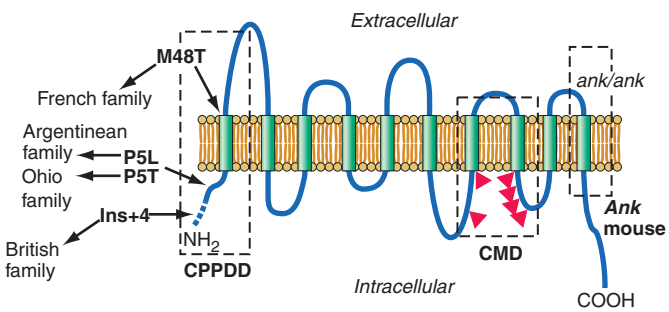

FIGURE 313-2 Mutations in *ANKH* gene associated with familial CPPD gout. CMD, cranial metaphyseal dysplasia.

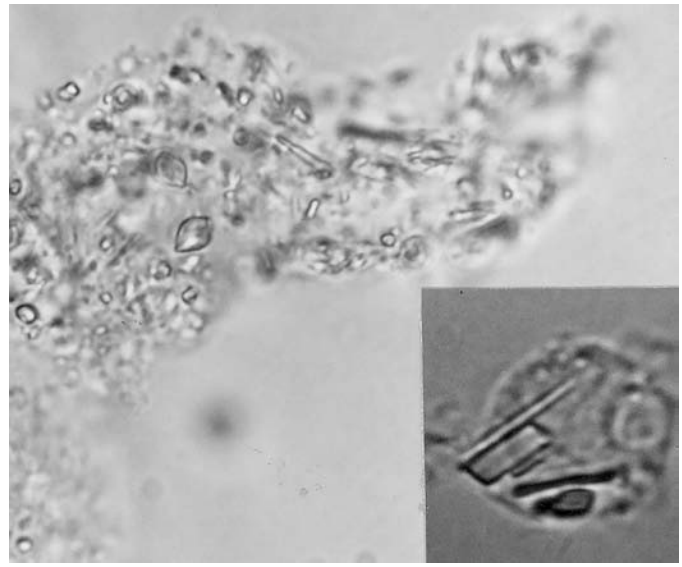

FIGURE 313-3 Intracellular and extracellular calcium pyrophosphate dihydrate crystals, as seen in a fresh preparation of synovial fluid, illustrate rectangular, rod-shaped, and rhomboid weakly positive birefringent crystals (compensated polarized light microscopy; 400×).

Other sites include the wrist, shoulder, ankle, elbow, and hands. Rarely, the temporomandibular joint and ligamentum flavum of the spinal canal are involved. Clinical and radiographic evidence indicates that CPPD deposition is polyarticular in at least two-thirds of patients. When the clinical picture resembles that of slowly progressive osteoarthritis, diagnosis may be more difficult. Joint distribution may provide important clues suggesting CPPD disease. For example, primary osteoarthritis rarely involves a metacarpophalangeal, wrist, elbow, shoulder, or ankle joint. If radiographs reveal punctate and/or linear radiodense deposits in fibrocartilaginous joint menisci or articular hyaline cartilage (chondrocalcinosis), the diagnostic certainty of CPPD is further enhanced. *Definitive diagnosis* requires demonstration of typical crystals in synovial fluid or articular tissue (Fig. 313-3). In the absence of joint effusion or indications to obtain a synovial biopsy, chondrocalcinosis is presumptive of CPPD deposition. One exception is chondrocalcinosis due to CaOx in some patients with chronic renal failure.

Acute attacks of CPPD arthritis may be precipitated by trauma, arthroscopy, or hyaluronate injections. Rapid diminution of serum calcium concentration, as may occur in severe medical illness or after surgery (especially parathyroidectomy), can also lead to pseudogout attacks.

In as many as 50% of cases, CPPD gout is associated with low-grade fever and, on occasion, temperatures as high as 40°C. Whether or not radiographic proof of chondrocalcinosis is evident in the involved joint(s), synovial analysis with microbial cultures is essential to rule out the possibility of infection. In fact, infection in a joint with any microcrystalline deposition process can lead to crystal shedding and subsequent synovitis from both crystals and microorganisms. Synovial fluid in acute CPPD gout has inflammatory qualities. The WBC count can range from several thousand cells to 100,000 cells/μL, the mean being about 24,000 cells/μL and the predominant cell being the neutrophil. Polarization microscopy usually reveals rhomboid crystals with weak positive birefringence inside fibrim clots and in neutrophils (Fig. 313-3).

℞ TREATMENT

Untreated acute attacks may last a few days to as long as a month. Treatment by joint aspiration and NSAIDs, or colchicine, or intraarticular glucocorticoid injection may result in return to prior status in ≤10 days. For patients with frequent recurrent attacks of CPPD gout, daily prophylactic treatment with low doses of colchicine may be helpful in decreasing the frequency of the attacks. Severe polyarticular

attacks usually require short courses of glucocorticoids. Unfortunately, there is no effective way to remove CPPD deposits from cartilage and synovium. Uncontrolled studies suggest that radioactive synovectomy (with yttrium 90) or the administration of antimalarial agents may be helpful in controlling persistent synovitis. Patients with progressive destructive large-joint arthropathy usually require joint replacement.

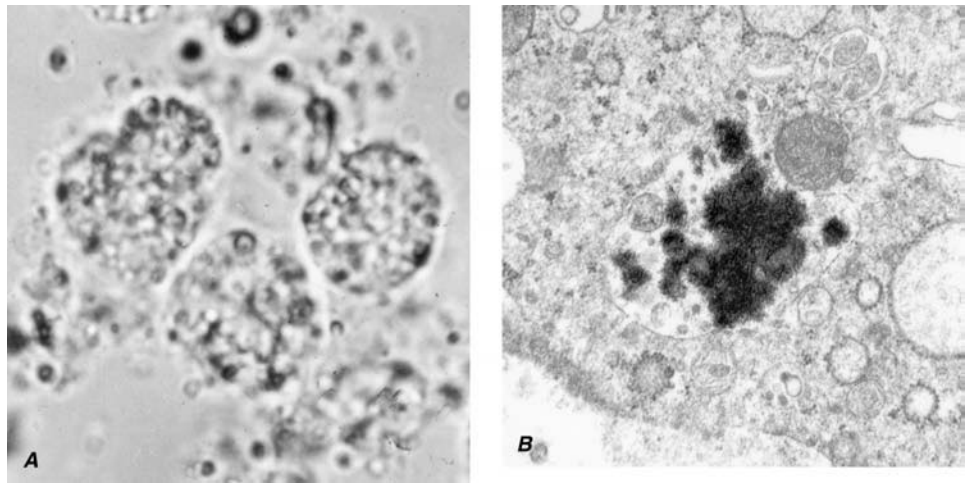

FIGURE 313-4 *A.* Cytoplasmic round inclusions inside synovial fluid cells represent aggregates of apatite crystals (fresh preparation, ordinary light microscopy; 288×). *B.* An electron micrograph demonstrates a cluster of dark apatite crystals within a synovial fluid mononuclear cell (21,600×).

CALCIUM HYDROXYAPATITE DEPOSITION DISEASE ■ Pathogenesis HA is the primary mineral of bone and teeth. Abnormal accumulation can occur in areas of tissue damage (dystrophic calcification), in hypercalcemic or hyperparathyroid states (metastatic calcification), and in certain conditions of unknown cause (Table 313-3). In chronic renal failure, hyperphosphatemia enhances HA deposition both in and around joints. Familial aggregation is rarely seen, but no association with human *ANK* mutations have been described thus far.

HA may be released from exposed bone and cause the acute synovitis occasionally seen in chronic stable osteoarthritis (e.g., "hot" Heberden's nodes). HA deposition is also an important factor in an extremely destructive chronic arthropathy of the elderly that occurs most often in knees and shoulders (Milwaukee shoulder). Joint destruction is associated with attenuation or rupture of supporting structures, leading to instability and deformity. Progression tends to be indolent, and synovial fluid WBC counts are usually <2000/μL. Symptoms range from minimal to severe pain and disability that may lead to joint replacement surgery. Whether severely affected patients merely represent an extreme synovial tissue response to the HA crystals that are so common in osteoarthritis is uncertain. Synovial membrane tissue cultures exposed to HA (or CPPD) crystals markedly increased the release of collagenases and neutral proteases, underscoring the destructive potential of abnormally stimulated synovial lining cells.

Clinical Manifestations Periarticular and articular deposits may coexist and be associated with acute and/or chronic damage to the joint capsule, tendons, bursa, or articular surfaces. The most common sites of HA deposition include bursae and tendons in and/or around the knees, shoulders, hips, and fingers. Clinical manifestations include asymptomatic radiographic abnormalities, acute synovitis, bursitis, tendinitis, and chronic destructive arthropathy. Most patients with HA arthropathy are elderly. Although the true incidence of HA arthritis is not known, 30 to 50% of patients with osteoarthritis have HA microcrystals in their synovial fluid. Such crystals can frequently be identified in clinically stable osteoarthritic joints, but they are more likely to come to attention in persons experiencing acute or subacute worsening of joint pain and swelling. The synovial fluid WBC count in HA arthritis is usually low (<2000/μL) but may at times have as many as 50,000/μL. Most synovial fluid analyses reveal a predominance of mononuclear cells. Occasionally, neutrophils may dominate.

Hereditary
Bursitis, arthritis
Tumoral calcinosis
Fibrodysplasia ossificans progressiva

Note: CREST, calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia; SLE, systemic lupus erythematosus.

Diagnosis Radiographic findings in HA arthropathy are not diagnostic. Intra- and/or periarticular calcifications with or without erosive, destructive, or hypertrophic changes may be present.

Definitive diagnosis of HA arthropathy depends on identification of crystals from synovial fluid or tissue (Fig. 313-4). Individual crystals are very small, nonbirefringent, and can only be seen by electron microscopy. Clumps of crystals may appear as 1- to 20-μm shiny intra- or extracellular globules that stain purplish with Wright's stain and bright red with alizarin red S. Absolute identification depends on electron microscopy with energy-dispersive elemental analysis, x-ray diffraction, or infrared spectroscopy.

TREATMENT

Treatment of HA arthritis is nonspecific. Acute attacks of bursitis or synovitis may be self-limiting, resolving in from days to several weeks. Aspiration of effusions and the use of either NSAIDs or oral colchicine for 2 weeks or intra- or periarticular injection of glucocorticoid salts appears to shorten the duration and intensity of symptoms. In patients with underlying severe destructive articular changes, response to medical therapy is usually less rewarding.

CaOx DEPOSITION DISEASE ■ Pathogenesis *Primary oxalosis* is a rare hereditary metabolic disorder (Chap. 343). Enhanced production of oxalic acid may result from at least two different enzyme defects, leading to hyperoxalemia and deposition of calcium oxalate crystals in tissues. Nephrocalcinosis, renal failure, and death usually occur before age 20. Acute and/or chronic CaOx arthritis and periarthritis may complicate primary oxalosis during later years of illness.

Secondary oxalosis is more common than the primary disorder. It is one of the many metabolic abnormalities that complicate end-stage renal disease (ESRD). In ESRD, calcium oxalate deposits have long been recognized in visceral organs, blood vessels, bones, and even cartilage. However, it was not until 1982 that such deposits were demonstrated to be one of the causes of arthritis in chronic renal failure. Thus far, reported patients have been dependent on long-term hemodialysis or peritoneal dialysis (Chap. 262), and many had received

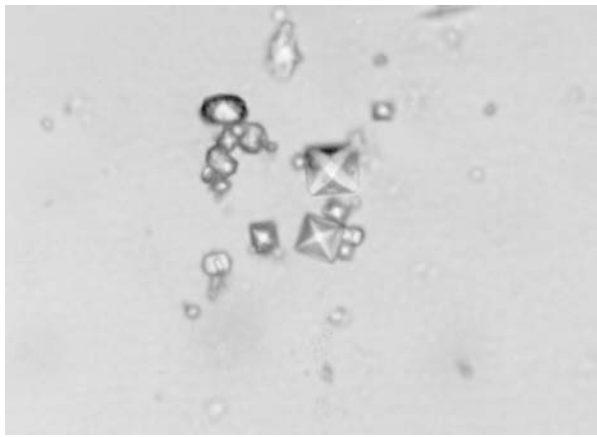

FIGURE 313-5 Bipyramidal and small polymorphic calcium oxalate crystals (ordinary light microscopy; 400×).

ascorbic acid supplements. Ascorbic acid is metabolized to oxalate, which is inadequately cleared in uremia and by dialysis. Such supplements are now usually avoided in dialysis programs because of the risk of enhancing hyperoxalosis and its sequelae.

Clinical Manifestations and Diagnosis As was noted for the other calcium salts, CaOx aggregates can be found in bone, articular cartilage, synovium, and periarticular tissues. From these sites, crystals may be shed, causing acute synovitis. Persistent aggregates of CaOx may, like HA and CPPD, stimulate synovial proliferation and enzyme release, resulting in progressive articular destruction. Deposits have been documented in fingers, wrists, elbows, knees, ankles, and feet.

Each of the known microcrystalline arthropathies may be a complication of ESRD, and rare patients have more than one type of crystal present in a joint effusion. The advent of crystallographic techniques has made it clear that most arthritic problems in ESRD are not, as was once believed, due to MSU gout. Clinical features of acute CaOx arthritis may not be distinguishable from those due to sodium urate, CPPD, or HA. Radiographs may reveal chondrocalcinosis, a feature of either CPPD or CaOx deposition. CaOx-induced synovial effusions are usually noninflammatory, with <2000 leukocytes/μL. Neutrophils or mononuclear cells have predominated. CaOx crystals have a variable shape and variable birefringence to polarized light. The most easily recognized forms are bipyramidal and have strong positive birefringence (Fig. 313-5).

℞ TREATMENT

Treatment of CaOx arthropathy with NSAIDs, colchicine, intraarticular glucocorticoids, and/or an increased frequency of dialysis has produced only slight improvement. In primary oxalosis, liver transplantation has induced a significant reduction in crystal deposits (Chap. 343).

314 INFECTIOUS ARTHRITIS

Lawrence C. Madoff, Scott J. Thaler, James H. Maguire

INTRODUCTION AND APPROACH TO THE PATIENT Although *Staphylococcus aureus*, *Neisseria gonorrhoeae*, and other bacteria are the most common causes of infectious arthritis, various mycobacteria, spirochetes, fungi, and viruses also infect joints. Since acute bacterial infection can rapidly destroy articular cartilage, all inflamed joints must be evaluated without delay to exclude noninfectious processes and to determine appropriate antimicrobial therapy and drainage procedures. For more detailed information on infectious arthritis due to specific organisms, the reader is referred to the chapters on those organisms.

Acute bacterial infection typically involves a single joint or a few joints. Subacute or chronic monarthritis or oligoarthritis suggests mycobacterial or fungal infection; episodic inflammation is seen in syphilis, Lyme disease, and the reactive arthritis that follows enteric infections and chlamydial urethritis (Table 314-1). Acute polyarticular inflammation occurs as an immunologic reaction during the course of endocarditis, rheumatic fever, disseminated neisserial infection, and acute hepatitis B. Bacteria and viruses occasionally infect multiple joints, the former most commonly in persons with rheumatoid arthritis.

Aspiration of synovial fluid—an essential element in the evaluation of potentially infected joints—can be performed without difficulty in most cases by the insertion of a large-bore needle into the site of maximal fluctuation or tenderness or by the route of easiest access. Ultrasonography or fluoroscopy may be used to guide aspiration of difficult-to-localize effusions of the hip and, occasionally, the shoulder and other joints. Normal synovial fluid contains <180 cells (predominantly mononuclear cells) per microliter. Synovial cell counts averaging 100,000/μL (range, 25,000 to 250,000/μL), with >90% neutrophils, are characteristic of acute bacterial infections. Crystal-induced, rheumatoid, and other noninfectious inflammatory arthritides are usually associated with <30,000 to 50,000 cells/μL; cell counts of 10,000 to 30,000/μL, with 50 to 70% neutrophils and the remainder lymphocytes, are common in mycobacterial and fungal infections. Definitive diagnosis of an infectious process relies on identification of the pathogen in stained smears of synovial fluid, isolation of the pathogen from cultures of synovial fluid and blood, or detection of microbial nucleic acids and proteins by polymerase chain reaction (PCR)–based assays and immunologic techniques.

ACUTE BACTERIAL ARTHRITIS ■ Pathogenesis Bacteria enter the joint from the bloodstream; from a contiguous site of infection in bone or soft tissue; or by direct inoculation during surgery, injection, or trauma. In hematogenous infection, bacteria escape from synovial capillaries, which have no limiting basement membrane, and within hours provoke neutrophilic infiltration of the synovium. Neutrophils and bacteria enter the joint space; later, bacteria adhere to articular cartilage. Degradation of cartilage begins within 48 h as a result of increased intraarticular pressure, release of proteases and cytokines from chondrocytes and synovial macrophages, and invasion of the cartilage by bacteria and inflammatory cells. Histologic studies reveal bacteria lining the synovium and cartilage as well as abscesses extending into the synovium, cartilage, and—in severe cases—subchondral bone. Synovial proliferation results in the formation of a pannus over the cartilage, and thrombosis of inflamed synovial vessels develops. Bacterial factors that appear important in the pathogenesis of infective arthritis include various surface-associated adhesins in *S. aureus* that permit adherence to cartilage and endotoxins that promote chondrocyte-mediated breakdown of cartilage.

Microbiology The hematogenous route of infection is the most common route in all age groups, and nearly every bacterial pathogen is

capable of causing septic arthritis. In infants, group B streptococci, gram-negative enteric bacilli, and *S. aureus* are the usual pathogens. Since the advent of the *Haemophilus influenzae* vaccine, *S. aureus*, *Streptococcus pyogenes* (group A *Streptococcus*), and (in some centers) *Kingella kingae* have predominated among children <5 years of age. Among young adults and adolescents, *N. gonorrhoeae* is the most commonly implicated organism. *S. aureus* accounts for most nongonococcal isolates in adults of all ages; gram-negative bacilli, pneumococci, and β-hemolytic streptococci—particularly groups A and B, but also groups C, G, and F—are involved in up to one-third of cases in older adults, especially those with underlying comorbid illnesses.

Infections following surgical procedures or penetrating injuries are due most often to *S. aureus* and occasionally to other gram-positive bacteria or gram-negative bacilli. Infections with coagulase-negative staphylococci are unusual except after the implantation of prosthetic joints or arthroscopy. Anaerobic organisms, often in association with aerobic or facultative bacteria, are found after human bites and when decubitus ulcers or intraabdominal abscesses spread into adjacent joints. Polymicrobial infections complicate traumatic injuries with extensive contamination. Bites and scratches from cats and other animals may introduce *Pasteurella multocida* into joints.

TABLE 314-1 *Differential Diagnosis of Arthritis Syndromes*

Acute Monarticular Arthritis	Chronic Monarticular Arthritis	Polyarticular Arthritis
Staphylococcus aureus	*Mycobacterium tuberculosis*	*Neisseria meningitidis*
Streptococcus pneumoniae	Nontuberculous mycobacteria	*N. gonorrhoeae*
β-Hemolytic streptococci	*Borrelia burgdorferi*	Nongonococcal bacterial arthritis
Gram-negative bacilli	*Treponema pallidum*	Bacterial endocarditis
Neisseria gonorrhoeae	*Candida* species	*Candida* species
Candida species	*Sporothrix schenckii*	Poncet's disease (tuberculous rheumatism)
Crystal-induced arthritis	*Coccidioides immitis*	Hepatitis B virus
Fracture	*Blastomyces dermatitidis*	Parvovirus B19
Hemarthrosis	*Aspergillus* species	HIV
Foreign body	*Cryptococcus neoformans*	Human T-lymphotropic virus type I
Osteoarthritis	*Nocardia* species	Rubella virus
Ischemic necrosis	*Brucella* species	Arthropod-borne viruses
Monarticular rheumatoid arthritis	Legg-Calvé-Perthes disease	Sickle cell disease flare
	Osteoarthritis	Reactive arthritis
		Serum sickness
		Acute rheumatic fever
		Inflammatory bowel disease
		Systemic lupus erythematosus
		Rheumatoid arthritis/Still's disease
		Other vasculitides
		Sarcoidosis

Nongonococcal Bacterial Arthritis ■ *EPIDEMIOLOGY* Although hematogenous infections with virulent organisms such as *S. aureus*, *H. influenzae*, and pyogenic streptococci occur in healthy persons, there is an underlying host predisposition in many cases of septic arthritis. Patients with rheumatoid arthritis have the highest incidence of infective arthritis (most often secondary to *S. aureus*) because of chronically inflamed joints; glucocorticoid therapy; and frequent breakdown of rheumatoid nodules, vasculitic ulcers, and skin overlying deformed joints. Diabetes mellitus, glucocorticoid therapy, hemodialysis, and malignancy all carry an increased risk of infection with *S. aureus* and gram-negative bacilli. Tumor necrosis factor (TNF) inhibitors (etanercept and infliximab), increasingly used for the treatment of rheumatoid arthritis, predispose to mycobacterial infections and possibly to other pyogenic bacterial infections and could be associated with septic arthritis in this population. Pneumococcal infections complicate alcoholism, deficiencies of humoral immunity, and hemoglobinopathies. Pneumococci, *Salmonella*, and *H. influenzae* cause septic arthritis in persons infected with HIV. Persons with primary immunoglobulin deficiency are at risk for mycoplasmal arthritis, which results in permanent joint damage if treatment with tetracycline and intravenous (IV) immunoglobulin replacement is not administered promptly. Intravenous drug users acquire staphylococcal and streptococcal infections from their own flora and acquire pseudomonal and other gram-negative infections from drugs and injection paraphernalia.

CLINICAL MANIFESTATIONS Some 90% of patients present with involvement of a single joint—most commonly the knee, less frequently the hip, and still less often the shoulder, wrist, or elbow. Small joints of the hands and feet are more likely to be affected after direct inoculation or a bite. Among IV drug users, infections of the spine, sacroiliac joints, or sternoclavicular joints are more common than infections of the appendicular skeleton. Polyarticular infection is most common among patients with rheumatoid arthritis and may resemble a flare of the underlying disease.

The usual presentation consists of moderate to severe pain that is uniform around the joint, effusion, muscle spasm, and decreased range of motion. Fever in the range of 38.3° to 38.9°C (101° to 102°F) and sometimes higher is common but may be lacking, especially in persons with rheumatoid arthritis, renal or hepatic insufficiency, or conditions requiring immunosuppressive therapy. The inflamed, swollen joint is usually evident on examination except in the case of a deeply situated joint, such as the hip, shoulder, or sacroiliac joint. Cellulitis, bursitis, and acute osteomyelitis, which may produce a similar clinical picture, should be distinguished from septic arthritis by their greater range of motion and less-than-circumferential swelling. A focus of extraarticular infection, such as a boil or pneumonia, should be sought. Peripheral-blood leukocytosis with a left shift and elevation of the erythrocyte sedimentation rate or C-reactive protein level are common.

Plain radiographs show evidence of soft tissue swelling, joint-space widening, and displacement of tissue planes by the distended capsule. Narrowing of the joint space and bony erosions indicate advanced infection and a poor prognosis. Ultrasound is useful for detecting effusions in the hip, and computed tomography or magnetic resonance imaging can demonstrate infections of the sacroiliac joint, the sternoclavicular joint, and the spine very well.

LABORATORY FINDINGS Specimens of peripheral blood and synovial fluid should be obtained before antibiotics are administered. Blood cultures are positive in up to 50% of *S. aureus* infections but are less frequently positive in infections due to other organisms. The synovial fluid is turbid, serosanguineous, or frankly purulent. Gram-stained smears confirm the presence of large numbers of neutrophils. Levels of total protein and lactate dehydrogenase in synovial fluid are elevated, and the glucose level is depressed; however, these findings are not specific for infection, and measurement of these levels is not necessary to make the diagnosis. The synovial fluid should be examined for crystals, because gout and pseudogout can resemble septic arthritis clinically, and infection and crystal-induced disease occasionally occur together. Organisms are seen on synovial fluid smears in nearly three-quarters of infections with *S. aureus* and streptococci and in 30 to 50% of infections due to gram-negative and other bacteria. Cultures of synovial fluid are positive in >90% of cases. Inoculation of synovial fluid into bottles containing liquid media for blood cultures increases the yield of culture, especially if the pathogen is a fastidious organism or the patient is taking an antibiotic. Although not yet widely available, PCR-based assays for bacterial DNA will also be useful for the diagnosis of partially treated or culture-negative bacterial arthritis.

TREATMENT

Prompt administration of systemic antibiotics and drainage of the involved joint can prevent destruction of cartilage, postinfectious degenerative arthritis, joint instability, or deformity. Once samples of blood and synovial fluid have been obtained for culture, empirical antibiotics should be given that are directed against bacteria visualized

on smears or against the pathogens that are likely, given the patient's age and risk factors. Initial therapy should consist of the IV administration of bactericidal agents; direct instillation of antibiotics into the joint is not necessary to achieve adequate levels in synovial fluid and tissue. An IV third-generation cephalosporin such as cefotaxime (1 g every 8 h) or ceftriaxone (1 to 2 g every 24 h) provides adequate empirical coverage for most community-acquired infections in adults when smears show no organisms. Either oxacillin or nafcillin (2 g every 4 h) is used if there are gram-positive cocci on the smear. If methicillin-resistant *S. aureus* is a possible pathogen (e.g., in hospitalized patients), IV vancomycin (1 g every 12 h) should be given. In addition, an aminoglycoside or third-generation cephalosporin should be given to IV drug users or other patients in whom *Pseudomonas aeruginosa* may be the responsible agent.

Definitive therapy is based on the identity and antibiotic susceptibility of the bacteria isolated in culture. Infections due to staphylococci are treated with oxacillin, nafcillin, or vancomycin for 4 weeks. Pneumococcal and streptococcal infections due to penicillin-susceptible organisms respond to 2 weeks of therapy with penicillin G (2 million units IV every 4 h); infections caused by *H. influenzae* and by strains of *S. pneumoniae* that are resistant to penicillin are treated with cefotaxime or ceftriaxone for 2 weeks. Most enteric gram-negative infections can be cured in 3 to 4 weeks by a second- or third-generation cephalosporin given intravenously or by a fluoroquinolone, such as levofloxacin (500 mg IV or orally every 24 h). *P. aeruginosa* infection should be treated for at least 2 weeks with a combination regimen of an aminoglycoside plus either an extended-spectrum penicillin, such as mezlocillin (3 g IV every 4 h), or an antipseudomonal cephalosporin, such as ceftazidime (1 g IV every 8 h). If tolerated, this regimen is continued for an additional 2 weeks; alternatively, a fluoroquinolone, such as ciprofloxacin (750 mg orally bid), is given by itself or with the penicillin or cephalosporin in place of the aminoglycoside.

Timely drainage of pus and necrotic debris from the infected joint is required for a favorable outcome. Needle aspiration of readily accessible joints such as the knee may be adequate if loculations or particulate matter in the joint does not prevent its thorough decompression. Arthroscopic drainage and lavage may be employed initially or within several days if repeated needle aspiration fails to relieve symptoms, decrease the volume of the effusion and the synovial white cell count, and clear bacteria from smears and cultures. In some cases, arthrotomy is necessary to remove loculations and debride infected synovium, cartilage, or bone. Septic arthritis of the hip is best managed with arthrotomy, particularly in young children, in whom infection threatens the viability of the femoral head. Septic joints do not require immobilization except for pain control before symptoms are alleviated by treatment. Weight bearing should be avoided until signs of inflammation have subsided, but frequent passive motion of the joint is indicated to maintain full mobility. While addition of glucocorticoids to antibiotic treatment improves the outcome of *S. aureus* arthritis in experimental animals, no clinical trials have yet evaluated this approach in humans.

Gonococcal Arthritis ■ *EPIDEMIOLOGY* Although its incidence has declined in recent years, gonococcal arthritis (Chap. 128) has accounted for up to 70% of episodes of infectious arthritis in persons <40 years of age in the United States. Arthritis due to *N. gonorrhoeae* is a consequence of bacteremia arising from gonococcal infection or, more frequently, from asymptomatic gonococcal mucosal colonization of the urethra, cervix, or pharynx. Women are at greatest risk during menses and during pregnancy and overall are two to three times more likely than men to develop disseminated gonoccal infection (DGI) and arthritis. Persons with complement deficiencies, especially of the terminal components, are prone to recurrent episodes of gonococcemia. Strains of gonococci that are most likely to cause DGI include those that produce transparent colonies in culture, have the type IA outermembrane protein, or are of the AUH-auxotroph type.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS The most common manifestation of DGI is a syndrome of fever, chills, rash, and articular symptoms. Small numbers of papules that progress to hemorrhagic pustules develop on the trunk and the extensor surfaces of the distal extremities. Migratory arthritis and tenosynovitis of the knees, hands, wrists, feet, and ankles are prominent. The cutaneous lesions and articular findings are believed to be the consequence of an immune reaction to circulating gonococci and immune-complex deposition in tissues. Thus, cultures of synovial fluid are consistently negative, and blood cultures are positive in <45% of patients. Synovial fluid may be difficult to obtain from inflamed joints and usually contains only 10,000 to 20,000 leukocytes/μL.

True gonococcal septic arthritis is less common than the DGI syndrome and always follows DGI, which is unrecognized in one-third of patients. A single joint, such as the hip, knee, ankle, or wrist, is usually involved. Synovial fluid, which contains >50,000 leukocytes/μL, can be obtained with ease; the gonococcus is only occasionally evident in gram-stained smears, and cultures of synovial fluid are positive in <40% of cases. Blood cultures are almost always negative.

Because it is difficult to isolate gonococci from synovial fluid and blood, specimens for culture should be obtained from potentially infected mucosal sites. Cultures and gram-stained smears of skin lesions are occasionally positive. All specimens for culture should be plated onto Thayer-Martin agar directly or in special transport media at the bedside and transferred promptly to the microbiology laboratory in an atmosphere of 5% CO_2, as generated in a candle jar. PCR-based assays are extremely sensitive in detecting gonococcal DNA in synovial fluid. A dramatic alleviation of symptoms within 12 to 24 h after the initiation of appropriate antibiotic therapy supports a clinical diagnosis of the DGI syndrome if cultures are negative.

℞ TREATMENT

Initial treatment consists of ceftriaxone (1 g IV or intramuscularly every 24 h) to cover possible penicillin-resistant organisms. Once local and systemic signs are clearly resolving and if the sensitivity of the isolate permits, the 7-day course of therapy can be completed with an oral agent such as ciprofloxacin (500 mg twice daily). Ciprofloxacin (500 mg orally/400 mg IV twice daily) may also be used as initial therapy in areas where resistance has not become prevalent; if penicillin-susceptible organisms are isolated, amoxicillin (500 mg three times daily) may be used. Suppurative arthritis usually responds to needle aspiration of involved joints and 7 to 14 days of antibiotic treatment. Arthroscopic lavage or arthrotomy is rarely required. Patients with disseminated gonococcal infection should be treated for *Chlamydia trachomatis* infection unless this infection is ruled out by appropriate testing.

It is noteworthy that arthritis symptoms similar to those seen in DGI occur in meningococcemia. A dermatitis-arthritis syndrome, purulent monarthritis, and reactive polyarthritis have been described. All respond to treatment with IV penicillin.

SPIROCHETAL ARTHRITIS ■ **Lyme Disease** Lyme disease (Chap. 157) due to infection with the spirochete *Borrelia burgdorferi* causes arthritis in up to 70% of persons who are not treated. Intermittent arthralgias and myalgias—but not arthritis—occur within days or weeks of inoculation of the spirochete by the *Ixodes* tick. Later, there are three patterns of joint disease: (1) Fifty percent of untreated persons experience intermittent episodes of monarthritis or oligoarthritis involving the knee and/or other large joints. The symptoms wax and wane without treatment over months, and each year 10 to 20% of patients report loss of joint symptoms. (2) Twenty percent of untreated persons develop a pattern of waxing and waning arthralgias. (3) Ten percent of untreated patients develop chronic inflammatory synovitis resulting in erosive lesions and destruction of the joint. Serologic tests for IgG

antibodies to *B. burgdorferi* are positive in >90% of persons with Lyme arthritis, and a PCR-based assay detects *Borrelia* DNA in 85%.

TREATMENT

Lyme arthritis generally responds well to therapy. A regimen of oral doxycycline (100 mg twice daily for 30 days), oral amoxicillin (500 mg four times daily for 30 days), or parenteral ceftriaxone (2 g/d for 2 to 4 weeks) is recommended. Patients who do not respond to a total of 2 months of oral therapy or 1 month of parenteral therapy are unlikely to benefit from additional antibiotic therapy and are treated with anti-inflammatory agents or synovectomy. Failure of therapy is associated with host features such as the HLA-DR4 genotype, persistent reactivity to OspA (outer-surface protein A), and the presence of hLFA-1 (human leukocyte function–associated antigen 1), which cross-reacts with OspA.

Syphilitic Arthritis Articular manifestations occur in different stages of syphilis (Chap. 153). In early congenital syphilis, periarticular swelling and immobilization of the involved limbs (Parrot's pseudoparalysis) complicate osteochondritis of long bones. Clutton's joint, a late manifestation of congenital syphilis that typically develops between the ages of 8 and 15 years, is caused by chronic painless synovitis with effusions of large joints, particularly the knees and elbows. Secondary syphilis may be associated with arthralgias; with symmetric arthritis of the knees and ankles and occasionally of the shoulders and wrists; and with sacroiliitis. The arthritis follows a subacute to chronic course with a mixed mononuclear and neutrophilic synovial-fluid pleocytosis (typical cell counts, 5000 to 15,000/μL). Immunologic mechanisms may contribute to the arthritis, and symptoms usually improve rapidly with penicillin therapy. In tertiary syphilis, Charcot's joint is a result of sensory loss due to tabes dorsalis. Penicillin is not helpful in this setting.

MYCOBACTERIAL ARTHRITIS Tuberculous arthritis (Chap. 150) accounts for ~1% of all cases of tuberculosis and for 10% of extrapulmonary cases. The most common presentation is chronic granulomatous monarthritis. An unusual syndrome, Poncet's disease, is a reactive symmetric form of polyarthritis that affects persons with visceral or disseminated tuberculosis. No mycobacteria are found in the joints, and symptoms resolve with antituberculous therapy.

Unlike tuberculous osteomyelitis (Chap. 111), which typically involves the thoracic and lumbar spine (50% of cases), tuberculous arthritis primarily involves the large weight-bearing joints, in particular the hips, knees, and ankles, and only occasionally involves smaller non-weight-bearing joints. Progressive monarticular swelling and pain develop over months to years, and systemic symptoms are seen in only half of all cases. Tuberculous arthritis occurs as part of a disseminated primary infection or through late reactivation, often in persons with HIV infection or other immunocompromised hosts. Coexistent active pulmonary tuberculosis is unusual.

Aspiration of the involved joint yields fluid with an average cell count of 20,000/μL, with ~50% neutrophils. Acid-fast staining of the fluid yields positive results in fewer than one-third of cases, and cultures are positive in 80%. Culture of synovial tissue taken at biopsy is positive in ~90% of cases and shows granulomatous inflammation in most. DNA amplification methods such as PCR can shorten the time to diagnosis to 1 or 2 days. Radiographs reveal peripheral erosions at the points of synovial attachment, periarticular osteopenia, and eventually joint-space narrowing. Therapy for tuberculous arthritis is the same as that for tuberculous pulmonary disease, requiring the administration of multiple agents for 6 to 9 months. Therapy is more prolonged in immunosuppressed individuals, such as those infected with HIV.

Various atypical mycobacteria (Chap. 152) found in water and soil may cause chronic indolent arthritis. Such disease results from trauma and direct inoculation associated with farming, gardening, or aquatic activities. Smaller joints, such as the digits, wrists, and knees, are usually involved. Involvement of tendon sheaths and bursae is typical. The mycobacterial species involved include *Mycobacterium marinum*, *M. avium-intracellulare*, *M. terrae*, *M. kansasii*, *M. fortuitum*, and *M. chelonae*. In persons who have HIV infection or are receiving immunosuppressive therapy, hematogenous spread to the joints has been reported for *M. kansasii*, *M. avium-intracellulare*, and *M. haemophilum*. Diagnosis usually requires biopsy and culture, and therapy is based on antimicrobial susceptibility patterns.

FUNGAL ARTHRITIS Fungi are an unusual cause of chronic monarticular arthritis. Granulomatous articular infection with the endemic dimorphic fungi *Coccidioides immitis*, *Blastomyces dermatitidis*, and (less commonly) *Histoplasma capsulatum* results from hematogenous seeding or direct extension from bony lesions in persons with disseminated disease. Joint involvement is an unusual complication of sporotrichosis (infection with *Sporothrix schenckii*) among gardeners and other persons who work with soil or sphagnum moss. Articular sporotrichosis is six times more common among men than among women, and alcoholics and other debilitated hosts are at risk for polyarticular infection.

Candida infection involving a single joint—usually the knee, hip, or shoulder—results from surgical procedures, intraarticular injections, or (among critically ill patients with debilitating illnesses, such as diabetes mellitus or hepatic or renal insufficiency, and patients receiving immunosuppressive therapy) hematogenous spread. *Candida* infections in IV drug users typically involve the spine, sacroiliac joints, or other fibrocartilaginous joints. Unusual cases of arthritis due to *Aspergillus* species, *Cryptococcus neoformans*, *Pseudallescheria boydii*, and the dematiaceous fungi have also resulted from direct inoculation or disseminated hematogenous infection in immunocompromised persons.

The synovial fluid in fungal arthritis usually contains 10,000 to 40,000 cells/μL, with ~70% neutrophils. Stained specimens and cultures of synovial tissue often confirm the diagnosis of fungal arthritis when studies of synovial fluid give negative results. Treatment consists of drainage and lavage of the joint and systemic administration of an antifungal agent directed at a specific pathogen. The doses and duration of therapy are the same as for disseminated disease (see Part VI, Section 16). Intraarticular instillation of amphotericin B has been used in addition to IV therapy.

VIRAL ARTHRITIS Viruses produce arthritis by infecting synovial tissue during systemic infection or by provoking an immunologic reaction that involves joints. As many as 50% of women report persistent arthralgias and 10% report frank arthritis within 3 days of the rash that follows natural infection with rubella virus and within 2 to 6 weeks after receipt of live-virus vaccine. Episodes of symmetric inflammation of fingers, wrists, and knees uncommonly recur for >1 year, but a syndrome of chronic fatigue, low-grade fever, headaches, and myalgias can persist for months or years. Intravenous immunoglobulin has been helpful in selected cases. Self-limited monarticular or migratory polyarthritis may develop within 2 weeks of the parotitis of mumps; this sequela is more common among men than among women. Approximately 10% of children and 60% of women develop arthritis after infection with parvovirus B19. In adults, arthropathy sometimes occurs without fever or rash. Pain and stiffness, with less prominent swelling (primarily of the hands but also of the knees, wrists, and ankles), usually resolve within weeks, although a small proportion of patients develop chronic arthropathy.

About 2 weeks before the onset of jaundice, up to 10% of persons with acute hepatitis B develop an immune complex–mediated, serum sickness–like reaction with maculopapular rash, urticaria, fever, and arthralgias. Less common developments include symmetric arthritis involving the hands, wrists, elbows, or ankles and morning stiffness that resembles a flare of rheumatoid arthritis. Symptoms resolve at the time jaundice develops. Many persons with chronic hepatitis C infec-

tion report persistent arthralgia or arthritis, both in the presence and in the absence of cryoglobulinemia. Painful arthritis involving larger joints often accompanies the fever and rash of several arthropod-borne viral infections, including those caused by chikungunya, O'nyong-nyong, Ross River, Mayaro, and Barmah Forest viruses. Symmetric arthritis involving the hands and wrists may occur during the convalescent phase of infection with lymphocytic choriomeningitis virus. Patients infected with an enterovirus frequently report arthralgias, and echovirus has been isolated from patients with acute polyarthritis.

Several arthritis syndromes are associated with HIV infection. Reiter's syndrome with painful lower-extremity oligoarthritis often follows an episode of urethritis in HIV-infected persons. HIV-associated Reiter's syndrome appears to be extremely common among persons with the HLA-B27 haplotype, but sacroiliac joint disease is unusual and is seen mostly in the absence of HLA-B27. Up to one-third of HIV-infected persons with psoriasis develop psoriatic arthritis. Painless monarthropathy and persistent symmetric polyarthropathy occasionally complicate HIV infection. Chronic persistent oligoarthritis of the shoulders, wrists, hands, and knees occurs in women infected with human T-cell lymphotropic virus type I. Synovial thickening, destruction of articular cartilage, and leukemic-appearing atypical lymphocytes in synovial fluid are characteristic, but progression to T cell leukemia is unusual.

PARASITIC ARTHRITIS Arthritis due to parasitic infection is rare. The guinea worm *Dracunculus medinensis* may cause destructive joint lesions in the lower extremities as migrating gravid female worms invade joints or cause ulcers in adjacent soft tissues that become secondarily infected. Hydatid cysts infect bones in 1 to 2% of cases of infection with *Echinococcus granulosus*. The expanding destructive cystic lesions may spread to and destroy adjacent joints, particularly the hip and pelvis. In rare cases, chronic synovitis has been associated with the presence of schistosomal eggs in synovial biopsies. Monarticular arthritis in children with lymphatic filariasis appears to respond to therapy with diethylcarbamazine, even in the absence of microfilariae in synovial fluid. Reactive arthritis has been attributed to hookworm, *Strongyloides*, *Cryptosporidium*, and *Giardia* infection in case reports, but confirmation is required.

POSTINFECTIOUS OR REACTIVE ARTHRITIS Reiter's syndrome, a reactive polyarthritis, develops several weeks after ~1% of cases of nongonococcal urethritis and 2% of enteric infections, particularly those due to *Yersinia enterocolitica*, *Shigella flexneri*, *Campylobacter jejuni*, and *Salmonella* species. Only a minority of these patients have the other findings of classic Reiter's syndrome, including urethritis, conjunctivitis, uveitis, oral ulcers, and rash. Studies have identified microbial DNA or antigen in synovial fluid or blood, but the pathogenesis of this condition is poorly understood.

Reiter's syndrome is most common among young men (except after *Yersinia* infection) and has been linked to the HLA-B27 locus as a potential genetic predisposing factor. Patients report painful, asymmetric oligoarthritis affecting mainly the knees, ankles, and feet. Low-back pain is common, and radiographic evidence of sacroiliitis is found in patients with long-standing disease. Most patients recover within 6 months, but prolonged recurrent disease is more common in cases following chlamydial urethritis. Anti-inflammatory agents help to relieve symptoms, but the role of prolonged antibiotic therapy in eliminating microbial antigen from the synovium is controversial.

Migratory polyarthritis and fever constitute the usual presentation of acute rheumatic fever in adults (Chap. 302). This presentation is distinct from that of poststreptococcal reactive arthritis, which also follows infections with group A *Streptococcus* but is not migratory, lasts beyond the typical 3-week maximum of acute rheumatic fever, and responds poorly to aspirin.

INFECTIONS IN PROSTHETIC JOINTS Infection complicates 1 to 4% of total joint replacements. The majority of infections are acquired intraoperatively or immediately postoperatively as a result of wound breakdown or infection; less commonly, these joint infections develop later after joint replacement and are the result of hematogenous spread or direct inoculation. The presentation may be acute, with fever, pain, and local signs of inflammation, especially in infections due to *S. aureus*, pyogenic streptococci, and enteric bacilli. Alternatively, infection may persist for months or years without causing constitutional symptoms when less virulent organisms, such as coagulase-negative staphylococci or diphtheroids, are involved. Such indolent infections are usually acquired during joint implantation and are discovered during evaluation of chronic unexplained pain or after a radiograph shows loosening of the prosthesis; the erythrocyte sedimentation rate and C-reactive protein level are usually elevated in such cases.

The diagnosis is best made by needle aspiration of the joint; accidental introduction of organisms during aspiration must be meticulously avoided. Synovial fluid pleocytosis with a predominance of polymorphonuclear leukocytes is highly suggestive of infection, since other inflammatory processes uncommonly affect prosthetic joints. Culture and Gram's stain usually yield the responsible pathogen. Use of special media for unusual pathogens such as fungi, atypical mycobacteria, and *Mycoplasma* may be necessary if routine and anaerobic cultures are negative.

TREATMENT

Treatment includes surgery and high doses of parenteral antibiotics, which are given for 4 to 6 weeks because bone is usually involved. In most cases, the prosthesis must be replaced to cure the infection. Implantation of a new prosthesis is best delayed for several weeks or months because relapses of infection occur most commonly within this time frame. In some cases, reimplantation is not possible, and the patient must manage without a joint, with a fused joint, or even with amputation. Cure of infection without removal of the prosthesis is occasionally possible in cases that are due to streptococci or pneumococci and that lack radiologic evidence of loosening of the prosthesis. In these cases, antibiotic therapy must be initiated within several days of the onset of infection, and the joint should be drained vigorously either by open arthrotomy or arthroscopically. In selected patients who prefer to avoid the high morbidity associated with joint removal and reimplantation, suppression of the infection with antibiotics may be a reasonable goal. A high cure rate with retention of the prosthesis has been reported when the combination of oral rifampin and ciprofloxacin is given for 3 to 6 months to persons with staphylococcal prosthetic joint infection of short duration. This approach, which is based on the ability of rifampin to kill organisms adherent to foreign material and in the stationary growth phase, requires confirmation in prospective trials.

Prevention To avoid the disastrous consequences of infection, candidates for joint replacement should be selected with care. Rates of infection are particularly high among patients with rheumatoid arthritis, persons who have undergone previous surgery on the joint, and persons with medical conditions requiring immunosuppressive therapy. Perioperative antibiotic prophylaxis, usually with cefazolin, and measures to decrease intraoperative contamination, such as laminar flow, have lowered the rates of perioperative infection to <1% in many centers. After implantation, measures should be taken to prevent or rapidly treat extraarticular infections that might give rise to hematogenous spread to the prosthesis. The effectiveness of prophylactic antibiotics for the prevention of hematogenous infection following dental procedures has not been demonstrated; in fact, viridans streptococci and other components of the oral flora are extremely unusual causes of prosthetic joint infection. Accordingly, the American Dental Association and the American Academy of Orthopaedic Surgeons do not recommend antibiotic prophylaxis for most dental patients with total joint replacements. They do, however, recommend prophylaxis for patients who may be at high risk of hematogenous infection, including those with inflammatory arthropathies, immunosuppression, type 1 diabetes mellitus, joint replacement within 2 years, previous prosthetic joint infection, malnourishment, or hemophilia. The recommended

regimen is amoxicillin (2 g orally) 1 h before dental procedures associated with a high incidence of bacteremia. Clindamycin (600 mg orally) is suggested for patients allergic to penicillin.

315 FIBROMYALGIA, ARTHRITIS ASSOCIATED WITH SYSTEMIC DISEASE, AND OTHER ARTHRITIDES

Bruce C. Gilliland

FIBROMYALGIA

Fibromyalgia is a commonly encountered disorder characterized by chronic widespread musculoskeletal pain, stiffness, paresthesia, disturbed sleep, and easy fatigability along with multiple painful tender points, which are widely and symmetrically distributed. Fibromyalgia affects predominantly women in a ratio of 9 to 1 compared to men. This disorder is found in most countries, in most ethnic groups, and in all types of climates. The prevalence of fibromyalgia in the general population of a community in the United States using the 1990 American College of Rheumatology (ACR) classification criteria (see below) was reported to be 3.4% in women and 0.5% in men. Contrary to some previous reports, fibromyalgia was not found to be present mainly in young women but, rather, to be most prevalent in women ≥50 years. The prevalence increased with age, being 7.4% in women between the ages of 70 and 79. Although not common, fibromyalgia also occurs in children. The reported prevalence of fibromyalgia in some rheumatology clinics has been as high as 20%. Most patients present with fibromyalgia between the ages of 30 to 50 years.

Pathogenesis Several causative mechanisms for fibromyalgia have been postulated to explain abnormal pain perception. Several abnormalities of the central nervous system have been suggested. Disturbed sleep has been implicated as a factor in the pathogenesis. Nonrestorative sleep or awakening unrefreshed has been observed in most patients with fibromyalgia. Sleep electroencephalographic studies in patients with fibromyalgia have shown disruption of normal stage 4 sleep [non–rapid eye movement (NREM) sleep] by many repeated α-wave intrusions. The idea that stage 4 sleep deprivation has a role in causing this disorder was supported by the observation that symptoms of fibromyalgia developed in normal subjects whose stage 4 sleep was disrupted artificially by induced α-wave intrusions. This sleep disturbance, however, has been demonstrated in healthy individuals; in emotionally distressed individuals; and in patients with sleep apnea, fever, osteoarthritis, or rheumatoid arthritis. Low levels of serotonin metabolites have been reported in the cerebrospinal fluid (CSF) of patients with fibromyalgia, suggesting that a deficiency of serotonin, a neurotransmitter that regulates pain and NREM sleep, might also be involved in the pathogenesis of fibromyalgia. Drugs that affect serotonin metabolism have not had a dramatic effect on fibromyalgia, however. Fibromyalgia patients as a group have been reported by some investigators to have reduced levels of growth hormone, which is important for muscle repair and strength. Growth hormone is secreted normally during stage 4 sleep, which is disturbed in patients with fibromyalgia. The reduction of growth hormone may explain the extended periods of muscle pain following exertion in these patients. The level of the neurotransmitter substance P has been reported to be increased in the CSF of fibromyalgia patients and may play a role in spreading muscle pain. Patients with fibromyalgia have a decreased cortisol response to stress. Low urinary free cortisol and a diminished cortisol response to corticotropin-releasing hormone suggest an abnormal hypothalamic-pituitary-adrenal axis. Autonomic dysfunction has also been suggested to play a role in the pathogenesis of fibromyalgia. Some patients experience orthostatic hypotension on tilt table testing and may have increased resting supine heart rates. Disturbances of the autonomic and peripheral nervous system may also account for the dry eyes and mouth and the cold sensitivity and Raynaud's-like symptoms seen in patients with fibromyalgia. Single photon emission computed tomography (SPECT) imaging has demonstrated reduced blood flow to the thalamus, caudate nucleus, and pontine tectum, which are areas in the brain involved in the signaling, integration, and modulation of pain. Patients with fibromyalgia have been shown to perceive stimuli such as heat or pressue as painful with less degree of stimulation than normal individuals. The actual threshold for detecting stimuli appears to be similar in both patients and normal subjects.

Many patients with fibromyalgia have psychological abnormalities; there has been disagreement as to whether some of these abnormalities represent reactions to the chronic pain or whether the symptoms of fibromyalgia are a reflection of psychiatric disturbance. Approximately 30% of patients fit a psychiatric diagnosis, the most common being depression, anxiety, somatization, and hypochondriases. Studies have also shown a high prevalence of sexual and physical abuse and eating disorders. However, fibromyalgia also occurs in patients without significant psychiatric problems.

Since patients experience pain from muscle and musculotendinous sites, many studies have been done to examine muscle, both structurally and physiologically. Inflammation or diagnostic muscle abnormalities have not been found. Evidence indicates deconditioning of muscles, and patients experience a greater degree of postexertional pain than do unaffected persons. A better understanding of fibromyalgia awaits further studies.

Clinical Manifestations Symptoms are generalized musculoskeletal aching and stiffness and fatigue. Patients may complain of low back pain, which may radiate into the buttocks and legs. Others complain of pain and tightness in the neck and across the upper posterior shoulders. Patients complain of muscle pain after even mild exertion and some degree of pain is always present. The pain has been described as a burning or gnawing pain or as soreness, stiffness, or aching. Pain may begin in one region, such as the shoulders, neck, or lower back (see "Myofascial Pain Syndrome," below) before it eventually becomes widespread. Patients may complain of joint pain and perceive that their joints are swollen; however, joint examination yields normal findings. Stiffness is usually present on arising in the morning; usually it improves during the day, but in some patients it lasts all day. Patients may complain of numbness of their hands and feet. They may also feel colder overall than others in the home, and some may experience Raynaud's-like phenomena or actual Raynaud's phenomenon. Patients complain of feeling fatigued and exhausted and wake up tired. They also awaken frequently at night and have trouble falling back to sleep.

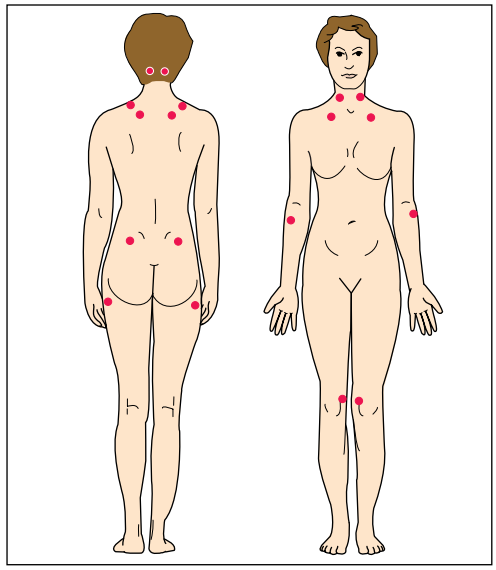

FIGURE 315-1 Tender points in fibromyalgia. Suboccipital muscle insertion at base of skull; anterior aspect of intertransverse process spaces at C5–7; midpoint of upper border of trapezius muscle; above scapular spine near medial border of scapula; second costochondral junction; lateral epicondyle; upper outer quadrant of buttocks; posterior aspect of trochanteric prominence; medial fat pad of knee (all bilateral). *(From the brochure "Fibromyalgia," Arthritis Information, Advise and Guidance, Disease Series. Used by permission of the Arthritis Foundation.)*

Patients may experience cognitive impairment with difficulty thinking and loss of short-term memory. Headaches, including migraine type, are also common symptons. Others experience episodes of light-headedness, dizziness, anxiety, or depression. Symptoms are made worse by stress or anxiety, cold, damp weather, and overexertion. Patients often feel better during warmer weather and vacations.

The characteristic feature on physical examination is the demonstration of specific sites or points, which are more tender or painful than the same sites in normal individuals. The ACR Criteria for Fibromyalgia defines 18 tender points (Fig. 315-1). These points of tenderness are remarkably constant in location. A moderate and consistent degree of pressure should be used in digital palpation of these tender points. As a guideline to reduce variability in the interpretation of point tenderness, the amount of force applied should be 4 kg (~9 lb), which is the degree of force required to just blanch the examiner's thumbnail. This amount of pressure does not produce significant tenderness or pain in normal subjects. Some workers recommend that the tender site be palpated using a rolling motion, which may be more effective in eliciting the tenderness. The tender sites can also be examined using a dolorimeter, which is a spring-loaded pressure gauge; however, digital palpation appears to be as effective and accurate. Some investigators have quantitated the degree of tenderness or pain, but the number of tender point sites is more diagnostic. Some patients are tender all over although still more tender or painful at the specific tender point sites.

Skinfold tenderness may be present, particularly over the upper scapular region. Subcutaneous nodules may be felt at sites of tenderness. Nodules in similar locations are present in normal persons but are not tender.

Fibromyalgia may be triggered by emotional stress, infections and other medical illness, surgery, hypothyroidism, and trauma. It has appeared in some patients with hepatitis C infection, HIV infection, parvovirus B19 infection, or Lyme disease. In the latter situation, fibromyalgia may persist despite adequate antibiotic treatment for Lyme disease, and especially anxious patients may believe that they still have Lyme disease. Disorders commonly associated with fibromyalgia include irritable bowel syndrome, irritable bladder, headaches (including migraine headaches), dysmenorrhea, premenstrual syndrome, restless leg syndrome, temporomandibular joint pain, non-cardiac chest pain, Raynaud's phenomenon, and sicca syndrome.

The course of fibromyalgia is variable. Symptoms wax and wane in some patients, while in others pain and fatigue are persistent regardless of therapy. Studies from tertiary medical centers indicate a poor prognosis for most patients. The prognosis may be better in community-treated patients. In a community-based study reported after 2 years of treatment, 24% of patients were in remission, and 47% no longer fulfilled the ACR criteria for fibromyalgia.

Diagnosis Fibromyalgia is diagnosed by a history of widespread musculoskeletal pain present for at least 3 months and the demonstration of significant tenderness or pain in at least 11 of the 18 tender point sites on digital palpation (Fig. 315-1). The ACR criteria are useful for standardizing the diagnosis; however, not all patients with fibromyalgia meet these criteria (Table 315-1). Some patients have fewer tender sites and more regional pain and may be considered to have fibromyalgia.

The musculoskeletal and neurologic examinations are normal in fibromyalgia patients, and there are no laboratory abnormalities. Fibromyalgia may occur in patients with rheumatoid arthritis, systemic lupus erythematosus (SLE), other connective tissue diseases, or other medical illness. A distinction is no longer made between primary and secondary fibromyalgia (concomitant with other disease), as the signs and symptoms are similar. Fibromyalgia and chronic fatigue syndrome have many similarities (Chap. 370). Both are associated with fatigue, abnormal sleep, musculoskeletal pain, impaired memory and concentration, and psychiatric conditions such as less severe forms of depression and anxiety. Patients with chronic fatigue syndrome, however, are more likely to have symptoms suggesting a viral illness. These include mild fever, sore throat, and pain in the axillary and anterior and posterior cervical lymph nodes. The onset of chronic fatigue syndrome is usually sudden; patients are usually able to date the onset. While many patients with chronic fatigue syndrome have tender or painful points, the diagnosis does not require their presence. Patients with fibromyalgia may be misdiagnosed with SLE or Sjögren's syndrome as these disorders have in common symptoms of musculoskeletal pain, dry eyes, cold hands, and fatigue. The antinuclear antibody (ANA) test may also be positive. The frequency of a positive ANA

TABLE 315-1 The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia[a]

1. History of widespread pain. Pain is considered widespread when all of the following are present:
   a. Pain in the left side of the body
   b. Pain in the right side of the body
   c. Pain above the waist
   d. Pain below the waist
   e. Axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back)
2. Pain on digital palpation in at least 11 of the following 18 tender point sites (see Fig. 315-1):
   a. Occiput: bilateral, at the suboccipital muscle insertion
   b. Low cervical: bilateral, at the anterior aspect of the intertransverse spaces at C5–7
   c. Trapezius: bilateral, at the midpoint of the upper border
   d. Supraspinatus: bilateral, at the origin, above the scapular spine near the medial border
   e. Second rib: bilateral, at the second costochondral junction, just lateral to the junction on the upper surface
   f. Lateral epicondyle: bilateral, 2 cm distal to the epicondyle
   g. Gluteal: bilateral, in the upper outer quadrant of the buttock
   h. Greater trochanter: bilateral, posterior to the trochanteric prominence
   i. Knee: bilateral, at the medial fat pad proximal to the joint line

Digital palpation should be performed with a moderate degree of pressure. For a tender point to be considered positive, the subject must state that the palpation was painful. "Tender" is not to be considered painful.

[a] For purposes of classification, patients will be said to have fibromyalgia if both criteria are satisfied. Widespread pain must have been present for at least 3 months. The presence of a second clinical disorder does not exclude the diagnosis of fibromyalgia.

Source: Modified from F Wolfe et al: Arthritis Rheum 33:171, 1990.

test in fibromyalgia patients, however, is the same as sex- and aged-matched normal controls. The predictive value of a positive ANA test in patients without characteristic symptoms and objective features of a connective tissue disease is quite low. Discretion is advised before ordering an ANA test. Patients with fibromyalgia may complain of muscle weakness, but on muscle strength testing, they have "give-away" weakness secondary to pain. Proximal muscle weakness and elevated muscle enzymes distinguish patients with polymyositis. Polymyalgia rheumatica is distinguished from fibromyalgia in an elderly patient by the presence of more proximal muscle stiffness and pain and an elevated erythrocyte sedimentation rate. Patients should be evaluated for hypothyroidism, which may have symptoms similar to fibromyalgia or may accompany fibromyalgia. Disturbed sleep, musculoskeletal pain, and fatigue occur in patients with sleep apnea and restless leg syndrome. A distinguishing feature of sleep apnea is the presence of significant daytime somnolence. These patients should be referred to a sleep laboratory for evaluation and treatment. Myofascial pain syndrome, which involves an area such as the shoulder or neck, may represent a localized form of fibromyalgia (see "Myofascial Pain Syndrome" below). Some patients with this syndrome progress to fibromyalgia.

The diagnosis of fibromyalgia has taken on a more complex significance in regard to labor and industry issues. This has become a significant issue since it has been reported that 10 to 25% of patients are not able to work in any capacity, while others require modification of their work. Disability evaluation in fibromyalgia is controversial. The diagnosis of fibromyalgia is not accepted by all. It is hard to evaluate patients' perceptions of their inability to function. The determination of tender points can also be subjective, on the part of both the physician and the patient, particularly when issues of compensation are pending. Patients also encounter difficulty in having their illness recognized as a disability. Physicians have been placed in the inappropriate role of assessing the patient's disability. Physicians are not in a position to quantitate disability at the workplace; that is better done by a work evaluation specialist. Better instruments are clearly needed for measuring disability, particularly in patients with fibromyalgia.

TREATMENT

Patients should be informed that they have a condition that is not crippling, deforming, or degenerative, and that treatment is available. The initial step in treatment is to improve the quality of sleep. The use of tricyclics such as amitriptyline (10 to 50 mg), nortriptyline (10 to 75 mg), and doxepin (10 to 25 mg) or a pharmacologically similar drug, cyclobenzaprine (10 to 40 mg), 1 to 2 h before bedtime will give the patient restorative sleep (stage 4 sleep), resulting in clinical improvement. Patients should be started on a low dose, which is increased gradually as needed. Side effects of these tricyclics and cyclobenzoprine limit their use; these include constipation, dry mouth, weight gain, drowsiness, and difficulty thinking. Trazodone or zolpidem also improves sleep quality. In patients with restless leg syndrome, clonazepam may be effective. Depression and anxiety should next be treated with appropriate drugs and, when indicated, with psychiatric counseling. Fluoxetine, sertraline, paroxetine, citalopram, or other newer selective serotonin reuptake inhibitors can be used as antidepressants. Other useful antidepressants are trazodone and venlafaxine. Alprazolam and lorazepam are effective for anxiety. Patients may also benefit by regular aerobic exercises, which are started after patients begin to have improved sleep and less pain and fatigue. Exercise should be of a low-impact type and begun at a low level. Eventually, the patient should be exercising 20 to 30 min 3 to 4 days a week. Regular stretching exercises are also very important. Salicylates or other nonsteroidal anti-inflammatory drugs (NSAIDs) only partially improve symptoms. Glucocorticoids have been of little benefit and should not be used in these patients. Opiate analgesics should be avoided. For pain, acetaminophen or tramadol may be useful. Also gabapentin (300 to 1200 mg/d in divided doses) may reduce pain. Local measures such as heat, massage, injection of tender sites with steroids or lidocaine, and acupuncture provide only temporary relief of symptoms. Other therapies that may help to varying degrees including biofeedback, behavioral modification, hypnotherapy, and stress management and relaxation response training. Life stresses should be identified and discussed with the patient, and the patient should be provided with help on how to cope with these stresses. Patients may benefit from a multidisciplinary team approach involving a mental health professional, a physical therapist, and a physical medicine and rehabilitation specialist. Group therapy may be beneficial. Patients should be well educated about their disorder and taught the importance of self help. There are patient support groups in many communities. While treatment of fibromyalgia is effective in some patients, others continue to have chronic disease, which is relieved only partially if at all.

ARTHRITIS ASSOCIATED WITH SYSTEMIC DISEASE

ARTHROPATHY OF ACROMEGALY Acromegaly is the result of excessive production of growth hormone by an adenoma in the anterior pituitary gland (Chap. 318). Middle-aged persons are most often affected. The excessive secretion of growth hormone along with insulin-like growth factor I stimulates proliferation of cartilage, periarticular connective tissue, and bone, resulting in several musculoskeletal abnormalities, including osteoarthritis, back pain, muscle weakness, and carpal tunnel syndrome.

An arthropathy resembling osteoarthritis is a common feature, affecting most often the knees, shoulders, hips, and hands. Single or multiple joints may be affected. The overgrowth of cartilage initially produces widening of the joint space. The newly synthesized cartilage is not developed in an organized manner, making it susceptible to fissuring, ulceration, and destruction. Ligamental laxity of the joint resulting from the growth of connective tissue also contributes to the development of osteoarthritis. With breakdown and loss of cartilage, the joint space narrows, and subchondral sclerosis and osteophytes appear on radiographs. Joint examination reveals marked crepitus and hypermobility. Joint fluid is noninflammatory. Calcium pyrophosphate dihydrate crystals are found in the cartilage in some cases of acromegaly arthropathy and, when shed into the joint, can produce attacks of pseudogout. Chondrocalcinosis may also be observed radiographically. Approximately half of the patients with acromegaly experience back pain, which is predominantly lumbosacral. Hypermobility of the spine may be a contributing factor in back pain. Radiograph of the spine shows normal or increased intervertebral disk spaces, hypertrophic anterior osteophytes, and ligamental calcification. These changes are similar to those observed in patients with diffuse idiopathic skeletal hyperostosis. Dorsal kyphosis in conjunction with elongation of the ribs contributes to the development of the barrel chest seen in acromegalic patients. The hands and feet become enlarged owing to soft tissue proliferation. The fingers are thickened and have spadelike distal tufts. One-third of patients have a thickened heel pad. Approximately 25% of patients have Raynaud's phenomenon.

Carpal tunnel syndrome occurs in about half of patients. The median nerve is compressed by the excessive growth of connective tissue in the carpal tunnel. The median nerve also becomes enlarged. Patients with acromegaly also develop proximal muscle weakness, which is thought to be caused by the effect of growth hormone on muscle. Results of muscle enzyme assays and electromyography are normal. Muscle biopsy specimens show muscle fibers of varying size and no inflammatory changes.

ARTHROPATHY OF HEMOCHROMATOSIS Hemochromatosis is a disorder of iron storage. Excessive amounts of iron are absorbed from the intestine, leading to iron deposition in parenchymal cells, which results in tissue damage and impairment of organ function (Chap. 336). Symptoms of hemochromatosis usually begin between the ages of 40 and 60 but can occur earlier. Arthritis, which occurs in 20 to 40% of patients, usually begins after the age of 50 and may be the first clinical

feature of hemochromatosis. The arthropathy is an osteoarthritis-like disorder affecting the small joints of the hands, followed later by larger joints such as knees, ankles, shoulders, and hips. The second and third metacarpophalangeal joints of both hands are often the first joints affected; they can provide an important clue to the possibility of hemochromatosis. Patients experience stiffness and pain. Morning stiffness usually lasts less than half an hour. The affected joints are enlarged and mildly tender. Synovial tissue is not appreciatively increased. Radiographs show irregular narrowing of the joint space, subchondral sclerosis, and subchondral cysts. There is juxtaarticular proliferation of bone, with frequent hooklike osteophytes. The synovial fluid is noninflammatory. The synovium shows mild to moderate proliferation of lining cells, fibrosis, and a low number of inflammatory cells, which are mononuclear. In approximately half of patients, there is evidence of calcium pyrophosphate deposition disease (CPDD), and patients may experience episodes of pseudogout. Iron can be demonstrated in the lining cells of the synovium and also in chondrocytes.

Iron may damage the articular cartilage in several ways. Iron catalyzes superoxide-dependent lipid peroxidation, which may play a role in joint damage. In animal models, ferric iron has been shown to interfere with collagen formation. Iron has also been shown to increase the release of lysosomal enzymes from cells in the synovial membrane. Iron may also play a role in the development of chondrocalcinosis. Iron inhibits synovial tissue pyrophosphatase in vitro and, therefore, may inhibit pyrophosphatase in vivo, resulting in chondrocalcinosis. Iron in synovial cells may also inhibit the clearance of calcium pyrophosphate from the joint.

TREATMENT

The treatment of hemochromatosis is repeated phlebotomy. Unfortunately, this treatment has little effect on the arthritis, which, along with chondrocalcinosis, usually continues to progress. Treatment of the arthritis consists of administration of acetaminophen and NSAIDs. Acute pseudogout attacks are treated with higher doses of an NSAID or a short cause of glucocorticoids. Placement of a hip or knee prosthesis has been successful in advanced disease.

HEMOPHILIC ARTHROPATHY Hemophilia is a sex-linked recessive genetic disorder characterized by the absence or deficiency of factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease) (Chap. 102). Hemophilia A is by far the more common type, constituting 85% of cases. Spontaneous hemarthrosis is a common problem with both types of hemophilia and can lead to a chronic deforming arthritis. The frequency and severity of hemarthrosis are related to the degree of clotting factor deficiency. Hemarthrosis is not common in other inherited disorders of coagulation, such as von Willebrand's disease or factor V deficiency.

Hemarthrosis becomes evident after 1 year of age, when the child begins to walk and run. In order of frequency, the joints most commonly affected are the knees, ankles, elbows, shoulders, and hips. Small joints of the hands and feet are occasionally involved.

In the initial stage of arthropathy, hemarthrosis produces a warm, tensely swollen, and painful joint. The patient holds the affected joint in flexion and guards against any movement. Blood in the joint remains liquid because of the absence of intrinsic clotting factors and the absence of tissue thromboplastin in the synovium. The blood in the joint space is resorbed over a period of a week or longer, depending on the size of the hemarthrosis. Joint function usually returns to normal or baseline in about 2 weeks.

Recurrent hemarthrosis leads to the development of a chronic arthritis. The involved joints remain swollen, and flexion deformities develop. In the later stages of arthropathy, joint motion is restricted and function is severely limited. Joint ankylosis, subluxation, and laxity are features of end-stage disease.

Bleeding into muscle and soft tissue also causes musculoskeletal disorders. When bleeding into the iliopsoas muscle occurs, the hip is held in flexion because of the pain, resulting in a hip flexion contracture. Rotation of the hip is preserved, which distinguishes this problem from intraarticular hemorrhage. Expansion of the hematoma may place pressure on the femoral nerve, resulting in a femoral neuropathy. Another problem is shortening of the heel cord secondary to bleeding into the gastrocnemius. Hemorrhage into a closed compartment space, such as the volar compartment in the forearm, can result in muscle necrosis, neuropathy and flexion deformities of the wrist and fingers. When bleeding involves periosteum or bone, a pseudotumor forms. These occur distal to the elbows or knees in children and improve with treatment of the hemophilia. Surgical removal is indicated if the pseudotumor continues to enlarge. In adults, they occur in the femur and pelvis and are usually refractory to treatment. When bleeding occurs in muscle, cysts may develop within the muscle. Needle aspiration of a cyst is contraindicated because it can induce bleeding.

Septic arthritis can occur in hemophilia and is difficult at times to distinguish from acute hemarthrosis on physical examination. Whenever there is suspicion of an infected joint, the joint should be aspirated immediately, the fluid cultured, and the patient started on antibiotics that provide broad coverage until the results of the culture are known. The patient should be infused with the deficient clotting factor before the joint is tapped to decrease the risk of further bleeding.

Radiographs of joints reflect the stage of disease. In early stages there is only capsule distention; later, juxtaarticular osteopenia, marginal erosions, and subchondral cysts develop. In late disease, the joint space is narrowed and there is bony overgrowth. The changes are similar to those observed in osteoarthritis. Unique features of hemophilic arthropathy are widening of the femoral intercondylar notch, enlargement of the proximal radius, and squaring of the distal end of the patella.

Recurrent hemarthrosis produces synovial hyperplasia and hypertrophy. A pannus covers the cartilage. Cartilage is damaged by collagenase and other degradative enzymes released by mononuclear cells in the overlying synovium. Hemosiderin is found in synovial lining cells, the subsynovium, and chondrocytes and may also play a role in cartilage destruction.

TREATMENT

The treatment of hemarthrosis is initiated with the immediate infusion of factor VIII or IX at the first sign of joint or muscle hemorrhage. The patient is placed at bed rest, with the involved joint in as much extension as the patient can tolerate. Analgesic doses of an NSAID and local icing may help with the pain. NSAIDs can be given safely for short periods even though they have a stabilizing effect on platelets. Studies have shown no significant abnormalities in platelet function or bleeding time in hemophiliacs receiving ibuprofen. The cyclooxygenase-2 inhibitors celecoxib, rofecoxib, and kaldecoxib do not interfere with platelet function and can be safely given for pain. Synovectomy, open or arthroscopic, may be indicated in patients with chronic synovial proliferation and recurrent hemarthrosis. Hypertrophied synovium is very vascular and subject to bleeding. Both types of synovectomy reduce the number of hemarthroses and slow the roentgenographic progression of hemophilic arthropathy. Open surgical synovectomy, however, is associated with some loss of range of motion. Radiosynovectomy with either yttrium 90 silicate or phosphorus 31 colloid has also been effective and may be a useful alternative when surgical synovectomy is not practical. Total joint replacement is indicated for severe joint destruction and incapacitating pain. Because of the young age of hemophilic patients, total-joint prostheses may need to be replaced more than once during their lives.

ARTHROPATHIES ASSOCIATED WITH HEMOGLOBINOPATHIES ■ Sickle Cell Disease

Sickle cell disease (Chap. 91) is associated with several musculoskeletal abnormalities (Table 315-2). Children under the age of 5 may develop diffuse swelling, tenderness, and warmth of the hands and feet lasting from 1 to 3 weeks. The condition, referred to as *sickle cell dactylitis* or *hand-foot syndrome*, has also been observed in sickle cell

TABLE 315-2 Musculoskeletal Abnormalities in Sickle Cell Disease

Sickle cell dactylitis	Avascular necrosis
Joint effusions in sickle cell crises	Bone changes secondary to marrow hyperplasia
Osteomyelitis	Septic arthritis
Infarction of bone	Gouty arthritis
Infarction of bone marrow	

disease and sickle cell thalassemia. Dactylitis is believed to result from infarction of the bone marrow and cortical bone leading to periostitis and soft tissue swelling. Radiographs show periosteal elevation, subperiosteal new bone formation, and areas of radiolucency and increased density involving the metacarpals, metatarsals, and proximal phalanges. These bone changes disappear after several months. The syndrome leaves little or no residual damage. Because hematopoiesis ceases in the small bones of hands and feet with age, the syndrome is rarely seen after age 4 or 5 and does not occur in adults.

Sickle cell crisis is often associated with periarticular pain and joint effusions. The joint and periarticular area are warm and tender. Knees and elbows are most often affected, but other joints can be involved. Joint effusions are noninflammatory, with white cell counts $<1000/\mu L$; mononuclear cells predominate. There have been a few reports of sterile inflammatory effusion with high cell counts consisting of mostly polymorphonuclear white cells. Synovial biopsies have shown mild lining cell proliferation and microvascular thrombosis. Scintigraphic studies have shown decreased marrow uptake adjacent to the involved joint. The joint effusion and periarticular pain are considered to be the result of ischemia and infarction of the synovium and adjacent bone and bone marrow. The treatment is that for sickle cell crisis (Chap. 91).

Patients with sickle cell disease may also develop osteomyelitis, which commonly involves the long tubular bones (Chap. 111). These patients are particularly susceptible to bacterial infections, especially *Salmonella* infections, which are found in more than half of cases. The most common isolate is *S. typhimurium* (Chap. 137). Radiographs of the involved site show periosteal elevation initially, followed by disruption of the cortex. Treatment of the infection results in healing of the bone lesion. Sickle cell disease is also associated with bone infarction resulting from thrombosis secondary to the sickling of red cells. Bone infarction also occurs in hemoglobin S-C disease and sickle cell thalassemia (Chap. 91). The bone pain in sickle cell crisis is due to bone and bone marrow infarction. In children, infarction of the epiphyseal growth plate interferes with normal growth of the affected extremity. Radiographically, infarction of the bone cortex results in periosteal elevation and irregular thickening of the bone cortex. Infarction in the bone marrow leads to lysis, fibrosis, and new bone formation.

Avascular necrosis of the head of the femur is seen in ~5% of patients. It also occurs in the humeral head and less commonly in the distal femur, tibial condyles, distal radius, vertebral bodies, and other juxtaarticular sites. The mechanism for avascular necrosis is most likely the same as for bone infarction. Subchondral hemorrhage may play a role in the deterioration of articular cartilage. Irregularity of the femoral head or of other bone surfaces affected by avascular necrosis eventually results in degenerative joint disease. Radiograph of the affected joint may show patchy radiolucency and density followed by flattening of the bone. Magnetic resonance imaging (MRI) is a sensitive technique for detecting early avascular necrosis as well as bone infarction elsewhere. Total hip replacement and placement of prostheses in other joints may improve function and relieve pain in those patients with severe joint destruction.

Septic arthritis is occasionally encountered in sickle cell disease (Chap. 314). Multiple joints may be infected. Joint infection may result from hematogenous spread or from spread of contiguous osteomyelitis. Microorganisms identified include *Staphylococcus aureus*, *Streptococcus*, *Escherichia coli*, and *Salmonella*. The latter is not seen as frequently in septic arthritis as it is in osteomyelitis. Acute gouty arthritis is uncommon in sickle cell disease, even though 40% of patients are hyperuremic. Hyperuricemia is due to overproduction of uric acid secondary to increased red cell turnover. Attacks may be polyarticular.

The bone marrow hyperplasia in sickle cell disease results in widening of the medullary cavities, thinning of the cortices, and coarse trabeculations and central cupping of the vertebral bodies. These changes are also seen to a lesser degree in hemoglobin S-C disease and sickle cell thalassemia. In normal individuals, red marrow is located mostly in the axial skeletal, but in sickle cell disease, red marrow is found in the bones of the extremities and even in the tarsal and carpal bones. Vertebral compression may lead to dorsal kyphosis, and softening of the bone in the acetabulum may result in protrusio acetabuli.

Thalassemia β-Thalassemia is a congenital disorder of hemoglobin synthesis characterized by impaired production of β chains (Chap. 91). Bone and joint abnormalities occur in β-thalassemia, being most common in the major and intermedia groups. In one study, ~50% of patients with β-thalassemia had evidence of symmetric ankle arthropathy, characterized by a dull aching pain aggravated by weight bearing. The onset was most often in the second or third decade of life. The degree of ankle pain in these patients varied. Some patients experienced self-limited ankle pain, which occurred only after strenuous physical activity and lasted several days to weeks. Other patients had chronic ankle pain, which became worse with walking. Symptoms eventually abated in a few patients. Compression of the ankle, calcaneus, or forefoot was painful in some patients. Synovial fluid from two patients was noninflammatory. Radiographs of ankle showed osteopenia, widened medullary spaces, thin cortices, and coarse trabeculations. These findings were largely the result of bone marrow expansion. The joint space was preserved. Specimens of bone from three patients revealed osteomalacia, osteopenia, and microfractures. Increased osteoblasts as well as increased foci of bone resorption were present on the bone surface. Iron staining was found in the bone trabeculae, in osteoid, and in the cement line. Synovium showed hyperplasia of lining cells, which contained deposits of hemosiderin. This arthropathy was considered to be related to the underlying bone pathology. The role of iron overload or abnormal bone metabolism in the pathogenesis of this arthropathy is not known. The arthropathy was treated with analgesics and splints. Patients were also transfused to decrease hematopoiesis and bone marrow expansion.

Patients with β-thalassemia major and intermedia also have involvement of other joints, including the knees, hips, and shoulders. Acquired hemochromatosis with arthropathy has been described in a patient with thalassemia. Gouty arthritis and septic arthritis can occur. Avascular necrosis is not a feature of thalassemia because there is no sickling of red cells leading to thrombosis and infarction.

β-Thalassemia minor (trait) is also associated with joint manifestations. Chronic seronegative oligoarthritis affecting predominantly ankles, wrists, and elbows has been described. These patients had mild persistent synovitis without large effusions. Joint erosions were not seen. Recurrent episodes of an acute asymmetric arthritis have also been reported; episodes last less than a week and may affect knees, ankles, shoulders, elbows, wrists, and metacarpal phalangeal joints. The mechanism for this arthropathy is unknown. Treatment with nonsteroidal drugs was not particularly effective.

MUSCULOSKELETAL DISORDERS ASSOCIATED WITH HYPERLIPIDEMIA (See also Chap. 335) Musculoskeletal manifestations may be the first indication of a hereditary disorder of lipoprotein metabolism. Patients with familial hypercholesterolemia (previously referred to as type II hyperlipoproteinemia) may have recurrent migratory polyarthritis involving knees and other large peripheral joints and, to a lesser degree, peripheral small joints. In a few patients, the arthritis is monarticular. Fever may accompany the arthritis. Pain ranges from moderate to very severe to incapacitating. The involved joints can be warm, erythematous, swollen, and tender. Arthritis usually has a sudden onset, lasts from a few days to 2 weeks, and does not cause joint damage. Episodes may

suggest acute gout attacks. Several attacks occur a year. Synovial fluid from involved joints is not inflammatory and contains few white cells and no crystals. Joint involvement may actually represent inflammatory periarthritis or peritendinitis and not intraarticular disease. The recurrent, transient nature of the arthritis may suggest rheumatic fever, especially since patients with hyperlipoproteinemia have an elevated erythrocyte sedimentation rate and a falsely elevated antistreptolysin O titer. Patients may also experience Achilles tendinitis, which can be very painful. Attacks of tendinitis come on gradually and last only a few days. Fever is not present. Patients may be asymptomatic between attacks. During an attack the Achilles tendon is warm, erythematous, swollen, and tender to palpation. Achilles tendinitis and other joint manifestations often precede the appearance of xanthomas and may be the first clinical indication of hyperlipoproteinemia. Attacks of tendinitis may occur following treatment with a lipid-lowering drug. Patients also have tendinous xanthomas in the Achilles, patellar, and extensor tendons of the hands over the knuckles and feet. Xanthomas have also been reported in the peroneal tendon, the plantar aponeurosis, and the periosteum overlying the distal tibia. These xanthomas are located within tendon fibers. Tuberous xanthomas are soft subcutaneous masses located over the extensor surfaces of the elbows, knees, and hands, as well as on the buttocks. They appear in childhood in homozygous patients and after the age of 30 in heterozygous patients. Patients with elevated plasma levels of very low density lipoprotein (VLDL) and triglyceride (previously referred to as type IV hyperlipoproteinemia) may also have a mild inflammatory arthritis affecting large and small peripheral joints, usually in an asymmetric pattern with only a few joints involved at a time. The onset of arthritis is usually in middle age. Arthritis may be persistent or recurrent, with episodes lasting a few days to weeks. Joint pain is severe in some patients. Patients may experience morning stiffness. Joint tenderness and periarticular hyperesthesia may also be present, as may synovial thickening. Joint fluid is usually noninflammatory and without crystals but may have increased white blood cell counts with predominantly mononuclear cells. The fluid is occasionally lactescent. Radiographs may show juxtaarticular osteopenia and cystic lesions. Large bone cysts have been noted in a few patients. Xanthoma and bone cysts are also observed in other lipoprotein disorders. The pathogenesis of arthritis in patients with familial hypercholesterolemia or with elevated levels of VLDL and triglyceride is not well understood. Salicylates, other NSAIDs, or analgesics usually provide relief of symptoms. Clinical improvement may also occur in patients treated with lipid-lowering agents; however, patients treated with a HMG CoA reductase agent may experience myalgias, and a few patients may develop polymyositis or even rhabdomyolysis. Myositis has also been reported with the use of niacin (Chap. 370).

OTHER ARTHRITIDES

NEUROPATHIC JOINT DISEASE Neuropathic joint disease (Charcot's joint) is a progressive destructive arthritis associated with loss of pain sensation, proprioception, or both. In addition, normal muscular reflexes that modulate joint movement are decreased. Without these protective mechanisms, joints are subjected to repeated trauma, resulting in progressive cartilage and bone damage. Neuropathic arthropathy was first described by Jean-Martin Charcot in 1868 in patients with tabes dorsalis. The term *Charcot joint* is commonly used interchangeably with *neuropathic joint*. Today, diabetes mellitus is the most frequent cause of neuropathic joint disease. A variety of other disorders are associated with neuropathic arthritis including leprosy, yaws, syringomyelia, meningomyelocoele, congenital indifference to pain, peroneal muscular atrophy (Charcot-Marie-Tooth disease), and amyloidosis. An arthritis resembling neuropathic joint disease is seen in patients who have received frequent intraarticular glucocorticoid injections into a weight-bearing joint and in patients with CPDD. The distribution of joint involvement depends on the underlying neurologic disorder (Table 315-3). In tabes dorsalis, knees, hips, and ankles are most commonly affected; in syringomyelia, the glenohumeral joint, elbow, and wrist; and in diabetes mellitus, the tarsal and tarsometatarsal joints.

TABLE 315-3 Disorders Associated with Neuropathic Joint Disease

Diabetes mellitus	Amyloidosis
Tabes dorsalis	Leprosy
Meningomyelocele	Congenital indifference to pain
Syringomyelia	Peroneal muscular atrophy

Pathology and Pathophysiology The pathologic changes in the neuropathic joint are similar to those found in the severe osteoarthritic joint. There is fragmentation and eventual loss of articular cartilage with eburnation of the underlying bone. Osteophytes are found at the joint margins. With more advanced disease, erosions are present on the joint surface. Fractures, devitalized bone, and intraarticular loose bodies may be present. Microscopic fragments of cartilage and bone are seen in the synovial tissue.

At least two underlying mechanisms are believed to be involved in the pathogenesis of neuropathic arthritis. An abnormal autonomic nervous system is thought to be responsible for the increased blood flow to the joint and subsequent resorption of bone. Loss of bone, particularly in the diabetic foot, may be the initial manifestation. With the loss of deep pain, proprioception, and protective neuromuscular reflexes, the joint is subjected to repeated injuries including ligamental tears and bone fractures. The mechanism of injury that occurs following frequent intraarticular glucocorticoid injections is thought to be due to the analgesic effect of glucocorticoids leading to overuse of an already damaged joint, which results in accelerated cartilage damage. It is not understood why only a few patients with neuropathies develop neuropathic arthritis.

Clinical Manifestations Neuropathic joint disease usually begins in a single joint and then progresses to involve other joints, depending on the underlying neurologic disorder. The involved joint progressively becomes enlarged from bony overgrowth and synovial effusion. Loose bodies may be palpated in the joint cavity. Joint instability, subluxation, and crepitus occur as the disease progresses. Neuropathic joints may develop rapidly, and a totally disorganized joint with multiple bony fragments may evolve in a patient within weeks or months. The amount of pain experienced by the patient is less than would be anticipated based on the degree of joint involvement. Patients may experience sudden joint pain from intraarticular fractures of osteophytes or condyles.

Neuropathic arthritis is encountered most often in patients with diabetes mellitus, with the incidence estimated in the range of 0.5%. The usual age of onset is $\geq$50 years following several years of diabetes, but exceptions occur. The tarsal and tarsometatarsal joints are most often affected, followed by the metatarsophalangeal and talotibial joints. The knees and spine are occasionally involved. In about 20%, neuropathic arthritis may be present in both feet. Patients often attribute the onset of foot pain to antecedent trauma such as twisting their foot. Neuropathic changes may develop rapidly following a foot fracture or dislocation. Swelling of the foot and ankle are often present. Downward collapse of the tarsal bones leads to convexity of the sole, referred to as a "rocker foot." Large osteophytes may protrude from the top of the foot. Calluses frequently form over the metatarsal heads and may lead to infected ulcers and osteomyelitis. Radiographs may show resorption and tapering of the distal metatarsal bones. The term *Lisfranc fracture-dislocation* is sometimes used to describe the destructive changes at the tarsometatarsal joints.

Diagnosis The diagnosis of neuropathic arthritis is based on the clinical features and characteristic radiographic findings in a patient with an underlying sensory neuropathy. The differential diagnosis of neuropathic arthritis includes osteomyelitis, osteonecrosis, advanced osteoarthritis, stress fractures, and CPDD. Radiographs in neuropathic arthritis initially show changes of osteoarthritis with joint space narrowing, subchondral bone sclerosis, osteophytes, and joint effusions

followed later by marked destructive and hypertrophic changes. Soft tissue swelling, bone resorption, fractures, large osteophytes, extraarticular bone fragments, and subluxation are present with advanced arthropathy. The radiographic findings of neuropathic arthritis may be difficult to differentiate from those of osteomyelitis, especially in the diabetic foot. The joint margins in a neuropathic joint tend to be distinct, while in osteomyelitis, they are blurred. Imaging studies and cultures of fluid and tissue from the joint are often required to exclude osteomyelitis. MRI is helpful in differentiating these disorders. Another useful study is a bone scan using indium 111–labeled white blood cells or indium 111–labeled immunoglobulin G, which will show an increased uptake in osteomyelitis but not in a neuropathic joint. A technetium bone scan will not distinguish osteomyelitis from neuropathic arthritis as increased uptake is observed in both. The joint fluid in neuropathic arthritis is noninflammatory; may be xanthochromic or even bloody; and may contain fragments of synovium, cartilage, and bone. The finding of calcium pyrophosphate dihydrate crystals suggests the diagnosis of a crystal-associated neuropathic-like arthropathy. In the absence of such crystals, the presence of increased number of leukocytes may indicate osteomyelitis.

TREATMENT

The primary focus of treatment is to provide stabilization of the joint. Treatment of the underlying disorder, even if successful, does not usually alter the joint disease. Braces and splints are helpful. Their use requires close surveillance, since patients may be unable to appreciate pressure from a poorly adjusted brace. In the diabetic patient, early recognition and treatment of a Charcot's foot by prohibiting weight bearing of the foot for at least 8 weeks may possibly prevent severe disease from developing. Fusion of a very unstable joint may improve function, but nonunion is frequent, especially when immobilization of the joint is inadequate.

HYPERTROPHIC OSTEOARTHROPATHY AND CLUBBING Hypertrophic osteoarthropathy (HOA) is characterized by clubbing of digits and, in more advanced stages, by periosteal new bone formation and synovial effusions. HOA occurs in primary or familial form and usually begins in childhood. The secondary form of HOA is associated with intrathoracic malignancies, suppurative lung disease, congenital heart disease, and a variety of other disorders and is more common in adults. Clubbing is almost always a feature of HOA but can occur as an isolated manifestation (Fig. 315-2). The presence of clubbing in isolation is generally considered to represent either an early stage or an element in the spectrum of HOA. The presence of only clubbing in a patient usually has the same clinical significance as HOA.

Pathology and Pathophysiology In HOA, the bone changes in the distal extremities begin as periostitis followed by new bone formation. At this stage, a radiolucent area may be observed between the new periosteal bone and subjacent cortex. As the process progresses, multiple layers of new bone are deposited, which become contiguous with the cortex and result in cortical thickening. The outer portion of bone is laminated in appearance, with an irregular surface. Initially, the process of periosteal new bone formation involves the proximal and distal diaphyses of the tibia, fibula, radius, and ulna and, less frequently, the femur, humerus, metacarpals, metatarsals, and phalanges. Occasionally, scapulae, clavicles, ribs, and pelvic bones are also affected. In long-standing disease, these changes extend to involve metaphyses and musculotendinous insertions. The adjacent interosseous membranes may become ossified. The distribution of the bone manifestations is usually bilateral and symmetric. The soft tissue overlying the distal third of the arms and legs may be thickened. Mononuclear cell infiltration may be present in the adjacent soft tissue. Proliferation of connective tissue occurs in the nail bed and volar pad of digits, giving the distal phalanges a clubbed appearance. Small blood vessels in the clubbed digits are dilated and have thickened walls. In addition, the number of arteriovenous anastomoses is increased. The synovia of involved joints show edema, varying degrees of synovial cell proliferation, thickening of the subsynovium, vascular congestion, vascular obliteration with thrombi, and small numbers of lymphocyte infiltrates.

FIGURE 315-2 Clubbing of fingers. *(Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, Copyright 1991, 1995. Used by permission of the American College of Rheumatology.)*

Several theories have been suggested for the pathogenesis of HOA. Most have either been disproved or have not explained the development in all clinical disorders associated with HOA. Previously proposed neurogenic and humoral theories are no longer considered likely explanations for HOA. The neurogenic theory was based on the observation that vagotomy resulted in symptomatic improvement in a small number of patients with lung tumors and HOA. It was postulated that vagal stimuli from the tumor site led via a neural reflex to efferent nerve impulses to the distal extremities, resulting in HOA. This theory, however, did not explain HOA in conditions where vagal stimulation did not occur, as in cyanotic congenital heart disease or arterial aneurysms. The humoral theory postulated that soluble substances that are normally inactivated or removed during passage through the lung reached the systemic circulation in an active form and stimulated the changes of HOA. Substances proposed included prostaglandins, ferritin, bradykinin, estrogen, and growth hormone. These substances seemed unlikely candidates, since their blood levels in HOA patients overlapped those in individuals without HOA. Furthermore, these substances did not explain the development of localized HOA associated with arterial aneurysms or infected arterial grafts.

Recent studies have suggested a role for platelets in the development of HOA. It has been observed that megakaryocytes and large platelet particles, present in venous circulation, were fragmented in their passage through normal lung. In patients with cyanotic congenital heart disease and in other disorders associated with right-to-left shunts, these large platelet particles bypass the lung and reach the distal extremities, where they can interact with endothelial cells. Platelet clumps have been demonstrated to form on an infected heart valve in bacterial endocarditis, in the wall of arterial aneurysms, and on infected arterial grafts. These platelet particles may also reach the distal extremities and interact with endothelial cells. Platelet-endothelial activation in the distal portion of extremities would then result in the release of platelet-derived growth factor (PDGF) and other factors leading to the proliferation of connective tissue and periosteum. Stimulation of fibroblasts by PDGF and transforming growth factor β results in cell growth and collagen synthesis. Elevated plasma levels of von Willebrand factor antigen have been found in patients with both primary and secondary forms of HOA, indicating endothelial activation or damage. Abnormalities of collagen synthesis have been demonstrated in the involved skin of patients with primary HOA. Fibroblasts from affected skin were shown to have increased collagen synthesis, increased α1(I) procollagen mRNA, and evidence for upregulation of collagen transcription. Other factors are undoubtedly involved in the pathogenesis of HOA, and further studies are needed to better understand this disorder.

Clinical Manifestations Primary or familial HOA, also referred to as *pachydermoperiostitis* or *Touraine-Solente-Golé syndrome*, usually begins insidiously at puberty. In a smaller number of patients, the onset is in the first year of life. The disorder is inherited as an autosomal dominant trait with variable expression and is nine times more common in boys than in girls. Approximately one-third of patients have a family history of primary HOA.

Primary HOA is characterized by clubbing, periostitis, and unusual skin features. A small number of patients with this syndrome do not express clubbing. The skin changes and periostitis are prominent features of this syndrome. The skin becomes thickened and coarse. Deep nasolabial folds develop, and the forehead may become furrowed. Patients may have heavy-appearing eyelids and ptosis. The skin is often greasy, and there may be excessive sweating of the hands and feet. Patients may also experience acne vulgaris, seborrhea, and folliculitis. In a few patients, the skin over the scalp becomes very thick and corrugated, a feature that has been descriptively termed *cutis verticis gyrata*. The distal extremities, particularly the legs, become thickened owing to proliferation of new bone and soft tissue; when the process is extensive, the distal lower extremities resemble those of an elephant. The periostitis is usually not painful, as it may be in secondary HOA. Clubbing of the fingers may be extensive, producing large, bulbous deformities and clumsiness. Clubbing also affects the toes. Patients may experience articular and periarticular pain, especially in the ankles and knees, and joint motion may be mildly restricted owing to periarticular bone overgrowth. Noninflammatory effusions occur in the wrists, knees, and ankles. Synovial hypertrophy is not found. Associated abnormalities observed in patients with primary HOA include hypertrophic gastropathy, bone marrow failure, female escutcheon, gynecomastia, and cranial suture defects. In patients with primary HOA, the symptoms disappear when adulthood is reached.

