Advanced Life Support Advanced life support is intended to achieve adequate ventilation, control cardiac arrhythmias, stabilize blood pressure and cardiac output, and restore organ perfusion. The activities carried out to achieve these goals include (1) defibrillation/cardioversion and/or pacing, (2) intubation with an endotracheal tube, and (3) insertion of an intravenous line. The speed with which defibrillation/cardioversion is carried out is an important element for successful resuscitation, both for restoration of spontaneous circulation and protection of the central nervous system. Immediate defibrillation should precede intubation and insertion of an intravenous line; CPR should be carried out while the defibrillator is being charged. As soon as a diagnosis of VF or VT is established, a shock of at least 200 J should be delivered. Additional shocks at higher energies, up to a maximum of 360 J, are tried if the initial shock does not successfully abolish VT or VF. Epinephrine, 1 mg intravenously, is given after failed defibrillation, and attempts to defibrillate are repeated. The dose of epinephrine may be repeated after intervals of 3 to 5 min (Fig. 256-3*A*). Vasopressin (a single 40 Unit dose given IV) has been suggested as an alternative to epinephrine.

If the patient is less than fully conscious upon reversion, or if two or three attempts fail, prompt intubation, ventilation, and arterial blood gas analysis should be carried out. Ventilation with O_2 (room air if O_2 is not immediately available) may promptly reverse hypoxemia and acidosis. The patient who is persistently acidotic after successful defibrillation and intubation should be given 1 meq/kg $NaHCO_3$ initially and an additional 50% of the dose repeated every 10 to 15 min. However, it should not be used routinely.

After initial unsuccessful defibrillation attempts, or with persistent/recurrent electrical instability, antiarrhythmic therapy should be instituted. Intravenous amiodarone has emerged as the initial treatment of choice (150 mg over 10 min, followed by 1 mg/min for up to 6 h and 0.5 mg/min thereafter) (Fig. 256-3*A*). A bolus of 1 mg/kg of lidocaine may be given intravenously (Chap. 228), and the dose repeated in 2 min, in those patients in whom amiodarone is unsuccessful, and possibly in those who clearly have an acute MI as the triggering mechanism for the cardiac arrest. Intravenous procainamide (loading infusion of 100 mg/5 min to a total dose of 500 to 800 mg, followed by continuous infusion at 2 to 5 mg/min) is rarely used in this setting any longer but may be tried for persisting, hemodynamically stable arrhythmias. Intravenous calcium gluconate is no longer considered safe or necessary for routine administration. It is used only in patients in whom acute hyperkalemia is known to be the triggering event for resistant VF, in the presence of known hypocalcemia, or in patients who have received toxic doses of calcium channel antagonists.

Cardiac arrest secondary to bradyarrhythmias or asystole is managed differently (Fig. 256-3*B*). The patient is promptly intubated, CPR is continued, and an attempt is made to control hypoxemia and acidosis. Epinephrine and/or atropine are given intravenously or by an intracardiac route. External pacing devices are now available to attempt to establish a regular rhythm, but the prognosis is generally very poor in this form of cardiac arrest, even with successful electrical pacing. PEA is treated similarly to bradyarrhythmias, but its outcome is also dismal. The one exception is bradyarrhythmic/asystolic cardiac arrest secondary to airway obstruction. This form of cardiac arrest may respond promptly to removal of foreign bodies by the Heimlich maneuver or, in hospitalized patients, by intubation and suctioning of obstructing secretions in the airway.

Postresuscitation Care This phase of management is determined by the clinical setting of the cardiac arrest. Primary VF in acute MI (Chap. 228) is generally very responsive to life-support techniques and easily controlled after the initial event. In the in-hospital setting, respirator support is usually not necessary or is needed for only a short time, and hemodynamics stabilize promptly after defibrillation or cardioversion. In secondary VF in acute MI (those events in which hemodynamic abnormalities predispose to the potentially fatal arrhythmia), resuscitative efforts are less often successful; and in those patients who are successfully resuscitated, the recurrence rate is high. The clinical picture and outcome are dominated by hemodynamic instability and the ability to control hemodynamic dysfunction. Bradyarrhythmias, asystole, and PEA are commonly secondary events in hemodynamically unstable patients. The in-hospital phase of care of the out-of-hospital

FIGURE 256-3 Management of cardiac arrest. *A*. The algorithm of ventricular fibrillation or hypotensive ventricular tachycardia begins with defibrillation attempts. If that fails, it is followed by epinephrine and then antiarrhythmic drugs. See text for details. *B*. The algorithms for bradyarrhythmia/asystole (left) or pulseless electrical activity (right) is dominated first by continued life support and a search for reversible causes. Subsequent therapy is nonspecific and accompanied by a low success rate. See text for details. CPR, cardiopulmonary resuscitation; MI, myocardial infarction.

cardiac arrest survivor is dictated by specific clinical circumstances. The most difficult is the presence of anoxic encephalopathy which is a strong predictor of in-hospital death. A recent addition to the management of this condition is induced hypothermia to reduce metabolic demands and cerebral edema.

The outcome after in-hospital cardiac arrest associated with noncardiac diseases is poor, and in the few successfully resuscitated patients, the postresuscitation course is dominated by the nature of the underlying disease. Patients with cancer, renal failure, acute central nervous system disease, and uncontrolled infections, as a group, have a survival rate of less than 10% after in-hospital cardiac arrest. Some major exceptions are patients with transient airway obstruction, electrolyte disturbances, proarrhythmic effects of drugs, and severe metabolic abnormalities, most of whom may have an excellent chance of survival if they can be resuscitated promptly and maintained while the transient abnormalities are being corrected.