HOA secondary to an underlying disease occurs more frequently than primary HOA. It accompanies a variety of disorders and may precede clinical features of the associated disorder by months. Clubbing is more frequent than the full syndrome of HOA in patients with associated illnesses. Because clubbing evolves over months and is usually asymptomatic, it is often recognized first by the physician and not the patient. Patients may experience a burning sensation in their fingertips. Clubbing is characterized by widening of the fingertips, enlargement of the distal volar pad, convexity of the nail contour, and the loss of the normal 15° angle between the proximal nail and cuticle. The thickness of the digit at the base of the nail is greater than the thickness at the distal interphalangeal joint. An objective measurement of finger clubbing can be made by determining the diameter at the base of the nail and at the distal interphalangeal joint of all 10 digits. Clubbing is present when the sum of the individual digit ratios is >10. At the bedside, clubbing can be appreciated by having the patient place the dorsal surface of the distal phalanges of the fourth fingers together with the nails of the fourth fingers opposing each other. Normally, an open area is visible between the bases of the opposing fingernails; when clubbing is present, this open space is no longer visible. The base of the nail feels spongy when compressed, and the nail can be easily rocked on its bed. Marked periungual erythema is usually present. When clubbing is advanced, the finger may have a drumstick appearance, and the distal interphalangeal joint can be hyperextended. Periosteal involvement in the distal extremities may produce a burning or deep-seated aching pain. The pain can be quite incapacitating and is aggravated by dependency and relieved by elevation of the affected limbs. The overlying soft tissue may be swollen, and the skin slightly erythematous. Pressure applied over the distal forearms and legs may be quite painful.

Patients may also experience joint pain, most often in the ankles, wrists, and knees. Joint effusions may be present; usually they are small and noninflammatory. The small joints of the hands are rarely affected. Severe joint or bone pain may be the presenting symptom of an underlying lung malignancy and may precede the appearance of clubbing. In addition, the progression of HOA tends to be more rapid when associated with malignancies, most notably bronchogenic carcinoma. Unlike primary HOA, excessive sweating and oiliness of the skin and thickening of the facial skin are uncommon in secondary HOA.

TABLE 315-4 Disorders Associated with Hypertrophic Osteoarthropathy

Pulmonary	Cardiovascular
Bronchogenic carcinoma and other neoplasms	Cyanotic congenital heart disease
Lung abscesses, empyema, bronchiectasis	Subacute bacterial endocarditis
Chronic interstitial pneumonitis	Infected arterial grafts[a]
Cystic fibrosis	Aortic aneurysm[b]
Chronic obstructive lung disease	Aneurysm of major extremity artery[a]
Sarcoidosis	Patent ductus arteriosus[b]
Gastrointestinal	Arteriovenous fistula of major extremity vessel[a]
Inflammatory bowel disease	Thyroid (thyroid acropachy)
Sprue	Hyperthyroidism (Graves' disease)
Neoplasms: esophagus, liver, bowel	

[a] Unilateral involvement.
[b] Bilateral lower extremity involvement.

HOA occurs in 5 to 10% of patients with intrathoracic malignancies, the most common being bronchogenic carcinoma and pleural tumors (Table 315-4). Lung metastases infrequently cause HOA. HOA is also seen in patients with intrathoracic infections, including lung abscesses, empyema, bronchiectasis, chronic obstructive lung disease, and, uncommonly, pulmonary tuberculosis. HOA may also accompany chronic interstitial pneumonitis, sarcoidosis, and cystic fibrosis. In the latter, clubbing is more common than the full syndrome of HOA. Other causes of clubbing include congenital heart disease with right-to-left shunts, bacterial endocarditis, Crohn's disease, ulcerative colitis, sprue, and neoplasms of the esophagus, liver, and small and large bowel. In patients with congenital heart disease with right-to-left shunts, clubbing alone occurs more often than the full syndrome of HOA.

Unilateral clubbing has been found in association with aneurysms of major extremity arteries, infected arterial grafts, and with arteriovenous fistulas of brachial vessels. Clubbing of the toes but not fingers has been associated with an infected abdominal aortic aneurysm and patent ductus arteriosus. Clubbing of a single digit may follow trauma and has been reported in tophaceous gout and sarcoidosis. While clubbing occurs more commonly than the full syndrome in most diseases, periostitis in the absence of clubbing has been observed in the affected limb of patients with infected arterial grafts.

Hyperthyroidism (Graves' disease), treated or untreated, is occasionally associated with clubbing and periostitis of the bones of the hands and feet. This condition is referred to as *thyroid acropachy*. Periostitis is asymptomatic and occurs in the midshaft and diaphyseal portion of the metacarpal and phalangeal bones. The long bones of the extremities are seldom affected. Elevated levels of long-acting thyroid stimulator are found in the serum of these patients.

Laboratory Findings The laboratory abnormalities reflect the underlying disorder. The synovial fluid of involved joints has <500 white cells per microliter, and the cells are predominantly mononuclear. Radiographs show a faint radiolucent line beneath the new periosteal bone along the shaft of long bones at their distal end. These changes are observed most frequently at the ankles, wrists, and knees. The ends of the distal phalanges may show osseous resorption. Radionuclide studies show pericortical linear uptake along the cortical margins of long bones that may be present before any radiographic changes.

TREATMENT

The treatment of HOA is to identify the associated disorder and treat it appropriately. The symptoms and signs of HOA may disappear completely with removal or effective chemotherapy of a tumor or with antibiotic therapy and drainage of a chronic pulmonary infection. Va-

gotomy or percutaneous block of the vagus nerve leads to symptomatic relief in some patients. Aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), or analgesics may help control symptoms of HOA.

REFLEX SYMPATHETIC DYSTROPHY SYNDROME The reflex sympathetic dystrophy syndrome is now referred to as *complex regional pain syndrome, type 1*, by the new Classification of the International Association for the Study of Pain. It is characterized by pain and swelling, usually of a distal extremity, accompanied by vasomotor instability, trophic skin changes, and the rapid development of bony demineralization. →***Reflex sympathetic dystrophy syndrome, including its treatment, is covered in greater detail in Chap. 355.***

TIETZE'S SYNDROME AND COSTOCHONDRITIS Tietze's syndrome is manifested by painful swelling of one or more costochondral articulations. The age of onset is usually before 40, and both sexes are affected equally. In most patients only one joint is involved, usually the second or third costochondral joint. The onset of anterior chest pain may be sudden or gradual. The pain may radiate to the arms or shoulders and is aggravated by sneezing, coughing, deep inspirations, or twisting motions of the chest. The term *costochondritis* is often used interchangeably with *Tietze's syndrome*, but some workers restrict the former term to pain of the costochondral articulations without swelling. Costochondritis is observed in patients over age 40; tends to affect the third, fourth, and fifth costochondral joints; and occurs more often in women. Both syndromes may mimic cardiac or upper abdominal causes of pain. Rheumatoid arthritis, ankylosing spondylitis, and Reiter's syndrome may involve costochondral joints but are distinguished easily by their other clinical features. Other skeletal causes of anterior chest wall pain are xiphoidalgia and the slipping rib syndrome, which usually involves the tenth rib. Malignancies such as breast cancer, prostate cancer, plasma cell cytoma, and sarcoma can invade the ribs, thoracic spine, or chest wall and produce symptoms suggesting Tietze's syndrome. They should be easily distinguishable by radiographs and biopsy. Analgesics, anti-inflammatory drugs, and local glucocorticoid injections usually relieve symptoms.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is characterized by localized musculoskeletal pain and tenderness in association with trigger points. The pain is deep and aching and may be accompanied by a burning sensation. Myofascial pain may follow trauma, overuse, or prolonged static contraction of a muscle or muscle group, which may occur when reading or writing at a desk or working at a computer. In addition, this syndrome may be associated with underlying osteoarthritis of the neck or low back. Trigger points are a diagnostic feature of this syndrome. Pain is referred from trigger points to defined areas distant from the original tender points. Palpation of the trigger point reproduces or accentuates the pain. The trigger points are usually located in the center of a muscle belly, but they can occur at other sites, such as costosternal junctions, the xyphoid process, ligamentous and tendinous insertions, fascia, and fatty areas. Trigger point sites in muscle have been described as feeling indurated and taut, and palpation may cause the muscle to twitch. These findings, however, have been shown not to be unique for myofascial pain syndrome, since in a controlled study they were also present in fibromyalgia patients and normal subjects. Myofascial pain most often involves the posterior neck, low back, shoulders, and chest. Chronic pain in the muscles of the posterior neck may involve referral of pain from the trigger point in the erector neck muscle or upper trapezius to the head, leading to persistent headaches, which may last for days. Trigger points in the paraspinal muscles of the low back may refer pain to the buttock. Pain may be referred down the leg from a trigger point in the gluteus medius and can mimic sciatica. A trigger point in the infraspinatus muscle may produce local and referred pain over the lateral deltoid and down the outside of the arm into the hand. Injection of a local anesthetic such as 1% lidocaine into the trigger point site often results in pain relief. Another useful technique is first to spray from the trigger point toward the area of referred pain with an agent such as ethyl chloride and then to stretch the muscle. This maneuver may need to be repeated several times. Massage and application of ultrasound to the affected area may also be beneficial. Patients should be instructed in methods to prevent muscle stresses related to work and recreation. Posture and resting positions are important in preventing muscle tension. The prognosis in most patients is good. In some patients, myofascial pain syndrome may evolve into fibromyalgia. Patients at risk for developing fibromyalgia are thought to be those with anxiety, depression, nonrestorative sleep, and fatigue.

TUMORS OF JOINTS Primary tumors and tumor-like disorders of synovium are uncommon but should be considered in the differential diagnosis of monarticular joint disease. In addition, metastases to bone and primary bone tumors adjacent to a joint may produce joint symptoms. →***For further discussion, see Chap. 84.***

Pigmented villonodular synovitis is characterized by the slowly progressive, exuberant, benign proliferation of synovial tissue, usually involving a single joint. The most common age of onset is in the third decade, and women are affected slightly more often than men. The cause of this disorder is unknown.

The synovium has a brownish color and numerous large, finger-like villi that fuse to form pedunculated nodules. There is marked hyperplasia of synovial cells in the stroma of the villi. Hemosiderin granules and lipids are found in the cytoplasm of macrophages and in the interstitial tissue. Multinucleated giant cells may be present. The proliferative synovium grows into the subsynovial tissue and invades adjacent cartilage and bone.

The clinical picture of pigmented villonodular synovitis is characterized by the insidious onset of swelling and pain in one joint, most commonly the knee. Other joints affected include the hips, ankles, calcaneocuboid joints, elbows, and small joints of the fingers or toes. The disease may also involve the common flexor sheath of the hands or fingers. Less commonly, tendon sheaths in the wrist, ankle, or foot may be involved. Symptoms may be mild and intermittent and may be present for years before the patient seeks medical attention. Radiographs may show joint space narrowing, erosions, and subchondral cysts. The joint fluid contains blood and is dark red or almost black in color. Lipid-containing macrophages may be present in the fluid. The joint fluid may be clear if hemorrhages have not occurred.

The treatment of pigmented villonodular synovitis is complete synovectomy. With incomplete synovectomy, the villonodular synovitis recurs, and the rate of tissue growth may be faster than originally. Irradiation of the involved joint has been successful in some patients.

Synovial chondromatosis is a disorder characterized by multiple focal metaplastic growths of normal-appearing cartilage in the synovium or tendon sheath. Segments of cartilage break loose and continue to grow as loose bodies. When calcification and ossification of loose bodies occur, the disorder is referred to as *synovial osteochondromatosis*. The disorder is usually monarticular and affects young to middle-aged individuals. The knee is most often involved, followed by hip, elbow, and shoulder. Symptoms are pain, swelling, and decreased motion of the joint. Radiographs may show several rounded calcifications within the joint cavity. Treatment is synovectomy; however, the tumor may recur.

Hemangiomas occur in synovium and in tendon sheaths. The knee is affected most commonly. Recurrent episodes of joint swelling and pain usually begin in childhood. The joint fluid is bloody. Treatment is excision of the lesion. *Lipomas* occur most often in the knee, originating in the subsynovial fat on either side of the patellar tendon. Lipomas also appear in tendon sheaths of the hands, wrists, feet, and ankles. In some instances, surgical removal is necessary.

Synovial sarcoma is a malignant neoplasm often found near a large joint of both upper and lower extremities, being more common in the lower extremity. It seldom arises within the joint itself. Synovial sarcomas comprise 10% of soft tissue sarcomas. The tumor is believed to arise from primitive mesenchymal tissue that differentiates into epithe-

lial cells and/or spindle cells. Small foci of calcification may be present in the tumor mass. It occurs most often in young adults and is more common in men. The tumor presents as a slowly growing deep seated mass near a joint, without much pain. The area of the knee is the most common site, followed by the foot, ankle, elbow, and shoulder. Other primary sites include the buttocks, abdominal wall, retroperitoneum, and mediastinum. The tumor spreads along tissue planes. The most common site of visceral metastasis is lung. The diagnosis is made by biopsy. Treatment is wide resection of the tumor including adjacent muscle and regional lymph nodes, followed by chemotherapy and radiation therapy. Currently used chemotherapeutic agents are doxorubicin, ifosfamide, and cisplatin. Amputation of the involved distal extremity may be required. Chemotherapy may be beneficial in some patients with metastatic disease. Isolated pulmonary metastasis can be surgically removed. The 5-year survival with treatment is variable depending on the staging of the tumor ranging from approximately 25 to 60% or higher. Synovial sarcomas tend to recur locally and eventually metastasize to regional lymph nodes, lungs, and skeleton.

316 PERIARTICULAR DISORDERS OF THE EXTREMITIES

Bruce C. Gilliland

A number of periarticular disorders have become increasingly common over the past two to three decades, due in part to greater participation in recreational sports by individuals of a wide range of ages. This chapter discusses some of the more common periarticular disorders of the extremities.

BURSITIS Bursitis is inflammation of a bursa, which is a thin-walled sac lined with synovial tissue. The function of the bursa is to facilitate movement of tendons and muscles over bony prominences. Excessive frictional forces from overuse, trauma, systemic disease (e.g., rheumatoid arthritis, gout), or infection may cause bursitis. *Subacromial bursitis* (subdeltoid bursitis) is the most common form of bursitis. The subacromial bursa, which is contiguous with the subdeltoid bursa, is located between the undersurface of the acromion and the humeral head, and is covered by the deltoid muscle. Bursitis is caused by repetitive overhead motion and often accompanies rotator cuff tendinitis. Another frequently encountered form is *trochanteric bursitis*, which involves the bursa around the insertion of the gluteus medius onto the greater trochanter of the femur. Patients experience pain over the lateral aspect of the hip and upper thigh and have tenderness over the posterior aspect of the greater trochanter. External rotation and resisted abduction of the hip elicit pain. *Olecranon bursitis* occurs over the posterior elbow, and when the area is acutely inflamed, infection or gout should be excluded by aspirating the bursa and performing a Gram stain and culture on the fluid as well as examining the fluid for urate crystals. *Achilles bursitis* involves the bursa located above the insertion of the tendon to the calcaneus and results from overuse and wearing tight shoes. *Retrocalcaneal bursitis* involves the bursa that is located between the calcaneus and posterior surface of the Achilles tendon. The pain is experienced at the back of the heel, and swelling appears on the medial and/or lateral side of the tendon. It occurs in association with spondyloarthropathies, rheumatoid arthritis, gout, or trauma. *Ischial bursitis* (weaver's bottom) affects the bursa separating the gluteus medius from the ischial tuberosity and develops from prolonged sitting and pivoting on hard surfaces. *Iliopsoas bursitis* affects the bursa that lies between the iliopsoas muscle and hip joint and is lateral to the femoral vessels. Pain is experienced over this area and is made worse by hip extension and flexion. *Anserine bursitis* is an inflammation of the sartorius bursa located over the medial side of the tibia just below the knee and under the conjoint tendon and is manifested by pain on climbing stairs. Tenderness is present over the insertion of the conjoint tendon of the sartorius, gracilis, and semitendinosus. *Prepatellar bursitis* (housemaid's knee) occurs in the bursa situated between the patella and overlying skin and is caused by kneeling on hard surfaces. Gout or infection may also occur at this site. Treatment of bursitis consists of prevention of the aggravating situation, rest of the involved part, administration of a nonsteroidal anti-inflammatory drug (NSAID), or local glucocorticoid injection.

ROTATOR CUFF TENDINITIS AND IMPINGEMENT SYNDROME Tendinitis of the rotator cuff is the major cause of a painful shoulder and is currently thought to be caused by inflammation of the tendon(s). The rotator cuff consists of the tendons of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles, and inserts on the humeral tuberosities. Of the tendons forming the rotator cuff, the supraspinatus tendon is the most often affected, probably because of its repeated impingement (impingement syndrome) between the humeral head and the undersurface of the anterior third of the acromion and coracoacromial ligament above as well as the reduction in its blood supply that occurs with abduction of the arm (Fig. 316-1). The tendon of the infraspinatus and that of the long head of the biceps are less commonly involved. The process begins with edema and hemorrhage of the rotator cuff, which evolves to fibrotic thickening and eventually to rotator cuff degeneration with tendon tears and bone spurs. Subacromial bursitis also accompanies this syndrome. Symptoms usually appear

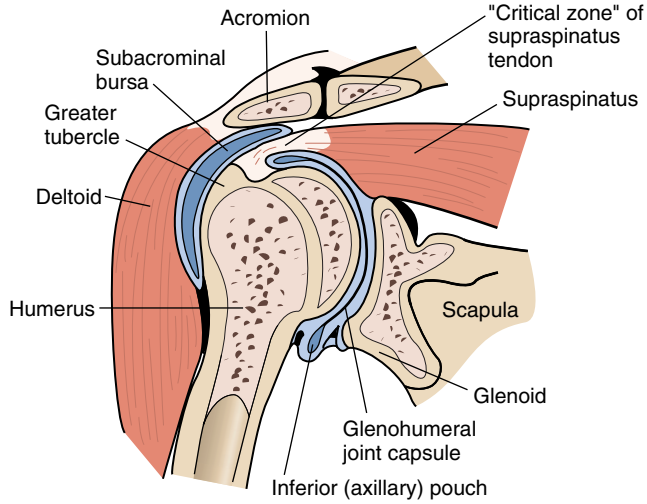

FIGURE 316-1 Coronal section of the shoulder illustrating the relationships of the glenohumeral joint, the joint capsule, the subacromial bursa, and the rotator cuff (supraspinatus tendon). *[From F Kozin, in WJ Koopman (ed): Arthritis and Allied Conditions, 13th ed. Baltimore, Williams & Wilkins, 1997, with permission.]*

after injury or overuse, especially with activities involving elevation of the arm with some degree of forward flexion. Impingement syndrome occurs in persons participating in baseball, tennis, swimming, or occupations that require repeated elevation of the arm. Those over age 40 are particularly susceptible. Patients complain of a dull aching in the shoulder, which may interfere with sleep. Severe pain is experienced when the arm is actively abducted into an overhead position. The arc between 60 and 120° is especially painful. Tenderness is present over the lateral aspect of the humeral head just below the acromion. NSAIDs, local glucocorticoid injection, and physical therapy may relieve symptoms. Surgical decompression of the subacromial space may be necessary in patients refractory to conservative treatment.

Patients may tear the supraspinatus tendon acutely by falling on an outstretched arm or lifting a heavy object. Symptoms are pain, along with weakness of abduction and external rotation of the shoulder. Atrophy of the supraspinatus muscles develops. The diagnosis is established by arthrogram, ultrasound or magnetic resonance imaging. Surgical repair may be necessary in patients who fail to respond to conservative measures. In patients with moderate to severe tears and functional loss, surgery is indicated.

CALCIFIC TENDINITIS This condition is characterized by deposition of calcium salts, primarily hydroxyapatite, within a tendon. The exact mechanism of calcification is not known but may be initiated by ischemia or degeneration of the tendon. The supraspinatus tendon is most often affected because it is frequently impinged on and has a reduced blood supply when the arm is abducted. The condition usually develops after age 40. Calcification within the tendon may evoke acute inflammation, producing sudden and severe pain in the shoulder. However, it may be asymptomatic or not related to the patient's symptoms.

BICIPITAL TENDINITIS AND RUPTURE Bicipital tendinitis, or tenosynovitis, is produced by friction on the tendon of the long head of the biceps as it passes through the bicipital groove. When the inflammation is acute, patients experience anterior shoulder pain that radiates down the biceps into the forearm. Abduction and external rotation of the arm are painful and limited. The bicipital groove is very tender to palpation. Pain may be elicited along the course of the tendon by resisting supination of the forearm with the elbow at 90° (Yergason's supination sign). Acute rupture of the tendon may occur with vigorous exercise of the arm and is often painful. In a young patient, it should be repaired surgically. Rupture of the tendon in an older person may be associated with little or no pain and is recognized by the presence of persistent swelling of the biceps ("Popeye" muscle) produced by the retraction of the long head of the biceps. Surgery is usually not necessary in this setting.

DE QUERVAINS' TENOSYNOVITIS In this condition, inflammation involves the abductor pollicis longus and the extensor pollicis brevis as these tendons pass through a fibrous sheath at the radial styloid process. The usual cause is repetitive twisting motion of the wrist. It may occur in pregnancy, and it also occurs in mothers from holding their babies with the thumb outstretched. Patients experience pain on grasping with their thumb such as with pinching. Swelling and tenderness are often present over the radial styloid process. The Finkelstein sign is positive, which is elicited by having the patient place the thumb in the palm and close the fingers over it. The wrist is then ulnarly deviated resulting in pain over the involved tendon sheath in the area of the radial styloid. Treatment consists initially of splinting the wrist and an NSAID. When severe or refractory to conservative treatment, glucocorticoid injections can be very effective.

PATELLAR TENDINITIS (JUMPER'S KNEE) Tendinitis involves the patellar tendon at its attachment to the lower pole of the patella. Patients may experience pain when jumping during basketball or volleyball, going up stairs, or when doing deep knee squats. Tenderness is noted on examination over the lower pole of the patella. Treatment consists of rest, icing, and NSAIDS, followed by strengthening and increasing flexibility.

ADHESIVE CAPSULITIS Often referred to as "frozen shoulder," adhesive capsulitis is characterized by pain and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. Night pain is often present in the affected shoulder. Adhesive capsulitis, however, may follow bursitis or tendinitis of the shoulder or be associated with systemic disorders such as chronic pulmonary disease, myocardial infarction, and diabetes mellitus. Prolonged immobility of the arm contributes to the development of adhesive capsulitis, and reflex sympathetic dystrophy is thought to be a pathogenic factor. The capsule of the shoulder is thickened, and a mild chronic inflammatory infiltrate and fibrosis may be present.

Adhesive capsulitis occurs more commonly in women after age 50. Pain and stiffness usually develop gradually over several months to a year but progress rapidly in some patients. Pain may interfere with sleep. The shoulder is tender to palpation, and both active and passive movement are restricted. Radiographs of the shoulder show osteopenia. The diagnosis is confirmed by arthrography, in that only a limited amount of contrast material, usually <15 mL, can be injected under pressure into the shoulder joint.

In most patients, the condition improves spontaneously 1 to 3 years after onset. While pain usually improves, most patients are left with some limitation of shoulder motion. Early mobilization of the arm following an injury to the shoulder may prevent the development of this disease. Slow but forceful injection of contrast material into the joint may lyse adhesions and stretch the capsule, resulting in improvement of shoulder motion. Manipulation under anesthesia may be helpful in some patients. Once the disease is established, therapy may have little effect on its natural course. Local injections of glucocorticoids, NSAIDs, and physical therapy may provide relief of symptoms.

LATERAL EPICONDYLITIS (TENNIS ELBOW) Lateral epicondylitis, or tennis elbow, is a painful condition involving the soft tissue over the lateral aspect of the elbow. The pain originates at or near the site of attachment of the common extensors to the lateral epicondyle and may radiate into the forearm and dorsum of the wrist. This painful condition is thought to be caused by small tears of the extensor aponeurosis resulting from repeated resisted contractions of the extensor muscles. The pain usually appears after work or recreational activities involving repeated motions of wrist extension and supination against resistance. Most patients with this disorder injure themselves in activities other than tennis, such as pulling weeds, carrying suitcases or briefcases, or using a screwdriver. The injury in tennis usually occurs when hitting a backhand with the elbow flexed. Shaking hands and opening doors can reproduce the pain. Striking the lateral elbow against a solid object may also induce pain.

The treatment is usually rest along with administration of an NSAID. Ultrasound, icing, and friction massage may also help relieve pain. When pain is severe, the elbow is placed in a sling or splinted at 90° of flexion. When the pain is acute and well localized, injection of a glucocorticoid using a small-gauge needle may be effective. Following injection, the patient should be advised to rest the arm for at least 1 month and avoid activities that would aggravate the elbow. Once symptoms have subsided, the patient should begin rehabilitation to strengthen and increase flexibility of the extensor muscles before resuming physical activity involving the arm. A forearm band placed 2.5 to 5.0 cm (1 to 2 in.) below the elbow may help to reduce tension on the extensor muscles at their attachment to the lateral epicondyle. The patient should be advised to restrict activities requiring forcible extension and supination of the wrist. Improvement may take several months. The patient may continue to experience mild pain but, with care, can usually avoid the return of debilitating pain. In an occasional patient, surgical release of the extensor aponeurosis may be necessary.

MEDIAL EPICONDYLITIS Medial epicondylitis is an overuse syndrome resulting in pain over the medial side of the elbow with radiation into the forearm. The cause of this syndrome is considered to be repetitive resisted motions of wrist flexion and pronation, which lead to micro-

tears and granulation tissue at the origin of the pronator teres and forearm flexors, particularly the flexor carpi radialis. This overuse syndrome is usually seen in patients >35 years and is much less common than lateral epicondylitis. It occurs most often in work-related repetitive activities but also occurs with recreational activities such as swinging a golf club (golfer's elbow) or throwing a baseball. On physical examination, there is tenderness just distal to the medial epicondyle over the origin of the forearm flexors. Pain can be reproduced by resisting wrist flexion and pronation with the elbow extended. Radiographs are usually normal. The differential diagnosis of patients with medial elbow symptoms include tears of the pronator teres, acute medial collateral ligament tear, and medial collateral ligament instability. Ulnar neuritis has been found in 25 to 50% of patients with medial epicondylitis and is associated with tenderness over the ulnar nerve at the elbow as well as hypesthesia and paresthesia on the ulnar side of the hand.

The initial treatment of medial epicondylitis is conservative, involving rest, NSAIDs, friction massage, ultrasound, and icing. Some patients may require splinting. Injections of glucocorticoids at the painful site may also be effective. Patients should be instructed to rest at least 1 month. Also, patients should be started on physical therapy once the pain has subsided. In patients with chronic debilitating medial epicondylitis that remains unresponsive after at least a year of treatment, surgical release of the flexor muscle at its origin may be necessary and is often successful.

317 PRINCIPLES OF ENDOCRINOLOGY

J. Larry Jameson

The management of endocrine disorders requires an understanding of such disparate areas as intermediary metabolism, reproductive physiology, bone metabolism, and growth. Accordingly, the practice of endocrinology is intimately linked to a conceptual framework for understanding hormone secretion, hormone action, and principles of feedback control systems. The endocrine system is evaluated primarily by measuring hormone concentrations, thereby arming the clinician with valuable diagnostic information. Most disorders of the endocrine system are amenable to effective treatment, once the correct diagnosis is determined. Endocrine deficiency disorders are treated with physiologic hormone replacement; hormone excess conditions, usually due to benign glandular adenomas, are managed by removing tumors surgically or by reducing hormone levels medically.

SCOPE OF ENDOCRINOLOGY

The specialty of endocrinology encompasses the study of glands and the hormones they produce. The term *endocrine* was coined by Starling to contrast the actions of hormones secreted internally (endocrine) with those secreted externally (*exocrine*) or into a lumen, such as the gastrointestinal tract. The term *hormone*, derived from a Greek phrase meaning "to set in motion," aptly describes the dynamic actions of hormones as they elicit cellular responses and regulate physiologic processes through feedback mechanisms.

Unlike many other specialties in medicine, it is not possible to define endocrinology strictly along anatomic lines. The classic endocrine glands—pituitary, thyroid, parathyroid, pancreatic islets, adrenal, and gonads—communicate broadly with other organs through the nervous system, hormones, cytokines, and growth factors. In addition to its traditional synaptic functions, the brain produces a vast array of peptide hormones, spawning the discipline of neuroendocrinology. Through the production of hypothalamic releasing factors, the central nervous system exerts a major regulatory influence over pituitary hormone secretion (Chap. 318). The peripheral nervous system modulates adrenal medulla and pancreatic islet hormone production. The immune and endocrine systems are also intimately intertwined. The adrenal glucocorticoid, cortisol, is a powerful immunosuppressant. Cytokines and interleukins (ILs) have profound effects on the functions of the pituitary, adrenal, thyroid, and gonads. Common endocrine diseases, such as autoimmune thyroid disease and type 1 diabetes mellitus, are caused by dysregulation of immune surveillance and tolerance. Less common diseases such as polyglandular failure, Addison's disease, and lymphocytic hypophysitis also have an immunologic basis.

The interdigitation of endocrinology with physiologic processes in other specialties sometimes blurs the role of hormones. For example, hormones play an important role in maintenance of blood pressure, intravascular volume, and peripheral resistance in the cardiovascular system. Vasoactive substances such as catecholamines, angiotensin II, endothelin, and nitric oxide are involved in dynamic changes of vascular tone, in addition to their multiple roles in other tissues. The heart is the principal source of atrial natriuretic peptide, which acts in classic endocrine fashion to induce natriuresis at a distant target organ (the kidney). Erythropoietin, a traditional circulating hormone, is made in the kidney and stimulates erythropoiesis in the bone marrow (Chap. 52). The kidney is also integrally involved in the renin-angiotensin axis (Chap. 321) and is a primary target of several hormones including parathyroid hormone (PTH), mineralocorticoids, and vasopressin. The gastrointestinal tract produces a surprising number of peptide hormones such as cholecystokinin, ghrelin, gastrin, secretin, and vasoactive intestinal peptide, among many others. Carcinoid and islet tumors can secrete excessive amounts of these hormones, leading to specific clinical syndromes (Chap. 329). Many of these gastrointestinal hormones are also produced in the central nervous system, where their functions remain poorly understood. As new hormones such as inhibin, ghrelin, and leptin are discovered, they become integrated into the science and practice of medicine on the basis of their functional roles rather than their tissues of origin or their structures or mechanisms of action.

Characterization of hormone receptors frequently reveals unexpected relationships to factors in nonendocrine disciplines. The growth hormone (GH) receptor, for example, is a member of the cytokine receptor family. The G protein–coupled receptors (GPCRs), which mediate the actions of many peptide hormones, are used in numerous physiologic processes including vision, smell, and neurotransmission.

It is apparent that hormones and growth factors play an important functional role in all organ systems. Though endocrinologists are not usually involved in the administration of the hormones or growth factors used to treat diseases in other specialties (e.g., cardiology, hematology), the principles of endocrinology can be applied in these cases, thus emphasizing the impact of endocrinology across multiple disciplines.

NATURE OF HORMONES

Hormones can be divided into five major classes: (1) *amino acid derivatives* such as dopamine, catecholamines, and thyroid hormone; (2) *small neuropeptides* such as gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), somatostatin, and vasopressin; (3) *large proteins* such as insulin, luteinizing hormone (LH), and PTH produced by classic endocrine glands; (4) *steroid hormones* such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) *vitamin derivatives* such as retinoids (vitamin A) and vitamin D. A variety of *peptide growth factors*, most of which act locally, share actions with hormones. As a rule, amino acid derivatives and peptide hormones interact with cell-surface membrane receptors. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and interact with intracellular nuclear receptors.

HORMONE AND RECEPTOR FAMILIES

Many hormones and receptors can be grouped into families, reflecting their structural similarities (Table 317-1). The evolution of these families generates diverse but highly selective pathways of hormone action. Recognizing these relationships allows extrapolation of information gleaned from one hormone or receptor to other family members.

The glycoprotein hormone family, consisting of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), LH, and human chorionic gonadotropin (hCG), illustrates many features of related hormones. The glycoprotein hormones are heterodimers that share the α subunit in common; the β subunits are distinct and confer specific biologic actions. The overall three-dimensional architecture of the β subunits is similar, reflecting the locations of conserved disulfide bonds that restrain protein conformation. The cloning of the β-subunit genes from multiple species suggests that this family arose from a common ancestral gene, probably by gene duplication and subsequent divergence to evolve new biologic functions.

As the hormone families enlarge and diverge, their receptors must co-evolve, if new biologic functions are to be derived. Related GPCRs, for example, have evolved for each of the glycoprotein hormones.

TABLE 317-1 *Membrane Receptor Families and Signaling Pathways*

Receptors	Effectors	Signaling Pathways
G protein–coupled seven-transmembrane (GPCR)		
β-Adrenergic	$G_s\alpha$, adenylate cyclase	Stimulation of cyclic AMP production, protein kinase A
LH, FSH, TSH	Ca^{2+} channels	
Glucagon		
PTH, PTHrP		Calmodulin, Ca^{2+}-dependent kinases
ACTH, MSH		
GHRH, CRH		
α-Adrenergic	$G_i\alpha$	Inhibition of cyclic AMP production
Somatostatin		Activation of K^+, Ca^{2+} channels
TRH, GnRH	G_q, G_{11}	Phospholipase C, diacylglycerol, IP_3, protein kinase C, voltage-dependent Ca^{2+} channels
Receptor tyrosine kinase		
Insulin, IGF-I	Tyrosine kinases, IRS-1 to IRS-4	MAP kinases, PI 3-kinase, RSK
EGF, NGF	Tyrosine kinases, ras	Raf, MAP kinases, RSK
Cytokine receptor–linked kinase		
GH, PRL	JAK, tyrosine kinases	STAT, MAP kinase, PI 3-kinase, IRS-1, IRS-2
Serine Kinase		
Activin, TGF-β, MIS	Serine kinase	Smads

Note: IP_3, inositol triphosphate; IRS, insulin receptor substrates; MAP, mitogen-activated protein; MSH, melanocyte-stimulating hormone; NGF, nerve growth factor; PI, phosphatylinositol; RSK, ribosomal S6 kinase; TGF-β, transforming growth factor β. For all other abbreviations, see text.

These receptors are structurally similar, and each is coupled to the $G_s\alpha$ signaling pathway. However, there is minimal overlap of hormone binding. For example, TSH binds with high specificity to the TSH receptor but interacts minimally with the LH or the FSH receptor. Nonetheless, there can be subtle physiologic consequences of hormone cross-reactivity with other receptors. Very high levels of hCG during pregnancy stimulate the TSH receptor and increase thyroid hormone levels.

Insulin, insulin-like growth factor (IGF) I, and IGF-II share structural similarities that are most apparent when precursor forms of the proteins are compared. In contrast to the high degree of specificity seen with the glycoprotein hormones, there is moderate cross-talk among the members of the insulin/IGF family. High concentrations of an IGF-II precursor produced by certain tumors (e.g., sarcomas) can cause hypoglycemia, partly because of binding to insulin and IGF-I receptors (Chap. 86). High concentrations of insulin also bind to the IGF-I receptor, perhaps accounting for some of the clinical manifestations seen in severe insulin resistance.

Another important example of receptor cross-talk is seen with PTH and parathyroid hormone–related peptide (PTHrP) (Chap. 332). PTH is produced by the parathyroid glands, whereas PTHrP is expressed at high levels during development and by a variety of tumors (Chap. 86). These hormones share amino acid sequence similarity, particularly in their amino-terminal regions. Both hormones bind to a single PTH receptor that is expressed in bone and kidney. Hypercalcemia and hypophosphatemia may therefore result from excessive production of either hormone, making it difficult to distinguish hyperparathyroidism from hypercalcemia of malignancy solely on the basis of serum chemistries. However, sensitive and specific assays for PTH and PTHrP now allow these disorders to be separated more readily.

Based on their specificities for DNA binding sites, the nuclear receptor family can be subdivided into type 1 receptors (GR, MR, AR, ER, PR) that bind steroids and type 2 receptors (TR, VDR, RAR, PPAR) that bind thyroid hormone, vitamin D, retinoic acid, or lipid derivatives. Certain functional domains in nuclear receptors, such as the zinc finger DNA-binding domains, are highly conserved. However, selective amino acid differences within this domain confer DNA sequence specificity. The hormone-binding domains are more variable, providing great diversity in the array of small molecules that can bind to different nuclear receptors. With few exceptions, hormone binding is highly specific for a single type of nuclear receptor. One exception involves the highly related glucocorticoid and mineralocorticoid receptors. Because the mineralocorticoid receptor also binds glucocorticoids with high affinity, an enzyme (11β-hydroxysteroid dehydrogenase) located in renal tubular cells inactivates glucocorticoids, allowing selective responses to mineralocorticoids such as aldosterone. However, when very high glucocorticoid concentrations occur, as in Cushing's syndrome, the glucocorticoid degradation pathway becomes saturated, allowing excessive cortisol levels to exert mineralocorticoid effects (sodium retention, potassium wasting). This phenomenon is particularly pronounced in ectopic adrenocorticotropic hormone (ACTH) syndromes (Chap. 321). Another example of relaxed nuclear receptor specificity involves the estrogen receptor, which can bind an array of compounds, some of which share little structural similarity to the high-affinity ligand estradiol. This feature of the estrogen receptor makes it susceptible to activation by "environmental estrogens" such as resveratrol, octylphenol, and many other aromatic hydrocarbons. On the other hand, this lack of specificity provides an opportunity to synthesize a remarkable series of clinically useful antagonists (e.g., tamoxifen) and selective estrogen response modulators (SERMs), such as raloxifene. These compounds generate distinct conformations that alter receptor interactions with components of the transcription machinery (see below), thereby conferring their unique actions.

HORMONE SYNTHESIS AND PROCESSING

The synthesis of peptide hormones and their receptors occurs through a classic pathway of gene expression: transcription → mRNA → protein → posttranslational protein processing → intracellular sorting, membrane integration, or secretion (Chap. 56). Though endocrine genes contain regulatory DNA elements similar to those found in many other genes, their exquisite control by other hormones also necessitates the presence of specific hormone response elements. For example, the TSH genes are repressed directly by thyroid hormones acting through the thyroid hormone receptor, a member of the nuclear receptor family. Steroidogenic enzyme gene expression requires specific transcription factors such as steroidogenic factor-1 (SF-1), acting in conjunction with signals transmitted by trophic hormones (e.g., ACTH or LH). For some hormones, substantial regulation occurs at the level of translational efficiency. Insulin biosynthesis, while requiring ongoing gene transcription, is regulated primarily at the translational level in response to elevated levels of glucose or amino acids.

Many hormones are embedded within larger precursor polypeptides that are proteolytically processed to yield the biologically active hormone. Examples include: proopiomelanocortin (POMC) → ACTH; proglucagon → glucagon; proinsulin → insulin; pro-PTH → PTH, among others. In many cases, such as POMC and proglucagon, these precursors generate multiple biologically active peptides. It is provocative that hormone precursors are typically inactive, presumably add-

ing an additional level of regulatory control. This is true not only for peptide hormones but also for certain steroids (testosterone → dihydrotestosterone) and thyroid hormone ($T_4 \rightarrow T_3$).

Hormone precursor processing is intimately linked to intracellular sorting pathways that transport proteins to appropriate vesicles and enzymes, resulting in specific cleavage steps, followed by protein folding and translocation to secretory vesicles. Hormones destined for secretion are translocated across the endoplasmic reticulum under the guidance of an amino-terminal signal sequence that is subsequently cleaved. Cell-surface receptors are inserted into the membrane via short segments of hydrophobic amino acids that remain embedded within the lipid bilayer. During translocation through the Golgi and endoplasmic reticulum, hormones and receptors are also subject to a variety of posttranslational modifications, such as glycosylation and phosphorylation, which can alter protein conformation, modify circulating half-life, and alter biologic activity.

Synthesis of most steroid hormones is based on modifications of the precursor, cholesterol. Multiple regulated enzymatic steps are required for the synthesis of testosterone (Chap. 325), estradiol (Chap. 326), cortisol (Chap. 321), and vitamin D (Chap. 331). This large number of synthetic steps predisposes to multiple genetic and acquired disorders of steroidogenesis.

HORMONE SECRETION, TRANSPORT, AND DEGRADATION

The circulating level of a hormone is determined by its rate of secretion and its circulating half-life. After protein processing, peptide hormones (GnRH, insulin, GH) are stored in secretory granules. As these granules mature, they are poised beneath the plasma membrane for imminent release into the circulation. In most instances, the stimulus for hormone secretion is a releasing factor or neural signal that induces rapid changes in intracellular calcium concentrations, leading to secretory granule fusion with the plasma membrane and release of its contents into the extracellular environment and bloodstream. Steroid hormones, in contrast, diffuse into the circulation as they are synthesized. Thus, their secretory rates are closely aligned with rates of synthesis. For example, ACTH and LH induce steroidogenesis by stimulating the activity of *st*eroidogenic *a*cute *r*egulatory (StAR) protein (transports cholesterol into the mitochondrion) along with other rate-limiting steps (e.g., cholesterol side-chain cleavage enzyme, CYP11A1) in the steroidogenic pathway.

Hormone transport and degradation dictate the rapidity with which a hormonal signal decays. Some hormonal signals are evanescent (e.g., somatostatin), whereas others are longer lived (e.g., TSH). Because somatostatin exerts effects in virtually every tissue, a short half-life allows its concentrations and actions to be controlled locally. Structural modifications that impair somatostatin degradation have been useful for generating long-acting therapeutic analogues, such as octreotide (Chap. 318). On the other hand, the actions of TSH are highly specific for the thyroid gland. Its prolonged half-life accounts for relatively constant serum levels, even though TSH is secreted in discrete pulses.

An understanding of circulating hormone half-life is important for achieving physiologic hormone replacement, as the frequency of dosing and the time required to reach steady state are intimately linked to rates of hormone decay. T_4, for example, has a circulating half-life of 7 days. Consequently, >1 month is required to reach a new steady state, but single daily doses are sufficient to achieve constant hormone levels. T_3, in contrast, has a half-life of 1 day. Its administration is associated with more dynamic serum levels and it must be administered two to three times per day. Similarly, synthetic glucocorticoids vary widely in their half-lives; those with longer half-lives (e.g., dexamethasone) are associated with greater suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Most protein hormones [e.g., ACTH, GH, prolactin (PRL); PTH, LH] have relatively short half-lives (<20 min), leading to sharp peaks of secretion and decay. The only accurate way to profile the pulse frequency and amplitude of these hormones is to measure levels in frequently sampled blood (every 10 min) over long durations (8 to 24 h). Because this is not practical in a clinical setting, an alternative strategy is to pool three to four samples drawn at about 30-min intervals, recognizing that pulsatile secretion makes it difficult to establish a narrow normal range. Rapid hormone decay is useful in certain clinical settings. For example, the short half-life of PTH allows the use of intraoperative PTH determinations to confirm successful removal of an adenoma. This is particularly valuable diagnostically when there is a possibility of multicentric disease or parathyroid hyperplasia, as occurs with multiple endocrine neoplasia (MEN) or renal insufficiency.

Many hormones circulate in association with serum-binding proteins. Examples include: (1) T_4 and T_3 binding to thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin (TBPA); (2) cortisol binding to cortisol-binding globulin (CBG); (3) androgen and estrogen binding to sex hormone–binding globulin (SHBG) (also called testosterone-binding globulin, TeBG); (4) IGF-I and -II binding to multiple IGF-binding proteins (IGFBPs); (5) GH interactions with GH-binding protein (GHBP), a circulating fragment of the GH receptor extracellular domain; and (6) activin binding to follistatin. These interactions provide a hormonal reservoir, prevent otherwise rapid degradation of unbound hormones, restrict hormone access to certain sites (e.g., IGFBPs), and modulate the unbound, or "free," hormone concentrations. Although a variety of binding protein abnormalities have been identified, most have little clinical consequence, aside from creating diagnostic problems. For example, TBG deficiency can greatly reduce total thyroid hormone levels, but the free concentrations of T_4 and T_3 remain normal. Liver disease and certain medications can also influence binding protein levels (e.g., estrogen increases TBG) or cause displacement of hormones from binding proteins (e.g., salsalate displaces T_4 from TBG). Only unbound hormone is available to interact with receptors and thereby elicit a biologic response. Short-term perturbations in binding proteins change the free hormone concentration, which in turn induces compensatory adaptations through feedback loops. SHBG changes in women are an exception to this self-correcting mechanism. When SHBG decreases because of insulin resistance or androgen excess, the unbound testosterone concentration is increased, potentially leading to hirsutism (Chap. 44). The increased unbound testosterone level does not result in an adequate compensatory feedback correction because estrogen, and not testosterone, is the primary regulator of the reproductive axis.

HORMONE ACTION THROUGH RECEPTORS

Receptors for hormones are divided into two major classes—membrane and nuclear. *Membrane receptors* primarily bind peptide hormones and catecholamines. *Nuclear receptors* bind small molecules that can diffuse across the cell membrane, such as thyroid hormone, steroids, and vitamin D. Certain general principles apply to hormone-receptor interactions, regardless of the class of receptor. Hormones bind to receptors with specificity and a high affinity that generally coincides with the dynamic range of circulating hormone concentrations. Low concentrations of free hormone (usually 10^{-12} to 10^{-9} *M*) rapidly associate and dissociate from receptors in a bimolecular reaction, such that the occupancy of the receptor at any given moment is a function of hormone concentration and the receptor's affinity for the hormone. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of specific cellular responses to circulating hormones. For example, ACTH receptors are located almost exclusively in the adrenal cortex, and FSH receptors are found only in the gonads. In contrast, insulin and thyroid hormone receptors are widely distributed, reflecting the need for metabolic responses in all tissues.

MEMBRANE RECEPTORS

Membrane receptors for hormones can be divided into several major groups: (1) seven transmembrane GPCRs, (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) serine kinase receptors (Fig. 317-

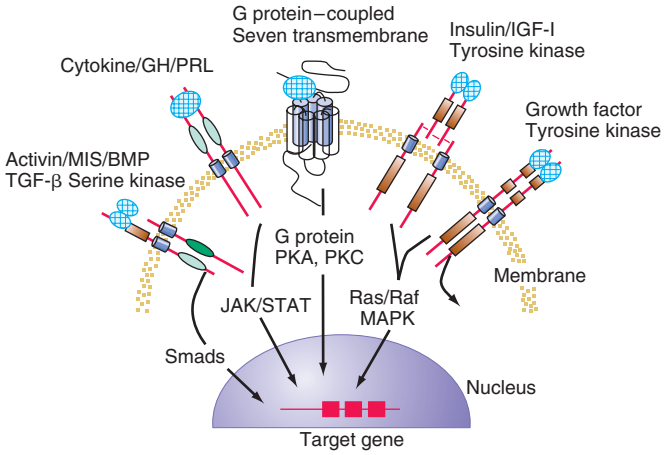

FIGURE 317-1 Membrane receptor signaling. MAPK, mitogen-activated protein kinase; PKA, -C, protein kinase A, C; TGF, transforming growth factor. For other abbreviations, see text.

1). The *seven transmembrane GPCR family* binds a remarkable array of hormones including large proteins (e.g., LH, PTH), small peptides (e.g., TRH, somatostatin), catecholamines (epinephrine, dopamine), and even minerals (e.g., calcium). The extracellular domains of GPCRs vary widely in size and are the major binding site for large hormones. The transmembrane-spanning regions are composed of hydrophobic α-helical domains that traverse the lipid bilayer. Like some channels, these domains are thought to circularize and form a hydrophobic pocket into which certain small ligands fit. Hormone binding induces conformational changes in these domains, transducing structural changes to the intracellular domain, which is a docking site for G proteins.

The large family of *G proteins*, so named because they bind guanine nucleotides (GTP, GDP), provides great diversity for coupling signaling pathways to different receptors. G proteins form a heterotrimeric complex that is composed of various α and $\beta\gamma$ subunits. The α subunit contains the guanine nucleotide–binding site and hydrolyzes GTP $\rightarrow$ GDP. The $\beta\gamma$ subunits are tightly associated and modulate the activity of the α subunit, as well as mediating their own effector signaling pathways. G protein activity is regulated by a cycle that involves GTP hydrolysis and dynamic interactions between the α and $\beta\gamma$ subunits. Hormone binding to the receptor induces GDP dissociation, allowing Gα to bind GTP and dissociate from the $\beta\gamma$ complex. Under these conditions, the Gα subunit is activated and mediates signal transduction through various enzymes such as adenylate cyclase or phospholipase C. GTP hydrolysis to GDP allows reassociation with the $\beta\gamma$ subunits and restores the inactive state. As described below, a variety of endocrinopathies result from G protein mutations or from mutations in receptors that modify their interactions with G proteins.

There are more than a dozen isoforms of the Gα subunit. $G_s\alpha$ stimulates, whereas $G_i\alpha$ inhibits adenylate cyclase, an enzyme that generates the second messenger, cyclic AMP, leading to activation of protein kinase A (Table 317-1). G_q subunits couple to phospholipase C, generating diacylglycerol and inositol triphosphate, leading to activation of protein kinase C and the release of intracellular calcium.

The *tyrosine kinase receptors* transduce signals for insulin and a variety of growth factors, such as IGF-I, epidermal growth factor (EGF), nerve growth factor, platelet-derived growth factor, and fibroblast growth factor. The cysteine-rich extracellular ligand-binding domains contain growth factor binding sites. After ligand binding, this class of receptors undergoes autophosphorylation, inducing interactions with intracellular adaptor proteins such as Shc and insulin receptor substrates 1 to 4. In the case of the insulin receptor, multiple kinases are activated including the Raf-Ras-MAPK and the Akt/protein kinase B pathways. The tyrosine kinase receptors play a prominent role in cell growth and differentiation as well as in intermediary metabolism.

The GH and PRL receptors belong to the *cytokine receptor* family (Chap. 295). Analogous to the tyrosine kinase receptors, ligand binding induces receptor interaction with intracellular kinases—the Janus kinases (JAKs), which phosphorylate members of the signal transduction and activators of transcription (STAT) family—as well as other signaling pathways (Ras, PI3-K, MAPK). The activated STAT proteins translocate to the nucleus and stimulate expression of target genes (Chap. 318).

The *serine kinase receptors* mediate the actions of activins, transforming growth factor β, müllerian-inhibiting substance (MIS, also known as anti-müllerian hormone, AMH), and bone morphogenic proteins (BMPs). This family of receptors (consisting of type I and II subunits) signal through proteins termed *smads* (fusion of terms for *Caenorhabditis elegans* sma + mammalian mad). Like the STAT proteins, the smads serve a dual role of transducing the receptor signal and acting as transcription factors. The pleomorphic actions of these growth factors dictate that they act primarily in a local (paracrine or autocrine) manner. Binding proteins, such as follistatin (which binds activin and other members of this family), function to inactivate the growth factors and restrict their distribution.

NUCLEAR RECEPTORS

The family of nuclear receptors has grown to nearly 100 members, many of which are still classified as orphan receptors because their ligands, if they exist, remain to be identified (Fig. 317-2). Otherwise, most nuclear receptors are classified based on the nature of their ligands. Though all nuclear receptors ultimately act to increase or decrease gene transcription, some (e.g., glucocorticoid receptor) reside primarily in the cytoplasm, whereas others (e.g., thyroid hormone receptor) are always located in the nucleus. After ligand binding, the cytoplasmically localized receptors translocate to the nucleus. There is growing evidence that certain nuclear receptors

(e.g., glucocorticoid, estrogen) can also activate or repress signal transduction pathways, providing a mechanism for cross-talk between membrane and nuclear receptors.

The structures of nuclear receptors have been extensively studied, including by x-ray crystallography. The DNA binding domain, consisting of two zinc fingers, contacts specific DNA recognition sequences in target genes. Most nuclear receptors bind to DNA as dimers. Consequently, each monomer recognizes an individual DNA motif, referred to as a "half-site." The steroid receptors, including the glucocorticoid, estrogen, progesterone, and androgen receptors, bind to DNA as homodimers. Consistent with this twofold symmetry, their DNA recognition half-sites are palindromic. The thyroid, retinoid, peroxisome proliferator activated, and vitamin D receptors bind to DNA preferentially as heterodimers in combination with retinoid X receptors (RXRs). Their DNA half-sites are arranged as direct repeats. Receptor specificity for DNA sequences is determined by (1) the sequence of the half-site, (2) the orientation of the half-sites (palindromic, direct repeat), and (3) the spacing between the half-sites. For example, vitamin D, thyroid, and retinoid receptors recognize similar tandemly repeated half-sites (TAAGTCA), but these DNA repeats are spaced by three, four, and five nucleotides, respectively.

The carboxy-terminal hormone-binding domain mediates transcriptional control. For type II receptors, such as thyroid hormone receptor (TR) and retinoic acid receptor (RAR), co-repressor proteins bind to the receptor in the absence of ligand and silence gene transcription. Hormone binding induces conformational changes, triggering the release of co-repressors and inducing the recruitment of coactivators that stimulate transcription. Thus, these receptors are capable of mediating dramatic changes in the level of gene activity. Certain disease states are associated with defective regulation of these events. For example, mutations in the TR prevent co-repressor dissociation, resulting in a dominant form of hormone resistance (Chap. 320). In promyelocytic leukemia, fusion of RARα to other nuclear proteins causes aberrant gene silencing and prevents normal cellular differentiation. Treatment with retinoic acid reverses this repression and allows cellular differentiation and apoptosis to occur (Chap. 96). Most type 1 steroid receptors do not interact with co-repressors, but ligand binding still mediates interactions with an array of coactivators. X-ray crystallography shows that various SERMs induce distinct receptor conformations. The tissue-specific responses caused by these agents in breast, bone, and uterus appear to reflect distinct interactions with coactivators. The receptor-coactivator complex stimulates gene transcription by several pathways including (1) recruitment of enzymes (histone acetyl transferases) that modify chromatin structure, (2) interactions with additional transcription factors on the target gene, and (3) direct interactions with components of the general transcription apparatus to enhance the rate of RNA polymerase II–mediated transcription.

FUNCTIONS OF HORMONES

The functions of individual hormones are described in detail in subsequent chapters. Nevertheless, it is useful to illustrate how most biologic responses require integration of several different hormonal pathways. The physiologic functions of hormones can be divided into three general areas: (1) growth and differentiation, (2) maintenance of homeostasis, and (3) reproduction.

GROWTH

Multiple hormones and nutritional factors mediate the complex phenomenon of growth (Chap. 318). Short stature may be caused by GH deficiency, hypothyroidism, Cushing's syndrome, precocious puberty, malnutrition or chronic illness, or genetic abnormalities that affect the epiphyseal growth plates (e.g., *FGFR3* or *SHOX* mutations). Many factors (GH, IGF-I, thyroid hormone) stimulate growth, whereas others (sex steroids) lead to epiphyseal closure. Understanding these hormonal interactions is important in the diagnosis and management of growth disorders. For example, delaying exposure to high levels of sex steroids may enhance the efficacy of GH treatment.

MAINTENANCE OF HOMEOSTASIS

Though virtually all hormones affect homeostasis, the most important among these are the following:

1. Thyroid hormone—controls about 25% of basal metabolism in most tissues
2. Cortisol—exerts a permissive action for many hormones in addition to its own direct effects
3. PTH—regulates calcium and phosphorus levels
4. Vasopressin—regulates serum osmolality by controlling renal free water clearance
5. Mineralocorticoids—control vascular volume and serum electrolyte (Na^+, K^+) concentrations
6. Insulin—maintains euglycemia in the fed and fasted states

The defense against hypoglycemia is an impressive example of integrated hormone action (Chap. 324). In response to the fasted state and falling blood glucose, insulin secretion is suppressed, resulting in decreased glucose uptake and enhanced glycogenolysis, lipolysis, proteolysis, and gluconeogenesis to mobilize fuel sources. If hypoglycemia develops (usually from insulin administration or sulfonylureas), an orchestrated counterregulatory response occurs—glucagon and epinephrine rapidly stimulate glycogenolysis and gluconeogenesis, whereas GH and cortisol act over several hours to raise glucose levels and antagonize insulin action.

Although free water clearance is primarily controlled by vasopressin, cortisol and thyroid hormone are also important for facilitating renal tubular responses to vasopressin (Chap. 319). PTH and vitamin D function in an interdependent manner to control calcium metabolism (Chap. 331). PTH stimulates renal synthesis of 1,25 dihydroxyvitamin D, which increases calcium absorption in the gastrointestinal tract and enhances PTH action in bone. Increased calcium, along with vitamin D, feeds back to suppress PTH, thereby maintaining calcium balance.

Depending on the severity of a given stress and whether it is acute or chronic, multiple endocrine and cytokine pathways are activated to mount an appropriate physiologic response (Chap. 318). In severe acute stress such as trauma or shock, the sympathetic nervous system is activated and catecholamines are released, leading to increased cardiac output and a primed musculoskeletal system. Catecholamines also increase mean blood pressure and stimulate glucose production. Multiple stress-induced pathways converge on the hypothalamus, stimulating several hormones including vasopressin and corticotropin-releasing hormone (CRH). These hormones, in addition to cytokines (tumor necrosis factor α, IL-2, IL-6), increase ACTH and GH production. ACTH stimulates the adrenal gland, increasing cortisol, which in turn helps to sustain blood pressure and dampen the inflammatory response. Increased vasopressin acts to conserve free water.

REPRODUCTION

The stages of reproduction include: (1) sex determination during fetal development (Chap. 328); (2) sexual maturation during puberty (Chaps. 325 and 326); (3) conception, pregnancy, lactation, and child-rearing (Chap. 326); and (4) cessation of reproductive capability at menopause (Chap. 327). Each of these stages involves an orchestrated interplay of multiple hormones, a phenomenon well illustrated by the dynamic hormonal changes that occur during each 28-day menstrual cycle. In the early follicular phase, pulsatile secretion of LH and FSH stimulates the progressive maturation of the ovarian follicle. This results in gradually increasing estrogen and progesterone levels, leading to enhanced pituitary sensitivity to GnRH, which, when combined with accelerated GnRH secretion, triggers the LH surge and rupture of the mature follicle. Inhibin, a protein produced by the granulosa cells, enhances follicular growth and feeds back to the pituitary to selectively suppress FSH, without affecting LH. Growth factors such as EGF and IGF-I modulate follicular responsiveness to gonadotropins. Vascular endothelial growth factor and prostaglandins play a role in follicle vascularization and rupture.

During pregnancy, the increased production of prolactin, in combination with placentally derived steroids (e.g., estrogen and progesterone), prepares the breast for lactation. Estrogens induce the production of progesterone receptors, allowing for increased responsiveness to progesterone. In addition to these and other hormones involved in lactation, the nervous system and oxytocin mediate the suckling response and milk release.

HORMONAL FEEDBACK REGULATORY SYSTEMS

Feedback control, both negative and positive, is a fundamental feature of endocrine systems. Each of the major hypothalamic-pituitary-hormone axes is governed by negative feedback, a process that maintains hormone levels within a relatively narrow range (Chap. 318). Examples of hypothalamic-pituitary negative feedback include (1) thyroid hormones on the TRH-TSH axis, (2) cortisol on the CRH-ACTH axis, (3) gonadal steroids on the GnRH-LH/FSH axis, and (4) IGF-I on the growth hormone–releasing hormone (GHRH)-GH axis (Fig. 317-3). These regulatory loops include both positive (e.g., TRH, TSH) and negative components (e.g., T_4, T_3), allowing for exquisite control of hormone levels. As an example, a small reduction of thyroid hormone triggers a rapid increase of TRH and TSH secretion, resulting in thyroid gland stimulation and increased thyroid hormone production. When the thyroid hormone reaches a normal level, it feeds back to suppress TRH and TSH, and a new steady state is attained. Feedback regulation also occurs for endocrine systems that do not involve the pituitary gland, such as calcium feedback on PTH, glucose inhibition of insulin secretion, and leptin feedback on the hypothalamus. An understanding of feedback regulation provides important insights into endocrine testing paradigms (see below).

Positive feedback control also occurs but is not well understood. The primary example is estrogen-mediated stimulation of the midcycle LH surge. Though chronic low levels of estrogen are inhibitory, gradually rising estrogen levels stimulate LH secretion. This effect, which is illustrative of an endocrine rhythm (see below), involves activation of the hypothalamic GnRH pulse generator. In addition, estrogen-primed gonadotropes are extroardinarily sensitive to GnRH, leading to a 10- to 20-fold amplification of LH release.

PARACRINE AND AUTOCRINE CONTROL

The aforementioned examples of feedback control involve classic endocrine pathways in which hormones are released by one gland and act on a distant target gland. However, local regulatory systems, often involving growth factors, are increasingly recognized. *Paracrine regulation* refers to factors released by one cell that act on an adjacent cell in the same tissue. For example, somatostatin secretion by pancreatic islet δ cells inhibits insulin secretion from nearby β cells. *Autocrine regulation* describes the action of a factor on the same cell from which it is produced. IGF-I acts on many cells that produce it, including chondrocytes, breast epithelium, and gonadal cells. Unlike endocrine actions, paracrine and autocrine control are difficult to document because local growth factor concentrations cannot be readily measured.

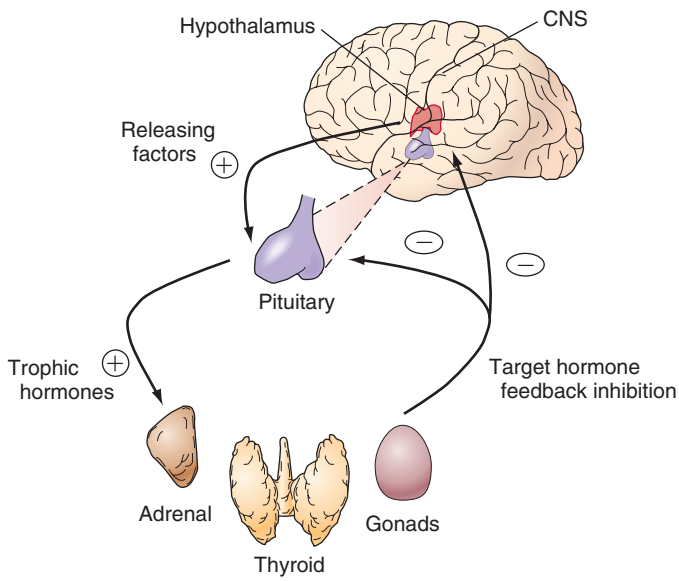

FIGURE 317-3 Feedback regulation of endocrine axes. CNS, central nervous system.

Anatomic relationships of glandular systems also greatly influence hormonal exposure—the physical organization of islet cells enhances their intercellular communication; the portal vasculature of the hypothalamic-pituitary system exposes the pituitary to high concentrations of hypothalamic releasing factors; testicular seminiferous tubules gain exposure to high testosterone levels produced by the interdigitated Leydig cells; the pancreas receives nutrient information from the gastrointestinal tract; and the liver is the proximal target of insulin action because of portal drainage from the pancreas.

HORMONAL RHYTHMS

The feedback regulatory systems described above are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycle, sleep, meals, and stress are examples of the many environmental events that affect hormonal rhythms. The *menstrual cycle* is repeated on average every 28 days, reflecting the time required to follicular maturation and ovulation (Chap. 326). Essentially all pituitary hormone rhythms are entrained to sleep and the *circadian cycle*, generating reproducible patterns that are repeated approximately every 24 h. The HPA axis, for example, exhibits characteristic peaks of ACTH and cortisol production in the early morning, with a nadir during the night. Recognition of these rhythms is important for endocrine testing and treatment. Patients with Cushing's syndrome characteristically exhibit increased midnight cortisol levels when compared to normal individuals (Chap. 321). In contrast, morning cortisol levels are similar in these groups, as cortisol is normally high at this time of day in normal individuals. The HPA axis is more susceptible to suppression by glucocorticoids administered at night as they blunt the early morning rise of ACTH. Understanding these rhythms allows glucocorticoid replacement that mimics diurnal production by administering larger doses in the morning than in the afternoon (Chap. 321). Disrupted sleep rhythms can alter hormonal regulation. For example, sleep deprivation causes mild insulin resistance and hypertension, which are reversible at least in the short term.

Other endocrine rhythms occur on a more rapid time scale. Many peptide hormones are secreted in discrete bursts every few hours. LH and FSH secretion are exquisitely sensitive to GnRH pulse frequency. Intermittent pulses of GnRH are required to maintain pituitary sensitivity, whereas continuous exposure to GnRH causes pituitary gonadotrope desensitization. This feature of the hypothalamic-pituitary-gonadotrope (HPG) axis forms the basis for using long-acting GnRH agonists to treat central precocious puberty or to decrease testosterone levels in the management of prostate cancer.

It is important to be aware of the pulsatile nature of hormone secretion and the rhythmic patterns of hormone production when relating serum hormone measurements to normal values. For some hormones, integrated markers have been developed to circumvent hormonal fluctuations. Examples include 24-h urine collections for cortisol, IGF-I as a biologic marker of GH action, and HbA1c as an index of long-term (weeks to months) blood glucose control.

Often, one must interpret endocrine data only in the context of other hormonal results. For example, PTH levels are typically assessed in combination with serum calcium concentrations. A high serum calcium level in association with elevated PTH is suggestive of hyperparathyroidism, whereas a suppressed PTH in this situation is more likely to be caused by hypercalcemia of malignancy or other causes of hypercalcemia. Similarly, TSH should be elevated when T_4 and T_3

concentrations are low, reflecting reduced feedback inhibition. When this is not the case, it is important to consider other abnormalities in the hormonal axis, such as secondary hypothyroidism, which is caused by a defect at the level of the pituitary.

PATHOLOGIC MECHANISMS OF ENDOCRINE DISEASE

Endocrine diseases can be divided into three major types of conditions: (1) hormone excess, (2) hormone deficiency, and (3) hormone resistance (Table 317-2).

CAUSES OF HORMONE EXCESS

Syndromes of hormone excess can be caused by neoplastic growth of endocrine cells, autoimmune disorders, and excess hormone administration. Benign endocrine tumors, including parathyroid, pituitary, and adrenal adenomas, often retain the capacity to produce hormones, perhaps reflecting the fact that they are relatively well differentiated. Many endocrine tumors exhibit subtle defects in their "set points" for feedback regulation. For example, in Cushing's disease, impaired feedback inhibition of ACTH secretion is associated with autonomous function. However, the tumor cells are not completely resistant to feedback, as evidenced by ACTH suppression by higher doses of dexamethasone (e.g., high-dose dexamethasone test) (Chap. 321). Similar set point defects are also typical of parathyroid adenomas and autonomously functioning thyroid nodules.

The molecular basis of some endocrine tumors, such as the MEN syndromes (MEN 1, 2A, 2B), have provided important insights into tumorigenesis (Chap. 330). MEN 1 is characterized primarily by the triad of parathyroid, pancreatic islet, and pituitary tumors. MEN 2 predisposes to medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. The *MEN1* gene, located on chromosome 11q13, encodes a putative tumor-suppressor gene, menin. Analogous to the paradigm first described for retinoblastoma, the affected individual inherits a mutant copy of the *MEN1* gene, and tumorigenesis ensues after a somatic "second hit" leads to loss of function of the normal *MEN1* gene (through deletion or point mutations).

In contrast to inactivation of a tumor-suppressor gene, as occurs in MEN 1 and most other inherited cancer syndromes, MEN 2 is caused by activating mutations in a single allele. In this case, activating mutations of the *RET* proto-oncogene, which encodes a receptor tyrosine kinase, leads to thyroid C-cell hyperplasia in childhood before the development of medullary thyroid carcinoma. Elucidation of the pathogenic mechanism has allowed early genetic screening for *RET* mutations in individuals at risk for MEN 2, permitting identification of those who may benefit from prophylactic thyroidectomy and biochemical screening for pheochromocytoma and hyperparathyroidism.

Mutations that activate hormone receptor signaling have been identified in several GPCRs. For example, activating mutations of the LH receptor cause a dominantly transmitted form of male-limited precocious puberty, reflecting premature stimulation of testosterone synthesis in Leydig cells (Chap. 325). Activating mutations in these GPCRs are predominantly located in the transmembrane domains and induce receptor coupling to $G_s\alpha$, even in the absence of hormone. Consequently, adenylate cyclase is activated and cyclic AMP levels increase in a manner that mimics hormone action. A similar phenomenon results from activating mutations in $G_s\alpha$. When these occur early in development, they cause McCune-Albright syndrome. When they occur only in somatotropes, the activating $G_s\alpha$ mutations cause GH-secreting tumors and acromegaly (Chap. 318).

In autoimmune Graves' disease, antibody interactions with the TSH receptor mimic TSH action, leading to hormone overproduction (Chap. 320). Analogous to the effects of activating mutations of the TSH receptor, these stimulating autoantibodies induce conformational changes that release the receptor from a constrained state, thereby triggering receptor coupling to G proteins.

TABLE 317-2 *Causes of Endocrine Dysfunction*

Type of Endocrine Disorder	Examples
Hyperfunction	
Neoplastic	
Benign	Pituitary adenomas, hyperparathyroidism, autonomous thyroid or adrenal nodules, pheochromocytoma
Malignant	Adrenal cancer, medullary thyroid cancer, carcinoid
Ectopic	Ectopic ACTH, SIADH secretion
Multiple endocrine neoplasia	MEN1, MEN2
Autoimmune	Graves' disease
Iatrogenic	Cushing's syndrome, hypoglycemia
Infectious/inflammatory	Subacute thyroiditis
Activating receptor mutations	LH, TSH, Ca^{2+} and PTH receptors, $G_s\alpha$
Hypofunction	
Autoimmune	Hashimoto's thyroiditis, type 1 diabetes mellitus, Addison's disease, polyglandular failure
Iatrogenic	Radiation-induced hypopituitarism, hypothyroidism, surgical
Infectious/inflammatory	Adrenal insufficiency, hypothalamic sarcoidosis
Hormone mutations	GH, LHβ, FSHβ, vasopressin
Enzyme defects	21-Hydroxylase deficiency
Developmental defects	Kallmann syndrome, Turner syndrome, transcription factors
Nutritional/vitamin deficiency	Vitamin D deficiency, iodine deficiency
Hemorrhage/infarction	Sheehan's syndrome, adrenal insufficiency
Hormone resistance	
Receptor mutations	
Membrane	GH, vasopressin, LH, FSH, ACTH, GnRH, GHRH, PTH, leptin, Ca^{2+}
Nuclear	AR, TR, VDR, ER, GR, $PPAR_\gamma$
Signaling pathway mutations	Albright's hereditary osteodystrophy
Postreceptor	Type 2 diabetes mellitus, leptin resistance

Note: AR, androgen receptor; ER, estrogen receptor; GR, glucocorticoid receptor; PPAR, peroxisome proliferator activated receptor; SIADH, syndrome of inappropriate antidiuretic hormone; TR, thyroid hormone receptor; VDR, vitamin D receptor. For all other abbreviations, see text.

CAUSES OF HORMONE DEFICIENCY

Most examples of hormone deficiency states can be attributed to glandular destruction caused by autoimmunity, surgery, infection, inflammation, infarction, hemorrhage, or tumor infiltration (Table 317-2). Autoimmune damage to the thyroid gland (Hashimoto's thyroiditis) and pancreatic islet β cells (type 1 diabetes mellitus) is a prevalent cause of endocrine disease. Mutations in a number of hormones, hormone receptors, transcription factors, enzymes, and channels can also lead to hormone deficiencies.

HORMONE RESISTANCE

Most severe hormone resistance syndromes are due to inherited defects in membrane receptors, nuclear receptors, or in the pathways that transduce receptor signals. These disorders are characterized by defective hormone action, despite the presence of increased hormone levels. In complete androgen resistance, for example, mutations in the androgen receptor cause genetic (XY) males to have a female phenotypic appearance, even though LH and testosterone levels are increased (Chap. 328). In addition to these relatively rare genetic disorders, more common acquired forms of functional hormone resistance include insulin resistance in type 2 diabetes mellitus, leptin resistance in obesity, and GH resistance in catabolic states. The pathogenesis of functional resistance involves receptor downregulation and

TABLE 317-3 *Examples of Prevalent Endocrine and Metabolic Disorders in the Adult*

Disorder	Approx. Prevalence in Adults[a]	Screening/Testing Recommendations[b]	Specific Guidelines	Chapter
Obesity	23% BMI > 30 50% BMI > 25	Calculate BMI Measure waist circumference Exclude secondary causes Consider comorbid complications	NHLBI Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity	64
Type 2 diabetes mellitus	>6%	Test every 3 years or more often in high-risk groups: Fasting plasma glucose (FPG) > 126 mg/dL Random plasma glucose > 200 mg/dL An elevated HbA1c Consider comorbid complications	Expert Committee on the Diagnosis and Classification of Diabetes Mellitus	323
Hyperlipidemia	15–20%	Cholesterol screening at least every 5 years; more often in high-risk groups Lipoprotein analysis (LDL, HDL) for increased cholesterol, CAD, diabetes Consider secondary causes	Expert Panel of the National Cholesterol Education Program (NCEP)	335
Hypothyroidism	5–10%, women 0.5–2%, men	TSH; confirm with free T_4 Screen women after age 35 and every 5 years thereafter	American Thyroid Association	320
Graves' disease	1–3%, women 0.1%, men	TSH, free T_4		320
Thyroid nodules and neoplasia	5%	Physical examination of thyroid Fine-needle aspiration biopsy	American Thyroid Association	320
Osteoporosis	5%, women 1%, men	Bone mineral density measurements in women >65 years or in postmenopausal women or men at risk Exclude secondary causes	World Health Organization National Osteoporosis Foundation	333
Hyperparathyroidism	0.1–0.5%, women > men	Serum calcium PTH, if calcium is elevated Assess comorbid conditions	NIH Consensus Conference on Diagnosis and Management of Asymptomatic Primary Hyperparathyroidism	332
Infertility	10%, couples	Investigate both members of couple Semen analysis in male Assess ovulatory cycles in female Specific tests as indicated		45
Polycystic ovarian syndrome	4–7% women	Free testosterone, DHEAS Consider comorbid conditions		326
Hirsutism	Variable	Free testosterone, DHEAS Exclude secondary causes Additional tests as indicated		44
Menopause	Median age, 51	FSH		327
Hyperprolactinemia	Common in women with amenorrhea or galactorrhea	PRL level MRI, if not medication-related		318
Erectile dysfunction	10–15%	PRL, testosterone Consider secondary causes (e.g., diabetes)		43
Gynecomastia	Common in older men	Often, no tests are indicated Consider Klinefelter syndrome Consider medications, hypogonadism, liver disease		325
Klinefelter syndrome	0.2%, men	Karyotype Testosterone		328
Turner syndrome	0.03%, women	Karyotype Consider comorbid conditions		328

[a] The prevalence of most disorders varies among ethnic groups and with aging.
[b] See individual chapters for additional information on evaluation and treatment. Early testing is indicated in patients with signs and symptoms of disease or in those at increased risk.

Note: BMI, body mass index; CAD, coronary artery disease; DHEAS, dehydroepiandrosterone; HDL, high-density lipoprotein; LDL, low-density lipoprotein. For other abbreviations, see text.

postreceptor desensitization of signaling pathways; functional forms of resistance are generally reversible.

APPROACH TO THE PATIENT

Because endocrinology interfaces with numerous physiologic systems, there is no standard endocrine history and examination. Moreover, because most glands are relatively inaccessible, the examination usually focuses on the manifestations of hormone excess or deficiency, as well as direct examination of palpable glands, such as the thyroid and gonads. For these reasons, it is important to evaluate patients in the context of their presenting symptoms, review of systems, family and social history, and exposure to medications that may affect the endocrine system. Astute clinical skills are required to detect subtle symptoms and signs suggestive of underlying endocrine disease. For example, a patient with Cushing's syndrome may manifest specific findings, such as central fat redistribution, striae, and proximal muscle weakness, in addition to features seen commonly in the general population, such as obesity, plethora, hypertension, and glucose intolerance. Similarly, the insidious onset of hypothyroidism—with mental slowing, fatigue, dry skin, and other features—can be difficult to distinguish from similar, nonspecific findings in the general population. Clinical judgment, based on knowledge of disease prevalence and pathophysiology, is required to decide when to embark on more extensive evaluation of these disorders. Laboratory testing plays an essential role in endocrinology by allowing quantitative assessment of hormone levels and dynamics. Radiologic imaging tests, such as computed tomography (CT) scan, magnetic resonance imaging (MRI), thyroid scan, and ultrasound, are also used for the diagnosis of endocrine disorders. However, these tests are generally employed only after a hormonal abnormality has been established by biochemical testing.

HORMONE MEASUREMENTS AND ENDOCRINE TESTING Radioimmunoassays are the most important diagnostic tool in endocrinology, as they allow sensitive, specific, and quantitative determination of steady-state and dynamic changes in hormone concentrations. Radioimmunoassays use antibodies to detect specific hormones. For many peptide hormones, these measurements are now configured as immunoradiometric assays (IRMAs), which use two different antibodies to increase binding affinity and specificity. There are many variations of these assays—a common format involves using one antibody to capture the antigen (hormone) onto an immobilized surface and a second antibody, labeled with a fluorescent or radioactive tag, to detect the antigen. These assays are sensitive enough to detect plasma hormone concentrations in the picomolar to nanomolar range, and they can readily distinguish structurally related proteins, such as PTH from PTHrP. A variety of other techniques are used to measure specific hormones, including mass spectroscopy, various forms of chromatography, and enzymatic methods; bioassays are now rarely used.

Most hormone measurements are based on plasma or serum samples. However, urinary hormone determinations remain useful for the evaluation of some conditions. Urinary collections over 24 h provide an integrated assessment of the production of a hormone or metabolite, many of which vary during the day. It is important to assure complete collections of 24-h urine samples; simultaneous measurement of creatinine provides an internal control for the adequacy of collection and can be used to normalize some hormone measurements. A 24-h urine free cortisol measurement largely reflects the amount of unbound cortisol, thus providing a reasonable index of biologically available hormone. Other commonly used urine determinations include: 17-hydroxycorticosteroids, 17-ketosteroids, vanillylmandelic acid (VMA), metanephrine, catecholamines, 5-hydroxyindoleacetic acid (5-HIAA), and calcium.

The value of quantitative hormone measurements lies in their correct interpretation in a clinical context. The normal range for most hormones is relatively broad, often varying by a factor of two- to tenfold. The normal ranges for many hormones are gender- and age-specific. Thus, using the correct normative database is an essential part of interpreting hormone tests. The pulsatile nature of hormones, and factors that can affect their secretion such as sleep, meals, and medications, must also be considered. Cortisol values increase fivefold between midnight and dawn; reproductive hormone levels vary dramatically during the female menstrual cycle.

For many endocrine systems, much information can be gained from basal hormone testing, particularly when different components of an endocrine axis are assessed simultaneously. For example, low testosterone and elevated LH levels suggest a primary gonadal problem, whereas a hypothalamic-pituitary disorder is likely if both LH and testosterone are low. Because TSH is a sensitive indicator of thyroid function, it is generally recommended as a first-line test for thyroid disorders. An elevated TSH level is almost always the result of primary hypothyroidism, whereas a low TSH is most often caused by thyrotoxicosis. These predictions can be confirmed by determining the free thyroxine level. Elevated calcium and PTH levels suggest hyperparathyroidism, whereas PTH is suppressed in hypercalcemia caused by malignancy or granulomatous diseases. A suppressed ACTH in the setting of hypercortisolemia, or increased urine free cortisol, is seen with hyperfunctioning adrenal adenomas.

It is not uncommon, however, for baseline hormone levels associated with pathologic endocrine conditions to overlap with the normal range. In this circumstance, dynamic testing is useful to further separate the two groups. There are a multitude of dynamic endocrine tests, but all are based on principles of feedback regulation, and most responses can be remembered based on the pathways that govern endocrine axes. *Suppression tests* are used in the setting of suspected endocrine hyperfunction. An example is the dexamethasone suppression test used to evaluate Cushing's syndrome (Chaps. 318 and 321). *Stimulation tests* are generally used to assess endocrine hypofunction. The ACTH stimulation test, for example, is used to assess the adrenal gland response in patients with suspected adrenal insufficiency. Other stimulation tests use hypothalamic-releasing factors such as TRH, GnRH, CRH, and GHRH to evaluate pituitary hormone reserve (Chap. 318). Insulin-induced hypoglycemia evokes pituitary ACTH and GH responses. Stimulation tests based on reduction or inhibition of endogenous hormones are now used infrequently. Examples include metyrapone inhibition of cortisol synthesis and clomiphene inhibition of estrogen feedback.

SCREENING AND ASSESSMENT OF COMMON ENDOCRINE DISORDERS Because many endocrine disorders are prevalent in the adult population (Table 317-3), most are diagnosed and managed by general internists, family practitioners, or other primary health care providers. The high prevalence and clinical impact of certain endocrine diseases justifies vigilance for features of these disorders during routine physical examinations; laboratory screening is indicated in selected high-risk populations.

318 DISORDERS OF THE ANTERIOR PITUITARY AND HYPOTHALAMUS

Shlomo Melmed, J. Larry Jameson

The anterior pituitary is often referred to as the "master gland" because, together with the hypothalamus, it orchestrates the complex regulatory functions of multiple other endocrine glands. The anterior pituitary gland produces six major hormones: (1) prolactin (PRL), (2) growth hormone (GH), (3) adrenocorticotropin hormone (ACTH), (4) luteinizing hormone (LH), (5) follicle-stimulating hormone (FSH), and (6) thyroid-stimulating hormone (TSH) (Table 318-1). Pituitary hormones are secreted in a pulsatile manner, reflecting stimulation by an array of specific hypothalamic releasing factors. Each of these pituitary hormones elicits specific responses in peripheral target tissues. The hormonal products of these peripheral glands, in turn, exert feedback control at the level of the hypothalamus and pituitary to modulate pituitary function (Fig. 318-1). Pituitary tumors cause characteristic hormone excess syndromes. Hormone deficiency may be inherited or acquired. Fortunately, efficacious treatments exist for the various pituitary hormone excess and deficiency syndromes. Nonetheless, these diagnoses are often elusive, emphasizing the importance of recognizing subtle clinical manifestations and performing the correct laboratory diagnostic tests. →***For discussion of disorders of the posterior pituitary, or neurohypophysis, see Chap. 319.***

ANATOMY AND DEVELOPMENT

ANATOMY The pituitary gland weighs ~600 mg and is located within the sella turcica ventral to the diaphragma sella; it comprises anatomically and functionally distinct anterior and posterior lobes. The sella is contiguous to vascular and neurologic structures, including the cavernous sinuses, cranial nerves, and optic chiasm. Thus, expanding intrasellar pathologic processes may have significant central mass effects in addition to their endocrinologic impact.

Hypothalamic neural cells synthesize specific releasing and inhibiting hormones that are secreted directly into the portal vessels of the pituitary stalk. Blood supply of the pituitary gland is derived from the superior and inferior hypophyseal arteries (Fig. 318-2). The hypothalamic-pituitary portal plexus provides the major blood source for the anterior pituitary, allowing reliable transmission of hypothalamic peptide pulses without significant systemic dilution; consequently, pituitary cells are exposed to sharp spikes of releasing factors and in turn release their hormones as discrete pulses (Fig. 318-3).

The posterior pituitary is supplied by the inferior hypophyseal arteries. In contrast to the anterior pituitary, the posterior lobe is directly innervated by hypothalamic neurons (supraopticohypophyseal and tuberohypophyseal nerve tracts) via the pituitary stalk (Chap. 319). Thus, posterior pituitary production of vasopressin (antidiuretic hormone; ADH) and oxytocin is particularly sensitive to neuronal damage by lesions that affect the pituitary stalk or hypothalamus.

PITUITARY DEVELOPMENT The embryonic differentiation and maturation of anterior pituitary cells have been elucidated in considerable detail. Pituitary development from Rathke's pouch involves a complex interplay of lineage-specific transcription factors expressed in pluripotential stem cells and gradients of locally produced growth factors (Table 318-1). The transcription factor Pit-1 determines cell-specific expression of GH, PRL, and TSH in somatotropes, lactotropes, and thyrotropes. Expression of high levels of estrogen receptors in cells that contain Pit-1 favors PRL expression, whereas thyrotrope embronic factor (TEF) induces TSH expression. Pit-1 binds to GH, PRL, and TSH gene regulatory elements, as well as to recognition sites on its own promoter, providing a mechanism for perpetuating selective pituitary phenotypic stability. The transcription factor Prop-1 induces the pituitary development of Pit-1-specific lineages, as well as gonadotropes. Gonadotrope cell development is further defined by the cell-specific expression of the nuclear receptors, steroidogenic factor (SF-1) and DAX-1. Development of corticotrope cells, which express the proopiomelanocortin (POMC) gene, requires corticotropin upstream transcription element (CUTE) and the PTX-1 transcription factor. Abnormalities of pituitary development caused by mutations of Pit-1, Prop-1, SF-1, and DAX-1 result in a series of rare, selective or combined, pituitary hormone deficits.

TABLE 318-1 *Anterior Pituitary Hormone Expression and Regulation*

Cell	*Corticotrope*	*Somatotrope*	*Lactotrope*	*Thyrotrope*	*Gonadotrope*
Tissue-specific transcription factor	PTX-1, CUTE	Prop-1, Pit-1	Prop-1, Pit-1	Prop-1, Pit-1, TEF	SF-1, DAX-1
Fetal appearance	6 weeks	8 weeks	12 weeks	12 weeks	12 weeks
Hormone	POMC	GH	PRL	TSH	FSH LH
Chromosomal locus	2p	17q	6	α −6q; β-1p	β-11p; β-19q
Protein	Polypeptide	Polypeptide	Polypeptide	Glycoprotein α, β subunits	Glycoprotein α, β subunits
Amino acids	266 (ACTH 1–39)	191	199	211	210 204
Stimulators	CRH, AVP, gp-130 cytokines	GHRH, GHRP	Estrogen, TRH, VIP	TRH	GnRH, activins, estrogen
Inhibitors	Glucocorticoids	Somatostatin, IGF-I	Dopamine	T_3, T_4, dopamine, somatostatin, glucocorticoids	Sex steroids, inhibin
Target gland	Adrenal	Liver, other tissues	Breast, other tissues	Thyroid	Ovary, testis
Trophic effect	Steroid production	IGF-I production, growth induction, insulin antagonism	Milk production	T_4 synthesis and secretion	Sex steroid production, follicle growth, germ cell maturation
Normal range	ACTH, 4–22 pg/L	<0.5 μg/L[a]	M < 15; F <20 μg/L	0.1–5 mU/L	M, 5–20 IU/L, F (basal), 5–20 IU/L

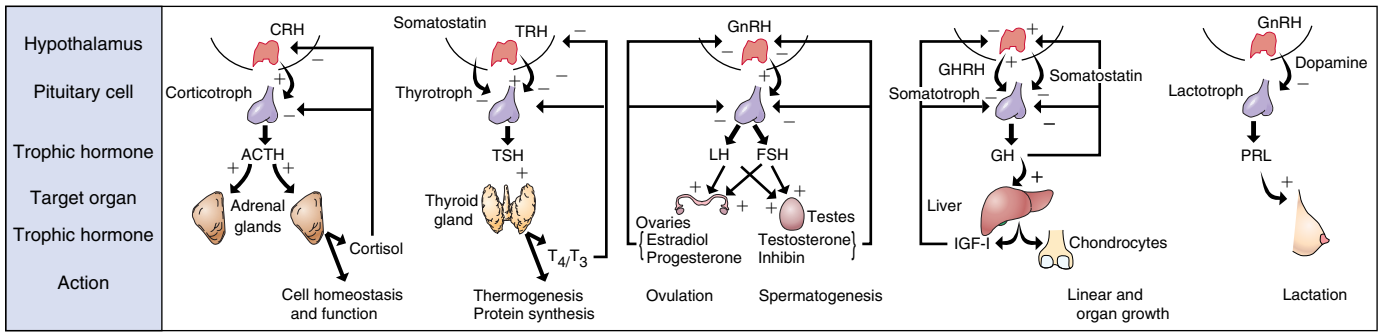

FIGURE 318-1 Diagram of pituitary axes. Hypothalamic hormones regulate anterior pituitary trophic hormones that, in turn, determine target gland secretion. Peripheral hormones feed back to regulate hypothalamic and pituitary hormones. For abbreviations, see text.

HYPOTHALAMIC AND ANTERIOR PITUITARY INSUFFICIENCY

Hypopituitarism results from impaired production of one or more of the anterior pituitary trophic hormones. Reduced pituitary function can result from inherited disorders; more commonly, it is acquired and reflects the mass effects of tumors or the consequences of inflammation or vascular damage. These processes may also impair synthesis or secretion of hypothalamic hormones, with resultant pituitary failure (Table 318-2).

DEVELOPMENTAL AND GENETIC CAUSES OF HYPOPITUITARISM ■ Pituitary Dysplasia Pituitary dysplasia may result in aplastic, hypoplastic, or ectopic pituitary gland development. Because pituitary development requires midline cell migration from the nasopharyngeal Rathke's pouch, midline craniofacial disorders may be associated with pituitary dysplasia. Acquired pituitary failure in the newborn can also be caused by birth trauma, including cranial hemorrhage, asphyxia, and breech delivery.

SEPTO-OPTIC DYSPLASIA Hypothalamic dysfunction and hypopituitarism may result from dysgenesis of the septum pellucidum or corpus callosum. Affected children have mutations in the *HESX1* gene, which is involved in early development of the ventral prosencephalon. These children exhibit variable combinations of cleft palate, syndactyly, ear deformities, hypertelorism, optic atrophy, micropenis, and anosmia. Pituitary dysfunction leads to diabetes insipidus, GH deficiency and short stature, and, occasionally, TSH deficiency.

Tissue-Specific Factor Mutations Several pituitary cell–specific transcription factors, such as Pit-1 and Prop-1, are critical for determining the development and function of specific anterior pituitary cell lineages. Autosomal dominant or recessive Pit-1 mutations cause combined GH, PRL, and TSH deficiencies. These patients present with growth failure and varying degrees of hypothyroidism. The pituitary may appear hypoplastic on magnetic resonance imaging (MRI).

Prop-1 is expressed early in pituitary development and appears to be required for Pit-1 function. Familial and sporadic *PROP1* mutations result in combined GH, PRL, TSH, and gonadotropin deficiency, with preservation of ACTH. Over 80% of these patients have growth retardation and, by adulthood, all are deficient in TSH and gonadotropins. Because of gonadotropin deficiency, they do not enter puberty spontaneously. In some cases, the pituitary gland is enlarged.

Developmental Hypothalamic Dysfunction ■ *KALLMANN SYNDROME* This syndrome results from defective hypothalamic gonadotropin-releasing hormone (GnRH) synthesis and is associated with anosmia or hyposmia due to olfactory bulb agenesis or hypoplasia (Chap. 325). The syndrome may also be associated with color blindness, optic atrophy, nerve deafness, cleft palate, renal abnormalities, cryptorchidism, and neurologic abnormalities such as mirror movements. Defects in the *KAL* gene, which maps to chromosome Xp22.3, prevent embryonic migration of GnRH neurons from the hypothalamic olfactory placode to the hypothalamus. Genetic abnormalities, in addition to *KAL* mutations, can also cause isolated GnRH deficiency, as autosomal recessive and dominant modes of transmission have been described. GnRH deficiency prevents progression through puberty. Males present with delayed puberty and pronounced hypogonadal features, including micropenis, probably the result of low testosterone levels during infancy. Female patients present with primary amenorrhea and failure of secondary sexual development.

Kallmann syndrome and other causes of congenital GnRH deficiency are characterized by low LH and FSH levels and low concentrations of sex steroids (testosterone or estradiol). In sporadic cases of isolated gonadotropin deficiency, the diagnosis is often one of exclusion after eliminating other causes of hypothalamic-pituitary dysfunction. Repetitive GnRH administration restores normal pituitary gonadotropin responses, pointing to a hypothalamic defect.

Long-term treatment of males with human chorionic gonadotropin

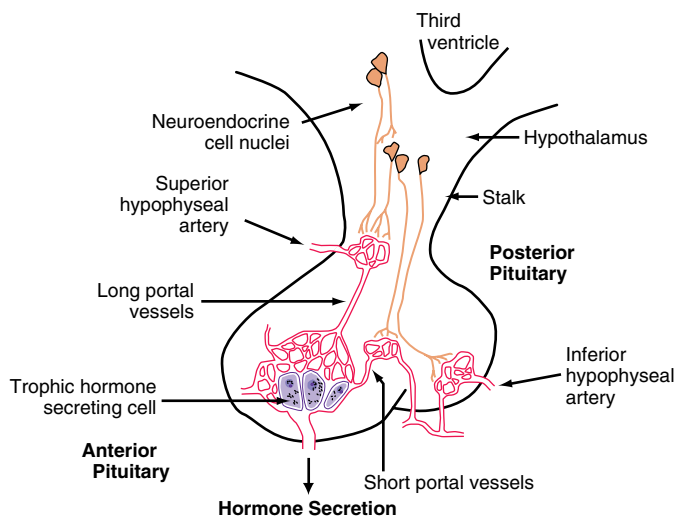

FIGURE 318-2 Diagram of hypothalamic-pituitary vasculature: The hypothalamic nuclei produce hormones that traverse the portal system and impinge on anterior pituitary cells to regulate pituitary hormone secretion. Posterior pituitary hormones are derived from direct neural extensions.

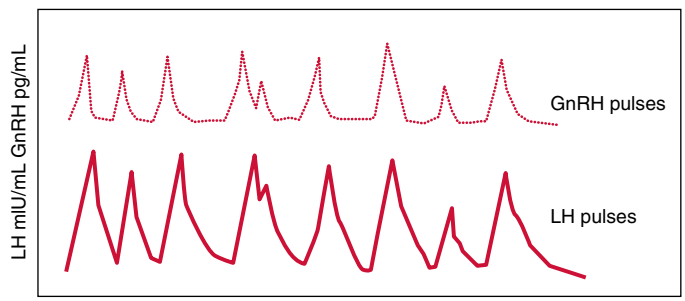

FIGURE 318-3 Hypothalamic gonadotropin-releasing hormone (GnRH) pulses induce secretory pulses of luteinizing hormone (LH).

TABLE 318-2 Etiology of Hypopituitarism[a]

Development/structural
Transcription factor defect
Pituitary dysplasia/aplasia
Congenital CNS mass, encephalocele
Primary empty sella
Congenital hypothalamic disorders (septo-optic dysplasia, Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, Kallmann syndrome)
Traumatic

Arteritis
Infections
Fungal (histoplasmosis)
Parasitic (toxoplasmosis)
Tuberculosis
Pneumocystis carinii

[a] Trophic hormone failure associated with pituitary compression or destruction usually occurs sequentially GH > FSH > LH > TSH > ACTH. During childhood, growth retardation is often the presenting feature, and in adults hypogonadism is the earliest symptom.

(hCG) or testosterone restores pubertal development and secondary sex characteristics; females can be treated with cyclic estrogen and progestin. Fertility may also be restored by the administration of gonadotropins or by using a portable infusion pump to deliver subcutaneous, pulsatile GnRH.

LAURENCE-MOON-BARDET-BIEDL SYNDROME This rare autosomal recessive disorder is characterized by mental retardation; obesity; and hexadactyly, brachydactyly, or syndactyly. Central diabetes insipidus may or may not be associated. GnRH deficiency occurs in 75% of males and half of affected females. Retinal degeneration begins in early childhood, and most patients are blind by age 30.

FRÖHLICH SYNDROME (ADIPOSE GENITAL DYSTROPHY) A broad spectrum of hypothalamic lesions may be associated with hyperphagia, obesity, and central hypogonadism. Decreased GnRH production in these patients results in attenuated pituitary FSH and LH synthesis and release. Deficiencies of leptin, or its receptor, cause these clinical features (Chap. 64).

Prader-Willi Syndrome Chromosome 15q deletions are associated with hypogonadotropic hypogonadism, hyperphagia-obesity, chronic muscle hypotonia, mental retardation, and adult-onset diabetes mellitus (Chap. 57). Multiple somatic defects also involve the skull, eyes, ears, hands, and feet. Diminished hypothalamic oxytocin- and vasopressin-producing nuclei have been reported. Deficient GnRH synthesis is suggested by the observation that chronic GnRH treatment restores pituitary LH and FSH release.

ACQUIRED HYPOPITUITARISM Hypopituitarism may be caused by accidental or neurosurgical trauma; vascular events such as apoplexy; pituitary or hypothalamic neoplasms such as pituitary adenomas, craniopharyngiomas, or metastatic tumors; inflammatory disease such as lymphocytic hypophysitis; infiltrative disorders such as sarcoidosis, hemochromatosis (Chap. 336), and tuberculosis; or irradiation.