Long-Term Management after Survival of Out-of-Hospital Cardiac Arrest Patients who survive cardiac arrest without irreversible damage to the central nervous system, and who achieve hemodynamic stability, should have extensive diagnostic testing and appropriate therapeutic interventions for their long-term management. This aggressive approach is driven by the fact that survival after out-of-hospital cardiac arrest was followed by a 25 to 30% mortality rate during the first 2 years after the event, and there are data suggesting that significant reductions in risk can be achieved by appropriate therapy.

Among patients in whom an acute transmural MI is identified as the specific mechanism triggering an out-of-hospital cardiac arrest, the management is dictated in part by the known transient nature of life-threatening arrhythmia risk in the acute phase of MI, and in part by the extent of permanent myocardial damage that results. Several clinical trials have now documented an improved mortality among cardiac arrest survivors who have EFs $< 40\%$ and receive ICDs. It is not clear whether ICDs provide a benefit over aminodarone therapy when the EF is between 35 and 40% or $>40\%$, but the data support the use of ICDs when the EF $< 35\%$. Since is is usually not possible to determine whether the EF reduction was preexisting or a consequence of the MI, the cut-offs described are those generally used as ICD indications. Earlier studies had suggested that inducibility of ventricular arrhythmias during programmed electrical stimulation (E-P) studies in the electrophysiology laboratory could stratify risk prediction, but this is not universally used any longer for patients with low EFs, since even without inducible arrhythmias, the risk remains high enough to warrant ICDs in these cardiac arrest survivors.

For patients with cardiac arrest thought to be due to a transient ischemic mechanism, particularly with higher EFs, anti-ischemic therapy by pharmacologic or interventional methods is generally accepted as appropriate management. However, despite the absence of supportive clinical trial evidence, some adopt a more aggressive attitude about the use of ICDs in this group of cardiac arrest survivors as well, given the unpredictability of recurrent ischemia as a triggering mechanism.

The principles guiding therapy for patients with coronary artery disease who survive a cardiac arrest generally apply to the other cardiac disorders as well, with the exception that there is less focus on the extent of disease in certain disorders. Generally, cardiac arrest survivors from other categories of disease, such as the hypertrophic or dilated cardiomyopathies and various rare inherited disorders (e.g., RV dysplasia, long QT syndrome, Brugada syndrome, arrhythmic VF) are all considered ICD candidates.

PREVENTION OF SCD IN HIGH-RISK INDIVIDUALS WITHOUT PRIOR CARDIAC ARREST

Post-MI patients have been the subject of clinical trials for ICD benefit. It is now established that for post-MI patients with EFs $< 40\%$, ambient ventricular arrhythmias, and inducible ventricular tachyarrhythmias in the electrophysiology laboratory, ICDs provide a significant reduction in relative risk of SCD and total mortality. Total mortality benefits in the range of a 20 to 30% reduction over 2 to 3 years have

been observed, and ICD has emerged as preferred therapy for such patients. One study suggests that when the EF $< 30\%$, electrophysiologic testing is not necessary to identify ICD benefit (see Chaps. 214 and 216).

Decision-making for primary prevention in disorders other than coronary artery disease is generally driven by observational data and judgment based on clinical observations. Controlled clinical trials providing evidence-based indicators for ICDs are lacking for these smaller population subgroups. In general, for both the cardiomyopathies and the rare disorders listed above, indicators of arrhythmic risk such as syncope, documented ventricular tachyarrhythmias, aborted cardiac arrest or perhaps a family history of SCD, and a number of other clinical or ECG markers, may be used as indicators for ICDs.

Section 3 Neurologic Critical Care

257 ACUTE CONFUSIONAL STATES AND COMA

Allan H. Ropper

Confusional states and coma are among the most common problems in general medicine. They account for a substantial portion of admissions to emergency wards and occur frequently on all hospital services. Because confusion and a diminished level of consciousness frequently coexist and are caused by many of the same diseases, they are presented together here, but from a medical perspective they have different clinical characteristics and physiologic explanations.

Almost all instances of diminished alertness can be traced to widespread abnormalities of the cerebral hemispheres or to reduced activity of a special thalamocortical alerting system termed the *reticular activating system* (RAS). The proper functioning of this system, its ascending projections to the cortex, and the cortex itself are required to maintain alertness and coherence of thought.

THE CONFUSIONAL STATE

Confusion is a mental and behavioral state of reduced comprehension, coherence, and capacity to reason. Inattention, as defined by the inability to sustain uninterrupted thought and actions, and disorientation are its earliest outward signs. As the state of confusion worsens, there are more global mental failings, including impairments of memory, perception, comprehension, problem solving, language, praxis, visuospatial function, and various aspects of emotional behavior that are attributable to particular regions of the brain. In some instances an apparent confusional state may be due to an isolated deficit in mental function such as an impairment of language (*aphasia*), loss of memory (*amnesia*), or lack of appreciation of spatial relations of self or the external environment (*agnosia*) (Chap. 23). Confusion is also a feature of dementia (Chap. 350), in which case the chronicity of the process distinguishes it from an acute encephalopathy.

The confused patient is usually subdued, not inclined to speak, and is physically inactive. A state of confusion that is accompanied by agitation, hallucinations, tremor, and illusions (misperceptions of environmental sight, sound, or touch) is termed *delirium*, as typified by delirium tremens from alcohol or drug withdrawal.

APPROACH TO THE PATIENT

Confusion and delirium always signify a disorder of the nervous system. They may be the major manifestations of a head injury; a seizure; drug toxicity (or drug withdrawal); a metabolic disorder resulting from hepatic, renal, pulmonary or cardiac failure; a systemic infection; meningitis or encephalitis; or a chronic dementing disease.

Evaluation begins with a careful history emphasizing the patient's condition before the onset of confusion. The clinical examination should focus on signs of diminished attentiveness, disorientation, and drowsiness and on the presence of localizing neurologic signs. From the clinical data the clinician is directed to the appropriate laboratory tests (see below.). Often, even after all diagnostic tests are completed, one may still not know the cause of a confusional state. The patient should then be observed in the hospital for a number of days under stable conditions. New clues may appear or confusion caused by a medication may resolve.

Orientation and memory are tested by asking the patient the date, inclusive of month, day, year, and day of week; the precise place; and some items of universally known information (the names of the President and Vice President, a recent national event, the state capital). Further probing may be necessary to reveal a defect in clarity—why is the patient in the hospital; what is his or her address, zip code, telephone number, social security number? Problems of increasing complexity may be pursued, but they usually provide little additional information. Attention and coherence of thought can be gauged by the accuracy and speed of responses but are examined more explicitly by having the patient repeat strings of numbers (most adults easily retain seven digits forward and four backward), spell a word such as "world" backwards, and perform serial calculations—tests of serial subtraction of 3 from 30 or 7 from 100 are useful. It is the inability to sustain coherent mental activity in performing tasks such as these that exposes the most subtle confusional states.

Other salient findings are the level of alertness, which fluctuates if there is drowsiness; indications of focal damage of the cerebrum such as hemiparesis, hemianopia, and aphasia; or adventitious movements of myoclonus or partial convulsions. The language of the confused patient may be disorganized and rambling, even to the extent of incorporating paraphasic words. These features, along with impaired comprehension that is due mainly to inattention, may be mistaken for aphasia.

One of the most specific signs of a metabolic encephalopathy is *asterixis*, which is an arrhythmic flapping tremor that is typically elicited by asking the patient to hold the arms outstretched with the wrists and hands fully extended. After a few seconds, there is a large jerking lapse in the posture of the hand and then a rapid return to the original position. The same movements can be found in any tonically held posture, even of the protruded tongue. Bilateral as-

terixis always signifies a metabolic encephalopathy, e.g., from hepatic failure, hypercapnia, or drug intoxication, especially with anticonvulsant medications. Myoclonic jerking and tremor are typical of uremic encephalopathy or exposure to antipsychotic drugs such as lithium, phenothiazines, or butyrophenones; myoclonus is also common with severe anoxic cerebral damage.

Confusion in the postoperative period, particularly after cardiac and extensive orthopedic procedures, is common but at times so subtle as to escape attention. Often a careful history will reveal that a mild but compensated dementia existed prior to the operation. Medications, particularly those with anticholinergic activity (including meperidine), inadvertent withdrawal from sleeping pills or alcohol, fever, and any of the endogenous metabolic derangements listed above may be responsible, or a stroke may have occurred. In many cases, particularly in the elderly, transient confusion and drowsiness arise with a febrile infection of the urinary tract, lungs, blood, or peritoneum. The term *septic encephalopathy* is used to describe this association, but the mechanism by which systemic infection leads to cerebral dysfunction is unknown.

Distinguishing dementia from an acute confusional state is a problem in the elderly. The two may coexist if an acute medical problem or a poorly tolerated medication supervenes in a mildly demented patient, producing a so-called beclouded dementia. The memory loss of dementia brings about a confusional state that varies little in severity from day to day. Poor mental performance in dementia is manifested primarily as incomplete recollection; inadequate access to names and words, and ideas; and the inability to retain new information, thus affecting orientation and factual knowledge. In contrast to the acute confusional states, attention, alertness, and coherence are preserved until the most advanced stages. Dementia in its advanced stages produces a chronic confusion with breakdown of all types of mental performance; the distinction from an acute encephalopathy then depends mainly on the longstanding nature of the condition.

Treatment of the confused patient requires that all unnecessary medication be stopped, metabolic alterations be rectified, and infection be treated. Skilled nursing and a quiet room with a window are important. Careful explanations should be given at regular intervals to the family. In the elderly, regular reorientation and active measures to lessen risk factors (sleep deprivation, immobility, and vision and hearing impairments) have been shown to reduce the number and severity of episodes of delirium in hospitalized patients.

COMA AND RELATED DISORDERS OF CONSCIOUSNESS

States of reduced alertness and responsiveness represent a continuum that in its severest form is called *coma*, a deep sleeplike state from which the patient cannot be aroused. *Stupor* refers to lesser degrees of unarousability in which the patient can be awakened only by vigorous stimuli, accompanied by motor behavior that leads to avoidance of uncomfortable or aggravating stimuli. *Drowsiness*, which is familiar to all persons, simulates light sleep and is characterized by easy arousal and the persistence of alertness for brief periods. Drowsiness and stupor are usually attended by some degree of confusion. A narrative description of the level of arousal and of the type of responses evoked by various stimuli precisely as observed at the bedside is preferable to ambiguous terms such as semicoma or obtundation.