Hypothalamic Infiltration Disorders These disorders—including sarcoidosis, histiocytosis X, amyloidosis, and hemochromatosis—frequently involve both hypothalamic and pituitary neuronal and neurochemical tracts. Consequently, diabetes insipidus occurs in half of patients with these disorders. Growth retardation is seen if attenuated GH secretion occurs before pubertal epiphyseal closure. Hypogonadotropic hypogonadism and hyperprolactinemia are also common.

Inflammatory Lesions Pituitary damage and subsequent dysfunction can be seen with chronic infections such as tuberculosis, opportunistic fungal infections associated with AIDS, and in tertiary syphilis. Other inflammatory processes, such as granulomas or sarcoidosis, may mimic a pituitary adenoma. These lesions may cause extensive hypothalamic and pituitary damage, leading to trophic hormone deficiencies.

Cranial Irradiation Cranial irradiation may result in long-term hypothalamic and pituitary dysfunction, especially in children and adolescents, as they are more susceptible to damage following whole-brain or head and neck therapeutic irradiation. The development of hormonal abnormalities correlates strongly with irradiation dosage and the time interval after completion of radiotherapy. Up to two-thirds of patients ultimately develop hormone insufficiency afer a median dose of 50 Gy (5000 rad) directed at the skull base. The development of hypopituitarism occurs over 5 to 15 years and usually reflects hypothalamic damage rather than absolute destruction of pituitary cells. Though the pattern of hormone loss is variable, GH deficiency is most common, followed by gonadotropin and ACTH deficiency. When deficiency of one or more hormones is documented, the possibility of diminished reserve of other hormones is likely. Accordingly, anterior pituitary function should be evaluated over the long term in previously irradiated patients, and replacement therapy instituted when appropriate (see below).

Lymphocytic Hypophysitis This occurs mainly in pregnant or post-partum women; it usually presents with hyperprolactinemia and MRI evidence of a prominent pituitary mass resembling an adenoma, with mildly elevated PRL levels. Pituitary failure caused by diffuse lymphocytic infiltration may be transient or permanent but requires immediate evaluation and treatment. Rarely, isolated pituitary hormone deficiencies have been described, suggesting a selective autoimmune process targeted to specific cell types. Most patients manifest symptoms of progressive mass effects with headache and visual disturbance. The erythrocyte sedimentation rate is often elevated. As the MRI image may be indistinguishable from that of a pituitary adenoma, hypophysitis should be considered in a post-partum woman with a newly diagnosed pituitary mass before embarking on unnecessary surgical intervention. The inflammatory process often resolves after several months of glucocorticoid treatment, and pituitary function may be restored, depending on the extent of damage.

Pituitary Apoplexy Acute intrapituitary hemorrhagic vascular events can cause substantial damage to the pituitary and surrounding sellar structures. Pituitary apoplexy may occur spontaneously in a preexisting adenoma (usually nonfunctioning); postpartum (Sheehan's syndrome); or in association with diabetes, hypertension, sickle cell anemia, or acute shock. The hyperplastic enlargement of the pituitary during pregnancy increases the risk for hemorrhage and infarction. Apoplexy is an endocrine emergency that may result in severe hypoglycemia, hypotension, central nervous system (CNS) hemorrhage, and death. Acute symptoms may include severe headache with signs of meningeal irritation, bilateral visual changes, ophthalmoplegia, and, in severe cases, cardiovascular collapse and loss of consciousness. Pituitary computed tomography (CT) or MRI may reveal signs of intratumoral or sellar hemorrhage, with deviation of the pituitary stalk and compression of pituitary tissue.

Patients with no evident visual loss or impaired consciousness can be observed and managed conservatively with high-dose glucocorticoids. Those with significant or progressive visual loss or loss of consciousness require urgent surgical decompression. Visual recovery after surgery is inversely correlated with the length of time after the acute event. Therefore, severe ophthalmoplegia or visual deficits are indications for early surgery. Hypopituitarism is very common after apoplexy.

Empty Sella A partial or apparently totally empty sella is often an incidental MRI finding. These patients usually have normal pituitary function, implying that the surrounding rim of pituitary tissue is fully functional. Hypopituitarism, however, may develop insidiously. Pituitary masses may undergo clinically silent infarction with development of a partial or totally empty sella by cerebrospinal fluid (CSF) filling the dural herniation. Rarely, functional pituitary adenomas may arise within the rim of pituitary tissue, and these are not always visible on MRI.

PRESENTATION AND DIAGNOSIS The clinical manifestations of hypopituitarism depend on which hormones are lost and the extent of the hormone deficiency. GH deficiency causes growth disorders in children and leads to abnormal body composition in adults (see below). Gonadotropin deficiency causes menstrual disorders and infertility in women and decreased sexual function, infertility, and loss of secondary sexual characteristics in men. TSH and ACTH deficiency usually develop later in the course of pituitary failure. TSH deficiency causes growth retardation in children and features of hypothyroidism in children and in adults. The secondary form of adrenal insufficiency caused by ACTH deficiency leads to hypocortisolism with relative preservation of mineralocorticoid production. PRL deficiency causes failure of lactation. When lesions involve the posterior pituitary, polyuria and polydipsia reflect loss of vasopressin secretion. Epidemiologic studies have documented an increased mortality rate in patients with long-standing pituitary damage, primarily from increased cardiovascular and cerebrovascular disease.

LABORATORY INVESTIGATION Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of trophic hormones in the setting of low target hormone levels. For example, low free thyroxine in the setting of a low or inappropriately normal TSH level suggests secondary hypothyroidism. Similarly, a low testosterone level without elevation of gonadotropins suggests hypogonadotropic hypogonadism. Provocative tests may be required to assess pituitary reserve (Table 318-3). GH responses to insulin-induced hypoglycemia, arginine, L-dopa, growth hormone–releasing hormone (GHRH), or growth hormone–releasing peptides (GHRPs) can be used to assess GH reserve. PRL and TSH responses to thyrotropin-releasing hormone (TRH) reflect lactotrope and thyrotrope function. Corticotropin-

TABLE 318-3 *Tests of Pituitary Insufficiency*

Hormone	*Test*	*Blood Samples*	*Interpretation*
Growth hormone	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg IV)	−30, 0, 30, 60, 120 min for glucose and GH	Glucose < 40 mg/dL; GH should be >3 μg/L
	GHRH test: 1 μg/kg IV	0, 15, 30, 45, 60, 120 min for GH	Normal response is GH >3 μg/L
	L-Arginine test: 30 g IV over 30 min	0, 30, 60, 120 min for GH	Normal response is GH >3 μg/L
	L-dopa test: 500 mg PO	0, 30, 60, 120 min for GH	Normal response is GH >3 μg/L
Prolactin	TRH test: 200–500 μg IV	0, 20, and 60 min for TSH and PRL	Normal prolactin is >2 μg/L and increase >200% of baseline
ACTH	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg IV)	−30, 0, 30, 60, 90 min for glucose and cortisol	Glucose <40 mg/dL Cortisol should increase by >7 μg/dL or to >20 μg/dL
	CRH test: 1 μg/kg ovine CRH IV at 0800 h	0, 15, 30, 60, 90, 120 min for ACTH and cortisol	Basal ACTH increases 2- to 4-fold and peaks at 20–100 pg/mL Cortisol levels >20–25 μg/dL
	Metyrapone test: Metyrapone (30 mg/kg) at midnight	Plasma 11-deoxycortisol and cortisol at 8 A.M.; ACTH can also be measured	Plasma cortisol should be <4 μg/dL to assure an adequate response Normal response is 11-deoxycortisol >7.5 μg/dL or ACTH >75 pg/mL
	Standard ACTH stimulation test: ACTH 1-24 (Cosyntropin), 0.25 mg IM or IV	0, 30, 60 min for cortisol and aldosterone	Normal response is cortisol >21 μg/dL and aldosterone response of >4 ng/dL above baseline
	Low-dose ACTH test: ACTH 1-24 (Cosyntropin), 1 μg IV	0, 30, 60 min for cortisol	Cortisol should be >21 μg/dL
	3-day ACTH stimulation test consists of 0.25 mg ACTH 1-24 given IV over 8 h each day		Cortisol >21 μg/dL
TSH	Basal thyroid function tests: T_4, T_3, TSH	Basal tests	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased
	TRH test: 200–500 μg IV	0, 20, 60 min for TSH and PRL	TSH should increase by >5 mU/L unless thyroid hormone levels are increased
LH, FSH	LH, FSH, testosterone, estrogen	Basal tests	Basal LH and FSH should be increased in postmenopausal women Low testosterone levels in the setting of low LH and FSH
	GnRH test: GnRH (100 μg) IV	0, 30, 60 min for LH and FSH	In most adults, LH should increase by 10 IU/L and FSH by 2 IU/L Normal responses are variable
Multiple hormones	Combined anterior pituitary test: GHRH (1 μg/kg), CRH (1 μg/kg), GnRH (100 μg), TRH (200 μg) are given IV	−30, 0, 15, 30, 60, 90, 120 min for GH, ACTH, cortisol, LH, FSH, and TSH	Combined or individual releasing hormone responses must be elevated in the context of basal target gland hormone values and may not be diagnostic (see text)

Note: For abbreviations, see text.

TABLE 318-4 *Hormone Replacement Therapy for Adult Hypopituitarism*[a]

Trophic Hormone Deficit	Hormone Replacement
ACTH	Hydrocortisone (10–20 mg A.M.; 10 mg P.M.) Cortisone acetate (25 mg A.M.; 12.5 mg P.M.) Prednisone (5 mg A.M.; 2.5 mg P.M.)
TSH	L-Thyroxine (0.075–0.15 mg daily)
FSH/LH	Males Testosterone enanthate (200 mg IM every 2 weeks) Testosterone skin patch (5 mg/d) Females Conjugated estrogen (0.65–1.25 mg qd for 25 days) Progesterone (5–10 mg qd) on days 16–25 Estradiol skin patch (0.5 mg, every other day) For fertility: Menopausal gonadotropins, human chorionic gonadotropins
GH	Adults: Somatotropin (0.3–1.0 mg SC qd) Children: Somatotropin [0.02–0.05 (mg/kg per day)]
Vasopressin	Intranasal desmopressin (5–20 μg twice daily) Oral 300–600 μg qd

[a] All doses shown should be individualized for specific patients and should be reassessed during stress, surgery, or pregnancy. Male and female fertility requirements should be managed as discussed in Chap. 45.
Note: For abbreviations, see text.

releasing hormone (CRH) administration induces ACTH release, and administration of synthetic ACTH (cortrosyn) evokes adrenal cortisol release as an indirect indicator of pituitary ACTH reserve (Chap. 321). ACTH reserve is most reliably assessed during insulin-induced hypoglycemia. However, this test should be performed cautiously in patients with suspected adrenal insufficiency because of increased risk of hypoglycemia and hypotension. Insulin-induced hypoglycemia is contraindicated in patients with coronary heart disease or seizure disorders.

TREATMENT

Hormone replacement therapy, including glucocorticoids, thyroid hormone, sex steroids, growth hormone, and vasopressin, is usually free of complications. Treatment regimens that mimic physiologic hormone production allow for maintenance of satisfactory clinical homeostasis. Effective dosage schedules are outlined in Table 318-4. Patients in need of glucocorticoid replacement require careful dose adjustments during stressful events such as acute illness, dental procedures, trauma, and acute hospitalization (Chap. 321).

HYPOTHALAMIC, PITUITARY, AND OTHER SELLAR MASSES

PITUITARY TUMORS Pituitary adenomas are the most common cause of pituitary hormone hypersecretion and hyposecretion syndromes in adults. They account for ~10% of all intracranial neoplasms. At autopsy, up to a quarter of all pituitary glands harbor an unsuspected microadenoma (<10 mm diameter). Similarly, pituitary imaging detects small pituitary lesions in at least 10% of normal individuals.

Pathogenesis Pituitary adenomas are benign neoplasms that arise from one of the five anterior pituitary cell types. The clinical and biochemical phenotype of pituitary adenomas depend on the cell type from which they are derived. Thus, tumors arising from lactotrope (PRL), somatotrope (GH), corticotrope (ACTH), thyrotrope (TSH), or gonadotrope (LH, FSH) cells hypersecrete their respective hormones (Table 318-5). Plurihormonal tumors that express combinations of GH, PRL, TSH, ACTH, and the glycoprotein hormone α subunit may be diagnosed by careful immunocytochemistry or may manifest as clinical syndromes that combine features of these hormonal hypersecretory syndromes. Morphologically, these tumors may arise from a single polysecreting cell type or consist of cells with mixed function within the same tumor.

Hormonally active tumors are characterized by autonomous hormone secretion with diminished responsiveness to the normal physiologic pathways of inhibition. Hormone production does not always correlate with tumor size. Small hormone-secreting adenomas may cause significant clinical perturbations, whereas larger adenomas that produce less hormone may be clinically silent and remain undiagnosed (if no central compressive effects occur). About one-third of all adenomas are clinically nonfunctioning and produce no distinct clinical hypersecretory syndrome. Most of these arise from gonadotrope cells and may secrete small amounts of α- and β-glycoprotein hormone subunits or, very rarely, intact circulating gonadotropins. True pituitary carcinomas with documented extracranial metastases are exceedingly rare.

Almost all pituitary adenomas are monoclonal in origin, implying the acquisition of one or more somatic mutations that confer a selective growth advantage. In addition to direct studies of oncogene mutations, this idea is supported by X-chromosomal inactivation analyses of tumors in female patients heterozygous for X-linked genes. Consistent with their clonal origin, complete surgical resection of small pituitary adenomas usually cures hormone hypersecretion. Nevertheless, hypothalamic hormones, such as GHRH or CRH, also enhance the mitotic activity of their respective pituitary target cells, in addition to their role in pituitary hormone regulation. Thus, patients harboring rare abdominal or chest tumors elaborating ectopic GHRH or CRH may present with somatotrope or corticotrope hyperplasia.

Several etiologic genetic events have been implicated in the development of pituitary tumors. The pathogenesis of sporadic forms of acromegaly has been particularly informative as a model of tumorigenesis. GHRH, after binding to its G protein–coupled somatotrope receptor, utilizes cyclic AMP as a second messenger to stimulate GH secretion and somatotrope proliferation. A subset (~35%) of GH-secreting pituitary tumors contain sporadic mutations in Gsα (Arg 201 → Cys or His; Gln 227 → Arg). These mutations inhibit intrinsic GTPase activity, resulting in constitutive elevation of cyclic AMP, Pit-1 induction, and activation of cyclic AMP response element binding protein (CREB), thereby promoting somatotrope cell proliferation.

TABLE 318-5 *Classification of Pituitary Adenomas*[a]

Adenoma Cell Origin	Hormone Product	Clinical Syndrome
Lactotrope	PRL	Hypogonadism, galactorrhea
Gonadotrope	FSH, LH, subunits	Silent or hypogonadism
Somatotrope	GH	Acromegaly/ gigantism
Corticotrope	ACTH	Cushing's disease
Mixed growth hormone and prolactin cell	GH, PRL	Acromegaly, hypogonadism, galactorrhea
Other plurihormonal cell	Any	Mixed
Acidophil stem cell	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Mammosomatotrope	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Thyrotrope	TSH	Thyrotoxicosis
Null cell	None	Pituitary failure
Oncocytoma	None	Pituitary failure

[a] Hormone-secreting tumors are listed in decreasing order of frequency. All tumors may cause local pressure effects, including visual disturbances, cranial nerve palsy, and headache.
Note: For abbreviations, see text.
Source: Adapted from S Melmed, in JL Jameson (ed): *Principles of Molecular Medicine*, Totowa, Humana Press, 1998.

Characteristic loss of heterozygosity (LOH) in various chromosomes has been documented in large or invasive macroadenomas, suggesting the presence of putative tumor suppressor genes at these loci. LOH of chromosome region on 11q13, 13, and 9 is present in up to 20% of sporadic pituitary tumors including GH-, PRL-, and ACTH-producing adenomas and in some nonfunctioning tumors.

Compelling evidence also favors growth factor promotion of pituitary tumor proliferation. Basic fibroblast growth factor (bFGF) is abundant in the pituitary and has been shown to stimulate pituitary cell mitogenesis. Other factors involved in initiation and promotion of pituitary tumors include loss of negative-feedback inhibition (as seen with primary hypothyroidism or hypogonadism) and estrogen-mediated or paracrine angiogenesis. Growth characteristics and neoplastic behavior may also be influenced by several activated oncogenes, including *RAS* and pituitary tumor transforming gene (*PTTG*).

Genetic Syndromes Associated with Pituitary Tumors Several familial syndromes are associated with pituitary tumors, and the genetic mechanisms for some of these have been unraveled.

Multiple endocrine neoplasia (MEN) 1 is an autosomal dominant syndrome characterized primarily by a genetic predisposition to parathyroid, pancreatic islet, and pituitary adenomas (Chap. 330). MEN1 is caused by inactivating germline mutations in *MENIN*, a constitutively expressed tumor-suppressor gene located on chromosome 11q13. Loss of heterozygosity, or a somatic mutation of the remaining normal *MENIN* allele, leads to tumorigenesis. About half of affected patients develop prolactinomas; acromegaly and Cushing's syndrome are less commonly encountered.

Carney syndrome is characterized by spotty skin pigmentation, myxomas, and endocrine tumors including testicular, adrenal, and pituitary adenomas. Acromegaly occurs in about 20% of patients. A subset of patients have mutations in the R1α regulatory subunit of protein kinase A (*PRKAR1A*).

McCune-Albright syndrome consists of polyostotic fibrous dysplasia, pigmented skin patches, and a variety of endocrine disorders, including GH-secreting pituitary tumors, adrenal adenomas, and autonomous ovarian function (Chap. 326). Hormonal hypersecretion is due to constitutive cyclic AMP production caused by inactivation of the GTPase activity of Gsα. The Gsα mutations occur postzygotically, leading to a mosaic pattern of mutant expression.

Familial acromegaly is a rare disorder in which family members may manifest either acromegaly or gigantism. The disorder is associated with LOH at a chromosome 11q13 locus distinct from that of *MENIN*.

OTHER SELLAR MASSES *Craniopharyngiomas* are derived from Rathke's pouch. They arise near the pituitary stalk and commonly extend into the suprasellar cistern. These tumors are often large, cystic, and locally invasive. Many are partially calcified, providing a characteristic appearance on skull x-ray and CT images. More than half of all patients present before age 20, usually with signs of increased intracranial pressure, including headache, vomiting, papilledema, and hydrocephalus. Associated symptoms include visual field abnormalities, personality changes and cognitive deterioration, cranial nerve damage, sleep difficulties, and weight gain. Anterior pituitary dysfunction and diabetes insipidus are common. About half of affected children present with growth retardation.

Treatment usually involves transcranial or transsphenoidal surgical resection followed by postoperative radiation of residual tumor. This approach can result in long-term survival and ultimate cure, but most patients require lifelong pituitary hormone replacement. If the pituitary stalk is uninvolved and can be preserved at the time of surgery, the incidence of subsequent anterior pituitary dysfunction is significantly diminished.

Developmental failure of Rathke's pouch obliteration may lead to *Rathke's cysts*, which are small (<5 mm) cysts entrapped by squamous epithelium; these cysts are found in about 20% of individuals at autopsy. Although Rathke's cleft cysts do not usually grow and are often diagnosed incidentally, about a third present in adulthood with compressive symptoms, diabetes insipidus, and hyperprolactinemia due to stalk compression. Rarely, internal hydrocephalus develops. The diagnosis is suggested preoperatively by visualizing the cyst wall on MRI, which distinguishes these lesions from craniopharyngiomas. Cyst contents range from CSF-like fluid to mucoid material. *Arachnoid cysts* are rare and generate an MRI image isointense with cerebrospinal fluid.

Sella chordomas usually present with bony clival erosion, local invasiveness, and, on occasion, calcification. Normal pituitary tissue may be visible on MRI, distinguishing chordomas from aggressive pituitary adenomas. Mucinous material may be obtained by fine-needle aspiration.

Meningiomas arising in the sellar region may be difficult to distinguish from nonfunctioning pituitary adenomas. Meningiomas typically enhance on MRI and may show evidence of calcification or bony erosion. Meningiomas may cause compressive symptoms.

Histiocytosis X comprises a variety of syndromes associated with foci of eosinophilic granulomas. Diabetes insipidus, exophthalmos, and punched-out lytic bone lesions (*Hand-Schüller-Christian disease*) are associated with granulomatous lesions visible on MRI, as well as a characteristic axillary skin rash. Rarely, the pituitary stalk may be involved.

Pituitary metastases occur in ~3% of cancer patients. Blood-borne metastatic deposits are found almost exclusively in the posterior pituitary. Accordingly, diabetes insipidus can be a presenting feature of lung, gastrointestinal, breast, and other pituitary metastases. About half of pituitary metastases originate from breast cancer; about 25% of patients with breast cancer have such deposits. Rarely, pituitary stalk involvement results in anterior pituitary insufficiency. The MRI diagnosis of a metastatic lesion may be difficult to distinguish from an aggressive pituitary adenoma; the diagnosis may require histologic examination of excised tumor tissue. Primary or metastatic lymphoma, leukemias, and plasmacytomas also occur within the sella.

Hypothalamic hamartomas and *gangliocytomas* may arise from astrocytes, oligodendrocytes, and neurons with varying degrees of differentiation. These tumors may overexpress hypothalamic neuropeptides including GnRH, GHRH, or CRH. In GnRH-producing tumors, children present with precocious puberty, psychomotor delay, and laughing-associated seizures. Medical treatment of GnRH-producing hamartomas with long-acting GnRH analogues effectively suppresses gonadotropin secretion and controls premature pubertal development. Rarely, hamartomas are also associated with craniofacial abnormalities; imperforate anus; cardiac, renal, and lung disorders; and pituitary failure (*Pallister-Hall syndrome*). Hypothalamic hamartomas are often contiguous with the pituitary, and preoperative MRI diagnosis may not be possible. Histologic evidence of hypothalamic neurons in tissue resected at transsphenoidal surgery may be the first indication of a primary hypothalamic lesion.

Hypothalamic gliomas and *optic gliomas* occur mainly in childhood and usually present with visual loss. Adults have more aggressive tumors; about a third are associated with neurofibromatosis.

Brain germ-cell tumors may arise within the sellar region. These include *dysgerminomas*, which are frequently associated with diabetes insipidus and visual loss. They rarely metastasize. *Germinomas*, *embryonal carcinomas*, *teratomas*, and *choriocarcinomas* may arise in the parasellar region and produce hCG. These germ-cell tumors present with precocious puberty, diabetes insipidus, visual field defects, and thirst disorders. Many patients are GH-deficient with short stature.

METABOLIC EFFECTS OF HYPOTHALAMIC LESIONS Lesions involving the anterior and preoptic hypothalamic regions cause paradoxical vasoconstriction, tachycardia, and hyperthermia. Acute hyperthermia is usually due to a hemorrhagic insult, but poikilothermia may also occur. Central disorders of thermoregulation result from posterior hypothalamic damage. The *periodic hypothermia syndrome* comprises episodic attacks of rectal temperatures <30°C, sweating, vasodilation, vomiting, and bradycardia (Chap. 19). Damage to the ventromedial nuclei by

craniopharyngiomas, hypothalamic trauma, or inflammatory disorders may be associated with *hyperphagia* and *obesity*. This region appears to contain an energy-satiety center where melanocortin receptors are influenced by leptin, insulin, POMC products, and gastrointestinal peptides (Chap. 64). Hypothalamic gliomas in early childhood may be associated with a diencephalic syndrome characterized by progressive severe emaciation and growth failure. Polydipsia and hypodipsia are associated with damage to central osmo-receptors located in preoptic nuclei (Chap. 319). Slow-growing hypothalamic lesions can cause increased somnolence and disturbed sleep cycles as well as obesity, hypothermia, and emotional outbursts. Lesions of the central hypothalamus may stimulate sympathetic neurons, leading to elevated serum catecholamine and cortisol levels. These patients are predisposed to cardiac arrhythmias, hypertension, and gastric erosions.

EVALUATION ■ Local Mass Effects Clinical manifestations of sellar lesions vary, depending on the anatomic location of the mass and direction of its extension (Table 318-6). The dorsal roof of the sella presents the least resistance to soft tissue expansion from within the confines of the sella; consequently, pituitary adenomas frequently extend in a suprasellar direction. Bony invasion may ultimately occur as well.

Headaches are common features of small intrasellar tumors, even with no demonstrable suprasellar extension. Because of the confined nature of the pituitary, small changes in intrasellar pressure stretch the dural plate; however, the severity of the headache correlates poorly with adenoma size or extension.

Suprasellar extension can lead to visual loss by several mechanisms, the most common being compression of the optic chiasm, but direct invasion of the optic nerves or obstruction of CSF flow leading to secondary visual disturbances also occurs. Pituitary stalk compression by a hormonally active or inactive intrasellar mass may compress the portal vessels, disrupting pituitary access to the hypothalamic hormones and dopamine; this results in hyperprolactinemia and concurrent loss of other pituitary hormones. This "stalk section" phenomenon may also be caused by trauma, whiplash injury with posterior clinoid stalk compression, or skull base fractures. Lateral mass invasion may impinge on the cavernous sinus and compress its neural contents, leading to cranial nerve III, IV, and VI palsies as well as effects on the ophthalmic and maxillary branches of the fifth cranial nerve (Chap. 355). Patients may present with diplopia, ptosis, ophthalmoplegia, and decreased facial sensation, depending on the extent of neural damage. Extension into the sphenoid sinus indicates that the pituitary mass has eroded through the sellar floor. Aggressive tumors rarely invade the palate roof and cause nasopharyngeal obstruction, infection, and CSF leakage. Both temporal and frontal lobes may be invaded, leading to uncinate seizures, personality disorders, and anosmia. Direct hypothalamic encroachment by an invasive pituitary mass may cause important metabolic sequelae, precocious puberty or hypogonadism, diabetes insipidus, sleep disturbances, dysthermia, and appetite disorders.

TABLE 318-6 *Features of Sellar Mass Lesions*[a]

Impacted Structure	*Clinical Impact*
Pituitary	Hypogonadism
	Hypothyroidism
	Growth failure and adult hyposomatotropism
	Hypoadrenalism
Optic chiasm	Loss of red perception
	Bitemporal hemianopia
	Superior or bitemporal field defect
	Scotoma
	Blindness
Hypothalamus	Temperature dysregulation
	Appetite and thirst disorders
	Obesity
	Diabetes insipidus
	Sleep disorders
	Behavioral dysfunction
	Autonomic dysfunction
Cavernous sinus	Opthalmoplegia ± ptosis or diplopia
	Facial numbness
Frontal lobe	Personality disorder
	Anosmia
Brain	Headache
	Hydrocephalus
	Psychosis
	Dementia
	Laughing seizures

[a] As the intrasellar mass expands, it first compresses intrasellar pituitary tissue, then usually invades dorsally through the dura to lift the optic chiasm or laterally to the cavernous sinuses. Bony erosion is rare, as is direct brain compression. Microadenomas may present with headache.

MRI Sagittal and coronal T1-weighted spin-echo MRI imaging, before and after administration of gadolinium, allow precise visualization of the pituitary gland with clear delineation of the hypothalamus, pituitary stalk, pituitary tissue and surrounding suprasellar cisterns, cavernous sinuses, sphenoid sinus, and optic chiasm. Pituitary gland height ranges from 6 mm in children to 8 mm in adults; during pregnancy and puberty, the height may reach 10 to 12 mm. The upper aspect of the adult pituitary is flat or slightly concave, but in adolescent and pregnant individuals, this surface may be convex, reflecting physiologic pituitary enlargement. The stalk should be vertical. CT scan is indicated to define the extent of bony erosion or the presence of calcification.

The soft tissue consistency of the pituitary gland is slightly heterogeneous on MRI. Anterior pituitary signal intensity resembles that of brain matter on T1-imaging (Fig. 318-4). Adenoma density is usually lower than that of surrounding normal tissue on T1-weighted imaging, and the signal intensity increases with T2-weighted images. The high phospholipid content of the posterior pituitary results in a "pituitary bright spot."

Sellar masses are commonly encountered as incidental findings on MRI, and most of these are pituitary adenomas (incidentalomas). In the absence of hormone hypersecretion, these small lesions can be safely monitored by MRI, which is performed annually and then less often if there is no evidence of growth. Resection should be considered for incidentally discovered macroadenomas, as about one-third become invasive or cause local pressure effects. If hormone hypersecretion is evident, specific therapies are indicated. When larger masses (>1 cm) are encountered, they should also be distinguished from nonadenomatous lesions. Meningiomas are often associated with bony hyperostosis; craniopharyngiomas may be calcified and are usually hypodense, whereas gliomas are hyperdense on T2-weighted images.

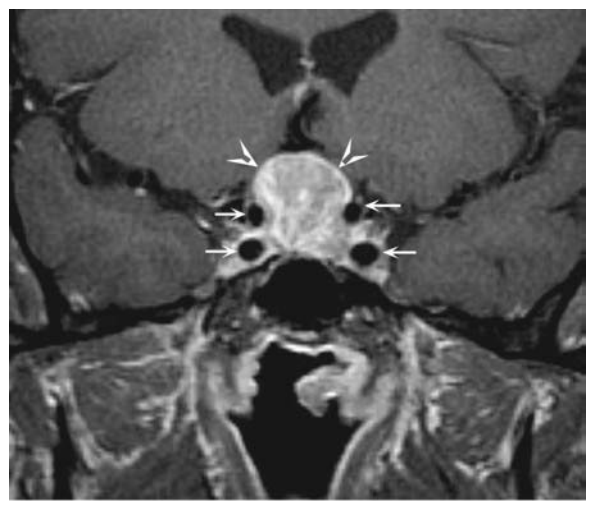

FIGURE 318-4 Pituitary adenoma. Coronal T1-weighted postcontrast MR image shows a homogeneously enhancing mass (*arrowheads*) in the sella turcica and suprasellar region compatible with a pituitary adenoma; the small arrows outline the carotid arteries.

Ophthalmologic Evaluation Because optic tracts may be contiguous to an expanding pituitary mass, reproducible visual field assessment that uses perimetry techniques should be performed on all patients with sellar mass lesions that abut the optic chiasm (Chap. 25). Bitemporal hemianopia or superior bitemporal defects are classically observed, reflecting the location of these tracts within the inferior and posterior part of the chiasm. Homonymous cuts are postchiasmal and monocular field cuts are prechiasmal. Loss of red perception is an early sign of optic tract pressure. Early diagnosis reduces the risk of blindness, scotomas, or other visual disturbances.

Laboratory Investigation The presenting clinical features of functional pituitary adenomas (e.g., acromegaly, prolactinomas, or Cushing's disease) should guide the laboratory studies (Table 318-7). However, for a sellar mass with no obvious clinical features of hormone excess, laboratory studies are geared towards determining the nature of the tumor and assessing the possible presence of hypopituitarism. When a pituitary adenoma is suspected based on MRI, initial hormonal evaluation usually includes: (1) basal PRL; (2) insulin-like growth factor (IGF) I; (3) 24-h urinary free cortisol (UFC) and/or overnight oral dexamethasone (1 mg) suppression test; (4) α-subunit, FSH, and LH levels; and (5) thyroid function tests. Additional hormonal evaluation may be indicated based on the results of these tests. Pending more detailed assessment of hypopituitarism, a menstrual history, testosterone level, 8 A.M. cortisol, and thyroid function tests usually identify patients with pituitary hormone deficiencies that require hormone replacement before further testing or surgery.

Histologic Evaluation Immunohistochemical staining of pituitary tumor specimens obtained at transsphenoidal surgery confirms clinical and laboratory studies and provides a histologic diagnosis when hormone studies are equivocal and in cases of clinically nonfunctioning tumors. Occasionally, ultrastructural assessment by electron microscopy is required for diagnosis.

TREATMENT

OVERVIEW Successful management of sellar masses requires accurate diagnosis as well as selection of optimal therapeutic modalities. Most pituitary tumors are benign and slow-growing. Clinical features result from local mass effects and hormonal hypo- or hypersecretion syndromes caused directly by the adenoma or as a consequence of treatment. Thus, lifelong management and follow-up are necessary for these patients.

MRI technology with gadolinium enhancement for pituitary visualization, new advances in transsphenoidal surgery and in stereotactic radiotherapy (including gamma-knife radiotherapy), and novel therapeutic agents have improved pituitary tumor management. The goals of pituitary tumor treatment include normalization of excess pituitary secretion, amelioration of symptoms and signs of hormonal hypersecretion syndromes, and shrinkage or ablation of large tumor masses with relief of adjacent structure compression. Residual anterior pituitary function should be preserved and can sometimes be restored by removing tumor mass. Ideally, adenoma recurrence should be prevented.

TABLE 318-7 *Screening Tests for Functional Pituitary Adenomas*

	Test	Comments
Acromegaly	Serum IGF-I	Interpret IGF-I relative to age- and gender-matched controls
	Oral glucose tolerance test with GH obtained at 0, 30, and 60 min	Normal subjects should suppress growth hormone to <1 μg/L
Prolactinoma	Exclude medications	MRI of the sella should be ordered if prolactin is elevated
Cushing's disease	24-h urinary free cortisol	Ensure urine collection is total and accurate
	Dexamethasone (1 mg) at 11 P.M. and fasting plasma cortisol measured at 8 A.M.	Normal subjects suppress to <5 μg/dL
	ACTH assay	Distinguishes adrenal adenoma (ACTH suppressed) from ectopic ACTH or Cushing's disease (ACTH normal or elevated)

Note: For abbreviations, see text.

TRANSSPHENOIDAL SURGERY Transsphenoidal rather than transfrontal resection is the desired surgical approach for pituitary tumors, except for the rare invasive suprasellar mass surrounding the frontal or middle fossa, the optic nerves, or invading posteriorly behind the clivus. Intraoperative microscopy facilitates visual distinction between adenomatous and normal pituitary tissue, as well as microdissection of small tumors that may not be visible by MRI (Fig. 318-5). Transsphenoidal surgery also avoids the cranial invasion and manipulation of brain tissue required by subfrontal surgical approaches. Endoscopic techniques with three-dimensional intraoperative localization have improved visualization and access to tumor tissue. The endoscopic approach is also less traumatic, as the technique is endonasal and does not require a transsphenoidal retractor.

In addition to correction of hormonal hypersecretion, pituitary surgery is indicated for mass lesions that impinge on surrounding structures. Surgical decompression and resection are required for an expanding pituitary mass accompanied by pesistent headache, progressive visual field defects, cranial nerve palsies, internal hydrocephalus, and, occasionally, intrapituitary hemorrhage and apoplexy. Transsphenoidal surgery is sometimes used for pituitary tissue biopsy and histologic diagnosis.

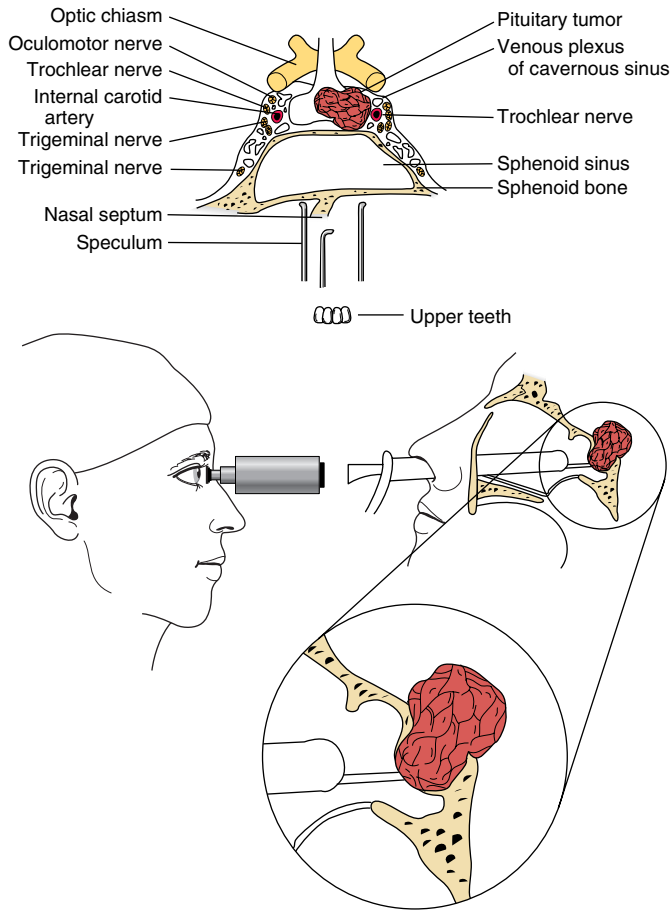

FIGURE 318-5 Transsphenoidal resection of pituitary mass via the endonasal approach. *(Adapted from Fahlbusch R: Endocrinol Metab Clin 21:669, 1992.)*

Whenever possible, the pituitary mass lesion should be selectively excised; normal tissue should be manipulated or resected only when critical for effective dissection. Nonselective hemihypophysectomy or total hypophysectomy may be indicated if no mass lesion is clearly discernible, multifocal lesions are present, or the remaining nontumorous pituitary tissue is obviously necrotic. This strategy increases the likelihood of hypopituitarism and the need for lifelong hormonal replacement.

Preoperative local compression signs, including visual field defects or compromised pituitary function, may be reversed by surgery, particularly when these deficits are not long-standing. For large and invasive tumors, it is necessary to determine the optimal balance between maximal tumor resection and preservation of anterior pituitary function, especially for preserving growth and reproductive function in younger patients. Similarly, tumor invasion outside of the sella is rarely amenable to surgical cure; the surgeon must judge the risk: benefit ratio of extensive tumor resection.

Side Effects Tumor size and the degree of invasiveness largely determine the incidence of surgical complications. Operative mortality is about 1%. Transient diabetes insipidus and hypopituitarism occur in up to 20% of patients. Permanent diabetes insipidus, cranial nerve damage, nasal septal perforation, or visual disturbances may be encountered in up to 10% of patients. CSF leaks occur in 4% of patients. Less common complications include carotid artery injury, loss of vision, hypothalamic damage, and meningitis. Permanent side effects are rarely encountered after surgery for microadenomas.

RADIATION Radiation is used either as a primary therapy for pituitary or parasellar masses or, more commonly, as an adjunct to surgery or medical therapy. Focused megavoltage irradiation is achieved by precise MRI localization, using a high-voltage linear accelerator and accurate isocentric rotational arcing. A major determinant of accurate irradiation is to reproduce the patient's head position during multiple visits and to maintain absolute head immobility. A total of <50 Gy (5000 rad) is given as 180-cGy (180 rad) fractions split over about 6 weeks. Stereotactic radiosurgery delivers a large single high-energy dose from a cobalt 60 source (gamma knife), linear accelerator, or cyclotron. Long-term effects of gamma-knife surgery are as yet unknown.

The role of radiation therapy in pituitary tumor management depends on multiple factors including the nature of the tumor, age of the patient, and the availability of surgical and radiation expertise. Because of its relatively slow onset of action, radiation therapy is usually reserved for postsurgical management. As an adjuvant to surgery, radiation is used to treat residual tumor and in an attempt to prevent regrowth. Irradiation offers the only effective means for ablating significant residual tumor tissue derived from nonfunctioning tumors. PRL-, GH-, and ACTH-secreting tumor tissues are also amenable to medical therapy.

Side Effects In the short term, radiation may cause transient nausea and weakness. Alopecia and loss of taste and smell may be more long-lasting. Failure of pituitary hormone synthesis is common in patients who have undergone head and neck or pituitary-directed irradiation. More than 50% of patients develop failure of GH, ACTH, TSH, and/or gonadotropin secretion within 10 years, usually due to hypothalamic damage. Lifelong follow-up with testing of anterior pituitary hormone reserve is therefore necessary after radiation treatment. Optic nerve damage with impaired vision due to optic neuritis is reported in about 2% of patients who undergo pituitary irradiation. Cranial nerve damage is uncommon now that radiation doses are ≤2 Gy (200 rad) at any one treatment session and the maximum dose is <50 Gy (5000 rad). The advent of stereotactic radiotherapy may reduce damage to adjacent structures. The cumulative risk of developing a secondary tumor after conventional radiation is 1.3% after 10 years and 1.9% after 20 years.

MEDICAL Medical therapy for pituitary tumors is highly specific and depends on tumor type. For prolactinomas, dopamine agonists are the treatment of choice. For acromegaly and TSH-secreting tumors, somatostatin analogues and, occasionally, dopamine agonists are indicated. ACTH-secreting tumors and nonfunctioning tumors are generally not responsive to medication and require surgery and/or irradiation.

PROLACTIN

SYNTHESIS PRL consists of 198 amino acids and has a molecular mass of 21,500 kDa; it is weakly homologous to GH and human placental lactogen (hPL), reflecting the duplication and divergence of a common GH-PRL-hPL precursor gene on chromosome 6. PRL is synthesized in lactotropes, which comprise about 20% of anterior pituitary cells. Lactotropes and somatotropes are derived from a common precursor cell that may give rise to a tumor secreting both PRL and GH. Marked lactotrope cell hyperplasia develops during the last two trimesters of pregnancy and the first few months of lactation. These transient adaptive changes in the lactotrope population are induced by estrogen.

SECRETION Normal adult serum PRL levels are about 10 to 25 μg/L in women and 10 to 20 μg/L in men. PRL secretion is pulsatile, with the highest secretory peaks occurring during rapid eye movement sleep. Peak serum PRL levels (up to 30 μg/L) occur between 4:00 and 6:00 A.M. The circulating half-life of PRL is about 50 min.

PRL is unique among the pituitary hormones in that the predominant central control mechanism is inhibitory, reflecting dopamine-mediated suppression of PRL release. This regulatory pathway accounts for the spontaneous PRL hypersecretion that occurs after pituitary stalk section, often a consequence of mass lesions at the skull base. Pituitary, dopamine type 2 (D_2) receptors mediate PRL inhibition. Targeted disruption (gene knockout) of the murine D_2 receptor results in hyperprolactinemia and lactotrope proliferation. As discussed below, dopamine agonists play a central role in the management of hyperprolactinemic disorders.

TRH (pyro Glu-His-Pro-NH2) is a hypothalamic tripeptide that releases prolactin within 15 to 30 min after intravenous injection. The physiologic relevance of TRH for PRL regulation is unclear, as it appears primarily to regulate TSH (Chap. 320). *Vasoactive intestinal peptide* (VIP) also induces PRL release, whereas glucocorticoids and thyroid hormone weakly suppress PRL secretion.

Serum PRL levels rise after exercise, meals, sexual intercourse, minor surgical procedures, general anesthesia, acute myocardial infarction, and other forms of acute stress. PRL levels also increase significantly (~tenfold) during pregnancy and decline rapidly within 2 weeks of parturition. If breastfeeding is initiated, basal PRL levels remain elevated; suckling stimulates reflex increases in PRL levels that last for about 30 to 45 min. Breast suckling activates neural afferent pathways in the hypothalamus that induce PRL release. With time, the suckling-induced responses diminish and interfeeding PRL levels return to normal.

ACTION The PRL receptor is a member of the type I cytokine receptor family that also includes GH and interleukin (IL) 6 receptors. Ligand binding leads to receptor dimerization followed by intracellular signaling mediated by Janus kinase (JAK) and components of the signal transduction and activators of transcription (STAT) family that translocate to the nucleus, where they act as transcription factors on target genes. In the breast, the lobuloalveolar epithelium proliferates in response to PRL, placental lactogens, estrogen, progesterone, and local paracrine growth factors.

PRL acts to induce and maintain lactation, decrease reproductive function, and suppress sexual drive. These functions are geared towards ensuring that maternal lactation is sustained and not interrupted by pregnancy. PRL inhibits reproductive function by suppressing hypothalamic GnRH and pituitary gonadotropin secretion and by impairing gonadal steroidogenesis in both female and male subjects. In the ovary, PRL blocks folliculogenesis and inhibits granulosa cell aromatase activity, leading to hypoestrogenism and anovulation. PRL also has a luteolytic effect, generating a shortened, or inadequate, luteal

phase of the menstrual cycle. In males, attenuated LH secretion leads to low testosterone levels and decreased spermatogenesis. These hormonal changes decrease libido and reduce fertility in patients with hyperprolactinemia.

HYPERPROLACTINEMIA ■ Etiology Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome in both males and females. PRL-secreting pituitary adenomas (prolactinomas) are the most common cause of PRL levels >100 μg/L (see below). Less pronounced PRL elevation can also be seen with microprolactinomas but is more commonly caused by drugs, pituitary stalk compression, hypothyroidism, or renal failure (Table 318-8).

Pregnancy and lactation are the important physiologic causes of hyperprolactinemia. Sleep-associated hyperprolactinemia reverts to normal within an hour of awakening. Nipple stimulation and sexual orgasm may also cause acute PRL increases. Chest wall stimulation or trauma (including chest surgery and herpes zoster) invoke the reflex suckling arc with resultant hyperprolactinemia. Chronic renal failure elevates PRL by decreasing peripheral PRL clearance. Primary hypothyroidism is associated with mild hyperprolactinemia, probably because of enhanced TRH secretion.

Lesions of the hypothalamic-pituitary region that disrupt hypothalamic dopamine synthesis, portal vessel delivery, or lactotrope responses are associated with hyperprolactinemia. Thus, hypothalamic tumors, cysts, infiltrative disorders, and radiation-induced damage cause elevated PRL levels, usually in the range of 30 to 100 μg/L. Plurihormonal adenomas (including GH and ACTH tumors) may directly hypersecrete PRL. Clinically nonfunctioning pituitary tumors commonly compress the pituitary stalk to cause hyperprolactinemia.

Drug-induced inhibition or disruption of dopaminergic receptor function is a common cause of hyperprolactinemia (Table 318-8). Thus, many antipsychotics and antidepressants cause hyperprolactinemia. Methyldopa inhibits dopamine synthesis and verapamil blocks dopamine release, also leading to hyperprolactinemia. Hormonal agents that induce PRL include estrogens, antiandrogens, and TRH.

Presentation and Diagnosis Amenorrhea, galactorrhea, and infertility are the hallmarks of hyperprolactinemia in women. If hyperprolactinemia develops prior to the menarche, primary amenorrhea results. More commonly, hyperprolactinemia develops later in life and leads to oligomenorrhea and, ultimately, to amenorrhea. If hyperprolactinemia is sustained, vertebral bone mineral density can be reduced compared to age-matched controls, particularly when associated with pronounced hypoestrogenemia. Galactorrhea is present in up to 80% of hyperprolactinemic women. Though usually bilateral and spontaneous, it may be unilateral or only expressed manually. Patients may also complain of decreased libido, weight gain, and mild hirsutism.

In men with hyperprolactinemia, diminished libido or visual loss (from optic nerve compression) are the usual presenting symptoms. Gonadotropin suppression leads to reduced testosterone, impotence, and oligospermia. True galactorrhea is uncommon in men with hyperprolactinemia. If the disorder is longstanding, secondary effects of hypogonadism are evident, including osteopenia, reduced muscle mass, and decreased beard growth.

The diagnosis of idiopathic hyperprolactinemia is made by exclusion of known causes of hyperprolactinemia in the setting of a normal pituitary MRI. Some of these patients may have small microadenomas below MRI sensitivity (~2 mm).

Laboratory Investigation Basal, fasting morning PRL levels (normally <20 μg/L) should be measured to assess hypersecretion. Because hormone secretion is pulsatile and levels vary widely in some individuals with hyperprolactinemia, it may be necessary to measure levels on several different occasions when clinical suspicion is high. Both false-positive and false-negative results may be encountered. In patients with markedly elevated PRL levels (>1000 μg/L), results may be falsely lowered because of assay artifacts; sample dilution is required to measure these high values accurately. Falsely elevated values may be caused by aggregated forms of circulating PRL, which are biologically inactive (macroprolactinemia). Hypothyroidism should be excluded by measuring TSH and T_4 levels.

Note: Hyperprolactinemia >100 μg/L almost invariably is indicative of a prolactin-secreting pituitary adenoma. Physiologic causes, hypothyroidism, and drug-induced hyperprolactinemia should be excluded before extensive evaluation.

℞ TREATMENT

Treatment of hyperprolactinemia depends on the cause of elevated PRL levels. Regardless of the etiology, however, treatment should be aimed at normalizing PRL levels to alleviate suppressive effects on gonadal function, halt galactorrhea, and preserve bone mineral density. Dopamine agonists are effective for many different causes of hyperprolactinemia (see "Treatment" for "Prolactinoma," below).

If the patient is taking a medication known to cause hyperprolactinemia, the drug should be withdrawn, if possible. For psychiatric patients who require neuroleptic agents, dose titration or the addition of a dopamine agonist can help restore normoprolactinemia and alleviate reproductive symptoms. However, dopamine agonists sometimes worsen the underlying psychiatric condition, especially at high doses. Hyperprolactinemia usually resolves after adequate thyroid hormone replacement in hypothyroid patients or after renal transplantation in patients receiving dialysis. Resection of hypothalamic or sellar mass lesions can reverse hyperprolactinemia caused by reduced dopamine tone. Granulomatous infiltrates occasionally respond to glucocorticoid administration. In patients with irreversible hypothalamic damage, no treatment may be warranted. In up to 30% of patients with hyperprolactinemia—with or without a visible pituitary microadenoma—the condition resolves spontaneously.

GALACTORRHEA *Galactorrhea*, the inappropriate discharge of milk-containing fluid from the breast, is considered abnormal if it persists for longer than 6 months after childbirth or discontinuation of breast-feeding. Post-partum galactorrhea associated with amenorrhea is a self-limiting disorder usually associated with moderately elevated PRL levels. Galactorrhea may occur spontaneously, or be elicited by nipple pressure. In both males and females, galactorrhea may vary in color and consistency (transparent, milky, or bloody) and arise either unilaterally or bilaterally. Mammography or ultrasound is indicated for

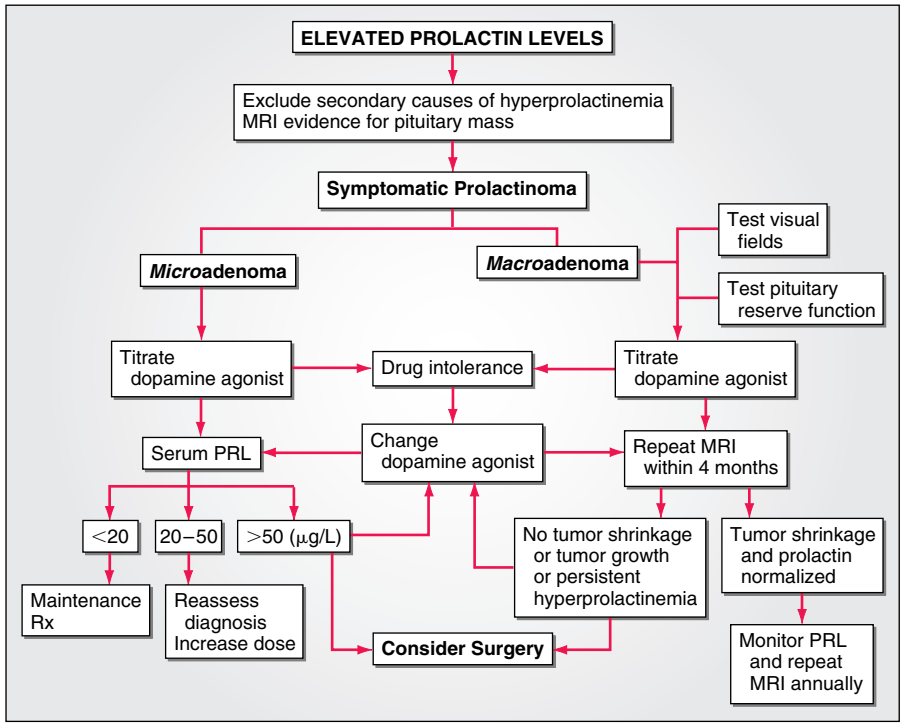

FIGURE 318-6 Management of prolactinoma. (MRI, magnetic resonance imaging; PRL, prolactin.)

bloody discharges (particularly from a single duct), which may be caused by breast cancer. Galactorrhea is commonly associated with hyperprolactinemia caused by any of the conditions listed in Table 318-8. Acromegaly is associated with galactorrhea in about one-third of patients. Treatment of galactorrhea usually involves managing the underlying disorder (e.g., replacing T_4 for hypothyroidism; discontinuing a medication; treating prolactinoma).

PROLACTINOMA ■ Etiology and Prevalence Tumors arising from lactotrope cells account for about half of all functioning pituitary tumors, with an annual incidence of ~3/100,000 population. Mixed tumors secreting combinations of GH and PRL, ACTH and PRL, and rarely TSH and PRL, are also seen. These plurihormonal tumors are usually recognized by immunohistochemistry, without apparent clinical manifestations from the production of additional hormones. Microadenomas are classified as <1 cm in diameter and do not usually invade the parasellar region. Macroadenomas are >1 cm in diameter and may be locally invasive and impinge on adjacent structures. The female:male ratio for microprolactinomas is 20:1, whereas the gender ratio is near 1:1 for macroadenomas. Tumor size generally correlates directly with PRL concentrations; values >100 μg/L are usually associated with macroadenomas. Males tend to present with larger tumors than females, possibly because the features of hypogonadism are less readily evident. PRL levels remain stable in most patients, reflecting the slow growth of these tumors. About 5% of microadenomas progress in the long term to macroadenomas. Hyperprolactinemia resolves spontaneously in about 30% of microadenomas.

Presentation and Diagnosis Women usually present with amenorrhea, infertility, and galactorrhea. If the tumor extends outside of the sella, visual field defects or other mass effects may be seen. Men often present with impotence, loss of libido, infertility, or signs of central CNS compression including headaches and visual defects. Assuming that known physiologic and medication-induced causes of hyperprolactinemia are excluded (Table 318-8), the diagnosis of prolactinoma is likely with a PRL level >100 μg/L. PRL levels <100 μg/L may be caused by microadenomas, other sellar lesions that decrease dopamine inhibition, or nonneoplastic causes of hyperprolactinemia. For this reason, an MRI should be performed in all patients with hyperprolactinemia. It is important to remember that hyperprolactinemia caused by the mass effects of nonlactotrope lesions is also corrected by treatment with dopamine agonists. Consequently, PRL suppression by dopamine agonists does not necessarily indicate that the lesion is a prolactinoma.

Rx TREATMENT

As microadenomas rarely progress to become macroadenomas, no treatment may be needed if fertility is not desired. Estrogen replacement is indicated to prevent bone loss and other consequences of hypoestrogenemia and does not appear to increase the risk of tumor enlargement. These patients should be monitored by regular serial PRL and MRI measurements.

For symptomatic microadenomas, therapeutic goals include control of hyperprolactinemia, reduction of tumor size, restoration of menses and fertility, and improvement of galactorrhea. Dopamine agonists should be titrated to achieve maximal PRL suppression and restoration of reproductive function (Fig. 318-6). A normalized PRL level does not assure reduced tumor size. However, tumor shrinkage is not usually seen in those who do not respond with lowered PRL levels. For macroadenomas, formal visual field testing should be performed before initiating dopamine agonists. MRI and visual fields should be assessed at 6- to 12-month intervals until the mass shrinks and annually thereafter until maximum size reduction has occurred.

MEDICAL Oral dopamine agonists (cabergoline or bromocriptine) are the mainstay of therapy for patients with micro- or macroprolactinomas. Dopamine agonists suppress PRL secretion and synthesis as well as lactotrope cell proliferation. About 20% of patients are resistant to dopaminergic treatment; they may have decreased D_2 dopamine receptor numbers or a postreceptor defect. D_2 receptor gene mutations in the pituitary have not been reported.

Cabergoline An ergoline derivative, cabergoline is a long-acting dopamine agonist with high D_2 receptor affinity. The drug effectively suppresses PRL for >14 days after a single oral dose and induces prolactinoma shrinkage in most patients. Cabergoline (0.5 to 1.0 mg twice weekly) achieves normoprolactinemia and resumption of normal gonadal function in ~80% of patients with microadenomas; galactorrhea improves or resolves in 90% of patients. Cabergoline normalizes PRL and shrinks ~70% of macroprolactinomas. Mass effect symptoms, including headaches and visual disorders, usually improve dramatically within days after cabergoline initiation; improvement of sexual function requires several weeks of treatment but may occur before complete normalization of prolactin levels. Drug withdrawal usually results in recurrent hyperprolactinemia and tumor reexpansion, with the risk of visual compromise. After initial control of PRL levels has been achieved, cabergoline should be reduced to the lowest effective maintenance dose. In ~5% of treated patients, hyperprolactinemia may resolve and not recur when dopamine agonists are discontinued after long-term treatment. Cabergoline may also be effective in patients resistant to bromocriptine. Adverse effects and drug intolerance are encountered less commonly than with bromocriptine.

Bromocriptine The ergot alkaloid bromocriptine mesylate is a dopamine receptor agonist that suppresses prolactin secretion. Because it is short-acting, the drug is preferred when pregnancy is desired. In microadenomas the drug rapidly lowers serum prolactin levels to normal in up to 70% of patients, decreases tumor size, and restores gonadal function. In patients with macroadenomas, prolactin levels are also normalized in 70% of patients and tumor mass shrinkage (≥50%) is achieved in up to 40% of patients.

Therapy is initiated by administering a low bromocriptine dose (0.625 to 1.25 mg) at bedtime with a snack, followed by gradually increasing the dose. Most patients are successfully controlled with a daily dose of ≤7.5 mg (2.5 mg tid).

Nausea, vomiting, and postural hypotension with faintness may occur in ~25% of patients after the initial dose. These symptoms may persist in some patients.

Other Dopamine Agonists These include *pergolide mesylate*, an ergot derivative with dopaminergic properties; *lisuride*, an ergot derivative; and *quinagolide* (CV 205-502, Norprolac), a nonergot oral dopamine agonist with specific D_2 receptor activity.

Side Effects Side effects of dopamine agonists include constipation, nasal stuffiness, dry mouth, nightmares, insomnia, and vertigo; decreasing the dose usually alleviates these problems. For the approximately 15% of patients who are intolerant of oral bromocriptine, dostinex may be better tolerated. Intravaginal administration of bromocriptine is often efficacious. Auditory hallucinations, delusions, and mood swings have been reported in up to 5% of patients and may be due to the dopamine agonist properties or to the lysergic acid derivative of the compounds. Rare reports of leukopenia, thrombocytopenia, pleural fibrosis, cardiac arrhythmias, and hepatitis have been described with bromocriptine.

Surgery Indications for surgical debulking include dopamine resistance or intolerance or the presence of an invasive macroadenoma with compromised vision that fails to improve rapidly after drug treatment. Initial PRL normalization is achieved in about 70% of microprolactinomas after surgical resection, but only 30% of macroadenomas can be successfully resected. Follow-up studies have shown that recurrence of hyperprolactinemia occurs in up to 20% of patients within the first year after surgery; long-term recurrence rates exceed 50% for macroadenomas. Radiotherapy for prolactinomas is reserved for patients with aggressive tumors that do not respond to maximally tolerated dopamine agonists and/or surgery.

PREGNANCY The pituitary increases in size during pregnancy, reflecting the stimulatory effects of estrogen and perhaps other growth factors. About 5% of microadenomas significantly increase in size, but 15 to 30% of macroadenomas grow during pregnancy. Bromocriptine has been used for over 25 years to restore fertility in women with hyperprolactinemia, without evidence of untoward teratogenic effects. Nonetheless, most authorities recommend strategies to minimize fetal exposure to the drug. For women taking bromocriptine who desire pregnancy, mechanical contraception should be used through three regular menstrual cycles to allow for conception timing. When pregnancy is confirmed, bromocriptine should be discontinued and PRL levels followed serially, especially if headaches or visual symptoms occur. For women harboring macroadenomas, regular visual field testing is recommended, and the drug should be reinstituted if tumor growth is apparent. Although pituitary MRI may be safe during pregnancy, this procedure should be reserved for symptomatic patients with severe headache and/or visual field defects. Alternatively, surgical decompression may be indicated if vision is threatened. Though comprehensive data support the efficacy and relative safety of bromocriptine-facilitated fertility, patients should be advised of potential unknown deleterious effects and the risk of tumor growth during pregnancy. As cabergoline is long-acting with a high D_2-receptor affinity, it is not approved for routine use when fertility is desired.

GROWTH HORMONE

SYNTHESIS GH is the most abundant anterior pituitary hormone, and GH-secreting somatotrope cells constitute up to 50% of the total anterior pituitary cell population. Mammosomatotrope cells, which coexpress PRL with GH, can be identified using double immunostaining techniques. Somatotrope development and GH transcription are determined by expression of the cell-specific Pit-1 nuclear transcription factor. Five distinct genes on chromosome 17q22 encode GH and related proteins. The pituitary GH gene (*hGH-N*) produces two alternatively spliced products that give rise to 22-kDa GH (191 amino acids) and a less abundant, 20-kDa GH molecule, with similar biologic activity. Placental syncytiotrophoblast cells express a GH variant (*hGH-V*) gene; the related hormone human chorionic somatotropin (HCS) is expressed by distinct members of the gene cluster.

SECRETION GH secretion is controlled by complex hypothalamic and peripheral factors. *GHRH* is a 44 amino acid hypothalamic peptide that stimulates GH synthesis and release. Ghrelin, or octonoylated gastric-derived peptide, as well as synthetic agonists of the *GHRP* receptor stimulate GHRH and also directly stimulate GH release. *Somatostatin* [somatotropin-release inhibiting factor (SRIF)] is synthesized in the medial preoptic area of the hypothalamus and inhibits GH secretion. GHRH is secreted as discrete spikes that elicit GH pulses, whereas SRIF sets basal GH tone. SRIF is also expressed in many extrahypothalamic tissues, including the CNS, gastrointestinal tract, and pancreas, where it also acts to inhibit islet hormone secretion. *IGF-I*, the peripheral target hormone for GH, feeds back to inhibit GH; estrogen induces GH, whereas glucocorticoid excess suppresses GH release.

Surface receptors on the somatotrope regulate GH synthesis and secretion. The GHRH receptor is a G protein–coupled receptor (GPCR) that signals through the intracellular cyclic AMP pathway. Activation of this receptor stimulates somatotrope cell proliferation as well as hormone production. Inactivating mutations of the GHRH receptor cause profound dwarfism (see below). A distinct surface receptor for ghrelin, a gastric-derived GH secretogogue, is expressed in the hypothalamus and pituitary. Somatostatin binds to five distinct receptor subtypes (SSTR1 to SSTR5); SSTR2 and SSTR5 subtypes preferentially suppress GH (and TSH) secretion.

GH secretion is pulsatile, with greatest levels at night, generally correlating with the onset of sleep. GH secretory rates decline markedly with age so that hormone production in middle age is about 15% of production during puberty. These changes are paralleled by an age-related decline in lean muscle mass. GH secretion is also reduced in obese individuals, though IGF-I levels are usually preserved, suggesting a change in the setpoint for feedback control. Elevated GH levels occur within an hour of deep sleep onset as well as after exercise, physical stress, trauma, and during sepsis. Integrated 24-h GH secretion is higher in women and is also enhanced by estrogen replacement. Using standard assays, random GH measurements are undetectable in ~50% of daytime samples obtained from healthy subjects and are undetectable in most obese and elderly subjects. Thus, single random GH measurements do not distinguish patients with adult GH deficiency from normal persons.

GH secretion is profoundly influenced by nutritional factors. Using newer ultrasensitive chemiluminescence-based GH assays with a sensitivity of 0.002 μg/L, a glucose load can be shown to suppress GH to <0.7 μg/L in female and to <0.07 μg/L in male subjects. Increased GH pulse frequency and peak amplitudes occur with chronic malnutrition or prolonged fasting. GH is stimulated by high-protein meals and by L-arginine. GH secretion is induced by dopamine and apomorphine (a dopamine receptor agonist), as well as by α-adrenergic pathways. β-Adrenergic blockage induces basal GH and enhances GHRH- and insulin-evoked GH release.

ACTION The pattern of GH secretion may affect tissue responses. The higher GH pulsatility observed in males, as compared to the relatively continuous GH secretion in females, may be an important biologic determinant of linear growth patterns and liver enzyme induction.

The 70-kDa peripheral GH receptor protein shares structural homology with the cytokine/hematopoietic superfamily. A fragment of the receptor extracellular domain generates a soluble GH binding protein (GHBP) that interacts with GH in the circulation. The liver contains the greatest number of GH receptors. GH binding induces recep-

tor dimerization, followed by signaling through the JAK/STAT pathway. The activated STAT proteins translocate to the nucleus, where they modulate expression of GH-regulated target genes. GH analogues that bind to the receptor, but are incapable of mediating receptor dimerization, are potent antagonists of GH action and are being investigated for potential use in the treatment of acromegaly and diabetic microangiopathy.

GH induces protein synthesis and nitrogen retention and impairs glucose tolerance by antagonizing insulin action. GH also stimulates lipolysis, leading to increased circulating fatty acid levels, reduced omental fat mass, and enhanced lean body mass. GH promotes sodium, potassium, and water retention and elevates serum levels of inorganic phosphate. Linear bone growth occurs as a result of complex hormonal and growth factor actions, including those of IGF-I. GH stimulates epiphyseal prechondrocyte differentiation. These precursor cells produce IGF-I locally and are also responsive to the growth factor.

INSULIN-LIKE GROWTH FACTORS Though GH exerts direct effects in target tissues, many of its physiologic effects are mediated indirectly through IGF-I, a potent growth and differentiation factor. The major source of circulating IGF-I is hepatic in origin. Peripheral tissue IGF-I exerts local paracrine actions that appear to be both dependent and independent of GH. Thus, GH administration induces circulating IGF-I as well as stimulating IGF-I expression in multiple tissues.

Both IGF-I and -II are bound to high-affinity circulating IGF-binding proteins (IGFBPs) that regulate IGF bioactivity. Levels of IGFBP3 are GH-dependent, and it serves as the major carrier protein for circulating IGF-I. GH deficiency and malnutrition are associated with low IGFBP3 levels. IGFBP1 and -2 regulate local tissue IGF action but do not bind appreciable amounts of circulating IGF-I.

Serum IGF-I concentrations are profoundly affected by various physiologic factors. Levels increase during puberty, peak at 16 years, and subsequently decline by >80% during the aging process. IGF-I concentrations are higher in females than in males. Because GH is the major determinant of hepatic IGF-I synthesis, abnormalities of GH synthesis or action (e.g., pituitary failure, GHRH receptor defect, or GH receptor defect) reduce IGF-I levels. Hypocaloric states are associated with GH resistance; IGF-I levels are therefore low with cachexia, malnutrition, and sepsis. In acromegaly, IGF-I levels are invariably high and reflect a log-linear relationship with GH concentrations.

IGF-I Physiology Though IGF-I is not an approved drug, investigational studies provide insight into its physiologic effects. Injected IGF-I (100 μg/kg) induces hypoglycemia, and lower doses improve insulin sensitivity in patients with severe insulin resistance and diabetes. In cachectic subjects, IGF-I infusion (12 μg/kg per hour) enhances nitrogen retention and lowers cholesterol levels. Longer-term subcutaneous IGF-I injections exert a marked anabolic effect with enhanced protein synthesis. Although bone formation markers are induced, bone turnover may also be stimulated by IGF-I.

IGF-I side effects are dose-dependent, and overdose may result in hypoglycemia, hypotension, fluid retention, temporomandibular jaw pain, and increased intracranial pressure, all of which are reversible. Avascular femoral head necrosis has been reported. Chronic excess IGF-I would presumably result in features of acromegaly.

DISORDERS OF GROWTH AND DEVELOPMENT ■ Skeletal Maturation and Somatic Growth The growth plate is dependent on a variety of hormonal stimuli including GH, IGF-I, sex steroids, thyroid hormones, paracrine growth factors, and cytokines. The growth-promoting process also requires caloric energy, amino acids, vitamins, and trace metals and consumes about 10% of normal energy production. Malnutrition impairs chondrocyte activity and reduces circulating IGF-I and IGFBP3 levels.

Bone age is delayed in patients with all forms of true GH deficiency or GH receptor defects that result in attenuated GH action. Rarely, GH excess accelerates growth, particularly in the setting of delayed bone age from concomitant hypogonadism. Bone age is delayed by thyroid hormone deficiency. Consequently, congenital or acquired hypothyroidism is associated with stunted growth, which is partially reversed by thyroid hormone replacement (Chap. 320). Elevated pubertal sex steroid levels (especially estrogen) induce the GHRH-GH-IGF-I axis and also directly stimulate epiphyseal growth. High doses of estrogen lead to epiphyseal closure. A mutation of the estrogen receptor α prevented epiphyseal closure, confirming the important role of this pathway in bone maturation. Several pathologic conditions accompanied by increased levels of sex steroids, including precocious puberty, androgen exposure (exogenous or endogenous), congenital adrenal hyperplasia, and obesity, are associated with accelerated bone maturation. Thus, children with these conditions have accelerated early growth, but end up with reduced final height. In contrast to sex steroids, glucocorticoid excess inhibits linear growth.

Linear bone growth rates are very high in infancy and are pituitary-dependent. Mean growth velocity is ~6 cm/year in later childhood and is usually maintained within a given range on a standardized percentile chart. Peak growth rates occur during midpuberty when bone age is 12 (girls) or 13 (boys). Secondary sexual development is associated with elevated sex steroids that cause progressive epiphyseal growth plate closure.

Short stature may occur as a result of constitutive intrinsic growth defects or because of acquired extrinsic factors that impair growth. In general, delayed bone age in a child with short stature is suggestive of a hormonal or systemic disorder, whereas normal bone age in a short child is more likely to be caused by a genetic cartilage dysplasia or growth plate disorder (Chap. 342).

GH Deficiency in Children ■ *GH DEFICIENCY* Isolated GH deficiency is characterized by short stature, micropenis, increased fat, high-pitched voice, and a propensity to hypoglycemia. Familial modes of inheritance are seen in one-third of these individuals and may be autosomal dominant, recessive, or X-linked. About 10% of children with GH deficiency have mutations in the *GH-N* gene, including gene deletions and a wide range of point mutations. Mutations in transcription factors Pit-1 and Prop-1, which control somatotrope development, cause GH deficiency in combination with other pituitary hormone deficiencies, which may only become manifest in adulthood. The diagnosis of *idiopathic GH deficiency* (IGHD) should be made only after known molecular defects have been excluded.

GHRH RECEPTOR MUTATIONS Recessive mutations of the GHRH receptor gene in subjects with severe proportionate dwarfism are associated with low basal GH levels that cannot be stimulated by exogenous GHRH, GHRP, or insulin-induced hypoglycemia. The syndrome exemplifies the importance of the GHRH receptor for somatotrope cell proliferation and hormonal responsiveness.

GROWTH HORMONE INSENSITIVITY This is caused by defects of GH receptor structure or signaling. Homozygous or heterozygous mutations of the GH receptor are associated with partial or complete GH insensitivity and growth failure (*Laron syndrome*). The diagnosis is based on normal or high GH levels, with decreased circulating GHBP, and low IGF-I levels. Very rarely, defective IGF-I, IGF-I receptor, or IGF-I signaling defects are also encountered.

NUTRITIONAL SHORT STATURE Caloric deprivation and malnutrition, uncontrolled diabetes, and chronic renal failure represent secondary causes of abrogated GH receptor function. These conditions also stimulate production of proinflammatory cytokines, which can block GH-mediated signal transduction. Children with these conditions typically exhibit features of acquired short stature with elevated GH and low IGF-I levels. Circulating GH receptor antibodies may rarely cause peripheral GH insensitivity.

PSYCHOSOCIAL SHORT STATURE Emotional and social deprivation lead to growth retardation accompanied by delayed speech, discordant hyperphagia, and attenuated response to administered GH. A nurturing environment restores growth rates.

Presentation and Diagnosis Short stature is commonly encountered in clinical practice, and the decision to evaluate these children requires clinical judgement in association with auxologic data and family history. Short stature should be comprehensively evaluated if a patient's height is >3 SD below the mean for age or if the growth rate has decelerated. Skeletal maturation is best evaluated by measuring a radiologic bone age, which is based mainly on the degree of growth plate fusion. Final height can be predicted using standardized scales (Bayley-Pinneau or Tanner-Whitehouse) or estimated by adding 6.5 cm (boys) or subtracting 6.5 cm (girls) from the midparental height.

Laboratory Investigation Because GH secretion is pulsatile, GH deficiency is best assessed by examining the response to provocative stimuli including exercise, insulin-induced hypoglycemia, and other pharmacologic tests which normally increase GH to >7 μg/L in children. Random GH measurements do not distinguish normal children from those with true GH deficiency. Adequate adrenal and thyroid hormone replacement should be assured before testing. Age- and gender-matched IGF-I levels are not sufficiently sensitive or specific to make the diagnosis but can be useful to confirm GH deficiency. Pituitary MRI may reveal pituitary mass lesions or structural defects.

TREATMENT

Replacement therapy with recombinant GH (0.02 to 0.05 mg/kg per day subcutaneously) restores growth velocity in GH-deficient children to ~10 cm/year. If pituitary insufficiency is documented, other associated hormone deficits should be corrected—especially adrenal steroids. GH treatment is also moderately effective for accelerating growth rates in children with Turner syndrome and chronic renal failure.

In patients with GH insensitivity and growth retardation due to mutations of the GH receptor, treatment with IGF-I bypasses the dysfunctional GH receptor. Growth rates have been maintained for several years, and this therapy now portends improved final adult stature in this group of patients.

ADULT GH DEFICIENCY (AGHD) This disorder is usually caused by hypothalamic or pituitary somatotrope damage. Acquired pituitary hormone deficiency follows a typical sequential pattern whereby loss of adequate GH reserve foreshadows subsequent hormone deficits. The sequential order of hormone loss is usually GH → FSH/LH → TSH → ACTH.

Presentation and Diagnosis The clinical features of AGHD include changes in body composition, lipid metabolism, and quality of life and cardiovascular dysfunction (Table 318-9). Body composition changes are common and include reduced lean body mass, increased fat mass with selective deposition of intraabdominal visceral fat, and increased waist-to-hip ratio. Hyperlipidemia, left ventricular dysfunction, hypertension, and increased plasma fibrinogen levels may also be present. Bone mineral content is reduced, with resultant increased fracture rates. Patients may experience social isolation, depression, and difficulty in maintaining gainful employment. Adult hypopituitarism is associated with a threefold increased cardiovascular mortality rate in comparison to age- and sex-matched controls, and this may be due to GH deficiency.

TABLE 318-9 Features of Adult Growth Hormone Deficiency

Clinical	Imaging
Impaired quality of life	Pituitary: Mass or structural damage
Decreased energy and drive	Bone: Reduced bone mineral density
Poor concentration	Abdomen: Excess omental adiposity
Low self-esteem	Laboratory
Social isolation	Evoked GH <3 ng/mL
Body composition changes	IGF-I and IGFBP3 low or normal
Increased body fat mass	Increased LDL-cholesterol
Central fat deposition	Concomitant gonadotropin, TSH, and/or ACTH reserve deficits may be present
Increased waist-hip ratio	
Decreased lean body mass	
Reduced exercise capacity	
Reduced maximum O_2 uptake	
Impaired cardiac function	
Reduced muscle mass	
Cardiovascular risk factors	
Impaired cardiac structure and function	
Abnormal lipid profile	
Decreased fibrinolytic activity	
Atherosclerosis	
Omental obesity	

Note: LDL, low-density lipoprotein; for other abbreviations, see text.

Laboratory Investigation AGHD is rare, and in light of the nonspecific nature of associated clinical symptoms, patients appropriate for testing should be carefully selected on the basis of well-defined criteria. With few exceptions, testing should be restricted to patients with the following predisposing factors: (1) pituitary surgery, (2) pituitary or hypothalamic tumor or granulomas, (3) cranial irradiation, (4) radiologic evidence of a pituitary lesion, (5) childhood requirement for GH replacement therapy, or, rarely, (6) unexplained low age- and sex-matched IGF-I level. The transition of the GH-deficient adolescent to adulthood requires retesting to document adult GH deficiency. Up to 20% of patients treated for childhood-onset GH deficiency are found to be GH-sufficient on repeat testing as adults.

A significant proportion (~25%) of truly GH-deficient adults have low-normal IGF-I levels. Thus, as in the evaluation of GH deficiency in children, valid age- and gender-matched IGF-I measurements provide a useful index of therapeutic responses but are not sufficiently sensitive for diagnostic purposes. The most validated test to distinguish pituitary-sufficient patients from those with AGHD is insulin-induced (0.05 to 0.1 U/kg) hypoglycemia. After glucose reduction to ~40 mg/dL, most individuals experience neuroglycopenic symptoms (Chap. 324), and peak GH release occurs at 60 min and remains elevated for up to 2 h. About 90% of healthy adults exhibit GH responses >5 μg/L; AGHD is defined by a peak GH response to hypoglycemia of <3 μg/L. Although insulin-induced hypoglycemia is safe when performed under appropriate supervision, it is contraindicated in patients with diabetes, ischemic heart disease, cerebrovascular disease, or epilepsy, and in elderly patients. Alternative stimulatory tests include intravenous arginine (30 g), GHRH (1 μg/kg), and GHRP-6 (90 μg). Combinations of these tests may evoke GH secretion in subjects not responsive to a single test.

TREATMENT

Once the diagnosis of AGHD is unequivocally established, replacement of GH may be indicated. Contraindications to therapy include the presence of an active neoplasm, intracranial hypertension, or uncontrolled diabetes and retinopathy. The starting dose of 0.15 to 0.3 mg/d should be titrated (up to a maximum of 1.25 mg/d) to maintain IGF-I levels in the mid-normal range for age- and gender-matched controls (Fig. 318-7). Women require higher doses than men, and elderly patients require less GH. Long-term GH maintenance sustains normal IGF-I levels and is associated with persistent body composition changes (e.g., enhanced lean body mass and lower body fat). High-density lipoprotein cholesterol increases, but total cholesterol and insulin levels do not change significantly. Lumbar spine bone mineral density increases, but this response is gradual (>1 year). Many patients note significant improvement in quality of life when evaluated by standardized questionnaires. The effect of GH replacement on mortality rates in GH-deficient patients is currently the subject of long-term prospective investigation.

About 30% of patients exhibit reversible dose-related fluid retention, joint pain, and carpal tunnel syndrome, and up to 40% exhibit myalgias and paresthesia. Patients receiving insulin require careful monitoring for dosing adjustments, as GH is a potent counterregulatory hormone for insulin action. Patients with type 2 diabetes mellitus initially develop further insulin resistance. However, glycemic control improves with the sustained loss of abdominal fat associated with

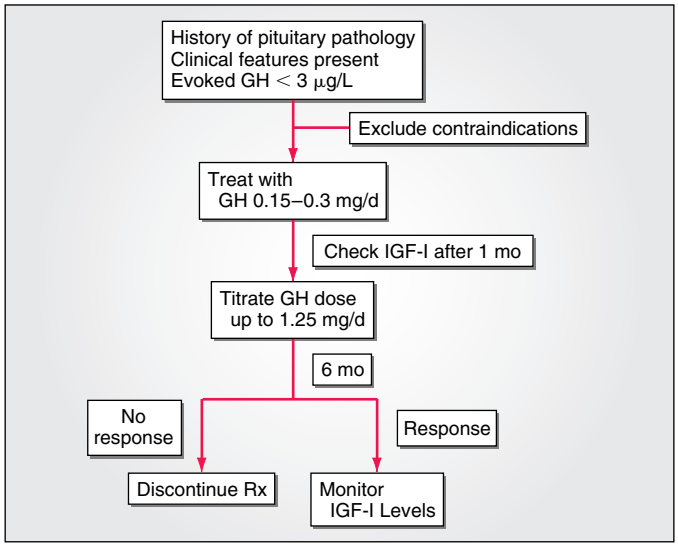

FIGURE 318-7 Management of adult growth hormone (GH) deficiency. (IGF, insulin-like growth factor.)

long-term GH replacement. Headache, increased intracranial pressure, hypertension, atrial fibrillation, and tinnitus occur rarely. Prevalence of pituitary tumor regrowth and potential progression of skin lesions are currently being assessed in long-term surveillance programs. To date, development of these potential side effects does not appear significant.

ACROMEGALY ■ Etiology GH hypersecretion is usually the result of somatotrope adenomas but is also rarely caused by extrapituitary lesions (Table 318-10). In addition to typical GH-secreting somatotrope adenomas, mixed mammosomatotrope tumors and acidophilic stem-cell adenomas can secrete both GH and PRL. In patients with acidophilic stem-cell adenomas, features of hyperprolactinemia (hypogonadism and galactorrhea) predominate over the less clinically evident signs of acromegaly. Occasionally, mixed plurihormonal tumors are encountered that secrete ACTH, the glycoprotein hormone α subunit, or TSH, in addition to GH. Patients with partially empty sella may present with GH hypersecretion due to a small GH-secreting adenoma within the compressed rim of pituitary tissue; some of these may reflect the spontaneous necrosis of tumors that were previously larger. GH-secreting tumors rarely arise from ectopic pituitary tissue remnants in the nasopharynx or midline sinuses.

TABLE 318-10 *Causes of Acromegaly*

	Prevalence, %
Excess growth hormone secretion	
Pituitary	98
Densely or sparsely granulated GH cell adenoma	60
Mixed GH cell and PRL cell adenoma	25
Mammosomatrope cell adenoma	10
Plurihormonal adenoma	
GH cell carcinoma or metastases	
Multiple endocrine neoplasia-1 (GH cell adenoma)	
McCune-Albright syndrome	
Ectopic sphenoid or parapharyngeal sinus pituitary adenoma	
Extrapituitary tumor	
Pancreatic islet cell tumor	<1
Excess growth hormone–releasing hormone secretion	
Central	<1
Hypothalamic hamartoma, choristoma, ganglioneuroma	<1
Peripheral	<1
Bronchial carcinoid, pancreatic islet cell tumor, small cell lung cancer, adrenal adenoma, medullary thyroid carcinoma, pheochromocytoma

There are case reports of ectopic GH secretion by tumors of pancreatic, ovarian, or lung origin. Excess GHRH production may cause acromegaly because of chronic stimulation of somatotropes. These patients present with classic features of acromegaly, elevated GH levels, pituitary enlargement on MRI, and pathologic characteristics of pituitary hyperplasia. The most common cause of GHRH-mediated acromegaly is a chest or abdominal carcinoid tumor. Although these tumors usually express positive GHRH immunoreactivity, clinical features of acromegaly are evident in only a minority of patients with carcinoid disease. Excessive GHRH may also be elaborated by hypothalamic tumors, usually choristomas or neuromas.

Presentation and Diagnosis Protean manifestations of GH and IGF-I hypersecretion are indolent and often are not clinically diagnosed for 10 years or more. Acral bony overgrowth results in frontal bossing, increased hand and foot size, mandibular enlargement with prognathism, and widened space between the lower incisor teeth. In children and adolescents, initiation of GH hypersecretion prior to epiphyseal long bone closure is associated with the development of pituitary gigantism (Fig. 318-8). Soft tissue swelling results in increased heel pad thickness, increased shoe or glove size, ring tightening, characteristic coarse facial features, and a large fleshy nose. Other commonly encountered clinical features include hyperhidrosis, deep and hollow-sounding voice, oily skin, arthropathy, kyphosis, carpal tunnel syndrome, proximal muscle weakness and fatigue, acanthosis nigricans, and skin tags. Generalized visceromegaly occurs, including cardiomegaly, macroglossia, and thyroid gland enlargement.

The most significant clinical impact of GH excess occurs with respect to the cardiovascular system. Coronary heart disease, cardiomyopathy with arrhythmias, left ventricular hypertrophy, decreased diastolic function, and hypertension occur in about 30% of patients. Upper airway obstruction with sleep apnea occurs in about 60% of patients and is associated with both soft tissue laryngeal airway obstruction and central sleep dysfunction. Diabetes mellitus develops in 25% of patients with acromegaly, and most patients are intolerant of a glucose load (as GH counteracts the action of insulin). Acromegaly is associated with an increased risk of colon polyps and colonic malignancy; polyps are diagnosed in up to one-third of acromegalic patients. Overall mortality is increased about threefold and is due primarily to cardiovascular and cerebrovascular disorders, malignancy, and respiratory disease. Unless GH levels are controlled, survival is reduced by an average of 10 years compared with an age-matched control population.

Laboratory Investigation Age- and gender-matched serum IGF-I levels are elevated in acromegaly. Consequently, an IGF-I level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Due to the pulsatility of GH secretion, measurement of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity. The diagnosis of acromegaly is confirmed by demonstrating the failure of GH suppression to < 1 μg/L within 1 to 2 h of an oral glucose load (75 g). About 20% of patients exhibit a paradoxical GH rise after glucose. About 60% of patients with GH-secreting tumors may exhibit paradoxical GH responses to TRH administration. PRL should be measured as it is elevated in ~25% of patients with acromegaly. Thyroid function, gonadotropins, and sex steroids may be attenuated because of tumor mass effects. Because most patients will undergo surgery with glucocorticoid coverage, tests of ACTH reserve in asymptomatic patients are more efficiently deferred until after surgery.

℞ TREATMENT

Surgical resection of GH-secreting adenomas is the initial treatment for most patients (Fig. 318-9). Somatostatin analogues are used as adjuvant treatment for preoperative shrinkage of large invasive

macroadenomas, immediate relief of debilitating symptoms, and reduction of GH hypersecretion, in elderly patients experiencing morbidity, in patients who decline surgery, or, when surgery fails, to achieve biochemical control. Irradiation or repeat surgery may be required for patients who cannot tolerate or do not respond to adjunctive medical therapy. The high rate of late hypopituitarism and the slow rate (5 to 15 years) of biochemical response are the main disadvantages of radiotherapy. Irradiation is relatively ineffective in normalizing IGF-I levels. Stereotactic ablation of GH-secreting adenomas by gamma-knife radiotherapy is promising, but long-term results are not available and the side effects have not been clearly delineated. Somatostatin analogues may be given while awaiting the full effect of radiotherapy. Systemic sequelae of acromegaly, including cardiovascular disease, diabetes, and arthritis, should also be managed aggressively. Maxillofacial surgery for mandibular repair may also be indicated.

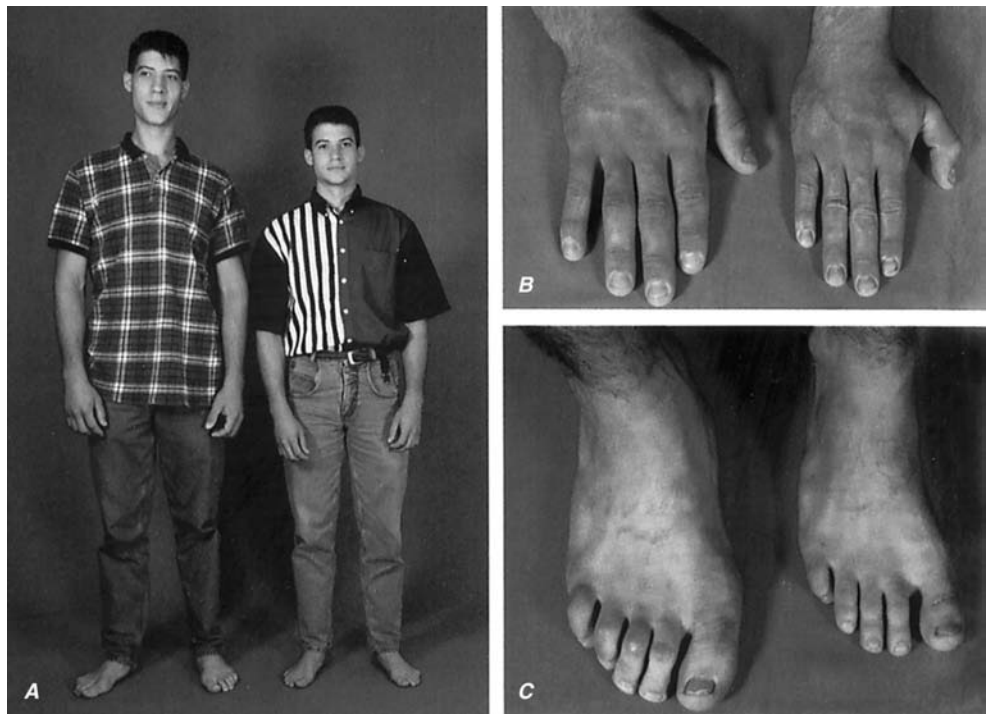

FIGURE 318-8 Features of acromegaly/gigantism. A 22-year-old man with gigantism due to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (*A*) and enlarged hand (*B*) and foot (*C*) of the affected twin are apparent. Their clinical features began to diverge at the age of approximately 13 years. *(Reproduced from R Gagel, IE McCutcheon: N Engl J Med 324:524, 1999, with permission.)*

SURGERY Transsphenoidal surgical resection by an experienced surgeon is the preferred primary treatment for both microadenomas (cure rate ~70%) and macroadenomas (<50% cured). Soft tissue swelling improves immediately after tumor resection. GH levels return to normal within an hour, and IGF-I levels are normalized within 3 to 4 days. In ~10% of patients, acromegaly may recur several years after apparently successful surgery; hypopituitarism develops in up to 15% of patients.

SOMATOSTATIN ANALOGUES Somatostatin analogues exert their therapeutic effects through SSTR2 and -5 receptors, both of which are expressed by GH-secreting tumors. Octreotide acetate is an 8-amino-acid synthetic somatostatin analogue. In contrast to native somatostatin, the analogue is relatively resistant to plasma degradation. It has a 2-h serum half-life and possesses 40-fold greater potency than native somatostatin to suppress GH. Octreotide is administered by subcutaneous injection, beginning with 50 μg tid; the dose can be gradually increased up to 1500 μg/d. Fewer than 10% of patients do not respond to the analogue. Octreotide suppresses integrated GH levels to <5 μg/L in ~70% of patients and to <2 μg/L in up to 60% of patients. It normalizes IGF-I levels in ~75% of treated patients. Prolonged use of the analogue is not associated with desensitization, even after ≥10 years of treatment. Rapid relief of headache and soft tissue swelling occurs in ~75% of patients within days to weeks of treatment initiation. Subjective clinical benefits of octreotide therapy occur more frequently than biochemical remission, and most patients report symptomatic improvement, including amelioration of headache, perspiration, obstructive apnea, and cardiac failure. Modest pituitary tumor size reduction occurs in about 40% of patients, but this effect is reversed when treatment is stopped.

Two long-acting somatostatin depot formulations, octreotide and lanreotide, are becoming the preferred medical treatment for acromegalic patients. *Sandostatin-LAR* is a sustained-release, long-acting formulation of octreotide incorporated into microspheres that sustain drug levels for several weeks after intramuscular injection. GH suppression occurs for as long as 6 weeks after a 30-mg injection; long-term monthly treatment sustains GH and IGF-I suppression and reduction of pituitary tumor size. *Lanreotide*, a slow-release depot somatostatin preparation, is a cyclic somatostatin octapeptide analogue that suppresses GH and IGF-I hypersecretion for 10 to 14 days after a 30-mg intramuscular injection. Long-term administration controls GH hypersecretion in two-thirds of

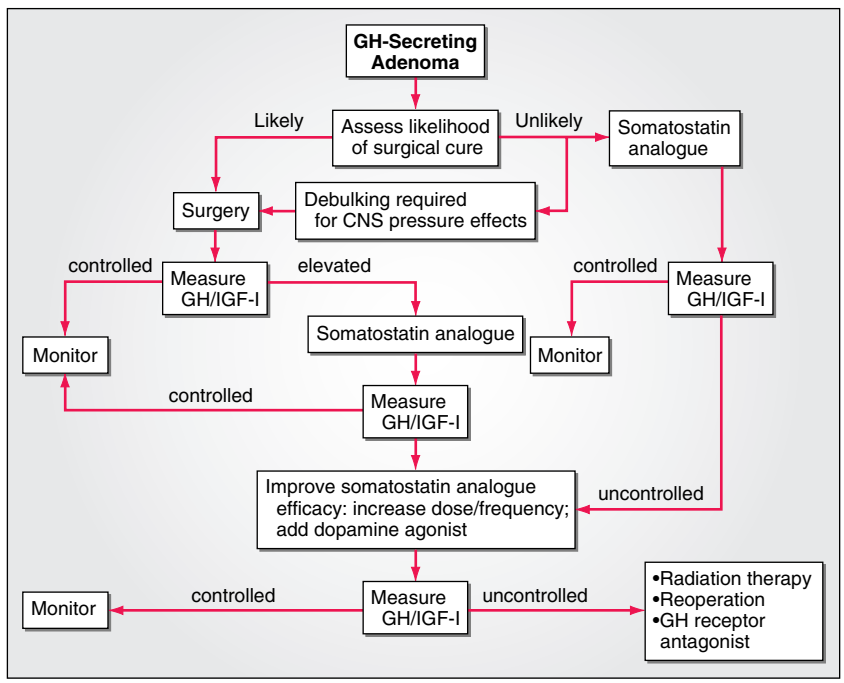

FIGURE 318-9 Management of acromegaly. (GH, growth hormone; CNS, central nervous system; IGF, insulin-like growth factor.) *(Adapted from S. Melmed et al: J Clin Endocrinol Metab 83:2646, 1998; © The Endocrine Society.)*

treated patients and improves patient compliance because of the long interval required between drug injections.

Side Effects Somatostatin analogues are well tolerated in most patients. Adverse effects are short-lived and mostly relate to drug-induced suppression of gastrointestinal motility and secretion. Nausea, abdominal discomfort, fat malabsorption, diarrhea, and flatulence occur in one-third of patients, though these symptoms usually remit within 2 weeks. Octreotide suppresses postprandial gallbladder contractility and delays gallbladder emptying; up to 30% of patients treated long-term develop echogenic sludge or asymptomatic cholesterol gallstones. Other side effects include mild glucose intolerance due to transient insulin suppression, asymptomatic bradycardia, hypothyroxinemia, and local pain at the injection site.

DOPAMINE AGONISTS Bromocriptine may suppress GH secretion in some acromegalic patients, particularly those with cosecretion of PRL. High doses (≥20 mg/d), administered as three to four daily doses, are usually required to lower GH, and therapeutic efficacy is modest. GH levels are suppressed to <5 μg/L in ~20% of patients, and IGF-I levels are normalized in only 10% of patients. Cabergoline also suppresses GH and decreases adenoma size when given at a relatively high dose of 0.5 mg/d. Combined treatment with octreotide and bromocriptine induces additive biochemical control compared to either drug alone.

GH ANTAGONISTS GH analogues (e.g., pegvisomant) antagonize endogenous GH action by blocking peripheral GH binding to its receptor. Consequently, serum IGF-I levels are suppressed, potentially reducing the deleterious effects of excess endogenous GH.

RADIATION External radiation therapy or high-energy stereotactic techniques are used as adjuvant therapy for acromegaly. An advantage of radiation is that patient compliance with long-term treatment is not required. Tumor mass is reduced, and GH levels are attenuated over time. However, 50% of patients require at least 8 years for GH levels to be suppressed to <5 μg/L; this level of GH reduction is achieved in about 90% of patients after 18 years but represents suboptimal GH suppression. Patients may require interim medical therapy for several years prior to attaining maximal radiation benefits. Most patients also experience hypothalamic-pituitary damage, leading to gonadotropin, ACTH, and/or TSH deficiency within 10 years of therapy.

In summary, surgery is the preferred primary treatment for GH-secreting microadenomas (Fig. 318-9). The high frequency of GH hypersecretion after macroadenoma resection usually necessitates adjuvant or primary medical therapy for these larger tumors. Patients unable to receive or respond to medical treatment can be offered radiation.

ADRENOCORTICOTROPIN HORMONE (See also Chap. 321)

SYNTHESIS ACTH-secreting corticotrope cells constitute about 20% of the pituitary cell population. ACTH (39 amino acids) is derived from the POMC precursor protein (266 amino acids) that also generates several other peptides, including β-lipotropin, β-endorphin, met-enkephalin, α melanocyte-stimulating hormone (MSH), and corticotropin-like intermediate lobe protein (CLIP). The POMC gene is powerfully suppressed by glucocorticoids and induced by CRH, arginine vasopressin (AVP), and proinflammatory cytokines, including IL-6, and leukemia inhibitory factor.

CRH, a 41-amino-acid hypothalamic peptide synthesized in the paraventricular nucleus as well as in higher brain centers, is the predominant stimulator of ACTH synthesis and release. The CRH receptor is a GPCR that is expressed on the corticotrope and induces POMC transcription.

SECRETION ACTH secretion is pulsatile and exhibits a characteristic circadian rhythm, peaking at 6 A.M. and reaching a nadir about midnight. Adrenal glucocorticoid secretion, which is driven by ACTH, follows a parallel diurnal pattern. ACTH circadian rhymicity is determined by variations in secretory pulse amplitude rather than changes in pulse frequency. Superimposed on this endogenous rhythm, ACTH levels are increased by AVP, physical stress, exercise, acute illness, and insulin-induced hypoglycemia.

Loss of cortisol feedback inhibition, as occurs in primary adrenal failure, results in extremely high ACTH levels. Glucocorticoid-mediated negative regulation of the hypothalamo-pituitary-adrenal (HPA) axis occurs as a consequence of both hypothalamic CRH suppression and direct attenuation of pituitary POMC gene expression and ACTH release.

Acute inflammatory or septic insults activate the HPA axis through the integrated actions of proinflammatory cytokines, bacterial toxins, and neural signals. The overlapping cascade of ACTH-inducing cytokines [tumor necrosis factor (TNF); IL-1, -2, and -6; and leukemia inhibitory factor] activates hypothalamic CRH and AVP secretion, pituitary POMC gene expression, and local paracrine pituitary cytokine networks. The resulting cortisol elevation restrains the inflammatory response and provides host protection. Concomitantly, cytokine-mediated central glucocorticoid receptor resistance impairs glucocorticoid suppression of the HPA. Thus, the neuroendocrine stress response reflects the net result of highly integrated hypothalamic, intrapituitary, and peripheral hormone and cytokine signals.

ACTION The major function of the HPA axis is to maintain metabolic homeostasis and to mediate the neuroendocrine stress response. ACTH induces cortical steroidogenesis by maintaining adrenal cell proliferation and function. The receptor for ACTH, designated *melanocortin-2 receptor*, is a GPCR that induces steroidogenesis by stimulating a cascade of steroidogenic enzymes (Chap. 321).

ACTH DEFICIENCY ■ Presentation and Diagnosis Secondary adrenal insufficiency occurs as a result of pituitary ACTH deficiency. It is characterized by fatigue, weakness, anorexia, nausea, vomiting, and, occasionally, hypoglycemia (due to diminished insulin counterregulation). In contrast to primary adrenal failure, hypocortisolism associated with pituitary failure is not usually accompanied by pigmentation changes or mineralocorticoid deficiency. ACTH deficiency is commonly due to glucocorticoid withdrawal following treatment-associated suppression of the HPA axis. Isolated ACTH deficiency may occur after surgical resection of an ACTH-secreting pituitary adenoma that has suppressed the HPA axis; this phenomenon is suggestive of a surgical cure. The mass effects of other pituitary adenomas or sellar lesions may lead to ACTH deficiency, but usually in combination with other pituitary hormone deficiencies. Partial ACTH deficiency may be unmasked in the presence of an acute medical or surgical illness, when clinically significant hypocortisolism reflects diminished ACTH reserve.

Laboratory Diagnosis Inappropriately low ACTH levels in the setting of low cortisol levels are characteristic of diminished ACTH reserve. Low basal serum cortisol levels are associated with blunted cortisol responses to ACTH stimulation and impaired cortisol response to insulin-induced hypoglycemia, or testing with metyrapone or CRH. ***→For description of provocative ACTH tests, see "Tests of Pituitary-Adrenal Responsiveness" in Chap. 321.***

℞ TREATMENT

Glucocorticoid replacement therapy improves most features of ACTH deficiency. The total daily dose of hydrocortisone replacement should not exceed 30 mg daily, divided into two or three doses. Prednisone (5 mg each morning; 2.5 mg each evening) is longer acting and has fewer mineralocorticoid effects than hydrocortisone. Some authorities advocate lower maintenance doses in an effort to avoid cushingoid side effects. Doses should be increased several-fold during periods of acute illness or stress.

CUSHING'S DISEASE (ACTH-PRODUCING ADENOMA) (See also Chap. 321)

Etiology and Prevalence Pituitary corticotrope adenomas account for 70% of patients with endogenous causes of Cushing's syndrome. However, it should be recalled that iatrogenic hypercortisolism is the most common cause of cushingoid features. Ectopic tumor ACTH production, cortisol-producing adrenal adenomas, carcinoma, and hyperplasia account for the other causes; rarely, ectopic tumor CRH production is encountered.

ACTH-producing adenomas account for about 10 to 15% of all pituitary tumors. Because the clinical features of Cushing's syndrome often lead to early diagnosis, most ACTH-producing pituitary tumors are relatively small microadenomas. However, macroadenomas are also seen, and some ACTH-secreting adenomas are clinically silent. Cushing's disease is 5 to 10 times more common in women than in men. These pituitary adenomas exhibit unrestrained ACTH secretion, with resultant hypercortisolemia. However, they retain partial suppressibility in the presence of high doses of administered glucocorticoids, providing the basis for dynamic testing to distinguish pituitary and nonpituitary causes of Cushing's syndrome.

Presentation and Diagnosis The diagnosis of Cushing's syndrome presents two great challenges: (1) to distinguish patients with pathologic cortisol excess from those with physiologic or other disturbances of cortisol production; and (2) to determine the etiology of cortisol excess.

Typical features of chronic cortisol excess include thin, brittle skin, central obesity, hypertension, plethoric moon facies, purple striae and easy bruisability, glucose intolerance or diabetes mellitus, gonadal dysfunction, osteoporosis, proximal muscle weakness, signs of hyperandrogenism (acne, hirsutism), and psychologic disturbances (depression, mania, and psychoses) (Table 318-11). Hematopoietic features of hypercortisolism include leukocytosis, lymphopenia, and eosinopenia. Immune suppression includes delayed hypersensitivity. The protean manifestations of hypercortisolism make it challenging to decide which patients mandate formal laboratory evaluation. Certain features make pathologic causes of hypercortisolism more likely—these include characteristic central redistribution of fat, thin skin with striae and bruising, and proximal muscle weakness. In children and in young females, early osteoporosis may be particularly prominent. The primary cause of death is cardiovascular disease, but infections and risk of suicide are also increased.

Rapid development of features of hypercortisolism associated with skin hyperpigmentation and severe myopathy suggests the possibility of ectopic sources of ACTH. Hypertension, hypokalemic alkalosis, glucose intolerance, and edema are also more pronounced in these patients. Serum potassium levels <3.3 mmol/L are evident in ~70% of patients with ectopic ACTH secretion but are seen in <10% of patients with pituitary-dependent Cushing's disease.

Laboratory Investigation The diagnosis of Cushing's syndrome is based on laboratory documentation of endogenous hypercortisolism. Measurements of 24-h urine free cortisol (UFC) is a precise and cost-effective screening test. Alternatively, the failure to suppress plasma cortisol after an overnight 1-mg dexamethasone suppression test can be used to identify patients with hypercortisolism. As nadir levels of cortisol occur at night, elevated midnight samples of cortisol are suggestive of Cushing's syndrome. Basal plasma ACTH levels often distinguish patients with ACTH-independent (adrenal or exogenous glucocorticoid) from those with ACTH-dependent (pituitary, ectopic ACTH) Cushing's disease. Mean basal ACTH levels are about eightfold higher in patients with ectopic ACTH secretion compared to those with pituitary ACTH-secreting adenomas. However, extensive overlap of ACTH levels in these two disorders precludes using ACTH to make the distinction. Instead, dynamic testing, based on differential sensitivity to glucocorticoid feedback, or ACTH stimulation in response to CRH or cortisol reduction is used to discriminate ectopic versus pituitary sources of excess ACTH (Table 318-12). Very rarely, circulating CRH levels are elevated, reflecting ectopic tumor-derived secretion of CRH and often ACTH. →***For discussion of dynamic testing for Cushing's syndrome, see Chap. 321.***

Most ACTH-secreting pituitary tumors are <5 mm in diameter, and about half are undetectable by sensitive MRI. The high prevalence of incidental pituitary microadenomas diminishes the ability to distinguish ACTH-secreting pituitary tumors accurately by MRI.

TABLE 318-11 *Clinical Features of Cushing's Syndrome (All Ages)*

Symptoms/Signs	Frequency, %
Obesity or weight gain (>115% ideal body weight)	80
Thin skin	80
Moon facies	75

TABLE 318-12 *Differential Diagnosis of ACTH-Dependent Cushing's Syndrome*[a]

	ACTH-Secreting Pituitary Tumor	Ectopic ACTH Secretion
Etiology	Pituitary corticotrope adenoma Plurihormonal adenoma	Bronchial, abdominal carcinoid Small cell lung cancer Thymoma
Gender	F > M	M > F
Clinical features	Slow onset	Rapid onset Pigmentation Severe myopathy
Serum potassium <3.3 μg/L	<10%	75%
24-h urinary free cortisol (UFC)	High	High
Basal ACTH level	Inappropriately high	Very high
Dexamethasone suppression		
1 mg overnight		
Low dose (0.5 mg q6h)	Cortisol >5 μg/dL	Cortisol >5 μg/dL
High dose (2 mg q6h)	Cortisol >5 μg/dL	Cortisol >5 μg/dL
UFC > 80% suppressed	Microadenomas: 90% Macroadenomas: 50%	10%
Inferior petrosal sinus sampling (IPSS)		
Basal		
IPSS: peripheral	>2	<2
CRH-induced		
IPSS: peripheral	>3	<3

[a] ACTH-independent causes of Cushing's syndrome are diagnosed by suppressed ACTH levels and an adrenal mass in the setting of hypercortisolism. Iatrogenic Cushing's syndrome is excluded by history.

Note: ACTH, adrenocorticotropin hormone; F, female; M, male; CRH, corticotropin-releasing hormone.

Inferior Petrosal Venous Sampling Because pituitary MRI with gadolinium enhancement is insufficiently sensitive to detect small (<2 mm) pituitary ACTH-secreting adenomas, bilateral inferior petrosal sinus ACTH sampling before and after CRH administration may be required to distinguish these lesions from ectopic ACTH-secreting tumors that may have similar clinical and biochemical characteristics. Simultaneous assessment of ACTH concentrations in each inferior petrosal vein and in the peripheral circulation provides a strategy for confirming and localizing pituitary ACTH production. Sampling is performed at baseline and 2, 5, and 10 min after intravenous ovine CRH (1 μg/kg) injection. An increased ratio (>2) of inferior petrosal: peripheral vein ACTH confirms pituitary Cushing's disease. After CRH injection, peak petrosal:peripheral ACTH ratios of ≥3 confirm the presence of a pituitary ACTH-secreting tumor. The sensitivity of this test is >95%, with very rare false-positive results. False-negative results may be encountered in patients with aberrant venous anatomic drainage. Petrosal sinus catheterizations are technically difficult, and about 0.05% of patients develop neurovascular complications. The procedure should not be performed in patients with hypertension or in the presence of a well-visualized pituitary adenoma on MRI.

TREATMENT

Selective transsphenoidal resection is the treatment of choice for Cushing's disease (Fig. 318-10). The remission rate for this procedure is ~80% for microadenomas but <50% for macroadenomas. After successful tumor resection, most patients experience a postoperative period of adrenal insufficiency that lasts for up to 12 months. This usually requires low-dose cortisol replacement, as patients experience steroid withdrawal symptoms as well as having a suppressed HPA axis. Biochemical recurrence occurs in approximately 5% of patients in whom surgery was initially successful.

When initial surgery is unsuccessful, repeat surgery is sometimes indicated, particularly when a pituitary source for ACTH is well documented. In older patients when growth and fertility are no longer important, hemi- or total hypophysectomy may be necessary if an adenoma is not recognized. Pituitary irradiation may be used after unsuccessful surgery, but it cures only about 15% of patients. Because radiation is slow and only partially effective in adults, steroidogenic inhibitors are used in combination with pituitary irradiation to block the adrenal effects of persistently high ACTH levels.

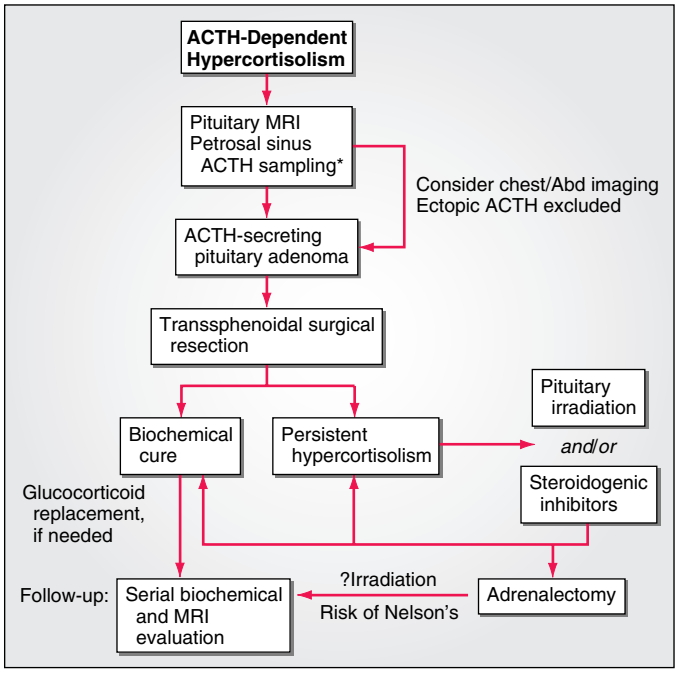

FIGURE 318-10 Management of Cushing's disease. (ACTH, adrenocorticotropin hormone; MRI, magnetic resonance imaging.) *, Not usually required.

Ketoconazole, an imidazole derivative antimycotic agent, inhibits several P450 enzymes and effectively lowers cortisol in most patients with Cushing's disease when administered twice daily (600 to 1200 mg/d). Elevated hepatic transaminases, gynecomastia, impotence, gastrointestinal upset, and edema are common side effects. *Metyrapone* (2 to 4 g/d) inhibits 11β-hydroxylase activity and normalizes plasma cortisol in up to 75% of patients. Side effects include nausea and vomiting, rash, and exacerbation of acne or hirsutism. *Mitotane* (*o*, *p'*-DDD; 3 to 6 g/d orally in four divided doses) suppresses cortisol hypersecretion by inhibiting 11β-hydroxylase and cholesterol side-chain cleavage enzymes and by destroying adrenocortical cells. Side effects of mitotane include gastrointestinal symptoms, dizziness, gynecomastia, hyperlipidemia, skin rash, and hepatic enzyme elevation. It may also lead to hypoaldosteronism. Other agents include *aminoglutethimide* (250 mg tid), *trilostane* (200 to 1000 mg/d), *cyproheptadine* (24 mg/d), and IV *etomidate* (0.3 mg/kg per hour). Glucocorticoid insufficiency is a potential side effect of agents used to block steroidogenesis.

The use of steroidogenic inhibitors has decreased the need for bilateral adrenalectomy. Removal of both adrenal glands corrects hypercortisolism but may be associated with significant morbidity and necessitates permanent glucocorticoid and mineralocorticoid replacement. Adrenalectomy in the setting of residual corticotrope adenoma tissue predisposes to the development of *Nelson's syndrome*, a disorder characterized by rapid pituitary tumor enlargement and increased pigmentation secondary to high ACTH levels. Radiation therapy may be indicated to prevent the development of Nelson's syndrome after adrenalectomy.

GONADOTROPINS: FSH AND LH

SYNTHESIS AND SECRETION Gonadotrope cells comprise about 10% of anterior pituitary cells and produce two gonadotropins—LH and FSH. Like TSH and hCG, LH and FSH are glycoprotein hormones consisting of α and β subunits. The α subunit is common to these glycoprotein hormones; specificity is conferred by the β subunits, which are expressed by separate genes.

Gonadotropin synthesis and release are dynamically regulated. This is particularly true in females, in whom the rapidly fluctuating gonadal steroid levels vary throughout the menstrual cycle. Hypothalamic GnRH, a 10-amino-acid peptide, regulates the synthesis and secretion of both LH and FSH. GnRH is secreted in discrete pulses every 60 to 120 min, which in turn elicit LH and FSH pulses (Fig. 318-3). The pulsatile mode of GnRH input is essential to its action; pulses prime gonadotrope responsiveness, whereas continuous GnRH exposure induces desensitization. Based on this phenomenon, long-acting GnRH agonists are used to suppress gonadotropin levels in children with precocious puberty and in men with prostate cancer (Chap. 81) and are used in some ovulation-induction protocols to reduce endogenous gonadotropins (Chap. 45). Estrogens act at the hypothalamic and pituitary levels to control gonadotropin secretion. Chronic estrogen exposure is inhibitory, whereas rising estrogen levels, as occurs during the preovulatory surge, exert positive feedback to increase gonadotropin pulse frequency and amplitude. Progesterone slows GnRH pulse frequency but enhances gonadotropin responses to GnRH. Testosterone feedback in males also occurs at the hypothalamic and pituitary levels and partially reflects its conversion to estrogens.

Though GnRH is the main regulator of LH and FSH secretion, FSH synthesis is also under separate control by the gonadal peptides inhibin and activin, which are members of the transforming growth factor β (TGF-β) family. Inhibin selectively suppresses FSH, whereas activin stimulates FSH synthesis (Chap. 326).

ACTION The gonadotropin hormones interact with their respective GPCRs expressed in the ovary and testis, evoking germ-cell development and maturation and steroid hormone biosynthesis. In women, FSH regulates ovarian follicle development and stimulates ovarian estrogen production. LH mediates ovulation and maintenance of the cor-

pus luteum. In men, LH induces Leydig cell testosterone synthesis and secretion and FSH stimulates seminiferous tubule development and regulates spermatogenesis.

GONADOTROPIN DEFICIENCY Hypogonadism is the most common presenting feature of adult hypopituitarism, even when other pituitary hormones are also deficient. It is often a harbinger of hypothalamic or pituitary diseases that impair GnRH production or delivery through the pituitary stalk. As noted above, hypogonadotropic hypogonadism is a common presenting feature of hyperprolactinemia.

A variety of inherited and acquired disorders are associated with *isolated hypogonadotropic hypogonadism* (IHH) (Chap. 325). Hypothalamic defects associated with GnRH deficiency include two X-linked disorders, Kallmann syndrome (see above) and mutations in the *DAX1* gene. GnRH receptor mutations and inactivating mutations of the LH β and FSH β subunit genes are rare causes of selective gonadotropin deficiency. Acquired forms of GnRH deficiency leading to hypogonadotropism are seen in association with anorexia nervosa (Chap. 65), stress, starvation, and extreme exercise, but may also be idiopathic. Hypogonadotropic hypogonadism in these disorders is reversed by removal of the stressful stimulus.

Presentation and Diagnosis In premenopausal women, hypogonadotropic hypogonadism presents as diminished ovarian function leading to oligomenorrhea or amenorrhea, infertility, decreased vaginal secretions, decreased libido, and breast atrophy. In hypogonadal adult males, secondary testicular failure is associated with decreased libido and potency, infertility, decreased muscle mass with weakness, reduced beard and body hair growth, soft testes, and characteristic fine facial wrinkles. Osteoporosis occurs in both untreated hypogonadal females and males.

Laboratory Investigation Central hypogonadism is associated with low or inappropriately normal serum gonadotropin levels in the setting of low sex hormone concentrations (testosterone in males, estradiol in females). Three pooled serum samples drawn 20 min apart are used for accurate measurement of serum LH and FSH levels, thus allowing for the effects of hormone secretory pulses. Male patients have abnormal semen analysis.

Intravenous GnRH (100 μg) stimulates gonadotropes to secrete LH (which peaks within 30 min) and FSH (which plateaus during the ensuing 60 min). Normal responses vary according to menstrual cycle stage, age, and sex of the patient. Generally, LH levels increase about threefold, whereas FSH responses are less pronounced. In the setting of gonadotropin deficiency, a normal gonadotropin response to GnRH indicates intact gonadotrope function and suggests a hypothalamic abnormality. An absent response, however, cannot reliably distinguish pituitary from hypothalamic causes of hypogonadism. For this reason, GnRH testing usually adds little to the information gained from baseline evaluation of the hypothalamic-pituitary-gonadotrope axis, except in cases of isolated GnRH deficiency (e.g., Kallmann syndrome).

MRI examination of the sellar region and assessment of other pituitary functions are usually indicated in patients with documented central hypogonadism.

TREATMENT

In males, testosterone replacement is necessary to achieve and maintain normal growth and development of the external genitalia, secondary sex characteristics, male sexual behavior, and androgenic anabolic effects including maintenance of muscle function and bone mass. Testosterone may be administered by intramuscular injections every 1 to 4 weeks or using patches that are replaced daily (Chap. 325). Testosterone creams are also available. Gonadotropin injections [hCG or human menopausal gonadotropin (hMG)] over 12 to 18 months are used to restore fertility. Pulsatile GnRH therapy (25 to 150 ng/kg every 2 h), administered by a subcutaneous infusion pump, is also effective for treatment of hypothalamic hypogonadism when fertility is desired.

In premenopausal women, cyclical replacement of estrogen and progesterone maintains secondary sexual characteristics and genitourinary tract integrity and prevents premature osteoporosis (Chap. 326). Gonadotropin therapy is used for ovulation induction. Follicular growth and maturation are initiated using hMG or recombinant FSH; hCG is subsequently injected to induce ovulation. As in men, pulsatile GnRH therapy can be used to treat hypothalamic causes of gonadotropin deficiency.

NONFUNCTIONING AND GONADOTROPIN-PRODUCING PITUITARY ADENOMAS

Etiology and Prevalence Nonfunctioning pituitary adenomas include those that secrete little or no pituitary hormones, as well as tumors that produce too little hormone to result in recognizable clinical features. They are the most common type of pituitary adenoma and are usually macroadenomas at the time of diagnosis because clinical features are inapparent until tumor mass effects occur. Based on immunohistochemistry, most clinically nonfunctioning adenomas can be shown to originate from gonadotrope cells. These tumors typically produce small amounts of intact gonadotropins (usually FSH) as well as uncombined α and LH β and FSH β subunits. Tumor secretion may lead to elevated α and FSH β subunits and, rarely, to increased LH β subunit levels. Some adenomas express α subunits without FSH or LH. TRH administration often induces an atypical increase of tumor-derived gonadotropins or subunits.

Presentation and Diagnosis Clinically nonfunctioning tumors may present with optic chiasm pressure and other symptoms of local expansion or be incidentally discovered on an MRI performed for another indication. Menstrual disturbances or ovarian hyperstimulation rarely occur in women with large tumors that produce FSH and LH. More commonly, adenoma compression of the pituitary stalk or surrounding pituitary tissue leads to attenuated LH and features of hypogonadism. PRL levels are usually slightly increased, also because of stalk compression. It is important to distinguish this circumstance from true prolactinomas, as most nonfunctioning tumors respond poorly to treatment with dopamine agonists.

Laboratory Investigation The goal of laboratory testing in clinically nonfunctioning tumors is to classify the type of the tumor, to identify hormonal markers of tumor activity, and to detect possible hypopituitarism. Free α subunit levels may be elevated in 10 to 15% of patients with nonfunctioning tumors. In female patients, peri- or postmenopausal basal FSH concentrations are difficult to distinguish from tumor-derived FSH elevation. Premenopausal women have cycling FSH levels, also preventing clear-cut diagnostic distinction from tumor-derived FSH. In men, gonadotropin-secreting tumors may be diagnosed because of slightly increased gonadotropins (FSH $>$ LH) in the setting of a pituitary mass. Testosterone levels are usually low, despite the normal or increased LH level, perhaps reflecting reduced LH bioactivity or the loss of normal LH pulsatility. Because this pattern of hormone tests is also seen in primary gonadal failure and, to some extent, with aging (Chap. 325), the increased gonadotropins alone are insufficient for the diagnosis of a gonadotropin-secreting tumor. In the majority of patients with gonadotrope adenomas, TRH administration stimulates LH β subunit secretion; this response is not seen in normal individuals. GnRH testing is not helpful for making the diagnosis. For nonfunctioning and gonadotropin-secreting tumors, the diagnosis usually rests on immunohistochemical analyses of resected tumor tissue, as the mass effects of these tumors usually necessitate resection.

Although acromegaly or Cushing's syndrome usually presents with unique clinical features, clinically inapparent somatotrope or corticotrope adenomas can be excluded by a normal IGF-I value and normal 24-h urinary free cortisol levels. If PRL levels are $<$100 μg/L in a patient harboring a pituitary mass, a nonfunctioning adenoma causing pituitary stalk compression should be considered.

TREATMENT

Asymptomatic small nonfunctioning adenomas with no threat to vision may be followed with regular MRI and visual field testing without immediate intervention. However, for larger macroadenomas, trans-

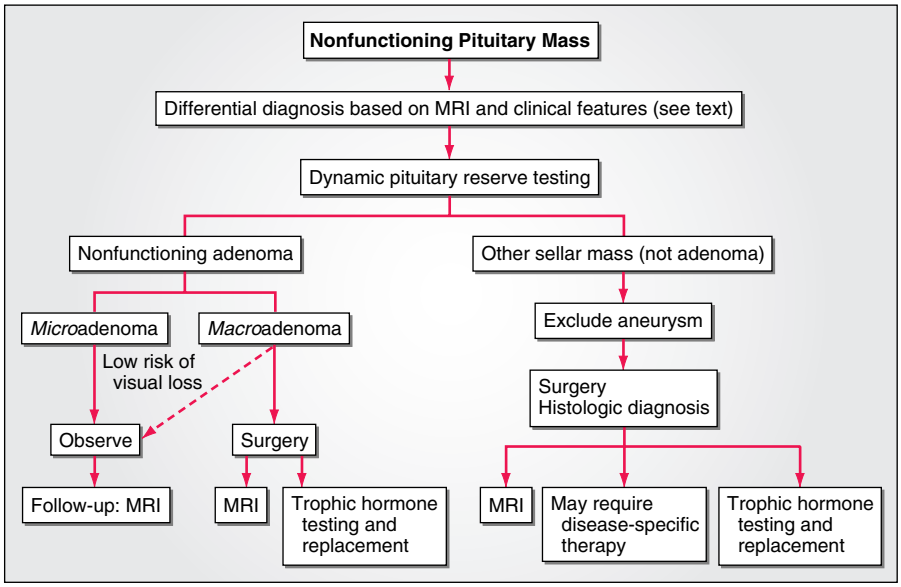

FIGURE 318-11 Management of a nonfunctioning pituitary mass.

sphenoidal surgery is the only effective way to reduce tumor size and relieve mass effects (Fig. 318-11). Although it is not usually possible to remove all adenoma tissue surgically, vision improves in 70% of patients with preoperative visual field defects. Preexisting hypopituitarism that results from tumor mass effects commonly improves or may resolve completely. Beginning about 6 months postoperatively, MRI scans should be performed yearly to detect tumor regrowth. Within 5 to 6 years following successful surgical resection, ~15% of nonfunctioning tumors recur. When substantial tumor remains after transsphenoidal surgery, adjuvant radiotherapy may be indicated to prevent tumor growth. Radiotherapy may be deferred if no postoperative residual mass is evident.

Nonfunctioning pituitary tumors respond poorly to dopamine agonist treatment, with modest tumor shrinkage occurring in <10% of patients. Although SSTR subtypes 2 and 5 have been identified on nonfunctioning pituitary adenomas, octreotide does not shrink these tumors and only modestly suppresses gonadotropin and α subunit levels. Visual improvement sometimes occurs without evident reduction of tumor size by MRI, presumably reflecting relief of pressure on the optic tracts. The selective GnRH antagonist, Nal-Glu GnRH, suppresses FSH hypersecretion but has no effect on adenoma size.

THYROID-STIMULATING HORMONE

SYNTHESIS AND SECRETION TSH-secreting thyrotrope cells comprise 5% of the anterior pituitary cell population. TSH is structurally related to LH and FSH. It shares a common α subunit with these hormones but contains a specific TSH β subunit. TRH is a hypothalamic tripeptide (pyroglutamyl histidylprolinamide) that acts through a GPCR to stimulate TSH synthesis and secretion; it also stimulates the lactotrope cell to secrete PRL. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, SRIF, and glucocorticoids suppress TSH by overriding TRH induction.

The thyrotrope is stimulated by a release from the negative feedback inhibition by thyroid hormones. Thus, thyroid damage, (including surgical thyroidectomy), radiation-induced hypothyroidism, chronic thyroiditis, or prolonged goitrogen exposure are associated with increased TSH. Long-standing untreated hypothyroidism can lead to thyrotrope hyperplasia and pituitary enlargement, which may be evident on MRI.

ACTION TSH is secreted in pulses, though the excursions are modest in comparison to other pituitary hormones because of the relatively low amplitude of the pulses and the relatively long half-life of TSH. Consequently, single determinations of TSH suffice to assess its circulating levels. TSH binds to a GPCR on thyroid follicular cells to stimulate thyroid hormone synthesis and release (Chap. 320).

TSH DEFICIENCY Features of central hypothyroidism, due to TSH deficiency, mimic those seen with primary hypothyroidism but are generally less severe. Pituitary hypothyroidism is characterized by low basal TSH levels in the setting of low free thyroid hormone. In contrast, patients with hypothyroidism of hypothalamic origin (presumably due to a lack of endogenous TRH) may exhibit normal or even slightly elevated TSH levels. There is evidence that the TSH produced in this circumstance has reduced biologic activity because of altered glycosylation.

TRH (200 μg) injected intravenously causes a two- to threefold increase in TSH (and PRL) levels within 30 min. Although TRH testing can be used to assess TSH reserve, abnormalities of the thyroid axis can usually be detected based on basal free T_4 and TSH levels, without the need for TRH testing.

Thyroid-replacement therapy should be initiated after establishing adequate adrenal function. Dose adjustment is based on thyroid hormone levels and clinical parameters rather than the TSH level.

TSH-SECRETING ADENOMAS TSH-producing macroadenomas are rare but are often large and locally invasive when they occur. Patients usually present with thyroid goiter and hyperthyroidism, reflecting overproduction of TSH. Diagnosis is based on demonstrating elevated serum free T_4 levels, inappropriately normal or high TSH secretion, and MRI evidence of a pituitary adenoma.

It is important to exclude other causes of inappropriate TSH secretion, such as resistance to thyroid hormone, an autosomal dominant disorder caused by mutations in the thyroid hormone β receptor (Chap. 320). The presence of a pituitary mass and elevated α subunit levels are suggestive of a TSH-secreting tumor. Dysalbuminemic hyperthyroxinemia syndromes, caused by various mutations in serum thyroid hormone binding proteins, are also characterized by elevated thyroid hormone levels, but with normal rather than suppressed TSH levels. Moreover, free thyroid hormone levels are normal in these disorders, most of which are familial.

TREATMENT

The initial therapeutic approach is to remove or debulk the tumor mass surgically, using either a transsphenoidal or subfrontal approach. Total resection is not often achieved as most of these adenomas are large and locally invasive. Normal circulating thyroid hormone levels are achieved in about two-thirds of patients after surgery. Thyroid ablation or antithyroid drugs (methimazole or propylthiouracil) can be used to reduce thyroid hormone levels. Dopamine agonists are rarely effective for suppressing TSH secretion from these tumors. However, somatostatin analogue treatment effectively normalizes TSH and α subunit hypersecretion, shrinks the tumor mass in 50% of patients, and improves visual fields in 75% of patients; euthyroidism is restored in most patients. In some patients, octreotide markedly suppresses TSH, causing biochemical hypothyroidism that requires concomitant thyroid hormone replacement. Lanreotide (30 mg intramuscularly), a long-acting somatostatin analogue (see above), effectively suppresses TSH and thyroid hormone in patients treated every 14 days.

319 DISORDERS OF THE NEUROHYPOPHYSIS

Gary L. Robertson

The neurohypophysis, or posterior pituitary gland, is formed by axons that originate in large cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus. It produces two hormones: (1) arginine vasopressin (AVP), also known as antidiuretic hormone; and (2) oxytocin. AVP acts on the renal tubules to reduce water loss by concentrating the urine. Oxytocin stimulates postpartum milk letdown in response to suckling. AVP deficiency causes diabetes insipidus (DI), characterized by the production of large amounts of dilute urine. Excessive or inappropriate AVP production predisposes to hyponatremia if water intake is not reduced in parallel with urine output.

VASOPRESSIN

ACTION AVP is a nonapeptide composed of a six-membered disulfide ring and a tripeptide tail (Fig. 319-1). The most important, if not the only, physiologic action of AVP is to reduce water excretion by promoting concentration of urine. This antidiuretic effect is achieved by increasing the hydroosmotic permeability of cells that line the distal tubule and medullary collecting ducts of the kidney (Fig. 319-2). In the absence of AVP, these cells are impermeable to water and reabsorb little, if any, of the relatively large volume of dilute filtrate that enters from the proximal nephron. This results in the excretion of very large volumes (as much as 0.2 mL/kg per min) of maximally dilute urine (specific gravity and osmolarity ~1.000 and 50 mosmol/L, respectively), a condition known as a *water diuresis*. In the presence of AVP, these cells become selectively permeable to water, allowing it to diffuse back down the osmotic gradient created by the hypertonic renal medulla. As a result, the dilute fluid passing through the tubules is concentrated and the rate of urine flow decreases. The magnitude of this effect varies in direct proportion to the plasma AVP concentration and, at maximum levels, approximates a urine flow rate as low as 0.35 mL/min and a urine osmolarity as high as 1200 mosmol/L. AVP action is mediated via binding to G protein–coupled V_2 receptors on the serosal surface of the cell, activation of adenyl cyclase, and insertion into the luminal surface of water channels composed of a protein known as *aquaporin 2*.

At high concentrations, AVP also causes contraction of smooth muscle in blood vessels and in the gastrointestinal tract, induces glycogenolysis in the liver, and potentiates adrenocorticotropic hormone (ACTH) release by corticotropin-releasing factor. These effects are mediated by V_{1a} or V_{1b} receptors that are coupled to phospholipase C. Their role, if any, in human physiology/pathophysiology is still uncertain.

SYNTHESIS AND SECRETION AVP secretion is synthesized via a polypeptide precursor that includes AVP, neurophysin, and copeptin. After preliminary processing and folding, the precursor is packaged in neurosecretory vesicles where it is transported down the axon, further processed to AVP, and stored until the hormone and other components are released by exocytosis into peripheral blood.

AVP secretion is regulated primarily by the "effective" osmotic pressure of body fluids. This control is mediated by specialized hypothalamic cells, known as *osmoreceptors*, which are extremely sensitive to small changes in the plasma concentration of sodium and certain other solutes but are insensitive to other solutes such as urea or glucose. The osmoreceptors appear to include inhibitory as well as stimulatory components that function in concert to form a threshold, or set point, control system for AVP release. Below this threshold, plasma AVP is suppressed to levels that permit the development of a maximum water diuresis. Above it, plasma AVP rises steeply in direct proportion to plasma osmolarity, quickly reaching levels sufficient to effect a maximum antidiuresis. The absolute levels of plasma osmolarity/sodium at which minimally and maximally effective levels of plasma AVP occur vary appreciably from person to person, owing apparently to genetic influences on the set and sensitivity of the system. However, the average threshold, or set point, for AVP release corresponds to a plasma osmolarity or sodium of about 280 mosmol/L or 135 meq/L, respectively; levels only 2 to 4% higher normally result in maximum antidiuresis. Though relatively stable in a healthy adult, the set of the osmoregulatory system can also be lowered by pregnancy, the menstrual cycle, and relatively large, acute reductions in blood pressure or volume.

The effects of acute changes in blood volume or pressure are mediated largely by neuronal afferents that originate in transmural pressure receptors of the heart and large arteries and project via the vagus and glossopharyngeal nerves to the brain stem, from whence postsynaptic projections ascend to the hypothalmus. These pathways maintain a tonic inhibitory tone that decreases when blood volume or pressure falls by >10 to 20%. This baroregulatory system is probably of minor importance in the physiology of AVP secretion because the hemodynamic changes required to affect it do not usually occur during normal activities. However, the baroregulatory system undoubtedly plays an important role in AVP secretion in patients with large, acute disturbances of hemodynamic function.

AVP secretion can also be stimulated by nausea, acute hypoglycemia, glucocorticoid deficiency, smoking, and, possibly, hyperangiotensinemia. The emetic stimuli are extremely potent since they typically elicit immediate, 50- to 100-fold increases in plasma AVP, even when the nausea is transient and unassociated with vomiting or other symptoms. They appear to act via the emetic center in the medulla and can be completely blocked by treatment with antiemetics such as fluphenazine. There is no evidence that pain or other noxious stresses have any affect on AVP unless they elicit a vasovagal reaction with its associated nausea and hypotension.

METABOLISM AVP distributes rapidly into a space roughly equal to the extracellular fluid volume. It is cleared irreversibly with a $t_{½}$ of 10 to 30 min. Most AVP clearance is due to degradation in the liver and kidneys. During pregnancy, the metabolic clearance of AVP is increased three- to fourfold due to placental production of an N-terminal peptidase.

THIRST Because AVP cannot reduce water loss below a certain minimum level obligated by urinary solute load and evaporation from skin

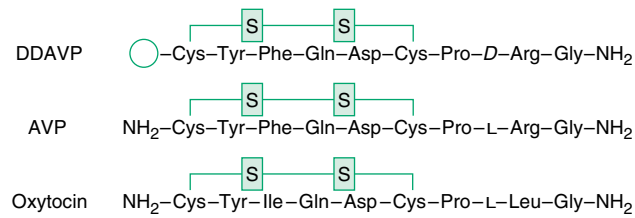

FIGURE 319-1 Primary structures of arginine vasopressin (AVP), oxytocin, and DDAVP.

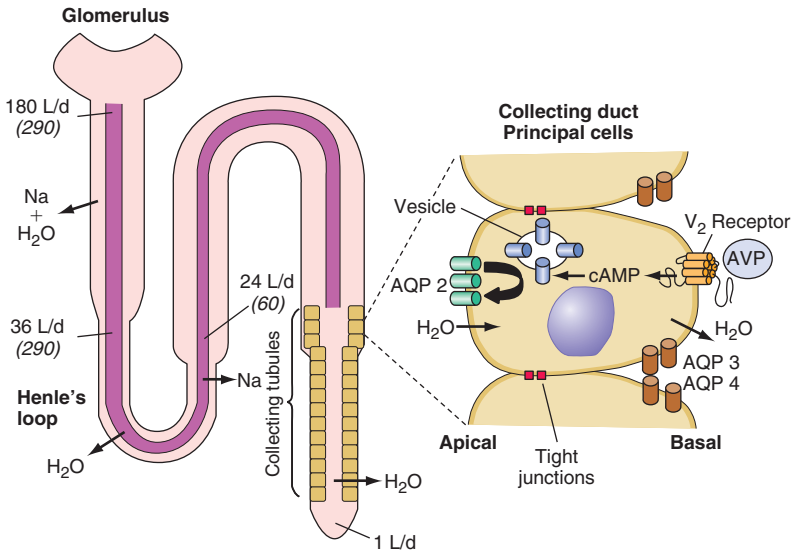

FIGURE 319-2 Antidiuretic effect of arginine vasopressin (AVP) in the regulation of urine volume. In a typical 70-kg adult, the kidney filters about 180 L/d of plasma. Of this, approximately 144 L (80%) is reabsorbed isosmotically in the proximal tubule and another 8 L (4 to 5%) is reabsorbed without solute in the descending limb of Henle's loop. The remainder is diluted to an osmolarity of about 60 mmol/kg by selective reabsorption of sodium and chloride in the ascending limb. In the absence of AVP, the urine issuing from the loop passes largely unmodified through the distal tubules and collecting ducts, resulting in a maximum water diuresis. In the presence of AVP, solute-free water is reabsorbed osmotically through the principal cells of the collecting ducts, resulting in the excretion of a much smaller volume of concentrated urine. This antidiuretic effect is mediated via a G protein–coupled V_2 receptor that increases intracellular cyclic AMP, thereby inducing translocation of aquaporin 2 (AQP 2) water channels into the apical membrane. The resultant increase in permeability permits an influx of water that diffuses out of the cell through AQP 3 and AQP 4 water channels on the basal-lateral surface. The net rate of flux across the cell is determined by the number of AQP 2 water channels in the apical membrane and the strength of the osmotic gradient between tubular fluid and the renal medulla. Tight junctions on the lateral surface of the cells serve to prevent unregulated water flow.

and lungs, a mechanism for ensuring adequate intake is essential for preventing dehydration. This vital function is performed by the thirst mechanism. Like AVP, thirst is regulated primarily by an osmostat that is located in the anteromedial hypothalamus and is able to detect very small changes in the plasma concentration of sodium and certain other effective solutes. The thirst osmostat appears to be "set" about 5% higher than the AVP osmostat. This arrangement ensures that thirst, polydipsia, and dilution of body fluids do not occur until plasma osmolarity/sodium start to exceed the defensive capacity of the antidiuretic mechanism.

OXYTOCIN

Oxytocin is also a nonapeptide and differs from AVP only at positions 3 and 8 (Fig. 319-1). However, it has relatively little antidiuretic effect and seems to act mainly on mammary ducts to facilitate milk letdown during nursing. It may also help to initiate or facilitate labor by stimulating contraction of uterine smooth muscle, but it is not yet clear if this action is physiologic or necessary for normal delivery.

DEFICIENCIES OF VASOPRESSIN SECRETION AND ACTION

DIABETES INSIPIDUS ■ Clinical Characteristics Decreased secretion or action of AVP usually manifests as DI, a syndrome characterized by the production of abnormally large volumes of dilute urine. The 24-h urine volume is >50 mL/kg body weight and the osmolarity is <300 mosmol/L. The polyuria produces symptoms of urinary frequency, enuresis, and/or nocturia, which may disturb sleep and cause mild daytime fatigue or somnolence. It is also associated with thirst and a commensurate increase in fluid intake (polydipsia). Clinical signs of dehydration are uncommon unless fluid intake is impaired.

Etiology Deficient secretion of AVP can be primary or secondary. The primary form usually results from agenesis or irreversible destruction of the neurohypophysis and is variously referred to as *neurohypophyseal DI*, *pituitary DI*, or *central DI*. It can be caused by a variety of congenital, acquired, or genetic disorders but almost half the time it is idiopathic (Table 319-1). The genetic form of neurohypophyseal DI is usually transmitted in an autosomal dominant mode and is caused by diverse mutations in the coding region of the AVP–neurophysin II (or AVP-NPII) gene. In this type, the AVP deficiency and DI begin several months to several years after birth and appear to be a result of selective degeneration of AVP-producing magnocellular neurons. An autosomal recessive form, due to inactivating mutations in the AVP gene, and an X-linked recessive form, due to an unidentified gene on Xq28, have also been described. A primary deficiency of plasma AVP can also result from increased metabolism by an N-terminal aminopeptidase produced by the placenta. It is referred to as *gestational DI* since the signs and symptoms manifest during pregnancy and usually remit several weeks after delivery. However, a subclinical deficiency in AVP secretion can often be demonstrated in the nonpregnant state, indicating that damage to the neurohypophysis may also contribute to the AVP deficiency. Finally, a primary deficiency of AVP can also result from malformation or destruction of the neurohypophysis by a variety of diseases or toxins (Table 319-1).

Secondary deficiencies of AVP result from inhibition of secretion by excessive intake of fluids. They are referred to as *primary polydipsia* and can be divided into three subcategories. One of them, called *dipsogenic DI*, is characterized by an inappropriate increase in thirst caused by a reduction in the "set" of the osmoregulatory mechanism. It sometimes occurs in association with multifocal diseases of the brain such as neurosarcoid, tuberculous meningitis, or multiple sclerosis but is often idiopathic. The second subtype, called *psychogenic polydipsia*, is not associated with thirst, and the polydipsia seems to be a feature of psychosis. The third subtype, which may be referred to as *iatrogenic polydipsia*, results from recommendations of health professionals or the popular media to increase fluid intake for its presumed preventive or therapeutic benefits for other disorders.

Primary deficiencies in the antidiuretic action of AVP result in *nephrogenic DI* (Table 319-1). It can be genetic, acquired, or caused by exposure to various drugs. The genetic form is usually transmitted in an X-linked mode and is caused by mutations in the coding region of the V_2 receptor gene. Autosomal recessive or dominant forms result from mutations in the gene encoding the aquaporin protein that forms the water channels in the distal nephron.

Secondary deficiencies in the antidiuretic response to AVP result from polyuria per se. They are caused by washout of the medullary concentration gradient and/or suppression of aquaporin function. They usually resolve 24 to 48 h after the polyuria is corrected but often complicate interpretation of tests commonly used for differential diagnosis.

Pathophysiology When the secretion or action of AVP is reduced to <80 to 85% of normal, urine concentration ceases and the rate of output increases to symptomatic levels. If the defect is primary (e.g., the patient has pituitary, gestational, or nephrogenic DI), the polyuria results in a small (1 to 2%) decrease in body water and a commensurate increase in plasma osmolarity and sodium concentration that stimulate thirst and a compensatory increase in water intake. As a result, *overt physical or laboratory signs of dehydration do not develop unless the patient also has a defect in thirst* (see below) *or fails to drink for some other reason.*

The severity of the antidiuretic defect varies markedly among patients with pituitary, gestational, or nephrogenic DI. In some, the deficiencies in AVP secretion or action are so severe that basal urine output approximates the maximum (10 to 15 mL/min); even an intense stimulus such as nausea or severe dehydration does not raise plasma AVP enough to concentrate the urine. In others, however, the defi-

ciency in AVP secretion or action is incomplete, and a modest stimulus such as a few hours of fluid deprivation, smoking, or a vasovagal reaction increases plasma AVP sufficiently to produce a profound antidiuresis. The maximum urine osmolarity achieved in these patients is usually less than normal, largely because their maximal concentrating capacity is temporarily impaired by chronic polyuria. However, in a few patients with partial pituitary or nephrogenic DI, it can reach levels as high as 800 mosmol/L.

In primary polydipsia, the pathogenesis of the polydipsia and polyuria is the reverse of that in pituitary, nephrogenic, and gestational DI. Thus, the excessive intake of fluids slightly increases body water, thereby reducing plasma osmolarity, AVP secretion, and urinary concentration. The latter results in a compensatory increase in urinary free-water excretion that varies in direct proportion to intake. Therefore, clinically appreciable overhydration is uncommon unless the compensatory water diuresis is impaired by a drug or disease that stimulates or mimics endogenous AVP.

In the dipsogenic form of primary polydipsia, fluid intake is excessive because the osmotic threshold for thirst appears to be reset to the left, often well below that for AVP release. When deprived of fluids or subjected to some other acute osmotic or nonosmotic stimulus, these individuals invariably increase plasma AVP normally, but the resultant increase in urine concentration is usually subnormal because their renal capacity to concentrate the urine is also blunted by chronic polyuria. Thus, their antidiuretic response to these stimuli may be indistinguishable from that in patients with partial pituitary, partial gestational, or partial nephrogenic DI. Patients with psychogenic or iatrogenic polydipsia respond similarly to fluid restriction but do not complain of thirst and usually offer other explanations for their high fluid intake.

TABLE 319-1 Causes of Diabetes Insipidus

      - Idiopathic
    - Iatrogenic

Differential Diagnosis When symptoms of urinary frequency, enuresis, nocturia, and/or persistent thirst are present, the presence of polyuria should be verified by documenting a 24-h urine output > 50 mL/kg per day (>3500 mL in a 70-kg man). If the osmolarity of the 24-h urine is >300 mosmol/L, the polyuria is due to a solute diuresis and the patient should be evaluated for uncontrolled diabetes mellitus or other less common causes of excessive solute excretion. However, if the 24-h urine osmolarity is <300 mosmol/L, the patient has a water diuresis and should be evaluated further to determine which type of DI is present.

In differentiating between the various types of DI, the history, physical examination, and routine laboratory tests may be helpful but are rarely sufficient because few, if any, of the findings are pathognomonic. Except in the rare patient who is clearly dehydrated under basal conditions of *ad libitum* fluid intake, this evaluation should begin with a *fluid deprivation test*. To minimize patient discomfort, avoid excessive dehydration, and maximize the information obtained, the test should be started in the morning and water balance should be monitored closely with hourly measurements of body weight, plasma osmolarity and/or sodium concentration, and urine volume and osmolarity.

If fluid deprivation does not result in urine concentration (osmolarity >300 mosmol/L, specific gravity >1.010) before body weight decreases by 5% or plasma osmolarity/sodium exceed the upper limit of normal, primary polydipsia or a partial defect in AVP secretion or action are largely excluded. In these patients, severe pituitary or nephrogenic DI are the only remaining possibilities, and they can usually be distinguished by administering desmopressin (DDAVP, 0.03 μg/kg subcutaneously or intravenously) and repeating the measurement of urine osmolarity 1 to 2 h later. An increase of >50% indicates severe pituitary DI, whereas a smaller or absent response is strongly suggestive of nephrogenic DI.

However, in patients who concentrate their urine during fluid deprivation, the change in urine osmolarity after administration of desmopressin is not useful for differential diagnosis because the values vary widely and over the same range in primary polydipsia, partial pituitary DI, and partial nephrogenic DI. The best way to differentiate these three conditions is to measure plasma or urine AVP before and during the fluid deprivation test and analyze the result in relation to the concurrent plasma or urine osmolarity (Fig. 319-3). This approach invariably differentiates partial nephrogenic DI from partial pituitary DI and primary polydipsia. It also differentiates pituitary DI from primary polydipsia if the hormone is measured when plasma osmolarity or sodium is clearly above the normal range. However, the requisite level of hypertonic dehydration is difficult to produce by fluid deprivation alone when urine concentration occurs. Therefore, it is usually

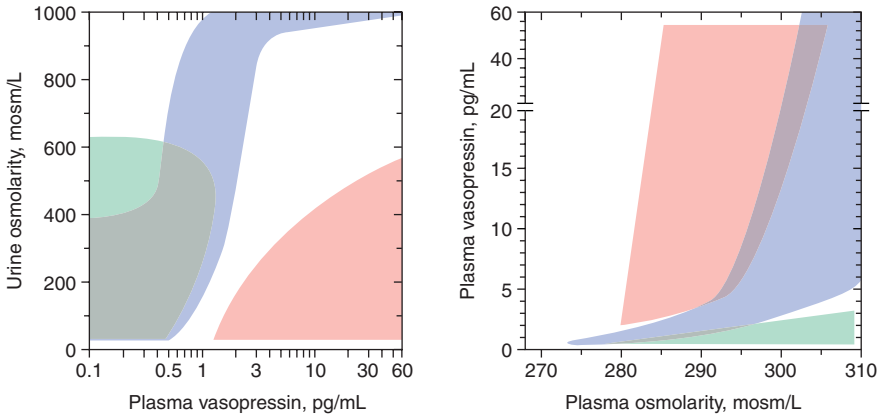

FIGURE 319-3 Relationship of plasma AVP to urine osmolarity (*left*) and plasma osmolarity (*right*) before and during fluid deprivation–hypertonic saline infusion test in patients who are normal or have primary polydipsia (■), pituitary diabetes insipidus (■), or nephrogenic diabetes insipidus (■).

necessary to add an infusion of hypertonic (3%) saline and repeat the AVP measurements when plasma osmolarity rises to >300 mosmol/L (Na^+ > 145 mmol/L). This endpoint is usually reached within 30 to 120 min if the hypertonic saline is infused at a rate of 0.1 mL/kg per min and the fluid deprivation is maintained.

The differential diagnosis of DI may also be facilitated by magnetic resonance imaging (MRI) of the pituitary and hypothalamus. In most healthy adults and children, the posterior pituitary emits a hyperintense signal in T1 weighted mid-saggital images. This "bright spot" is almost invariably absent or abnormally small in patients with pituitary DI but is present in 80 to 90% of patients with primary polydipsia. Thus, the presence of a normal bright spot virtually excludes pituitary DI, whereas its absence supports but does not prove this diagnosis. Therefore, the MRI findings must be interpreted with caution and only in conjunction with other diagnostic studies based on assays of AVP or the differential responses to treatment.

TREATMENT

The signs and symptoms of uncomplicated pituitary DI can be eliminated completely by treatment with DDAVP (Fig. 319-4). It is a synthetic analogue of AVP (Fig. 319-1) that acts selectively at V_2 receptors to increase urine concentration and decrease urine flow in a dose-dependent manner. It is also more resistant to degradation than AVP and has a three- to fourfold longer duration of action. DDAVP can be given by intravenous or subcutaneous injection, nasal inhalation, or oral tablet. The doses required to completely control pituitary DI vary widely, depending on the patient and the route of administration. However, they usually range from 1 to 2 μg qd or bid by injection, 10 to 20 μg bid or tid by nasal spray, or 100 to 400 μg bid or tid orally. The onset of action is rapid, ranging from as little as 15 min after injection to 60 min after oral administration. When given in doses sufficient to completely normalize urinary osmolarity and flow, desmopressin produces a slight (1 to 3%) increase in total-body water and a commensurate decrease in plasma osmolarity and sodium concentration that rapidly eliminate thirst and polydipsia. Consequently, water balance is maintained and hyponatremia does not develop unless the patient has an associated abnormality in the osmoregulation of thirst or ingests/receives excessive amounts of fluid for some other reason. Fortunately, abnormal thirst occurs in <10% of patients with pituitary DI, and the other causes of excessive intake can usually be eliminated by educating the patient about the risks of drinking for reasons other than thirst. Therefore, most patients with pituitary DI can take DDAVP in doses sufficient to maintain a normal urine output continuously and do not need to endure the inconvenience and discomfort of allowing intermittent escape to prevent water intoxication.

Pituitary DI can also be treated with chlorpropamide (Diabinese). The mechanism of its antidiuretic action is uncertain but may involve potentiation of the effect of small amounts of AVP or direct activation of the V_2 receptor. In patients with severe or partial pituitary DI, doses of chlorpropamide similar to those used in the treatment of diabetes mellitus (125 to 500 mg once daily) increase urine concentration and decrease urine flow, thirst, and polydipsia in a manner similar to desmopressin. The antidiuresis is almost always sufficient to reduce urine output by 30 to 70%. Moreover, its antidiuretic effect can be enhanced appreciably by cotreatment with a thiazide diuretic. Side effects of chlorpropamide include hypoglycemia, which can be precipitated by severe reductions in caloric intake or heavy exercise, and it may cause a disulfiram (Antabuse)-like reaction to ethanol. Chlorpropamide is contraindicated in the treatment of gestational DI because its teratogenicity is unknown.

Primary polydipsia cannot be treated with desmopressin because a sustained inhibition of the compensatory water diuresis almost invariably results in the development of water intoxication within 24 to 48 h. Iatrogenic polydipsia can often be corrected by patient counseling; however, there is no effective treatment for either psychogenic or dipsogenic DI. In the latter, nocturia or nocturnal enuresis can often be controlled safely by administering a single small dose of desmopressin at bedtime. If the dose is adjusted carefully to provide no more than 8 to 10 h of antidiuresis, it will not result in water intoxication, because patients with dipsogenic, as well as other forms of DI, tend to drink less fluid at night than during the day.

The symptoms and signs of nephrogenic DI are not affected by treatment with DDAVP or chlorpropamide but may be reduced by treatment with a thiazide diuretic and/or amiloride in conjunction with a low-sodium diet. Inhibitors of prostaglandin synthesis (e.g., indomethacin) are also effective in some patients.

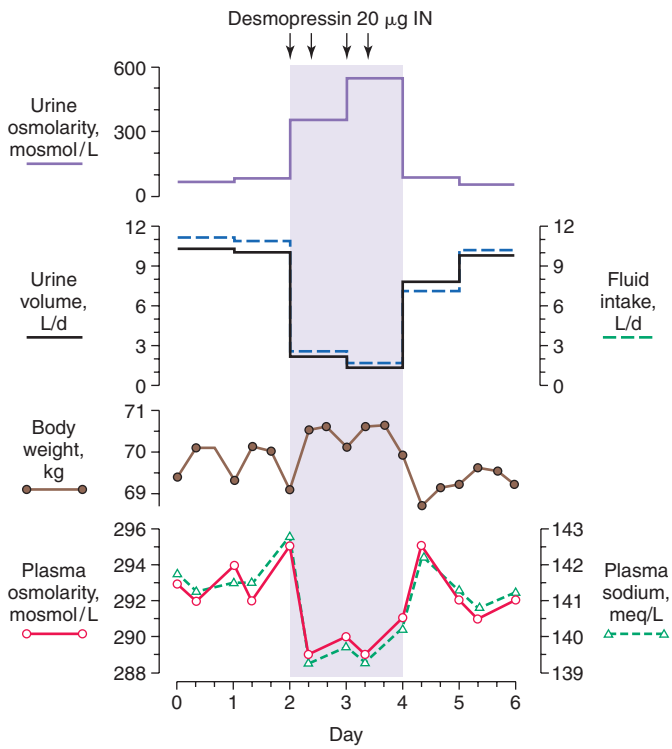

FIGURE 319-4 Effect of desmopressin therapy on water balance in patient with uncomplicated pituitary diabetes insipidus. Note that treatment rapidly reduces thirst and fluid intake as well as urine output to normal, with only a slight increase in body water (weight) and decrease in plasma osmolarity/sodium. *[From Endocrinology and Metabolism, 4th ed, P Felig, L Frohman (eds). New York, McGraw-Hill, 2001, with permission.]*

ADIPSIC HYPERNATREMIA ■ Clinical Characteristics Adipsic hypernatremia is characterized by chronic or recurrent hypertonic dehydration and a deficient AVP response to osmotic stimulation. Despite hypertonic dehydration, these patients have little or no thirst and may even resist efforts to increase their oral intake of fluids. The hypernatremia varies in severity and usually is associated with commensurate signs of hypovolemia such as tachycardia, postural hypotension, azotemia, hyperuricemia, and hypokalemia. Muscle weakness, pain, rhabdomyolysis, hyperglycemia, hyperlipidemia, and acute renal failure may also occur.

Pathophysiology Adipsic hypernatremia is caused by agenesis or destruction of the hypothalamic osmoreceptors that normally regulate thirst and AVP secretion (Fig. 319-5). Lack of thirst and failure to drink enough water to replenish renal and extrarenal losses decrease total-body water and increase plasma osmolarity/sodium. Plasma renin activity and aldosterone secretion also increase, and plasma potassium falls due to increased urinary excretion. The osmoreceptor deficiency can usually be traced to an identifiable congenital or acquired disease in the hypothalamus but is sometimes idiopathic (Table 319-2). An MRI typically shows a normal posterior pituitary bright spot, and the AVP response to nonosmotic stimuli is also normal. Occasionally, the neurohypophysis is also affected, resulting in a combined defect in water balance that is particularly severe and difficult to manage.

Differential Diagnosis Adipsic hypernatremia should be distinguished from the hypernatremia that results from various other causes. These distinctions can usually be made from the history, physical examination, and routine laboratory tests. If a conscious patient denies thirst and/or does not drink vigorously in the presence of significant hypernatremia, the diagnosis of hypodipsia or adipsia can be made with confidence. This diagnosis is supported by physical laboratory evidence of hypovolemia (postural hypotension, azotemia, hypokalemia, hyperuricemia, hyperreninemia) and a relative deficiency of plasma AVP. During rehydration, patients may develop either DI or the syndrome of inappropriate antidiuretic hormone (SIADH) depending on whether they have partial or total deficiency of the osmoregulation of AVP (Fig. 319-5). If the patient is obtunded or otherwise unable to answer questions or drink at the time of presentation, the possibility of adipsic hypernatremia can be evaluated after rehydration by assessing the thirst and plasma AVP response to a controlled fluid deprivation–hypertonic saline infusion test similar to that described for evaluation of DI.

TABLE 319-2 Causes of Adipsic Hypernatremia

Acquired
Vascular: Occlusion anterior communicating artery
Tumors
Primary
Craniopharyngioma
Pinealoma, germinoma
Meningioma
Glioma
Metastatic (lung, breast)
Granulomas: Neurosarcoid
Histiocytosis
Trauma: Closed
Penetrating (pituitary-hypothalamic surgery)
Psychogenic: Psychotic depression
Other: Hydrocephalus
Neurodegenerative
AIDS, cytomegalovirus encephalitis
Idiopathic
Congenital
Midline malformation (septum and corpus callosum)
Microcephaly
Genetic: Autosomal recessive (Schinzel-Giedion syndrome)

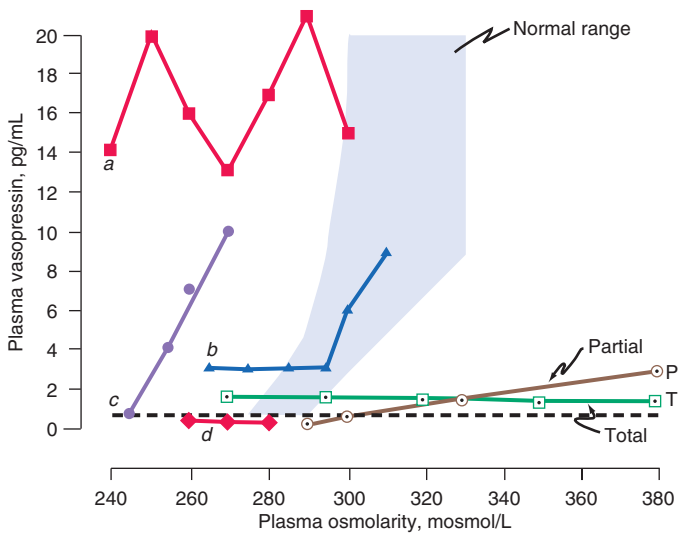

FIGURE 319-5 Heterogeneity of osmoregulatory dysfunction in adipsic hypernatremia (AH) and the syndrome of inappropriate antidiuretic hormone (SIADH). Each line depicts schematically the relationship of plasma arginine vasopressin (AVP) to plasma osmolarity during water loading and/or infusion of 3% saline in a patient with either AH (open symbols) or SIADH (closed symbols). The shaded area indicates the normal range of the relationship. The horizontal broken line indicates the plasma AVP level below which the hormone is undetectable and urinary concentration usually does not occur. Lines P and T represent patients with a selective deficiency in the osmoregulation of thirst and AVP that is either partial (○) or total (□). In the latter, plasma AVP does not change in response to increases or decreases in plasma osmolarity but remains within a range sufficient to concentrate the urine even if overhydration produces hypotonic hyponatremia. In contrast, if the osmoregulatory deficiency is partial (○), rehydration of the patient suppresses plasma AVP to levels that result in urinary dilution and polyuria before plasma osmolarity and sodium are reduced to normal. Lines *a*–*d* represent different defects in the osmoregulation of plasma AVP observed in patients with SIADH. In *a* (■), plasma AVP is markedly elevated and fluctuates widely without relation to changes in plasma osmolarity, indicating complete loss of osmoregulation. In *b* (▲), plasma AVP remains fixed at a slightly elevated level until plasma osmolarity reaches the normal range at which point it begins to rise appropriately, indicating a selective defect in the inhibitory component of the osmoregulatory mechanism. In *c* (●), plasma AVP rises in close correlation with plasma osmolarity before the latter reaches the normal range, indicating downward resetting of the osmostat. In *d* (♦), plasma AVP appears to be osmoregulated normally, suggesting that the inappropriate antidiuresis is caused by some other abnormality.

℞ TREATMENT

Adipsic hypernatremia should be treated by administering water by mouth, if the patient is alert, or 0.45% saline intravenously, if the patient is obtunded or uncooperative. The number of liters of free water that will be required to correct the deficit (ΔFW) can be estimated from body weight in kg (BW) and the serum sodium concentration in mmol/L (S_{Na}) by the formula $\Delta FW = 0.5BW \times [(S_{Na} - 140)/140]$. If serum glucose ($S_{Glu}$) is elevated, the measured S_{Na} should be corrected (S_{Na}*) by the formula $S_{Na}* = S_{Na} + [(S_{Glu} - 90)/36]$. This amount plus an allowance for continuing insensible and urinary losses should be given over a 24- to 48-h period. If DI is present or develops before rehydration is complete, desmopressin should also be given in standard doses to minimize urinary losses. If hyperglycemia and/or hypokalemia are present, insulin and/or potassium supplements should be given with the expectation that both can be discontinued after rehydration is complete. These variables plus urine output and plasma urea/creatinine should be monitored closely during treatment for signs of emerging DI, SIADH, or acute renal failure.

Once the acute fluid and electrolyte imbalances are corrected, an MRI of the brain and tests of anterior pituitary function should be performed. A long-term management plan to prevent or minimize recurrence of the fluid and electrolyte imbalance should also be developed. This should include a practical method that the patient can use to regulate fluid intake in accordance with day-to-day variations in water balance. The most effective way to accomplish these objectives is to prescribe desmopressin or chlorpropamide to completely control

DI, if it is present, and teach the patient how to use day-to-day changes in body weight as a guide for adjusting fluid intake. Prescribing a constant fluid intake is less satisfactory because it does not take into account the large, uncontrolled variations in insensible loss that inevitably occur.

EXCESS VASOPRESSIN SECRETION AND ACTION

HYPONATREMIA (See also Chap. 41) ■ **Clinical Characteristics** Excessive secretion or action of AVP results in the production of decreased volumes of more highly concentrated urine. If not accompanied by a commensurate reduction in fluid intake, the reduced suppressibility of AVP results in water retention and a decrease in plasma osmolarity/sodium. If the hyponatremia develops gradually or has been present for more than a few days, it may be asymptomatic. However, if it develops acutely, it is almost always accompanied by symptoms and signs of water intoxication that may include mild headache, confusion, anorexia, nausea, vomiting, coma, and convulsions. Severe hyponatremia may be lethal. Depending on the cause of the antidiuresis, osmotically inappropriate thirst and/or fluid intake and other disturbances of fluid and electrolyte balance may also be present.

Etiology Osmotically inappropriate antidiuresis can be caused by a primary defect in AVP secretion or action or can be secondary to a recognized nonosmotic stimulus such as hypovolemia, hypotension, or glucocorticoid deficiency. The primary forms are generally referred to as SIADH or euvolemic (type III) hyponatremia. They have many different causes, including ectopic production of AVP by lung cancer or other neoplasms, eutopic release by various diseases or drugs, and exogenous administration of AVP, desmopressin, or large doses of oxytocin (Table 319-3). The ectopic forms result from abnormal expression of the AVP-NPII gene by primary or metastatic malignancies. They do not usually remit unless the ectopic source is eliminated. The eutopic forms manifest most often in patients with acute infections or strokes, but the mechanisms by which these diseases disrupt osmoregulation are not known. A form of acute or chronic euvolemic hyponatremia very similar to SIADH can also result from stimulation of AVP secretion by protracted nausea or isolated glucocorticoid deficiency. In these patients the excess AVP secretion can be corrected quickly and completely by specific treatments (antiemetics or glucocorticoids) that are not useful in other forms of SIADH.

The secondary forms of osmotically inappropriate antidiuresis are usually divided into two groups: type I (hypervolemic) and type II (hypovolemic) hyponatremia. Type I occurs in sodium-retaining, edema-forming states such as congestive heart failure, cirrhosis, or nephrosis and is thought to be due to a reduction in "effective" blood volume. Type II occurs in sodium-depleted states such as severe gastroenteritis, diuretic abuse, or mineralocorticoid deficiency and is probably a result of reduction in extracellular volume as well as blood volume and/or pressure.

Pathophysiology In SIADH, interference with the osmotic suppression of AVP release results in significant expansion and dilution of body fluids only if water intake exceeds the rate of insensible and urinary output. The excess water intake often results from an associated defect in the osmoregulation of thirst but can also be due to psychogenic or iatrogenic factors, including the administration of intravenous fluids.

In SIADH, the abnormal osmoregulation of antidiuretic function can take any of four distinct forms (Fig. 319-5). For example, AVP secretion remains fully responsive to changes in plasma osmolarity/sodium, but the threshold, or set point, of the osmoregulatory system is abnormally low. Patients with this type of downward resetting of the osmostat differ from those with the other types of osmoregulatory defect in that they are able to maximally suppress plasma AVP and dilute their urine if their fluid intake is high enough to reduce their plasma osmolarity/sodium to the new set point. Another, smaller subgroup (about 10% of the total) does not have a demonstrable defect in the osmoregulation of AVP (Fig. 319-5). Thus, their inappropriate antidiuresis may be due to other abnormalities such as enhanced renal sensitivity to the antidiuretic effect of normally low levels of AVP or activation of aquaporin 2 water channels by a mechanism that is independent of AVP and V_2 receptors.

The extracellular volume expansion that results from excessive retention of water in SIADH also produces an increase in atrial natriuretic hormone, suppression of plasma renin activity, and a compensatory increase in urinary sodium excretion that serves to reduce the hypervolemia but aggravates the hyponatremia. Thus, hyponatremia is due to a decrease in total-body sodium as well as an increase in total-body water. The acute retention of water and fall in plasma sodium also increase intracellular volume. The resultant brain swelling increases intracranial pressure and probably causes the acute symptoms of water intoxication. After several days, this intracellular volume expansion may be reduced by inactivation or elimination of intracellular solutes, resulting in the remission of symptoms that often occur with hyponatremia of longer duration.

In type I (edematous) or type II (hypovolemic) hyponatremia, the osmotic inhibition of AVP and urine concentration is counteracted by a hemodynamic stimulus that results from a substantial reduction in effective or absolute blood volume. In both cases, the reduced suppression of AVP appears to be due to downward resetting of the osmostat. The resultant antidiuresis is usually enhanced by decreased distal delivery of filtrate that results from increased reabsorption of sodium in proximal nephrons secondary to the hypovolemia. If it is not associated with a commensurate reduction in water intake, the marked reduction in urine output that ensues also leads to expansion and dilution of body fluids with symptoms of hyponatremia. This attenuates, but does not completely eliminate, the antidiuresis because the amount of water retained is usually insufficient to fully correct the effective or absolute hypovolemia. Unlike in SIADH, therefore, plasma renin activity is elevated, causing secondary hyperaldosteronism and hypokalemia. The disturbance in salt and water balance that underlies the hyponatremia also differs from SIADH in that total-body sodium and water are increased in type I but decreased in type II.

Differential Diagnosis SIADH is a diagnosis of exclusion that can usually be accomplished with routine historic, physical, and laboratory information. In a patient with hyponatremia, the possibility of simple

dilution caused by an osmotically driven shift of water from the intracellular to the extracellular space should be excluded by measuring plasma glucose and/or plasma osmolarity. If the glucose is not elevated enough to account for the hyponatremia [serum sodium decreases ~1 meq/L for each rise in glucose 2.0 mmol/L (36 mg/dL)] and/or plasma osmolarity is reduced in proportion to sodium (each decrease in serum sodium of 1 meq/L should reduce plasma osmolarity by about 2 mosmol/L), the hyponatremia is "true" and can be typed or classified by standard clinical indicators of the extracellular fluid volume (Table 319-4). If these findings are ambiguous or contradictory, measuring the rate of urinary sodium excretion or plasma renin activity may be helpful. These measurements can be misleading, however, if SIADH is stable or resolving or if the patient has type II hyponatremia due to a primary defect in renal conservation of sodium, surreptitious diuretic abuse, or hyporeninemic hypoaldosteronism. The latter may be suspected if serum potassium is elevated instead of low as is usually seen in types I and II hyponatremia. Measurements of plasma AVP are currently of no diagnostic value since they exhibit the same wide variation in abnormalities in all three types of hyponatremia. In patients who fulfill the clinical criteria for type III (euvolemic) hyponatremia, plasma cortisol should also be measured to rule out unsuspected secondary adrenal insufficiency. If this is normal and there is no other obvious cause for SIADH, a careful search for occult lung cancer should also be undertaken.

TABLE 319-4 *Differential Diagnosis of Hyponatremia Based on Clinical Assessment of Extracellular Fluid Volume (ECFV)*

Clinical Findings	Type I, Hypervolemic	Type II, Hypovolemic	Type IIIA, Euvolemic	Type IIIB, Euvolemic (SIADH)
History				
CHF, cirrhosis, or nephrosis	Yes	No	No	No
Salt and water loss	No	Yes	No	No
ACTH–cortisol deficiency and/or nausea and vomiting	No	No	Yes	No
Physical examination				
Generalized edema, ascites	Yes	No	No	No
Postural hypotension	Maybe	Maybe	Maybe[a]	No
Laboratory				
BUN, creatinine	High-normal	High-normal	Low-normal	Low-normal
Uric acid	High-normal	High-normal	Low-normal	Low-normal
Serum potassium	Low-normal	Low-normal[b]	Normal[c]	Normal
Serum albumin	Low-normal	High-normal	Normal	Normal
Serum cortisol	Normal-high	Normal-high[d]	Low[e]	Normal
Plasma renin activity	High	High	Low[f]	Low
Urinary sodium (meq unit of time)[g]	Low	Low[h]	High[i]	High[i]

[a] Postural hypotension may occur in secondary (ACTH-dependent) adrenal insufficiency even though ECFV and aldosterone are usually normal.
[b] Serum potassium may be high if hypovolemia is due to aldosterone deficiency.
[c] Serum potassium may be low if vomiting causes alkalosis.
[d] Serum cortisol is low if hypovolemia is due to primary adrenal insufficiency (Addison's disease).
[e] Serum cortisol will be normal or high if the cause is nausea and vomiting rather than secondary (ACTH-dependent) adrenal insufficiency.
[f] Plasma renin activity may be high if the cause is secondary (ACTH) adrenal insufficiency.
[g] Urinary sodium should be expressed as the *rate of excretion* rather than the concentration. In a hyponatremic adult, an excretion rate > 25 meq/day (or 25 μeq/mg of creatinine) could be considered high.
[h] The rate of urinary sodium excretion may be high if the hypovolemia is due to diuretic abuse, primary adrenal insufficiency, or other causes of renal sodium wasting.
[i] The rate of urinary sodium excretion may be low if intake is curtailed by symptoms or treatment.
Note: SIADH, syndrome of inappropriate antidiuretic hormone; CHF, congestive heart failure; ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen.

TREATMENT

In acute SIADH, the keystone to treatment of hyponatremia is to restrict total fluid intake to less than the sum of insensible losses and urinary output. Total intake should include the water derived from food (300 to 500 mL/d). Because insensible losses in adults usually approximate 500 mL/d, total discretionary intake (all water in liquid form) should be at least 500 mL less than urinary output. If achieved, this deficit usually reduces body water and increases serum sodium by about 1 to 2% per day. If more rapid correction of the hyponatremia is desired to eliminate severe symptoms or signs, the fluid restriction can be supplemented by intravenous infusion of hypertonic (3%) saline. This treatment has the advantage of correcting the sodium deficiency that is partly responsible for the hyponatremia as well as producing a solute diuresis that serves to remove some of the excess water. However, if the hyponatremia has been present for more than 24 to 48 h, correction that is too rapid has the potential to produce central pontine myelinolysis, an acute, potentially fatal neurologic syndrome characterized by quadriparesis, ataxia, and abnormal extraocular movements. The following guidelines appear to minimize, if not eliminate, the risk of this complication: the 3% saline should be infused at a rate ≤0.05 mL/kg body weight per min; the effect should be monitored continuously by STAT measurements of serum sodium at least once every 2 h; and the infusion should be stopped as soon as serum sodium increases by 12 mmol/L or to 130 mmol/L, whichever comes first. Urinary output should also be monitored continuously since spontaneous remission of the SIADH can occur at any time and can result in an acute water diuresis that greatly accelerates the rate of rise in serum sodium produced by fluid restriction and 3% saline infusion.

In chronic SIADH, the hyponatremia can be corrected by treatment with demeclocycline, 150 to 300 mg orally three or four times a day, or fludrocortisone, 0.05 to 0.2 mg orally twice a day. The effect of the demeclocycline manifests in 7 to 14 days and is due to production of a reversible form of nephrogenic DI. Potential side effects include phototoxicity and azotemia. The effect of fludrocortisone also requires 1 to 2 weeks and is partly due to increased retention of sodium and possibly inhibition of thirst. It also increases urinary potassium excretion, which may require replacement through dietary adjustments or supplements. Fludrocortisone may induce hypertension, occasionally necessitating discontinuation of the treatment.

One or more nonpeptide AVP antagonists that block the antidiuretic effect of AVP may soon be approved for use in the United States. Preliminary studies with these antagonists in acute or chronic SIADH indicate that they produce a dose-dependent increase in urinary free-water excretion, which, if combined with a modest restriction of fluid intake, gradually reduces body water and corrects the hyponatremia without any recognized adverse effect. Thus, they may become the treatment of choice for those forms of SIADH in which there is inappropriate secretion of AVP that cannot be corrected by other, more specific therapy such as antiemetics or glucocorticoids.

When an SIADH-like syndrome is due to protracted nausea and vomiting or isolated glucocorticoid deficiency, all abnormalities can be corrected quickly and completely by giving an antiemetic or hydrocortisone. As with other treatments, care must be taken to ensure that serum sodium does not rise too quickly or too far.

In type I hyponatremia, the only treatment currently available is severe fluid restriction, administration of urea or mannitol to produce a solute diuresis, and/or administration of cardiotonics or serum albumin to correct the effective hypovolemia. None of these treatments is particularly effective, and some (e.g., administration of mannitol or albumin) carry significant risks. Infusion of hypertonic saline is contraindicated because it worsens the sodium retention and edema and may precipitate cardiovascular decompensation. However, preliminary

studies indicate that the AVP antagonists may be almost as effective and safe in type I hyponatremia as they are in SIADH. Thus, they may become the treatment of choice for this form of hyponatremia also.

In type II hyponatremia, the defect in AVP secretion and water balance can usually be corrected easily and quickly by stopping the loss of sodium and water and/or replacing the deficits by mouth or intravenous infusion of normal or hypertonic saline. As with the treatment of other forms of hyponatremia, care must be taken to ensure that plasma sodium does not increase too rapidly. Fluid restriction or administration of AVP antagonists is contraindicated as they would only aggravate the underlying volume depletion and could result in cardiovascular decompensation.

320 DISORDERS OF THE THYROID GLAND

J. Larry Jameson, Anthony P. Weetman

The thyroid gland produces two related hormones, thyroxine (T_4) and triiodothyronine (T_3) (Fig. 320-1). Acting through nuclear receptors, these hormones play a critical role in cell differentiation during development and help maintain thermogenic and metabolic homeostasis in the adult. Disorders of the thyroid gland result primarily from autoimmune processes that either stimulate the overproduction of thyroid hormones (*thyrotoxicosis*) or cause glandular destruction and hormone deficiency (*hypothyroidism*). In addition, benign nodules and various forms of thyroid cancer are relatively common and amenable to detection by physical examination.

ANATOMY AND DEVELOPMENT

The thyroid gland is located in the neck, anterior to the trachea, between the cricoid cartilage and the suprasternal notch. The thyroid (Greek *thyreos*, shield, plus *eidos*, form) consists of two lobes that are connected by an isthmus. It is normally 12 to 20 g in size, highly vascular, and soft in consistency. Four parathyroid glands, which produce parathyroid hormone (Chap. 332), are located in the posterior region of each pole of the thyroid. The recurrent laryngeal nerves traverse the lateral borders of the thyroid gland and must be identified during thyroid surgery to avoid vocal cord paralysis.

The thyroid gland develops from the floor of the primitive pharynx during the third week of gestation. The gland migrates from the foramen cecum, at the base of the tongue, along the thyroglossal duct to reach its final location in the neck. This feature accounts for the rare ectopic location of thyroid tissue at the base of the tongue (lingual thyroid), as well as for the presence of thyroglossal duct cysts along this developmental tract. Thyroid hormone synthesis normally begins at about 11 weeks' gestation.

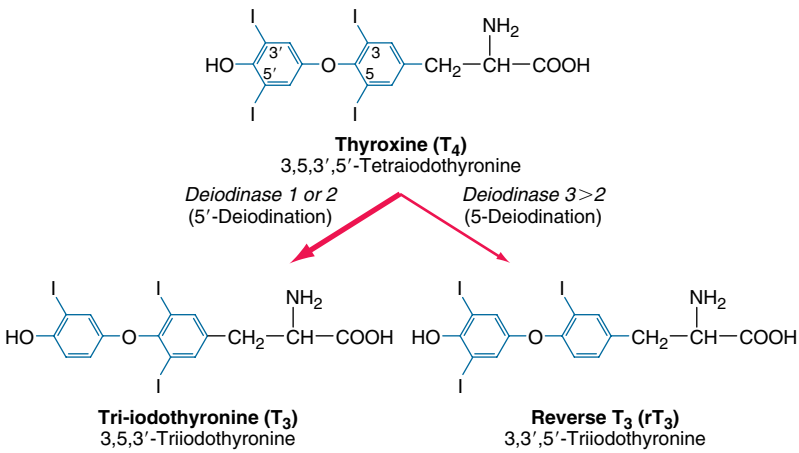

FIGURE 320-1 Structures of thyroid hormones. Thyroxine (T_4) contains four iodine atoms. Deiodination leads to production of the potent hormone, triiodothyronine (T_3), or the inactive hormone, reverse T_3.

The parathyroid glands migrate from the third (inferior glands) and fourth (superior glands) pharyngeal pouches and become embedded in the thyroid gland. Neural crest derivatives from the ultimobranchial body give rise to thyroid medullary C cells that produce calcitonin, a calcium-lowering hormone. The C cells are interspersed throughout the thyroid gland, although their density is greatest in the juncture of the upper one-third and lower two-thirds of the gland.

Thyroid gland development is controlled by a series of developmental transcription factors. Thyroid transcription factor (TTF) 1 (also known as NKX2A), TTF-2 (also known as FKHL15), and paired homeobox-8 (PAX-8) are expressed selectively, but not exclusively, in the thyroid gland. In combination, they orchestrate thyroid cell development and the induction of thyroid-specific genes such as thyroglobulin (Tg), thyroid peroxidase (TPO), the sodium iodide symporter (NIS), and the thyroid-stimulating hormone receptor (TSH-R). Mutations in these developmental transcription factors or their downstream target genes are rare causes of thyroid agenesis or dyshormonogenesis and can cause congenital hypothyroidism (Table 320-1). Congenital hypothyroidism is common enough (approximately 1 in 4000 newborns) that neonatal screening is performed in most industrialized countries (see below). Though the underlying causes of most cases of congenital hypothyroidism are unknown, early treatment with thyroid hormone replacement precludes potentially severe developmental abnormalities.

The mature thyroid gland contains numerous spherical follicles composed of thyroid follicular cells that surround secreted colloid, a proteinaceous fluid that contains large amounts of thyroglobulin, the protein precursor of thyroid hormones (Fig. 320-2). The thyroid follicular cells are polarized—the basolateral surface is apposed to the bloodstream and an apical surface faces the follicular lumen. Increased demand for thyroid hormone, usually signaled by thyroid-stimulating hormone (TSH) binding to its receptor on the basolateral surface of the follicular cells, leads to Tg reabsorption from the follicular lumen and proteolysis within the cell to yield thyroid hormones for secretion into the bloodstream.

REGULATION OF THE THYROID AXIS

TSH, secreted by the thyrotrope cells of the anterior pituitary, plays a pivotal role in control of the thyroid axis and serves as the most useful physiologic marker of thyroid hormone action. TSH is a 31-kDa hormone composed of α and β subunits; the α subunit is common to the other glycoprotein hormones [luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin (hCG)], whereas the TSH β subunit is unique to TSH. The extent and nature of carbohydrate modification are modulated by thyrotropin-releasing hormone (TRH) stimulation and influence the biologic activity of the hormone.

The thyroid axis is a classic example of an endocrine feedback loop. Hypothalamic TRH stimulates pituitary production of TSH, which, in turn, stimulates thyroid hor-

mone synthesis and secretion. Thyroid hormones feed back negatively to inhibit TRH and TSH production (Fig. 320-2). The "set-point" in this axis is established by TSH. TRH is the major positive regulator of TSH synthesis and secretion. Peak TSH secretion occurs ~15 min after administration of exogenous TRH. Dopamine, glucocorticoids, and somatostatin suppress TSH but are not of major physiologic importance except when these agents are administered in pharmacologic doses. Reduced levels of thyroid hormone increase basal TSH production and enhance TRH-mediated stimulation of TSH. High thyroid hormone levels rapidly and directly suppress TSH and inhibit TRH-mediated stimulation of TSH, indicating that thyroid hormones are the dominant regulator of TSH production. Like other pituitary hormones, TSH is released in a pulsatile manner and exhibits a diurnal rhythm; its highest levels occur at night. However, these TSH excursions are modest in comparison to those of other pituitary hormones, in part because TSH has a relatively long plasma half-life (50 min). Consequently, single measurements of TSH are adequate for assessing its circulating level. TSH is measured using immunoradiometric assays that are highly sensitive and specific. These assays readily distinguish between normal and suppressed TSH values; thus, TSH can be used for the diagnosis of hyperthyroidism (low TSH) as well as hypothyroidism (high TSH).

TABLE 320-1 *Genetic Causes of Congenital Hypothyroidism*

Defective Gene Protein	*Inheritance*	*Consequences*
PROP-1	Autosomal recessive	Combined pituitary hormone deficiencies with preservation of adrenocorticotropic hormone
PIT-1	Autosomal recessive Autosomal dominant	Combined deficiencies of growth hormone, prolactin, thyroid-stimulating hormone (TSH)
TSHβ	Autosomal recessive	TSH deficiency
TTF-1	Autosomal dominant	Variable thyroid hypoplasia, choreoathetosis, pulmonary problems
TTF-2	Autosomal recessive	Thyroid agenesis, choanal atresia, spiky hair
PAX-8	Autosomal dominant	Thyroid dysgenesis
TSH-receptor	Autosomal recessive	Resistance to TSH
$G_{s\alpha}$ (Albright hereditary osteodystrophy)	Autosomal dominant	Resistance to TSH
Na^+/I^- symporter	Autosomal recessive	Inability to transport iodide
THOX2	Autosomal dominant	Organification defect
Thyroid peroxidase	Autosomal recessive	Defective organification of iodide
Thyroglobulin	Autosomal recessive	Defective synthesis of thyroid hormone
Pendrin	Autosomal recessive	Pendred's syndrome: sensorineural deafness and partial organification defect in thyroid
Dehalogenase	Autosomal recessive	Loss of iodide reutilization

THYROID HORMONE SYNTHESIS, METABOLISM, AND ACTION

THYROID HORMONE SYNTHESIS Thyroid hormones are derived from Tg, a large iodinated glycoprotein. After secretion into the thyroid follicle, Tg is iodinated on selected tyrosine residues that are subsequently coupled via an ether linkage. Reuptake of Tg into the thyroid follicular cell initiates proteolysis and the release of newly synthesized T_4 and T_3.

Iodine Metabolism and Transport Iodide uptake is a critical first step in thyroid hormone synthesis. Ingested iodine is bound to serum proteins, particularly albumin. Unbound iodine is excreted in the urine. The thyroid gland extracts iodine from the circulation in a highly efficient manner. For example, 10 to 25% of radioactive tracer (e.g., ^{123}I) is taken up by the normal thyroid gland over 24 h; this value can rise to 70 to 90% in Graves' disease. Iodide uptake is mediated by the Na^+/I^- symporter (NIS), which is expressed at the basolateral membrane of thyroid follicular cells. NIS is most highly expressed in the thyroid gland but low levels are present in the salivary glands, lactating breast, and placenta. The iodide transport mechanism is highly regulated, allowing adaptation to variations in dietary supply. Low iodine levels increase the amount of NIS and stimulate uptake, whereas high iodine levels suppress NIS expression and uptake. The selective expression of the NIS in the thyroid allows isotopic scanning, treatment of hyperthyroidism, and ablation of thyroid cancer with radioisotopes of iodine, without significant effects on other organs. Mutation of the *NIS* gene is a rare cause of congenital hypothyroidism, underscoring its importance in thyroid hormone synthesis. Another iodine transporter, pendrin, is located on the apical surface of thyroid cells and mediates iodine efflux into the lumen. Mutation of the *PENDRIN* gene causes *Pendred syndrome*, a disorder characterized by defective organification of iodine, goiter, and sensorineural deafness.

Iodine deficiency is prevalent in many mountainous regions and in central Africa, central South America, and northern Asia. In areas of relative iodine deficiency, there is an increased prevalence of goiter and, when deficiency is severe, hypothyroidism and cretinism. *Cretinism* is characterized by mental and growth retardation and occurs when children who live in iodine-deficient regions are not treated with iodine or thyroid hormone to restore normal thyroid hormone levels during early childhood. These children are often born to mothers with iodine deficiency, and it is likely that maternal thyroid hormone deficiency worsens the condition. Concomitant selenium deficiency may also contribute to the neurologic manifestations of cretinism. Iodine supplementation of salt, bread, and other food substances has markedly reduced the prevalence of cretinism. Unfortunately, however, iodine deficiency remains the most common cause of preventable mental deficiency, often because of resistance to the use of food additives or the cost of supplementation. In addition to overt cretinism, mild iodine deficiency can lead to subtle reduction of IQ. Oversupply of iodine,

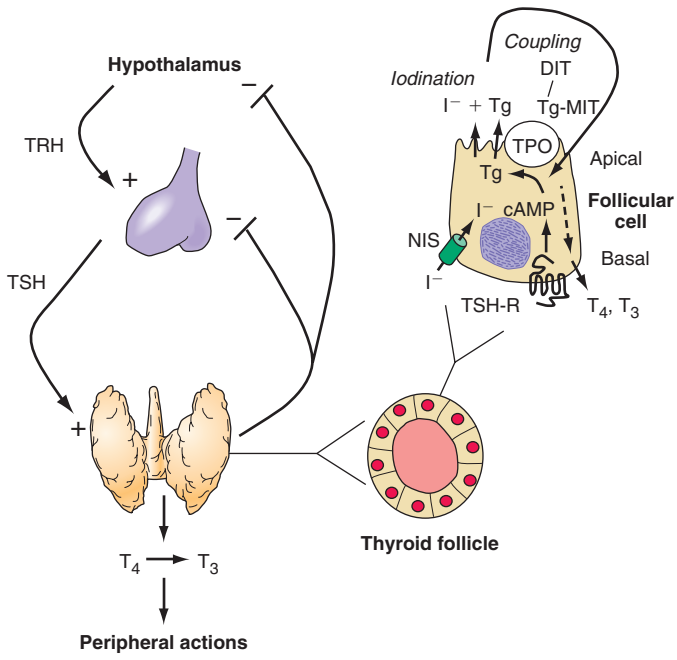

FIGURE 320-2 Regulation of thyroid hormone synthesis. *Left*. Thyroid hormones T_4 and T_3 feed back to inhibit hypothalamic production of thyrotropin-releasing hormone (TRH) and pituitary production of thyroid-stimulating hormone (TSH). TSH stimulates thyroid gland production of T_4 and T_3. *Right*. Thyroid follicles are formed by thyroid epithelial cells surrounding proteinaceous colloid, which contains thyroglobulin. Follicular cells, which are polarized, synthesize thyroglobulin and carry out thyroid hormone biosynthesis (see text for details). TSH-R, thyroid-stimulating hormone receptor; Tg, thyroglobulin; NIS, sodium-iodide symporter; TPO, thyroid peroxidase; DIT, di-iodotyrosine; MIT, monoiodotyrosine

through supplements or foods enriched in iodine (e.g., shellfish, kelp), is associated with an increased incidence of autoimmune thyroid disease. The recommended average daily intake of iodine is 150 μg/d for adults, 90 to 120 μg/d for children, and 200 μg/d for pregnant women. Urinary iodine is >10 μg/dL in iodine-sufficient populations.

Organification, Coupling, Storage, Release After iodide enters the thyroid, it is trapped and transported to the apical membrane of thyroid follicular cells where it is oxidized in an organification reaction that involves TPO and hydrogen peroxide. The reactive iodine atom is added to selected tyrosyl residues within Tg, a large (660 kDa) dimeric protein that consists of 2769 amino acids. The iodotyrosines in Tg are then coupled via an ether linkage in a reaction that is also catalyzed by TPO. Either T_4 or T_3 can be produced by this reaction, depending on the number of iodine atoms present in the iodotyrosines. After coupling, Tg is taken back into the thyroid cell where it is processed in lysosomes to release T_4 and T_3. Uncoupled mono- and diiodotyrosines (MIT, DIT) are deiodinated by the enzyme dehalogenase, thereby recycling any iodide that is not converted into thyroid hormones.

Disorders of thyroid hormone synthesis are rare causes of congenital hypothyroidism. The vast majority of these disorders are due to recessive mutations in TPO or Tg, but defects have also been identified in the TSH-R, NIS, pendrin, hydrogen peroxide generation, and in dehalogenase. Because of the biosynthetic defect, the gland is incapable of synthesizing adequate amounts of hormone, leading to increased TSH and a large goiter.

TSH Action TSH regulates thyroid gland function through the TSH-R, a seven-transmembrane G protein–coupled receptor (GPCR). The TSH-R is coupled to the α subunit of stimulatory G protein ($G_{s\alpha}$), which activates adenylyl cyclase, leading to increased production of cyclic AMP. TSH also stimulates phosphatidylinositol turnover by activating phospholipase C. The functional roles of the TSH-R are exemplified by the consequences of naturally occurring mutations. Recessive loss-of-function mutations are a rare cause of thyroid hypoplasia and congenital hypothyroidism. Dominant gain-of-function mutations cause sporadic or familial nonautoimmune hyperthyroidism that is characterized by goiter, thyroid cell hyperplasia, and autonomous function. Most of these activating mutations occur in the transmembrane domain of the receptor. They are thought to mimic conformational changes similar to those induced by TSH binding or the interactions of thyroid-stimulating immunoglobulins (TSI) in Graves' disease. Activating TSH-R mutations also occur as somatic events and lead to clonal selection and expansion of the affected thyroid follicular cell (see below).

Other Factors that Influence Hormone Synthesis and Release Although TSH is the dominant hormonal regulator of thyroid gland growth and function, a variety of growth factors, most produced locally in the thyroid gland, also influence thyroid hormone synthesis. These include insulin-like growth factor I (IGF-I), epidermal growth factor, transforming growth factor β (TGF-β), endothelins, and various cytokines. The quantitative roles of these factors are not well understood, but they are important in selected disease states. In acromegaly, for example, increased levels of growth hormone and IGF-I are associated with goiter and predisposition to multinodular goiter. Certain cytokines and interleukins (ILs) produced in association with autoimmune thyroid disease induce thyroid growth, whereas others lead to apoptosis. Iodine deficiency increases thyroid blood flow and upregulates the NIS, stimulating more efficient uptake. Excess iodide transiently inhibits thyroid iodide organification, a phenomenon known as the *Wolff-Chaikoff effect*. In individuals with a normal thyroid, the gland escapes from this inhibitory effect and iodide organification resumes; the suppressive action of high iodide may persist, however, in patients with underlying autoimmune thyroid disease.

THYROID HORMONE TRANSPORT AND METABOLISM ■ Serum Binding Proteins

T_4 is secreted from the thyroid gland in at least 20-fold excess over T_3 (Table 320-2). Both hormones are bound to plasma proteins, including thyroxine-binding globulin (TBG), transthyretin (TTR), formerly known as thyroxine-binding prealbumin, or TBPA), and albumin. The plasma-binding proteins increase the pool of circulating hormone, delay hormone clearance, and may modulate hormone delivery to selected tissue sites. The concentration of TBG is relatively low (1 to 2 mg/dL), but because of its high affinity for thyroid hormones ($T_4 > T_3$), it carries about 80% of the bound hormones. Albumin has relatively low affinity for thyroid hormones but has a high plasma concentration (~3.5 g/dL), and it binds up to 10% of T_4 and 30% of T_3. TTR carries about 10% of T_4 but little T_3.

When the effects of the various binding proteins are combined, approximately 99.98% of T_4 and 99.7% of T_3 are protein-bound. Because T_3 is less tightly bound than T_4, the amount of unbound T_3 is greater than unbound T_4, even though there is less total T_3 in the circulation. The unbound, or free, concentrations of the hormones are $\sim 2 \times 10^{-11}$ *M* for T_4 and $\sim 6 \times 10^{-12}$ *M* for T_3, which roughly correspond to the thyroid hormone receptor binding constants for these hormones (see below). Only the unbound hormone is biologically available to tissues. Therefore, homeostatic mechanisms that regulate the thyroid axis are directed towards maintenance of normal concentrations of unbound hormones.