Several other neurologic conditions render patients apparently unresponsive and simulate coma, and certain subsyndromes of coma must be considered separately because of their special significance. Among the latter, the *vegetative state* signifies an awake but unresponsive state. These patients have emerged from coma after a period of days or weeks to an unresponsive state in which the eyelids are open, giving the appearance of wakefulness. Yawning, coughing, swallowing, as well as limb and head movements persist, but there are few, if any, meaningful responses to the external and internal environment—in essence, an "awake coma." Respiratory and autonomic functions are retained. The term "vegetative" is unfortunate as it is subject to misinterpretation by lay persons. There are always accompanying signs that indicate extensive damage in both cerebral hemispheres, e.g., decerebrate or decorticate limb posturing and absent responses to visual stimuli (see below). In the closely related *minimally conscious state* the patient may make intermittent rudimentary vocal or motor responses. Cardiac arrest and head injuries are the most common causes of the vegetative state (Chaps. 258 and 357). The prognosis for regaining mental faculties once the vegetative state has supervened for several months is almost nil, hence the term *persistent vegetative state*. Most reports of dramatic recovery, when investigated carefully, are found to yield to the usual rules for prognosis, but there have been rare instances of awakening to a demented condition.

Certain clinical states are prone to be misinterpreted as stupor or coma. *Akinetic mutism* refers to a partially or fully awake patient who is able to form impressions and think but remains immobile and mute, particularly when unstimulated. The condition results from damage in the regions of the medial thalamic nuclei, the frontal lobes (particularly situated deeply or on the orbitofrontal surfaces), or from hydrocephalus. The term *abulia* is used to describe a mental and physical slowness and diminished ability to initiate activity that is in essence a mild form of akinetic mutism, with the same anatomic origins. *Catatonia* is a curious hypomobile and mute syndrome associated with a major psychosis. In the typical form patients appear awake with eyes open but make no voluntary or responsive movements, although they blink spontaneously, swallow, and may not appear distressed. Often, the eyes are half-open as if the patient is in a fog or light sleep. There are signs that indicate the patient is responsive, though it may take some ingenuity on the part of the examiner to demonstrate these. For example, eyelid elevation is actively resisted, blinking occurs in response to a visual threat, and the eyes move concomitantly with head rotation, all of which are inconsistent with a brain lesion. It is characteristic but not invariable in catatonia for the limbs to retain the posture, no matter how bizarre, in which they have been placed by the examiner ("waxy flexibility," or catalepsy.) Upon recovery, such patients have some memory of events that occurred during their catatonic stupor. The appearance is superficially similar to akinetic mutism, but clinical evidence of cerebral damage is lacking.

The *locked-in state* describes a pseudocoma in which an awake patient has no means of producing speech or volitional movement in order to indicate that he is awake, but vertical eye movements and lid elevation remain unimpaired, thus allowing the patient to signal. Such individuals have written entire treatises using Morse code. Infarction or hemorrhage of the ventral pons, which transects all descending corticospinal and corticobulbar pathways, is the usual cause. A similar awake but de-efferented state occurs as a result of total paralysis of the musculature in severe cases of Guillain-Barré syndrome (Chap. 365), critical illness neuropathy (Chap. 258), and pharmacologic neuromuscular blockade.

THE ANATOMY AND PHYSIOLOGY OF UNCONSCIOUSNESS To the extent that all complex waking behaviors require the widespread participation of the cerebral cortex, consciousness cannot exist without the activity of this structure. The RAS, a loosely grouped aggregation of neurons located in the upper brainstem and medial thalamus, maintains the cerebral cortex in a state of wakeful consciousness. It follows that the principal causes of coma are (1) lesions that damage the RAS or its projections; (2) destruction of large portions of both cerebral hemispheres; and (3) suppression of reticulo-cerebral function by drugs, toxins, or metabolic derangements such as hypoglycemia, anoxia, azotemia, or hepatic failure.

The regions of the reticular formation that are critical to the maintenance of wakefulness extend from the caudal midbrain to the lower thalamus. The neurons of the RAS project rostrally to the cortex primarily via thalamic relay nuclei that in turn exert a tonic influence on the activity of the entire cerebral cortex. The behavioral arousal ef-

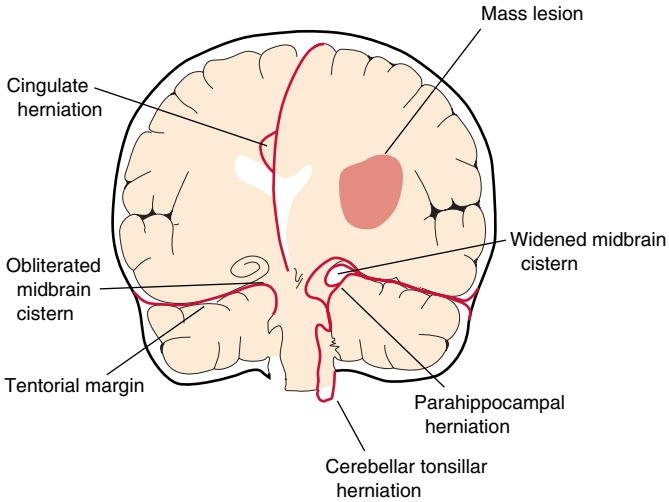

FIGURE 257-1 Types of cerebral herniation.

fected by somesthetic, auditory, and visual stimuli depends upon the rich reciprocal innervation that the RAS receives from these sensory systems. A most important practical consideration derives from the anatomic proximity of the RAS to structures that control pupillary function and eye movements. Pupillary enlargement and loss of vertical and adduction movements of the globes suggest that upper brainstem damage may be the source of coma.

Coma due to Cerebral Mass Lesions and Herniations The cranial cavity is separated into compartments by infoldings of the dura—the two cerebral hemispheres are separated by the falx, and the anterior and posterior fossae by the tentorium. *Herniation* refers to displacement of brain tissue into a compartment that it normally does not occupy. Many of the signs associated with coma, and indeed coma itself, can be attributed to these tissue shifts (Fig. 257-1).