Dysalbuminemic Hyperthyroxinemia A number of inherited and acquired abnormalities affect thyroid hormone binding proteins. X-linked TBG deficiency is associated with very low levels of total T_4 and T_3. However, because unbound hormone levels are normal, patients are euthyroid and TSH levels are normal. The importance of recognizing this disorder is to avoid efforts to normalize total T_4 levels, as this leads to thyrotoxicosis and is futile because of rapid hormone clearance in the absence of TBG. TBG levels are elevated by estrogen, which increases sialylation and delays TBG clearance. Consequently, in women who are pregnant or taking estrogen-containing contraceptives, elevated TBG increases total T_4 and T_3 levels; however, unbound T_4 and T_3 levels are normal. Mutations in TBG, TTR, and albumin that increase binding affinity for T_4 and/or T_3 cause disorders known as *euthyroid hyperthyroxinemia* or *familial dysalbuminemic hyperthyroxinemia* (FDH) (Table 320-3). These disorders result in increased total T_4 and/or T_3, but unbound hormone levels are normal. The familial nature of the disorders, and the fact that TSH levels are normal rather than suppressed, suggest this diagnosis. Unbound hormone levels (ideally measured by dialysis) are normal in FDH. The diagnosis can be confirmed by using tests that measure the affinities of radiolabeled hormone binding to specific transport proteins or by performing DNA sequence analyses of the abnormal transport protein genes.

Certain medications, such as salicylates and salsalate, can displace thyroid hormones from circulating binding proteins. Although these drugs transiently perturb the thyroid axis by increasing free thyroid hormone levels, TSH is suppressed until a new steady state is reached, thereby restoring euthyroidism. Circulating factors associated with acute illness may also displace thyroid hormone from binding proteins (see "Sick Euthyroid Syndrome," below).

TABLE 320-2 *Characteristics of Circulating T_4 and T_3*

Hormone Property	T_4	T_3
Serum concentrations		
Total hormone	8 μg/dL	0.14 μg/dL
Fraction of total hormone in the free form	0.02%	0.3%
Free (unbound) hormone	21×10^{-12} *M*	6×10^{-12} *M*
Serum half-life	7 d	0.75 d
Fraction directly from the thyroid	100%	20%
Production rate, including peripheral conversion	90 μg/d	32 μg/d
Intracellular hormone fraction	~20%	~70%
Relative metabolic potency	0.3	1
Receptor binding	10^{-10} *M*	10^{-11} *M*

Deiodinases T_4 may be thought of as a precursor for the more potent T_3. T_4 is converted to T_3 by the deiodinase enzymes (Fig. 320-1). Type I deiodinase, which is located primarily in thyroid, liver, and kidney, has a relatively low affinity for T_4. Type II deiodinase has a higher affinity for T_4 and is found primarily in the pituitary gland, brain, brown fat, and thyroid gland. The presence of type II deiodinase allows it to regulate T_3 concentrations locally, a property that may be important in the context of levothyroxine (T_4) replacement. Type II deiodinase is also regulated by thyroid hormone—hypothyroidism induces the enzyme, resulting in enhanced $T_4 \rightarrow T_3$ conversion in tissues such as brain and pituitary. $T_4 \rightarrow T_3$ conversion is impaired by fasting, systemic illness or acute trauma, oral contrast agents, and a variety of medications (e.g., propylthiouracil, propranolol, amiodarone, glucocorticoids). Type III deiodinase inactivates T_4 and T_3 and is the most important source of reverse T_3 (rT_3). Massive hemangiomas that express type III deiodinase are a rare cause of hypothyroidism in infants.

TABLE 320-3 *Conditions Associated with Euthyroid Hyperthyroxinemia*

Disorder	Cause	Transmission	Characteristics
Familial dysalbuminemic hyperthyroxinemia (FDH)	Albumin mutations, usually R218H	AD	Increased T_4 Normal unbound T_4 Rarely increased T_3
TBG			
Familial excess	Increased TBG production	XL	Increased total T_4, T_3 Normal unbound T_4, T_3
Acquired excess	Medications (estrogen), pregnancy, cirrhosis, hepatitis	Acquired	Increased total T_4, T_3 Normal unbound T_4, T_3
Transthyretin[a]			
Excess	Islet tumors	Acquired	Usually normal T_4, T_3
Mutations	Increased affinity for T_4 or T_3	AD	Increased total T_4, T_3 Normal unbound T_4, T_3
Medications: propranolol, ipodate, iopanoic acid, amiodarone	Decreased $T_4 \rightarrow T_3$ conversion	Acquired	Increased T_4 Decreased T_3 Normal or increased TSH
Sick-euthyroid syndrome	Acute illness, especially psychiatric disorders	Acquired	Transiently increased unbound T_4 Decreased TSH T_4 and T_3 may also be decreased (see text)
Resistance to thyroid hormone (RTH)	Thyroid hormone receptor β mutations	AD	Increased unbound T_4, T_3 Normal or increased TSH Some patients clinically thyrotoxic

[a] Also known as thyroxine-binding prealbumin, TBPA.
Note: AD, autosomal dominant; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; XL, X-linked.

THYROID HORMONE ACTION ■ Nuclear Thyroid Hormone Receptors Thyroid hormones act by binding to nuclear *thyroid hormone receptors* (TRs) α and β. Both TRα and TRβ are expressed in most tissues, but their relative levels of expression vary among organs; TRα is particularly abundant in brain, kidney, gonads, muscle, and heart, whereas TRβ expression is relatively high in the pituitary and liver. Both receptors are variably spliced to form unique isoforms. The TRβ2 isoform, which has a unique amino terminus, is selectively expressed in the hypothalamus and pituitary, where it plays a role in feedback control of the thyroid axis. The TRα2 isoform contains a unique carboxy terminus that prevents thyroid hormone binding; it may function to block the action of other TR isoforms.

The TRs contain a central DNA-binding domain and a C-terminal ligand-binding domain. They bind to specific DNA sequences, termed *thyroid response elements* (TREs), in the promoter regions of target genes (Fig. 320-3). The receptors bind as homodimers or as heterodimers with retinoic acid X receptors (RXRs) (Chap. 317). The activated receptor can either stimulate gene transcription (e.g., myosin heavy chain α) or inhibit transcription (e.g., TSH β-subunit gene), depending on the nature of the regulatory elements in the target gene.

Thyroid hormones bind with similar affinities to TRα and TRβ. However, T_3 is bound with 10 to 15 times greater affinity than T_4, which explains its increased hormonal potency. Though T_4 is produced in excess of T_3, receptors are occupied mainly by T_3, reflecting $T_4 \rightarrow T_3$ conversion by peripheral tissues, greater T_3 bioavailability in the plasma, and receptors' greater affinity for T_3. After binding to TRs, thyroid hormone induces conformational changes in the receptors that modify its interactions with accessory transcription factors. In the absence of thyroid hormone binding, the aporeceptors bind to co-repressor proteins that inhibit gene transcription. Hormone binding dissociates the co-repressors and allows the recruitment of coactivators that enhance transcription. The discovery of TR interactions with co-repressors explains the fact that TR silences gene expression in the absence of hormone binding. Consequently, hormone deficiency has a profound effect on gene expression because it causes gene repression as well as loss of hormone-induced stimulation. This concept has been corroborated by the finding that targeted deletion of the TR genes in mice has a less pronounced phenotypic effect than hormone deficiency.

Thyroid Hormone Resistance Resistance to thyroid hormone (RTH) is an autosomal dominant disorder characterized by elevated thyroid hormone levels and inappropriately normal or elevated TSH. Individuals with RTH do not, in general, exhibit signs and symptoms that are typical of hypothyroidism because hormone resistance is partial and is compensated by increased levels of thyroid hormone. The clinical features of RTH can include goiter, attention deficit disorder, mild reduction in IQ, delayed skeletal maturation, tachycardia, and impaired metabolic responses to thyroid hormone.

The disorder is caused by mutations in the TRβ receptor gene. These mutations, located in restricted regions of the ligand-binding domain, cause loss of receptor function. However, because the mutant receptors retain the capacity to dimerize with RXRs, bind to DNA, and recruit co-repressor proteins, they function as antagonists of the remaining, normal TRβ and TRα receptors. This property, referred to

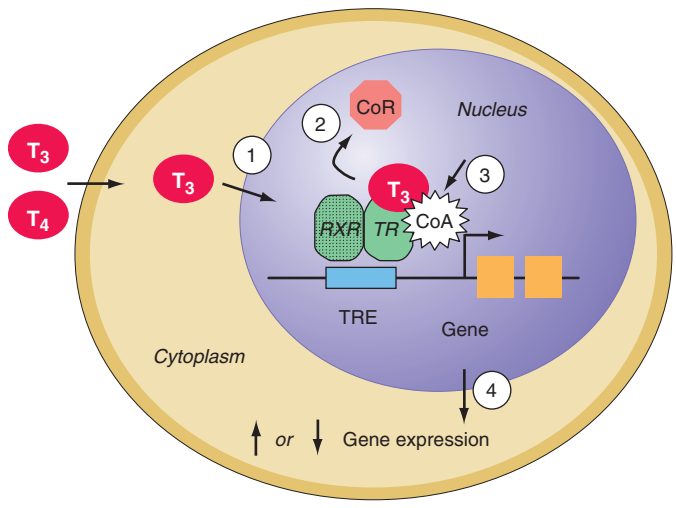

FIGURE 320-3 Mechanism of thyroid hormone receptor action. The thyroid hormone receptor (TR) and retinoid X receptor (RXR) form heterodimers that bind specifically to thyroid hormone response elements (TRE) in the promoter regions of target genes. In the absence of hormone, TR binds co-repressor (CoR) proteins that silence gene expression. The numbers refer to a series of ordered reactions that occur in response to thyroid hormone: (1) T_4 or T_3 enters the nucleus; (2) T_3 binding dissociates CoR from TR; (3) Coactivators (CoA) are recruited to the T_3-bound receptor; (4) gene expression is altered.

as "dominant negative" activity, explains the autosomal dominant mode of transmission. The diagnosis is suspected when unbound thyroid hormone levels are increased without suppression of TSH. Similar hormonal abnormalities are found in other affected family members, although the TRβ mutation arises de novo in about 20% of patients. DNA sequence analysis of the TRβ gene provides a definitive diagnosis. RTH must be distinguished from other causes of euthyroid hyperthyroxinemia (e.g., FDH) and inappropriate secretion of TSH by TSH-secreting pituitary adenomas (Chap. 318). In most patients, no treatment is indicated; the importance of making the diagnosis is to avoid inappropriate treatment of mistaken hyperthyroidism and to provide genetic counseling.

PHYSICAL EXAMINATION

In addition to the examination of the thyroid itself, the physical examination should include a search for signs of abnormal thyroid function and the extrathyroidal features of ophthalmopathy and dermopathy (see below). Examination of the neck begins by inspecting the seated patient from the front and side, and noting any surgical scars, obvious masses, or distended veins. The thyroid can be palpated with both hands from behind or while facing the patient, using the thumbs to palpate each lobe. It is best to use a combination of these methods, especially when the nodules are small. The patient's neck should be slightly flexed to relax the neck muscles. After locating the cricoid cartilage, the isthmus can be identified and followed laterally to locate either lobe (normally the right lobe is slightly larger than the left). By asking the patient to swallow sips of water, thyroid consistency can be better appreciated as the gland moves beneath the examiner's fingers.

Features to be noted include thyroid size, consistency, nodularity, and any tenderness or fixation. An estimate of thyroid size (normally 12 to 20 g) should be made, and a drawing is often the best way to record findings. However, ultrasound is the method of choice when it is important to determine thyroid size accurately. The size, location, and consistency of any nodules should also be defined. A bruit over the gland indicates increased vascularity, as occurs in hyperthyroidism. If the lower borders of the thyroid lobes are not clearly felt, a goiter may be retrosternal. Large retrosternal goiters can cause venous distention over the neck and difficulty breathing, especially when the arms are raised (Pemberton's sign). With any central mass above the thyroid, the tongue should be extended, as thyroglossal cysts then move upward. The thyroid examination is not complete without assessment for lymphadenopathy in the supraclavicular and cervical regions of the neck.

LABORATORY EVALUATION

MEASUREMENT OF THYROID HORMONES The enhanced sensitivity and specificity of *TSH assays* have greatly improved laboratory assessment of thyroid function. Because TSH levels change dynamically in response to alterations of T_4 and T_3, a logical approach to thyroid testing is to first determine whether TSH is suppressed, normal, or elevated. With rare exceptions (see below), a normal TSH level excludes a primary abnormality of thyroid function. This strategy depends on the use of immunoradiometric assays (IRMAs) for TSH that are sensitive enough to discriminate between the lower limit of the reference range and the suppressed values that occur with thyrotoxicosis. Extremely sensitive (fourth generation) assays can detect TSH levels $\leq$0.004 mU/L, but for practical purposes assays sensitive to $\leq$0.1 mU/L are sufficient. The widespread availability of the TSH IRMA has rendered the TRH stimulation test obsolete, as the failure of TSH to rise after an intravenous bolus of 200 to 400 μg TRH has the same implications as a suppressed basal TSH measured by IRMA.

The finding of an abnormal TSH level must be followed by measurements of circulating thyroid hormone levels to confirm the diagnosis of hyperthyroidism (suppressed TSH) or hypothyroidism (elevated TSH). Radioimmunoassays are widely available for serum *total* T_4 and *total* T_3. T_4 and T_3 are highly protein-bound, and numerous factors (illness, medications, genetic factors) can influence protein binding. It is useful, therefore, to measure the free, or unbound, hormone levels, which correspond to the biologically available hormone pool. Two direct methods are used to measure *unbound thyroid hormones*: (1) unbound thyroid hormone competition with radiolabeled T_4 (or an analogue) for binding to a solid-phase antibody, and (2) physical separation of the unbound hormone fraction by ultracentrifugation or equilibrium dialysis. Though early unbound hormone immunoassays suffered from artifacts, newer assays correlate well with the results of the more technically demanding and expensive physical separation methods. An indirect method to estimate unbound thyroid hormone levels is to calculate the free T_3 or free T_4 index from the total T_4 or T_3 concentration and the *thyroid hormone binding ratio* (THBR). The latter is derived from the *T_3-resin uptake test*, which determines the distribution of radiolabeled T_3 between an absorbent resin and the unoccupied thyroid hormone binding proteins in the sample. The binding of the labeled T_3 to the resin is increased when there is reduced unoccupied protein binding sites (e.g., TBG deficiency) or increased total thyroid hormone in the sample; it is decreased under the opposite circumstances. The product of THBR and total T_3 or T_4 provides the *free T_3 or T_4 index*. In effect, the index corrects for anomalous total hormone values caused by abnormalities in hormone-protein binding.

Total thyroid hormone levels are *elevated* when TBG is increased due to estrogens (pregnancy, oral contraceptives, hormone replacement therapy, tamoxifen), and *decreased* when TBG binding is reduced (androgens, the nephrotic syndrome). Genetic disorders and acute illness can also cause abnormalities in thyroid hormone binding proteins, and various drugs (phenytoin, carbamazepine, salicylates, and nonsteroidal anti-inflammatory drugs) can interfere with thyroid hormone binding. Because unbound thyroid hormone levels are normal and the patient is euthyroid in all of these circumstances, assays that measure unbound hormone are preferable to those for total thyroid hormones.

For most purposes, the unbound T_4 level is sufficient to confirm thyrotoxicosis, but 2 to 5% of patients have only an elevated T_3 level (T_3 toxicosis). Thus, unbound T_3 levels should be measured in patients with a suppressed TSH but normal unbound T_4 levels.

There are several clinical conditions in which the use of TSH as a screening test may be misleading, particularly without simultaneous unbound T_4 determinations. Any severe nonthyroidal illness can cause abnormal TSH levels (see below). Although hypothyroidism is the most common cause of an elevated TSH level, rare causes include a TSH-secreting pituitary tumor (Chap. 318), thyroid hormone resistance, and assay artifact. Conversely, a suppressed TSH level, particularly $<$0.1 mU/L, usually indicates thyrotoxicosis but may also be seen during the first trimester of pregnancy (due to hCG secretion), after treatment of hyperthyroidism (because TSH remains suppressed for several weeks), and in response to certain medications (e.g., high doses of glucocorticoids or dopamine). Importantly, secondary hypothyroidism, caused by hypothalamic-pituitary disease, is associated with a variable (low to high-normal) TSH level, which is inappropriate for the low T_4 level. Thus, *TSH should not be used to assess thyroid function in patients with suspected or known pituitary disease*.

Tests for the end-organ effects of thyroid hormone excess or depletion, such as estimation of basal metabolic rate, tendon reflex relaxation rates, or serum cholesterol, are not useful as clinical determinants of thyroid function.

TESTS TO DETERMINE THE ETIOLOGY OF THYROID DYSFUNCTION Autoimmune thyroid disease is detected most easily by measuring circulating antibodies against TPO and Tg. As antibodies to Tg alone are uncommon, it is reasonable to measure only TPO antibodies. About 5 to 15% of euthyroid women and up to 2% of euthyroid men have thyroid antibodies; such individuals are at increased risk of developing thyroid dysfunction. Almost all patients with autoimmune hypothyroidism, and up to 80% of those with Graves' disease, have TPO antibodies, usually at high levels.

TSI are antibodies that stimulate the TSH-R in Graves' disease. They can be measured in bioassays or indirectly in assays that detect antibody binding to the receptor. The main use of these assays is to predict neonatal thyrotoxicosis caused by high maternal levels of TSI in the last trimester of pregnancy.

Serum Tg levels are increased in all types of thyrotoxicosis except *thyrotoxicosis factitia* caused by self-administration of thyroid hormone. The main role for Tg measurement, however, is in the follow-up of thyroid cancer patients. After total thyroidectomy and radioablation, Tg levels should be undetectable; measurable levels (>1 to 2 ng/mL) suggest incomplete ablation or recurrent cancer.

RADIOIODINE UPTAKE AND THYROID SCANNING The thyroid gland selectively transports radioisotopes of iodine (^{123}I, ^{125}I, ^{131}I) and ^{99m}Tc pertechnetate, allowing thyroid imaging and quantitation of radioactive tracer fractional uptake.

Nuclear imaging of Graves' disease is characterized by an enlarged gland and increased tracer uptake that is distributed homogeneously. Toxic adenomas appear as focal areas of increased uptake, with suppressed tracer uptake in the remainder of the gland. In toxic multinodular goiter, the gland is enlarged—often with distorted architecture—and there are multiple areas of relatively increased or decreased tracer uptake. Subacute thyroiditis is associated with very low uptake because of follicular cell damage and TSH suppression. Thyrotoxicosis factitia is also associated with low uptake.

Although the use of fine-needle aspiration (FNA) biopsy has diminished the use of thyroid scans in the evaluation of solitary thyroid nodules, the functional features of thyroid nodules have some prognostic significance. So-called cold nodules, which have diminished tracer uptake, are usually benign. However, these nodules are more likely to be malignant (~5 to 10%) than so-called hot nodules, which are almost never malignant.

Thyroid scanning is also used in the follow-up of thyroid cancer. After thyroidectomy and ablation using ^{131}I, there is diminished radioiodine uptake in the thyroid bed, allowing the detection of metastatic thyroid cancer deposits that retain the ability to transport iodine. Whole-body scans using 111 to 185 MBq (3 to 5 mCi) ^{131}I are typically performed after thyroid hormone withdrawal to raise the TSH level or after the administration of recombinant human TSH.

THYROID ULTRASOUND Ultrasonography is used increasingly to assist in the diagnosis of nodular thyroid disease, a reflection of the limitations of the physical examination and improvements in ultrasound technology. Using 10-MHz instruments, spatial resolution and image quality are excellent, allowing the detection of nodules and cysts >3 mm. In addition to detecting thyroid nodules, ultrasound is useful for monitoring nodule size, for guiding FNA biopsies, and for the aspiration of cystic lesions. Ultrasound is also used in the evaluation of recurrent thyroid cancer, including possible spread to cervical lymph nodes.

TABLE 320-4 Causes of Hypothyroidism

Primary
Autoimmune hypothyroidism: Hashimoto's thyroiditis, atrophic thyroiditis
Iatrogenic: ^{131}I treatment, subtotal or total thyroidectomy, external irradiation of neck for lymphoma or cancer
Drugs: iodine excess (including iodine-containing contrast media and amiodarone), lithium, antithyroid drugs, *p*-aminosalicyclic acid, interferon-α and other cytokines, aminoglutethimide
Congenital hypothyroidism: absent or ectopic thyroid gland, dyshormonogenesis, TSH-R mutation
Iodine deficiency
Infiltrative disorders: amyloidosis, sarcoidosis, hemochromatosis, scleroderma, cystinosis, Riedel's thyroiditis
Overexpression of type 3 deoiodinase in infantile hemangioma
Transient
Silent thyroiditis, including postpartum thyroiditis
Subacute thyroiditis
Withdrawal of thyroxine treatment in individuals with an intact thyroid
After ^{131}I treatment or subtotal thyroidectomy for Graves' disease
Secondary
Hypopituitarism: tumors, pituitary surgery or irradiation, infiltrative disorders, Sheehan's syndrome, trauma, genetic forms of combined pituitary hormone deficiencies
Isolated TSH deficiency or inactivity
Bexarotene treatment
Hypothalamic disease: tumors, trauma, infiltrative disorders, idiopathic

Note: TSH, thyroid-stimulating hormone; TSH-R, TSH receptor.

HYPOTHYROIDISM

Iodine deficiency remains the most common cause of hypothyroidism worldwide. In areas of iodine sufficiency, autoimmune disease (Hashimoto's thyroiditis) and iatrogenic causes (treatment of hyperthyroidism) are most common (Table 320-4).

CONGENITAL HYPOTHYROIDISM ■ Prevalence Hypothyroidism occurs in about 1 in 4000 newborns. It may be transient, especially if the mother has TSH-R blocking antibodies or has received antithyroid drugs, but permanent hypothyroidism occurs in the majority. Neonatal hypothyroidism is due to thyroid gland dysgenesis in 80 to 85%, inborn errors of thyroid hormone synthesis in 10 to 15%, and is TSH-R antibody-mediated in 5% of affected newborns. The developmental abnormalities are twice as common in girls. Mutations that cause congenital hypothyroidism are being increasingly recognized, but the vast majority remain idiopathic (Table 320-1).

Clinical Manifestations The majority of infants appear normal at birth, and <10% are diagnosed based on clinical features, which include prolonged jaundice, feeding problems, hypotonia, enlarged tongue, delayed bone maturation, and umbilical hernia. Importantly, permanent neurologic damage results if treatment is delayed. Typical features of adult hypothyroidism may also be present (Table 320-5). Other congenital malformations, especially cardiac, are four times more common in congenital hypothyroidism.

Diagnosis and Treatment Because of the severe neurologic consequences of untreated congenital hypothyroidism, neonatal screening programs have been established in developed countries. These are generally based on measurement of TSH or T_4 levels in heel-prick blood specimens. When the diagnosis is confirmed, T_4 is instituted at a dose of 10 to 15 μg/kg per day and the dosage is adjusted by close monitoring of TSH levels. T_4 requirements are relatively great during the first year of life, and a high circulating T_4 level is usually needed to normalize TSH. Early treatment with T_4 results in normal IQ levels, but subtle neurodevelopmental abnormalities may occur in those with the most severe hypothyroidism at diagnosis or when treatment is suboptimal.

TABLE 320-5 Signs and Symptoms of Hypothyroidism (Descending Order of Frequency)

Symptoms	Signs
Tiredness, weakness	Dry coarse skin; cool peripheral extremities
Dry skin	Puffy face, hands, and feet (myxedema)
Feeling cold	Diffuse alopecia
Hair loss	Bradycardia
Difficulty concentrating and poor memory	Peripheral edema
Constipation	Delayed tendon reflex relaxation
Weight gain with poor appetite	Carpal tunnel syndrome
Dyspnea	Serous cavity effusions
Hoarse voice	
Menorrhagia (later oligomenorrhea or amenorrhea)	
Paresthesia	
Impaired hearing	

AUTOIMMUNE HYPOTHYROIDISM ■ Classification Autoimmune hypothyroidism may be associated with a goiter (Hashimoto's, or *goitrous thyroiditis*) or, at the later stages of the disease, minimal residual thyroid tissue (*atrophic thyroiditis*). Because the autoimmune process gradually reduces thyroid function, there is a phase of compensation when normal thyroid hormone levels are maintained by a rise in TSH. Though some patients may have minor symptoms, this state is called *subclinical hypothyroidism* or *mild hypothyroidism*. Later, free T_4 levels fall and TSH levels rise further; symptoms become more readily apparent at this stage (usually TSH $>$ 10 mU/L), which is referred to as *clinical hypothyroidism* or *overt hypothyroidism*.

Prevalence The mean annual incidence rate of autoimmune hypothyroidism is up to 4 per 1000 women and 1 per 1000 men. It is more common in certain populations, such as the Japanese, probably because of genetic factors and chronic exposure to a high-iodine diet. The mean age at diagnosis is 60 years, and the prevalence of overt hypothyroidism increases with age. Subclinical hypothyroidism is found in 6 to 8% of women (10% over the age of 60) and 3% of men. The annual risk of developing clinical hypothyroidism is about 4% when subclinical hypothyroidism is associated with positive TPO antibodies.

Pathogenesis In Hashimoto's thyroiditis, there is a marked lymphocytic infiltration of the thyroid with germinal center formation, atrophy of the thyroid follicles accompanied by oxyphil metaplasia, absence of colloid, and mild to moderate fibrosis. In atrophic thyroiditis, the fibrosis is much more extensive, lymphocyte infiltration is less pronounced, and thyroid follicles are almost completely absent. Atrophic thyroiditis likely represents the end stage of Hashimoto's thyroiditis rather than a distinct disorder.

As with most autoimmune disorders, susceptibility to autoimmune hypothyroidism is determined by a combination of genetic and environmental factors, and the risk of either autoimmune hypothyroidism or Graves' disease is increased among siblings. HLA-DR polymorphisms are the best documented genetic risk factors for autoimmune hypothyroidism, especially HLA-DR3, -DR4, and -DR5 in Caucasians. A weak association also exists between polymorphisms in *CTLA-4*, a T cell–regulating gene, and autoimmune hypothyroidism. Both of these genetic associations are shared by other autoimmune diseases, which may explain the relationship between autoimmune hypothyroidism and other autoimmune diseases, especially type 1 diabetes mellitus, Addison disease, pernicious anemia, and vitiligo (Chap. 330). HLA-DR and *CTLA*-4 polymorphisms account for approximately half of the genetic susceptibility to autoimmune hypothyroidism. The other contributory loci remain to be identified. A gene on chromosome 21 may be responsible for the association between autoimmune hypothyroidism and Down syndrome. The female preponderance of thyroid autoimmunity is most likely due to the effects of sex steroids on the immune response, but an X chromosome–related genetic factor is also possible, which may account for the high frequency of autoimmune hypothyroidism in Turner syndrome. Environmental susceptibility factors are also poorly defined at present. A high iodine intake may increase the risk of autoimmune hypothyroidism by immunologic effects or direct thyroid toxicity. There is no convincing evidence for a role of infection, except for the congenital rubella syndrome, in which there is a high frequency of autoimmune hypothyroidism. Viral thyroiditis does not induce subsequent autoimmune thyroid disease.

The thyroid lymphocytic infiltrate in autoimmune hypothyroidism is composed of activated CD4+ and CD8+ T cells, as well as B cells. Thyroid cell destruction is believed to be primarily mediated by the CD8+ cytotoxic T cells, which destroy their targets by either perforin-induced cell necrosis or granzyme B–induced apoptosis. In addition, local T cell production of cytokines, such as tumor necrosis factor (TNF), IL-1, and interferon (IFN) γ, may render thyroid cells more susceptible to apoptosis mediated by death receptors, such as Fas, which are activated by their respective ligands on T cells. These cytokines also impair thyroid cell function directly, and induce the expression of other proinflammatory molecules by the thyroid cells themselves, such as cytokines, HLA class I and class II molecules, adhesion molecules, CD40, and nitric oxide. Administration of high concentrations of cytokines for therapeutic purposes (especially IFN-α) is associated with increased autoimmune thyroid disease, possibly through mechanisms similar to those in sporadic disease.

Antibodies to Tg and TPO are clinically useful markers of thyroid autoimmunity, but any pathogenic effect is restricted to a secondary role in amplifying an ongoing autoimmune response. TPO antibodies fix complement, and complement membrane attack complexes are present in the thyroid in autoimmune hypothyroidism. However, transplacental passage of Tg or TPO antibodies has no effect on the fetal thyroid, which suggests that T cell–mediated injury is required to initiate autoimmune damage to the thyroid. Up to 20% of patients with autoimmune hypothyroidism have antibodies against the TSH-R, which, in contrast to TSI, do not stimulate the receptor but prevent the binding of TSH. These TSH-R-blocking antibodies therefore cause hypothyroidism and, especially in Asian patients, thyroid atrophy. Their transplacental passage may induce transient neonatal hypothyroidism. Rarely, patients have a mixture of TSI- and TSH-R-blocking antibodies, and thyroid function can oscillate between hyperthyroidism and hypothyroidism as one or the other antibody becomes dominant. Predicting the course of disease in such individuals is difficult, and they require close monitoring of thyroid function. Bioassays can be used to document that TSH-R-blocking antibodies reduce the cyclic AMP–inducing effect of TSH on cultured TSH-R-expressing cells, but these assays are difficult to perform. Assays that measure the binding of antibodies to the receptor by competition with radiolabeled TSH [TSH-binding inhibiting immunoglobulins (TBII)] do not distinguish between TSI- and TSH-R-blocking antibodies, but a positive result in a patient with spontaneous hypothyroidism is strong evidence for the presence of blocking antibodies. The use of these assays does not generally alter clinical management, although they may be useful to confirm the cause of transient neonatal hypothyroidism.

Clinical Manifestations The main clinical features of hypothyroidism are summarized in Table 320-5. The onset is usually insidious, and the patient may become aware of symptoms only when euthyroidism is restored. Patients with Hashimoto's thyroiditis may present because of goiter rather than symptoms of hypothyroidism. The goiter may not be large but is usually irregular and firm in consistency. It is often possible to palpate a pyramidal lobe, normally a vestigial remnant of the thyroglossal duct. Rarely, uncomplicated Hashimoto's thyroiditis is associated with pain.

Patients with atrophic thyroiditis, or the late stage of Hashimoto's thyroiditis, present with symptoms and signs of hypothyroidism. The skin is dry, and there is decreased sweating, thinning of the epidermis, and hyperkeratosis of the stratum corneum. Increased dermal glycosaminoglycan content traps water, giving rise to skin thickening without pitting (*myxedema*). Typical features include a puffy face with edematous eyelids and nonpitting pretibial edema (Fig. 320-4). There is pallor, often with a yellow tinge to the skin due to carotene accumulation. Nail growth is retarded, and hair is dry, brittle, difficult to manage, and falls out easily. In addition to diffuse alopecia, there is thinning of the outer third of the eyebrows, although this is not a specific sign of hypothyroidism.

Other common features include constipation and weight gain (despite a poor appetite). In contrast to popular perception, the weight gain is usually modest and due mainly to fluid retention in the myxedematous tissues. Libido is decreased in both sexes, and there may be oligomenorrhea or amenorrhea in long-standing disease, but menorrhagia is also common. Fertility is reduced and the incidence of miscarriage is increased. Prolactin levels are often modestly increased (Chap. 318) and may contribute to alterations in libido and fertility and cause galactorrhea.

Myocardial contractility and pulse rate are reduced, leading to a

FIGURE 320-4 Facial appearance in hypothyroidism. Note puffy eyes and thickened, pale skin.

reduced stroke volume and bradycardia. Increased peripheral resistance may be accompanied by hypertension, particularly diastolic. Blood flow is diverted from the skin, producing the cool extremities. Pericardial effusions occur in up to 30% of patients but rarely compromise cardiac function. Though alterations in myosin heavy chain isoform expression have been documented, cardiomyopathy is unusual. Fluid may also accumulate in other serous cavities and in the middle ear, giving rise to conductive deafness. Pulmonary function is generally normal, but dyspnea may be caused by pleural effusion, impaired respiratory muscle function, diminished ventilatory drive, or sleep apnea.

Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. On examination, there may be slow relaxation of tendon reflexes and pseudomyotonia. Memory and concentration are impaired. Rare neurologic problems include reversible cerebellar ataxia, dementia, psychosis, and myxedema coma. *Hashimoto's encephalopathy* is a rare and distinctive syndrome associated with myoclonus and slow-wave activity on electroencephalography, which can progress to confusion, coma, and death. It is steroid-responsive and may occur in the presence of autoimmune thyroiditis, without hypothyroidism. The hoarse voice and occasionally clumsy speech of hypothyroidism reflect fluid accumulation in the vocal cords and tongue.

The features described above are the consequence of thyroid hormone deficiency. However, autoimmune hypothyroidism may be associated with signs or symptoms of other autoimmune diseases, particularly vitiligo, pernicious anemia, Addison disease, alopecia areata, and type 1 diabetes mellitus. Less common associations include celiac disease, dermatitis herpetiformis, chronic active hepatitis, rheumatoid arthritis, systemic lupus erythematosus (SLE), and Sjögren's syndrome. Thyroid-associated ophthalmopathy, which usually occurs in Graves' disease (see below), occurs in about 5% of patients with autoimmune hypothyroidism.

Autoimmune hypothyroidism is uncommon in children and usually presents with slow growth and delayed facial maturation. The appearance of permanent teeth is also delayed. Myopathy, with muscle swelling, is more common in children than in adults. In most cases, puberty is delayed, but precocious puberty sometimes occurs. There may be intellectual impairment if the onset is before 3 years and the hormone deficiency is severe.

Laboratory Evaluation A summary of the investigations used to determine the existence and cause of hypothyroidism is provided in Fig. 320-5. A normal TSH level excludes primary (but not secondary) hypothyroidism. If the TSH is elevated, an unbound T_4 level is needed to confirm the presence of clinical hypothyroidism, but T_4 is inferior to TSH when used as a screening test, as it will not detect subclinical or mild hypothyroidism. Circulating unbound T_3 levels are normal in about 25% of patients, reflecting adaptive responses to hypothyroidism. T_3 measurements are therefore not indicated.

Once clinical or subclinical hypothyroidism is confirmed, the etiology is usually easily established by demonstrating the presence of TPO antibodies, which are present in 90 to 95% of patients with autoimmune hypothyroidism. TBII can be found in 10 to 20% of patients, but these determinations are not needed routinely. If there is any doubt about the cause of a goiter associated with hypothyroidism, FNA biopsy can be used to confirm the presence of autoimmune thyroiditis. Other abnormal laboratory findings in hypothyroidism may include increased creatine phosphokinase, elevated cholesterol and triglycerides, and anemia (usually normocytic or macrocytic). Except when accompanied by iron deficiency, the anemia and other abnormalities gradually resolve with thyroxine replacement.

Differential Diagnosis An asymmetric goiter in Hashimoto's thyroiditis may be confused with a multinodular goiter or thyroid carcinoma, in which thyroid antibodies may also be present. Ultrasound can be used to show the presence of a solitary lesion or a multinodular goiter, rather than the heterogeneous thyroid enlargement typical of Hashimoto's thyroiditis. FNA biopsy is useful in the investigation of focal nodules. Other causes of hypothyroidism are discussed below but rarely cause diagnostic confusion (Table 320-4).

OTHER CAUSES OF HYPOTHYROIDISM *Iatrogenic hypothyroidism* is a common cause of hypothyroidism and can often be detected by screening before symptoms develop. In the first 3 to 4 months after radioiodine treatment, transient hypothyroidism may occur due to reversible radiation damage rather than to cellular destruction. Low-dose thyroxine treatment can be withdrawn if recovery occurs. Because TSH levels are suppressed by hyperthyroidism, unbound T_4 levels are a better measure of thyroid function than TSH in the months following ra-

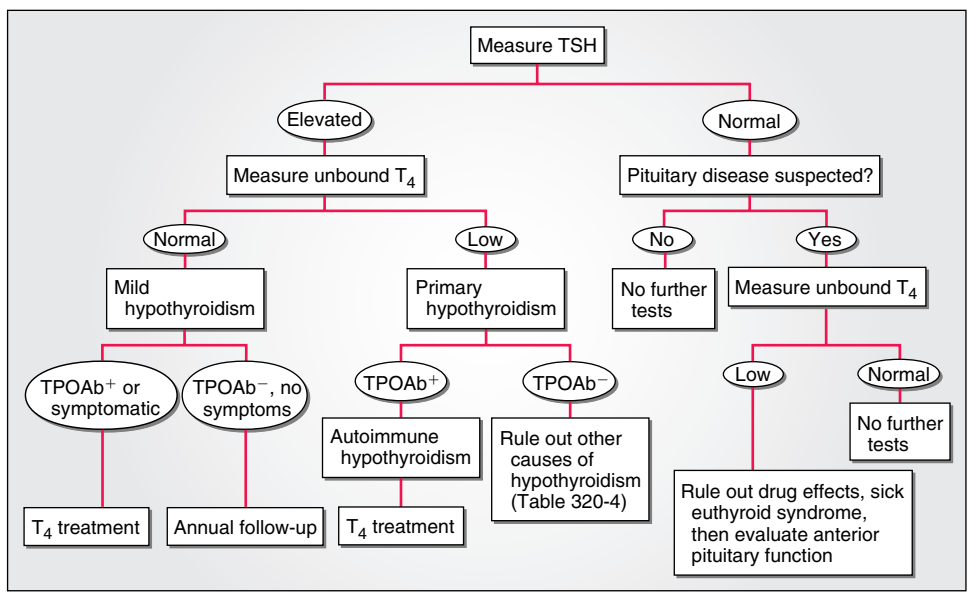

FIGURE 320-5 Evaluation of hypothyroidism. $TPOAb^+$, thyroid peroxidase antibodies present; $TPOAb^-$, thyroid peroxidase antibodies not present. TSH, thyroid-stimulating hormone.

dioiodine treatment. Mild hypothyroidism after subtotal thyroidectomy may also resolve after several months, as the gland remnant is stimulated by increased TSH levels.

Iodine deficiency is responsible for endemic goiter and cretinism but is an uncommon cause of adult hypothyroidism unless the iodine intake is very low or there are complicating factors, such as the consumption of thiocyanates in cassava or selenium deficiency. Though hypothyroidism due to iodine deficiency can be treated with thyroxine, public health measures to improve iodine intake should be advocated to eliminate this problem. Iodized salt or bread or a single bolus of oral or intramuscular iodized oil have all been used successfully.

Paradoxically, chronic iodine excess can also induce goiter and hypothyroidism. The intracellular events that account for this effect are unclear, but individuals with autoimmune thyroiditis are especially susceptible. Iodine excess is responsible for the hypothyroidism that occurs in up to 13% of patients treated with amiodarone (see below). Other drugs, particularly lithium, may also cause hypothyroidism. Transient hypothyroidism caused by thyroiditis is discussed below.

Secondary hypothyroidism is usually diagnosed in the context of other anterior pituitary hormone deficiencies; isolated TSH deficiency is very rare (Chap. 318). TSH levels may be low, normal, or even slightly increased in secondary hypothyroidism; the latter is due to secretion of immunoactive but bioinactive forms of TSH. The diagnosis is confirmed by detecting a low unbound T_4 level. The goal of treatment is to maintain unbound T_4 levels in the upper half of the reference range, as TSH levels cannot be used to monitor therapy.

Rx TREATMENT

Clinical Hypothyroidism If there is no residual thyroid function, the daily replacement dose of levothyroxine is usually 1.6 μg/kg body weight (typically 100 to 150 μg). In many patients, however, lower doses suffice until residual thyroid tissue is destroyed. In patients who develop hypothyroidism after the treatment of Graves' disease, there is often underlying autonomous function, necessitating lower replacement doses (typically 75 to 125 μg/d).

Adult patients under 60 without evidence of heart disease may be started on 50 to 100 μg levothyroxine (T_4) daily. The dose is adjusted on the basis of TSH levels, with the goal of treatment being a normal TSH, ideally in the lower half of the reference range. TSH responses are gradual and should be measured about 2 months after instituting treatment or after any subsequent change in levothyroxine dosage. The clinical effects of levothyroxine replacement are often slow to appear. Patients may not experience full relief from symptoms until 3 to 6 months after normal TSH levels are restored. Adjustment of levothyroxine dosage is made in 12.5- or 25-μg increments if the TSH is high; decrements of the same magnitude should be made if the TSH is suppressed. Patients with a suppressed TSH of any cause, including T_4 overtreatment, have an increased risk of atrial fibrillation and reduced bone density.

Although dessicated animal thyroid preparations (thyroid extract USP) are available, they are not recommended as potency and composition vary between batches. Interest in using levothyroxine combined with liothyronine (triiodothyronine, T_3) has been revived, based on studies suggesting that patients feel better when taking the T_4/T_3 combination compared to T_4 alone. However, a long-term benefit from this combination is not established. There is no place for liothyronine alone as long-term replacement, because the short half-life necessitates three or four daily doses and is associated with fluctuating T_3 levels.

Once full replacement is achieved and TSH levels are stable, follow-up measurement of TSH is recommended at annual intervals and may be extended to every 2 to 3 years, if a normal TSH is maintained over several years. It is important to ensure ongoing compliance, however, as patients do not feel any difference after missing a few doses of levothyroxine, this sometimes leads to self-discontinuation.

In patients of normal body weight who are taking $\geq$200 μg of levothyroxine per day, an elevated TSH level is often a sign of poor compliance. This is also the likely explanation for fluctuating TSH levels, despite a constant levothyroxine dosage. Such patients often have normal or high unbound T_4 levels, despite an elevated TSH, because they remember to take medication for a few days before testing; this is sufficient to normalize T_4, but not TSH, levels. It is important to consider variable compliance, as this pattern of thyroid function tests is otherwise suggestive of disorders associated with inappropriate TSH secretion (Table 320-3). Because T_4 has a long half-life (7 days), patients who miss doses can be advised to take up to three doses of the skipped tablets at once. Other causes of increased levothyroxine requirements must be excluded, particularly malabsorption (e.g., celiac disease, small-bowel surgery), estrogen therapy, and drugs that interfere with T_4 absorption or clearance such as cholestyramine, ferrous sulfate, calcium supplements, lovastatin, aluminum hydroxide, rifampicin, amiodarone, carbamazepine, and phenytoin.

Mild Hypothyroidism By definition, subclinical or mild hypothyroidism refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism. There are no universally accepted guidelines for the treatment of mild hypothyroidism. As long as excessive treatment is avoided, there is little risk in correcting a slightly increased TSH, and some patients likely derive modest clinical benefit from treatment. Moreover, there is some risk that patients will progress to overt hypothyroidism, particularly when the TSH level is >6 mU/L and TPO antibodies are present. Treatment is administered by starting with a low dose of levothyroxine (25 to 50 μg/d) with the goal of normalizing TSH. If thyroxine is not given, thyroid function should be evaluated annually.

Special Treatment Considerations Rarely, levothyroxine replacement is associated with pseudotumor cerebri in *children*. Presentation appears to be idiosyncratic and occurs months after treatment has begun. Women with a history or high risk of hypothyroidism should ensure that they are euthyroid prior to conception and during early pregnancy as maternal hypothyroidism may adversely affect fetal neural development. Thyroid function should be evaluated once pregnancy is confirmed and at the beginning of the second and third trimesters. The dose of levothyroxine may need to be increased by $\geq$50% during pregnancy and returned to previous levels after delivery. *Elderly* patients may require up to 20% less thyroxine than younger patients. In the elderly, especially patients with known coronary artery disease, the starting dose of levothyroxine is 12.5 to 25 μg/d with similar increments every 2 to 3 months until TSH is normalized. In some patients it may be impossible to achieve full replacement, despite optimal antianginal treatment. *Emergency surgery* is generally safe in patients with untreated hypothyroidism, although routine surgery in a hypothyroid patient should be deferred until euthyroidism is achieved.

Myxedema coma still has a high mortality rate, despite intensive treatment. Clinical manifestations include reduced level of consciousness, sometimes associated with seizures, as well as the other features of hypothyroidism (Table 320-5). Hypothermia can reach 23°C (74°F). There may be a history of treated hypothyroidism with poor compliance, or the patient may be previously undiagnosed. Myxedema coma almost always occurs in the elderly and is usually precipitated by factors that impair respiration, such as drugs (especially sedatives, anesthetics, antidepressants), pneumonia, congestive heart failure, myocardial infarction, gastrointestinal bleeding, or cerebrovascular accidents. Sepsis should also be suspected. Exposure to cold may also be a risk factor. Hypoventilation, leading to hypoxia and hypercapnia, plays a major role in pathogenesis; hypoglycemia and dilutional hyponatremia also contribute to the development of myxedema coma.

Levothyroxine can initially be administered as a single intravenous bolus of 500 μg, which serves as a loading dose. Although further levothyroxine is not strictly necessary for several days, it is usually continued at a dose of 50 to 100 μg/d. If suitable intravenous preparation is not available, the same initial dose of levothyroxine can be given by nasogastric tube (though absorption may be impaired in myxedema). An alternative is to give liothyronine (T_3) intravenously or

via nasogastric tube, in doses ranging from 10 to 25 μg every 8 to 12 h. This treatment has been advocated because $T_4 \rightarrow T_3$ conversion is impaired in myxedema coma. However, excess liothyroxine has the potential to provoke arrhythmias. Another option is to combine levothyroxine (200 μg) and liothyronine (25 μg) as a single, initial intravenous bolus followed by daily treatment with levothyroxine (50 to 100 μg/d) and liothyronine (10 μg every 8 h).

Supportive therapy should be provided to correct any associated metabolic disturbances. External warming is indicated only if the temperature is <30°C, as it can result in cardiovascular collapse (Chap. 16). Space blankets should be used to prevent further heat loss. Parenteral hydrocortisone (50 mg every 6 h) should be administered, as there is impaired adrenal reserve in profound hypothyroidism. Any precipitating factors should be treated, including the early use of broad-spectrum antibiotics, pending the exclusion of infection. Ventilatory support with regular blood gas analysis is usually needed during the first 48 h. Hypertonic saline or intravenous glucose may be needed if there is hyponatremia or hypoglycemia; hypotonic intravenous fluids should be avoided because they may exacerbate water retention secondary to reduced renal perfusion and inappropriate vasopressin secretion. The metabolism of most medications is impaired, and sedatives should be avoided if possible or used in reduced doses. Medication blood levels should be monitored, when available, to guide dosage.

THYROTOXICOSIS

Thyrotoxicosis is defined as the state of thyroid hormone excess and is not synonymous with *hyperthyroidism*, which is the result of excessive thyroid function. However, the major etiologies of thyrotoxicosis are hyperthyroidism caused by Graves' disease, toxic multinodular goiter, and toxic adenomas. Other causes are listed in Table 320-6.

GRAVES' DISEASE ■ Epidemiology Graves' disease accounts for 60 to 80% of thyrotoxicosis, but the prevalence varies among populations, depending mainly on iodine intake (high iodine intake is associated with an increased prevalence of Graves' disease). Graves' disease occurs in up to 2% of women but is one-tenth as frequent in men. The disorder rarely begins before adolescence and typically occurs between 20 and 50 years of age, but it also occurs in the elderly.

PATHOGENESIS As in autoimmune hypothyroidism, a combination of genetic factors, including HLA-DR and *CTLA-4* polymorphisms, and environmental factors contribute to Graves' disease susceptibility. The concordance for Graves' disease in monozygotic twins is 20 to 30%, compared to <5% in dizygotic twins. Indirect evidence suggests that stress is an important environmental factor, presumably operating through neuroendocrine effects on the immune system. Smoking is a minor risk factor for Graves' disease and a major risk factor for the development of ophthalmopathy. Sudden increases in iodine intake may precipitate Graves' disease, and there is a threefold increase in the occurrence of Graves' disease in the postpartum period.

The hyperthyroidism of Graves' disease is caused by TSI that are synthesized in the thyroid gland as well as in bone marrow and lymph nodes. Such antibodies can be detected by bioassays or using the more widely available TBII assays. The presence of TBII in a patient with thyrotoxicosis is strong indirect evidence for the existence of TSI, and these assays are useful in monitoring pregnant Graves' patients in whom high levels of TSI can cross the placenta and cause neonatal thyrotoxicosis. Other thyroid autoimmune responses, similar to those in autoimmune hypothyroidism (see above), occur concurrently in patients with Graves' disease. In particular, TPO antibodies occur in up to 80% of cases and serve as a readily measurable marker of autoimmunity. Because T cell–mediated cytotoxicity can also affect thyroid function, there is no direct correlation between the level of TSI and thyroid hormone levels. In the long term, spontaneous autoimmune hypothyroidism may develop in up to 15% of Graves' patients.

Cytokines appear to play a major role in thyroid-associated ophthalmopathy. There is infiltration of the extraocular muscles by activated T cells; the release of cytokines such as IFN-γ, TNF, and IL-1 results in fibroblast activation and increased synthesis of glycosaminoglycans that trap water, thereby leading to characteristic muscle swelling. Late in the disease, there is fibrosis and only then do the muscle cells show evidence of injury. Orbital fibroblasts may be uniquely sensitive to cytokines, perhaps explaining the anatomic localization of the immune response. Though the pathogenesis of thyroid-associated ophthalmopathy remains unclear, there is mounting evidence that expression of the TSH-R may provide an important orbital autoantigen. In support of this idea, injection of TSH-R into certain strains of mice induces autoimmune hyperthyroidism, as well as features of ophthalmopathy. A variety of autoantibodies against orbital muscle and fibroblast antigens have been detected in patients with ophthalmopathy, but these antibodies most likely arise as a secondary phenomenon, dependent on T cell–mediated autoimmune responses. Similar mechanisms are involved in dermopathy.

Clinical Manifestations Signs and symptoms include features that are common to any cause of thyrotoxicosis (Table 320-7) as well as those specific for Graves' disease. The clinical presentation depends on the severity of thyrotoxicosis, the duration of disease, individual susceptibility to excess thyroid hormone, and the patient's age. In the elderly, features of thyrotoxicosis may be subtle or masked, and patients may present mainly with fatigue and weight loss, leading to *apathetic hyperthyroidism*.

Thyrotoxicosis may cause unexplained weight loss, despite an enhanced appetite, due to the increased metabolic rate. Weight gain occurs in 5% of patients, however, because of increased food intake.

TABLE 320-6 Causes of Thyrotoxicosis

Primary hyperthyroidism
Graves' disease
Toxic multinodular goiter
Toxic adenoma
Functioning thyroid carcinoma metastases
Activating mutation of the TSH receptor
Activating mutation of $G_{s\alpha}$ (McCune-Albright syndrome)
Struma ovarii
Drugs: iodine excess (Jod-Basedow phenomenon)
Thyrotoxicosis without hyperthyroidism
Subacute thyroiditis
Silent thyroiditis
Other causes of thyroid destruction: amiodarone, radiation, infarction of adenoma
Ingestion of excess thyroid hormone (thyrotoxicosis factitia) or thyroid tissue
Secondary hyperthyroidism
TSH-secreting pituitary adenoma
Thyroid hormone resistance syndrome: occasional patients may have features of thyrotoxicosis
Chorionic gonadotropin-secreting tumors[a]
Gestational thyrotoxicosis[a]

[a] Circulating TSH levels are low in these forms of secondary hyperthyroidism.
Note: TSH, thyroid-stimulating hormone.

TABLE 320-7 Signs and Symptoms of Thyrotoxicosis (Descending Order of Frequency)

Symptoms	Signs[a]
Hyperactivity, irritability, dysphoria	Tachycardia; atrial fibrillation in the elderly
Heat intolerance and sweating	Tremor
Palpitations	Goiter
Fatigue and weakness	Warm, moist skin
Weight loss with increased appetite	Muscle weakness, proximal myopathy
Diarrhea	Lid retraction or lag
Polyuria	Gynecomastia
Oligomenorrhea, loss of libido	

[a] Excludes the signs of ophthalmopathy and dermopathy specific for Graves' disease.

FIGURE 320-6 Features of Graves' disease. *A*. Facial appearance in Graves' disease; lid retraction, periorbital edema, and proptosis are marked. *B*. Thyroid dermopathy over the lateral aspects of the shins. *C*. Thyroid acropachy.

Other prominent features include hyperactivity, nervousness, and irritability, ultimately leading to a sense of easy fatiguability in some patients. Insomnia and impaired concentration are common; apathetic thyrotoxicosis may be mistaken for depression in the elderly. Fine tremor is a frequent finding, best elicited by having patients stretch out their fingers and feeling the fingertips with the palm. Common neurologic manifestations include hyperreflexia, muscle wasting, and proximal myopathy without fasciculation. Chorea is a rare feature. Thyrotoxicosis is sometimes associated with a form of hypokalemic periodic paralysis; this disorder is particularly common in Asian males with thyrotoxicosis.

The most common cardiovascular manifestation is sinus tachycardia, often associated with palpitations, occasionally caused by supraventricular tachycardia. The high cardiac output produces a bounding pulse, widened pulse pressure, and an aortic systolic murmur and can lead to worsening of angina or heart failure in the elderly or those with preexisting heart disease. Atrial fibrillation is more common in patients >50 years. Treatment of the thyrotoxic state alone reverts atrial fibrillation to normal sinus rhythm in fewer than half of patients, suggesting the existence of an underlying cardiac problem in the remainder.

The skin is usually warm and moist, and the patient may complain of sweating and heat intolerance, particularly during warm weather. Palmar erythema; onycholysis; and, less commonly, pruritus, urticaria, and diffuse hyperpigmentation may be evident. Hair texture may become fine, and a diffuse alopecia occurs in up to 40% of patients, persisting for months after restoration of euthyroidism. Gastrointestinal transit time is decreased, leading to increased stool frequency, often with diarrhea and occasionally mild steatorrhea. Women frequently experience oligomenorrhea or amenorrhea; in men there may be impaired sexual function and, rarely, gynecomastia. The direct effect of thyroid hormones on bone resorption leads to osteopenia in long-standing thyrotoxicosis; mild hypercalcemia occurs in up to 20% of patients, but hypercalciuria is more common. There is a small increase in fracture rate in patients with a previous history of thyrotoxicosis.

In Graves' disease the thyroid is usually diffusely enlarged to two to three times its normal size. The consistency is firm, but less so than in multinodular goiter. There may be a thrill or bruit due to the increased vascularity of the gland and the hyperdynamic circulation.

Lid retraction, causing a staring appearance, can occur in any form of thyrotoxicosis and is the result of sympathetic overactivity. However, Graves' disease is associated with specific eye signs that comprise *Graves' ophthalmopathy* (Fig. 320-6*A*). This condition is also called *thyroid-associated ophthalmopathy*, as it occurs in the absence of Graves' disease in 10% of patients. Most of these individuals have autoimmune hypothyroidism or thyroid antibodies. The onset of Graves' ophthalmopathy occurs within the year before or after the diagnosis of thyrotoxicosis in 75% of patients but can sometimes precede or follow thyrotoxicosis by several years, accounting for some cases of euthyroid ophthalmopathy.

Many patients with Graves' disease have little clinical evidence of ophthalmopathy. However, the enlarged extraocular muscles typical of the disease, and other subtle features, can be detected in almost all patients when investigated by ultrasound or computed tomography (CT) imaging of the orbits. Unilateral signs are found in up to 10% of patients. The earliest manifestations of ophthalmopathy are usually a sensation of grittiness, eye discomfort, and excess tearing. About a third of patients have proptosis, best detected by visualization of the sclera between the lower border of the iris and the lower eyelid, with the eyes in the primary position. Proptosis can be measured using an exophthalmometer. In severe cases, proptosis may cause corneal exposure and damage, especially if the lids fail to close during sleep. Periorbital edema, scleral injection, and chemosis are also frequent. In 5 to 10% of patients, the muscle swelling is so severe that diplopia results, typically but not exclusively when the patient looks up and laterally. The most serious manifestation is compression of the optic nerve at the apex of the orbit, leading to papilledema, peripheral field defects, and, if left untreated, permanent loss of vision.

Many scoring systems have been used to gauge the extent and activity of the orbital changes in Graves' disease. The "NO SPECS" scheme is an acronym derived from the following classes of eye change:

0 = No signs or symptoms
1 = Only signs (lid retraction or lag), no symptoms
2 = Soft tissue involvement (periorbital edema)
3 = Proptosis (>22 mm)
4 = Extraocular muscle involvement (diplopia)
5 = Corneal involvement
6 = Sight loss

Although useful as a mnemonic, the NO SPECS scheme is inadequate to describe the eye disease fully, and patients do not necessarily progress from one class to another. When Graves' eye disease is active and severe, referral to an ophthalmologist is indicated and objective measurements are needed, such as lid fissure width; corneal staining with fluorescein; and evaluation of extraocular muscle function (e.g., Hess chart), intraocular pressure and visual fields, acuity, and color vision.

Thyroid dermopathy occurs in <5% of patients with Graves' dis-

ease (Fig. 320-6*B*), almost always in the presence of moderate or severe ophthalmopathy. Although most frequent over the anterior and lateral aspects of the lower leg (hence the term *pretibial myxedema*), skin changes can occur at other sites, particularly after trauma. The typical lesion is a noninflamed, indurated plaque with a deep pink or purple color and an "orange-skin" appearance. Nodular involvement can occur, and the condition can rarely extend over the whole lower leg and foot, mimicking elephantiasis. *Thyroid acropachy* refers to a form of clubbing found in <1% of patients with Graves' disease (Fig. 320-6*C*). It is so strongly associated with thyroid dermopathy that an alternative cause of clubbing should be sought in a Graves' patient without coincident skin and orbital involvement.

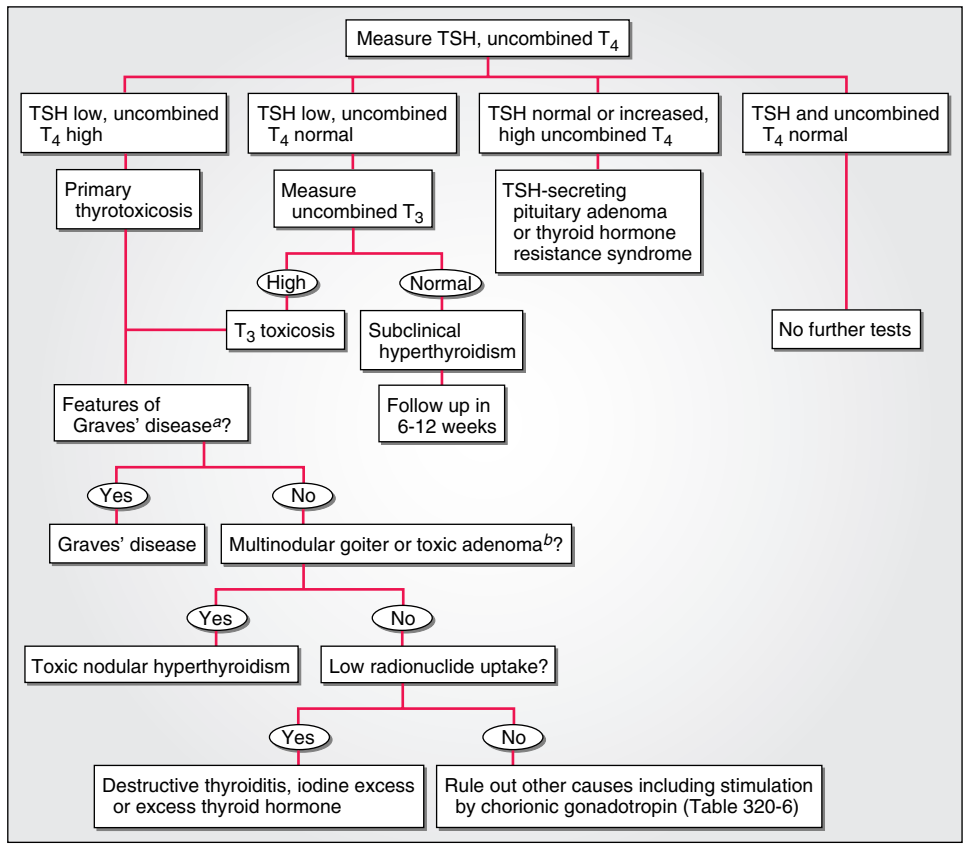

FIGURE 320-7 Evaluation of thyrotoxicosis. [a]Diffuse goiter, positive TPO antibodies, ophthalmopathy, dermopathy; [b]can be confirmed by radionuclide scan. TSH, thyroid-stimulating hormone.

Laboratory Evaluation Investigations used to determine the existence and cause of thyrotoxicosis are summarized in Fig. 320-7. In Graves' disease, the TSH level is suppressed and total and unbound thyroid hormone levels are increased. In 2 to 5% of patients (and more in areas of borderline iodine intake), only T_3 is increased (T_3 toxicosis). The converse state of T_4 toxicosis, with elevated total and unbound T_4 and normal T_3 levels, is occasionally seen when hyperthyroidism is induced by excess iodine, providing surplus substrate for thyroid hormone synthesis. Measurement of TPO antibodies is useful in differential diagnosis. Measurement of TBII or TSI will confirm the diagnosis but is not needed routinely. Associated abnormalities that may cause diagnostic confusion in thyrotoxicosis include elevation of bilirubin, liver enzymes, and ferritin. Microcytic anemia and thrombocytopenia may occur.

Differential Diagnosis Diagnosis of Graves' disease is straightforward in a patient with biochemically confirmed thyrotoxicosis, diffuse goiter on palpation, ophthalmopathy, positive TPO antibodies, and often a personal or family history of autoimmune disorders. For patients with thyrotoxicosis who lack these features, the most reliable diagnostic method is a radionuclide (^{99m}Tc, ^{123}I, or ^{131}I) scan of the thyroid, which will distinguish the diffuse, high uptake of Graves' disease from nodular thyroid disease, destructive thyroiditis, ectopic thyroid tissue, and factitious thyrotoxicosis. In secondary hyperthyroidism due to a TSH-secreting pituitary tumor, there is also a diffuse goiter. The presence of a nonsuppressed TSH level and the finding of a pituitary tumor on CT or magnetic resonance imaging (MRI) scan readily identify such patients.

Clinical features of thyrotoxicosis can mimic certain aspects of other disorders including panic attacks, mania, pheochromocytoma, and the weight loss associated with malignancy. The diagnosis of thyrotoxicosis can be easily excluded if the TSH and T_3 levels are normal. A normal TSH also excludes Graves' disease as a cause of diffuse goiter.

Clinical Course Clinical features generally worsen without treatment; mortality was 10 to 30% before the introduction of satisfactory therapy. Some patients with mild Graves' disease experience spontaneous relapses and remissions. Rarely, there may be fluctuation between hypo- and hyperthyroidism due to changes in the functional activity of TSH-R antibodies. About 15% of patients who enter remission after treatment with antithyroid drugs develop hypothyroidism 10 to 15 years later as a result of the destructive autoimmune process. The clinical course of ophthalmopathy does not follow that of the thyroid disease. Ophthalmopathy typically worsens over the initial 3 to 6 months, followed by a plateau phase over the next 12 to 18 months, with spontaneous improvement, particularly in the soft tissue changes. However, the course is more fulminant in up to 5% of patients, requiring intervention in the acute phase if there is optic nerve compression or corneal ulceration. Diplopia may appear late in the disease due to fibrosis of the extraocular muscles. Some studies suggest that radioiodine treatment for hyperthyroidism worsens the eye disease in a small proportion of patients (especially smokers). Antithyroid drugs or surgery have no adverse effects on the clinical course of ophthalmopathy. Thyroid dermopathy, when it occurs, usually appears 1 to 2 years after the development of Graves' hyperthyroidism; it may improve spontaneously.

TREATMENT

The *hyperthyroidism* of Graves' disease is treated by reducing thyroid hormone synthesis, using antithyroid drugs, or by reducing the amount of thyroid tissue with radioiodine (^{131}I) treatment or by subtotal thyroidectomy. Antithyroid drugs are the predominant therapy in many centers in Europe and Japan, whereas radioiodine is more often the first line of treatment in North America. These differences reflect the fact that no single approach is optimal and that patients may require multiple treatments to achieve remission.

The main *antithyroid drugs* are the thionamides, such as propylthiouracil, carbimazole, and the active metabolite of the latter, methimazole. All inhibit the function of TPO, reducing oxidation and organification of iodide. These drugs also reduce thyroid antibody levels by mechanisms that remain unclear, and they appear to enhance rates of remission. Propylthiouracil inhibits deiodination of $T_4 \rightarrow T_3$. However, this effect is of minor benefit, except in the most severe thyrotoxicosis, and is offset by the much shorter half-life of this drug (90 min) compared to methimazole (6 h).

There are many variations of antithyroid drug regimens. The initial

dose of carbimazole or methimazole is usually 10 to 20 mg every 8 or 12 h, but once-daily dosing is possible after euthyroidism is restored. Propylthiouracil is given at a dose of 100 to 200 mg every 6 to 8 h, and divided doses are usually given throughout the course. Lower doses of each drug may suffice in areas of low iodine intake. The starting dose of antithyroid drugs can be gradually reduced (titration regimen) as thyrotoxicosis improves. Alternatively, high doses may be given combined with levothyroxine supplementation (block-replace regimen) to avoid drug-induced hypothyroidism. Initial reports suggesting superior remission rates with the block-replace regimen have not been reproduced in several other trials. The titration regimen is often preferred to minimize the dose of antithyroid drug and provide an index of treatment response.

Thyroid function tests and clinical manifestations are reviewed 3 to 4 weeks after starting treatment, and the dose is titrated based on unbound T_4 levels. Most patients do not achieve euthyroidism until 6 to 8 weeks after treatment is initiated. TSH levels often remain suppressed for several months and therefore do not provide a sensitive index of treatment response. The usual daily maintenance doses of antithyroid drugs in the titration regimen are 2.5 to 10 mg of carbimazole or methimazole and 50 to 100 mg of propylthiouracil. In the block-replace regimen, the initial dose of antithyroid drug is held constant and the dose of levothyroxine is adjusted to maintain normal unbound T_4 levels. When TSH suppression is alleviated, TSH levels can also be used to monitor therapy.

Maximum remission rates (up to 30 to 50% in some populations) are achieved by 18 to 24 months. For unclear reasons, remission rates appear to vary in different geographic regions. Patients with severe hyperthyroidism and large goiters are most likely to relapse when treatment stops, but outcome is difficult to predict. All patients should be followed closely for relapse during the first year after treatment and at least annually thereafter.

The common side effects of antithyroid drugs are rash, urticaria, fever, and arthralgia (1 to 5% of patients). These may resolve spontaneously or after substituting an alternative antithyroid drug. Rare but major side effects include hepatitis, an SLE-like syndrome, and, most importantly, agranulocytosis (<1%). It is essential that antithyroid drugs are stopped and not restarted if a patient develops major side effects. Written instructions should be provided regarding the symptoms of possible agranulocytosis (e.g., sore throat, fever, mouth ulcers) and the need to stop treatment pending a complete blood count to confirm that agranulocytosis is not present. Management of agranulocytosis is described in Chap. 94. It is not useful to monitor blood counts prospectively, as the onset of agranulocytosis is idiosyncratic and abrupt.

Propranolol (20 to 40 mg every 6 h) or longer acting beta blockers, such as atenolol, may be helpful to control adrenergic symptoms, especially in the early stages before antithyroid drugs take effect. The need for anticoagulation with warfarin should be considered in all patients with atrial fibrillation. If digoxin is used, increased doses are often needed in the thyrotoxic state.

Radioiodine causes progressive destruction of thyroid cells and can be used as initial treatment or for relapses after a trial of antithyroid drugs. There is a small risk of thyrotoxic crisis (see below) after radioiodine, which can be minimized by pretreatment with antithyroid drugs for at least a month before treatment. Antecedent treatment with antithyroid drugs should be considered for all elderly patients or for those with cardiac problems, to deplete thyroid hormone stores before administration of radioiodine. Antithyroid drugs must be stopped at least 3 days before radioiodine administration to achieve optimum iodine uptake.

Efforts to calculate an optimal dose of radioiodine that achieves euthyroidism, without a high incidence of relapse or progression to hypothyroidism, have not been successful. Some patients inevitably relapse after a single dose because the biologic effects of radiation vary between individuals, and hypothyroidism cannot be uniformly avoided even using accurate dosimetry. A practical strategy is to give a fixed dose based on clinical features, such as the severity of thyrotoxicosis, the size of the goiter (increases the dose needed), and the level of radioiodine uptake (decreases the dose needed). ^{131}I dosage generally ranges between 185 MBq (5 mCi) to 555 MBq (15 mCi). Incomplete treatment or early relapse is more common in males and in patients <40 years of age. Many authorities favor an approach aimed at thyroid ablation (as opposed to euthyroidism), given that levothyroxine replacement is straightforward and most patients ultimately progress to hypothyroidism over 5 to 10 years, frequently with some delay in the diagnosis of hypothyroidism.

Certain radiation safety precautions are necessary in the first few days after radioiodine treatment, but the exact guidelines vary depending on local protocols. In general, patients need to avoid close, prolonged contact with children and pregnant women for several days because of possible transmission of residual isotope and excessive exposure to radiation emanating from the gland. Rarely there may be mild pain due to radiation thyroiditis 1 to 2 weeks after treatment. Hyperthyroidism can persist for 2 to 3 months before radioiodine takes full effect. For this reason, β-adrenergic blockers or antithyroid drugs can be used to control symptoms during this interval. Persistent hyperthyroidism can be treated with a second dose of radioiodine, usually 6 months after the first dose. The risk of hypothyroidism after radioiodine depends on the dosage but is at least 10 to 20% in the first year and 5% per year thereafter. Patients should be informed of this possibility before treatment and require close follow-up during the first year and annual thyroid function testing.

Pregnancy and breast feeding are absolute contraindications to radioiodine treatment, but patients can conceive safely 6 months after treatment. The presence of severe ophthalmopathy requires caution, and some authorities advocate the use of prednisone, 40 mg/d, at the time of radioiodine treatment, tapered over 2 to 3 months to prevent exacerbation of ophthalmopathy. The overall risk of cancer after radioiodine treatment in adults is not increased, but many physicians avoid radioiodine in children and adolescents because of the theoretical risks of malignancy.

Subtotal thyroidectomy is an option for patients who relapse after antithyroid drugs and prefer this treatment to radioiodine. Some experts recommend surgery in young individuals, particularly when the goiter is very large. Careful control of thyrotoxicosis with antithyroid drugs, followed by potassium iodide (3 drops SSKI orally tid), is needed prior to surgery to avoid thyrotoxic crisis and to reduce the vascularity of the gland. The major complications of surgery—i.e., bleeding, laryngeal edema, hypoparathyroidism, and damage to the recurrent laryngeal nerves—are unusual when the procedure is performed by highly experienced surgeons. Recurrence rates in the best series are <2%, but the rate of hypothyroidism is only slightly less than that following radioiodine treatment.

The titration regimen of antithyroid drugs should be used to manage Graves' disease in *pregnancy*, as blocking doses of these drugs produce fetal hypothyroidism. Propylthiouracil is usually used because of relatively low transplacental transfer and its ability to block $T_4 \rightarrow T_3$ conversion. Also, carbimazole and methimazole have been associated with rare cases of fetal *aplasia cutis* and other defects, such as choanal atresia. The lowest effective dose of propylthiouracil should be given, and it is often possible to stop treatment in the last trimester since TSH-R antibodies tend to decline in pregnancy. Nonetheless, the transplacental transfer of these antibodies rarely causes *fetal thyrotoxicosis* or *neonatal thyrotoxicosis*. Poor intrauterine growth, a fetal heart rate of >160 beats/min, and high levels of maternal TSH-R antibodies in the last trimester may herald this complication. Antithyroid drugs given to the mother can be used to treat the fetus and may be needed for 1 to 3 months after delivery, until the maternal antibodies disappear from the baby's circulation. The postpartum period is a time of major risk for relapse of Graves' disease. Breast feeding is safe with low doses of antithyroid drugs. Graves' disease in *children* is best managed with antithyroid drugs, often given as a prolonged course of the titration regimen. Surgery may be indicated for severe disease. Radioio-

dine can also be used in children, although most experts defer this treatment until adolescence or later.

Thyrotoxic crisis, or *thyroid storm*, is rare and presents as a life-threatening exacerbation of hyperthyroidism, accompanied by fever, delirium, seizures, coma, vomiting, diarrhea, and jaundice. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is as high as 30%, even with treatment. Thyrotoxic crisis is usually precipitated by acute illness (e.g., stroke, infection, trauma, diabetic ketoacidosis), surgery (especially on the thyroid), or radioiodine treatment of a patient with partially treated or untreated hyperthyroidism. Management requires intensive monitoring and supportive care, identification and treatment of the precipitating cause, and measures that reduce thyroid hormone synthesis. Large doses of propylthiouracil (600-mg loading dose and 200 to 300 mg every 6 h) should be given orally or by nasogastric tube or per rectum; the drug's inhibitory action on $T_4 \rightarrow T_3$ conversion makes it the antithyroid drug of choice. One hour after the first dose of propylthiouracil, stable iodide is given to block thyroid hormone synthesis via the Wolff-Chaikoff effect (the delay allows the antithyroid drug to prevent the excess iodine from being incorporated into new hormone). A saturated solution of potassium iodide (5 drops SSKI every 6 h), or ipodate or iopanoic acid (0.5 mg every 12 h), may be given orally. (Sodium iodide, 0.25 g intravenously every 6 h is an alternative but is not generally available.) Propranolol should also be given to reduce tachycardia and other adrenergic manifestations (40 to 60 mg orally every 4 h; or 2 mg intravenously every 4 h). Although other β-adrenergic blockers can be used, high doses of propranolol decrease $T_4 \rightarrow T_3$ conversion, and the doses can be easily adjusted. Caution is needed to avoid acute negative inotropic effects, but controlling the heart rate is important, as some patients develop a form of high-output heart failure. Additional therapeutic measures include glucocorticoids (e.g., dexamethasone, 2 mg every 6 h), antibiotics if infection is present, cooling, oxygen, and intravenous fluids.

Ophthalmopathy requires no active treatment when it is mild or moderate, as there is usually spontaneous improvement. General measures include meticulous control of thyroid hormone levels, advice about cessation of smoking, and an explanation of the natural history of ophthalmopathy. Discomfort can be relieved with artificial tears (e.g., 1% methylcellulose) and the use of dark glasses with side frames. Periorbital edema may respond to a more upright sleeping position or a diuretic. Corneal exposure during sleep can be avoided by taping the eyelids shut. Minor degrees of diplopia improve with prisms fitted to spectacles. Severe ophthalmopathy, with optic nerve involvement or chemosis resulting in corneal damage, is an emergency requiring joint management with an ophthalmologist. Short-term benefit can be gained in about two-thirds of patients by the use of high-dose glucocorticoids (e.g., prednisone, 40 to 80 mg daily), sometimes combined with cyclosporine. Glucocorticoid doses are tapered by 5 mg every 1 to 2 weeks, but the taper often results in reemergence of congestive symptoms. Pulse therapy with intravenous methylprednisolone (1 g of methylprednisolone in 250 mL of saline infused over 2 h daily for 1 week) followed by an oral regimen is also used. Once the eye disease has stabilized, surgery may be indicated for relief of diplopia and correction of the appearance of the eyes. Orbital decompression can be achieved by removing bone from any wall of the orbit, thereby allowing displacement of fat and swollen extraocular muscles. The transantral route is used most often, as it requires no external incision. Proptosis recedes an average of 5 mm, but there may be residual or even worsened diplopia. Alternatively, retrobulbar tissue can be decompressed without the removal of bony tissue. External beam radiotherapy of the orbits has been used for many years, especially for ophthalmopathy of recent onset, but the objective evidence that this therapy is beneficial remains equivocal.

Thyroid dermopathy does not usually require treatment but can cause cosmetic problems or interfere with the fit of shoes. Surgical removal is not indicated. If necessary, treatment consists of topical, high-potency glucocorticoid ointment under an occlusive dressing. Octreotide may be beneficial.

OTHER CAUSES OF THYROTOXICOSIS Destructive thyroiditis (subacute or silent thyroiditis) typically presents with a short thyrotoxic phase due to the release of preformed thyroid hormones and catabolism of Tg (see "Subacute Thyroiditis," below). True hyperthyroidism is absent, as demonstrated by a low radionuclide uptake. Circulating Tg and IL-6 levels are usually increased. Other causes of thyrotoxicosis with low or absent thyroid radionuclide uptake include *thyrotoxicosis factitia*; iodine excess and, rarely, ectopic thyroid tissue, particularly teratomas of the ovary (*struma ovarii*); and functional metastatic follicular carcinoma. Whole-body radionuclide studies can demonstrate ectopic thyroid tissue, and thyrotoxicosis factitia can be distinguished from destructive thyroiditis by the clinical features and low levels of Tg. Amiodarone treatment is associated with thyrotoxicosis in up to 10% of patients, particularly in areas of low iodine intake.

TSH-secreting pituitary adenoma is a rare causes of thyrotoxicosis. It can be identified by the presence of an inappropriately normal or increased TSH level in a patient with hyperthyroidism, diffuse goiter, and elevated T_4 and T_3 levels (Chap. 318). Elevated levels of the α subunit of TSH, released by the TSH-secreting adenoma, support this diagnosis, which can be confirmed by demonstrating the pituitary tumor on CT or MRI scan. A combination of transsphenoidal surgery, sella irradiation, and octreotide may be required to normalize TSH, as many of these tumors are large and locally invasive at the time of diagnosis. Radioiodine or antithyroid drugs can be used to control thyrotoxicosis.

Thyrotoxicosis caused by *toxic multinodular goiter* and *hyperfunctioning solitary nodules* is discussed below.

THYROIDITIS

A clinically useful classification of thyroiditis is based on the onset and duration of disease (Table 320-8).

ACUTE THYROIDITIS Acute thyroiditis is rare and due to suppurative infection of the thyroid. In children and young adults, the most common cause is the presence of a piriform sinus, a remnant of the fourth branchial pouch that connects the oropharynx with the thyroid. Such sinuses are predominantly left sided. A long-standing goiter and degeneration in a thyroid malignancy are risk factors in the elderly. The patient presents with thyroid pain, often referred to the throat or ears, and a small, tender goiter that may be asymmetric. Fever, dysphagia, and erythema over the thyroid are common, as are systemic symptoms of a febrile illness and lymphadenopathy.

The differential diagnosis of *thyroid pain* includes subacute or, rarely, chronic thyroiditis, hemorrhage into a cyst, malignancy including lymphoma, and, rarely, amiodarone-induced thyroiditis or amyloidosis. However, the abrupt presentation and clinical features of acute thyroiditis rarely cause confusion. The erythrocyte sedimentation rate (ESR) and white cell count are usually increased, but thyroid

TABLE 320-8 Causes of Thyroiditis

Acute
Bacterial infection: especially *Staphylcoccus*, *Streptococcus*, and *Enterobacter*
Fungal infection: *Aspergillus*, *Candida*, *Coccidioides*, *Histoplasma*, and *Pneumocystis*
Radiation thyroiditis after ^{131}I treatment
Amiodarone (may also be subacute or chronic)
Subacute
Viral (or granulomatous) thyroiditis
Silent thyroiditis (including postpartum thyroiditis)
Mycobacterial infection
Chronic
Autoimmunity: focal thyroiditis, Hashimoto's thyroiditis, atrophic thyroiditis
Riedel's thyroiditis
Parasitic thyroiditis: echinococcosis, strongyloidiasis, cysticercosis
Traumatic: after palpation

function is normal. FNA biopsy shows infiltration by polymorphonuclear leukocytes; culture of the sample can identify the organism. Caution is needed in immunocompromised patients as fungal, mycobacterial, or *Pneumocystis* thyroiditis can occur in this setting. Antibiotic treatment is guided initially by Gram stain and subsequently by cultures of the FNA biopsy. Surgery may be needed to drain an abscess, which can be localized by CT scan or ultrasound. Tracheal obstruction, septicemia, retropharyngeal abscess, mediastinitis, and jugular venous thrombosis may complicate acute thyroiditis but are uncommon with prompt use of antibiotics.

SUBACUTE THYROIDITIS This is also termed *de Quervain's thyroiditis*, *granulomatous thyroiditis*, or *viral thyroiditis*. Many viruses have been implicated, including mumps, coxsackie, influenza, adenoviruses, and echoviruses, but attempts to identify the virus in an individual patient are often unsuccessful and do not influence management. The diagnosis of subacute thyroiditis is often overlooked because the symptoms can mimic pharyngitis. The peak incidence occurs at 30 to 50 years, and women are affected three times more frequently than men.

Pathophysiology The thyroid shows a characteristic patchy inflammatory infiltrate with disruption of the thyroid follicles and multinucleated giant cells within some follicles. The follicular changes progress to granulomas accompanied by fibrosis. Finally, the thyroid returns to normal, usually several months after onset. During the initial phase of follicular destruction, there is release of Tg and thyroid hormones, leading to increased circulating T_4 and T_3 and suppression of TSH (Fig. 320-8). During this destructive phase, radioactive iodine uptake is low or undetectable. After several weeks, the thyroid is depleted of stored thyroid hormone and a phase of hypothyroidism typically occurs, with low unbound T_4 (and sometimes T_3) and moderately increased TSH levels. Radioactive iodine uptake returns to normal or is even increased as a result of the rise in TSH. Finally, thyroid hormone and TSH levels return to normal as the disease subsides.

Clinical Manifestations The patient usually presents with a painful and enlarged thyroid, sometimes accompanied by fever. There may be features of thyrotoxicosis or hypothyroidism, depending on the phase of the illness. Malaise and symptoms of an upper respiratory tract infection may precede the thyroid-related features by several weeks. In other patients, the onset is acute, severe, and without obvious antecedent. The patient typically complains of a sore throat, and examination reveals a small goiter that is exquisitely tender. Pain is often referred to the jaw or ear. Complete resolution is the usual outcome,

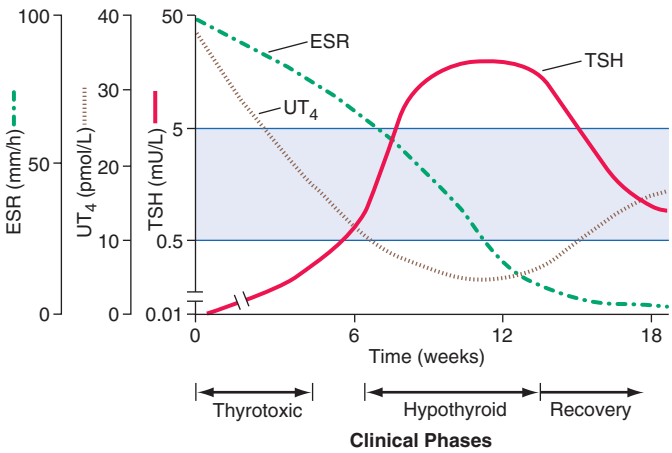

FIGURE 320-8 Clinical course of subacute thyroiditis. The release of thyroid hormones is initially associated with a thyrotoxic phase and suppressed thyroid-stimulating hormone (TSH). A hypothyroid phase then ensues, with low T_4 and TSH levels that are initially low but gradually increase. During the recovery phase, increased TSH levels combined with resolution of thyroid follicular injury leads to normalization of thyroid function, often several months after the beginning of the illness. ESR, erythrocyte sedimentation rate; UT_4, unbound T_4.

but permanent hypothyroidism can occur, particularly in those with coincidental thyroid autoimmunity. A prolonged course over many months, with one or more relapses, occurs in a small percentage of patients.

Laboratory Evaluation As depicted in Fig. 320-8, thyroid function tests characteristically evolve through three distinct phases over about 6 months: (1) thyrotoxic phase, (2) hypothyroid phase, and (3) recovery phase. In the thyrotoxic phase, T_4 and T_3 levels are increased, reflecting their discharge from the damaged thyroid cells, and TSH is suppressed. The T_4/T_3 ratio is greater than in Graves' disease or thyroid autonomy, in which T_3 is often disproportionately increased. The diagnosis is confirmed by a high ESR and low radioiodine uptake. Serum IL-6 levels increase during the thyrotoxic phase. The white blood cell count may be increased, and thyroid antibodies are negative. If the diagnosis is in doubt, FNA biopsy may be useful, particularly to distinguish unilateral involvement from bleeding into a cyst or neoplasm.

Rx TREATMENT

Relatively large doses of aspirin (e.g., 600 mg every 4 to 6 h) or nonsteroidal anti-inflammatory drugs are sufficient to control symptoms in most cases. If this treatment is inadequate, or if the patient has marked local or systemic symptoms, glucocorticoids should be given. The usual starting dose is 40 to 60 mg prednisone, depending on severity. The dose is gradually tapered over 6 to 8 weeks, in response to improvement in symptoms and the ESR. If a relapse occurs during glucocorticoid withdrawal, treatment should be started again and withdrawn more gradually. In these patients, it is useful to wait until the radioactive iodine uptake normalizes before stopping treatment. Thyroid function should be monitored every 2 to 4 weeks using TSH and unbound T_4 levels. Symptoms of thyrotoxicosis improve spontaneously but may be ameliorated by β-adrenergic blockers; antithyroid drugs play no role in treatment of the thyrotoxic phase. Levothyroxine replacement may be needed if the hypothyroid phase is prolonged, but doses should be low enough (50 to 100 μg daily) to allow TSH-mediated recovery.

SILENT THYROIDITIS *Painless thyroiditis*, or *"silent" thyroiditis*, occurs in patients with underlying autoimmune thyroid disease. It has a clinical course similar to that of subacute thyroiditis, except that there is little or no thyroid tenderness. The condition occurs in up to 5% of women 3 to 6 months after pregnancy and is then termed *postpartum thyroiditis*. Typically, patients have a brief phase of thyrotoxicosis, lasting 2 to 4 weeks, followed by hypothyroidism for 4 to 12 weeks, and then resolution; often, however, only one phase is apparent. The condition is associated with the presence of TPO antibodies antepartum, and is three times more common in women with type 1 diabetes mellitus. As in subacute thyroiditis, the radioactive iodine uptake is initially suppressed. In addition to the painless goiter, silent thyroiditis can be distinguished from subacute thyroiditis by the normal ESR and the presence of TPO antibodies. Glucocorticoid treatment is not indicated for silent thyroiditis. Severe thyrotoxic symptoms can be managed with a brief course of propranolol, 20 to 40 mg three or four times daily. Thyroxine replacement may be needed for the hypothyroid phase but should be withdrawn after 6 to 9 months, as recovery is the rule. Annual follow-up thereafter is recommended, as a proportion of these individuals develop permanent hypothyroidism.

DRUG-INDUCED THYROIDITIS Patients receiving IFN-α, IL-2, or amiodarone may develop painless thyroiditis. IFN-α, which is used to treat chronic hepatitis B or C, causes thyroid dysfunction in up to 5% of treated patients. It has been associated with painless thyroiditis, hypothyroidism, and Graves' disease. IL-2, which has been used to treat various malignancies, has also been associated with thyroiditis and hypothyroidism, though fewer patients have been studied. For discussion of amiodarone, see "Amiodarone Effects on Thyroid Function," below.

CHRONIC THYROIDITIS Focal thyroiditis is present in 20 to 40% of euthyroid autopsy cases and is associated with serologic evidence of

autoimmunity, particularly the presence of TPO antibodies. These antibodies are 4 to 10 times more common in otherwise healthy women than men. The most common clinically apparent cause of chronic thyroiditis is *Hashimoto's thyroiditis*, an autoimmune disorder that often presents as a firm or hard goiter of variable size (see above). *Riedel's thyroiditis* is a rare disorder that typically occurs in middle-aged women. It presents with an insidious, painless goiter with local symptoms due to compression of the esophagus, trachea, neck veins, or recurrent laryngeal nerves. Dense fibrosis disrupts normal gland architecture and can extend outside the thyroid capsule. Despite these extensive histologic changes, thyroid dysfunction is uncommon. The goiter is hard, nontender, often asymmetric and fixed, leading to suspicion of a malignancy. Diagnosis requires open biopsy as FNA biopsy is usually inadequate. Treatment is directed to surgical relief of compressive symptoms. Tamoxifen may also be beneficial. There is an association between Riedel's thyroiditis and idiopathic fibrosis at other sites (retroperitoneum, mediastinum, biliary tree, lung, and orbit).

SICK EUTHYROID SYNDROME

Any acute, severe illness can cause abnormalities of circulating TSH or thyroid hormone levels in the absence of underlying thyroid disease, making these measurements potentially misleading. The major cause of these hormonal changes is the release of cytokines. Unless a thyroid disorder is strongly suspected, the routine testing of thyroid function should be avoided in acutely ill patients.

The most common hormone pattern in sick euthyroid syndrome (SES) is a decrease in total and unbound T_3 levels (low T_3 syndrome) with normal levels of T_4 and TSH. The magnitude of the fall in T_3 correlates with the severity of the illness. T_4 conversion to T_3 via peripheral deiodination is impaired, leading to increased reverse T_3 (rT_3). Despite this effect, decreased clearance rather than increased production is the major basis for increased rT_3. Also, T_4 is alternately metabolized to the hormonally inactive T_3 sulfate. It is generally assumed that this low T_3 state is adaptive, as it can be induced in normal individuals by fasting. Teleologically, the fall in T_3 may limit catabolism in starved or ill patients.

Very sick patients may exhibit a dramatic fall in total T_4 and T_3 levels (low T_4 syndrome). This state has a poor prognosis. A key factor in the fall in T_4 levels is altered binding to TBG. T_4 assays usually demonstrate a normal unbound T_4 level in such patients, depending on the assay method used. Fluctuation in TSH levels also creates challenges in the interpretation of thyroid function in sick patients. TSH levels may range from <0.1 to >20 mU/L; these alterations reverse after recovery, confirming the absence of underlying thyroid disease. A rise in cortisol or administration of glucocorticoids may provide a partial explanation for decreased TSH levels. However, the exact mechanisms underlying the subnormal TSH seen in 10% of sick patients and the increased TSH seen in 5% remain unclear.

Any severe illness can induce changes in thyroid hormone levels, but certain disorders exhibit a distinctive pattern of abnormalities. Acute liver disease is associated with an initial rise in total (but not unbound) T_3 and T_4 levels, due to TBG release; these levels become subnormal with progression to liver failure. A transient increase in total and unbound T_4 levels, usually with a normal T_3 level, is seen in 5 to 30% of acutely ill psychiatric patients. TSH values may be transiently low, normal, or high in these patients. In the early stage of HIV infection, T_3 and T_4 levels rise, even if there is weight loss. T_3 levels fall with progression to AIDS, but TSH usually remains normal. Renal disease is often accompanied by low T_3 concentrations, but with normal rather than increased rT_3 levels, due to an unknown factor that increases uptake of rT_3 into the liver.

The diagnosis of SES is challenging. Historic information may be limited, and patients often have multiple metabolic derangements. Useful features to consider include previous history of thyroid disease and thyroid function tests, evaluation of the severity and time course of the patient's acute illness, documentation of medications that may affect thyroid function or thyroid hormone levels, and measurements of rT_3 together with unbound thyroid hormones and TSH. The diagnosis of SES is frequently presumptive, given the clinical context and pattern of laboratory values; only resolution of the test results with clinical recovery can clearly establish this disorder. Treatment of SES with thyroid hormone (T_4 and/or T_3) is controversial, but most authorities recommend monitoring the patient's thyroid function tests during recovery, without administering thyroid hormone, unless there is historic or clinical evidence suggestive of hypothyroidism. Sufficiently large randomized controlled trials using thyroid hormone are unlikely to resolve this therapeutic controversy in the near future, because clinical presentations and outcomes are highly variable.

AMIODARONE EFFECTS ON THYROID FUNCTION

Amiodarone is a commonly used type III antiarrhythmic agent (Chap. 214). It is structurally related to thyroid hormone and contains 39% iodine by weight. Thus, typical doses of amiodarone (200 mg/d) are associated with very high iodine intake, leading to >40-fold increases in plasma and urinary iodine levels. Moreover, because amiodarone is stored in adipose tissue, high iodine levels persist for >6 months after discontinuation of the drug. Amiodarone inhibits deiodinase activity, and its metabolites function as weak antagonists of thyroid hormone action. Amiodarone has the following effects on thyroid function: (1) acute, transient suppression of thyroid function; (2) hypothyroidism in patients susceptible to the inhibitory effects of a high iodine load; and (3) thyrotoxicosis that may be caused by at least three mechanisms—a Jod-Basedow effect from the iodine load in the setting of multinodular goiter, a thyroiditis-like condition, and possibly induction of autoimmune Graves' disease.

The initiation of amiodarone treatment is associated with a transient decrease of T_4 levels, reflecting the inhibitory effect of iodine on T_4 release. Soon thereafter, most individuals escape from iodide-dependent suppression of the thyroid (Wolff-Chaikoff effect), and the inhibitory effects on deiodinase activity and thyroid hormone receptor action become predominant. These events lead to the following pattern of thyroid function tests: increased T_4, decreased T_3, increased rT_3, and a transient increase of TSH (up to 20 mU/L). TSH levels normalize or are slightly suppressed by 1 to 3 months.

The incidence of hypothyroidism from amiodarone varies geographically, apparently correlating with iodine intake. Hypothyroidism occurs in up to 13% of amiodarone-treated patients in iodine-replete countries, such as the United States, but is less common (<6% incidence) in areas of lower iodine intake, such as Italy or Spain. The pathogenesis appears to involve an inability of the thyroid to escape from the high iodine load. Consequently, amiodarone-associated hypothyroidism is more common in women and individuals with positive TPO antibodies. It is usually unnecessary to discontinue amiodarone for this side effect, as levothyroxine can be used to normalize thyroid function. TSH levels should be monitored, because T_4 levels are often increased for the reasons described above.

The management of amiodarone-induced thyrotoxicosis (AIT) is complicated by the fact that there are several causes of thyrotoxicosis and because the increased thyroid hormone levels exacerbate underlying arrhythmias and coronary artery disease. Amiodarone treatment causes thyrotoxicosis in 10% of patients living in areas of low iodine intake and in 2% of patients in regions of high iodine intake. There are two major forms of AIT, although some patients have features of both. Type 1 AIT is associated with an underlying thyroid abnormality (preclinical Graves' disease or nodular goiter). Thyroid hormone synthesis becomes excessive as a result of increased iodine exposure (Jod-Basedow phenomenon). Type 2 AIT occurs in individuals with no intrinsic thyroid abnormalities and is the result of drug-induced lysosomal activation leading to destructive thyroiditis with histiocyte accumulation in the thyroid. Mild forms of type 2 AIT can resolve spontaneously or can occasionally lead to hypothyroidism. Color-flow doppler thyroid scanning shows increased vascularity in type 1 AIT

but decreased vascularity in type 2 AIT. Thyroid scans are difficult to interpret in this setting, because the high endogenous iodine levels diminish tracer uptake. However, the presence of normal or increased uptake favors type 1 AIT.

In AIT the drug should be stopped, if possible, although this is often impractical because of the underlying cardiac disorder. Discontinuation of amiodarone will not have an acute effect because of its storage and prolonged half-life. High doses of antithyroid drugs can be used in type 1 AIT but are often ineffective. In type 2 AIT, oral contrast agents, such as sodium ipodate (500 mg/d) or sodium tyropanoate (500 mg, 1 to 2 doses/d), rapidly reduce T_4 and T_3 levels, decrease $T_4 \rightarrow T_3$ conversion, and may block tissue uptake of thyroid hormones. Potassium perchlorate, 200 mg every 6 h, has been used to reduce thyroidal iodide content. Perchlorate treatment has been associated with agranulocytosis, though the risk appears relatively low with short-term use. Glucocorticoids, administered as for subacute thyroiditis, are of variable benefit in type 2 AIT. Lithium blocks thyroid hormone release and can provide modest benefit. Near-total thyroidectomy rapidly decreases thyroid hormone levels and may be the most effective long-term solution, if the patient can undergo the procedure safely.

THYROID FUNCTION IN PREGNANCY

Four factors alter thyroid function in pregnancy: (1) the transient increase in hCG during the first trimester, which stimulates the TSH-R; (2) the estrogen-induced rise in TBG during the first trimester, which is sustained during pregnancy; (3) alterations in the immune system, leading to the onset, exacerbation, or amelioration of an underlying autoimmune thyroid disease (see above); and (4) increased urinary iodide excretion, which can cause impaired thyroid hormone production in areas of marginal iodine sufficiency. Women with a precarious iodine intake (<50 μg/d) are most at risk of developing a goiter during pregnancy, and iodine supplementation should be considered to prevent maternal and fetal hypothyroidism and the development of neonatal goiter.

The rise in circulating hCG levels during the first trimester is accompanied by a reciprocal fall in TSH that persists into the middle of pregnancy. This appears to reflect weak binding of hCG, which is present at very high levels, to the TSH-R. Rare individuals have been described with variant TSH-R sequences that enhance hCG binding and TSH-R activation. hCG-induced changes in thyroid function can result in transient gestational hyperthyroidism and/or *hyperemesis gravidarum*, a condition characterized by severe nausea and vomiting and risk of volume depletion. Antithyroid drugs are rarely needed, and parenteral fluid replacement usually suffices until the condition resolves.

Maternal hypothyroidism occurs in 2 to 3% of women of childbearing age and is associated with increased risk of developmental delay in the offspring. Thyroid hormone requirements are increased by 25 to 50 μg/d during pregnancy.

GOITER AND NODULAR THYROID DISEASE

Goiter refers to an enlarged thyroid gland. Biosynthetic defects, iodine deficiency, autoimmune disease, and nodular diseases can each lead to goiter, though by different mechanisms. Biosynthetic defects and iodine deficiency are associated with reduced efficiency of thyroid hormone synthesis, leading to increased TSH, which stimulates thyroid growth as a compensatory mechanism to overcome the block in hormone synthesis. Graves' disease and Hashimoto's thyroiditis are also associated with goiter. In Graves' disease, the goiter results mainly from the TSH-R-mediated effects of TSI. The goitrous form of Hashimoto's thyroiditis occurs because of acquired defects in hormone synthesis, leading to elevated levels of TSH and its consequent growth effects. Lymphocytic infiltration and immune system–induced growth factors also contribute to thyroid enlargement in Hashimoto's thyroiditis. Nodular disease is characterized by the disordered growth of thyroid cells, often combined with the gradual development of fibrosis. Because the management of goiter depends on the etiology, the detection of thyroid enlargement on physical examination should prompt further evaluation to identify its cause.

Nodular thyroid disease is common, occurring in about 3 to 7% of adults when assessed by physical examination. Using more sensitive techniques, such as ultrasound, it is present in $>25\%$ of adults. Thyroid nodules may be solitary or multiple, and they may be functional or nonfunctional.

DIFFUSE NONTOXIC (SIMPLE) GOITER ■ Etiology and Pathogenesis When diffuse enlargement of the thyroid occurs in the absence of nodules and hyperthyroidism, it is referred to as a *diffuse nontoxic goiter*. This is sometimes called *simple goiter*, because of the absence of nodules, or *colloid goiter*, because of the presence of uniform follicles that are filled with colloid. Worldwide, diffuse goiter is most commonly caused by iodine deficiency and is termed *endemic goiter* when it affects $>5\%$ of the population. In nonendemic regions, *sporadic goiter* occurs, and the cause is usually unknown. Thyroid enlargement in teenagers is sometimes referred to as *juvenile goiter*. In general, goiter is more common in women than men, probably because of the greater prevalence of underlying autoimmune disease and the increased iodine demands associated with pregnancy.

In *iodine-deficient areas*, thyroid enlargement reflects a compensatory effort to trap iodide and produce sufficient hormone under conditions in which hormone synthesis is relatively inefficient. Somewhat surprisingly, TSH levels are usually normal or only slightly increased, suggesting increased sensitivity to TSH or activation of other pathways that lead to thyroid growth. Iodide appears to have direct actions on thyroid vasculature and may indirectly affect growth through vasoactive substances such as endothelins and nitric oxide. Endemic goiter is also caused by exposure to environmental *goitrogens* such as cassava root, which contains a thiocyanate, vegetables of the Cruciferae family (e.g., brussels sprouts, cabbage, and cauliflower), and milk from regions where goitrogens are present in grass. Though relatively rare, inherited defects in thyroid hormone synthesis lead to a diffuse nontoxic goiter. Abnormalities at each step in hormone synthesis, including iodide transport (NIS), Tg synthesis, organification and coupling (TPO), and the regeneration of iodide (dehalogenase), have been described.

CLINICAL MANIFESTATIONS AND DIAGNOSIS If thyroid function is preserved, most goiters are asymptomatic. Spontaneous hemorrhage into a cyst or nodule may cause the sudden onset of localized pain and swelling. Examination of a diffuse goiter reveals a symmetrically enlarged, nontender, generally soft gland without palpable nodules. Goiter is defined, somewhat arbitrarily, as a lateral lobe with a volume greater than the thumb of the individual being examined. If the thyroid is markedly enlarged, it can cause tracheal or esophageal compression. These features are unusual, however, in the absence of nodular disease and fibrosis. *Substernal goiter* may obstruct the thoracic inlet. *Pemberton's sign* refers to symptoms of faintness with evidence of facial congestion and external jugular venous obstruction when the arms are raised above the head, a maneuver that draws the thyroid into the thoracic inlet. Respiratory flow measurements and CT or MRI should be used to evaluate substernal goiter in patients with obstructive signs or symptoms.

Thyroid function tests should be performed in all patients with goiter to exclude thyrotoxicosis or hypothyroidism. It is not unusual, particularly in iodine deficiency, to find a low total T_4, with normal T_3 and TSH, reflecting enhanced $T_4 \rightarrow T_3$ conversion. A low TSH, particularly in older patients, suggests the possibility of thyroid autonomy or undiagnosed Graves' disease, causing subclinical thyrotoxicosis. TPO antibodies may be useful to identify patients at increased risk of autoimmune thyroid disease. Low urinary iodine levels (<10 μg/dL) support a diagnosis of iodine deficiency. Thyroid scanning is not generally necessary but will reveal increased uptake in iodine deficiency and most cases of dyshormonogenesis. Ultrasound is not generally

indicated in the evaluation of diffuse goiter, unless a nodule is palpable on physical examination.

TREATMENT

Iodine or thyroid hormone replacement induces variable regression of goiter in iodine deficiency, depending on how long it has been present and the degree of fibrosis that has developed. Because of the possibility of underlying thyroid autonomy, caution should be exercised when instituting suppressive thyroxine therapy in other causes of diffuse nontoxic goiter, particularly if the baseline TSH is in the low-normal range. In younger patients, the dose of levothyroxine can be started at 100 μg/d and adjusted to suppress the TSH into the low-normal but detectable range. Treatment of elderly patients should be initiated at 50 μg/d. The efficacy of suppressive treatment is greater in younger patients and for those with soft goiters. Significant regression is usually seen within 3 to 6 months of treatment; after this time it is unlikely to occur. In older patients, and in those with some degree of nodular disease or fibrosis, fewer than one-third demonstrate significant shrinkage of the goiter. Surgery is rarely indicated for diffuse goiter. Exceptions include documented evidence of tracheal compression or obstruction of the thoracic inlet, which are more likely to be associated with substernal multinodular goiters (see below). Subtotal or near-total thyroidectomy for these or cosmetic reasons should be performed by an experienced surgeon to minimize complication rates, which occur in up to 10% of cases. Surgery should be followed by mild suppressive treatment with levothyroxine to prevent regrowth of the goiter. Radioiodine reduces goiter size by about 50% in the majority of patients. It is rarely associated with transient acute swelling of the thyroid, which is usually inconsequential unless there is severe tracheal narrowing. If not treated with levothyroxine, patients should be followed after radioiodine treatment for the possible development of hypothyroidism.

NONTOXIC MULTINODULAR GOITER ■ Etiology and Pathogenesis Depending on the population studied, multinodular goiter (MNG) occurs in up to 12% of adults. MNG is more common in women than men and increases in prevalence with age. It is more common in iodine-deficient regions but also occurs in regions of iodine sufficiency, reflecting multiple genetic, autoimmune, and environmental influences on the pathogenesis.

There is typically wide variation in nodule size. Histology reveals a spectrum of morphologies ranging from hypercellular regions to cystic areas filled with colloid. Fibrosis is often extensive, and areas of hemorrhage or lymphocytic infiltration may be seen. Using molecular techniques, most nodules within a MNG are polyclonal in origin, suggesting a hyperplastic response to locally produced growth factors and cytokines. TSH, which is usually not elevated, may play a permissive or contributory role. Monoclonal lesions also occur within a MNG, reflecting mutations in genes that confer a selective growth advantage to the progenitor cell.

Clinical Manifestations Most patients with nontoxic MNG are asymptomic and, by definition, euthyroid. MNG typically develops over many years and is detected on routine physical examination or when an individual notices an enlargement in the neck. If the goiter is large enough, it can ultimately lead to compressive symptoms including difficulty swallowing, respiratory distress (tracheal compression), or plethora (venous congestion), but these symptoms are uncommon. Symptomatic MNGs are usually extraordinarily large and/or develop fibrotic areas that cause compression. Sudden pain in a MNG is usually caused by hemorrhage into a nodule but should raise the possibility of invasive malignancy. Hoarseness, reflecting laryngeal nerve involvement, also suggests malignancy.

Diagnosis On examination, thyroid architecture is distorted and multiple nodules of varying size can be appreciated. Because many nodules are deeply embedded in thyroid tissue or reside in posterior or substernal locations, it is not possible to palpate all nodules. A TSH level should be measured to exclude subclinical hyper- or hypothyroidism, but thyroid function is usually normal. Tracheal deviation is common, but compression must usually exceed 70% of the tracheal diameter before there is significant airway compromise. Pulmonary function testing can be used to assess the functional effects of compression and to detect tracheomalacia, which characteristically causes inspiratory stridor. CT or MRI can be used to evaluate the anatomy of the goiter and the extent of substernal extension, which is often much greater than is apparent on physical examination. A barium swallow may reveal the extent of esophageal compression. MNG does not appear to predispose to thyroid carcinoma or to more aggressive carcinoma. For this reason, and because it is not possible to biopsy all nodular lesions, thyroid biopsies should be performed only if malignancy is suspected because of a dominant or enlarging nodule.

TREATMENT

Most nontoxic MNGs can be managed conservatively. T_4 suppression is rarely effective for reducing goiter size and introduces the risk of thyrotoxicosis, particularly if there is underlying autonomy or if it develops during treatment. If levothyroxine is used, it should be started at low doses (50 μg) and advanced gradually while monitoring the TSH level to avoid excessive suppression. Contrast agents and other iodine-containing substances should be avoided because of the risk of inducing the *Jod-Basedow effect*, characterized by enhanced thyroid hormone production by autonomous nodules. Radioiodine is being used with increasing frequency because it often decreases goiter size and may selectively ablate regions of autonomy. Dosage of ^{131}I depends on the size of the goiter and radioiodine uptake but is usually about 3.7 MBq (0.1 mCi) per gram of tissue, corrected for uptake [typical dose, 370 to 1070 Mbq (10 to 29 mCi)]. Repeat treatment may be needed. It is possible to achieve a 40 to 50% reduction in goiter size in most patients. Earlier concerns about radiation-induced thyroid swelling and tracheal compression have diminished as recent studies have shown this complication to be rare. When acute compression occurs, glucocorticoid treatment or surgery may be needed. Radiation-induced hypothyroidism is less common than after treatment for Graves' disease. However, posttreatment autoimmune thyrotoxicosis may occur in up to 5% of patients treated for nontoxic MNG. Surgery remains highly effective but is not without risk, particularly in older patients with underlying cardiopulmonary disease.

TOXIC MULTINODULAR GOITER The pathogenesis of toxic MNG appears to be similar to that of nontoxic MNG; the major difference is the presence of functional autonomy in toxic MNG. The molecular basis for autonomy in toxic MNG remains unknown. As in nontoxic goiters, many nodules are polyclonal, while others are monoclonal and vary in their clonal origins. Genetic abnormalities known to confer functional autonomy, such as activating TSH-R or $G_{s\alpha}$ mutations (see below), are not usually found in the autonomous regions of toxic MNG goiter.

In addition to features of goiter, the clinical presentation of toxic MNG includes subclinical hyperthyroidism or mild thyrotoxicosis. The patient is usually elderly and may present with atrial fibrillation or palpitations, tachycardia, nervousness, tremor, or weight loss. Recent exposure to iodine, from contrast dyes or other sources, may precipitate or exacerbate thyrotoxicosis. The TSH level is low. The T_4 level may be normal or minimally increased; T_3 is often elevated to a greater degree than T_4. Thyroid scan shows heterogeneous uptake with multiple regions of increased and decreased uptake; 24-h uptake of radioiodine may not be increased.

TREATMENT

The management of toxic MNG is challenging. Antithyroid drugs, often in combination with beta blockers, can normalize thyroid function and address clinical features of thyrotoxicosis. This treatment, however, often stimulates the growth of the goiter, and, unlike in

Graves' disease, spontaneous remission does not occur. Radioiodine can be used to treat areas of autonomy, as well as to decrease the mass of the goiter. Usually, however, some degree of autonomy remains, presumably because multiple autonomous regions emerge as soon as others are treated. Nonetheless, a trial of radioiodine should be considered before subjecting patients, many of whom are elderly, to surgery. Surgery provides definitive treatment of underlying thyrotoxicosis as well as goiter. Patients should be rendered euthyroid using antithyroid drugs before operation.

HYPERFUNCTIONING SOLITARY NODULE A solitary, autonomously functioning thyroid nodule is referred to as *toxic adenoma*. The pathogenesis of this disorder has been unraveled by demonstrating the functional effects of mutations that stimulate the TSH-R signaling pathway. Most patients with solitary hyperfunctioning nodules have acquired somatic, activating mutations in the TSH-R (Fig. 320-9). These mutations, located primarily in the receptor transmembrane domain, induce constitutive receptor coupling to $G_{s\alpha}$, increasing cyclic AMP levels and leading to enhanced thyroid follicular cell proliferation and function. Less commonly, somatic mutations are identified in $G_{s\alpha}$. These mutations, which are similar to those seen in McCune-Albright syndrome (Chap. 326) or in a subset of somatotrope adenomas (Chap. 318), impair GTP hydrolysis, also causing constitutive activation of the cyclic AMP signaling pathway. In most series, activating mutations in either the TSH-R or the $G_{s\alpha}$ subunit genes are identified in >90% of patients with solitary hyperfunctioning nodules.

Thyrotoxicosis is usually mild. The disorder is suggested by the presence of the thyroid nodule, which is generally large enough to be palpable, and by the absence of clinical features suggestive of Graves' disease or other causes of thyrotoxicosis. A thyroid scan provides a definitive diagnostic test, demonstrating focal uptake in the hyperfunctioning nodule and diminished uptake in the remainder of the gland, as activity of the normal thyroid is suppressed.

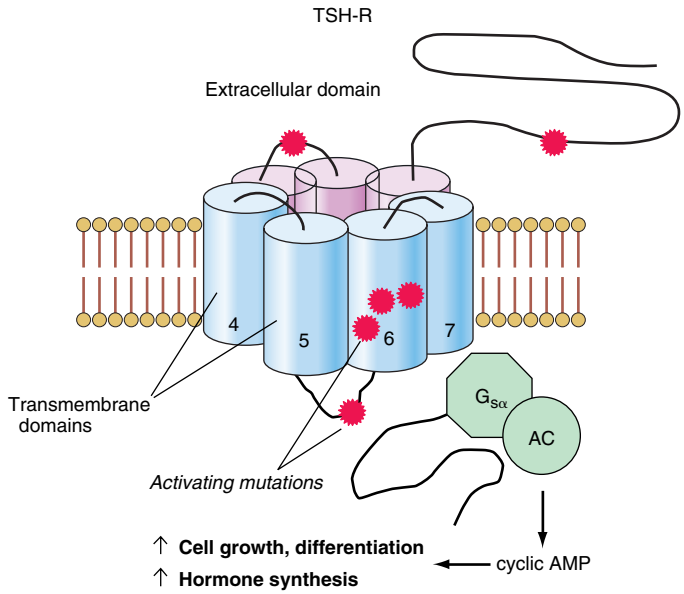

FIGURE 320-9 Activating mutations of the TSH-R. Mutations (*) that activate the thyroid-stimulating hormone receptor (TSH-R) reside mainly in transmembrane 5 and intracellular loop 3, though mutations have occurred in a variety of different locations. The effect of these mutations is to induce conformational changes that mimic TSH binding, thereby leading to coupling to stimulatory G protein ($G_{s\alpha}$) and activation of adenylate cyclase (AC), an enzyme that generates cyclic AMP.

TREATMENT

Radioiodine ablation is usually the treatment of choice. Because normal thyroid function is suppressed, ^{131}I is concentrated in the hyperfunctioning nodule with minimal uptake and damage to normal thyroid tissue. Relatively large radioiodine doses [e.g., 370 to 1110 MBq (10 to 29.9 mCi)^{131}I] have been shown to correct thyrotoxicosis in about 75% of patients within 3 months. Hypothyroidism occurs in <10% of patients over the next 5 years. Surgical resection is also effective and is usually limited to enucleation of the adenoma or lobectomy, thereby preserving thyroid function and minimizing risk of hypoparathyroidism or damage to the recurrent laryngeal nerves. Medical therapy using antithyroid drugs and beta blockers can normalize thyroid function but is not an optimal long-term treatment. Ethanol injection under ultrasound guidance has been used successfully in some centers to ablate hyperfunctioning nodules. Repeated injections (often more than 5 sessions) are required to reduce nodule size. Normal thyroid function can be achieved in most patients using this technique.

BENIGN NEOPLASMS

The various types of benign thyroid nodules are listed in Table 320-9. These lesions are common (5 to 10% adults), particularly when assessed by sensitive techniques such as ultrasound. The risk of malignancy is very low for *macrofollicular adenomas* and *normofollicular adenomas*. *Microfollicular, trabecular, and Hürthle cell variants* raise greater concern, and the histology is more difficult to interpret. About one-third of palpable nodules are *thyroid cysts*. These may be recognized by their ultrasound appearance or based on aspiration of large amounts of pink or straw-colored fluid (colloid). Many are mixed cystic/solid lesions, in which case it is desirable to aspirate cellular components under ultrasound or harvest cells after cytospin of cyst fluid. Cysts frequently recur, even after repeated aspiration, and may require surgical excision if they are large or if the cytology is suspicious. Sclerosis has been used with variable success but is often painful and may be complicated by infiltration of the sclerosing agent.

The treatment approach for benign nodules is similar to that for MNG. TSH suppression with levothyroxine decreases the size of about 30% of nodules and may prevent further growth. The TSH level should

be suppressed into the low-normal range, assuming there are no contraindications; alternatively, nodule size can be monitored without suppression. If a nodule has not decreased in size after 6 to 12 months of suppressive therapy, treatment should be discontinued as little benefit is likely to accrue from long-term treatment.

THYROID CANCER

Thyroid carcinoma is the most common malignancy of the endocrine system. Malignant tumors derived from the follicular epithelium are classified according to histologic features. Differentiated tumors, such as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC), are often curable, and the prognosis is good for patients identified with early-stage disease. In contrast, anaplastic thyroid cancer (ATC) is aggressive, responds poorly to treatment, and is associated with a bleak prognosis.

The incidence of thyroid cancer (~9/100,000 per year) increases with age, plateauing after about age 50 (Fig. 320-10). Age is also an important prognostic factor—thyroid cancer at a young age (<20) or in older persons (>65) is associated with a worse prognosis. Thyroid cancer is twice as common in women as men, but male sex is associated with a worse prognosis. Additional important risk factors include a history of childhood head or neck irradiation, large nodule size (≥4 cm), evidence for local tumor fixation or invasion into lymph nodes, and the presence of metastases (Table 320-10).

Several unique features of thyroid cancer facilitate its management: (1) thyroid nodules are readily palpable, allowing early detection and biopsy by FNA; (2) iodine radioisotopes can be used to diagnose (^{123}I) and treat (^{131}I) differentiated thyroid cancer, reflecting the unique uptake of this anion by the thyroid gland; and (3) serum markers allow the detection of residual or recurrent disease, including the use of Tg levels for PTC and FTC and calcitonin for medullary thyroid cancer (MTC).

CLASSIFICATION Thyroid neoplasms can arise in each of the cell types that populate the gland, including thyroid follicular cells, calcitonin-producing C cells, lymphocytes, and stromal and vascular elements, as well as metastases from other sites (Table 320-9). The American Joint Committee on Cancer (AJCC) has designated a staging system using the TNM classification (Table 320-11). Several other classification and staging systems are also widely used, some of which place greater emphasis on histologic features or risk factors such as age or gender.

PATHOGENESIS AND GENETIC BASIS ■ Radiation Early studies of the pathogenesis of thyroid cancer focused on the role of external radiation, which predisposes to chromosomal breaks, presumably leading to genetic rearrangements and loss of tumor-suppressor genes. External radiation of the mediastinum, face, head, and neck region was administered in the past to treat an array of conditions including acne and enlargement of the thymus, tonsils, and adenoids. Radiation exposure increases the risk of benign and malignant thyroid nodules, is associated with multicentric cancers, and shifts the incidence of thyroid cancer to an earlier age group. Radiation from nuclear fallout also increases the risk of thyroid cancer. Children seem more predisposed to the effects of radiation than adults. Of note, radiation derived from ^{131}I therapy appears to contribute little, if any, increased risk of thyroid cancer.

TABLE 320-10 *Risk Factors for Thyroid Carcinoma in Patients with Thyroid Nodule*

History of head and neck irradiation	Family history of thyroid cancer or MEN 2
Age <20 or >70 years	Vocal cord paralysis, hoarse voice
Increased nodule size (>4 cm)	Nodule fixed to adjacent structures
New or enlarging neck mass	Suspected lymph node involvement
Male gender	Iodine deficiency (follicular cancer)

Note: MEN, multiple endocrine neoplasia.

TSH and Growth Factors Thyroid growth is regulated primarily by TSH but also by a variety of growth factors and cytokines. Many differentiated thyroid cancers express TSH receptors and, therefore, remain responsive to TSH. This observation provides the rationale for T_4 suppression of TSH in patients with thyroid cancer. Residual expression of TSH receptors also allows TSH-stimulated uptake of ^{131}I therapy (see below).

Oncogenes and Tumor-Suppressor Genes Thyroid cancers are monoclonal in origin, consistent with the idea that they originate as a consequence of mutations that confer a growth advantage to a single cell. In addition to increased rates of proliferation, some thyroid cancers exhibit impaired apoptosis and features that enhance invasion, angiogenesis, and metastasis. By analogy with the model of multistep carcinogenesis proposed for colon cancer (Chap. 68), thyroid neoplasms have been analyzed for a variety of genetic alterations, but without clear evidence of an ordered acquisition of somatic mutations as they progress from the benign to the malignant state. On the other hand, certain mutations are relatively specific for thyroid neoplasia, some of which correlate with histologic classification (Table 320-12). For example, activating mutations of the TSH-R and the $G_{s\alpha}$ subunit are associated with autonomously functioning nodules. Though these mutations induce thyroid cell growth, this type of nodule is almost always benign. A variety of rearrangements involving the *RET* gene on chromosome 10 bring this receptor tyrosine kinase under the control of other promoters, leading to receptor overexpression. *RET* rearrangements occur in 20 to

40% of PTCs in different series and were observed with increased frequency in tumors developing after the Chernobyl radiation disaster. Rearrangements in PTC have also been observed for another tyrosine kinase gene, *TRK1*, which is located on chromosome 1. To date, the identification of PTC with *RET* or *TRK1* rearrangements has not proven useful for predicting prognosis or treatment responses. Another rearrangement, linking the thyroid developmental transcription factor PAX8 to the nuclear receptor PPARγ, has been identified in a significance fraction of follicular adenomas and FTCs. *RAS* mutations are found in about 20 to 30% of thyroid neoplasms, including adenomas as well as PTC and FTC, suggesting that these mutations do not strongly affect tumor phenotype. Loss of heterozygosity, consistent with deletions of tumor-suppressor genes, is particularly common in FTC, often involving chromosomes 3p or 11q. Mutations of the tumor suppressor, p53, play an important role in the development of ATC. Because p53 plays a role in cell cycle surveillance, DNA repair, and apoptosis, its loss may contribute to the rapid acquisition of genetic instability as well as poor treatment responses (Chap. 69). The role of other tumor-suppressor genes in thyroid cancer is under investigation (Table 320-12).

MTC, when associated with multiple endocrine neoplasia (MEN) type 2, harbors an inherited mutation of the *RET* gene. Unlike the rearrangements of *RET* seen in PTC, the mutations in MEN2 are point mutations that induce constitutive activity of the tyrosine kinase (Chap. 330). MTC is preceded by hyperplasia of the C cells, raising the likelihood that as-yet-unidentified "second hits" lead to cellular transformation. A subset of sporadic MTC contain somatic mutations that activate *RET*.

WELL-DIFFERENTIATED THYROID CANCER ■ Papillary PTC is the most common type of thyroid cancer, accounting for 70 to 90% of well-differentiated thyroid malignancies. Microscopic PTC is present in up to 25% of thyroid glands at autopsy, but most of these lesions are very small (several millimeters) and are not clinically significant. Characteristic cytologic features of PTC help make the diagnosis by FNA or after surgical resection; these include psammoma bodies, cleaved nuclei with an "orphan-Annie" appearance caused by large nucleoli, and the formation of papillary structures.

PTC tends to be multifocal and to invade locally within the thyroid gland as well as through the thyroid capsule and into adjacent structures in the neck. It has a propensity to spread via the lymphatic system but can metastasize hematogenously as well, particularly to bone and lung. Because of the relatively slow growth of the tumor, a significant burden of pulmonary metastases may accumulate, sometimes with remarkably few symptoms. The prognostic implication of lymph node spread is debated. Lymph node involvement by thyroid cancer can be remarkably well tolerated but probably increases the risk of recurrence and mortality, particularly in older patients. The staging of PTC by the TNM system is outlined in Table 320-11. Most papillary cancers are identified in the early stages (>80% stages I or II) and have an excellent prognosis, with survival curves similar to expected survival (Fig. 320-11*A*). Mortality is markedly increased in stage IV disease (distant metastases), but this group comprises only about 1% of patients. The treatment of PTC is described below.

Follicular The incidence of FTC varies widely in different parts of the world; it is more common in iodine-deficient regions. FTC is difficult

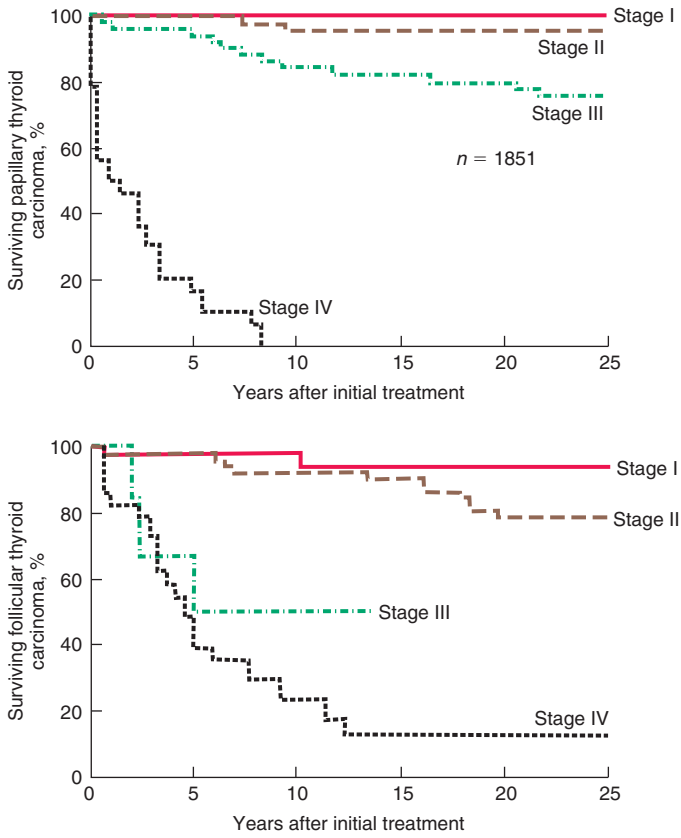

FIGURE 320-11 Survival rates in patients with differentiated thyroid cancer. *A*. Papillary cancer, cohort of 1851 patients. I, 1107 (60%), II, 408 (22%), III, 312 (17%), IV, 24 (1%); $n = 1185$. *B*. Follicular cancer, cohort of 153 patients. I, 42 (27%), II, 82 (54%), III, 6 (4%); IV, 23 (15%); $n = 153$. *[Adapted from PR Larsen et al: William's Textbook of Endocrinology, 9th ed, JD Wilson et al (eds). Philadelphia, Saunders, 1998, pp 389–575; with permission.]*

to diagnose by FNA because the distinction between benign and malignant follicular neoplasms rests largely on evidence of invasion into vessels, nerves, or adjacent structures. FTC tends to spread by hematogenous routes leading to bone, lung, and central nervous system metastases. Mortality rates associated with FTC are less favorable than for PTC, in part because a larger proportion of patients present with stage IV disease (Fig. 320-11*B*). Poor prognostic features include distant metastases, age >50 years, primary tumor size >4 cm, Hürthle cell histology, and the presence of marked vascular invasion.

TREATMENT

Surgery All well-differentiated thyroid cancers should be surgically excised. In addition to removing the primary lesion, surgery allows accurate histologic diagnosis and staging, and multicentric disease is commonly found in the contralateral thyroid lobe. Lymph node spread can also be assessed at the time of surgery, and involved nodes can be removed. Recommendations about the extent of surgery vary for stage I disease, as survival rates are similar for lobectomy and near-total thyroidectomy. Lobectomy is associated with a lower incidence of hypoparathyroidism and injury to the recurrent laryngeal nerves. However, it is not possible to monitor Tg levels or to perform whole-body ^{131}I scans in the presence of the residual lobe. Moreover, if final staging or subsequent follow-up indicates the need for radioiodine scanning or treatment, repeat surgery is necessary to remove the remaining thyroid tissue. Therefore, near-total thyroidectomy is preferable in almost all patients; complication rates are acceptably low if the surgeon is highly experienced in the procedure. This approach, in combination with postsurgical radioablation of the remnant thyroid tissue, facilitates the use of radioiodine scanning and Tg determinations to assess disease recurrence.

TSH Suppression Therapy As most tumors are still TSH-responsive, levothyroxine suppression of TSH is a mainstay of thyroid cancer treatment. Though TSH suppression clearly provides therapeutic benefit, there are no prospective studies that identify the optimal level of TSH suppression. A reasonable goal is to suppress TSH as much as possible without subjecting the patient to unnecessary side effects from excess thyroid hormone, such as atrial fibrillation, osteopenia, anxiety, and other manifestations of thyrotoxicosis. For patients at low risk of recurrence, TSH should be suppressed into the low but detectable range (0.1 to 0.5 IU/L). For patients at high risk of recurrence, or with known metastatic disease, complete TSH suppression is indicated, if there are no strong contraindications to mild thyrotoxicosis. In this instance, unbound T_4 must also be monitored to avoid excessive treatment.

Radioiodine Treatment Well-differentiated thyroid cancer still incorporates radioiodine, though less efficiently than normal thyroid follicular cells. Radioiodine uptake is determined primarily by expression of the NIS and is stimulated by TSH, requiring expression of the TSH-R. The retention time for radioactivity is influenced by the extent to which the tumor retains differentiated functions such as iodide trapping and organification. After near-total thyroidectomy, substantial thyroid tissue remains, particularly in the thyroid bed and surrounding the parathyroid glands. Consequently, ^{131}I ablation is necessary to eliminate remaining normal thyroid tissue and to treat residual tumor cells.

INDICATIONS The use of therapeutic doses of radioiodine remains an area of controversy in thyroid cancer management. Postoperative thyroid ablation and radiodine treatment of known residual PTC or FTC reduce recurrence rates. For tumors that take up iodine, ^{131}I treatment can reduce or eliminate residual disease with relatively little associated toxicity. However, it is not clear that prophylactic radioiodine treatment reduces mortality for patients at relatively low risk. Most patients with stage 1 PTC with primary tumors <1.5 cm in size can be managed safely with thyroxine suppression, without radiation treatment, as the risk of recurrence and mortality is very low. For patients with larger papillary tumors, spread to the adjacent lymph nodes, FTC, or evidence of metastases, thyroid ablation and radioiodine treatment are generally indicated.

^{131}I THYROID ABLATION AND TREATMENT As noted above, the decision to use ^{131}I for thyroid ablation should be coordinated with the surgical approach, as radioablation is much more effective when there is minimal remaining normal thyroid tissue. A typical strategy is to treat the patient for several weeks postoperatively with liothyronine (25 μg bid or tid), followed by thyroid hormone withdrawal. Ideally, the TSH level should increase to >50 IU/L over 3 to 4 weeks. The level to which TSH rises is dictated largely by the amount of normal thyroid tissue remaining postoperatively. A scanning dose of ^{131}I [usually 148 to 185 MBq (4 to 5 mCi)] will reveal the amount of residual tissue and provides guidance about the dose needed to accomplish ablation. A maximum outpatient ^{131}I dose is 1110 MBq (29.9 mCi) in the United States, though ablation is often more complete using greater doses [1850 to 2775 MBq (50 to 75 mCi)]. In patients with known residual cancer, the larger doses ensure thyroid ablation and may destroy remaining tumor cells. A whole-body scan following the high-dose radioiodine treatment is useful to identify possible metastatic disease.

FOLLOW-UP WHOLE-BODY THYROID SCANNING AND THYROGLOBULIN DETERMINATIONS An initial whole-body scan should be performed about 6 months after surgery and thyroid ablation. The strategy for follow-up management of thyroid cancer has been altered by the availability of recombinant human TSH (rhTSH) to stimulate ^{131}I uptake and by the improved sensitivity of Tg assays to detect residual or recurrent disease. A scheme for using either rhTSH or thyroid hormone withdrawal for thyroid scanning is summarized in Fig. 320-12. After thyroid ablation, rhTSH can be used to stimulate ^{131}I uptake without subjecting patients to thyroid hormone withdrawal and its associated symptoms of hypothyroidism and the risk of prolonged TSH-stimulated tumor growth.

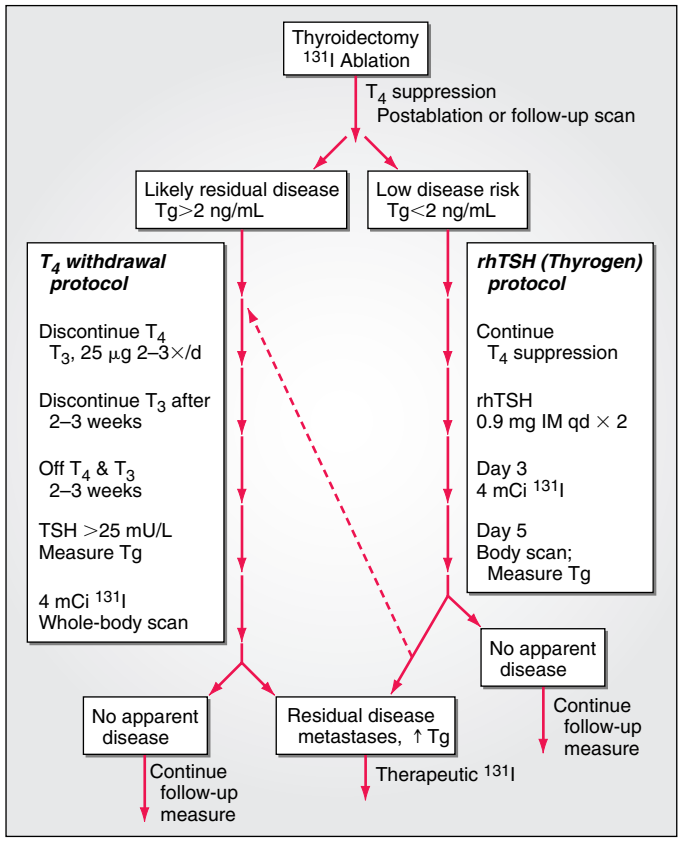

FIGURE 320-12 Use of recombinant thyroid-stimulating hormone (TSH) in the follow-up of patients with thyroid cancer. Tg, thyroglobulin; rhTSH, recombinant human TSH.

This approach is recommended for patients predicted to be at low risk of disease recurrence, since rhTSH is not currently approved for use in conjunction with therapeutic doses of ^{131}I. Alternatively, in patients who are likely to require ^{131}I treatment, the traditional approach of thyroid hormone withdrawal can be used to increase TSH. This involves switching patients from levothyroxine (T_4) to the more rapidly cleared hormone, liothyronine (T_3), thereby allowing TSH to increase more quickly. If residual disease is detected on the initial whole-body scan [148 to 185 MBq (4 to 5 mCi)], a larger treatment dose, usually between 2775 and 5550 MBq (75 and 150 mCi), can be administered depending on the degree of residual uptake and assessment of cancer risk. Because TSH stimulates Tg levels, Tg measurements should be obtained after administration of rhTSH or when TSH levels have risen after thyroid hormone withdrawal. Investigational protocols are measuring Tg levels after rhTSH stimulation but without radioiodine scanning. If the initial whole-body scan is negative and Tg levels are low, a repeat scan should be performed 1 year later. If still negative, the patient can be managed with suppressive therapy and measurements of Tg every 6 to 12 months. If a second follow-up scan is negative, no further scanning may be necessary if the patient is at low risk and there is no clinical or laboratory evidence of recurrence. Many authorities advocate radioiodine treatment for scan-negative, Tg-positive (Tg >5 to 10 ng/mL) patients, as many derive therapeutic benefit from a large dose of ^{131}I.

In addition to radioiodine, external beam radiotherapy is also used to treat specific metastatic lesions, particularly when they cause bone pain or threaten neurologic injury (e.g., vertebral metastases).

ANAPLASTIC AND OTHER FORMS OF THYROID CANCER

Anaplastic Thyroid Cancer As noted above, ATC is a poorly differentiated and aggressive cancer. The prognosis is poor, and most patients die within 6 months of diagnosis. Because of the undifferentiated state of these tumors, the uptake of radioiodine is usually negligible, but it can be used therapeutically if there is residual uptake. Chemotherapy has been attempted with multiple agents, including anthracyclines and paclitaxel, but is usually ineffective. External radiation therapy can be attempted and continued if tumors are responsive.

Thyroid Lymphoma Lymphoma in the thyroid gland often arises in the background of Hashimoto's thyroiditis. A rapidly expanding thyroid mass suggests the possibility of this diagnosis. Diffuse large cell lymphoma is the most common type in the thyroid. Biopsies reveal sheets of lymphoid cells that can be difficult to distinguish from small cell lung cancer or ATC. These tumors are often highly sensitive to external radiation. Surgical resection should be avoided as initial therapy because it may spread disease that is otherwise localized to the thyroid. If staging indicates disease outside of the thyroid, treatment should follow guidelines used for other forms of lymphoma (Chap. 97).

MEDULLARY THYROID CARCINOMA

MTC can be sporadic or familial and accounts for about 5 to 10% of thyroid cancers. There are three familial forms of MTC: MEN 2A, MEN 2B, and familial MTC without other features of MEN (Chap. 330). In general, MTC is more aggressive in MEN 2B than in MEN 2A, and familial MTC is more aggressive than sporadic MTC. Elevated serum calcitonin provides a marker of residual or recurrent disease. It is reasonable to test all patients with MTC for *RET* mutations, as genetic counseling and testing of family members can be offered to those individuals who test positive for mutations.

The management of MTC is primarily surgical. Unlike tumors derived from thyroid follicular cells, these tumors do not take up radioiodine. External radiation treatment and chemotherapy may provide palliation in patients with advanced disease (Chap. 330).

APPROACH TO THE PATIENT

Patient with a Thyroid Nodule Palpable thyroid nodules are found in about 5% of adults, but the prevalence varies considerably worldwide. Given this high prevalence rate, it is common for the practitioner to identify thyroid nodules. The main goal of this evaluation is to identify, in a cost-effective manner, the small subgroup of individuals with malignant lesions.

As described above, nodules are more common in iodine-deficient areas, in women, and with aging. Most palpable nodules are >1 cm in diameter, but the ability to feel a nodule is influenced by its location within the gland (superficial versus deeply embedded), the anatomy of the patient's neck, and the experience of the examiner. More sensitive methods of detection, such as thyroid ultrasound and pathologic studies, reveal thyroid nodules in >20% of glands. These findings have led to much debate about how to detect nodules and which nodules to investigate further. Most authorities still rely on physical examination to detect thyroid nodules, reserving ultrasound for monitoring nodule size or as an aid in thyroid biopsy.

It is important to distinguish whether a patient presents with a solitary thyroid nodule or a prominent nodule in the context of a MNG, as the incidence of malignancy is greater in solitary nodules. An approach to the evaluation of a solitary nodule is outlined in Fig. 320-13. Most patients with thyroid nodules have normal thyroid function tests. Nonetheless, thyroid function should be assessed by measuring a TSH level, which may be suppressed by one or more autonomously functioning nodules. If the TSH is suppressed, a radionuclide scan is indicated to determine if the identified nodule is "hot," as lesions with increased uptake are almost never malignant and FNA is unnecessary. Otherwise, FNA biopsy should be the first step in the evaluation of a thyroid nodule. FNA has good sensitivity and specificity when performed by physicians familiar with the procedure and when the results are interpreted by experienced cytopathologists. The technique is particularly accurate for detecting PTC. The distinction of benign and malignant follicular lesions is often not possible using cytology alone.

In several large studies, FNA biopsies yielded the following findings: 70% benign, 10% malignant or suspicious for malig-

nancy, and 20% nondiagnostic or yielding insufficient material for diagnosis. Characteristic features of malignancy mandate surgery. A diagnosis of follicular neoplasm also warrants surgery, as benign and malignant lesions cannot be distinguished based on cytopathology or frozen section. The management of patients with benign lesions is more variable. Many authorities advocate TSH suppression, whereas others monitor nodule size without suppression. With either approach, thyroid nodule size should be monitored, either by palpation or ultrasound. Repeat FNA is indicated if a nodule enlarges, and a second biopsy should be performed within 2 to 5 years to confirm the benign status of the nodule.

Nondiagnostic biopsies occur for many reasons, including a fibrotic reaction with relatively few cells available for aspiration, a cystic lesion in which cellular components reside along the cyst margin, or a nodule that may be too small for accurate aspiration. For these reasons, ultrasound-guided FNA is useful when the FNA is repeated. Ultrasound is also increasingly used for initial biopsies in an effort to enhance nodule localization and the accuracy of sampling.

The evaluation of a thyroid nodule is stressful for most patients. They are concerned about the possibility of thyroid cancer, whether verbalized or not. It is constructive, therefore, to review the diagnostic approach and to reassure patients when malignancy is not found. When a suspicious lesion or thyroid cancer is identified, an explanation of the generally favorable prognosis and available treatment options should be provided.

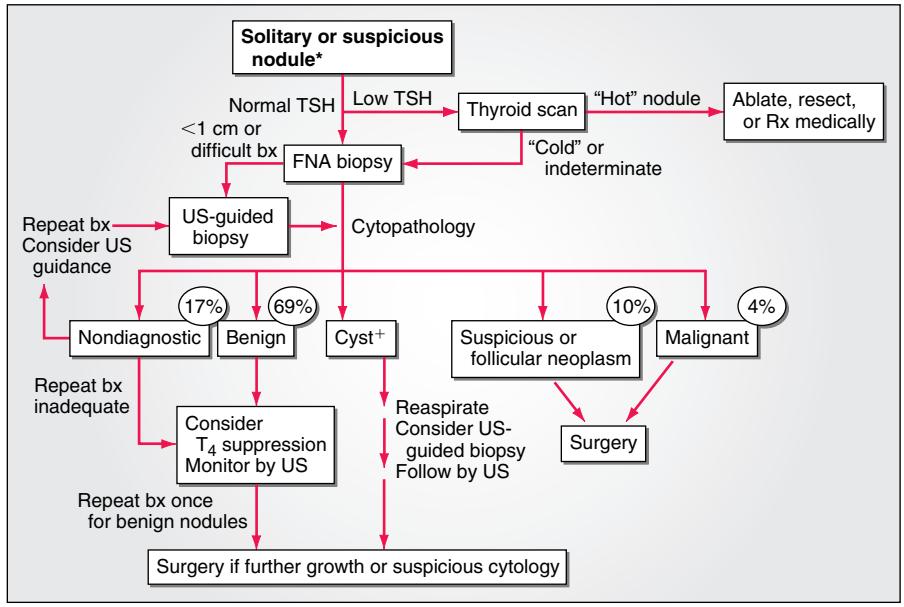

FIGURE 320-13 Approach to the patient with a thyroid nodule. *There are many exceptions to the suggested options. See text and references for details. †About one-third of nodules are cystic or mixed solid-cystic. US, ultrasound; TSH, thyroid-stimulating hormone; FNA, fine-needle aspiration.

321 DISORDERS OF THE ADRENAL CORTEX

Gordon H. Williams, Robert G. Dluhy

BIOCHEMISTRY AND PHYSIOLOGY

The adrenal cortex produces three major classes of steroids: (1) glucocorticoids, (2) mineralocorticoids, and (3) adrenal androgens. Consequently, normal adrenal function is important for modulating intermediary metabolism and immune responses through glucocorticoids; blood pressure, vascular volume, and electrolytes through mineralocorticoids; and secondary sexual characteristics (in females) through androgens. The adrenal axis plays an important role in the stress response by rapidly increasing cortisol levels. Adrenal disorders include hyperfunction (Cushing's syndrome) and hypofunction (adrenal insufficiency), as well as a variety of genetic abnormalities of steroidogenesis.

STEROID NOMENCLATURE The basic structure of steroids is built upon a five-ring nucleus (Fig. 321-1). The carbon atoms are numbered in a sequence beginning with ring A. Adrenal steroids contain either 19 or 21 carbon atoms. The C_{19} steroids have methyl groups at C-18 and C-19. C_{19} steroids with a ketone group at C-17 are termed *17-ketosteroids*; C_{19} steroids have predominantly androgenic activity. The C_{21} steroids have a 2-carbon side chain (C-20 and C-21) attached at position 17 and methyl groups at C-18 and C-19; C_{21} steroids with a hydroxyl group at position 17 are termed *17-hydroxycorticosteroids*. The C_{21} steroids have either glucocorticoid or mineralocorticoid properties.

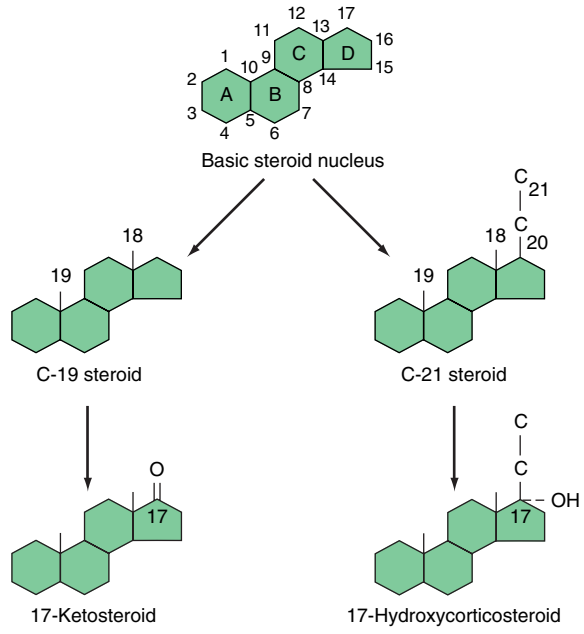

FIGURE 321-1 Basic steroid structure and nomenclature.

BIOSYNTHESIS OF ADRENAL STEROIDS Cholesterol, derived from the diet and from endogenous synthesis, is the substrate for steroidogenesis. Uptake of cholesterol by the adrenal cortex is mediated by the low-density lipoprotein (LDL) receptor. With long-term stimulation of the adrenal cortex by adrenocorticotropic hormone (ACTH), the number of LDL receptors increases. The three major adrenal biosynthetic pathways lead to the production of glucocorticoids (cortisol), mineralocorticoids (aldosterone), and adrenal androgens (dehydroepiandrosterone). Separate zones of the adrenal cortex synthesize specific hormones (Fig. 321-2). This zonation is accompanied by the selective expression of the genes encoding the enzymes unique to the formation of each type of steroid: aldosterone synthase is normally expressed only in the outer (glomerulosa) cell layer, whereas 21- and 17-hydroxylase are expressed in the (inner) faciculata-reticularis cell layers, which are the sites of cortisol and androgen biosynthesis, respectively.

STEROID TRANSPORT Cortisol circulates in the plasma as free cortisol, protein-bound cortisol, and cortisol metabolites. *Free cortisol* is a physiologically active hormone that is not protein-bound and therefore can act directly on tissue sites. Normally, <5% of circulating cortisol is free. Only the unbound cortisol and its metabolites are filterable at the glomerulus. Increased quantities of free steroid are excreted in the urine in states characterized by hypersecretion of cortisol, because the

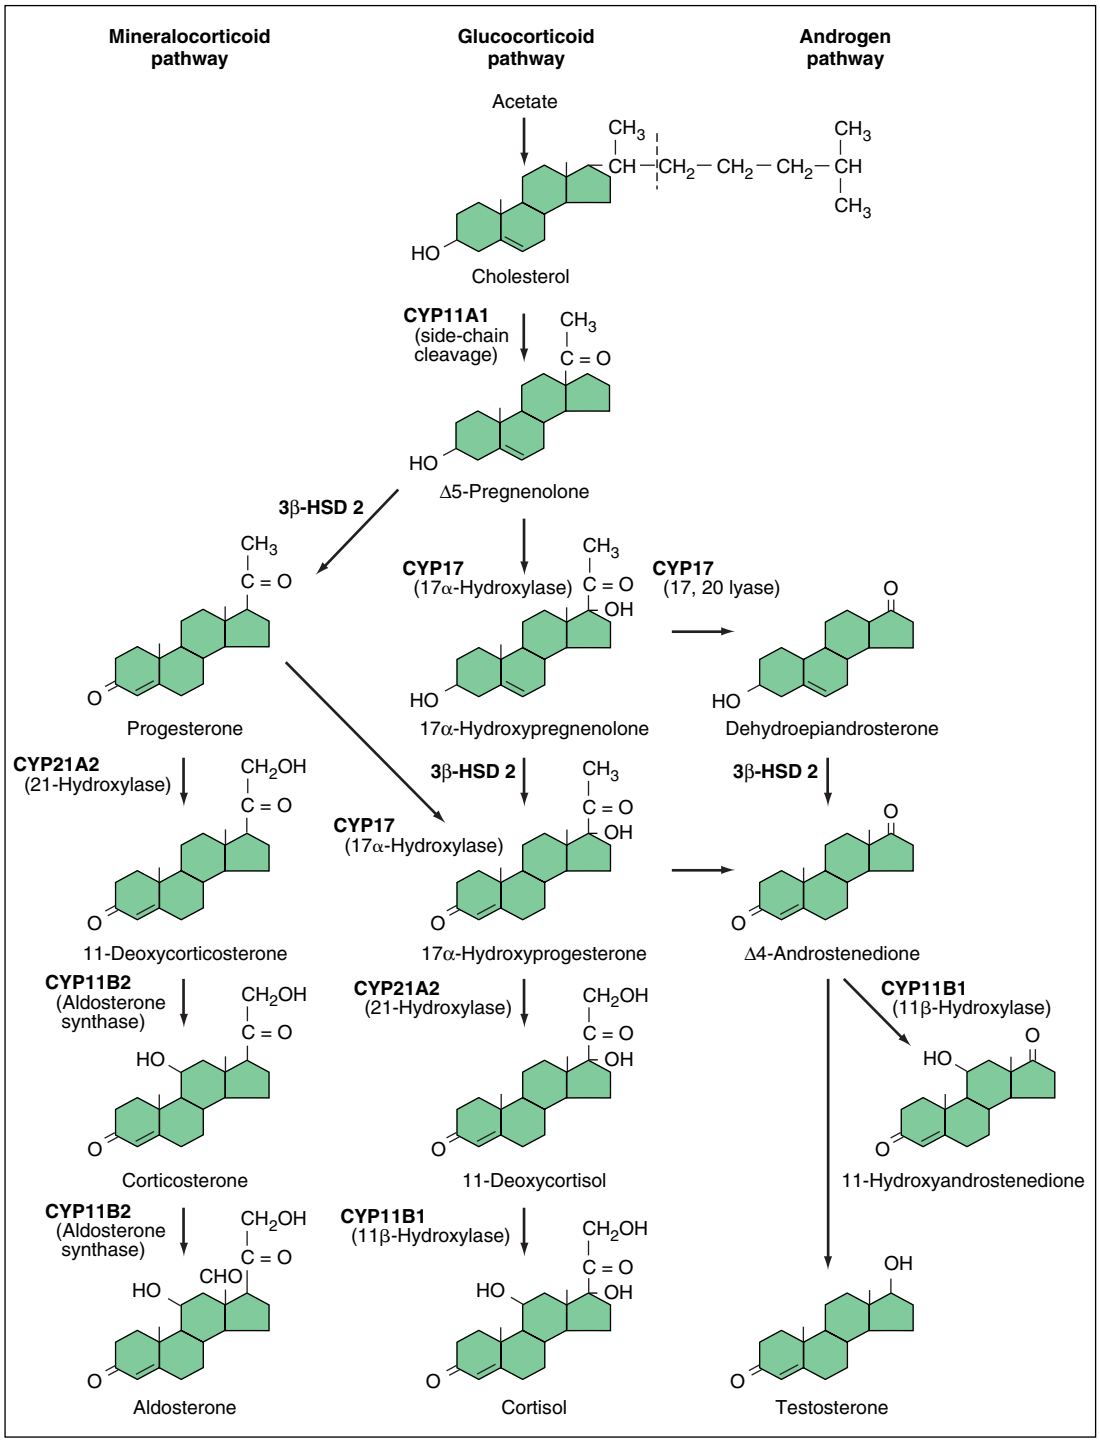

FIGURE 321-2 Biosynthetic pathways for adrenal steroid production; major pathways to mineralocorticoids, glucocorticoids, and androgens. 3β-HSD, 3β-hydroxysteroid dehydrogenase.

unbound fraction of plasma cortisol rises. Plasma has two cortisol-binding systems. One is a high-affinity, low-capacity α_2-globulin termed *transcortin* or *cortisol-binding globulin* (CBG), and the other is a low-affinity, high-capacity protein, *albumin*. Cortisol binding to CBG is reduced in areas of inflammation, thus increasing the local concentration of free cortisol. When the concentration of cortisol is >700 nmol/L (25 μg/dL), part of the excess binds to albumin, and a greater proportion than usual circulates unbound. CBG is increased in high-estrogen states (e.g., pregnancy, oral contraceptive administration). The rise in CBG is accompanied by a parallel rise in *protein-bound cortisol*, with the result that the total plasma cortisol concentration is elevated. However, the free cortisol level probably remains normal, and manifestations of glucocorticoid excess are absent. Most synthetic glucocorticoid analogues bind less efficiently to CBG (~70% binding). This may explain the propensity of some synthetic analogues to produce cushingoid effects at low doses. *Cortisol metabolites* are biologically inactive and bind only weakly to circulating plasma proteins.

Aldosterone is bound to proteins to a smaller extent than cortisol, and an ultrafiltrate of plasma contains as much as 50% of circulating aldosterone.

STEROID METABOLISM AND EXCRETION ■ Glucocorticoids The daily secretion of cortisol ranges between 40 and 80 μmol (15 and 30 mg; 8–10 mg/m^2), with a pronounced circadian cycle. The plasma concentration of cortisol is determined by the rate of secretion, the rate of inactivation, and the rate of excretion of free cortisol. The liver is the major organ responsible for steroid inactivation. A major enzyme regulating cortisol metabolism is 11β-hydroxysteroid dehydrogenase (11β-HSD). There are two isoforms: 11β-HSD I is primarily expressed in the liver and acts as a reductase, converting the inactive cortisone to the active glucocorticoid, cortisol; the 11β-HSD II isoform is expressed in a number of tissues and converts cortisol to the inactive metabolite, cortisone. Mutations in the *11BHSD1* gene are associated with rapid cortisol turnover, leading to activation of the hypothalamic-pituitary-adrenal (HPA) axis and excessive adrenal androgen production in women. In animal models, excess omental expression of 11β-HSD I increases local glucocorticoid production and is associated with central obesity and insulin resistance. The oxidative reaction of 11β-HSD I is increased in hypothyroidism. Mutations in the *11BHSD2* gene cause the syndrome of *apparent mineralocorticoid excess*, reflecting insufficient inactivation of cortisol in the kidney, allowing inappropriate cortisol activation of the mineralocorticoid receptor (see below).

Mineralocorticoids In individuals with normal salt intake, the average daily secretion of aldosterone ranges between 0.1 and 0.7 μmol (50 and 250 μg). During a single passage through the liver, >75% of circulating aldosterone is normally inactivated by conjugation with glucuronic acid. However, under certain conditions, such as congestive failure, this rate of inactivation is reduced.

Adrenal Androgens The major androgen secreted by the adrenal is dehydroepiandrosterone (DHEA) and its sulfuric acid ester (DHEAS). Approximately 15 to 30 mg of these compounds is secreted daily. Smaller amounts of androstenedione, 11β-hydroxyandrostenedione, and testosterone are secreted. DHEA is the major precursor of the urinary 17-ketosteroids. Two-thirds of the urine 17-ketosteroids in the male are derived from adrenal metabolites, and the remaining one-third comes from testicular androgens. In the female, almost all urine 17-ketosteroids are derived from the adrenal.

Steroids diffuse passively through the cell membrane and bind to intracellular receptors (Chap. 317). Glucocorticoids and mineralocorticoids bind with nearly equal affinity to the mineralocorticoid receptor (MR). However, only glucocorticoids bind to the glucocorticoid receptor (GR). After the steroid binds to the receptor, the steroid-receptor complex is transported to the nucleus, where it binds to specific sites on steroid-regulated genes, altering levels of transcription. Some actions of glucocorticoids (e.g., anti-inflammatory effects) are mediated by GR-mediated inhibition of other transcription factors, such as activating protein-1 (AP-1) or nuclear factor kappa B (NFκB), which normally stimulate the activity of various cytokine genes. Because cortisol binds to the MR with the same affinity as aldosterone, mineralocorticoid specificity is achieved by local metabolism of cortisol to the inactive compound cortisone by 11β-HSD II. The glucocorticoid effects of other steroids, such as high-dose progesterone, correlate with their relative binding affinities for the GR. Inherited defects in the GR cause glucocorticoid resistance states. Individuals with GR defects have high levels of cortisol but do not have manifestations of hypercortisolism.

ACTH PHYSIOLOGY ACTH and a number of other peptides (lipotropins, endorphins, and melanocyte-stimulating hormones) are processed from a larger precursor molecule of 31,000 mol wt—proopiomelanocortin (POMC) (Chap. 318). POMC is made in a variety of tissues, including brain, anterior and posterior pituitary, and lymphocytes. The constellation of POMC-derived peptides secreted depends on the tissue. ACTH, a 39-amino-acid peptide, is synthesized and stored in basophilic cells of the anterior pituitary. The *N*-terminal 18-amino-acid fragment of ACTH has full biologic potency, and shorter *N*-terminal fragments have partial biologic activity. Release of ACTH and related peptides from the anterior pituitary gland is stimulated by corticotropin-releasing hormone (CRH), a 41-amino-acid peptide produced in the median eminence of the hypothalamus (Fig. 321-3). Urocortin, a neuropeptide related to CRH, mimics many of the central effects of CRH (e.g., appetite suppression, anxiety), but its role in ACTH reg-

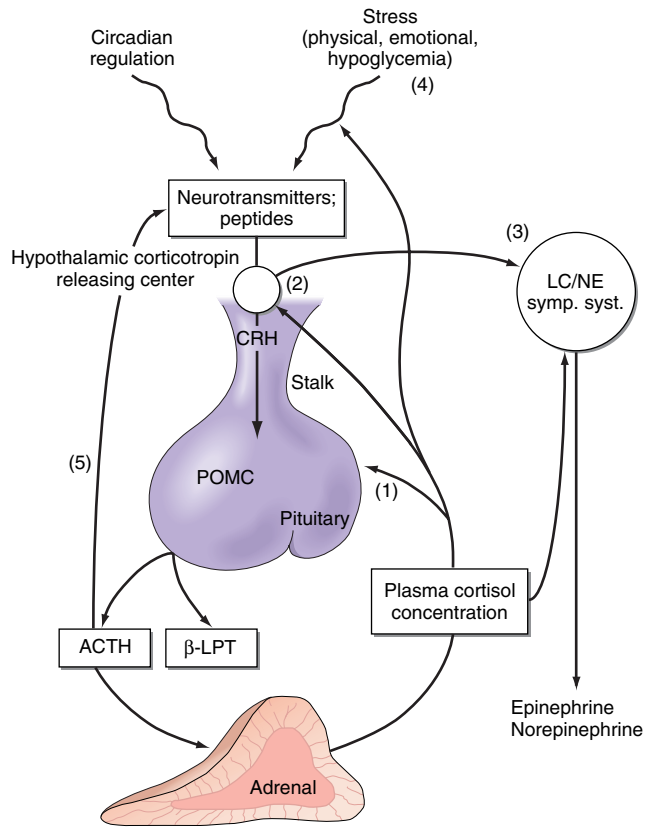

FIGURE 321-3 The hypothalamic-pituitary-adrenal axis. The main sites for feedback control by plasma cortisol are the pituitary gland (1) and the hypothalamic corticotropin-releasing center (2). Feedback control by plasma cortisol also occurs at the locus coeruleus/sympathetic system (3) and may involve higher nerve centers (4) as well. There may also be a short feedback loop involving inhibition of corticotropin-releasing hormone (CRH) by adrenocorticotropic hormone (ACTH) (5). Hypothalamic neurotransmitters influence CRH release; serotoninergic and cholinergic systems stimulate the secretion of CRH and ACTH; α-adrenergic agonists and γ-aminobutyric acid (GABA) probably inhibit CRH release. The opioid peptides β-endorphin and enkephalin inhibit, and vasopressin and angiotensin II augment, the secretion of CRH and ACTH. β-LPT, β-lipotropin; POMC, pro-opiomelanocortin; LC, locus coeruleus; NE, norepinephrine.

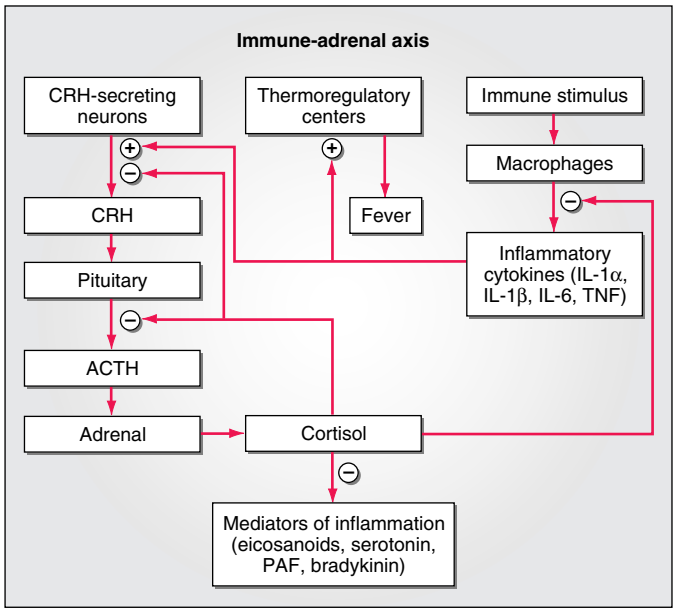

FIGURE 321-4 The immune-adrenal axis. Cortisol has anti-inflammatory properties that include effects on the microvasculature, cellular actions, and the suppression of inflammatory cytokines (the so-called immune-adrenal axis). A stress such as sepsis increases adrenal secretion, and cortisol in turn suppresses the immune response via this system. −, suppression; +, stimulation; CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; IL, interleukin; TNF, tumor necrosis factor; PAF, platelet activating factor.

ulation is unclear. Some related peptides such as β-lipotropin (β-LPT) are released in equimolar concentrations with ACTH, suggesting that they are cleaved enzymatically from the parent POMC before or during the secretory process. However, β-endorphin levels may or may not correlate with circulating levels of ACTH, depending on the nature of the stimulus.

The major factors controlling ACTH release include CRH, the free cortisol concentration in plasma, stress, and the sleep-wake cycle (Fig. 321-3). Plasma ACTH varies during the day as a result of its pulsatile secretion, and follows a circadian pattern with a peak just prior to waking and a nadir before sleeping. If a new sleep-wake cycle is adopted, the pattern changes over several days to conform to it. ACTH and cortisol levels also increase in response to eating. Stress (e.g., pyrogens, surgery, hypoglycemia, exercise, and severe emotional trauma) causes the release of CRH and arginine vasopressin (AVP) and activation of the sympathetic nervous system. These changes in turn enhance ACTH release, acting individually or in concert. For example, AVP release acts synergistically with CRH to amplify ACTH secretion; CRH also stimulates the locus coeruleus/sympathetic system. Stress-related secretion of ACTH abolishes the circadian periodicity of ACTH levels but is, in turn, suppressed by prior high-dose glucocorticoid administration. The normal pulsatile, circadian pattern of ACTH release is regulated by CRH; this mechanism is the so-called open feedback loop. CRH secretion, in turn, is influenced by hypothalamic neurotransmitters including the serotoninergic and cholinergic pathways. The immune system also influences the HPA axis (Fig. 321-4). For example, inflammatory cytokines [tumor necrosis factor (TNF)-α, interleukin (IL) 1α, IL-1β, and IL-6] produced by monocytes increase ACTH release by stimulating secretion of CRH and/or AVP. Finally, ACTH release is regulated by the level of free cortisol in plasma. Cortisol decreases the responsiveness of pituitary corticotropic cells to CRH; the response of the POMC mRNA to CRH is also inhibited by glucocorticoids. In addition, glucocorticoids inhibit the locus coeruleus/sympathetic system and CRH release. The latter servomechanism establishes the primacy of cortisol in the control of ACTH secretion. The suppression of ACTH secretion that results in adrenal atrophy following *prolonged* glucocorticoid therapy is caused primarily by suppression of hypothalamic CRH release, as exogenous CRH administration in this circumstance produces a rise in plasma ACTH. Cortisol also exerts feedback effects on higher brain centers (hippocampus, reticular system, and septum) and perhaps on the adrenal cortex (Fig. 321-4).

The biologic half-life of ACTH in the circulation is <10 min. The action of ACTH is also rapid; within minutes of its release, the concentration of steroids in the adrenal venous blood increases. ACTH stimulates steroidogenesis via activation of adenyl cyclase. Adenosine-3′,5′-monophosphate (cyclic AMP), in turn, stimulates the synthesis of protein kinase enzymes, thereby resulting in the phosphorylation of proteins that activate steroid biosynthesis.

RENIN-ANGIOTENSIN PHYSIOLOGY Renin is a proteolytic enzyme that is produced and stored in the granules of the juxtaglomerular cells surrounding the afferent arterioles of glomeruli in the kidney. Renin acts on the basic substrate angiotensinogen (a circulating α_2-globulin made in the liver) to form the decapeptide angiotensin I (Fig. 321-5). Angiotensin I is then enzymatically transformed by angiotensin-converting enzyme (ACE), which is present in many tissues (particularly the pulmonary vascular endothelium), to the octapeptide angiotensin II by the removal of the two C-terminal amino acids. Angiotensin II is a potent pressor agent and exerts its action by a direct effect on arteriolar smooth muscle. In addition, angiotensin II stimulates production of aldosterone by the zona glomerulosa of the adrenal cortex; the heptapeptide angiotensin III may also stimulate aldosterone production. The two major classes of angiotensin receptors are termed *AT1* and *AT2*; AT1 may exist as two subtypes α and β. Most of the effects of angiotensins II and III are mediated by the AT1 receptor. Angiotensinases rapidly destroy angiotensin II (half-life, ~1 min), while the half-life of renin is more prolonged (10 to 20 min). In addition to circulating renin-angiotensin, many tissues have a local renin-angiotensin system and the ability to produce angiotensin II. These tissues include the uterus, placenta, vascular tissue, heart, brain, and, particularly, the adrenal cortex and kidney. Although the role of locally generated angiotensin II is not established, it may modulate the growth and function of the adrenal cortex and vascular smooth muscle.

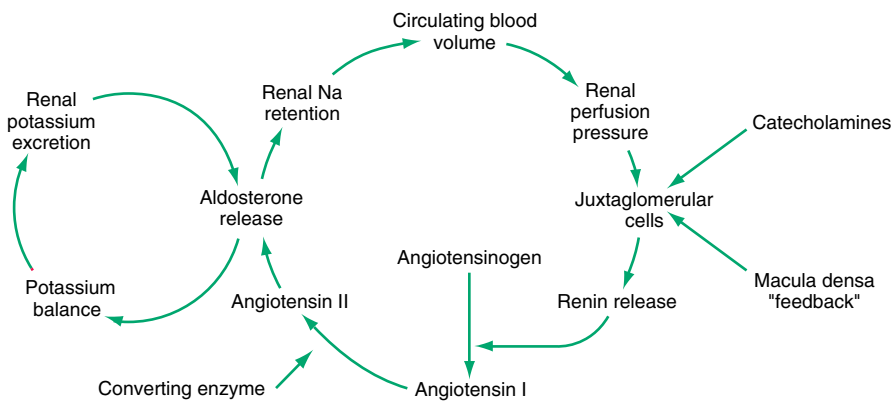

FIGURE 321-5 The interrelationship of the volume and potassium feedback loops on aldosterone secretion. Integration of signals from each loop determines the level of aldosterone secretion.

The amount of renin released reflects the combined effects of four interdependent factors. The *juxtaglomerular cells*, which are specialized myoepithelial cells that cuff the afferent arterioles, act as miniature pressure transducers, sensing renal perfusion pressure and corresponding changes in afferent arteriolar perfusion pressures. For example, a reduction in circulating blood volume leads to a corresponding reduction in renal perfusion pressure and

afferent arteriolar pressure (Fig. 321-5). This change is perceived by the juxtaglomerular cells as a decreased stretch exerted on the afferent arteriolar walls, and the juxtaglomerular cells release more renin into the renal circulation. This results in the formation of angiotensin I, which is converted in the kidney and peripherally to angiotensin II by ACE. Angiotensin II influences sodium homeostasis via two major mechanisms: it changes renal blood flow so as to maintain a constant glomerular filtration rate, thereby changing the filtration fraction of sodium, and it stimulates the adrenal cortex to release aldosterone. Increasing plasma levels of aldosterone enhance renal sodium retention and thus result in expansion of the extracellular fluid volume, which, in turn, dampens the stimulus for renin release. In this context, the renin-angiotensin-aldosterone system regulates volume by modifying renal hemodynamics and tubular sodium transport.

A second control mechanism for renin release is centered in the *macula densa cells*, a group of distal convoluted tubular epithelial cells directly opposed to the juxtaglomerular cells. They may function as chemoreceptors, monitoring the sodium (or chloride) load presented to the distal tubule. Under conditions of increased delivery of filtered sodium to the macula densa, a signal is conveyed to decrease juxtaglomerular cell release of renin, thereby modulating the glomerular filtration rate and the filtered load of sodium.

The *sympathetic nervous system* regulates the release of renin in response to assumption of the upright posture. The mechanism is either a direct effect on the juxtaglomerular cell to increase adenyl cyclase activity or an indirect effect on either the juxtaglomerular or the macula densa cells via vasoconstriction of the afferent arteriole.

Finally, circulating factors influence renin release. Increased dietary intake of potassium decreases renin release, whereas decreased potassium intake increases it. The significance of these effects is unclear. *Angiotensin II* exerts negative feedback control on renin release that is independent of alterations in renal blood flow, blood pressure, or aldosterone secretion. *Atrial natriuretic peptides* also inhibit renin release. Thus, the control of renin release involves both *intrarenal* (pressor receptor and macula densa) and *extrarenal* (sympathetic nervous system, potassium, angiotensin, etc.) mechanisms. Steady-state renin levels reflect all these factors, with the intrarenal mechanism predominating.

GLUCOCORTICOID PHYSIOLOGY The division of adrenal steroids into glucocorticoids and mineralocorticoids is arbitrary in that most glucocorticoids have some mineralocorticoid-like properties. The descriptive term *glucocorticoid* is used for adrenal steroids whose predominant action is on intermediary metabolism. Their overall actions are directed at enhancing the production of the high-energy fuel, glucose, and reducing all other metabolic activity not directly involved in that process. Sustained activation, however, results in a pathophysiologic state, e.g., Cushing's syndrome. The principal glucocorticoid is cortisol (hydrocortisone). The effect of glucocorticoids on intermediary metabolism is mediated by the GR. Physiologic effects of glucocorticoids include the regulation of protein, carbohydrate, lipid, and nucleic acid metabolism. Glucocorticoids raise the blood glucose level by antagonizing the secretion and actions of insulin, thereby inhibiting peripheral glucose uptake, which promotes hepatic glucose synthesis (gluconeogenesis) and hepatic glycogen content. The actions on protein metabolism are mainly catabolic, resulting in an increase in protein breakdown and nitrogen excretion. In large part, these actions reflect a mobilization of glycogenic amino acid precursors from peripheral supporting structures, such as bone, skin, muscle, and connective tissue, due to protein breakdown and inhibition of protein synthesis and amino acid uptake. Hyperaminoacidemia also facilitates gluconeogenesis by stimulating glucagon secretion. Glucocorticoids act directly on the liver to stimulate the synthesis of certain enzymes, such as tyrosine aminotransferase and tryptophan pyrrolase. Glucocorticoids regulate fatty acid mobilization by enhancing the activation of cellular lipase by lipid-mobilizing hormones (e.g., catecholamines and pituitary peptides).

The actions of cortisol on protein and adipose tissue vary in different parts of the body. For example, pharmacologic doses of cortisol can deplete the protein matrix of the vertebral column (trabecular bone), whereas long bones (which are primarily compact bone) are affected only minimally; similarly, peripheral adipose tissue mass decreases, whereas abdominal and interscapular fat expand.

Glucocorticoids have anti-inflammatory properties, which are probably related to effects on the microvasculature and to suppression of inflammatory cytokines. In this sense, glucocorticoids modulate the immune response via the so-called immune-adrenal axis (Fig. 321-4). This "loop" is one mechanism by which a stress, such as sepsis, increases adrenal hormone secretion, and the elevated cortisol level in turn suppresses the immune response. For example, cortisol maintains vascular responsiveness to circulating vasoconstrictors and opposes the increase in capillary permeability during acute inflammation. Glucocorticoids cause a leukocytosis that reflects release from the bone marrow of mature cells as well as inhibition of their egress through the capillary wall. Glucocorticoids produce a depletion of circulating eosinophils and lymphoid tissue, specifically T cells, by causing a redistribution from the circulation into other compartments. Thus, cortisol impairs cell-mediated immunity. Glucocorticoids also inhibit the production and action of the mediators of inflammation, such as the lymphokines and prostaglandins. Glucocorticoids inhibit the production and action of interferon by T lymphocytes and the production of IL-1 and IL-6 by macrophages. The antipyretic action of glucocorticoids may be explained by an effect on IL-1, which appears to be an endogenous pyrogen (Chap. 16). Glucocorticoids also inhibit the production of T cell growth factor (IL-2) by T lymphocytes. Glucocorticoids reverse macrophage activation and antagonize the action of migration-inhibiting factor (MIF), leading to reduced adherence of macrophages to vascular endothelium. Glucocorticoids reduce prostaglandin and leukotriene production by inhibiting the activity of phospholipase A_2, thus blocking release of arachidonic acid from phospholipids. Finally, glucocorticoids inhibit the production and inflammatory effects of bradykinin, platelet-activating factor, and serotonin. It is probably only at pharmacologic dosages that antibody production is reduced and lysosomal membranes are stabilized, the latter effect suppressing the release of acid hydrolases.

Cortisol levels respond within minutes to stress, whether physical (trauma, surgery, exercise), psychological (anxiety, depression), or physiologic (hypoglycemia, fever). The reasons why elevated glucocorticoid levels protect the organism under stress are not understood, but in conditions of glucocorticoid deficiency, such stresses may cause hypotension, shock, and death. Consequently, in individuals with adrenal insufficiency, glucocorticoid administration should be increased during stress.

Cortisol has major effects on body water. It helps regulate the extracellular fluid volume by retarding the migration of water into cells and by promoting renal water excretion, the latter effect mediated by suppression of vasopressin secretion, by an increase in the rate of glomerular filtration, and by a direct action on the renal tubule. The consequence is to prevent water intoxication by increasing solute-free water clearance. Glucocorticoids also have weak mineralocorticoid-like properties, and high doses promote renal tubular sodium reabsorption and increased urine potassium excretion. Glucocorticoids can also influence behavior; emotional disorders may occur with either an excess or a deficit of cortisol. Finally, cortisol suppresses the secretion of pituitary POMC and its derivative peptides (ACTH, β-endorphin, and β-LPT) and the secretion of hypothalamic CRH and vasopressin.

MINERALOCORTICOID PHYSIOLOGY Mineralocorticoids modify function in two classes of cells—epithelial and nonepithelial.

Effects on Epithelia Classically, mineralocorticoids are considered major regulators of extracellular fluid volume and are the major determinants of potassium metabolism. These effects are mediated by the binding of aldosterone to the MR in epithelial cells, primarily the principal cells in the renal cortical collecting duct. Because of its electro-

chemical gradient, sodium passively enters these cells from the urine via epithelial sodium channels located on the luminal membrane and is actively extruded from the cell via the Na/K-activated ATPase ("sodium pump") located on the basolateral membrane. The sodium pump also provides the driving force of potassium loss into the urine through potassium-selective luminal channels, again assisted by the electrochemical gradient for potassium in these cells. Aldosterone stimulates all three of these processes by increasing gene expression directly (for the sodium pump and the potassium channels) or via a complex process (for epithelial sodium channels) to increase both the number and activity of the sodium channels. Water passively follows the transported sodium, thus expanding intra- and extravascular volume.

Because the concentration of hydrogen ion is greater in the lumen than in the cell, hydrogen ion is also actively secreted. Mineralocorticoids also act on the epithelium of the salivary ducts, sweat glands, and gastrointestinal tract to cause reabsorption of sodium in exchange for potassium.

When normal individuals are given aldosterone, an initial period of sodium retention is followed by natriuresis, and sodium balance is reestablished after 3 to 5 days. As a result, edema does not develop. This process is referred to as the *escape phenomenon*, signifying an "escape" by the renal tubules from the sodium-retaining action of aldosterone. While renal hemodynamic factors may play a role in the escape, the level of atrial natriuretic peptide also increases. However, it is important to realize that there is no escape from the potassium-losing effects of mineralocorticoids.

Effect on Nonepithelial Cells The MR has been identified in a number of nonepithelial cells, e.g., neurons in the brain, myocytes, endothelial cells, and vascular smooth-muscle cells. In these cells, the actions of aldosterone differ from those in epithelial cells in several ways:

1. They do not modify sodium-potassium homeostasis.
2. The groups of regulated genes differ, although only a few are known; for example, in nonepithelial cells, aldosterone modifies the expression of several collagen genes and/or genes controlling tissue growth factors, e.g., transforming growth factor (TGF) β and plasminogen activator inhibitor, type 1 (PAI-1).
3. In some of these tissues (e.g., myocardium and brain), the MR is not protected by the 11β-HSD II enzyme. Thus, cortisol rather than aldosterone may be activating the MR. In other tissues (e.g., the vasculature), 11β-HSD II is expressed in a manner similar to that of the kidney. Therefore, aldosterone is activating the MR.
4. Some effects on nonepithelial cells may be via nongenomic mechanisms. These actions are too rapid—occurring within 1 to 2 min and peaking within 5 to 10 min—to be considered genomic, suggesting that they are secondary to activation of a cell-surface receptor. However, no cell-surface MR has been identified, raising the possibility that the same MR is mediating both genomic and nongenomic effects. Rapid, nongenomic effects have also been described for other steroids including estradiol, progesterone, thyroxine, and vitamin D.
5. Some of these tissues—the myocardium and vasculature—may also produce aldosterone, although this theory is controversial.

Regulation of Aldosterone Secretion Three primary mechanisms control adrenal aldosterone secretion: the renin-angiotensin system, potassium, and ACTH (Table 321-1). Whether these are also the primary regulatory mechanisms modifying nonadrenal production is uncertain. The renin-angiotensin system controls extracellular fluid volume via regulation of aldosterone secretion (Fig. 321-5). In effect, the renin-angiotensin system maintains the circulating blood volume constant by causing aldosterone-induced sodium retention during volume deficiency and by decreasing aldosterone-dependent sodium retention when volume is ample. There is an increasing body of evidence indicating that some tissues, in addition to the kidney, produce angiotensin II and may participate in the regulation of aldosterone secretion either from the adrenal or extraadrenal sources. Intriguingly, the adrenal itself is capable of synthesizing angiotensin II. What role(s) the extrarenal production of angiotensin II plays in normal physiology is still largely unknown. However, the tissue renin-angiotensin system is activated in utero in response to growth and development and/or later in life in response to injury.

TABLE 321-1 *Factors Regulating Aldosterone Biosynthesis*

Factor	Effect
Renin-angiotensin system	Stimulation
Sodium ion	Inhibition (?physiologic)
Potassium ion	Stimulation
Neurotransmitters	
Dopamine	Inhibition
Serotonin	Stimulation
Pituitary hormones	
ACTH	Stimulation
Non-ACTH pituitary hormones (e.g., growth hormone)	Permissive (for optimal response to sodium restriction)
β-Endorphin	Stimulation
γ-Melanocyte-stimulating hormone	Permissive
Atrial natriuretic peptide	Inhibition
Ouabain-like factors	Inhibition
Endothelin	Stimulation

Note: ACTH, adrenocorticotropic hormone.

Potassium ion directly stimulates aldosterone secretion, independent of the circulating renin-angiotensin system, which it suppresses (Fig. 321-5). In addition to a direct effect, potassium also modifies aldosterone secretion indirectly by activating the local renin-angiotensin system in the zona glomerulosa. This effect can be blocked by the administration of ACE inhibitors that reduce the local production of angiotensin II and thereby reduce the acute aldosterone response to potassium. An increase in serum potassium of as little as 0.1 mmol/L increases plasma aldosterone levels under certain circumstances. Oral potassium loading therefore increases aldosterone secretion, plasma levels, and excretion.

Physiologic amounts of ACTH stimulate aldosterone secretion acutely, but this action is not sustained unless ACTH is administered in a pulsatile fashion. Most studies relegate ACTH to a minor role in the control of aldosterone. For example, subjects receiving high-dose glucocorticoid therapy, and with presumed complete suppression of ACTH, have normal aldosterone secretion in response to sodium restriction.

Prior dietary intake of both potassium and sodium can alter the magnitude of the aldosterone response to acute stimulation. This effect results from a change in the expression and activity of aldosterone synthase. Increasing potassium intake or decreasing sodium intake sensitizes the response of the glomerulosa cells to acute stimulation by ACTH, angiotensin II, and/or potassium.

Neurotransmitters (dopamine and serotonin) and some peptides, such as atrial natriuretic peptide, γ-melanocyte-stimulating hormone (γ-MSH), and β-endorphin, also participate in the regulation of aldosterone secretion (Table 321-1). Thus, the control of aldosterone secretion involves both stimulatory and inhibitory factors.

ANDROGEN PHYSIOLOGY Androgens regulate male secondary sexual characteristics and can cause virilizing symptoms in women (Chap. 44). Adrenal androgens have a minimal effect in males whose sexual characteristics are predominately determined by gonadal steroids (testosterone). In females, however, several androgen-like effects, e.g., sexual hair, are largely mediated by adrenal androgens. The principal adrenal androgens are DHEA, androstenedione, and 11-hydroxyandrostenedione. DHEA and androstenedione are weak androgens and exert their effects via conversion to the potent androgen testosterone in extraglandular tissues. DHEA also has poorly understood effects on the immune and cardiovascular systems. Adrenal androgen formation is regulated by ACTH, not by gonadotropins. Adrenal androgens are suppressed by exogenous glucocorticoid administration.

LABORATORY EVALUATION OF ADRENOCORTICAL FUNCTION

A basic assumption is that measurements of the plasma or urinary level of a given steroid reflect the rate of adrenal *secretion* of that steroid. However, urine *excretion* values may not truly reflect the secretion rate because of improper collection or altered metabolism. Plasma levels reflect the level of secretion only at the time of measurement. The plasma level (*PL*) depends on two factors: the secretion rate (*SR*) of the hormone and the rate at which it is metabolized, i.e., its metabolic clearance rate (*MCR*). These three factors can be related as follows:

$$PL = \frac{SR}{MCR} \quad \text{or} \quad SR = MCR \times PL$$

BLOOD LEVELS ■ Peptides The plasma levels of ACTH and angiotensin II can be measured by immunoassay techniques. Basal ACTH secretion shows a circadian rhythm, with lower levels in the early evening than in the morning. However, ACTH is secreted in a pulsatile manner, leading to rapid fluctuations superimposed on this circadian rhythm. Angiotensin II levels also vary diurnally and are influenced by dietary sodium and potassium intakes and posture. Both upright posture and sodium restriction elevate angiotensin II levels.

Most clinical determinations of the renin-angiotensin system, however, involve measurements of peripheral *plasma renin activity* (PRA) in which the renin activity is gauged by the generation of angiotensin I during a standardized incubation period. This method depends on the presence of sufficient angiotensinogen in the plasma as substrate. The generated angiotensin I is measured by radioimmunoassay. The PRA depends on the dietary sodium intake and on whether the patient is ambulatory. In normal humans, the PRA shows a diurnal rhythm characterized by peak values in the morning and a nadir in the afternoon. An alternative approach is to measure plasma active renin, which is easier and not dependent on endogenous substrate concentration. PRA and active renin correlate very well on low-sodium diets but less well on high-sodium diets.

Steroids Cortisol and aldosterone are both secreted episodically, and levels vary during the day, with peak values in the morning and low levels in the evening. In addition, the plasma level of aldosterone, but not of cortisol, is increased by dietary potassium loading, by sodium restriction, or by assumption of the upright posture. Measurement of the sulfate conjugate of DHEA may be a useful index of adrenal androgen secretion, as little DHEA sulfate is formed in the gonads and because the half-life of DHEA sulfate is 7 to 9 h. However, DHEA sulfate levels reflect both DHEA production and sulfatase activity.

URINE LEVELS For the assessment of glucocorticoid secretion, the urine 17-hydroxycorticosteroid assay has been replaced by measurement of urinary free cortisol. Elevated levels of urinary free cortisol correlate with states of hypercortisolism, reflecting changes in the levels of unbound, physiologically active circulating cortisol. Normally, the rate of excretion is higher in the daytime (7 A.M. to 7 P.M.) than at night (7 P.M. to 7 A.M.).

Urinary 17-ketosteroids originate in either the adrenal gland or the gonad. In normal women, 90% of urinary 17-ketosteroids is derived from the adrenal, and in men 60 to 70% is of adrenal origin. Urine 17-ketosteroid values are highest in young adults and decline with age.

A carefully timed urine collection is a prerequisite for all excretory determinations. Urinary creatinine should be measured simultaneously to determine the accuracy and adequacy of the collection procedure.

STIMULATION TESTS Stimulation tests are useful in the diagnosis of hormone deficiency states.

Tests of Glucocorticoid Reserve Within minutes after administration of ACTH, cortisol levels increase. This responsiveness can be used as an index of the functional reserve of the adrenal gland for production of cortisol. Under maximal ACTH stimulation, cortisol secretion increases tenfold, to 800 μmol/d (300 mg/d), but maximal stimulation can be achieved only with prolonged ACTH infusions.

A screening test (the so-called rapid ACTH stimulation test) involves the administration of 25 units (0.25 mg) of cosyntropin intravenously or intramuscularly and measurement of plasma cortisol levels before administration and 30 and 60 min after administration, the test can be performed at any time of the day. The most clear-cut criterion for a normal response is a stimulated cortisol level of >500 nmol/L (>18 μg/dL), and the minimal stimulated normal increment of cortisol is >200 nmol/L (>7 μg/dL) above baseline. Severely ill patients with elevated basal cortisol levels may show no further increases following acute ACTH administration.

Tests of Mineralocorticoid Reserve and Stimulation of the Renin-Angiotensin System Stimulation tests use protocols designed to create a programmed volume depletion, such as sodium restriction, diuretic administration, or upright posture. A simple, potent test consists of severe sodium restriction and upright posture. After 3 to 5 days of a 10-mmol/d sodium intake, rates of aldosterone secretion or excretion should increase two- to threefold over the control values. Supine morning plasma aldosterone levels are usually increased three- to sixfold, and they increase a further two- to fourfold in response to 2 to 3 h of upright posture.

When the dietary sodium intake is normal, stimulation testing requires the administration of a potent diuretic, such as 40 to 80 mg furosemide, followed by 2 to 3 h of upright posture. The normal response is a two- to fourfold rise in plasma aldosterone levels.

SUPPRESSION TESTS Suppression tests to document hypersecretion of adrenal hormones involve measurement of the target hormone response after standardized suppression of its tropic hormone.

Tests of Pituitary-Adrenal Suppressibility The ACTH release mechanism is sensitive to the circulating glucocorticoid level. When blood levels of glucocorticoid are increased in normal individuals, less ACTH is released from the anterior pituitary and less steroid is produced by the adrenal gland. The integrity of this feedback mechanism can be tested clinically by giving a glucocorticoid and judging the suppression of ACTH secretion by analysis of urine steroid levels and/or plasma cortisol and ACTH levels. A potent glucocorticoid such as dexamethasone is used, so that the agent can be given in an amount small enough not to contribute significantly to the pool of steroids to be analyzed.

The best *screening* procedure is the overnight dexamethasone suppression test. This involves the measurement of plasma cortisol levels at 8 A.M. following the oral administration of 1 mg dexamethasone the previous midnight. The 8 A.M. value for plasma cortisol in normal individuals should be <140 nmol/L (5 μg/dL).

The definitive test of adrenal suppressibility involves administering 0.5 mg dexamethasone every 6 h for two successive days while collecting urine over a 24-h period for determination of creatinine and free cortisol and/or measuring plasma cortisol levels. In a patient with a normal hypothalamic-pituitary ACTH release mechanism, a fall in the urine free cortisol to <25 nmol/d (10 μg/d) or of plasma cortisol to <140 nmol/L (5 μg/dL) is seen on the second day of administration.

A normal response to either suppression test implies that the glucocorticoid regulation of ACTH and its control of the adrenal glands is physiologically normal. However, an isolated abnormal result, particularly to the overnight suppression test, does not in itself demonstrate pituitary and/or adrenal disease.

Tests of Mineralocorticoid Suppressibility These tests rely on an expansion of extracellular fluid volume, which should decrease circulating plasma renin activity and decrease the secretion and/or excretion of aldosterone. Various tests differ in the rate at which extracellular fluid volume is expanded. One convenient suppression test involves the intravenous infusion of 500 mL/h of normal saline solution for 4 h, which normally suppresses plasma aldosterone levels to <220 pmol/L (<8 ng/dL) from a sodium-restricted diet or to <140 pmol/L (<5 ng/dL) from a normal sodium intake. Alternatively, a high-sodium diet can be administered for 3 days with 0.2 mg fludrocortisone twice daily. Aldosterone excretion is measured on the third day and should be <28 nmol/d (10 μg/d). These tests should not be performed in potassium-

depleted individuals since they carry a risk of precipitating hypokalemia.

TESTS OF PITUITARY-ADRENAL RESPONSIVENESS Stimuli such as insulin-induced hypoglycemia, AVP, and pyrogens induce the release of ACTH from the pituitary by an action on higher neural centers or on the pituitary itself. Insulin-induced hypoglycemia is particularly useful, because it stimulates the release of both growth hormone and ACTH. In this test, regular insulin (0.05 to 0.1 U/kg body weight) is given intravenously as a bolus to reduce the fasting glucose level to at least 50% below basal. The normal cortisol response is a rise to >500 nmol/L (18 μg/dL). Glucose levels must be monitored during insulin-induced hypoglycemia, and it should be terminated by feeding or intravenous glucose, if subjects develop symptoms of hypoglycemia. This test is contraindicated in individuals with coronary artery disease or a seizure disorder.

Metyrapone inhibits 11β-hydroxylase in the adrenal. As a result, the conversion of 11-deoxycortisol (compound S) to cortisol is impaired, causing 11-deoxycortisol to accumulate in the blood and the blood level of cortisol to decrease (Fig. 321-2). The hypothalamic-pituitary axis responds to the declining cortisol blood levels by releasing more ACTH. Note that assessment of the response depends on both an intact hypothalamic-pituitary axis and an intact adrenal gland.

Although modifications of the original metyrapone test have been described, a commonly used protocol involves administering 750 mg of the drug by mouth every 4 h over a 24-h period and comparing the control and postmetyrapone plasma levels of 11-deoxycortisol, cortisol, and ACTH. In normal individuals, plasma 11-deoxycortisol levels should exceed 210 nmol/L (7 μg/dL) and ACTH levels should exceed 17 pmol/L (75 pg/mL) following metyrapone administration. The metyrapone test does not accurately reflect ACTH reserve if subjects are ingesting exogenous glucocorticoids or drugs that accelerate the metabolism of metyrapone (e.g., phenytoin).

A direct and selective test of the pituitary corticotrophs can be achieved with CRH. The bolus injection of ovine CRH (corticorelin ovine triflutate; 1 μg/kg body weight) stimulates secretion of ACTH and β-LPT in normal human subjects within 15 to 60 min. In normal individuals, the mean increment in ACTH is 9 pmol/L (40 pg/mL). However, the magnitude of the ACTH response is less than that produced by insulin-induced hypoglycemia, implying that additional factors (such as vasopressin) augment stress-induced increases in ACTH secretion.

The rapid ACTH test can often distinguish between primary and secondary adrenal insufficiency, because aldosterone secretion is preserved in secondary adrenal failure by the renin-angiotensin system and potassium. Cosyntropin (25 units) is given intravenously or intramuscularly, and plasma cortisol and aldosterone levels are measured before and at 30 and 60 min after administration. The cortisol response is abnormal in both groups, but patients with secondary insufficiency show an increase in aldosterone levels of at least 140 pmol/L (5 ng/dL). No aldosterone response is seen in patients in whom the adrenal cortex is destroyed. Alternatively, ACTH at a physiologic dose (1 μg), the so-called low-dose ACTH test, may be used to detect secondary adrenal insufficiency. An abnormal response is similar to that in the rapid ACTH test. However, levels need to be measured at 30 min, and the ACTH needs to be directly injected intravenously because it can be absorbed by plastic tubing. Because the use of a bolus of exogenous ACTH does not invariably exclude a diagnosis of secondary adrenocortical insufficiency, direct tests of pituitary ACTH reserve (metyrapone test, insulin-induced hypoglycemia) may be required in the appropriate clinical setting.

HYPERFUNCTION OF THE ADRENAL CORTEX

Excess cortisol is associated with Cushing's syndrome; excess aldosterone causes aldosteronism; and excess adrenal androgens cause adrenal virilism. These syndromes do not always occur in the "pure" form but may have overlapping features.

CUSHING'S SYNDROME ■ Etiology Cushing described a syndrome characterized by truncal obesity, hypertension, fatigability and weakness, amenorrhea, hirsutism, purplish abdominal striae, edema, glucosuria, osteoporosis, and a basophilic tumor of the pituitary. As awareness of this syndrome has increased, the diagnosis of Cushing's syndrome has been broadened into the classification shown in Table 321-2. Regardless of etiology, all cases of endogenous Cushing's syndrome are due to increased production of cortisol by the adrenal. In most cases the cause is *bilateral adrenal hyperplasia* due to hypersecretion of pituitary ACTH or ectopic production of ACTH by a nonpituitary source. The incidence of pituitary-dependent adrenal hyperplasia is three times greater in women than in men, and the most frequent age of onset is the third or fourth decade. Most evidence indicates that the primary defect is the de novo development of a pituitary adenoma, as tumors are found in >90% of patients with pituitary-dependent adrenal hyperplasia. Alternatively, the defect may occasionally reside in the hypothalamus or in higher neural centers, leading to release of CRH inappropriate to the level of circulating cortisol. This primary defect leads to hyperstimulation of the pituitary, resulting in hyperplasia or tumor formation. In surgical series, most individuals with hypersecretion of pituitary ACTH are found to have a microadenoma (<10 mm in diameter; 50% are ≤5 mm in diameter), but a pituitary macroadenoma (>10 mm) or diffuse hyperplasia of the corticotrope cells may be found. Traditionally, only an individual who has an ACTH-producing pituitary tumor is defined as having *Cushing's disease*, whereas Cushing's syndrome refers to all causes of excess cortisol: exogenous ACTH tumor, adrenal tumor, pituitary ACTH-secreting tumor, or excessive glucocorticoid treatment.