Uncal transtentorial herniation refers to impaction of the anterior medial temporal gyrus (the uncus) into the anterior portion of the tentorial opening. The displaced tissue compresses the third nerve as it traverses the subarachnoid space and results in enlargement of the ipsilateral pupil (putatively because the fibers subserving parasympathetic pupillary function are located peripherally in the nerve). The coma that follows may be due to lateral compression of the midbrain against the opposite tentorial edge by the displaced parahippocampal gyrus (Fig. 257-2). In some cases the lateral displacement causes compression of the opposite cerebral peduncle, producing a Babinski response and hemiparesis contralateral to the original hemiparesis (the Kernohan-Woltman sign). In addition to compressing the upper brainstem, tissue shifts, including herniations, may compress major blood vessels, particularly the anterior and posterior cerebral arteries as they pass over the tentorial reflections, thus producing brain infarctions. The distortions may also entrap portions of the ventricular system, resulting in regional hydrocephalus.

Central transtentorial herniation denotes a symmetric downward movement of the upper thalamic region through the tentorial opening. Miotic pupils and drowsiness are the heralding signs. Both temporal and central herniations are thought to cause progressive compression of the brainstem from above: first the midbrain, then the pons, and finally the medulla. The result is a sequential appearance of neurologic signs that correspond to the affected level. Other forms of herniation are *transfalcial herniation* (displacement of the cingulate gyrus under the falx and across the midline), and *foraminal herniation* (downward forcing of the cerebellar tonsils into the foramen magnum).

A direct relationship between the various configurations of transtentorial herniations and coma is not always found. Displacement of deep brain structures by a mass in any direction, with or without herniation, is adequate to compress the region of the RAS and result in coma. Furthermore, drowsiness and stupor typically occur with moderate horizontal shifts at the level of the diencephalon (thalami) well before transtentorial or other herniations are evident. Lateral shift is easily quantified on axial images of computed tomography (CT) and magnetic resonance imaging (MRI) scans (Fig. 257-2). In cases of *acutely appearing masses*, a fairly consistent relationship exists between the degree of horizontal displacement of midline structures and the level of consciousness. Specifically, horizontal displacement of the pineal calcification of 3 to 5 mm is generally associated with drowsiness, 6 to 8 mm with stupor, and >9 mm with coma. At the same time, intrusion of the medial temporal lobe into the tentorial opening may be apparent on MRI and CT scan by an obliteration of the cisterns that surround the upper brainstem.

Coma and Confusional States due to Metabolic Disorders Many systemic metabolic abnormalities cause coma by interrupting the delivery of energy substrates (hypoxia, ischemia, hypoglycemia) or by altering neuronal excitability (drug and alcohol intoxication, anesthesia, and epilepsy). The same metabolic abnormalities that produce coma may in milder form induce widespread cortical dysfunction and an acute confusional state. Thus, in metabolic encephalopathies, clouded consciousness and coma are in a continuum. Neuropathologic changes are variable—prominent in hypoxia-ischemia, evident as astrocytic changes in hepatic coma, and negligible in renal and other metabolic encephalopathies.

Cerebral neurons are fully dependent on cerebral blood flow (CBF) and the related delivery of oxygen and glucose. CBF approximates 75 mL per 100 g/min in gray matter and 30 mL per 100 g/min in white matter (mean = 55 mL per 100 g/min); oxygen consumption is 3.5 mL per 100 g/min, and glucose utilization is 5 mg per 100 g/min. Brain stores of glucose provide energy for approximately 2 min after blood flow is interrupted, and oxygen stores last 8 to 10 s after the cessation of blood flow. Simultaneous hypoxia and ischemia exhaust glucose more rapidly. The electroencephalogram (EEG) rhythm in these circumstances becomes diffusely slowed, typical of metabolic encephalopathies, and as conditions of substrate delivery worsen, eventually all recordable brain electrical activity ceases. In almost all instances of metabolic encephalopathy, the global metabolic activity of the brain is reduced in proportion to the degree of unconsciousness.

Conditions such as hypoglycemia, hyponatremia, hyperosmolarity, hypercapnia, hypercalcemia, and hepatic and renal failure are associated with a variety of alterations in neurons and

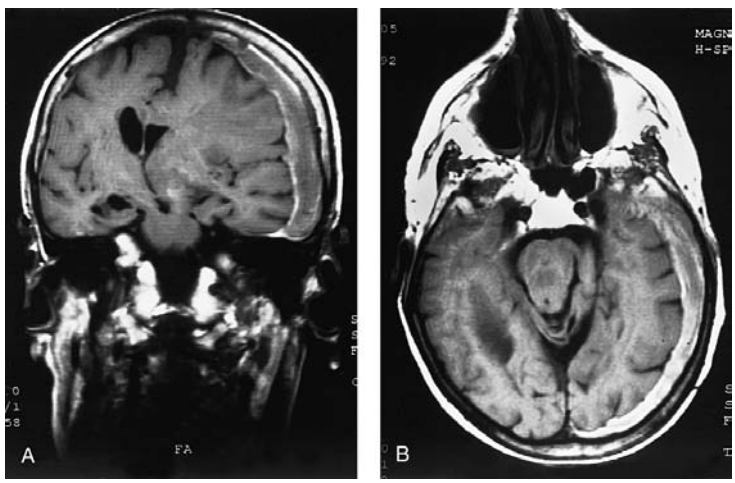

FIGURE 257-2 Coronal *(A)* and axial *(B)* magnetic resonance images from a stuporous patient with a left third nerve palsy as a result of a large left-sided subdural hematoma (seen as a gray-white rim). The upper midbrain and lower thalamic regions are compressed and displaced horizontally away from the mass, and there is transtentorial herniation of the medial temporal lobe structures, including the uncus anteriorly. The lateral ventricle opposite to the hematoma has become enlarged as a result of compression of the third ventricle.