The *ectopic ACTH syndrome* is caused by nonpituitary tumors that secrete either ACTH and/or CRH and cause bilateral adrenal hyperplasia (Chap. 86). The ectopic production of CRH results in clinical, biochemical, and radiologic features indistinguishable from those caused by hypersecretion of pituitary ACTH. The typical signs and symptoms of Cushing's syndrome may be absent or minimal with ectopic ACTH production, and hypokalemic alkalosis is a prominent manifestation. Most of these cases are associated with the primitive small cell (oat cell) type of bronchogenic carcinoma or with carcinoid tumors of the thymus, pancreas, or ovary; medullary carcinoma of the thyroid; or bronchial adenomas. The onset of Cushing's syndrome may be sudden, particularly in patients with carcinoma of the lung, and this feature accounts in part for the failure of these patients to exhibit the classic manifestations. On the other hand, patients with carcinoid tumors or pheochromocytomas have longer clinical courses and usually exhibit the typical cushingoid features. The ectopic secretion of ACTH is also accompanied by the accumulation of ACTH fragments in plasma and by elevated plasma levels of ACTH precursor molecules.

TABLE 321-2 Causes of Cushing's Syndrome

Adrenal hyperplasia
Secondary to pituitary ACTH overproduction
Pituitary-hypothalamic dysfunction
Pituitary ACTH-producing micro- or macroadenomas
Secondary to ACTH or CRH-producing nonendocrine tumors (bronchogenic carcinoma, carcinoid of the thymus, pancreatic carcinoma, bronchial adenoma)
Adrenal macronodular hyperplasia (including ectopic expression of GIP receptors in the adrenal cortex)
Adrenal micronodular dysplasia
Sporadic
Familial (Carney's syndrome)
Adrenal neoplasia
Adenoma
Carcinoma
Exogenous, iatrogenic causes
Prolonged use of glucocorticoids
Prolonged use of ACTH

Note: ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; GIP, gastric inhibitory peptide.

Because such tumors may produce large amounts of ACTH, baseline steroid values are usually very high and increased skin pigmentation may be present.

Approximately 20 to 25% of patients with Cushing's syndrome have an adrenal neoplasm. These tumors are usually unilateral, and about half are malignant. Occasionally, patients have biochemical features both of pituitary ACTH excess and of an adrenal adenoma. These individuals may have *nodular hyperplasia* of both adrenal glands, often the result of prolonged ACTH stimulation in the absence of a pituitary adenoma. Two additional entities cause nodular hyperplasia: a familial disorder in children or young adults (so-called pigmented micronodular dysplasia; see below) and an abnormal cortisol response to gastric inhibitory polypeptide or luteinizing hormone, secondary to ectopic expression of receptors for these hormones in the adrenal cortex.

The most common cause of Cushing's syndrome is *iatrogenic* administration of steroids for a variety of reasons. Although the clinical features bear some resemblance to those seen with adrenal tumors, these patients are usually distinguishable on the basis of history and laboratory studies.

Clinical Signs, Symptoms, and Laboratory Findings Many of the signs and symptoms of Cushing's syndrome follow logically from the known action of glucocorticoids (Table 321-3). Catabolic responses in peripheral supportive tissue causes muscle weakness and fatigability, osteoporosis, broad violaceous cutaneous striae, and easy bruisability. The latter signs are secondary to weakening and rupture of collagen fibers in the dermis. Osteoporosis may cause collapse of vertebral bodies and pathologic fractures of other bones. Decreased bone mineralization is particularly pronounced in children. Increased hepatic gluconeogenesis and insulin resistance can cause impaired glucose tolerance. Overt diabetes mellitus occurs in <20% of patients, who probably are individuals with a predisposition to this disorder. Hypercortisolism promotes the deposition of adipose tissue in characteristic sites, notably the upper face (producing the typical "moon" facies), the interscapular area (producing the "buffalo hump"), supraclavicular fat pads, and the mesenteric bed (producing "truncal" obesity) (Fig. 321-6). Rarely, episternal fatty tumors and mediastinal widening secondary to fat accumulation occur. The reason for this peculiar distribution of adipose tissue is not known, but it is associated with insulin resistance and/or elevated insulin levels. The face appears plethoric, even in the absence of any increase in red blood cell concentration. Hypertension is common, and emotional changes may be profound, ranging from irritability and emotional lability to severe depression, confusion, or even frank psychosis. In women, increased levels of adrenal androgens can cause acne, hirsutism, and oligomenorrhea or amenorrhea. Some signs and symptoms in patients with hypercortisolism—i.e., obesity, hypertension, osteoporosis, and diabetes—are nonspecific and therefore are less helpful in diagnosing the condition. On the other hand, easy bruising, typical striae, myopathy, and virilizing signs (although less frequent) are, if present, more suggestive of Cushing's syndrome (Table 321-3).

Except in iatrogenic Cushing's syndrome, plasma and urine cortisol levels are elevated. Occasionally, hypokalemia, hypochloremia, and metabolic alkalosis are present, particularly with ectopic production of ACTH.

Diagnosis The diagnosis of Cushing's syndrome depends on the demonstration of increased cortisol production and failure to suppress cortisol secretion normally when dexamethasone is administered (Chap. 318). Once the diagnosis is established, further testing is designed to determine the etiology (Fig. 321-7 and Table 321-4).

For initial screening, the overnight dexamethasone suppression test is recommended (see above). In difficult cases (e.g., in obese or depressed patients), measurement of a 24-h urine free cortisol can also be used as a screening test. A level >140 nmol/d (50 μg/d) is suggestive of Cushing's syndrome. The definitive diagnosis is then established by failure of urinary cortisol to fall to less than <25 nmol/d (10 μg/d) or of plasma cortisol to fall to <140 nmol/L (5 μg/dL) after a standard low-dose dexamethasone suppression test (0.5 mg every 6 h for 48 h). Owing to circadian variability, plasma cortisol and, to a certain extent, ACTH determinations are not meaningful when performed in isolation, but the absence of the normal fall of plasma cortisol at midnight is consistent with Cushing's syndrome because there is loss of the diurnal cortisol rhythm.

TABLE 321-3 *Frequency of Signs and Symptoms in Cushing's Syndrome*

Sign or Symptom	Percent of Patients
Typical habitus (centripetal obesity)[a]	97
Increased body weight	94
Fatigability and weakness	87
Hypertension (blood pressure >150/90)	82
Hirsutism[a]	80
Amenorrhea	77
Broad violaceous cutaneous striae[a]	67
Personality changes	66
Ecchymoses[a]	65
Proximal myopathy[a]	62
Edema	62
Polyuria, polydipsia	23
Hypertrophy of clitoris	19

[a] Features more specific for Cushing's syndrome.

The task of determining the etiology of Cushing's syndrome is complicated by the fact that all the available tests lack specificity and by the fact that the tumors producing this syndrome are prone to spontaneous and often dramatic changes in hormone secretion (periodic hormonogenesis). No test has a specificity >95%, and it may be necessary to use a combination of tests to arrive at the correct diagnosis.

Plasma ACTH levels can be useful in distinguishing the various causes of Cushing's syndrome, particularly in separating ACTH-dependent from ACTH-independent causes. In general, measurement of plasma ACTH is useful in the diagnosis of ACTH-independent etiologies of the syndrome, since most adrenal tumors cause low or undetectable ACTH levels [<2 pmol/L (10 pg/mL)]. Furthermore, ACTH-secreting pituitary macroadenomas and ACTH-producing nonendocrine tumors usually result in elevated ACTH levels. In the ectopic ACTH syndrome, ACTH levels may be elevated to >110 pmol/L (500 pg/mL), and in most patients the level is >40 pmol/L (200 pg/mL). In Cushing's syndrome as the result of a microadenoma or pituitary-hypothalamic dysfunction, ACTH levels range from 6 to 30 pmol/L (30 to 150 pg/mL) [normal, <14 pmol/L (<60 pg/mL)],

FIGURE 321-6 A woman with Cushing's syndrome due to a right adrenal cortical adenoma. *A*. One month prior to surgery, age 20. *B*. One year after surgery, age 21.

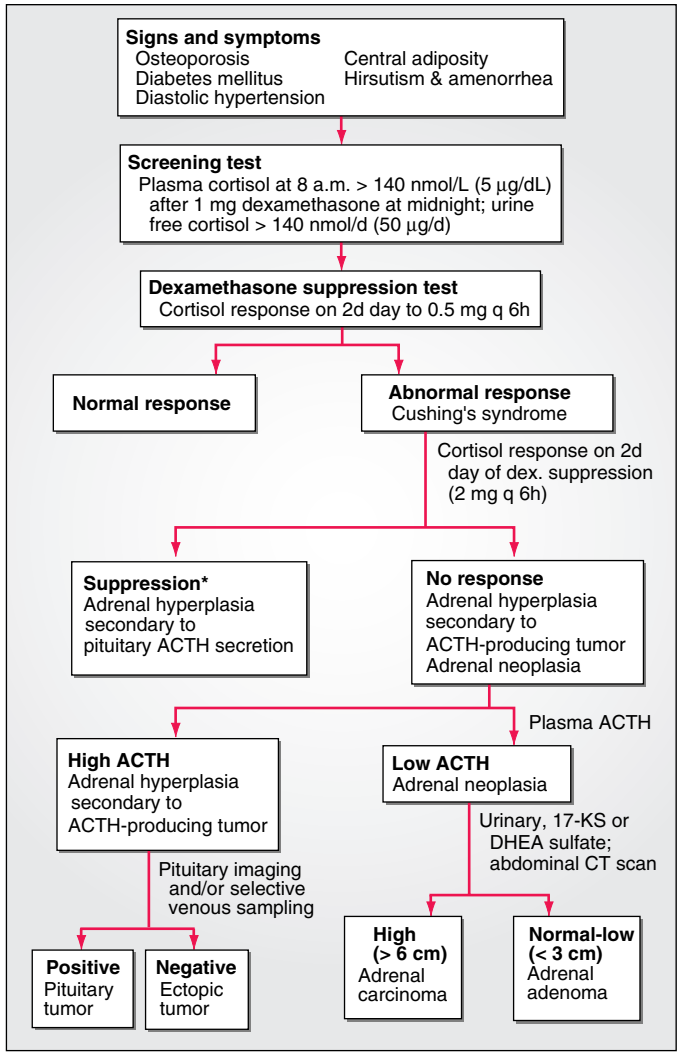

FIGURE 321-7 Diagnostic flowchart for evaluating patients suspected of having Cushing's syndrome. *This group probably includes some patients with pituitary-hypothalamic dysfunction and some with pituitary microadenomas. In some instances, a microadenoma may be visualized by pituitary magnetic resonance scanning. 17-KS, 17-ketosteroids; DHEA, dehydroepiandrosterone; ACTH, adrenocorticotropic hormone; CT, computed tomography.

with half of values falling in the normal range. However, the main problem with the use of ACTH levels in the differential diagnosis of Cushing's syndrome is that ACTH levels may be similar in individuals with hypothalamic-pituitary dysfunction, pituitary microadenomas, ectopic CRH production, and ectopic ACTH production (especially carcinoid tumors) (Table 321-4).

TABLE 321-4 *Diagnostic Tests to Determine the Type of Cushing's Syndrome*

Test	Pituitary Macroadenoma	Pituitary Microadenoma	Ectopic ACTH or CRH Production	Adrenal Tumor
Plasma ACTH level	↑ to ↑↑	N to ↑	↑ to ↑↑↑	↓
Percent who respond to high-dose dexamethasone	<10	95	<10	<10
Percent who respond to CRH	>90	>90	<10	<10

Note: ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; N, normal; ↑, elevated; ↓, decreased. See text for definition of a response.

A useful step to distinguish patients with an ACTH-secreting pituitary microadenoma or hypothalamic-pituitary dysfunction from those with other forms of Cushing's syndrome is to determine the response of cortisol output to administration of high-dose dexamethasone (2 mg every 6 h for 2 days). An alternative 8-mg, overnight high-dose dexamethasone test has been developed; however, this test has a lower sensitivity and specificity than the standard test. When the diagnosis of Cushing's syndrome is clear-cut on the basis of baseline urinary and plasma assays, the high-dose dexamethasone suppression test may be used without performing the preliminary low-dose suppression test. The high-dose suppression test provides close to 100% specificity if the criterion used is suppression of urinary free cortisol by >90%. Occasionally, in individuals with bilateral nodular hyperplasia and/or ectopic CRH production, steroid output is also suppressed. Failure of low- and high-dose dexamethasone administration to suppress cortisol production (Table 321-4) can occur in patients with adrenal hyperplasia secondary to an ACTH-secreting pituitary macroadenoma or an ACTH-producing tumor of nonendocrine origin and in those with adrenal neoplasms.

Because of these difficulties, several additional tests have been advocated, such as the metyrapone and CRH infusion tests. The rationale underlying these tests is that steroid hypersecretion by an adrenal tumor or the ectopic production of ACTH will suppress the hypothalamic-pituitary axis so that inhibition of pituitary ACTH release can be demonstrated by either test. Thus, most patients with pituitary-hypothalamic dysfunction and/or a microadenoma have an increase in steroid or ACTH secretion in response to metyrapone or CRH administration, whereas most patients with ectopic ACTH-producing tumors do not. Most pituitary macroadenomas also respond to CRH, but their response to metyrapone is variable. However, false-positive and false-negative CRH tests can occur in patients with ectopic ACTH and pituitary tumors.

The main diagnostic dilemma in Cushing's syndrome is to distinguish those instances due to microadenomas of the pituitary from those due to ectopic sources (e.g., carcinoids or pheochromocytoma) that produce CRH and/or ACTH. The clinical manifestations are similar unless the ectopic tumor produces other symptoms, such as diarrhea and flushing from a carcinoid tumor or episodic hypertension from a pheochromocytoma. Sometimes, one can distinguish between ectopic and pituitary ACTH production by using metyrapone or CRH tests, as noted above. In these situations, computed tomography (CT) of the pituitary gland is usually normal. Magnetic resonance imaging (MRI) with the enhancing agent gadolinium may be better than CT for this purpose but demonstrates pituitary microadenomas in only half of patients with Cushing's disease. Because microadenomas can be detected in up to 10 to 20% of individuals without known pituitary disease, a positive imaging study does not prove that the pituitary is the source of ACTH excess. In those with negative imaging studies, selective petrosal sinus venous sampling for ACTH is now used in many referral centers. ACTH levels are measured at baseline, 2, 5, and 10 min after ovine CRH (1 μ/kg IV) injections. Peak petrosal:peripheral ACTH ratios of >3 confirm the presence of a pituitary ACTH-secreting tumor. In centers where petrosal sinus sampling is performed frequently, it has proved highly sensitive for distinguishing pituitary and nonpituitary sources of ACTH excess. However, the catheterization procedure is technically difficult, and complications have occurred.

The diagnosis of a *cortisol-producing adrenal adenoma* is suggested by low ACTH and disproportionate elevations in baseline urine free cortisol levels with only modest changes in urinary 17-ketosteroids or plasma DHEA sulfate. Adrenal androgen secretion is usually reduced in these patients owing to the cortisol-induced suppression of ACTH and subsequent involution of the androgen-producing zona reticularis.

The diagnosis of *adrenal carcinoma* is suggested by a palpable abdominal mass and by markedly elevated baseline values of both urine 17-ketosteroids and plasma DHEA sulfate. Plasma and urine cortisol levels are variably elevated. Adrenal carcinoma is usually resistant to both ACTH stimulation and dexamethasone suppression. El-

evated adrenal androgen secretion often leads to virilization in the female. Estrogen-producing adrenocortical carcinoma usually presents with gynecomastia in men and dysfunctional uterine bleeding in women. These adrenal tumors secrete increased amounts of androstenedione, which is converted peripherally to the estrogens estrone and estradiol. Adrenal carcinomas that produce Cushing's syndrome are often associated with elevated levels of the intermediates of steroid biosynthesis (especially 11-deoxycortisol), suggesting inefficient conversion of the intermediates to the final product. This feature also accounts for the characteristic increase in 17-ketosteroids. Approximately 20% of adrenal carcinomas are not associated with endocrine syndromes and are presumed to be nonfunctioning or to produce biologically inactive steroid precursors. In addition, the excessive production of steroids is not always clinically evident (e.g., androgens in adult men).

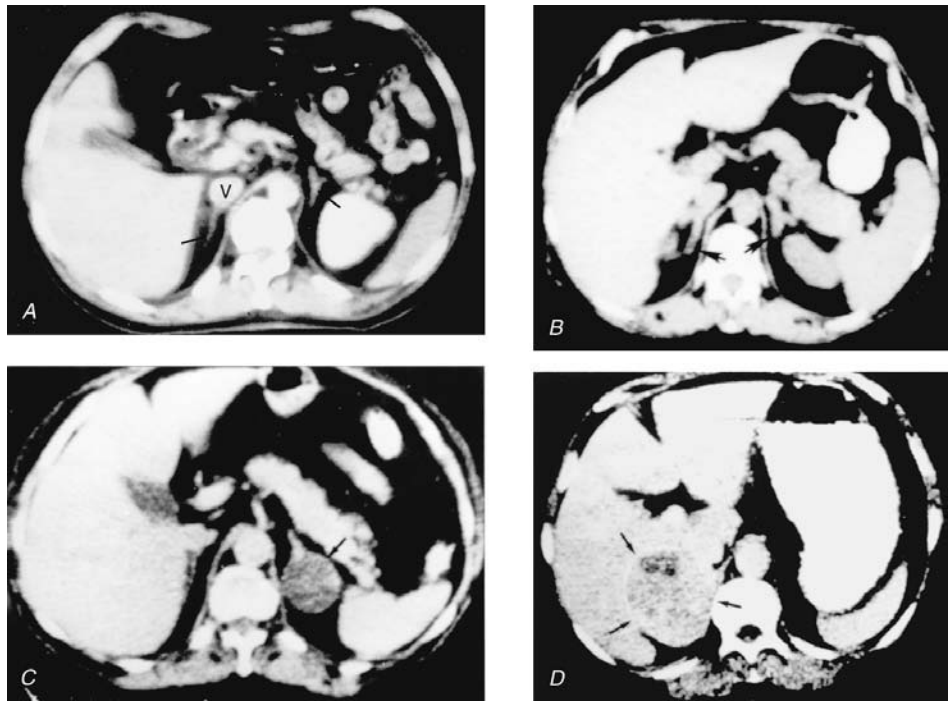

FIGURE 321-8 Computed tomography (CT) is the preferred method for visualizing the adrenal glands (*arrows*). *A*. The normal right adrenal gland is adjacent to the inferior vena cava (V) where it emerges from the liver. Approximately 90% of right adrenal glands appear as linear structures extending posteriorly from the inferior vena cava into the space between the right lobe of the liver and the crus of the diaphragm. The normal left adrenal gland is lateral to the left crus of the diaphragm and below the stomach. Most left adrenal glands are shaped like an inverted V or Y. *B*. Adrenal CT scan of a patient with ectopic ACTH production. Both adrenal glands (*arrows*) are enlarged (compare with *A*). In contrast, only 50% of patients with bilateral adrenal hyperplasia secondary to pituitary ACTH hypersecretion show enlargement of the adrenals when imaged by CT scan. *C*. CT scan of a patient with Cushing's syndrome with biochemical evidence only of cortisol overproduction. The left adrenal has been replaced by a racquet-shaped 2-cm tumor (*arrow*). Attenuation of the tumor is low because of its high lipid content. *D*. CT scan in a patient with Cushing's syndrome and biochemical evidence of an adrenal carcinoma. In contrast to the tumor in *C*, the right-sided mass in this patient is large and has a heterogeneous appearance—usual characteristics of an adrenal carcinoma.

Differential Diagnosis ■ ***PSEUDO-CUSHING'S SYNDROME*** Problems in diagnosis include patients with obesity, chronic alcoholism, depression, and acute illness of any type. Extreme *obesity* is uncommon in Cushing's syndrome; furthermore, with exogenous obesity, the adiposity is generalized, not truncal. On adrenocortical testing, abnormalities in patients with exogenous obesity are usually modest. Basal urine steroid excretion levels in obese patients are also either normal or slightly elevated, and the diurnal pattern in blood and urine levels is normal. Patients with *chronic alcoholism* and those with *depression* share similar abnormalities in steroid output: modestly elevated urine cortisol, blunted circadian rhythm of cortisol levels, and resistance to suppression using the overnight dexamethasone test. In contrast to alcoholic subjects, depressed patients do not have signs and symptoms of Cushing's syndrome. Following discontinuation of alcohol and/or improvement in the emotional status, results of steroid testing usually return to normal. One or more of three tests have been used to differentiate mild Cushing's syndrome and pseudo-Cushing's syndrome. The serum cortisol level following the standard 2-day low-dose dexamethasone test has very high sensitivity and specificity. Although the CRH test alone is less useful, in combination with the low-dose dexamethasone test, there is nearly complete discrimination between these two conditions. Finally, a midnight cortisol level obtained in awake patients may have similar predictive value as the low-dose dexamethasone test if a cut-off of 210 nmol/L (7.5 μg/dL) is used. Patients with *acute illness* often have abnormal results on laboratory tests and fail to exhibit pituitary-adrenal suppression in response to dexamethasone, since major stress (such as pain or fever) interrupts the normal regulation of ACTH secretion. *Iatrogenic Cushing's syndrome*, induced by the administration of glucocorticoids or other steroids such as megestrol that bind to the glucocorticoid receptor, is indistinguishable by physical findings from endogenous adrenocortical hyperfunction. The distinction can be made, however, by measuring blood or urine cortisol levels in a basal state; in the iatrogenic syndrome these levels are low secondary to suppression of the pituitary-adrenal axis. The severity of iatrogenic Cushing's syndrome is related to the total steroid dose, the biologic half-life of the steroid, and the duration of therapy. Also, individuals taking afternoon and evening doses of glucocorticoids develop Cushing's syndrome more readily and with a smaller total daily dose than do patients taking morning doses only.

Radiologic Evaluation for Cushing's Syndrome The preferred radiologic study for visualizing the adrenals is a CT scan of the abdomen (Fig. 321-8). CT is of value both for localizing adrenal tumors and for diagnosing bilateral hyperplasia. All patients believed to have hypersecretion of pituitary ACTH should have a pituitary MRI scan with gadolinium contrast. Even with this technique, small microadenomas may be undetectable; alternatively, false-positive masses due to cysts or nonsecretory lesions of the normal pituitary may be imaged. In patients with ectopic ACTH production, high-resolution chest CT is a useful first step.

Evaluation of Asymptomatic Adrenal Masses With abdominal CT scanning, many incidental adrenal masses (so-called incidentalomas) are discovered. This is not surprising, since 10 to 20% of subjects at autopsy have adrenocortical adenomas. The first step in evaluating such patients is to determine whether the tumor is functioning by means of appropriate screening tests, e.g., measurement of 24-h urine catecholamines and metabolites and serum potassium and assessment of adrenal cortical function by dexamethasone-suppression testing. However, 90% of incidentalomas are nonfunctioning. If an extra-adrenal malignancy is present, there is a 30 to 50% chance that the adrenal tumor is a metastasis. If the primary tumor is being treated and there are no other metastases, it is prudent to obtain a fine-needle aspirate of the adrenal mass to establish the diagnosis. In the absence of a known malignancy the next step is unclear. The probability of adrenal carcinoma is $<0.01\%$, the vast majority of adrenal masses being benign adenomas. Features suggestive of malignancy include large size (a size $>$ 4 to 6 cm suggests carcinoma); irregular margins;

and inhomogeneity, soft tissue calcifications visible on CT (Fig. 321-8), and findings characteristic of malignancy on a chemical-shift MRI image. If surgery is not performed, a repeat CT scan should be obtained in 3 to 6 months. Fine-needle aspiration is not useful to distinguish between benign and malignant primary adrenal tumors.

TREATMENT

Adrenal Neoplasm When an adenoma or carcinoma is diagnosed, adrenal exploration is performed with excision of the tumor. Adenomas may be resected using laparoscopic techniques. Because of the possibility of atrophy of the contralateral adrenal, the patient is treated pre- and postoperatively as if for total adrenalectomy, even when a unilateral lesion is suspected, the routine being similar to that for an Addisonian patient undergoing elective surgery (see Table 321-8).

Despite operative intervention, most patients with adrenal carcinoma die within 3 years of diagnosis. Metastases occur most often to liver and lung. The principal drug for the treatment of adrenocortical carcinoma is mitotane (*o,p′*-DDD), an isomer of the insecticide DDT. This drug suppresses cortisol production and decreases plasma and urine steroid levels. Although its cytotoxic action is relatively selective for the glucocorticoid-secreting zone of the adrenal cortex, the zona glomerulosa may also be inhibited. Because mitotane also alters the extraadrenal metabolism of cortisol, plasma and urinary cortisol levels must be assessed to titrate the effect. The drug is usually given in divided doses three to four times a day, with the dose increased gradually to tolerability (usually <6 g daily). At higher doses, almost all patients experience side effects, which may be gastrointestinal (anorexia, diarrhea, vomiting) or neuromuscular (lethargy, somnolence, dizziness). All patients treated with mitotane should receive long-term glucocorticoid maintenance therapy, and, in some, mineralocorticoid replacement is appropriate. In approximately one-third of patients, both tumor and metastases regress, but long-term survival is not altered. In many patients, mitotane only inhibits steroidogenesis and does not cause regression of tumor metastases. Osseous metastases are usually refractory to the drug and should be treated with radiation therapy. Mitotane can also be given as adjunctive therapy after surgical resection of an adrenal carcinoma, although there is no evidence that this improves survival. Because of the absence of a long-term benefit with mitotane, alternative chemotherapeutic approaches based on platinum therapy have been used. However, there are no data presently available indicating a prolongation of life.

BILATERAL HYPERPLASIA Patients with hyperplasia usually have a relative or absolute increase in ACTH levels. Since therapy would logically be directed at reducing ACTH levels, the ideal primary treatment for ACTH- or CRH-producing tumors, whether pituitary or ectopic, is surgical removal. Occasionally (particularly with ectopic ACTH production) surgical excision is not possible because the disease is far advanced. In this situation, "medical" or surgical adrenalectomy may correct the hypercortisolism.

Controversy exists as to the proper treatment for bilateral adrenal hyperplasia when the source of the ACTH overproduction is not apparent. In some centers, these patients (especially those who suppress after the administration of a high-dose dexamethasone test) undergo surgical exploration of the pituitary via a transsphenoidal approach in the expectation that a microadenoma will be found (Chap. 318). However, in most circumstances selective petrosal sinus venous sampling is recommended, and the patient is referred to an appropriate center if the procedure is not available locally. If a microadenoma is not found at the time of exploration, total hypophysectomy may be needed. Complications of transsphenoidal surgery include cerebrospinal fluid rhinorrhea, diabetes insipidus, panhypopituitarism, and optic or cranial nerve injuries.

In other centers, total adrenalectomy is the treatment of choice. The cure rate with this procedure is close to 100%. The adverse effects include the certain need for lifelong mineralocorticoid and glucocorticoid replacement and a 10 to 20% probability of a pituitary tumor developing over the next 10 years (Nelson's syndrome; Chap. 318). It is uncertain whether these tumors arise de novo or if they were present prior to adrenalectomy but were too small to be detected. Periodic radiologic evaluation of the pituitary gland by MRI as well as serial ACTH measurements should be performed in all individuals after bilateral adrenalectomy for Cushing's disease. Such pituitary tumors may become locally invasive and impinge on the optic chiasm or extend into the cavernous or sphenoid sinuses.

Except in children, pituitary irradiation is rarely used as primary treatment, being reserved rather for postoperative tumor recurrences. In some centers, high levels of gamma radiation can be focused on the desired site with less scattering to surrounding tissues by using stereotactic techniques. Side effects of radiation include ocular motor palsy and hypopituitarism. There is a long lag time between treatment and remission, and the remission rate is usually <50%.

Finally, in occasional patients in whom a surgical approach is not feasible, "medical" adrenalectomy may be indicated (Table 321-5). Inhibition of steroidogenesis may also be indicated in severely cushingoid subjects prior to surgical intervention. Chemical adrenalectomy may be accomplished by the administration of the inhibitor of steroidogenesis ketoconazole (600 to 1200 mg/d). In addition, mitotane (2 or 3 g/d) and/or the blockers of steroid synthesis aminoglutethimide (1 g/d) and metyrapone (2 or 3 g/d) may be effective either alone or in combination. Mitotane is slow to take effect (weeks). Mifepristone, a competitive inhibitor of the binding of glucocorticoid to its receptor, may be a treatment option. Adrenal insufficiency is a risk with all these agents, and replacement steroids may be required.

ALDOSTERONISM

Aldosteronism is a syndrome associated with hypersecretion of the mineralocorticoid aldosterone. In *primary* aldosteronism the cause for the excessive aldosterone production resides within the adrenal gland; in *secondary* aldosteronism the stimulus is extraadrenal.

Primary Aldosteronism In the original descriptions of excessive and inappropriate aldosterone production, the disease was the result of an *aldosterone-producing adrenal adenoma* (Conn's syndrome). Most cases involve a unilateral adenoma, which is usually small and may occur on either side. Rarely, primary aldosteronism is due to an adrenal carcinoma. Aldosteronism is twice as common in women as in men, usually occurs between the ages of 30 and 50, and is present in ~1% of unselected hypertensive patients. However, the prevalence may be as high as 5%, depending on the criteria and study population. In many patients with clinical and biochemical features of primary aldosteronism, a solitary adenoma is not found at surgery. Instead, these patients have *bilateral cortical nodular hyperplasia*. In the literature, this disease is also termed *idiopathic hyperaldosteronism*, and/or *nodular hyperplasia*. The cause is unknown.

SIGNS AND SYMPTOMS Hypersecretion of aldosterone increases the renal distal tubular exchange of intratubular sodium for secreted potassium and hydrogen ions, with progressive depletion of body potassium and development of hypokalemia. Most patients have diastolic hypertension, which may be very severe, and headaches. The hypertension is probably due to the increased sodium reabsorption and extracellular volume expansion. *Potassium depletion* is responsible for the muscle

TABLE 321-5 Treatment Modalities for Patients with Adrenal Hyperplasia Secondary to Pituitary ACTH Hypersecretion

Treatments to reduce pituitary ACTH production
Transsphenoidal resection of microadenoma
Radiation therapy
Treatments to reduce or eliminate adrenocortical cortisol secretion
Bilateral adrenalectomy
Medical adrenalectomy (metyrapone, mitotane, aminoglutethimide, ketoconazole)[a]

[a] Not curative but effective as long as chronically administered in selected patients.
Note: ACTH, adrenocorticotropic hormone.

weakness and fatigue and is due to the effect of potassium depletion on the muscle cell membrane. The polyuria results from impairment of urinary concentrating ability and is often associated with polydipsia. However, some individuals with mild disease, particularly the bilateral hyperplasia type, may have normal potassium levels and therefore have no symptoms associated with hypokalemia.

Electrocardiographic and roentgenographic signs of left ventricular enlargement are, in part, secondary to the hypertension. However, the left ventricular hypertrophy is disproportionate to the level of blood pressure when compared to individuals with essential hypertension, and regression of the hypertrophy occurs even if blood pressure is not reduced after removal of an aldosteronoma. Electrocardiographic signs of potassium depletion include prominent U waves, cardiac arrhythmias, and premature contractions. In the absence of associated congestive heart failure, renal disease, or preexisting abnormalities (such as thrombophlebitis), edema is characteristically absent. However, structural damage to the cerebral circulation, retinal vasculature, and kidney occurs more frequently than would be predicted based on the level and duration of the hypertension. Proteinuria may occur in as many as 50% of patients with primary aldosteronism, and renal failure occurs in up to 15%. Thus, it is probable that excess aldosterone production induces cardiovascular damage independent of its effect on blood pressure.

LABORATORY FINDINGS Laboratory findings depend on both the duration and the severity of potassium depletion. An overnight concentration test often reveals impaired ability to concentrate the urine, probably secondary to the hypokalemia. Urine pH is neutral to alkaline because of excessive secretion of ammonium and bicarbonate ions to compensate for the metabolic alkalosis.

Hypokalemia may be severe (<3 mmol/L) and reflects body potassium depletion, usually >300 mmol. In mild forms of primary aldosteronism, potassium levels may be normal. *Hypernatremia* is infrequent but may be caused by sodium retention, concomitant water loss from polyuria, and resetting of the osmostat. Metabolic alkalosis and elevation of serum bicarbonate are caused by hydrogen ion loss into the urine and migration into potassium-depleted cells. The alkalosis is perpetuated by potassium deficiency, which increases the capacity of the proximal convoluted tubule to reabsorb filtered bicarbonate. If hypokalemia is severe, serum magnesium levels are also reduced.

DIAGNOSIS The diagnosis is suggested by persistent hypokalemia in a nonedematous patient with a normal sodium intake who is not receiving potassium-wasting diuretics (furosemide, ethacrynic acid, thiazides). If hypokalemia occurs in a hypertensive patient taking a potassium-wasting diuretic, the diuretic should be discontinued and the patient should be given potassium supplements. After 1 to 2 weeks, the potassium level should be remeasured, and if hypokalemia persists, the patient should be evaluated for a mineralocorticoid excess syndrome (Fig. 321-9).

The criteria for the diagnosis of primary aldosteronism are (1) diastolic hypertension without edema, (2) hyposecretion of renin (as judged by low plasma renin activity levels) that fails to increase appropriately during volume depletion (upright posture, sodium depletion), and (3) hypersecretion of aldosterone that does not suppress appropriately in response to volume expansion.

Patients with primary aldosteronism characteristically *do not have edema*, since they exhibit an "escape" phenomenon from the sodium-retaining aspects of mineralocorticoids. Rarely, pretibial edema is present in patients with associated nephropathy and azotemia.

The estimation of plasma renin activity is of limited value in separating patients with primary aldosteronism from those with hypertension of other causes. Although failure of plasma renin activity to rise normally during volume-depletion maneuvers is a criterion for a diagnosis of primary aldosteronism, suppressed renin activity also occurs in ~25% of patients with essential hypertension.

Although a renin measurement alone lacks specificity, the ratio of serum aldosterone to plasma renin activity is a very useful screening test. A high ratio (>30), when aldosterone is expressed as ng/dL and plasma renin activity as ng/mL per hour, strongly suggests autonomy of aldosterone secretion. Aldosterone levels need to be >500 pmol/L (>15 ng/dL) when salt intake is not restricted. In some centers, the aldosterone/plasma renin activity ratio is used as a primary screen test in all normokalemic, difficult-to-control hypertensive patients, in addition to those with hypokalemia. Ultimately, it is necessary to demonstrate a lack of aldosterone suppression to diagnose primary aldosteronism (Fig. 321-9). The autonomy exhibited in these patients refers only to the resistance to suppression of secretion during volume expansion; aldosterone can and does respond in a normal or above-normal fashion to the stimulus of potassium loading or ACTH infusion.

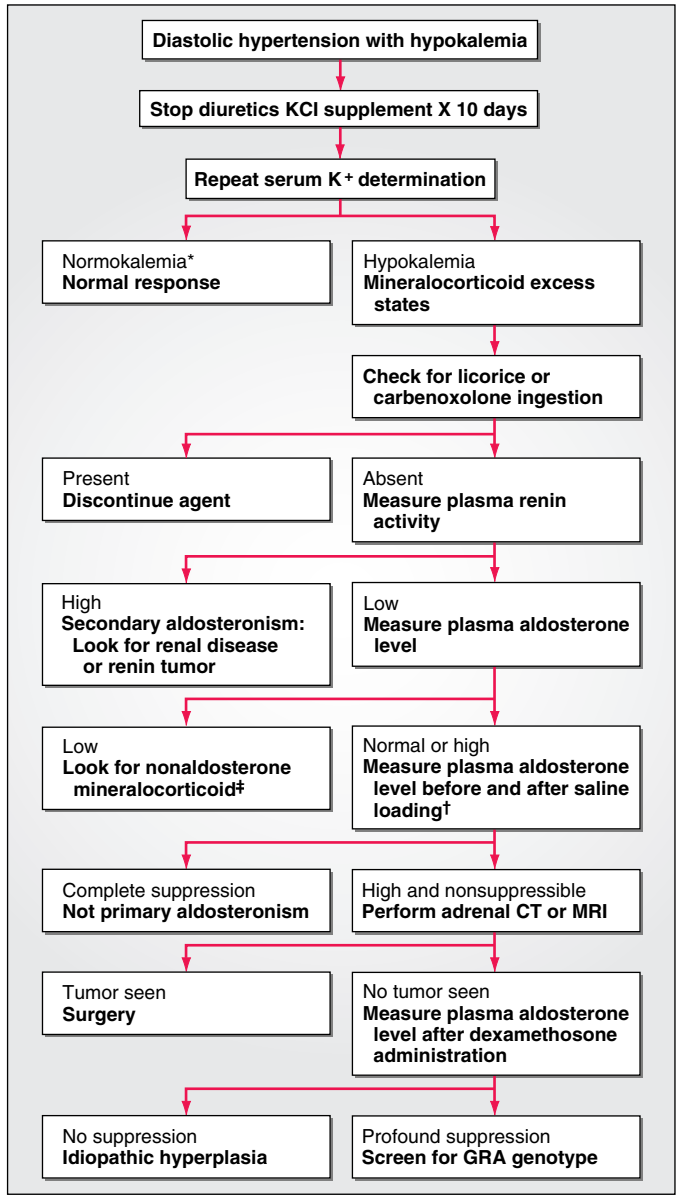

FIGURE 321-9 Diagnostic flowchart for evaluating patients with suspected primary aldosteronism. *Serum K^+ may be normal in some patients with hyperaldosteronism who are taking potassium-sparing diuretics (spironolactone, triamterene) or who have a low sodium intake and a high potassium intake. †This step should not be taken if hypertension is severe (diastolic pressure > 115 mmHg) or if cardiac failure is present. Also, serum potassium levels should be corrected before the infusion of saline solution. Alternative methods that produce comparable suppression of aldosterone secretion include oral sodium loading (200 mmol/d) and the administration of fludrocortisone, 0.2 mg bid, for 3 days. ‡For example, Liddle's syndrome, apparent mineralocorticoid excess syndrome, or a deoxycorticosterone-secreting tumor. (GRA, glucocorticoid-remediable aldosteronism; CT, computed tomography; MRI, magnetic resonance imaging.)

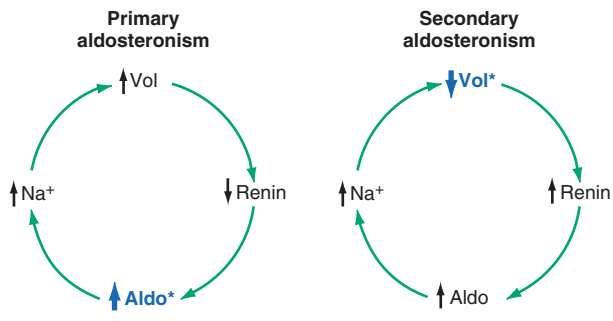
Once hyposecretion of renin and failure of aldosterone secretion suppression are demonstrated, aldosterone-producing adenomas should be localized by abdominal CT scan, using a high-resolution scanner as many aldosteronomas are <1 cm in size. If the CT scan is negative, percutaneous transfemoral bilateral adrenal vein catheterization with adrenal vein sampling may demonstrate a two- to threefold increase in plasma aldosterone concentration on the involved side. In cases of hyperaldosteronism secondary to cortical nodular hyperplasia, no lateralization is found. It is important for samples to be obtained simultaneously if possible and for cortisol levels to be measured to ensure that false localization does not reflect dilution or an ACTH- or stress-induced rise in aldosterone levels. In a patient with an adenoma, the aldosterone/cortisol ratio lateralizes to the side of the lesion.

DIFFERENTIAL DIAGNOSIS Patients with hypertension and hypokalemia may have either primary or secondary hyperaldosteronism (Fig. 321-10). A useful maneuver to distinguish between these conditions is the measurement of plasma renin activity. Secondary hyperaldosteronism in patients with accelerated hypertension is due to elevated plasma renin levels; in contrast, patients with primary aldosteronism have suppressed plasma renin levels. Indeed, in patients with a serum potassium concentration of <2.5 mmol/L, a high ratio of plasma aldosterone to plasma renin activity in a random sample is usually sufficient to establish the diagnosis of primary aldosteronism without additional testing. Ectopic ACTH production should also be considered in patients with hypertension and severe hypokalemia.

Primary aldosteronism must also be distinguished from other *hypermineralocorticoid states*. Nonaldosterone mineralocorticoid states will have suppressed plasma renin activity but low aldosterone levels. The most common problem is to distinguish between hyperaldosteronism due to an adenoma and that due to idiopathic bilateral nodular hyperplasia. This distinction is important because hypertension associated with idiopathic hyperplasia does not usually benefit from bilateral adrenalectomy, whereas hypertension associated with aldosterone-producing tumors is usually improved or cured by removal of the adenoma. Although patients with idiopathic bilateral nodular hyperplasia tend to have less severe hypokalemia, lower aldosterone secretion, and higher plasma renin activity than do patients with primary aldosteronism, differentiation is impossible solely on clinical and/or biochemical grounds. An anomalous postural decrease in plasma aldosterone and elevated plasma 18-hydroxycorticosterone levels are present in most patients with a unilateral lesion. However, these tests are also of limited diagnostic value in the individual patient, because some adenoma patients have an increase in plasma aldosterone with upright posture, so-called renin-responsive aldosteronoma. A definitive diagnosis is best made by radiographic studies, including bilateral adrenal vein catheterization, as noted above.

In a few instances, hypertensive patients with hypokalemic alkalosis have adenomas that secrete deoxycorticosterone. Such patients have reduced plasma renin activity levels, but aldosterone levels are either normal or reduced, suggesting the diagnosis of mineralocorticoid excess due to a hormone other than aldosterone. Several inherited disorders have clinical features similar to those of primary aldosteronism (see below).



*Initiating event

FIGURE 321-10 Responses of the renin-aldosterone volume control loop in primary versus secondary aldosteronism.

TREATMENT

Primary aldosteronism due to an adenoma is usually treated by surgical excision of the adenoma. Where possible a laparoscopic approach is favored. However, dietary sodium restriction and the administration of an aldosterone antagonist—e.g., spironolactone—are effective in many cases. Hypertension and hypokalemia are usually controlled by doses of 25 to 100 mg spironolactone every 8 h. In some patients medical management has been successful for years, but chronic therapy in men is usually limited by side effects of spironolactone such as gynecomastia, decreased libido, and impotence.

When idiopathic bilateral hyperplasia is suspected, surgery is indicated only when significant, symptomatic hypokalemia cannot be controlled with medical therapy, i.e., by spironolactone, triamterene, or amiloride. Hypertension associated with idiopathic hyperplasia is usually not benefited by bilateral adrenalectomy.

Secondary Aldosteronism *Secondary aldosteronism* refers to an appropriately increased production of aldosterone in response to activation of the renin-angiotensin system (Fig. 321-10). The production rate of aldosterone is often higher in patients with secondary aldosteronism than in those with primary aldosteronism. Secondary aldosteronism usually occurs in association with the accelerated phase of hypertension or on the basis of an underlying edema disorder. Secondary aldosteronism in pregnancy is a normal physiologic response to estrogen-induced increases in circulating levels of renin substrate and plasma renin activity and to the anti-aldosterone actions of progestogens.

Secondary aldosteronism in hypertensive states is due either to a primary overproduction of renin (primary reninism) or to an overproduction of renin secondary to a decrease in renal blood flow and/or perfusion pressure (Fig. 321-10). Secondary hypersecretion of renin can be due to a narrowing of one or both of the major renal arteries by atherosclerosis or by fibromuscular hyperplasia. Overproduction of renin from both kidneys also occurs in severe arteriolar nephrosclerosis (malignant hypertension) or with profound renal vasoconstriction (the accelerated phase of hypertension). The secondary aldosteronism is characterized by hypokalemic alkalosis, moderate to severe increases in plasma renin activity, and moderate to marked increases in aldosterone levels.

Secondary aldosteronism with hypertension can also be caused by rare renin-producing tumors (primary reninism). In these patients, the biochemical characteristics are of renal vascular hypertension, but the primary defect is renin secretion by a juxtaglomerular cell tumor. The diagnosis can be made by demonstration of normal renal vasculature and/or demonstration of a space-occupying lesion in the kidney by radiographic techniques and documentation of a unilateral increase in renal vein renin activity. Rarely, these tumors arise in tissues such as the ovary.

Secondary aldosteronism is present in many forms of *edema*. The rate of aldosterone secretion is usually increased in patients with edema caused by either cirrhosis or the nephrotic syndrome. In congestive heart failure, elevated aldosterone secretion varies depending on the severity of cardiac failure. The stimulus for aldosterone release in these conditions appears to be *arterial hypovolemia* and/or hypotension. Thiazides and furosemide often exaggerate secondary aldosteronism via volume depletion; hypokalemia and, on occasion, alkalosis can then become prominent features. On occasion secondary hyperaldosteronism occurs without edema or hypertension (Bartter and Gitelman syndromes, see below).

Aldosterone and Cardiovascular Damage Although many studies have investigated the role of angiotensin II in mediating cardiovascular damage, additional evidence indicates that aldosterone has an important

role that is independent of angiotensin II. Patients with primary aldosteronism (in which angiotensin II levels are usually very low) have a higher incidence of left ventricular hypertrophy (LVH), albuminuria, and stroke than do patients with essential hypertension. Experimental animal models mimicking secondary aldosteronism (angiotensin infusion) or primary aldosteronism (aldosterone infusion) reveal a common pathophysiologic sequence. Within the first few days there is activation of proinflammatory molecules with a histologic picture of perivascular macrophage infiltrate and inflammation, followed by cellular death, fibrosis, and ventricular hypertrophy. These events are prevented if an aldosterone receptor antagonist is used or if adrenalectomy is performed initially. The same pathophysiologic sequence is seen in animals with average aldosterone levels and cardiovascular damage, i.e., diabetes mellitus, or genetic hypertensive rats. Importantly, the level of sodium intake is a critical co-factor. If salt intake is severely restricted, no damage occurs even though the aldosterone levels are markedly elevated. Thus, it is not the level of aldosterone per se that is responsible for the damage, but its level relative to the volume or sodium status of the individual.

Four clinical studies support these experimental results. In the RALES trial, patients with class II/IV heart failure were randomized to standard care or a low dose of the mineralocorticoid receptor antagonist, spironolactone. There was a 30% reduction in all-cause mortality and cardiovascular mortality and hospitalizations after 36 months. Two studies in hypertensive subjects addressed the question of the relative importance of a reduction of angiotensin II formation versus blockade of the MR in mediating cardiovascular damage. Subjects were randomized to eplerenone (an MR antagonist), enalapril (an ACE inhibitor), or both agents. In the first study the subjects had LVH, with the end point being a reduction in LVH. In the second, the subjects had diabetes mellitus and proteinuria, with the end point being a reduction in proteinuria. In both studies all three treatment arms substantially reduced the primary end point; however, the most potent effect occurred in the combination arms of the studies. In the monotherapy LVH arms, the reduction in LVH was similar, while in the proteinuria study, eplerenone produced a greater reduction than did enalapril. The final study was the EPHESUS trial, where individuals who developed congestive heart failure after an acute myocardial infarction were randomized to standard-of-care treatment with or without a small dose of eplerenone. Eplerenone administration produced a significantly greater reduction in mortality (15 to 17%) and in cardiovascular-related hospitalizations than the placebo arm. Thus, these four clinical studies provide strong support to the hypothesis that MR blockade has a significant added advantage over standard-of-care therapy in reducing cardiovascular mortality and surrogate end points. However, regulatory approval is pending.

SYNDROMES OF ADRENAL ANDROGEN EXCESS Adrenal androgen excess results from excess production of DHEA and androstenedione, which are converted to testosterone in extraglandular tissues; elevated testosterone levels account for most of the virilization. Adrenal androgen excess may be associated with the secretion of greater or smaller amounts of other adrenal hormones and may, therefore, present as "pure" syndromes of virilization or as "mixed" syndromes associated with excessive glucocorticoids and Cushing's syndrome. →***For further discussion of hirsutism and virilization, see Chap. 44.***

HYPOFUNCTION OF THE ADRENAL CORTEX

Cases of adrenal insufficiency can be divided into two general categories: (1) those associated with primary inability of the adrenal to elaborate sufficient quantities of hormone, and (2) those associated with a secondary failure due to inadequate ACTH formation or release (Table 321-6).

PRIMARY ADRENOCORTICAL DEFICIENCY (ADDISON'S DISEASE) The original description of Addison's disease—"general languor and debility, feebleness of the heart's action, irritability of the stomach, and a peculiar change of the color of the skin"—summarizes the dominant clinical features. Advanced cases are usually easy to diagnose, but recognition of the early phases can be a real challenge.

TABLE 321-6 Classification of Adrenal Insufficiency

PRIMARY ADRENAL INSUFFICIENCY
Anatomic destruction of gland (chronic or acute)
"Idiopathic" atrophy (autoimmune, adrenoleukodystrophy)
Surgical removal
Infection (tuberculous, fungal, viral—especially in AIDS patients)
Hemorrhage
Invasion: metastatic
Metabolic failure in hormone production
Congenital adrenal hyperplasia
Enzyme inhibitors (metyrapone, ketoconazole, aminoglutethimide)
Cytotoxic agents (mitotane)
ACTH-blocking antibodies
Mutation in ACTH receptor gene
Adrenal hypoplasia congenita
SECONDARY ADRENAL INSUFFICIENCY
Hypopituitarism due to hypothalamic-pituitary disease
Suppression of hypothalamic-pituitary axis
By exogenous steroid
By endogenous steroid from tumor

Note: ACTH, adrenocorticotropic hormone.

Incidence Acquired forms of primary insufficiency are relatively rare, may occur at any age, and affect both sexes equally. Because of the common therapeutic use of steroids, secondary adrenal insufficiency is relatively common.

Etiology and Pathogenesis Addison's disease results from progressive destruction of the adrenals, which must involve >90% of the glands before adrenal insufficiency appears. The adrenal is a frequent site for chronic granulomatous diseases, predominantly tuberculosis but also histoplasmosis, coccidioidomycosis, and cryptococcosis. In early series, tuberculosis was responsible for 70 to 90% of cases, but the most frequent cause now is *idiopathic* atrophy, and an autoimmune mechanism is probably responsible. Rarely, other lesions are encountered, such as adrenoleukodystrophy, bilateral hemorrhage, tumor metastases, HIV, cytomegalovirus (CMV), amyloidosis, adrenomyeloneuropathy, familial adrenal insufficiency, or sarcoidosis.

Although half of patients with idiopathic atrophy have circulating adrenal antibodies, autoimmune destruction is probably secondary to cytotoxic T lymphocytes. Specific adrenal antigens to which autoantibodies may be directed include 21-hydroxylase (CYP21A2) and side chain cleavage enzyme, but the significance of these antibodies in the pathogenesis of adrenal insufficiency is unknown. Some antibodies cause adrenal insufficiency by blocking the binding of ACTH to its receptors. Some patients also have antibodies to thyroid, parathyroid, and/or gonadal tissue (Chap. 330). There is also an increased incidence of chronic lymphocytic thyroiditis, premature ovarian failure, type 1 diabetes mellitus, and hypo- or hyperthyroidism. The presence of two or more of these autoimmune endocrine disorders in the same person defines the polyglandular autoimmune syndrome type II. Additional features include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis. Within families, multiple generations are affected by one or more of the above diseases. Type II polyglandular syndrome is the result of a mutant gene on chromosome 6 and is associated with the HLA alleles B8 and DR3.

The combination of parathyroid and adrenal insufficiency and chronic mucocutaneous candidiasis constitutes type I polyglandular autoimmune syndrome. Other autoimmune diseases in this disorder include pernicious anemia, chronic active hepatitis, alopecia, primary hypothyroidism, and premature gonadal failure. There is no HLA association; this syndrome is inherited as an autosomal recessive trait. It is caused by mutations in the *a*utoimmune *p*oly*e*ndocrinopathy *c*andidiasis *e*ctodermal *d*ystrophy (APECED) gene located on chromo-

some 21q22.3. The gene encodes a transcription factor thought to be involved in lymphocyte function. The type I syndrome usually presents during childhood, whereas the type II syndrome is usually manifested in adulthood.

Clinical suspicion of adrenal insufficiency should be high in patients with AIDS (Chap. 173). CMV regularly involves the adrenal glands (so-called CMV necrotizing adrenalitis), and involvement with *Mycobacterium avium-intracellulare*, *Cryptococcus*, and Kaposi's sarcoma has been reported. Adrenal insufficiency in AIDS patients may not be manifest, but tests of adrenal reserve frequently give abnormal results. When interpreting tests of adrenocortical function, it is important to remember that medications such as rifampin, phenytoin, ketoconazole, megestrol, and opiates may cause or potentiate adrenal insufficiency. Adrenal hemorrhage and infarction occur in patients on anticoagulants and in those with circulating anticoagulants and hypercoagulable states, such as the antiphospholipid syndrome.

There are several rare genetic causes of adrenal insufficiency that present primarily in infancy and childhood (see below).

Clinical Signs and Symptoms Adrenocortical insufficiency caused by gradual adrenal destruction is characterized by an insidious onset of fatigability, weakness, anorexia, nausea and vomiting, weight loss, cutaneous and mucosal pigmentation, hypotension, and occasionally hypoglycemia (Table 321-7). Depending on the duration and degree of adrenal hypofunction, the manifestations vary from mild chronic fatigue to fulminating shock associated with acute destruction of the glands, as described by Waterhouse and Friderichsen.

Asthenia is the cardinal symptom. Early it may be sporadic, usually most evident at times of stress; as adrenal function becomes more impaired, the patient is continuously fatigued, and bed rest is necessary.

Hyperpigmentation may be striking or absent. It commonly appears as a diffuse brown, tan, or bronze darkening of parts such as the elbows or creases of the hand and of areas that normally are pigmented such as the areolae about the nipples. Bluish-black patches may appear on the mucous membranes. Some patients develop dark freckles, and irregular areas of vitiligo may paradoxically be present. As an early sign, tanning following sun exposure may be persistent.

Arterial hypotension with postural accentuation is frequent, and blood pressure may be in the range of 80/50 or less.

Abnormalities of gastrointestinal function are often the presenting complaint. Symptoms vary from mild anorexia with weight loss to fulminating nausea, vomiting, diarrhea, and ill-defined abdominal pain, which may be so severe as to be confused with an acute abdomen. Patients may have personality changes, usually consisting of excessive irritability and restlessness. Enhancement of the sensory modalities of taste, olfaction, and hearing is reversible with therapy. Axillary and pubic hair may be decreased in women due to loss of adrenal androgens.

Laboratory Findings In the early phase of gradual adrenal destruction, there may be no demonstrable abnormalities in the routine laboratory parameters, but adrenal reserve is decreased—that is, while basal steroid output may be normal, a subnormal increase occurs after stress. Adrenal stimulation with ACTH uncovers abnormalities in this stage of the disease, eliciting a subnormal increase of cortisol levels or no increase at all. In more advanced stages of adrenal destruction, serum sodium, chloride, and bicarbonate levels are reduced, and the serum potassium level is elevated. The hyponatremia is due both to loss of sodium into the urine (due to aldosterone deficiency) and to movement into the intracellular compartment. This extravascular sodium loss depletes extracellular fluid volume and accentuates hypotension. Elevated plasma vasopressin and angiotensin II levels may contribute to the hyponatremia by impairing free water clearance. Hyperkalemia is due to a combination of aldosterone deficiency, impaired glomerular filtration, and acidosis. Basal levels of cortisol and aldosterone are subnormal and fail to increase following ACTH administration. Mild to moderate hypercalcemia occurs in 10 to 20% of patients for unclear reasons. The electrocardiogram may show nonspecific changes, and the electroencephalogram exhibits a generalized reduction and slowing. There may be a normocytic anemia, a relative lymphocytosis, and a moderate eosinophilia.

TABLE 321-7 *Frequency of Symptoms and Signs in Adrenal Insufficiency*

Sign or Symptom	Percent of Patients
Weakness	99
Pigmentation of skin	98
Weight loss	97
Anorexia, nausea, and vomiting	90
Hypotension (<110/70)	87
Pigmentation of mucous membranes	82
Abdominal pain	34
Salt craving	22
Diarrhea	20
Constipation	19
Syncope	16
Vitiligo	9

Diagnosis The diagnosis of adrenal insufficiency should be made only with ACTH stimulation testing to assess adrenal reserve capacity for steroid production (see above for ACTH test protocols). In brief, the best screening test is the cortisol response 60 min after 250 μg of cosyntropin given intramuscularly or intravenously. Cortisol levels should exceed 495 nmol/L (18 μg/dL). If the response is abnormal, then primary and secondary adrenal insufficiency can be distinguished by measuring aldosterone levels from the same blood samples. In secondary, but not primary, adrenal insufficiency the aldosterone increment will be normal [$\geq$150 pmol/l (5 ng/dL)]. Furthermore, in primary adrenal insufficiency, plasma ACTH and associated peptides (β-LPT) are elevated because of loss of the usual cortisol-hypothalamic-pituitary feedback relationship, whereas in secondary adrenal insufficiency, plasma ACTH values are low or "inappropriately" normal (Fig. 321-11).

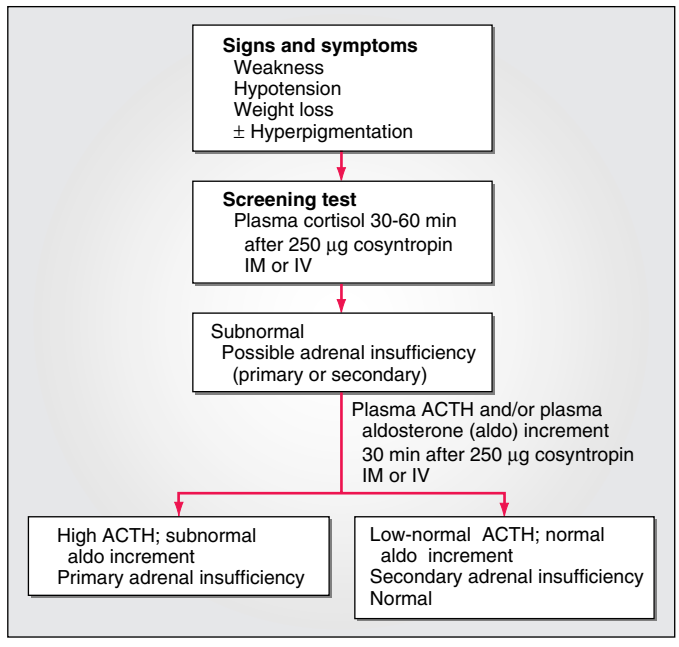


FIGURE 321-11 Diagnostic flowchart for evaluating patients with suspected adrenal insufficiency. Plasma adrenocorticotropic hormone (ACTH) levels are low in secondary adrenal insufficiency. In adrenal insufficiency secondary to pituitary tumors or idiopathic panhypopituitarism, other pituitary hormone deficiencies are present. On the other hand, ACTH deficiency may be isolated, as seen following prolonged use of exogenous glucocorticoids. Because the isolated blood levels obtained in these screening tests may not be definitive, the diagnosis may need to be confirmed by a continuous 24-h ACTH infusion. Normal subjects and patients with secondary adrenal insufficiency may be distinguished by insulin tolerance or metyrapone testing.

Differential Diagnosis Because weakness and fatigue are common, diagnosis of early adrenocortical insufficiency may be difficult. However, the combination of mild gastrointestinal distress, weight loss, anorexia, and a suggestion of increased pigmentation makes it mandatory to perform ACTH stimulation testing to rule out adrenal insufficiency, particularly before steroid treatment is begun. Weight loss is useful in evaluating the significance of weakness and malaise. Racial pigmentation may be a problem, but a *recent* and progressive *increase* in pigmentation is usually reported by the patient with gradual adrenal destruction. Hyperpigmentation is usually absent when adrenal destruction is rapid, as in bilateral adrenal hemorrhage. The fact that hyperpigmentation occurs with other diseases may also present a problem, but the appearance and distribution of pigment in adrenal insufficiency are usually characteristic. When doubt exists, measurement of ACTH levels and testing of adrenal reserve with the infusion of ACTH provide clear-cut differentiation.

TABLE 321-8 *Steroid Therapy Schedule for a Patient with Adrenal Insufficiency Undergoing Surgery*[a]

	Hydrocortisone Infusion, Continuous, mg/h		Hydrocortisone (Orally)		Fludrocortisone (Orally), 8 A.M.
			8 A.M.	4 P.M.	
Routine daily medication			20	10	0.1
Day before operation			20	10	0.1
Day of operation	10				
Day 1	5–7.5				
Day 2	2.5–5				
Day 3	2.5–5	*or*	40	20	0.1
Day 4	2.5–5	*or*	40	20	0.1
Day 5			40	20	0.1
Day 6			20	20	0.1
Day 7			20	10	0.1

[a] All steroid doses are given in milligrams. An alternative approach is to give 100 mg hydrocortisone as an intravenous bolus injection every 8 h on the day of the operation (see text).

TREATMENT

All patients with adrenal insufficiency should receive specific hormone replacement. These patients require careful education about the disease. Replacement therapy should correct both glucocorticoid and mineralocorticoid deficiencies. Hydrocortisone (cortisol) is the mainstay of treatment. The dose for most adults (depending on size) is 20 to 30 mg/d. Patients are advised to take glucocorticoids with meals or, if that is impractical, with milk or an antacid, because the drugs may increase gastric acidity and exert direct toxic effects on the gastric mucosa. To simulate the normal diurnal adrenal rhythm, two-thirds of the dose is taken in the morning, and the remaining one-third is taken in the late afternoon. Some patients exhibit insomnia, irritability, and mental excitement after initiation of therapy; in these, the dosage should be reduced. Other situations that may necessitate smaller doses are hypertension and diabetes mellitus. Obese individuals and those on anticonvulsive medications may require increased dosages. Measurements of plasma ACTH or cortisol or of urine cortisol levels do not appear to be useful in determining optimal glucocorticoid dosages.

Since the replacement dosage of hydrocortisone does not replace the mineralocorticoid component of the adrenal hormones, mineralocorticoid supplementation is usually needed. This is accomplished by the administration of 0.05 to 0.1 mg fludrocortisone per day by mouth. Patients should also be instructed to maintain an ample intake of sodium (3 to 4 g/d).

The adequacy of mineralocorticoid therapy can be assessed by measurement of blood pressure and serum electrolytes. Blood pressure should be normal and without postural changes; serum sodium, potassium, creatinine, and urea nitrogen levels should also be normal. Measurement of plasma renin levels may also be useful in titrating the dose.

In female patients with adrenal insufficiency, androgen levels are also low. Thus, some physicians believe that daily replacement with 25 to 50 mg of DHEA orally may improve quality of life and bone mineral density.

Complications of glucocorticoid therapy, with the exception of gastritis, are *rare* at the dosages recommended for treatment of adrenal insufficiency. Complications of mineralocorticoid therapy include hypokalemia, hypertension, cardiac enlargement, and even congestive heart failure due to sodium retention. Periodic measurements of body weight, serum potassium level, and blood pressure are useful. All patients with adrenal insufficiency should carry medical identification, should be instructed in the parenteral self-administration of steroids, and should be registered with a medical alerting system.

Special Therapeutic Problems During periods of intercurrent illness, especially in the setting of fever, the dose of hydrocortisone should be doubled. With severe illness it should be increased to 75 to 150 mg/d. When oral administration is not possible, parenteral routes should be employed. Likewise, before surgery or dental extractions, supplemental glucocorticoids should be administered. Patients should also be advised to increase the dose of fludrocortisone and to add salt to their otherwise normal diet during periods of strenuous exercise with sweating, during extremely hot weather, and with gastrointestinal upsets such as diarrhea. A simple strategy is to supplement the diet one to three times daily with salty broth (1 cup of beef or chicken bouillon contains 35 mmol of sodium). For a representative program of steroid therapy for the patient with adrenal insufficiency who is undergoing major surgery, see Table 321-8. This schedule is designed so that on the day of surgery it will mimic the output of cortisol in normal individuals undergoing prolonged major stress (10 mg/h, 250 to 300 mg/d). Thereafter, if the patient is improving and is afebrile, the dose of hydrocortisone is tapered by 20 to 30% daily. Mineralocorticoid administration is unnecessary at hydrocortisone doses >100 mg/d because of the mineralocorticoid effects of hydrocortisone at such dosages.

SECONDARY ADRENOCORTICAL INSUFFICIENCY ACTH deficiency causes *secondary* adrenocortical insufficiency; it may be a selective deficiency, as is seen following prolonged administration of excess glucocorticoids, or it may occur in association with deficiencies of multiple pituitary hormones (panhypopituitarism) (Chap. 318). Patients with secondary adrenocortical hypofunction have many symptoms and signs in common with those having primary disease but are *not hyperpigmented*, since ACTH and related peptide levels are low. In fact, plasma ACTH levels distinguish between primary and secondary adrenal insufficiency, since they are elevated in the former and decreased to absent in the latter. Patients with total pituitary insufficiency have manifestations of multiple hormone deficiencies. An additional feature distinguishing primary adrenocortical insufficiency is the *near-normal level of aldosterone secretion* seen in pituitary and/or isolated ACTH deficiencies (Fig. 321-11). Patients with pituitary insufficiency may have hyponatremia, which can be dilutional or secondary to a subnormal increase in aldosterone secretion in response to severe sodium restriction. However, severe *dehydration*, *hyponatremia*, and *hyperkalemia* are characteristic of severe mineralocorticoid insufficiency and favor a diagnosis of primary adrenocortical insufficiency.

Patients receiving long-term steroid therapy, despite physical findings of Cushing's syndrome, may develop adrenal insufficiency because of prolonged pituitary-hypothalamic suppression and adrenal atrophy secondary to the loss of endogenous ACTH. These patients have two deficits, a loss of adrenal responsiveness to ACTH and a failure of pituitary ACTH release. They are characterized by low blood cortisol and ACTH levels, a low baseline rate of steroid excretion, and abnormal ACTH and metyrapone responses. Most patients with steroid-induced adrenal insufficiency eventually recover normal HPA re-

sponsiveness, but recovery time varies from days to months. The rapid ACTH test provides a convenient assessment of recovery of HPA function. Because the plasma cortisol concentrations after injection of cosyntropin and during insulin-induced hypoglycemia are usually similar, the rapid ACTH test assesses the integrated HPA function (see "Tests of Pituitary-Adrenal Responsiveness," above). Some investigators suggest using the low-dose (1 μg) ACTH test for suspected secondary ACTH deficiency. Additional tests to assess pituitary ACTH reserve include the standard metyrapone and insulin-induced hypoglycemia tests.

Glucocorticoid therapy in patients with secondary adrenocortical insufficiency does not differ from that for the primary disorder. Mineralocorticoid therapy is usually not necessary, as aldosterone secretion is preserved.

ACUTE ADRENOCORTICAL INSUFFICIENCY Acute adrenocortical insufficiency may result from several processes. On the one hand, *adrenal crisis* may be a rapid and overwhelming intensification of chronic adrenal insufficiency, usually precipitated by sepsis or surgical stress. Alternatively, acute hemorrhagic destruction of both adrenal glands can occur in previously well individuals. In children, this event is usually associated with septicemia with *Pseudomonas* or meningococcemia (Waterhouse-Friderichsen syndrome). In adults, anticoagulant therapy or a coagulation disorder may result in bilateral adrenal hemorrhage. Occasionally, bilateral adrenal hemorrhage in the newborn results from birth trauma. Hemorrhage has been observed during pregnancy, following idiopathic adrenal vein thrombosis, and as a complication of venography (e.g., infarction of an adenoma). The third and most frequent cause of acute insufficiency is the rapid withdrawal of steroids from patients with adrenal atrophy owing to chronic steroid administration. Acute adrenocortical insufficiency may also occur in patients with congenital adrenal hyperplasia or those with decreased adrenocortical reserve when they are given drugs capable of inhibiting steroid synthesis (mitotane, ketoconazole) or of increasing steroid metabolism (phenytoin, rifampin).

Adrenal Crisis The long-term survival of patients with adrenocortical insufficiency depends largely on the prevention and treatment of adrenal crisis. Consequently, the occurrence of infection, trauma (including surgery), gastrointestinal upsets, or other stresses necessitates an immediate increase in hormone. In untreated patients, preexisting symptoms are intensified. Nausea, vomiting, and abdominal pain may become intractable. Fever may be severe or absent. Lethargy deepens into somnolence, and hypovolemic vascular collapse ensues. In contrast, patients previously maintained on chronic glucocorticoid therapy may not exhibit dehydration or hypotension until they are in a preterminal state, since mineralocorticoid secretion is usually preserved. In all patients in crisis, a precipitating cause should be sought.

TREATMENT

Treatment is directed primarily toward repletion of circulating glucocorticoids and replacement of the sodium and water deficits. Hence an intravenous infusion of 5% glucose in normal saline solution should be started with a bolus intravenous infusion of 100 mg hydrocortisone followed by a continuous infusion of hydrocortisone at a rate of 10 mg/h. An alternative approach is to administer a 100-mg bolus of hydrocortisone intravenously every 6 h. However, only continuous infusion maintains the plasma cortisol constantly at stress levels [>830 nmol/L (30 μg/dL)]. Effective treatment of hypotension requires glucocorticoid replacement and repletion of sodium and water deficits. If the crisis was preceded by prolonged nausea, vomiting, and dehydration, several liters of saline solution may be required in the first few hours. Vasoconstrictive agents (such as dopamine) may be indicated in extreme conditions as adjuncts to volume replacement. With large doses of steroid, i.e., 100 to 200 mg hydrocortisone, the patient receives a maximal mineralocorticoid effect, and supplementary mineralocorticoid is superfluous. Following improvement, the steroid dosage is tapered over the next few days to maintenance levels, and mineralocorticoid therapy is reinstituted if needed (Table 321-8).

ADRENAL CORTICOL INSUFFICIENCY IN ACUTELY ILL PATIENTS The physiology of the HPA axis is dramatically altered during critical illnesses such as trauma, surgery, sepsis, and shock. In such situations cortisol levels rise four- to sixfold, diurnal variation is abolished, and the unbound fractions of cortisol rise in the circulation and in target tissues. Inadequate cortisol production during critical illness can result in hypotension, reduced systemic vascular resistance, shock, and death.

A major area of controversy in presumably normal individuals is the correlation of clinical outcomes with the cortisol levels measured during critical illness. Subnormal cortisol production during acute severe illness has been termed "functional" or "relative" adrenal insufficiency. Conceptually, the elevated cortisol levels that are observed are viewed as insufficient to control the inflammatory response and maintain blood pressure. If such patients can be identified, treatment with supplementary cortisol could be beneficial.

A level of cortisol in a critically ill patient below which replacement glucocorticoids may improve prognosis is not firmly established, although many have accepted a level of ≤441 nmol/L (15 μg/dL). On the other hand, a random cortisol >938 nmol/L (34 μg/dL) in the setting of critical illness is unlikely to be associated with relative adrenal insufficiency. In patients who have random cortisol levels between 441 and 938 nmol/L (15 and 34 μg/dL), a cosyntropin stimulation test may identify patients with diminished adrenal reserve [increment <255 nmol/L (9 μg/dL)] who may benefit from supplementary cortisol treatment. If the diagnosis of relative or functional adrenal insufficiency is considered in an acutely ill, hypotensive patient, treatment with supplementary cortisol should be initiated promptly following the measurement of a random cortisol level and/or performing a cosyntropin stimulation test. Supplemental cortisol may be particularly beneficial in patients with septic shock where glucocorticoids have been reported to reduce mortality and the duration of vasopressor therapy. Such patients should be treated with 50 to 75 mg of intravenous hydrocortisone every 6 h as bolus treatment or the same amount as a continuous infusion. Treatment can be terminated if the cortisol levels obtained at the outset are normal. On the other hand, those patients with abnormal testing should be treated for 1 week and then tapered. In surviving patients, adrenal function should be reevaluated after resolution of the critical illness.

HYPOALDOSTERONISM

Isolated aldosterone deficiency accompanied by normal cortisol production occurs in association with hyporeninism, as an inherited biosynthetic defect, postoperatively following removal of aldosterone-secreting adenomas, during protracted heparin administration, in pretectal disease of the nervous system, and in severe postural hypotension.

The feature common to all forms of hypoaldosteronism is the inability to increase aldosterone secretion appropriately in response to salt restriction. Most patients have unexplained hyperkalemia, which is often exacerbated by restriction of dietary sodium intake. In severe cases, urine sodium wastage occurs at a normal salt intake, whereas in milder forms, excessive loss of urine sodium occurs only with salt restriction.

Most cases of isolated hypoaldosteronism occur in patients with a deficiency in renin production (so-called hyporeninemic hypoaldosteronism), most commonly in adults with diabetes mellitus and mild renal failure and in whom hyperkalemia and metabolic acidosis are out of proportion to the degree of renal impairment. Plasma renin levels fail to rise normally following sodium restriction and postural changes. The pathogenesis is uncertain. Possibilities include renal disease (the most likely), autonomic neuropathy, extracellular fluid volume expansion, and defective conversion of renin precursors to active renin. Aldosterone levels also fail to rise normally after salt restriction and volume contraction; this effect is probably related to the hyporeninism, since biosynthetic defects in aldosterone secretion usually can-

not be demonstrated. In these patients, aldosterone secretion increases promptly after ACTH stimulation, but it is uncertain whether the magnitude of the response is normal. On the other hand, the level of aldosterone appears to be subnormal in relationship to the hyperkalemia.

Hypoaldosteronism can also be associated with high renin levels and low or elevated levels of aldosterone (see below). Severely ill patients may also have hyperreninemic hypoaldosteronism; such patients have a high mortality rate (80%). Hyperkalemia is not present. Possible explanations for the hypoaldosteronism include adrenal necrosis (uncommon) or a shift in steroidogenesis from mineralocorticoids to glucocorticoids, possibly related to prolonged ACTH stimulation.

Before the diagnosis of isolated hypoaldosteronism is considered for a patient with hyperkalemia, "pseudohyperkalemia" (e.g., hemolysis, thrombocytosis) should be excluded by measuring the *plasma* potassium level. The next step is to demonstrate a normal cortisol response to ACTH stimulation. Then, the response of renin and aldosterone levels to stimulation (upright posture, sodium restriction) should be measured. Low renin and aldosterone levels establish the diagnosis of hyporeninemic hypoaldosteronism. A combination of high renin levels and low aldosterone levels is consistent with an aldosterone biosynthetic defect or a selective unresponsiveness to angiotensin II. Finally, there is a condition that clinically and biochemically mimics hypoaldosteronism with elevated renin levels. However, the aldosterone levels are not low but high—so-called pseudohypoaldosteronism. This inherited condition is caused by a mutation in the epithelial sodium channel (see below).

TREATMENT

The treatment is to replace the mineralocorticoid deficiency. For practical purposes, the oral administration of 0.05 to 0.15 mg fludrocortisone daily should restore electrolyte balance if salt intake is adequate (e.g., 150 to 200 mmol/d). However, patients with hyporeninemic hypoaldosteronism may require higher doses of mineralocorticoid to correct hyperkalemia. This need poses a potential risk in patients with hypertension, mild renal insufficiency, or congestive heart failure. An alternative approach is to reduce salt intake and to administer furosemide, which can ameliorate acidosis and hyperkalemia. Occasionally, a combination of these two approaches is efficacious.

GENETIC CONSIDERATIONS Glucocorticoid Diseases ■ *CONGENITAL ADRENAL HYPERPLASIA*

Congenital adrenal hyperplasia (CAH) is the consequence of recessive mutations that cause one of several distinct enzymatic defects (see below). Because cortisol is the principal adrenal steroid regulating ACTH elaboration and because ACTH stimulates adrenal growth and function, a block in cortisol synthesis may result in the enhanced secretion of adrenal androgens and/or mineralocorticoids depending on the site of the enzyme block. In severe congenital virilizing hyperplasia, the adrenal output of cortisol may be so compromised as to cause adrenal deficiency despite adrenal hyperplasia.

CAH is the most common adrenal disorder of infancy and childhood (Chap. 328). Partial enzyme deficiencies can be expressed after adolescence, predominantly in women with hirsutism and oligomenorrhea but minimal virilization. Late-onset adrenal hyperplasia may account for 5 to 25% of cases of hirsutism and oligomenorrhea in women, depending on the population.

Etiology Enzymatic defects have been described in 21-hydroxylase (CYP21A2), 17α-hydroxylase/17,20-lyase (CYP17), 11β-hydroxylase (CYP11B1), and in (3β-HSD2) (Fig. 321-2). Although the genes encoding these enzymes have been cloned, the diagnosis of specific enzyme deficiencies with genetic techniques is not practical because of the large number of different deletions and missense mutations. CYP21A2 deficiency is closely linked to the HLA-B locus of chromosome 6 so that HLA typing and/or DNA polymorphism can be used to detect the heterozygous carriers and to diagnose affected individuals in some families (Chap. 296). The clinical expression in the different disorders is variable, ranging from virilization of the female (CYP2/A2) to feminization of the male (3β-HSD2) (Chap. 328).

Adrenal virilization in the female at birth is associated with ambiguous external genitalia (*female pseudohermaphroditism*). Virilization begins after the fifth month of intrauterine development. At birth there may be enlargement of the clitoris, partial or complete fusion of the labia, and sometimes a urogenital sinus in the female. If the labial fusion is nearly complete, the female infant has external genitalia resembling a penis with hypospadias. In the *postnatal* period, CAH is associated with virilization in the female and isosexual precocity in the male. The excessive androgen levels result in accelerated growth, so that bone age exceeds chronologic age. Because epiphyseal closure occurs early, growth stops, but truncal development continues, the characteristic appearance being a short child with a well-developed trunk.

The most common form of CAH (95% of cases) is a result of impairment of CYP21A2. In addition to cortisol deficiency, aldosterone secretion is decreased in approximately one-third of the patients. Thus, with CYP21A2 deficiency, adrenal virilization occurs with or without a salt-losing tendency due to aldosterone deficiency (Fig. 321-2).

CYP11B1 deficiency causes a "hypertensive" variant of CAH. Hypertension and hypokalemia occur because of the impaired conversion of 11-deoxycorticosterone to corticosterone, resulting in the accumulation of 11-deoxycorticosterone, a potent mineralocorticoid. The degree of hypertension is variable. Steroid precursors are shunted into the androgen pathway.

CYP17 deficiency is characterized by hypogonadism, hypokalemia, and hypertension. This rare disorder causes decreased production of cortisol and shunting of precursors into the mineralocorticoid pathway with hypokalemic alkalosis, hypertension, and suppressed plasma renin activity. Usually, 11-deoxycorticosterone production is elevated. Because CYP17 hydroxylation is required for biosynthesis of both adrenal androgens and gonadal testosterone and estrogen, this defect is associated with sexual immaturity, high urinary gonadotropin levels, and low urinary 17-ketosteroid excretion. Female patients have primary amenorrhea and lack of development of secondary sexual characteristics. Because of deficient androgen production, male patients have either ambiguous external genitalia or a female phenotype (*male pseudohermaphroditism*). Exogenous glucocorticoids can correct the hypertensive syndrome, and treatment with appropriate gonadal steroids results in sexual maturation.

With 3β-HSD2 deficiency, conversion of pregnenolone to progesterone is impaired, so that the synthesis of both cortisol and aldosterone is blocked, with shunting into the adrenal androgen pathway via 17α-hydroxypregnenolone and DHEA. Because DHEA is a weak androgen, and because this enzyme deficiency is also present in the gonad, the genitalia of the male fetus may be incompletely virilized or feminized. Conversely, in the female, overproduction of DHEA may produce partial virilization.

Diagnosis The diagnosis of CAH should be considered in infants having episodes of acute adrenal insufficiency or salt-wasting or hypertension. The diagnosis is further suggested by the finding of hypertrophy of the clitoris, fused labia, or a urogenital sinus in the female or of isosexual precocity in the male. In infants and children with a CYP21A2 defect, increased urine 17-ketosteroid excretion and increased plasma DHEA sulfate levels are typically associated with an increase in the blood levels of 17-hydroxyprogesterone and the excretion of its urinary metabolite pregnanetriol. Demonstration of elevated levels of 17-hydroxyprogesterone in amniotic fluid at 14 to 16 weeks of gestation allows prenatal detection of affected female infants.

The diagnosis of a *salt-losing form* of CAH due to defects in CYP21A2 is suggested by episodes of acute adrenal insufficiency with hyponatremia, hyperkalemia, dehydration, and vomiting. These infants and children often crave salt and have laboratory findings indicating deficits in both cortisol and aldosterone secretion.

With the *hypertensive form* of CAH due to CYP11B1 deficiency, 11-deoxycorticosterone and 11-deoxycortisol accumulate. The diagnosis is confirmed by demonstrating increased levels of 11-deoxycortisol in the blood or increased amounts of tetrahydro-11-deoxycortisol in the urine. Elevation of 17-hydroxyprogesterone levels does not imply a coexisting CYP21A2 deficiency.

Very high levels of urine DHEA with low levels of pregnanetriol and of cortisol metabolites in urine are characteristic of children with 3β-HSD2 deficiency. Marked salt-wasting may also occur.

Adults with *late-onset adrenal hyperplasia* (partial deficiency of CYP21A2, CYP11B1, or 3β-HSD2) are characterized by normal or moderately elevated levels of urinary 17-ketosteroids and plasma DHEA sulfate. A high basal level of a precursor of cortisol biosynthesis (such as 17-hydroxyprogesterone, 17-hydroxypregnenolone, or 11-deoxycortisol), or elevation of such a precursor after ACTH stimulation, confirms the diagnosis of a partial deficiency. Measurement of steroid precursors 60 min after bolus administration of ACTH is usually sufficient. Adrenal androgen output is easily suppressed by the standard low-dose (2 mg) dexamethasone test.

TREATMENT

Therapy in CAH patients consists of daily administration of glucocorticoids to suppress pituitary ACTH secretion. Because of its low cost and intermediate half-life, prednisone is the drug of choice except in infants, in whom hydrocortisone is usually used. In adults with late-onset adrenal hyperplasia, the smallest single bedtime dose of a long- or intermediate-acting glucocorticoid that suppresses pituitary ACTH secretion should be administered. The amount of steroid required by children with CAH is approximately 1 to 1.5 times the normal cortisol production rate of 27 to 35 μmol (10 to 13 mg) of cortisol per square meter of body surface per day and is given in divided doses two or three times per day. The dosage schedule is governed by repetitive analysis of the urinary 17-ketosteroids, plasma DHEA sulfate, and/or precursors of cortisol biosynthesis. Skeletal growth and maturation must also be monitored closely, as overtreatment with glucocorticoid replacement therapy retards linear growth.

Receptor Mutations *Isolated glucocorticoid deficiency* is a rare autosomal recessive disease secondary to a mutation in the ACTH receptor. Usually mineralocorticoid function is normal. Adrenal insufficiency is manifest within the first 2 years of life as hyperpigmentation, convulsions, and/or frequent episodes of hypoglycemia. In some patients the adrenal insufficiency is associated with achalasia and alacrima—Allgrove's, or triple A, syndrome. However, in some triple A syndrome patients, no mutation in the ACTH receptor has been identified, suggesting that a distinct genetic abnormality causes this syndrome. *Adrenal hypoplasia congenita* is a rare X-linked disorder caused by a mutation in the *DAX1* gene. This gene encodes an orphan nuclear receptor that plays an important role in the development of the adrenal cortex and also the hypothalamic-pituitary-gonadal axis. Thus, patients present with signs and symptoms secondary to deficiencies of all three major adrenal steroids—cortisol, aldosterone, and adrenal androgens—as well as gonadotropin deficiency. Finally a rare cause of hypercortisolism without cushingoid stigmata is *primary cortisol resistance* due to mutations in the glucocorticoid receptor. The resistance is incomplete because patients do not exhibit signs of adrenal insufficiency.

Miscellaneous Conditions Adrenoleukodystrophy causes severe demyelination and early death in children, and adrenomyeloneuropathy is associated with a mixed motor and sensory neuropathy with spastic paraplegia in adults; both disorders are associated with elevated circulating levels of very long chain fatty acids and cause adrenal insufficiency. Autosomal recessive mutations in the *st*eroidogenic *a*cute *r*egulatory (STAR) protein gene cause congenital lipoid adrenal hyperplasia (Chap. 328), which is characterized by adrenal insufficiency and defective gonadal steroidogenesis. Because STAR mediates cholesterol transport into the mitochondrion, mutations in the protein cause massive lipid accumulation in steroidogenic cells, ultimately leading to cell toxicity.

MINERALOCORTICOID DISEASES Some forms of CAH have a mineralocorticoid component (see above). Others are caused by a mutation in other enzymes or ion channels important in mediating or mimicking aldosterone's action.

Hypermineralocorticoidism ■ *LOW PLASMA RENIN ACTIVITY* Rarely, hypermineralocorticoidism is due to a defect in cortisol biosynthesis, specifically 11- or 17-hydroxylation. ACTH levels are increased, with a resultant increase in the production of the mineralocorticoid 11-deoxycorticosterone. Hypertension and hypokalemia can be corrected by glucocorticoid administration. The definitive diagnosis is made by demonstrating an elevation of precursors of cortisol biosynthesis in the blood or urine or by direct demonstration of the genetic defect.

Glucocorticoid administration can also ameliorate hypertension or produce normotension even though a hydroxylase deficiency cannot be identified (Fig. 321-9). These patients have normal to slightly elevated aldosterone levels that do not suppress in response to saline but do suppress in response to 2 days of dexamethasone (2 mg/d). The condition is inherited as an autosomal dominant trait and is termed *glucocorticoid-remediable aldosteronism* (GRA). This entity is secondary to a chimeric gene duplication whereby the 11-β hydroxylase gene promoter (which is under the control of ACTH) is fused to the aldosterone synthase coding sequence. Thus, aldosterone synthase activity is ectopically expressed in the zona fasciculata and is regulated by ACTH, in a fashion similar to the regulation of cortisol secretion. Screening for this defect is best performed by assessing the presence or absence of the chimeric gene. Because the abnormal gene may be present in the absence of hypokalemia, its frequency as a cause of hypertension is unknown. Individuals with suppressed plasma renin levels and juvenile-onset hypertension or a history of early-onset hypertension in first-degree relatives should be screened for this disorder. Early hemorrhagic stroke also occurs in GRA-affected individuals.

GRA documented by genetic analysis may be treated with glucocorticoid administration or antimineralocorticoids, i.e., spironolactone, triamterene, or amiloride. Glucocorticoids should be used only in small doses to avoid inducing iatrogenic Cushing's syndrome. A combination approach is often necessary.

HIGH PLASMA RENIN ACTIVITY *Bartter syndrome* is characterized by severe hyperaldosteronism (hypokalemic alkalosis) with moderate to marked increases in renin activity and hypercalciuria, but normal blood pressure and no edema; this disorder usually begins in childhood. Renal biopsy shows juxtaglomerular hyperplasia. Bartter syndrome is caused by a mutation in the renal Na-K-2Cl co-transporter gene. The pathogenesis involves a defect in the renal conservation of sodium or chloride. The renal loss of sodium is thought to stimulate renin secretion and aldosterone production. Hyperaldosteronism produces potassium depletion, and hypokalemia further elevates prostaglandin production and plasma renin activity. In some cases, the hypokalemia may be potentiated by a defect in renal conservation of potassium.

Gitelman syndrome is an autosomal recessive trait characterized by renal salt wasting and as a result, as in Bartter syndrome, activation of the renin-angiotensin-aldosterone system. As a consequence affected individuals have low blood pressure, low serum potassium, low serum magnesium, and high serum bicarbonate. In contrast to Bartter syndrome, urinary calcium excretion is reduced. Gitelman syndrome results from loss-of-function mutations of the renal thiazide-sensitive Na-Cl co-transporter.

Increased Mineralocorticoid Action *Liddle syndrome* is a rare autosomal dominant disorder that mimicks hyperaldosteronism. The defect is in the genes encoding the β or η subunits of the epithelial sodium channel. Both renin and aldosterone levels are low, owing to the constitutively activated sodium channel and the resulting excess sodium reabsorption in the renal tubule.

TABLE 321-9 A Checklist for Use Prior to the Administration of Glucocorticoids in Pharmacologic Doses

Presence of tuberculosis or other chronic infection (chest x-ray, tuberculin test)
Evidence of glucose intolerance or history of gestational diabetes mellitus
Evidence of preexisting osteoporosis (bone density assessment in organ transplant recipients or postmenopausal patients)
History of peptic ulcer, gastritis, or esophagitis (stool guaiac test)
Evidence of hypertension or cardiovascular disease
History of psychological disorders

A rare autosomal recessive cause of hypokalemia and hypertension is 11β-HSD II deficiency, in which cortisol cannot be converted to cortisone and hence binds to the MR and acts as a mineralocorticoid. This condition, also termed *apparent mineralocorticoid excess syndrome*, is caused by a defect in the gene encoding the renal isoform of this enzyme, 11β-HSD II. Patients can be identified either by documenting an increased ratio of cortisol to cortisone in the urine or by genetic analysis. Patients with the 11β-HSD deficiency syndrome can be treated with small doses of dexamethasone, which suppresses ACTH and endogenous cortisol production but binds less well to the mineralocorticoid receptor than does cortisol.

The ingestion of candies or chewing tobacco containing certain forms of licorice produces a syndrome that mimics primary aldosteronism. The component of such agents that causes sodium retention is glycyrrhizinic acid, which inhibits 11β-HSD II and hence allows cortisol to act as a mineralocorticoid. The diagnosis is established or excluded by a careful history.

Decreased Mineralocorticoid Production or Action In patients with a deficiency in aldosterone biosynthesis, the transformation of corticosterone into aldosterone is impaired, owing to a mutation in the aldosterone synthase (CYP11B2) gene. These patients have low to absent aldosterone secretion, elevated plasma renin levels, and elevated levels of the intermediates of aldosterone biosynthesis (corticosterone and 18-hydroxycorticosterone).

Pseudohypoaldosteronism type I (PHA-I) is an autosomal recessive disorder that is seen in the neonatal period and is characterized by salt wasting, hypotension, hyperkalemia, and high renin and aldosterone levels. In contrast to the gain-of-function mutations in the epithelial sodium channel in Liddle syndrome, mutations in PHA-I result in loss of epithelial sodium channel function.

PHARMACOLOGIC CLINICAL USES OF ADRENAL STEROIDS

The widespread use of glucocorticoids emphasizes the need for a thorough understanding of the metabolic effects of these agents. Before adrenal hormone therapy is instituted, the expected gains should be weighed against undesirable effects. Several important questions should be addressed before initiating therapy. First, how serious is the disorder (the more serious, the greater the likelihood that the risk/benefit ratio will be positive)? Second, how long will therapy be required (the longer the therapy, the greater the risk of adverse side effects)? Third, does the individual have preexisting conditions that glucocorticoids may exacerbate (Table 321-9)? If so, then a careful risk/benefit assessment is required to ensure that the ratio is favorable given the increased likelihood of harm by steroids in these patients. Supplementary measures to minimize undesirable metabolic effects are shown in Table 321-10. Fourth, which preparation is best?

THERAPEUTIC CONSIDERATIONS The following considerations should be taken into account in deciding which steroid preparation to use:

1. *The biologic half-life*. The rationale behind alternate-day therapy is to decrease the metabolic effects of the steroids for a significant part of each 48 h period while still producing a pharmacologic effect durable enough to be effective. Too long a half-life would defeat the first purpose, and too short a half-life would defeat the second. In general, the more potent the steroid, the longer its biologic half-life.

TABLE 321-10 Supplementary Measures to Minimize Undesirable Metabolic Effects of Glucocorticoids

Monitor caloric intake to prevent weight gain.
Restrict sodium intake to prevent edema and minimize hypertension and potassium loss.
Provide supplementary potassium if necessary.
Provide antacid, H_2 receptor antagonist, and/or H^+,K^+-ATPase inhibitor therapy.
Institute alternate-day steroid schedule if possible. Patients receiving steroid therapy over a prolonged period should be protected by an appropriate increase in hormone level during periods of acute stress. A rule of thumb is to *double* the maintenance dose.
Minimize osteopenia by
Administering gonadal hormone replacement therapy: 0.625–1.25 mg conjugated estrogens given cyclically with progesterone, unless the uterus is absent; testosterone replacement for hypogonadal men
Ensuring high calcium intake (should be approximately 1200 mg/d)
Administering supplemental vitamin D if blood levels of calciferol or $1,25(OH)_2$ vitamin D are reduced
Administering bisphosphonate prophylactically, orally or parenterally, in high-risk patients

2. *The mineralocorticoid effects of the steroid*. Most synthetic steroids have less mineralocorticoid effect than hydrocortisone (Table 321-11).
3. *The biologically active form of the steroid*. Cortisone and prednisone have to be converted to biologically active metabolites before anti-inflammatory effects can occur. Because of this, in a condition for which steroids are known to be effective and when an adequate dose has been given without response, one should consider substituting hydrocortisone or prednisolone for cortisone or prednisone.
4. *The cost of the medication*. This is a serious consideration if chronic administration is planned. Prednisone is the least expensive of available steroid preparations.
5. *The type of formulation*. Topical steroids have the distinct advantage over oral steroids in reducing the likelihood of systemic side effects. In addition, some inhaled steroids have been designed to minimize side effects by increasing their hepatic inactivation if they are swallowed (Chap. 236). However, all topical steroids can be absorbed into the systemic circulation.

TABLE 321-11 Glucocorticoid Preparations

Commonly Used Name[a]	Estimated Potency[b]	
	Glucocorticoid	Mineralocorticoid
SHORT-ACTING		
Hydrocortisone	1	1
Cortisone	0.8	0.8
INTERMEDIATE-ACTING		
Prednisone	4	0.25
Prednisolone	4	0.25
Methylprednisolone	5	<0.01
Triamcinolone	5	<0.01
LONG-ACTING		
Paramethasone	10	<0.01
Betamethasone	25	<0.01
Dexamethasone	30–40	<0.01

[a] The steroids are divided into three groups according to the duration of biologic activity. Short-acting preparations have a biologic half-life <12 h; long-acting, >48 h; and intermediate, between 12 and 36 h. Triamcinolone has the longest half-life of the intermediate-acting preparations.

[b] Relative milligram comparisons with hydrocortisone, setting the glucocorticoid and mineralocorticoid properties of hydrocortisone as 1. Sodium retention is insignificant for commonly employed doses of methylprednisolone, triamcinolone, parathasone, betamethasone, and dexamethasone.

ALTERNATE-DAY STEROID THERAPY The most effective way to minimize the cushingoid effects of glucocorticoids is to administer the total 48-h dose as a *single* dose of *intermediate-acting steroid* in the morning, *every other day*. If symptoms of the underlying disorder can be controlled by this technique, it offers distinct advantages. Three considerations deserve mention: (1) The alternate-day schedule may be approached through transition schedules that allow the patient to adjust gradually; (2) supplementary nonsteroid medications may be needed on the "off" day to minimize symptoms of the underlying disorder; and (3) many symptoms that occur during the off day (e.g., fatigue, joint pain, muscle stiffness or tenderness, and fever) may represent relative adrenal insufficiency rather than exacerbation of the underlying disease.

The alternate-day approach capitalizes on the fact that cortisol secretion and plasma levels normally are highest in the early morning and lowest in the evening. The normal pattern is mimicked by administering an intermediate-acting steroid in the morning (7 to 8 A.M.) (Table 321-11).

Initially, the steroid regimen often requires daily or more frequent doses of steroid to achieve the desired anti-inflammatory or immunity-suppressing action. *Only after this desired effect is achieved is an attempt made to switch to an alternate-day program.* A number of schedules can be used for transferring from a daily to an alternate-day program. The key points to be considered are flexibility in arranging a program and the use of supportive measures on the off day. One may attempt a gradual transition to the alternate-day schedule rather than an abrupt changeover. One approach is to keep the steroid dose constant on one day and gradually reduce it on the alternate day. Alternatively, the steroid dose can be increased on one day and reduced on the alternate day. In any case, it is important to anticipate that some increase in pain or discomfort may occur in the 36 to 48 h following the last dose.