astrocytes. The reversible effects of these conditions on the brain are not understood, but may result from impaired energy supplies, changes in ion fluxes across neuronal membranes, and neurotransmitter abnormalities. For example, the high brain ammonia concentration of hepatic coma interferes with cerebral energy metabolism and with the Na^+, K^+-ATPase pump, increases the number and size of astrocytes, alters nerve cell function, and causes increased concentrations of potentially toxic products of ammonia metabolism; it may also result in abnormalities of neurotransmitters, including putative "false" neurotransmitters that are active at receptor sites. Apart from hyperammonemia, which of these mechanisms is of critical importance is not clear. The mechanism of the encephalopathy of renal failure is also not known. Unlike ammonia, urea itself does not produce central nervous system (CNS) toxicity. A multifactorial causation has been proposed, including increased permeability of the blood-brain barrier to toxic substances such as organic acids and an increase in brain calcium or cerebrospinal fluid (CSF) phosphate content.

Coma and seizures are a common accompaniment of any large shifts in sodium and water balance. These changes in osmolarity arise from systemic medical disorders including diabetic ketoacidosis, the nonketotic hyperosmolar state, and hyponatremia from any cause (e.g., water intoxication, excessive secretion of antidiuretic hormone or atrial natriuretic peptides). The volume of brain water correlates with the level of consciousness in these states, but other factors also play a role. Sodium levels below 125 mmol/L induce confusion, and below 115 mmol/L are associated with coma and convulsions. In hyperosmolar coma the serum osmolarity generally exceeds 350 mosmol/L. *As in most other metabolic encephalopathies, the severity of neurologic change depends to a large degree on the rapidity with which the serum changes occur*. Hypercapnia depresses the level of consciousness in proportion to the rise in CO_2 tension in the blood; the level of consciousness also depends on the rapidity of change. The pathophysiology of other metabolic encephalopathies such as hypercalcemia, hypothyroidism, vitamin B_{12} deficiency, and hypothermia are incompletely understood but must also reflect derangements of CNS biochemistry and membrane function.

Epileptic Coma Continuous, generalized electrical discharges of the cortex (*seizures*) are associated with coma even in the absence of epileptic motor activity (*convulsions*). The self-limited coma that follows seizures, termed the *postictal state*, may be due to exhaustion of energy reserves or effects of locally toxic molecules that are the byproduct of seizures. The postictal state produces a pattern of continuous, generalized slowing of the background EEG activity similar to that of other metabolic encephalopathies.

Pharmacologic Coma This class of encephalopathy is in large measure reversible and leaves no residual damage providing hypoxia does not supervene. Many drugs and toxins are capable of depressing nervous system function. Some produce coma by affecting both the brainstem nuclei, including the RAS, and the cerebral cortex. The combination of cortical and brainstem signs, which occurs in certain drug overdoses, may lead to an incorrect diagnosis of structural brainstem disease.

APPROACH TO THE PATIENT

Acute respiratory and cardiovascular problems should be attended to prior to neurologic assessment. In most instances, a complete medical evaluation, except for vital signs, funduscopy, and examination for nuchal rigidity, may be deferred until the neurologic evaluation has established the severity and nature of coma. →***The approach to the patient with trauma is discussed in Chap. 357.***

History In many cases, the cause of coma is immediately evident (e.g., trauma, cardiac arrest, or known drug ingestion). In the remainder, certain points are especially useful: (1) the circumstances and rapidity with which neurologic symptoms developed; (2) the antecedent symptoms (confusion, weakness, headache, fever, seizures, dizziness, double vision, or vomiting); (3) the use of medications, illicit drugs, or alcohol; and (4) chronic liver, kidney, lung, heart, or other medical disease. Direct interrogation or telephone calls to family and observers on the scene are an important part of the initial evaluation. Ambulance technicians often provide the most useful information.

General Physical Examination The temperature, pulse, respiratory rate and pattern, and blood pressure should be measured quickly. Fever suggests a systemic infection, bacterial meningitis, or encephalitis; only rarely is it attributable to a brain lesion that has disturbed temperature-regulating centers. A slight elevation in temperature may follow vigorous convulsions. High body temperature, 42 to 44°C, associated with dry skin should arouse the suspicion of heat stroke or anticholinergic drug intoxication. Hypothermia is observed with alcoholic, barbiturate, sedative, or phenothiazine intoxication; hypoglycemia; peripheral circulatory failure; or hypothyroidism. Hypothermia itself causes coma only when the temperature is <31°C. Tachypnea may indicate acidosis or pneumonia. Aberrant respiratory patterns that reflect brainstem disorders are discussed below. Marked hypertension indicates hypertensive encephalopathy or a rapid rise in intracranial pressure (ICP) and may occur acutely after head injury. Hypotension is characteristic of coma from alcohol or barbiturate intoxication, internal hemorrhage, myocardial infarction, sepsis, profound hypothyroidism, or Addisonian crisis. The funduscopic examination can detect subarachnoid hemorrhage (subhyaloid hemorrhages), hypertensive encephalopathy (exudates, hemorrhages, vessel-crossing changes, papilledema), and increased ICP (papilledema). Petechiae suggest thrombotic thrombocytopenic purpura, meningococcemia, or a bleeding diathesis from which an intracerebral hemorrhage arises.

Neurologic Assessment First, the patient should be observed without intervention by the examiner. Patients who toss about, reach up toward the face, cross their legs, yawn, swallow, cough, or moan are close to being awake. Lack of restless movements on one side or an outturned leg suggests a hemiplegia. Intermittent twitching movements of a foot, finger, or facial muscle may be the only sign of seizures. Multifocal myoclonus almost always indicates a metabolic disorder, particularly uremia, anoxia, or drug intoxication (lithium and haloperidol are particularly likely to cause this sign), or the rarer conditions of spongiform encephalopathy and Hashimoto disease. In a drowsy and confused patient bilateral asterixis is a certain sign of metabolic encephalopathy or drug intoxication.

The terms *decorticate rigidity* and *decerebrate rigidity*, or "posturing," describe stereotyped arm and leg movements occurring spontaneously or elicited by sensory stimulation. Flexion of the elbows and wrists and supination of the arm (decortication) suggests bilateral damage rostral to the midbrain, whereas extension of the elbows and wrists with pronation (decerebration) indicates damage to motor tracts in the midbrain or caudal diencephalon. The less frequent combination of arm extension with leg flexion or flaccid legs is associated with lesions in the pons. These concepts have been adapted from animal work and cannot be applied with the same precision to coma in humans. In fact, acute and widespread cerebral disorders of any type, regardless of location, frequently cause limb extension, and almost all such extensor posturing becomes predominantly flexor as time passes. Posturing may also be unilateral and may coexist with purposeful limb movements, usually reflecting incomplete damage to the motor system.

Level of Arousal and Elicited Movements If the patient is not aroused by a conversational volume of voice, a sequence of increasingly intense stimuli is used to determine the threshold for arousal and the optimal motor response of each side of the body. The results of testing may vary from minute to minute and serial examinations are most useful. Tickling the nostrils with a cotton wisp is a mod-

erate stimulus to arousal—all but deeply stuporous and comatose patients will move the head away and rouse to some degree. Using the hand to remove the offending stimulus represents an even greater degree of responsiveness.

Responses to noxious stimuli should be appraised critically. Stereotyped posturing indicates severe dysfunction of the corticospinal system. Abduction-avoidance movement of a limb is usually purposeful and denotes an intact corticospinal system. Pressure on the knuckles or bony prominences and pinprick are humane forms of noxious stimuli; pinching the skin causes unsightly ecchymoses and is generally not necessary but may be useful in eliciting abduction withdrawal movements of the limbs.

Brainstem Reflexes Assessment of brainstem function is essential to localization of the lesion in coma (Fig. 257-3). The brainstem reflexes that are conveniently examined are pupillary responses to light, spontaneous and elicited eye movements, corneal responses, and the respiratory pattern. As a rule, when these brainstem activities are preserved, particularly the pupil reactions and eye movements, coma must be ascribed to bilateral hemispheral disease. The converse, however, is not always true as a mass in the hemispheres may be the underlying cause of coma but nonetheless produce brainstem signs.

PUPILS Pupillary reactions are examined with a bright, diffuse light (not an ophthalmoscope); if the response is absent, this should be confirmed by observation through a magnifying lens. Normally reactive and round pupils of midsize (2.5 to 5 mm) essentially exclude midbrain damage, either primary or secondary to compression. Reaction to light is often difficult to appreciate in pupils <2 mm in diameter, and bright room lighting mutes pupillary reactivity. One unreactive and enlarged pupil (>6 mm) or one that is poorly reactive signifies a compression or stretching of the third nerve from the effects of a mass above. Enlargement of the pupil contralateral to a mass may occur first but is infrequent. An oval and slightly eccentric pupil is a transitional sign that accompanies early midbrain–third nerve compression. The most extreme pupillary sign, bilaterally dilated and unreactive pupils, indicates severe midbrain damage, usually from compression by a mass. Ingestion of drugs with anticholinergic activity, the use of mydriatic eye drops, and direct ocular trauma are among the causes of misleading pupillary enlargement.

Unilateral miosis in coma has been attributed to dysfunction of sympathetic efferents originating in the posterior hypothalamus and descending in the tegmentum of the brainstem to the cervical cord. It is an occasional finding with a large cerebral hemorrhage that affects the thalamus. Reactive and bilaterally small (1 to 2.5 mm) but not pinpoint pupils are seen in metabolic encephalopathies or in deep bilateral hemispheral lesions such as hydrocephalus or thalamic hemorrhage. Very small but reactive pupils (<1 mm) characterize narcotic or barbiturate overdoses but also occur with extensive pontine hemorrhage. The response to naloxone and the presence of reflex eye movements (see below) distinguish these.

OCULAR MOVEMENTS The eyes are first observed by elevating the lids and noting the resting position and spontaneous movements of the globes. Lid tone, tested by lifting the eyelids and noting their resistance to opening and the speed of closure, is reduced progressively as coma deepens. Horizontal divergence of the eyes at rest is normal in drowsiness. As coma deepens, the ocular axes may become parallel again.

Spontaneous eye movements in coma often take the form of conjugate horizontal roving. This finding alone exonerates the midbrain and pons and has the same significance as normal reflex eye movements (see below). Conjugate horizontal ocular deviation to one side indicates damage to the pons on the opposite side or a lesion in the frontal lobe on the same side. This phenomenon may