WITHDRAWAL OF GLUCOCORTICOIDS FOLLOWING LONG-TERM USE It is possible to reduce a daily steroid dose gradually and eventually to discontinue it, but under most circumstances withdrawal of steroids should be initiated by first implementing an alternate-day schedule. Patients who have been on an alternate-day program for a month or more experience less difficulty during termination regimens. The dosage is gradually reduced and finally discontinued after a replacement dosage has been reached (e.g., 5 to 7.5 mg prednisone). Complications rarely ensue unless undue stress is experienced, and patients should understand that for ≥1 year after withdrawal from long-term high-dose steroid therapy, supplementary hormone should be given in the event of a serious infection, operation, or injury. A useful strategy in patients with symptoms of adrenal insufficiency on a tapering regimen is to measure plasma cortisol levels prior to the steroid dose. A level <140 nmol/L (5 μg/dL) indicates suppression of the pituitary-adrenal axis and implies that a more cautious tapering of steroids is indicated.

In patients on high-dose daily steroid therapy, it is advised to reduce dosage to ~20 mg prednisone daily as a single morning dose before beginning the transition to alternate-day therapy. If a patient cannot tolerate an alternate-day program, consideration should be given to the possibility that the patient has developed primary adrenal insufficiency.

322 PHEOCHROMOCYTOMA

Lewis Landsberg, James B. Young

Pheochromocytomas produce, store, and secrete catecholamines. They are usually derived from the adrenal medulla but may develop from chromaffin cells in or about sympathetic ganglia (extraadrenal pheochromocytomas or paragangliomas). Related tumors that secrete catecholamines and produce similar clinical syndromes include chemodectomas derived from the carotid body and ganglioneuromas derived from the postganglionic sympathetic neurons.

The clinical features are due predominantly to the release of catecholamines and, to a lesser extent, to the secretion of other substances. Hypertension is the most common sign, and hypertensive paroxysms or crises, often spectacular and alarming, occur in over half the cases.

Pheochromocytoma occurs in approximately 0.1% of the hypertensive population but is, nevertheless, an important correctable cause of high blood pressure. Indeed, it is usually curable if diagnosed and treated, but it may be fatal if undiagnosed or mistreated. Postmortem series indicate that most pheochromocytomas are unsuspected clinically, even when the tumor is related to the fatal outcome.

PATHOLOGY

Location and Morphology

In adults, approximately 80% of pheochromocytomas are unilateral and solitary, 10% are bilateral, and 10% are extraadrenal. In children, a fourth of tumors are bilateral, and an additional fourth are extraadrenal. Solitary lesions inexplicably favor the right side. Although pheochromocytomas may grow to large size (>3 kg), most weigh <100 g and are <10 cm in diameter. Pheochromocytomas are highly vascular.

The tumors are made up of large, polyhedral, pleomorphic chromaffin cells. Fewer than 10% of these tumors are malignant. As with several other endocrine tumors, malignancy cannot be determined from the histologic appearance; tumors that contain large numbers of aneuploid or tetraploid cells, as determined by flow cytometry, are more likely to recur. Local invasion of surrounding tissues or distant metastases indicate malignancy.

EXTRAADRENAL PHEOCHROMOCYTOMAS Extraadrenal pheochromocytomas usually weigh 20 to 40 g and are <5 cm in diameter. Most are located within the abdomen in association with the celiac, superior mesenteric, and inferior mesenteric ganglia. Approximately 10% are in the thorax, 1% are within the urinary bladder, and <3% are in the neck, usually in association with the sympathetic ganglia or the extracranial branches of the ninth or tenth cranial nerves.

Catecholamine Synthesis, Storage, and Release

Pheochromocytomas synthesize and store catecholamines by processes resembling those of the normal adrenal medulla. Little is known about the mechanisms of catecholamine release from pheochromocytomas, but changes in blood flow and necrosis within the tumor may be the cause in some instances. These tumors are not innervated, and catecholamine release does not result from neural stimulation. Pheochromocytomas also store and secrete a variety of peptides, including endogenous opioids, adrenomedullin, endothelin, erythropoietin, parathyroid hormone–related protein, neuropeptide Y, and chromagranin A. These peptides contribute to the clinical manifestations in selected cases, as noted below.

EPINEPHRINE, NOREPINEPHRINE, AND DOPAMINE Most pheochromocytomas produce both norepinephrine and epinephrine, and the percentage of norepinephrine is usually greater than in the normal adrenal. Most extraadrenal pheochromocytomas secrete norepinephrine exclusively. Rarely, pheochromocytomas produce epinephrine alone, particularly in association with multiple endocrine neoplasia (MEN). Although

epinephrine-producing tumors may cause a preponderance of metabolic and beta-receptor effects, in general the major catecholamine secreted cannot be predicted from the clinical presentation. Increased production of dopamine and homovanillic acid (HVA) is uncommon with benign lesions but may occur with malignant pheochromocytoma.

FAMILIAL PHEOCHROMOCYTOMA Pheochromocytoma may be inherited as an autosomal dominant trait either alone or in combination with other abnormalities such as MEN type 2A (Sipple's syndrome) or type 2B (mucosal neuroma syndrome) (Chap. 330), von Hippel–Lindau's (VHL) retinal cerebellar hemangioblastomosis, or von Recklinghausen's neurofibromatosis (type 1) and in association with paragangliomas of the neck. Recent evidence suggests that 25% of patients with pheochromocytoma may have an inherited form of the disease. Features that suggest familial disease include bilaterality, multicentricity (within the adrenal and at diverse sites), and age of onset <30 years.

GENETIC CONSIDERATIONS **MEN 2** The MEN 2A and 2B syndromes are associated with abnormalities in the *RET* protooncogene located in pericentromeric region of chromosome 10 (Chap. 330). These mutations result in the constitutive activation of the receptor tyrosine kinase, causing adrenal medullary chromaffin cell and thyroid parafollicular C cell hyperplasia and rendering the cells susceptible to malignant transformation. The *RET* mutations are located in the extracellular domain in MEN 2A and in the intracellular portion of the receptor in families with the MEN 2B syndrome. Mutations at specific sites in the *RET* protooncogene are highly predictive of pheochromocytoma. Pheochromocytomas in MEN 2 are multicentric and bilateral but not extraadrenal. Individuals at risk for MEN 2A and 2B should be screened periodically for pheochromocytoma by assay of a 24-h urine sample for catecholamines, including measurement of epinephrine. Pheochromocytoma should be excluded or removed before thyroid or parathyroid surgery.

VHL In the VHL syndrome, mutation of one copy of the VHL tumor-suppressor gene is associated with the development of tumors characteristic of the syndrome, including pheochromocytomas. Loss of function of the VHL tumor-suppressor gene promotes tumor formation by mechanisms that are incompletely understood but may involve alterations in mRNA transcript elongation. In the VHL syndrome, the frequency of pheochromocytoma varies considerably but may be as high as 60% in some kindreds. As in the MEN 2 syndromes, certain VHL mutations are highly associated with the development of pheochromocytoma. Of further interest is the recent finding that the VHL mutation has been identified in some kindreds with familial pheochromocytoma as the sole manifestation without other clinical evidence of the VHL syndrome. Missense mutations, as opposed to deletions, insertions, or nonsense mutations, appear to be more commonly associated with pheochromocytoma, which may be adrenal, extraadrenal, or multifocal. A high incidence of germ-line VHL mutations in patients with thoracic extraadrenal pheochromocytomas has also been reported.

Familial Paraganglioma Syndromes Mutations in the genes encoding succinate dehydrogenase subunit B (SDHB) and subunit D (SDHD) may occur in kindreds with inherited paraganglioma, usually located in the head or neck (glomus tumors) or carotid body. Paraganglioma in these syndromes are distinct from extraadrenal pheochromocytomas, which are also commonly referred to as *paragangliomas*. Adrenal or extraadrenal pheochromocytomas are often inherited in association with these paragangliomas.

Neurofibromatosis Type I Mutations in the *NF-I* gene predispose to the development of pheochromocytoma, although the association is not very common. It has been estimated that 1% of patients with pheochromocytoma have an *NF-I* mutation. Pheochromocytomas may occur in patients with minor clinical manifestations of neurofibromatosis such as a few café au lait spots, vertebral abnormalities, or kyphoscoliosis.

Nonsyndromic Familial Pheochromocytoma Patients presenting with a solitary adrenal pheochromocytoma, negative family history, and no evidence of associated disease may still have an inherited form of the disease. This is most common with the *SDHB* and *SDHD* mutations but also occurs with alterations in the *VHL* gene.

Screening for Genetic Disease Genetic screening for the *RET* mutation is available and of established utility in the evaluation of families for the MEN 2 syndromes. Genetic tests for the *SDH*, *NF-I*, and *VHL* mutations are not yet generally available. Screening in these kindreds therefore is dependent on a vigorous search for the associated diseases and a complete evaluation of family history.

CLINICAL FEATURES Pheochromocytoma occurs at all ages but is most common in young to midadult life. Some series show a slight female preponderance. Most patients come to medical attention as a result of hypertensive crisis, paroxysmal symptoms suggestive of seizure disorder or anxiety attacks, or hypertension that responds poorly to conventional treatment. Less commonly, unexplained hypotension or shock in association with surgery or trauma will suggest the diagnosis. Aberrant reactions to medications such as opioids or tricyclic antidepressants may bring the patient to clinical attention. In most patients the hypertension is associated with other symptoms, such as headaches, excessive sweating, and/or palpitations.

Hypertension Hypertension is the most common manifestation. In approximately 60% of cases the hypertension is sustained, although significant blood pressure lability is usually present, and half of patients with sustained hypertension have distinct crises or paroxysms. The other 40% have blood pressure elevations only during an attack. The hypertension is often severe, occasionally malignant, and may be resistant to treatment with standard antihypertensive drugs.

Paroxysms or Crises The paroxysm or crisis occurs in over half of patients. In an individual patient, the symptoms are often similar with each attack. The paroxysms may be frequent or sporadic, occurring at intervals as long as weeks or months. With time, the paroxysms usually increase in frequency, duration, and severity.

The attack usually has a sudden onset. It may last from a few minutes to several hours or longer. Headache, profuse sweating, palpitations, and apprehension, often with a sense of impending doom, are common. Pain in the chest or abdomen may be associated with nausea and vomiting. Either pallor or flushing may occur during the attack. The blood pressure is elevated, often to alarming levels, and the elevation is usually accompanied by tachycardia.

The paroxysm may be precipitated by any activity that displaces the abdominal contents. In some cases a particular stimulus may induce an attack in a characteristic fashion, but in others no clearly defined precipitating event can be found. Although anxiety may accompany the attacks, mental or psychological stress does not usually provoke a crisis.

Other Distinctive Clinical Features Symptoms and signs of an increased metabolic rate, such as profuse sweating and mild to moderate weight loss, are common. Orthostatic hypotension is a consequence of diminished plasma volume and blunted sympathetic reflexes. Both these factors predispose the patient with unsuspected pheochromocytoma to hypotension or shock during surgery or trauma. Secretion of the hypotensive peptide adrenomedullin may contribute to the hypotension in some patients.

CARDIAC MANIFESTATIONS Sinus tachycardia, sinus bradycardia, supraventricular arrhythmias, and ventricular premature contractions have all been noted. Angina and acute myocardial infarction may occur even in the absence of coronary artery disease. A catecholamine-induced increase in myocardial oxygen consumption and, perhaps, coronary spasm may play a role in these ischemic events. Electrocardiographic changes, including nonspecific ST-T wave changes, prominent U

waves, left ventricular strain patterns, and right and left bundle branch blocks may be present in the absence of demonstrable ischemia or infarction. Cardiomyopathy, either congestive with myocarditis and myocardial fibrosis or hypertrophic with concentric or asymmetric hypertrophy, may be associated with heart failure and cardiac arrhythmias. Multiorgan system failure with noncardiogenic pulmonary edema may be the presenting manifestation. Elevated levels of amylase originating from damaged pulmonary endothelium and abdominal pain may suggest acute pancreatitis, although serum lipase levels are normal.

CARBOHYDRATE INTOLERANCE Over half of patients have impaired carbohydrate tolerance due to suppression of insulin and stimulation of hepatic glucose output. The impaired glucose tolerance may require treatment with insulin and disappears after removal of the tumor.

HEMATOCRIT An elevated hematocrit may be secondary to diminished plasma volume. Rarely, production of erythropoietin by the tumor may cause a true erythrocytosis.

OTHER MANIFESTATIONS Hypercalcemia has been attributed to the ectopic secretion of parathyroid hormone–related protein. Fever and an elevated erythrocyte sedimentation rate have been reported in association with the production of interleukin 6. Elevated temperature more commonly reflects catecholamine-mediated increases in metabolic rate and diminished heat dissipation secondary to vasoconstriction. Polyuria is an occasional finding, and rhabdomyolysis with myoglobinuric renal failure may result from extreme vasoconstriction with muscle ischemia. Ectopic production of adrenocorticotropic hormone and vasoactive intestinal peptide have been documented in association with the characteristic manifestations of inappropriate secretion of these hormones (Chap. 317).

PHEOCHROMOCYTOMA OF THE URINARY BLADDER Pheochromocytoma in the wall of the urinary bladder may result in typical paroxysms in relation to micturition. The location in the bladder wall is responsible for the occurrence of symptoms while the tumors are quite small, and, consequently, catecholamine excretion may be normal or minimally elevated. Hematuria is present in over half of patients, and the tumor can often be visualized at cystoscopy.

Adverse Drug Interactions Severe and occasionally fatal paroxysms have been induced by opiates, histamine, adrenocorticotropin, saralasin, and glucagon. These agents appear to release catecholamines directly from the tumor. Indirect-acting sympathomimetic amines, including methyldopa (when administered intravenously), may increase blood pressure by releasing catecholamines from the augmented stores within nerve endings. Drugs that block neuronal uptake of catecholamines, such as tricyclic antidepressants, may enhance the physiologic effects of circulating catecholamines. Indeed, all medications should be considered carefully and administered cautiously in patients with known or suspected pheochromocytoma.

DIAGNOSIS The diagnosis is established by the demonstration of increased production of catecholamines or catecholamine metabolites. The diagnosis can usually be made by the analysis of a single 24-h urine sample, provided the patient is hypertensive or symptomatic at the time of collection.

Biochemical Tests The assays employed include those for vanillylmandelic acid (VMA), the metanephrines, and unconjugated or "free" catecholamines. The VMA assay is both less sensitive and less specific than assays of metanephrines or catecholamines. Accuracy of diagnosis is improved when two of three determinations are employed. The following considerations apply to all the urinary tests: (1) Despite claims for the adequacy of determinations made on random urine samples, analysis of a full 24-h urine sample is preferable. Creatinine should also be determined to assess the adequacy of collection. (2) Where possible, the collection should be made when the patient is at rest, on no medication, and without recent exposure to radiographic contrast media. When it is not practical to discontinue all medications, drugs known specifically to interfere with these assays (as noted below) should be avoided. (3) The urine should be acidified and refrigerated during and after collection. (4) With high-quality assays, dietary restrictions are minimal and should be specified by the laboratory performing the analyses. (5) Although most patients with pheochromocytoma excrete increased amounts of catecholamines and catecholamine metabolites at all times, the yield is increased in patients with paroxysmal hypertension if a 24-h urine collection is initiated during a crisis.

FREE CATECHOLAMINES The upper limit of normal for total urinary catecholamines is between 590 and 885 nmol (100 and 150 μg) per 24 h. In most patients with pheochromocytoma, values $>$1480 nmol (250 μg) per day are obtained. Measurement of epinephrine is often of value, since increased epinephrine excretion [$>$275 nmol (50 μg) per 24 h] is usually due to an adrenal lesion and may be the only abnormality in cases associated with MEN 2. False-positive increases in catecholamine excretion result from exogenous catecholamines and related drugs such as methyldopa, levodopa, labetalol, and sympathomimetic amines, which may elevate catecholamine excretion for up to 2 weeks. Endogenous catecholamines from stimulation of the sympathoadrenal system may also increase urinary catecholamine excretion. Relevant clinical situations that cause such increases include hypoglycemia, strenuous exertion, central nervous system disease with increased intracranial pressure, severe hypoxia, and clonidine withdrawal.

METANEPHRINES AND VMA In most laboratories, the upper limit of normal is 7 μmol (1.3 mg) of total metanephrines and 35 μmol (7.0 mg) of VMA excretion per 24 h. In most patients with pheochromocytoma, the increase in these urinary metabolites is considerable, often to more than three times the normal range. Metanephrine excretion is increased by exogenous and endogenous catecholamines and by treatment with monoamine oxidase inhibitors; propranolol may cause a spurious increase in metanephrine excretion, since a propranolol metabolite interferes in the commonly used spectrophotometric assay. VMA is less affected by endogenous and exogenous catecholamines but is spuriously increased by a variety of drugs, including carbidopa. VMA excretion is decreased by monoamine oxidase inhibitors.

PLASMA CATECHOLAMINES Measurement of plasma catecholamines has a limited application. The care required in obtaining basal levels and the satisfactory results with urinary determinations make measurement of plasma catecholamines unnecessary in most cases. Plasma catecholamine levels are affected by the same drugs and physiologic perturbations that increase urinary catecholamine excretion. In addition, α- and β-adrenergic receptor blocking agents may elevate plasma catecholamines by impairing clearance.

When the clinical features suggest pheochromocytoma and the urinary assay results are borderline, measurement of plasma catecholamines may be worthwhile. Markedly elevated basal levels of total catecholamines support the diagnosis, although approximately one-third of patients with pheochromocytoma have normal or slightly elevated basal values. The usefulness of plasma catecholamine determinations may be increased by agents that suppress sympathetic nervous system activity. Clonidine and ganglionic blocking agents reduce plasma catecholamine levels in normal subjects and in patients with essential hypertension. These drugs have little effect on catecholamine levels in patients with pheochromocytoma. In patients with elevated or borderline basal catecholamine values, failure to suppress plasma or urinary levels with clonidine supports the diagnosis of pheochromocytoma.

PLASMA METANEPHRINES Measurement of free (unconjugated) total plasma metanephrines, fractionated into normetanephrine and metanephrine, is a highly sensitive technique for the diagnosis of pheochromocytoma. Questions of specificity, particularly among the elderly, as well as the availability of high-quality assays need to be addressed before plasma metanephrines replace the 24-h urinary meas-

urement of free catecholamines and metanephrines as the screening test of choice.

Pharmacologic Tests Reliable methods for the measurement of catecholamines and catecholamine metabolites in urine have rendered obsolete both the provocative and adrenolytic tests, which are nonspecific and entail considerable risk. A modified version of the adrenolytic test may be of some use, however, as a therapeutic trial in a patient in hypertensive crisis with features suggestive of pheochromocytoma. A positive response to phentolamine (5-mg bolus following a test dose of 0.5 mg) is a reduction in blood pressure of at least 35/25 mmHg after 2 min that persists for 10 to 15 min. The pharmacologic response is never diagnostic, and biochemical confirmation is essential. Provocative tests in normotensive patients are potentially dangerous and rarely indicated. However, a glucagon provocative test may be of use in patients with paroxysmal hypertension and nondiagnostic basal catecholamine levels. Glucagon has a negligible effect on blood pressure or plasma catecholamine levels in normal or hypertensive subjects. In patients with pheochromocytoma, on the other hand, glucagon may increase both blood pressure and circulating catecholamine levels. The elevation in plasma catecholamine concentration, moreover, may occur without a blood pressure response. It must be emphasized, however, that life-threatening pressor crises have occurred after administration of glucagon to patients with pheochromocytoma, so the test should never be performed casually. Careful continuous monitoring of the blood pressure is required, intravenous access must be adequate, and phentolamine must be at hand to terminate the test if a significant pressor reaction ensues.

Differential Diagnosis Since the manifestations of pheochromocytoma can be protean, the diagnosis must be considered and excluded in many patients with suggestive clinical features. In patients with essential hypertension and "hyperadrenergic" features such as tachycardia, sweating, and increased cardiac output, and in patients with anxiety attacks associated with blood pressure elevations, analysis of a 24-h urine collection is usually decisive in excluding the diagnosis. Repeated determinations on urine collected during attacks may be necessary, however, before the diagnosis can be excluded with certainty. Pressor crises associated with clonidine withdrawal and the use of cocaine or monoamine oxidase inhibitors may mimic the paroxysms of pheochromocytoma. Factitious crises may be produced by self-administration of sympathomimetic amines in psychiatrically disturbed patients.

Intracranial lesions, particularly posterior fossa tumors or subarachnoid hemorrhage, may cause hypertension and increased excretion of catecholamines or catecholamine metabolites. While this is most common in patients with an obvious neurologic catastrophe, the possibility of subarachnoid or intracranial hemorrhage secondary to pheochromocytoma should be considered. Diencephalic or autonomic epilepsy may be associated with paroxysmal spells, hypertension, and increased plasma catecholamine levels. This rare entity may be difficult to distinguish from pheochromocytoma, but an aura, an abnormal electroencephalogram, and a beneficial response to anticonvulsant medications will often suggest this diagnosis.

TREATMENT

Preoperative Management The induction of stable α-adrenergic blockade provides the foundation for successful surgical treatment. Once the diagnosis is established, the patient should be placed on phenoxybenzamine to induce a long-lasting, noncompetitive α-receptor blockade. The usual initial dose is 10 mg every 12 h, with increments of 10 to 20 mg added every few days until the blood pressure is controlled and the paroxysms disappear. Because of the long duration of action, the therapeutic effects are cumulative, and the optimal dose must be achieved gradually with careful monitoring of supine and upright blood pressures. Most patients require between 40 and 80 mg phenoxybenzamine per day, although $\geq$200 mg may be necessary. Phenoxybenzamine should be administered for at least 10 to 14 days prior to surgery. Over this time, the combination of α-receptor blockade and a liberal salt intake will restore the contracted plasma volume to normal. Before adequate α-adrenergic blockade with phenoxybenzamine is achieved, paroxysms may be treated with oral prazosin or intravenous phentolamine. Selective α_1 antagonists have been employed for preoperative preparation, but their role in preparative management should be limited to the treatment of individual paroxysms. They may be useful as antihypertensive agents in patients with suspected pheochromocytoma while workup is in progress, since they are usually better tolerated than phenoxybenzamine and will prevent serious pressor crises if pheochromocytoma is present. Nitroprusside, calcium channel blocking agents, and possibly angiotensin-converting enzyme inhibitors reduce blood pressure in patients with pheochromocytoma. Nitroprusside may also be useful in the treatment of pressor crises.

β-Adrenergic receptor blocking agents should be given only after alpha blockade has been induced, since administration of such agents by themselves may cause a paradoxic increase in blood pressure by antagonizing beta-mediated vasodilation in skeletal muscle. Beta blockade is usually initiated when tachycardia develops during the induction of α-adrenergic blockade. Low doses often suffice, and a reasonable starting dose is 10 mg propranolol three to four times per day, increased as needed to control the pulse rate. Beta blockade is effective for catecholamine-induced arrhythmias, particularly those potentiated by anesthetic agents.

Preoperative Localization of the Tumor Once pheochromocytoma is diagnosed, localization should be undertaken while the patient is being prepared for surgery. Computed tomography (CT) or magnetic resonance imaging (MRI) of the adrenals is usually successful in identifying intraadrenal lesions. Extraadrenal tumors within the chest can frequently be identified by conventional chest films or CT. MRI or positron emission tomography (PET) scanning with ^{18}F dopa is useful in identifying extraadrenal tumors. Abdominal aortography (once α-adrenergic blockade is complete) or venous sampling at different levels of the inferior and superior vena cava in search of catecholamine gradients has been useful in the past but are rarely necessary now. An additional localization technique involves a radionuclide scintiscan after administration of the radiopharmaceutical [^{131}I]metaiodobenzylguanidine (MIBG). This agent is concentrated by the amine uptake process and produces an external scintigraphic image at the site of the tumor. This type of scanning may be useful in characterizing lesions discovered by CT when biochemical confirmation is indeterminate but is less useful at localizing extraadrenal pheochromocytomas than MRI or PET. Percutaneous fine-needle aspiration of chromaffin tumors is contraindicated; indeed, pheochromocytoma should be considered before adrenal lesions are aspirated.

Surgery Surgical treatment of pheochromocytoma is best performed in centers with experience in the preoperative, anesthetic, and intraoperative management of pheochromocytoma. Surgical mortality is $<$2 or 3%. Extensive experience with the laparoscopic approach over the past decade has demonstrated that in experienced hands pheochromocytoma can be safely and efficiently removed by this technique.

Monitoring during the surgical procedure should include continuous recording of arterial pressure and central venous pressure as well as electrocardiography; in the presence of cardiac disease or if congestive failure has been present, pulmonary capillary wedge pressure should be monitored. Adequate fluid replacement is crucial. Intraoperative hypotension responds better to volume replacement than to vasoconstrictors. Hypertension and cardiac arrhythmias are most likely during induction of anesthesia, intubation, and manipulation of the tumor. Intravenous phentolamine is usually sufficient to control the blood pressure, but nitroprusside may be required. Propranolol may be given in the treatment of tachycardia or ventricular ectopy.

PHEOCHROMOCYTOMA IN PREGNANCY Spontaneous labor and vaginal delivery in unprepared patients are usually disastrous for mother and fetus. In early pregnancy, the patient should be prepared with phenoxyben-

zamine, and the tumor should be removed as soon as the diagnosis is confirmed. The pregnancy need not be terminated, but the operative procedure itself may result in spontaneous abortion. In the third trimester, treatment with adrenergic blocking agents should be undertaken; when the fetus is of sufficient size, cesarean section may be followed by extirpation of the tumor. Although the safety of adrenergic blocking drugs in pregnancy is not established, these agents have been administered in several cases without obvious adverse effect. Antepartum diagnosis and treatment lowers the maternal death rate to that approaching nonpregnant pheochromocytoma patients; fetal death rate, however, remains elevated.

UNRESECTABLE AND MALIGNANT TUMORS In cases of metastatic or locally invasive tumor in patients with intercurrent illness that precludes surgery, long-term medical management is required. When the manifestations cannot be adequately controlled by adrenergic blocking agents, the concomitant administration of metyrosine may be required. This agent inhibits tyrosine hydroxylase, diminishes catecholamine production by the tumor, and often simplifies chronic management. Malignant pheochromocytoma frequently recurs in the retroperitoneum, and it metastasizes most commonly to bone and lung. Although these malignant tumors are resistant to radiotherapy, combination chemotherapy is occasionally of some benefit. Use of ^{131}I-MIBG has had limited success in the treatment of malignant pheochromocytoma, due to poor uptake of the radioligand.

PROGNOSIS AND FOLLOW-UP The 5-year survival rate after surgery is usually >95%, the recurrence rate is <10%. After successful surgery, catecholamine excretion returns to normal in about 2 weeks and should be measured to ensure complete tumor removal. Catecholamine excretion should be assessed at the reappearance of suggestive symptoms or yearly if the patient remains asymptomatic. For malignant pheochromocytoma, the 5-year survival rate is usually <50%, although long-term survival is occasionally noted.

Complete removal cures the hypertension in approximately three-fourths of patients. In the remainder, hypertension recurs but is usually well controlled by standard antihypertensive agents. In this group, either underlying essential hypertension or irreversible vascular damage induced by catecholamines may cause the persistence of the hypertension.

323 DIABETES MELLITUS

Alvin C. Powers

Diabetes mellitus (DM) comprises a group of common metabolic disorders that share the phenotype of hyperglycemia. Several distinct types of DM exist and are caused by a complex interaction of genetics, environmental factors, and life-style choices. Depending on the etiology of the DM, factors contributing to hyperglycemia may include reduced insulin secretion, decreased glucose utilization, and increased glucose production. The metabolic dysregulation associated with DM causes secondary pathophysiologic changes in multiple organ systems that impose a tremendous burden on the individual with diabetes and on the health care system. In the United States, DM is the leading cause of end-stage renal disease (ESRD), nontraumatic lower extremity amputations, and adult blindness. With an increasing incidence worldwide, DM will be a leading cause of morbidity and mortality for the foreseeable future.

CLASSIFICATION

DM is classified on the basis of the pathogenic process that leads to hyperglycemia, as opposed to earlier criteria such as age of onset or type of therapy (Fig. 323-1). The two broad categories of DM are designated type 1 and type 2 (Table 323-1). Type 1A DM results from autoimmune beta cell destruction, which leads to insulin deficiency. Individuals with type 1B DM lack immunologic markers indicative of an autoimmune destructive process of the beta cells. However, they develop insulin deficiency by unknown mechanisms and are ketosis prone. Relatively few patients with type 1 DM are in the type 1B idiopathic category; many of these individuals are either African-American or Asian in heritage.

Type 2 DM is a heterogeneous group of disorders characterized by variable degrees of insulin resistance, impaired insulin secretion, and increased glucose production. Distinct genetic and metabolic defects in insulin action and/or secretion give rise to the common phenotype of hyperglycemia in type 2 DM (see below). Distinct pathogenic processes in type 2 DM have important potential therapeutic implications, as pharmacologic agents that target specific metabolic derangements

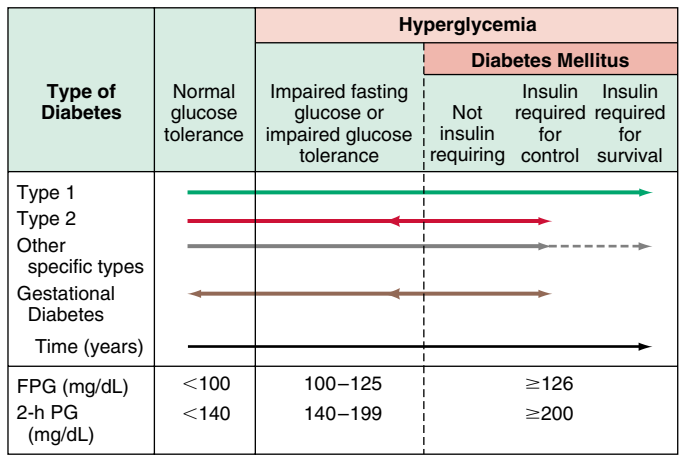

FIGURE 323-1 Spectrum of glucose homeostasis and diabetes mellitus (DM). The spectrum from normal glucose tolerance to diabetes in type 1 DM, type 2 DM, other specific types of diabetes, and gestational DM is shown from left to right. In most types of DM, the individual traverses from normal glucose tolerance to impaired glucose tolerance to overt diabetes. Arrows indicate that changes in glucose tolerance may be bi-directional in some types of diabetes. For example, individuals with type 2 DM may return to the impaired glucose tolerance category with weight loss; in gestational DM diabetes may revert to impaired glucose tolerance or even normal glucose tolerance after delivery. The fasting plasma glucose (FPG) and 2-h plasma glucose (PG), after a glucose challenge for the different categories of glucose tolerance, are shown at the lower part of the figure. These values do not apply to the diagnosis of gestational DM. Some types of DM may or may not require insulin for survival, hence the dotted line. (Conventional units are used in the figure.) *(Adapted from American Diabetes Association, 2004.)*

TABLE 323-1 Etiologic Classification of Diabetes Mellitus

I. Type 1 diabetes (β-cell destruction, usually leading to absolute insulin deficiency)
  A. Immune-mediated
  B. Idiopathic
II. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)
III. Other specific types of diabetes
  A. Genetic defects of β-cell function characterized by mutations in:
    1. Hepatocyte nuclear transcription factor (HNF) 4α (MODY 1)
    2. Glucokinase (MODY 2)
    3. HNF-1α (MODY 3)
    4. Insulin promoter factor (IPF) 1 (MODY 4)
    5. HNF-1β (MODY 5)
    6. NeuroD1 (MODY 6)
    7. Mitochondrial DNA
    8. Proinsulin or insulin conversion
  B. Genetic defects in insulin action
    1. Type A insulin resistance
    2. Leprechaunism
    3. Rabson-Mendenhall syndrome
    4. Lipodystrophy syndromes
  C. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy
  D. Endocrinopathies—acromegaly, Cushing's syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
  E. Drug- or chemical-induced—Vacor, pentamidine, nicotinic acid, glucocorticoids, thyroid hormone, diazoxide, β-adrenergic agonists, thiazides, phenytoin, α-interferon, protease inhibitors, clozapine, beta blockers
  F. Infections—congenital rubella, cytomegalovirus, coxsackie
  G. Uncommon forms of immune-mediated diabetes—"stiff-man" syndrome, anti-insulin receptor antibodies
  H. Other genetic syndromes sometimes associated with diabetes—Down's syndrome, Klinefelter's syndrome, Turner's syndrome, Wolfram's syndrome, Friedreich's ataxia, Huntington's chorea, Laurence-Moon-Biedl syndrome, myotonic dystrophy, porphyria, Prader-Willi syndrome
IV. Gestational diabetes mellitus (GDM)

Note: MODY, maturity onset of diabetes of the young.
Source: Adapted from American Diabetes Association, 2004.

have become available. Type 2 DM is preceded by a period of abnormal glucose homeostasis classified as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT).

Two features of the current classification of DM diverge from previous classifications. First, the terms *insulin-dependent diabetes mellitus* (IDDM) and *noninsulin-dependent diabetes mellitus* (NIDDM) are obsolete. Since many individuals with type 2 DM eventually require insulin treatment for control of glycemia, the use of the term NIDDM generated considerable confusion. A second difference is that age is not a criterion in the classification system. Although type 1 DM most commonly develops before the age of 30, an autoimmune beta cell destructive process can develop at any age. It is estimated that between 5 and 10% of individuals who develop DM after age 30 have type 1A DM. Likewise, type 2 DM more typically develops with increasing age, but it also occurs in children, particularly in obese adolescents.

OTHER TYPES OF DM Other etiologies for DM include specific genetic defects in insulin secretion or action, metabolic abnormalities that impair insulin secretion, mitochondrial abnormalities, and a host of conditions that impair glucose tolerance (Table 323-1). *Maturity onset diabetes of the young* (MODY) is a subtype of DM characterized by autosomal dominant inheritance, early onset of hyperglycemia, and impairment in insulin secretion (discussed below). Mutations in the insulin receptor cause a group of rare disorders characterized by severe insulin resistance.

DM can result from pancreatic exocrine disease when the majority of pancreatic islets (>80%) are destroyed. Hormones that antagonize the action of insulin can lead to DM. Thus, DM is often a feature of endocrinopathies, such as acromegaly and Cushing's disease. Viral infections have been implicated in pancreatic islet destruction, but are an extremely rare cause of DM. Congenital rubella greatly increases the risk for DM; however, most of these individuals also have immunologic markers indicative of autoimmune beta cell destruction.

GESTATIONAL DIABETES MELLITUS (GDM) Glucose intolerance may develop during pregnancy. Insulin resistance related to the metabolic changes of late pregnancy increases insulin requirements and may lead to IGT. GDM occurs in approximately 4% of pregnancies in the United States; most women revert to normal glucose tolerance post-partum but have a substantial risk (30 to 60%) of developing DM later in life.

EPIDEMIOLOGY

The worldwide prevalence of DM has risen dramatically over the past two decades. Likewise, prevalence rates of IFG are also increasing. Although the prevalence of both type 1 and type 2 DM is increasing worldwide, the prevalence of type 2 DM is expected to rise more rapidly in the future because of increasing obesity and reduced activity levels. DM increases with aging. In 2000, the prevalence of DM was estimated to be 0.19% in people <20 years old and 8.6% in people >20 years old. In individuals >65 years the prevalence of DM was 20.1%. The prevalence is similar in men and women throughout most age ranges but is slightly greater in men >60 years.

There is considerable geographic variation in the incidence of both type 1 and type 2 DM. Scandinavia has the highest incidence of type 1 DM (e.g., in Finland, the incidence is 35/100,000 per year). The Pacific Rim has a much lower rate (in Japan and China, the incidence is 1 to 3/100,000 per year) of type 1 DM; Northern Europe and the United States share an intermediate rate (8 to 17/100,000 per year). Much of the increased risk of type 1 DM is believed to reflect the frequency of high-risk HLA alleles among ethnic groups in different geographic locations. The prevalence of type 2 DM and its harbinger, IGT, is highest in certain Pacific islands, intermediate in countries such as India and the United States, and relatively low in Russia and China. This variability is likely due to genetic, behavioral, and environmental factors. DM prevalence also varies among different ethnic populations within a given country. In 2000, the prevalence of DM in the United States was 13% in African Americans, 10.2% in Hispanic Americans, 15.5% in Native Americans (American Indians and Alaska natives), and 7.8% in non-Hispanic whites. The onset of type 2 DM occurs, on average, at an earlier age in ethnic groups other than non-Hispanic whites.

DIAGNOSIS

The National Diabetes Data Group and World Health Organization have issued diagnostic criteria for DM (Table 323-2) based on the following premises: (1) the spectrum of fasting plasma glucose (FPG) and the response to an oral glucose load varies among normal indi-

TABLE 323-2 Criteria for the Diagnosis of Diabetes Mellitus

- Symptoms of diabetes plus random blood glucose concentration ≥11.1 mmol/L (200 mg/dL)[a] *or*
- Fasting plasma glucose ≥7.0 mmol/L (126 mg/dL)[b] *or*
- Two-hour plasma glucose ≥11.1 mmol/L (200 mg/dL) during an oral glucose tolerance test[c]

[a] Random is defined as without regard to time since the last meal.
[b] Fasting is defined as no caloric intake for at least 8 h.
[c] The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; not recommended for routine clinical use.
Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.
Source: Modified from American Diabetes Association, 2004.

viduals, and (2) DM is defined as the level of glycemia at which diabetes-specific complications occur rather than on deviations from a population-based mean. For example, the prevalence of retinopathy in Native Americans (Pima Indian population) begins to increase at a FPG > 6.4 mmol/L (116 mg/dL) (Fig. 323-2).

Glucose tolerance is classified into three categories based on the FPG: (1) FPG < 5.6 mmol/L (100 mg/dL) is considered normal; (2) FPG ≥ 5.6 mmol/L (100 mg/dL) but <7.0 mmol/L (126 mg/dL) is defined as IFG; and (3) FPG ≥ 7.0 mmol/L (126 mg/dL) warrants the diagnosis of DM. IFG is comparable to IGT, which is defined as plasma glucose levels between 7.8 and 11.1 mmol/L (140 and 200 mg/dL) 2 h after a 75-g oral glucose load (Table 323-2). Individuals with IFG or IGT are at substantial risk for developing type 2 DM (40% risk over the next 5 years) and cardiovascular disease.

The revised criteria for the diagnosis of DM emphasize the FPG as a reliable and convenient test for diagnosing DM in asymptomatic individuals. A random plasma glucose concentration ≥11.1 mmol/L (200 mg/dL) accompanied by classic symptoms of DM (polyuria, polydipsia, weight loss) is sufficient for the diagnosis of DM (Table 323-2). Oral glucose tolerance testing, although still a valid mechanism for diagnosing DM, is not recommended as part of routine care.

Some investigators have advocated the hemoglobin A1c (A1C) as a diagnostic test for DM. Though there is a strong correlation between elevations in the plasma glucose and the A1C (discussed below), the relationship between the FPG and the A1C in individuals with normal glucose tolerance or mild glucose intolerance is less clear and thus the use of the A1C is not currently recommended for the diagnosis of diabetes.

The diagnosis of DM has profound implications for an individual from both a medical and financial standpoint. Thus, these diagnostic criteria must be satisfied before assigning the diagnosis of DM. Abnormalities on screening tests for diabetes should be repeated before making a definitive diagnosis of DM, unless acute metabolic derangements or a markedly elevated plasma glucose are present (Table 323-2). The revised criteria also allow for the diagnosis of DM to be withdrawn in situations where the FPG reverts to normal.

SCREENING Widespread use of the FPG as a screening test for type 2 DM is recommended because: (1) a large number of individuals who meet the current criteria for DM are asymptomatic and unaware that they have the disorder, (2) epidemiologic studies suggest that type 2 DM may be present for up to a decade before diagnosis, (3) as many as 50% of individuals with type 2 DM have one or more diabetes-specific complications at the time of their diagnosis, and (4) treatment of type 2 DM may favorably alter the natural history of DM. The American Diabetes Association (ADA) recommends screening all individuals >45 years every 3 years and screening individuals with additional risk factors (Table 323-3) at an earlier age. In contrast to type 2 DM, a long asymptomatic period of hyperglycemia is rare prior to the diagnosis of type 1 DM. A number of immunologic markers for type 1 DM are becoming available (discussed below), but their routine use is discouraged pending the identification of clinically beneficial interventions for individuals at high risk for developing type 1 DM.

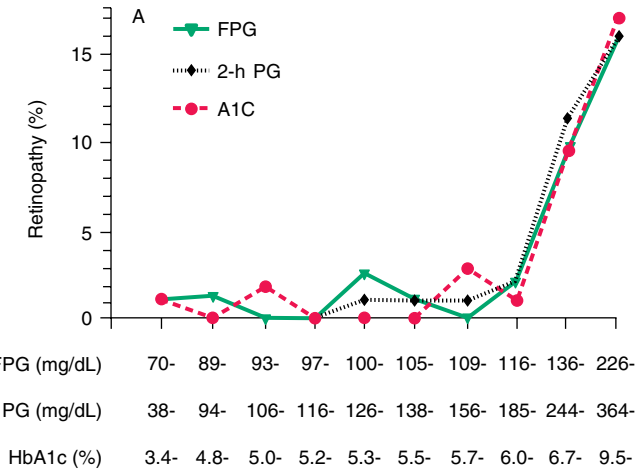

FIGURE 323-2 Relationship of diabetes-specific complication and glucose tolerance. This figure shows the incidence of retinopathy in Pima Indians as a function of the fasting plasma glucose (FPG), the 2-h plasma glucose after a 75-g oral glucose challenge (2-h PG), or glycated hemoglobin (A1C). Note that the incidence of retinopathy greatly increases at a fasting plasma glucose >116 mg/dL, or a 2-h plasma glucose of 185 mg/dL, or a A1C >6.0%. (Conventional units for blood glucose are used in the figure.) *(Copyright 2002, American Diabetes Association. From Diabetes Care 25(Suppl 1): 55–520, 2002.)*

INSULIN BIOSYNTHESIS, SECRETION, AND ACTION

BIOSYNTHESIS Insulin is produced in the beta cells of the pancreatic islets. It is initially synthesized as a single-chain 86-amino-acid precursor polypeptide, preproinsulin. Subsequent proteolytic processing removes the aminoterminal signal peptide, giving rise to proinsulin. Proinsulin is structurally related to insulin-like growth factors I and II, which bind weakly to the insulin receptor (Chap. 317). Cleavage of an internal 31-residue fragment from proinsulin generates the C peptide and the A (21 amino acids) and B (30 amino acids) chains of insulin, which are connected by disulfide bonds. The mature insulin molecule and C peptide are stored together and cosecreted from secretory granules in the beta cells. Because the C peptide is less susceptible than insulin to hepatic degradation, it is a useful marker of insulin secretion and allows discrimination of endogenous and exogenous sources of insulin in the evaluation of hypoglycemia (Chap. 324). Human insulin is now produced by recombinant DNA technology; structural alterations at one or more residues are useful for modifying its physical and pharmacologic characteristics (see below).

SECRETION Glucose is the key regulator of insulin secretion by the pancreatic beta cell, although amino acids, ketones, various nutrients, gastrointestinal peptides, and neurotransmitters also influence insulin secretion. Glucose levels >3.9 mmol/L (70 mg/dL) stimulate insulin synthesis, primarily by enhancing protein translation and processing. Glucose stimulation of insulin secretion begins with its transport into the beta cell by the GLUT2 glucose transporter (Fig. 323-3). Glucose phosphorylation by glucokinase is the rate-limiting step that controls glucose-regulated insulin secretion. Further metabolism of glucose-6-phosphate via glycolysis generates ATP, which inhibits the activity of an ATP-sensitive K^+ channel. This channel consists of two separate proteins: one is the receptor for certain oral hypoglycemics (e.g., sulfonylureas, meglitinides); the other is an inwardly rectifying K^+ channel protein. Inhibition of this K^+ channel induces beta cell membrane depolarization, which opens voltage-dependent calcium channels (leading to an influx of calcium), and stimulates insulin secretion. Insulin secretory profiles reveal a pulsatile pattern of hormone release, with small secretory bursts occurring about every 10 min, superimposed upon greater amplitude oscillations of about 80 to 150 min. Meals or other major stimuli of insulin secretion induce large (four-

TABLE 323-3 *Risk Factors for Type 2 Diabetes Mellitus*

- Family history of diabetes (i.e., parent or sibling with type 2 diabetes)
- Obesity (BMI ≥ 25 kg/m^2)
- Habitual physical inactivity
- Race/ethnicity (e.g., African American, Hispanic American, Native American, Asian American, Pacific Islander)
- Previously identified IFG or IGT
- History of GDM or delivery of baby >4 kg (>9 lb)
- Hypertension (blood pressure ≥ 140/90 mmHg)
- HDL cholesterol level ≤ 35 mg/dL (0.90 mmol/L) and/or a triglyceride level ≥250 mg/dL (2.82 mmol/L)
- Polycystic ovary syndrome or acanthosis nigracans
- History of vascular disease

Note: BMI, body mass index; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein.
Source: Adapted from American Diabetes Association, 2004.

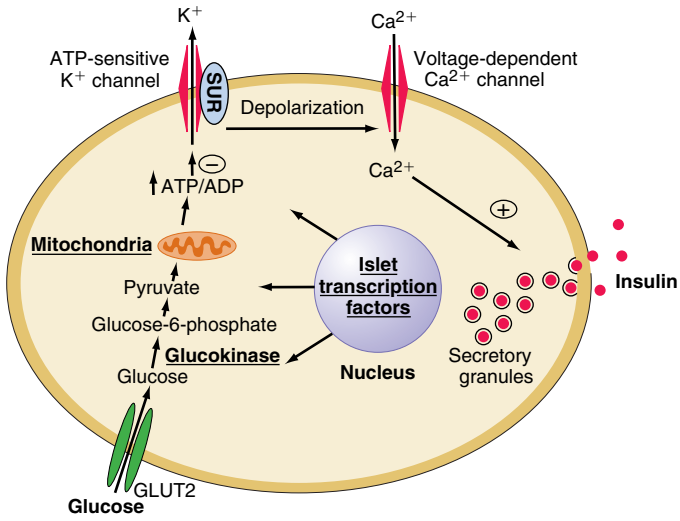

FIGURE 323-3 Diabetes and abnormalities in glucose-stimulated insulin secretion. Glucose and other nutrients regulate insulin secretion by the pancreatic beta cell. Glucose is transported by the GLUT2 glucose transporter; subsequent glucose metabolism by the beta cell alters ion channel activity, leading to insulin secretion. The SUR receptor is the binding site for drugs that act as insulin secretagogues. Mutations in the events or proteins underlined are a cause of maturity onset diabetes of the young (MODY) or other forms of diabetes. SUR, sulfonylurea receptor; ATP, adenosine triphosphate; ADP, adenosine diphosphate. *(Adapted from WL Lowe, in JL Jameson (ed): Principles of Molecular Medicine. Totowa, NJ, Humana, 1998.)*

to fivefold increase versus baseline) bursts of insulin secretion that usually last for 2 to 3 h before returning to baseline. Derangements in these normal secretory patterns are one of the earliest signs of beta cell dysfunction in DM.

ACTION Once insulin is secreted into the portal venous system, ~50% is degraded by the liver. Unextracted insulin enters the systemic circulation where it binds to receptors in target sites. Insulin binding to its receptor stimulates intrinsic tyrosine kinase activity, leading to receptor autophosphorylation and the recruitment of intracellular signaling molecules, such as insulin receptor substrates (IRS) (Fig. 323-4). These and other adaptor proteins initiate a complex cascade of phosphorylation and dephosphorylation reactions, resulting in the widespread metabolic and mitogenic effects of insulin. As an example, activation of the phosphatidylinositol-3′-kinase (PI-3-kinase) pathway stimulates translocation of glucose transporters (e.g., GLUT4) to the cell surface, an event that is crucial for glucose uptake by skeletal muscle and fat. Activation of other insulin receptor signaling pathways induces glycogen synthesis, protein synthesis, lipogenesis, and regulation of various genes in insulin-responsive cells.

Glucose homeostasis reflects a precise balance between hepatic glucose production and peripheral glucose uptake and utilization. Insulin is the most important regulator of this metabolic equilibrium, but neural input, metabolic signals, and hormones (e.g., glucagon) result in integrated control of glucose supply and utilization (Chap. 324; see Fig. 324-1). In the fasting state, low insulin levels increase glucose production by promoting hepatic gluconeogenesis and glycogenolysis. Glucagon also stimulates glycogenolysis and gluconeogenesis by the liver and renal medulla. Low insulin levels decrease glycogen synthesis, reduce glucose uptake in insulin-sensitive tissues, and promote mobilization of stored precursors. Postprandially, the glucose load elicits a rise in insulin and fall in glucagon, leading to a reversal of these processes. The major portion of postprandial glucose is utilized by skeletal muscle, an effect of insulin-stimulated glucose uptake. Other tissues, most notably the brain, utilize glucose in an insulin-independent fashion.

PATHOGENESIS

TYPE 1 DM Type 1A DM develops as a result of the synergistic effects of genetic, environmental, and immunologic factors that ultimately destroy the pancreatic beta cells. The temporal development of type 1A DM is shown schematically as a function of beta cell mass in Fig. 323-5. Individuals with a genetic susceptibility have normal beta cell mass at birth but begin to lose beta cells secondary to autoimmune destruction that occurs over months to years. This autoimmune process is thought to be triggered by an infectious or environmental stimulus and to be sustained by a beta cell–specific molecule. In the majority of individuals, immunologic markers appear after the triggering event but before diabetes becomes clinically overt. Beta cell mass then begins to decline, and insulin secretion becomes progressively impaired, although normal glucose tolerance is maintained. The rate of decline in beta cell mass varies widely among individuals, with some patients progressing rapidly to clinical diabetes and others evolving more slowly. Features of diabetes do not become evident until a majority of beta cells are destroyed (~80%). At this point, residual functional beta cells still exist but are insufficient in number to maintain glucose tolerance. The events that trigger the transition from glucose intolerance to frank diabetes are often associated with increased insulin requirements, as might occur during infections or puberty. After the initial clinical presentation of type 1A DM, a "honeymoon" phase may ensue during which time glycemic control is achieved with modest doses of insulin or, rarely, insulin is not needed. However, this fleeting phase of endogenous insulin production from residual beta cells disappears

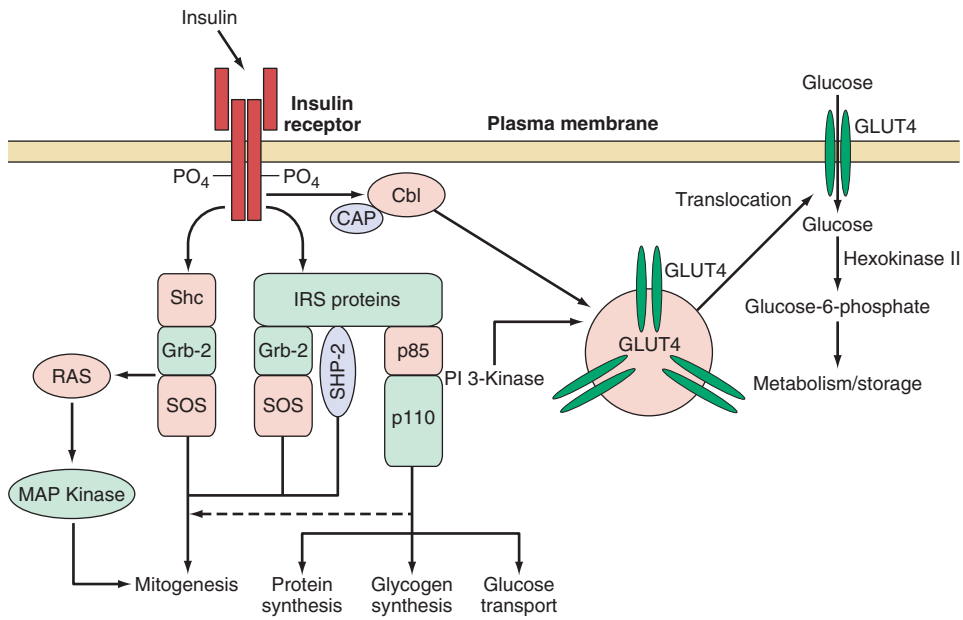

FIGURE 323-4 Insulin signal transduction pathway in skeletal muscle. The insulin receptor has intrinsic tyrosine kinase activity and interacts with insulin receptor substrates (IRS and Shc) proteins. A number of "docking" proteins bind to these cellular proteins and initiate the metabolic actions of insulin [GrB-2, SOS, SHP-2, p65, p110, and phosphatidylinositol-3′-kinase (PI-3-kinase)]. Insulin increases glucose transport through PI-3-kinase and the Cbl pathway, which promotes the translocation of intracellular vesicles containing GLUT4 glucose transporter to the plasma membrane. *(Adapted from WL Lowe, in Principles of Molecular Medicine, JL Jameson (ed). Totowa, NJ, Humana, 1998; A Virkamaki et al: J Clin Invest 103:931, 1999. For additional details see Saltiel and Kahn, 2001.)*

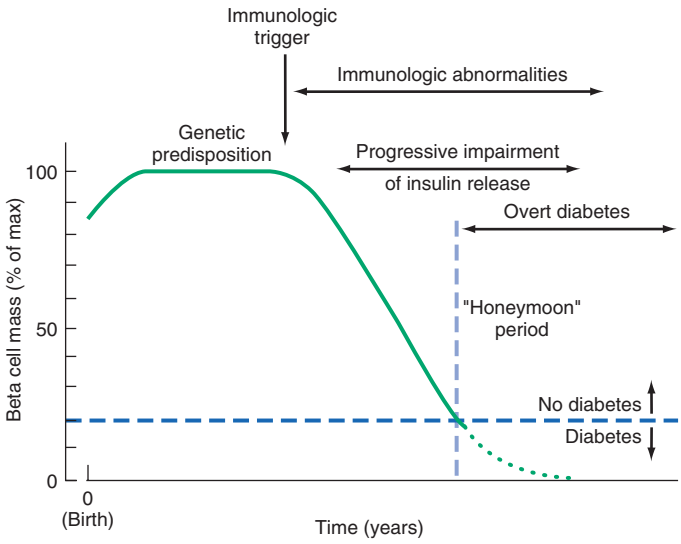

FIGURE 323-5 Temporal model for development of type 1 diabetes. Individuals with a genetic predisposition are exposed to an immunologic trigger that initiates an autoimmune process, resulting in a gradual decline in beta cell mass. The downward slope of the beta cell mass varies among individuals. This progressive impairment in insulin release results in diabetes when ~80% of the beta cell mass is destroyed. A "honeymoon" phase may be seen in the first 1 or 2 years after the onset of diabetes and is associated with reduced insulin requirements. *(Adapted from Medical Management of Type 1 Diabetes, 3d ed, JS Skyler (ed). Alexandria, VA, American Diabetes Association, 1998.)*

as the autoimmune process destroys the remaining beta cells, and the individual becomes completely insulin deficient.

GENETIC CONSIDERATIONS Genetic susceptibility to type 1A DM involves multiple genes. The concordance of type 1A DM in identical twins ranges between 30 and 70%, indicating that additional modifying factors must be involved in determining whether diabetes develops. The major susceptibility gene for type 1A DM is located in the HLA region on chromosome 6. Polymorphisms in the HLA complex account for 40 to 50% of the genetic risk of developing type 1A DM. This region contains genes that encode the class II MHC molecules, which present antigen to helper T cells and thus are involved in initiating the immune response (Chap. 296). The ability of class II MHC molecules to present antigen is dependent on the amino acid composition of their antigen-binding sites. Amino acid substitutions may influence the specificity of the immune response by altering the binding affinity of different antigens for class II molecules.

Most individuals with type 1A DM have the HLA DR3 and/or DR4 haplotype. Refinements in genotyping of HLA loci have shown that the haplotypes DQA1*0301, DQB1*0302, DQA1*501, and DQB1*0201 are most strongly associated with type 1A DM. These haplotypes are present in 40% of children with type 1A DM as compared to 2% of the normal U.S. population.

In addition to MHC class II associations, at least 17 different genetic loci contribute susceptibility to type 1A DM. For example, polymorphisms in the promoter region of the insulin gene account for ~10% of the predisposition to type 1A DM. Genes that confer protection against the development of the disease also exist. The haplotype DQA1*0102, DQB1*0602 is present in 20% of the U.S. population but is extremely rare in individuals with type 1A DM (<1%).

The risk of developing type 1A DM is increased tenfold in relatives of individuals with the disease. Nevertheless, most individuals with predisposing haplotypes do not develop diabetes. In addition, most individuals with type 1A DM do not have a first-degree relative with this disorder.

Autoimmune Factors Although other islet cell types [alpha cells (glucagon-producing), delta cells (somatostatin-producing), or PP cells (pancreatic polypeptide-producing)] are functionally and embryologically similar to beta cells and express most of the same proteins as beta cells, they are inexplicably spared from the autoimmune process. Pathologically, the pancreatic islets are infiltrated with lymphocytes (in a process termed *insulitis*). After all beta cells are destroyed, the inflammatory process abates, the islets become atrophic, and immunologic markers disappear. Studies of the autoimmune process in humans and animal models of type 1A DM (NOD mouse and BB rat) have identified the following abnormalities in both the humoral and cellular arms of the immune system: (1) islet cell autoantibodies; (2) activated lymphocytes in the islets, peripancreatic lymph nodes, and systemic circulation; (3) T lymphocytes that proliferate when stimulated with islet proteins; and (4) release of cytokines within the insulitis. Beta cells seem to be particularly susceptible to the toxic effect of some cytokines [tumor necrosis factor α (TNF-α), interferon γ, and interleukin-1 (IL-1)]. The precise mechanisms of beta cell death are not known but may involve formation of nitric oxide metabolites, apoptosis, and direct CD8+ T cell cytotoxicity. Islet autoantibodies are not thought to be involved in the destructive process, as these antibodies do not generally react with the cell surface of islet cells and are not capable of transferring diabetes mellitus to animals.

Pancreatic islet molecules targeted by the autoimmune process include insulin, glutamic acid decarboxylase (GAD, the biosynthetic enzyme for the neurotransmitter GABA), ICA-512/IA-2 (homology with tyrosine phosphatases), and phogrin (insulin secretory granule protein). Other less clearly defined autoantigens include an islet ganglioside and carboxypeptidase H. With the exception of insulin, none of the autoantigens are beta cell specific, which raises the question of how the beta cells are selectively destroyed. Current theories favor initiation of an autoimmune process directed at one beta cell molecule, which then spreads to other islet molecules as the immune process destroys beta cells and creates a series of secondary autoantigens. The beta cells of individuals who develop type 1A DM do not differ from beta cells of normal individuals, since transplanted islets are destroyed by a recurrence of the autoimmune process of type 1A DM.

Immunologic Markers Islet cell autoantibodies (ICAs) are a composite of several different antibodies directed at pancreatic islet molecules such as GAD, insulin, IA-2/ICA-512, and an islet ganglioside and serve as a marker of the autoimmune process of type 1A DM. Assays for autoantibodies to GAD-65 are commercially available. Testing for ICAs can be useful in classifying the type of DM as type IA and in identifying nondiabetic individuals at risk for developing type 1A DM. ICAs are present in the majority of individuals (>75%) diagnosed with new-onset type 1A DM, in a significant minority of individuals with newly diagnosed type 2 DM (5 to 10%), and occasionally in individuals with GDM (<5%). ICAs are present in 3 to 4% of first-degree relatives of individuals with type 1A DM. In combination with impaired insulin secretion after intravenous glucose tolerance testing, they predict a >50% risk of developing type 1A DM within 5 years. Without this impairment in insulin secretion, the presence of ICAs predicts a 5-year risk of <25%. Based on these data, the risk of a first-degree relative developing type 1A DM is relatively low. At present, the measurement of ICAs in nondiabetic individuals is a research tool because no treatments have been approved to prevent the occurrence or progression of type 1A DM.

Environmental Factors Numerous environmental events have been proposed to trigger the autoimmune process in genetically susceptible individuals; however, none have been conclusively linked to diabetes. Identification of an environmental trigger has been difficult because the event may precede the onset of DM by several years (Fig. 323-5). Putative environmental triggers include viruses (coxsackie and rubella most prominently), bovine milk proteins, and nitrosourea compounds.

Prevention of Type 1A DM A number of interventions have successfully delayed or prevented diabetes in animal models. Some interventions have targeted the immune system directly (immunosuppression, selec-

tive T cell subset deletion, induction of immunologic tolerance to islet proteins), whereas others have prevented islet cell death by blocking cytotoxic cytokines or increasing islet resistance to the destructive process. Though results in animal models are promising, these interventions have not been successful in preventing type 1A DM in humans. The Diabetes Prevention Trial—type 1 recently concluded that administering insulin to individuals at high risk for developing type 1A DM did not prevent type 1A DM.

TYPE 2 DM Insulin resistance and abnormal insulin secretion are central to the development of type 2 DM. Although controversy remains regarding the primary defect, most studies support the view that insulin resistance precedes insulin secretory defects and that diabetes develops only if insulin secretion becomes inadequate.

GENETIC CONSIDERATIONS Type 2 DM has a strong genetic component. Major genes that predispose to this disorder have yet to be identified, but it is clear that the disease is polygenic and multifactorial. Various genetic loci contribute to susceptibility, and environmental factors (such as nutrition and physical activity) further modulate phenotypic expression of the disease. The concordance of type 2 DM in identical twins is between 70 and 90%. Individuals with a parent with type 2 DM have an increased risk of diabetes; if both parents have type 2 DM, the risk approaches 40%. Insulin resistance, as demonstrated by reduced glucose utilization in skeletal muscle, is present in many nondiabetic, first-degree relatives of individuals with type 2 DM. However, definition of the genetic susceptibility remains a challenge because the genetic defect in insulin secretion or action may not manifest itself unless an environmental event or another genetic defect, such as obesity, is superimposed. Mutations in various molecules involved in insulin action (e.g., the insulin receptor and enzymes involved in glucose homeostasis) account for a very small fraction of type 2 DM. Likewise, genetic defects in proteins involved in insulin secretion have not been found in most individuals with type 2 DM. Genome-wide scanning for mutations or polymorphisms associated with type 2 DM is being used in an effort to identify genes associated with type 2 DM. The gene for the protease, calpain 10, is associated with type 2 DM in Hispanic and some other populations.

Pathophysiology Type 2 DM is characterized by three pathophysiologic abnormalities: impaired insulin secretion, peripheral insulin resistance, and excessive hepatic glucose production. Obesity, particularly visceral or central (as evidenced by the hip-waist ratio), is very common in type 2 DM. Adipocytes secrete a number of biologic products (leptin, TNF-α, free fatty acids, resistin, and adiponectin) that modulate insulin secretion, insulin action, and body weight and may contribute to the insulin resistance. In the early stages of the disorder, glucose tolerance remains normal, despite insulin resistance, because the pancreatic beta cells compensate by increasing insulin output (Fig. 323-6). As insulin resistance and compensatory hyperinsulinemia progress, the pancreatic islets in certain individuals are unable to sustain the hyperinsulinemic state. IGT, characterized by elevations in postprandial glucose, then develops. A further decline in insulin secretion and an increase in hepatic glucose production lead to overt diabetes with fasting hyperglycemia. Ultimately, beta cell failure may ensue. Markers of inflammation such as IL-6 and C-reactive protein are often elevated in type 2 diabetes.

Metabolic Abnormalities ■ *INSULIN RESISTANCE* The decreased ability of insulin to act effectively on peripheral target tissues (especially muscle and liver) is a prominent feature of type 2 DM and results from a combination of genetic susceptibility and obesity. Insulin resistance is relative, however, since supernormal levels of circulating insulin will normalize the plasma glucose. Insulin dose-response curves exhibit a rightward shift, indicating reduced sensitivity, and a reduced maximal response, indicating an overall decrease in maximum glucose utilization (30 to 60% lower than normal individuals). Insulin resistance impairs glucose utilization by insulin-sensitive tissues and increases hepatic glucose output; both effects contribute to the hyperglycemia.

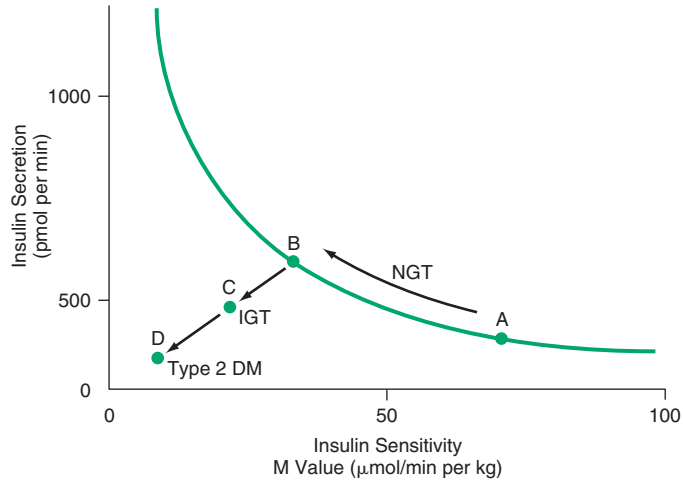

FIGURE 323-6 Metabolic changes during the development of type 2 diabetes mellitus (DM). Insulin secretion and insulin sensitivity are related, and as an individual becomes more insulin resistant (by moving from point A to point B), insulin secretion increases. A failure to compensate by increasing the insulin secretion results initially in impaired glucose tolerance (IGT; point C) and ultimately in type 2 DM (point D). *(Adapted from SE Kahn, J Clin Endocrinol Metab 86:4047, 2001; RN Bergman, M Ader, Trends Endocrinol Metab 11:351, 2000.)*

Increased hepatic glucose output predominantly accounts for increased FPG levels, whereas decreased peripheral glucose usage results in postprandial hyperglycemia. In skeletal muscle, there is a greater impairment in nonoxidative glucose usage (glycogen formation) than in oxidative glucose metabolism through glycolysis. Glucose metabolism in insulin-independent tissues is not altered in type 2 DM.

The precise molecular mechanism of insulin resistance in type 2 DM has not been elucidated. Insulin receptor levels and tyrosine kinase activity in skeletal muscle are reduced, but these alterations are most likely secondary to hyperinsulinemia and are not a primary defect. Therefore, postreceptor defects are believed to play the predominant role in insulin resistance (Fig. 323-4). Polymorphisms in IRS-1 may be associated with glucose intolerance, raising the possibility that polymorphisms in various postreceptor molecules may combine to create an insulin-resistant state. The pathogenesis of insulin resistance is currently focused on a PI-3-kinase signaling defect, which reduces translocation of GLUT4 to the plasma membrane, among other abnormalities. Of note, not all insulin signal transduction pathways are resistant to the effects of insulin [e.g., those controlling cell growth and differentiation and using the mitogen-activated protein (MAP) kinase pathway; Fig. 323-4]. Consequently, hyperinsulinemia may increase the insulin action through these pathways, potentially accelerating diabetes-related conditions such as atherosclerosis.

Another emerging theory proposes that elevated levels of free fatty acids, a common feature of obesity, may contribute to the pathogenesis of type 2 DM. Free fatty acids can impair glucose utilization in skeletal muscle, promote glucose production by the liver, and impair beta cell function.

IMPAIRED INSULIN SECRETION Insulin secretion and sensitivity are interrelated (Fig. 323-6). In type 2 DM, insulin secretion initially increases in response to insulin resistance to maintain normal glucose tolerance. Initially, the insulin secretory defect is mild and selectively involves glucose-stimulated insulin secretion. The response to other nonglucose secretagogues, such as arginine, is preserved. Eventually, the insulin secretory defect progresses to a state of grossly inadequate insulin secretion.

The reason(s) for the decline in insulin secretory capacity in type 2 DM is unclear. Despite the assumption that a second genetic defect—superimposed upon insulin resistance—leads to beta cell failure, intense genetic investigation has so far excluded mutations in islet

candidate genes. Islet amyloid polypeptide or amylin is cosecreted by the beta cell and likely forms the amyloid fibrillar deposit found in the islets of individuals with long-standing type 2 DM. Whether such islet amyloid deposits are a primary or secondary event is not known. The metabolic environment of diabetes may also negatively impact islet function. For example, chronic hyperglycemia paradoxically impairs islet function ("glucose toxicity") and leads to a worsening of hyperglycemia. Improvement in glycemic control is often associated with improved islet function. In addition, elevation of free fatty acid levels ("lipotoxicity") and dietary fat may also worsen islet function.

INCREASED HEPATIC GLUCOSE PRODUCTION In type 2 DM, insulin resistance in the liver reflects the failure of hyperinsulinemia to suppress gluconeogenesis, which results in fasting hyperglycemia and decreased glycogen storage by the liver in the postprandial state. Increased hepatic glucose production occurs early in the course of diabetes, though likely after the onset of insulin secretory abnormalities and insulin resistance in skeletal muscle.

Insulin Resistance Syndromes The insulin resistance condition comprises a spectrum of disorders, with hyperglycemia representing one of the most readily diagnosed features. The *metabolic syndrome*, the *insulin resistance syndrome*, or *syndrome X* are terms used to describe a constellation of metabolic derangements that includes insulin resistance, hypertension, dyslipidemia [low high-density lipoprotein (HDL) and elevated triglycerides], central or visceral obesity, type 2 diabetes or IGT/IFG, and accelerated cardiovascular disease. This syndrome is very common. The Centers for Disease Control and Prevention (CDC) estimates that 20% of U.S. adults have this syndrome. Epidemiologic evidence supports hyperinsulinemia as a marker for coronary artery disease risk, though an etiologic role has not been demonstrated.

A number of relatively rare forms of severe insulin resistance include features of type 2 DM or IGT (Table 323-1). *Acanthosis nigricans* and signs of hyperandrogenism (hirsutism, acne, and oligomenorrhea in women) are also common physical features. Two distinct syndromes of severe insulin resistance have been described in adults: (1) type A, which affects young women and is characterized by severe hyperinsulinemia, obesity, and features of hyperandrogenism; and (2) type B, which affects middle-aged women and is characterized by severe hyperinsulinemia, features of hyperandrogenism, and autoimmune disorders. Individuals with the type A insulin resistance syndrome have an undefined defect in the insulin-signaling pathway; individuals with the type B insulin resistance syndrome have autoantibodies directed at the insulin receptor. These receptor autoantibodies may block insulin binding or may stimulate the insulin receptor, leading to intermittent hypoglycemia.

Polycystic ovary syndrome (PCOS) is a common disorder that affects premenopausal women and is characterized by chronic anovulation and hyperandrogenism (Chap. 326). Insulin resistance is seen in a significant subset of women with PCOS, and the disorder substantially increases the risk for type 2 DM, independent of the effects of obesity. Both metformin and the thiazolidinediones attenuate hyperinsulinemia, ameliorate hyperandrogenism, induce ovulation, and improve plasma lipids, but they are not approved for this indication.

Prevention Type 2 DM is preceded by a period of IGT, and a number of life-style modifications and pharmacologic agents prevent or delay the onset of DM. The Diabetes Prevention Program (DPP) demonstrated that intensive changes in life-style (diet and exercise for 30 min/day five times/week) in individuals with IGT prevented or delayed the development of type 2 diabetes by 58% compared to placebo. This effect was seen in individuals regardless of age, sex, or ethnic group. In the same study, metformin prevented or delayed diabetes by 31% compared to placebo. The life-style intervention group lost 5 to 7% of their body weight during the 3 years of the study. Studies in Finnish and Chinese populations noted similar efficacy of diet and exercise in preventing or delaying type 2 DM; acarbose, metformin, and the thiazolidinediones prevent or delay type 2 DM, but are not approved for this purpose. When administered to nondiabetic individuals for other reasons (cardiac, cholesterol lowering, etc.), two pharmacologic agents (ramipril, pravastatin) reduced the number of new cases of diabetes. Individuals with a strong family history, those at high risk for developing DM, or those with IFG or IGT should be strongly encouraged to maintain a normal body mass index (BMI) and engage in regular physical activity.

GENETICALLY DEFINED, MONOGENIC FORMS OF DIABETES MELLITUS

Several monogenic forms of DM have been identified. Five different variants of MODY, caused by mutations in genes encoding islet cell transcription factors or glucokinase (Fig. 323-3), have been identified so far, and all are transmitted as autosomal dominant disorders (Table 323-1). MODY 2 is the result of mutations in the glucokinase gene that lead to mild-to-moderate hyperglycemia. Glucokinase catalyzes the formation of glucose-6-phosphate from glucose, a reaction that is important for glucose sensing by the beta cells and for glucose utilization by the liver. As a result of glucokinase mutations, higher glucose levels are required to elicit insulin secretory responses, thus altering the set point for insulin secretion. Homozygous mutations in glucokinase cause severe, neonatal diabetes. MODY 1, MODY 3, and MODY 5 are caused by mutations in the hepatocyte nuclear transcription factors (HNF) 4α, HNF-1α, and HNF-1β, respectively. As their names imply, these transcription factors are expressed in the liver but also in other tissues, including the pancreatic islets and kidney (as a result, patients may also have renal absorption abnormalities and renal cysts). The mechanisms by which such mutations lead to DM is not well understood, but it is likely that these factors affect islet development or the transcription of genes that are important in stimulating insulin secretion. MODY 1 and 3 begin with mild hyperglycemia, but progressive impairment of insulin secretion requires treatment with oral agents or insulin. MODY 4 is a rare variant caused by mutations in the insulin promoter factor (IPF) 1, which is a transcription factor that regulates pancreatic development and insulin gene transcription. Homozygous inactivating mutations cause pancreatic agenesis, whereas heterozygous mutations result in DM. Studies of populations with type 2 DM suggest that mutations in the glucokinase gene and various islet cell transcription factors are very rare in ordinary type 2 DM.

ACUTE COMPLICATIONS OF DM

Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS) are acute complications of diabetes. DKA was formerly considered a hallmark of type 1 DM, but it also occurs in individuals who lack immunologic features of type 1A DM and who can subsequently be treated with oral glucose-lowering agents (these individuals with type 2 DM are often of Hispanic or African-American descent). HHS is primarily seen in individuals with type 2 DM. Both disorders are associated with absolute or relative insulin deficiency, volume depletion, and acid-base abnormalities. DKA and HHS exist along a continuum of hyperglycemia, with or without ketosis. The metabolic similarities and differences in DKA and HHS are highlighted in Table 323-4. Both disorders are associated with potentially serious complications if not promptly diagnosed and treated.

DIABETIC KETOACIDOSIS ■ Clinical Features The symptoms and physical signs of DKA are listed in Table 323-5 and usually develop over 24 hours. DKA may be the initial symptom complex that leads to a diagnosis of type 1 DM, but more frequently it occurs in individuals with established diabetes. Nausea and vomiting are often prominent, and their presence in an individual with diabetes warrants laboratory evaluation for DKA. Abdominal pain may be severe and can resemble acute pancreatitis or ruptured viscous. Hyperglycemia leads to glucosuria, volume depletion, and tachycardia. Hypotension can occur because of volume depletion in combination with peripheral vasodilation. Kussmaul respirations and a fruity odor on the patient's breath (secondary to metabolic acidosis and increased acetone) are classic signs of the disorder. Lethargy and central nervous system depression

may evolve into coma with severe DKA but should also prompt evaluation for other reasons for altered mental status (infection, hypoxia, etc.). Cerebral edema, an extremely serious complication of DKA, is seen most frequently in children. Signs of infection, which may precipitate DKA, should be sought on physical examination, even in the absence of fever. Tissue ischemia (heart, brain) can also be a precipitating factor.

TABLE 323-4 *Laboratory Values in Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar State (HHS) (Representative Ranges at Presentation)*

	DKA	HHS
Glucose,[a] mmol/L (mg/dL)	13.9–33.3 (250–600)	33.3–66.6 (600–1200)
Sodium, meq/L	125–135	135–145
Potassium,[a] meq/L	Normal to ↑[b]	Normal
Magnesium[a]	Normal[b]	Normal
Chloride[a]	Normal	Normal
Phosphate[a]	↓	Normal
Creatinine, μmol/L (mg/dL)	Slightly ↑	Moderately ↑
Osmolality (mOsm/mL)	300–320	330–380
Plasma ketones[a]	++++	+/−
Serum bicarbonate,[a] meq/L	<15 meq/L	Normal to slightly ↓
Arterial pH	6.8–7.3	>7.3
Arterial P_{CO_2},[a] mmHg	20–30	Normal
Anion gap[a] [Na − (Cl + HCO_3)], meq/L	↑	Normal to slightly ↑

[a] Large changes occur during treatment of DKA.
[b] Although plasma levels may be normal or high at presentation, total-body stores are usually depleted.

Pathophysiology DKA results from relative or absolute insulin deficiency combined with counterregulatory hormone excess (glucagon, catecholamines, cortisol, and growth hormone). Both insulin deficiency and glucagon excess, in particular, are necessary for DKA to develop. The decreased ratio of insulin to glucagon promotes gluconeogenesis, glycogenolysis, and ketone body formation in the liver, as well as increases in substrate delivery from fat and muscle (free fatty acids, amino acids) to the liver.

The combination of insulin deficiency and hyperglycemia reduces the hepatic level of fructose-2,6-phosphate, which alters the activity of phosphofructokinase and fructose-1,6-bisphosphatase. Glucagon excess decreases the activity of pyruvate kinase, whereas insulin deficiency increases the activity of phosphoenolpyruvate carboxykinase. These changes shift the handling of pyruvate toward glucose synthesis and away from glycolysis. The increased levels of glucagon and catecholamines in the face of low insulin levels promote glycogenolysis. Insulin deficiency also reduces levels of the GLUT4 glucose transporter, which impairs glucose uptake into skeletal muscle and fat and reduces intracellular glucose metabolism (Fig. 323-4).

Ketosis results from a marked increase in free fatty acid release from adipocytes, with a resulting shift toward ketone body synthesis in the liver. Reduced insulin levels, in combination with elevations in catecholamines and growth hormone, increase lipolysis and the release of free fatty acids. Normally, these free fatty acids are converted to triglycerides or very low density lipoproteins (VLDL) in the liver. However, in DKA, hyperglucagonemia alters hepatic metabolism to favor ketone body formation, through activation of the enzyme carnitine palmitoyltransferase I. This enzyme is crucial for regulating fatty acid transport into the mitochondria, where beta oxidation and conversion to ketone bodies occur. At physiologic pH, ketone bodies exist as ketoacids, which are neutralized by bicarbonate. As bicarbonate stores are depleted, metabolic acidosis ensues. Increased lactic acid production also contributes to the acidosis. The increased free fatty acids increase triglyceride and VLDL production. VLDL clearance is also reduced because the activity of insulin-sensitive lipoprotein lipase in muscle and fat is decreased. Hypertriglyceridemia may be severe enough to cause pancreatitis.

DKA is initiated by inadequate levels of plasma insulin (Table 323-5). Most commonly, DKA is precipitated by increased insulin requirements, as might occur during a concurrent illness. Failure to augment insulin therapy often compounds the problem. Occasionally, complete omission of insulin by the patient or health care team (in a hospitalized patient with type 1 DM) precipitates DKA. Patients using insulin infusion devices with short-acting insulin are at increased risk of DKA, since even a brief interruption in insulin delivery (e.g., mechanical malfunction) quickly leads to insulin deficiency.

Laboratory Abnormalities and Diagnosis The timely diagnosis of DKA is crucial and allows for prompt initiation of therapy. DKA is characterized by hyperglycemia, ketosis, and metabolic acidosis (increased anion gap) along with a number of secondary metabolic derangements (Table 323-4). Occasionally, the serum glucose is only minimally elevated. Serum bicarbonate is frequently <10 mmol/L, and arterial pH ranges between 6.8 and 7.3, depending on the severity of the acidosis. Despite a total-body potassium deficit, the serum potassium at presentation may be mildly elevated, secondary to the acidosis. Total-body stores of sodium, chloride, phosphorous, and magnesium are also reduced in DKA but are not accurately reflected by their levels in the serum because of dehydration and hyperglycemia. Elevated blood urea nitrogen (BUN) and serum creatinine levels reflect intravascular volume depletion. Interference from acetoacetate may falsely elevate the serum creatinine measurement. Leukocytosis, hypertriglyceridemia, and hyperlipoproteinemia are commonly found as well. Hyperamylasemia may suggest a diagnosis of pancreatitis, especially when accompanied by abdominal pain. However, in DKA the amylase is usually of salivary origin and thus is not diagnostic of pancreatitis. Serum lipase should be obtained if pancreatitis is suspected.

The measured serum sodium is reduced as a consequence of the hyperglycemia [1.6 mmol/L (1.6 meq) reduction in serum sodium for each 5.6 mmol/L (100 mg/dL) rise in the serum glucose]. A normal serum sodium in the setting of DKA indicates a more profound water deficit. In "conventional" units, the calculated serum osmolality [2 × (serum sodium + serum potassium) + plasma glucose (mg/dL)/18 + BUN/2.8] is mildly to moderately elevated, though to a lesser degree than that found in HHS (see below).

In DKA, the ketone body, β-hydroxybutyrate, is synthesized at a threefold greater rate than acetoacetate; however, acetoacetate is preferentially detected by a commonly used ketosis detection reagent (nitroprusside). Serum ketones are present at significant levels (usually positive at serum dilution of 1:8 or greater). The nitroprusside tablet, or stick, is often used to detect urine ketones; certain medications such as captopril or penicillamine may cause false-positive reactions. Serum or plasma assays for β-hydroxybutyrate more accurately reflect the true ketone body level.

The metabolic derangements of DKA exist along a spectrum, beginning with mild acidosis with moderate hyperglycemia evolving into more severe findings. The degree of acidosis and hyperglycemia do not necessarily correlate closely since a variety of factors determine

TABLE 323-5 *Manifestations of Diabetic Ketoacidosis*

Symptoms	Physical findings
Nausea/vomiting	Tachycardia
Thirst/polyuria	Dry mucous membranes/reduced skin turgor
Abdominal pain	Dehydration / hypotension
Shortness of breath	Tachypnea / Kussmaul respirations/respiratory distress
Precipitating events	Abdominal tenderness (may resemble acute pancreatitis or surgical abdomen)
Inadequate insulin administration	Lethargy /obtundation / cerebral edema / possibly coma
Infection (pneumonia/UTI/ gastroenteritis/sepsis)	
Infarction (cerebral, coronary, mesenteric, peripheral)	
Drugs (cocaine)	
Pregnancy	

Note: UTI, urinary tract infection.

the level of hyperglycemia (oral intake, urinary glucose loss). Ketonemia is a consistent finding in DKA and distinguishes it from simple hyperglycemia. The differential diagnosis of DKA includes starvation ketosis, alcoholic ketoacidosis (bicarbonate >15 meq/L) and other increased anion gap acidosis (Chap. 42).

TREATMENT

The management of DKA is outlined in Table 323-6. After initiating intravenous fluid replacement and insulin therapy, the agent or event that precipitated the episode of DKA should be sought and aggressively treated. If the patient is vomiting or has altered mental status, a nasogastric tube should be inserted to prevent aspiration of gastric contents. Central to successful treatment of DKA is careful monitoring and frequent reassessment to ensure that the patient and the metabolic derangements are improving. A comprehensive flow sheet should record chronologic changes in vital signs, fluid intake and output, and laboratory values as a function of insulin administered.

After the initial bolus of normal saline, replacement of the sodium and free water deficit is carried out over the next 24 h (fluid deficit is often 3 to 5 L). When hemodynamic stability and adequate urine output are achieved, intravenous fluids should be switched to 0.45% saline at a rate of 200 to 300 mL/h, depending on the calculated volume deficit. The change to 0.45% saline helps to reduce the trend toward hyperchloremia later in the course of DKA. Alternatively, initial use of lactated Ringer's intravenous solution may reduce the hyperchloremia that commonly occurs with normal saline.

A bolus of intravenous (0.15 units/kg) or intramuscular (0.4 units/kg) regular insulin should be administered immediately (Table 323-6), and subsequent treatment should provide continuous and adequate levels of circulating insulin. Intravenous administration is preferred (0.1 units/kg per hour), because it assures rapid distribution and allows adjustment of the infusion rate as the patient responds to therapy. Intravenous regular insulin should be continued until the acidosis resolves and the patient is metabolically stable. As the acidosis and insulin resistance associated with DKA resolve, the insulin infusion rate can be decreased (to 0.05 to 0.1 units/kg per hour). Intermediate or long-acting insulin, in combination with subcutaneous regular insulin, should be administered as soon as the patient resumes eating, as this facilitates transition to an outpatient insulin regimen and reduces length of hospital stay. It is crucial to continue the insulin infusion until adequate insulin levels are achieved by the subcutaneous route. Even relatively brief periods of inadequate insulin administration in this transition phase may result in DKA relapse.

Hyperglycemia usually improves at a rate of 4.2 to 5.6 mmol/L (75 to 100 mg/dL) per hour as a result of insulin-mediated glucose disposal, reduced hepatic glucose release, and rehydration. The latter reduces catecholamines, increases urinary glucose loss, and expands the intravascular volume. The decline in the plasma glucose within the first 1 to 2 h may be more rapid and is mostly related to volume expansion. When the plasma glucose reaches 13.9 mmol/L (250 mg/dL), glucose should be added to the 0.45% saline infusion to maintain the plasma glucose in the 11.1 to 13.9 mmol/L (200 to 250 mg/dL) range, and the insulin infusion should be continued. Ketoacidosis begins to resolve as insulin reduces lipolysis, increases peripheral ketone body use, suppresses hepatic ketone body formation, and promotes bicarbonate regeneration. However, the acidosis and ketosis resolve more slowly than hyperglycemia. As ketoacidosis improves, β-hydroxybutyrate is converted to acetoacetate. Ketone body levels may appear to increase if measured by laboratory assays that use the nitroprusside reaction, which only detects acetoacetate and acetone. The improvement in acidosis and anion gap, a result of bicarbonate regeneration and decline in ketone bodies, is reflected by a rise in the serum bicarbonate level and the arterial pH. Depending on the rise of serum chloride, the anion gap (but not bicarbonate) will normalize. A hyperchloremic acidosis [serum bicarbonate of 15 to 18 mmol/L (15 to 18 meq/L)] often follows successful treatment and gradually resolves as the kidneys regenerate bicarbonate and excretes chloride.

Potassium stores are depleted in DKA [estimated deficit 3 to 5 mmol/kg (3 to 5 meq/kg)]. During treatment with insulin and fluids, various factors contribute to the development of hypokalemia. These include insulin-mediated potassium transport into cells, resolution of the acidosis (which also promotes potassium entry into cells), and urinary loss of potassium salts of organic acids. Thus, potassium repletion should commence as soon as adequate urine output and a normal serum potassium are documented. If the initial serum potassium level is elevated, then potassium repletion should be delayed until the potassium falls into the normal range. Inclusion of 20 to 40 meq of potassium in each liter of intravenous fluid is reasonable, but additional potassium supplements may also be required. To reduce the amount of chloride administered, potassium phosphate or acetate can be substituted for the chloride salt. The goal is to maintain the serum potassium >3.5 mmol/L (3.5 meq/L). If the initial serum potassium is less than 3.3 mmol/L (3.3 meq/L), do not administer insulin until the potassium is supplemented to >3.3 mmol/L (3.3 meq/L).

Despite a bicarbonate deficit, bicarbonate replacement is not usually necessary. In fact, theoretical arguments suggest that bicarbonate administration and rapid reversal of acidosis may impair cardiac function, reduce tissue oxygenation, and promote hypokalemia. The results of most clinical trials do not support the routine use of bicarbonate replacement, and one study in children found that bicarbonate use was associated with an increased risk of cerebral edema. However, in the presence of severe acidosis (arterial pH < 7.0 after initial hydration), the ADA advises bicarbonate [50 mmol/L (meq/L) of sodium bicarbonate in 200 mL of 0.45% saline over 1 h if pH = 6.9 to 7.0; or 100 mmol/L (meq/L) of sodium bicarbonate in 400 mL of 0.45% saline over 2 h if pH 7 < 6.9]. Hypophosphatemia may result from increased glucose usage, but randomized clinical trials have not demonstrated

TABLE 323-6 Management of Diabetic Ketoacidosis

1. Confirm diagnosis (↑ plasma glucose, positive serum ketones, metabolic acidosis).
2. Admit to hospital; intensive-care setting may be necessary for frequent monitoring or if pH < 7.00 or unconscious.
3. Assess: Serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate)
   Acid-base status—pH, HCO_3^-, P_{CO_2}, β-hydroxybutyrate
   Renal function (creatinine, urine output)
4. Replace fluids: 2–3 L of 0.9% saline over first 1–3 h (5–10 mL/kg per hour); subsequently, 0.45% saline at 150–300 mL/h; change to 5% glucose and 0.45% saline at 100–200 mL/h when plasma glucose reaches 250 mg/dL (14 mmol/L).
5. Administer regular insulin: IV (0.1 units/kg) or IM (0.4 units/kg), then 0.1 units/kg per hour by continuous IV infusion; increase 2- to 10-fold if no response by 2–4 h. If initial serum potassium is < 3.3 mmol/L (3.3 meq/L), do not administer insulin until the potassium is corrected to > 3.3 mmol/L (3.3.meq/L).
6. Assess patient: What precipitated the episode (noncompliance, infection, trauma, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, CXR, ECG).
7. Measure capillary glucose every 1–2 h; measure electrolytes (especially K^+, bicarbonate, phosphate) and anion gap every 4 h for first 24 h.
8. Monitor blood pressure, pulse, respirations, mental status, fluid intake and output every 1–4 h.
9. Replace K^+: 10 meq/h when plasma K^+ < 5.5 meq/L, ECG normal, urine flow and normal creatinine documented; administer 40–80 meq/h when plasma K^+ <3.5 meq/L or if bicarbonate is given.
10. Continue above until patient is stable, glucose goal is 150–250 mg/dL, and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 units/kg per hour.
11. Administer intermediate or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and subcutaneous insulin injection.

Note: CXR, chest x-ray; ECG, electrocardiogram.

that phosphate replacement is beneficial in DKA. If the serum phosphate is <0.32 mmol/L (1.0 mg/dL), then phosphate supplement should be considered and the serum calcium monitored. Hypomagnesemia may develop during DKA therapy and may also require supplementation.

With appropriate therapy, the mortality of DKA is low (<5%) and is related more to the underlying or precipitating event, such as infection or myocardial infarction. The major nonmetabolic complication of DKA therapy is cerebral edema, which most often develops in children as DKA is resolving. The etiology and optimal therapy for cerebral edema are not well established, but overreplacement of free water should be avoided. Venous thrombosis, upper gastrointestinal bleeding, and acute respiratory distress syndrome occasionally complicate DKA.

Following treatment, the physician and patient should review the sequence of events that led to DKA to prevent future recurrences. Foremost is patient education about the symptoms of DKA, its precipitating factors, and the management of diabetes during a concurrent illness. During illness or when oral intake is compromised, patients should: (1) frequently measure the capillary blood glucose; (2) measure urinary ketones when the serum glucose >16.5 mmol/L (300 mg/dL); (3) drink fluids to maintain hydration; (4) continue or increase insulin; and (5) seek medical attention if dehydration, persistent vomiting, or uncontrolled hyperglycemia develop. Using these strategies, early DKA can be prevented or detected and treated appropriately on an outpatient basis.

HYPERGLYCEMIC HYPEROSMOLAR STATE ■ Clinical Features The prototypical patient with HHS is an elderly individual with type 2 DM, with a several week history of polyuria, weight loss, and diminished oral intake that culminates in mental confusion, lethargy, or coma. The physical examination reflects profound dehydration and hyperosmolality and reveals hypotension, tachycardia, and altered mental status. Notably absent are symptoms of nausea, vomiting, and abdominal pain and the Kussmaul respirations characteristic of DKA. HHS is often precipitated by a serious, concurrent illness such as myocardial infarction or stroke. Sepsis, pneumonia, and other serious infections are frequent precipitants and should be sought. In addition, a debilitating condition (prior stroke or dementia) or social situation that compromises water intake may contribute to the development of the disorder.

Pathophysiology Relative insulin deficiency and inadequate fluid intake are the underlying causes of HHS. Insulin deficiency increases hepatic glucose production (through glycogenolysis and gluconeogenesis) and impairs glucose utilization in skeletal muscle (see above discussion of DKA). Hyperglycemia induces an osmotic diuresis that leads to intravascular volume depletion, which is exacerbated by inadequate fluid replacement. The absence of ketosis in HHS is not completely understood. Presumably, the insulin deficiency is only relative and less severe than in DKA. Lower levels of counterregulatory hormones and free fatty acids have been found in HHS than in DKA in some studies. It is also possible that the liver is less capable of ketone body synthesis or that the insulin/glucagon ratio does not favor ketogenesis.

Laboratory Abnormalities and Diagnosis The laboratory features in HHS are summarized in Table 323-4. Most notable are the marked hyperglycemia [plasma glucose may be >55.5 mmol/L (1000 mg/dL)], hyperosmolality (>350 mosmol/L), and prerenal azotemia. The measured serum sodium may be normal or slightly low despite the marked hyperglycemia. The corrected serum sodium is usually increased [add 1.6 meq to measured sodium for each 5.6-mmol/L (100 mg/dL) rise in the serum glucose]. In contrast to DKA, acidosis and ketonemia are absent or mild. A small anion gap metabolic acidosis may be present secondary to increased lactic acid. Moderate ketonuria, if present, is secondary to starvation.

℞ TREATMENT

Volume depletion and hyperglycemia are prominent features of both HHS and DKA. Consequently, therapy of these disorders shares several elements (Table 323-6). In both disorders, careful monitoring of the patient's fluid status, laboratory values, and insulin infusion rate is crucial. Underlying or precipitating problems should be aggressively sought and treated. In HHS, fluid losses and dehydration are usually more pronounced than in DKA due to the longer duration of the illness. The patient with HHS is usually older, more likely to have mental status changes, and more likely to have a life-threatening precipitating event with accompanying comorbidities. Even with proper treatment, HHS has a substantially higher mortality than DKA (up to 15% in some clinical series).

Fluid replacement should initially stabilize the hemodynamic status of the patient (1 to 3 L of 0.9% normal saline over the first 2 to 3 h). Because the fluid deficit in HHS is accumulated over a period of days to weeks, the rapidity of reversal of the hyperosmolar state must balance the need for free water repletion with the risk that too rapid a reversal may worsen neurologic function. If the serum sodium is >150 mmol/L (150 meq/L), 0.45% saline should be used. After hemodynamic stability is achieved, the intravenous fluid administration is directed at reversing the free water deficit using hypotonic fluids (0.45% saline initially then 5% dextrose in water, D_5W). The calculated free water deficit (which averages 9 to 10 L) should be reversed over the next 1 to 2 days (infusion rates of 200 to 300 mL/h of hypotonic solution). Potassium repletion is usually necessary and should be dictated by repeated measurements of the serum potassium. In patients taking diuretics, the potassium deficit can be quite large and may be accompanied by magnesium deficiency. Hypophosphatemia may occur during therapy and can be improved by using KPO_4 and beginning nutrition.

As in DKA, rehydration and volume expansion lower the plasma glucose initially, but insulin is also required. A reasonable regimen for HHS begins with an intravenous insulin bolus of 5 to 10 units followed by intravenous insulin at a constant infusion rate (3 to 7 units/h). As in DKA, glucose should be added to intravenous fluid when the plasma glucose falls to 13.9 mmol/L (250 mg/dL), and the insulin infusion rate should be decreased to 1 to 2 units/h. The insulin infusion should be continued until the patient has resumed eating and can be transferred to a subcutaneous insulin regimen. The patient should be discharged from the hospital on insulin, though some patients can later switch to oral glucose-lowering agents.

CHRONIC COMPLICATIONS OF DM

The chronic complications of DM affect many organ systems and are responsible for the majority of morbidity and mortality associated with the disease. Chronic complications can be divided into vascular and nonvascular complications (Table 323-7). The vascular complications

TABLE 323-7 Chronic Complications of Diabetes Mellitus

Microvascular
Eye disease
Retinopathy (nonproliferative/proliferative)
Macular edema
Neuropathy
Sensory and motor (mono- and polyneuropathy)
Autonomic
Nephropathy
Macrovascular
Coronary artery disease
Peripheral vascular disease
Cerebrovascular disease
Other
Gastrointestinal (gastroparesis, diarrhea)
Genitourinary (uropathy/sexual dysfunction)
Dermatologic
Infectious
Cataracts
Glaucoma