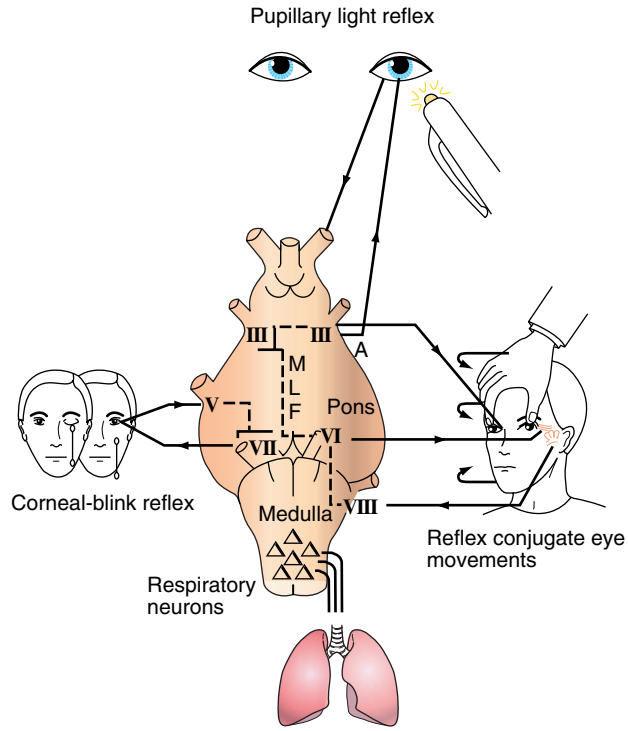

FIGURE 257-3 Examination of brainstem reflexes in coma. Midbrain and third nerve function are tested by pupillary reaction to light, pontine function by spontaneous and reflex eye movements and corneal responses, and medullary function by respiratory and pharyngeal responses. Reflex conjugate, horizontal eye movements are dependent on the medial longitudinal fasciculus (MLF) interconnecting the sixth and contralateral third nerve nuclei. Head rotation (oculocephalic reflex) or caloric stimulation of the labyrinths (oculovestibular reflex) elicits contraversive eye movements (for details see text).

be summarized by the following maxim: *The eyes look toward a hemispheral lesion and away from a brainstem lesion.* Seizures also drive the eyes to one side. On rare occasions, the eyes may turn paradoxically away from the side of a deep hemispheral lesion ("wrong-way eyes"). The eyes turn down and inward as a result of thalamic and upper midbrain lesions, typically with thalamic hemorrhage. "Ocular bobbing" describes a brisk downward and slow upward movement of the eyes associated with loss of horizontal eye movements and is diagnostic of bilateral pontine damage, usually from thrombosis of the basilar artery. "Ocular dipping" is a slower, arrhythmic downward movement followed by a faster upward movement in patients with normal reflex horizontal gaze; it indicates diffuse cortical anoxic damage. Many other complex eye movements are known but do not have the same significance as the ones already mentioned.

The oculocephalic reflexes depend on the integrity of the ocular motor nuclei and their interconnecting tracts that extend from the midbrain to the pons and medulla. These reflexes are elicited by moving the head from side to side or vertically and observing evoked eye movements in the direction opposite to the head movement (Fig. 257-3). These movements, called somewhat inappropriately "doll's eyes" (which refers more accurately to the reflex elevation of the eyelids with flexion of the neck), are normally suppressed in the awake patient by visual fixation. Their presence therefore indicates a reduced cortical influence on the brainstem. Furthermore, preservation of evoked reflex eye movements signifies the integrity of the brainstem and, by implication, that the origin of unconsciousness lies in the cerebral hemispheres. The opposite—the absence of reflex eye movements—signifies damage within the brainstem but can be produced infrequently by profound overdoses of certain drugs. Normal pupillary size and light reaction distinguishes most drug-induced comas from structural brainstem damage.

Thermal, or "caloric," stimulation of the vestibular apparatus (oculovestibular response) provides a more intense stimulus for the oculocephalic reflex but gives fundamentally the same information. The test is performed by irrigating the external auditory canal with cool water in order to induce convection currents in the labyrinths. After a brief latency, the result is tonic deviation of both eyes to the side of cool-water irrigation and nystagmus in the opposite direction. (The acronym "COWS" has been used to remind generations of medical students of the direction of nystagmus—"cold water opposite, warm water same"). The absence of nystagmus despite conjugate deviation of the globes signifies that the cerebral hemispheres are damaged or suppressed. The loss of conjugate ocular movements indicates brainstem damage.

By touching the cornea with a wisp of cotton, a response consisting of brief bilateral lid closure is normally observed. The corneal reflexes depend on the integrity of pontine pathways between the fifth (afferent) and both seventh (efferent) cranial nerves; although rarely useful alone, in conjunction with reflex eye movements they are important clinical tests of pontine function. CNS depressant drugs diminish or eliminate the corneal responses soon after reflex eye movements are paralyzed but before the pupils become unreactive to light. The corneal (and pharyngeal) response may be lost for a time on the side of an acute hemiplegia.

RESPIRATION Respiratory patterns are of less localizing value in comparison to other brainstem signs. Shallow, slow, but regular breathing suggests metabolic or drug depression. Cheyne-Stokes respiration in its classic cyclic form, ending with a brief apneic period, signifies bihemispheral damage or metabolic suppression and commonly accompanies light coma. Rapid, deep (Kussmaul) breathing usually implies metabolic acidosis but may also occur with pontomesencephalic lesions. Agonal gasps reflect bilateral lower brainstem damage and are well known as the terminal respiratory pattern of severe brain damage. A number of other cyclic breathing variations are of lesser significance.

LABORATORY STUDIES AND IMAGING The studies that are most useful in the diagnosis of confusional states and coma are: chemical-toxicologic analysis of blood and urine, cranial CT or MRI, EEG, and CSF examination. Arterial blood-gas analysis is helpful in patients with lung disease and acid-base disorders. The metabolic aberrations commonly encountered in clinical practice require measurements of electrolytes, glucose, calcium, osmolarity, and renal (blood urea nitrogen) and hepatic (NH_3) function. Toxicologic analysis is necessary in any case of coma where the diagnosis is not immediately clear. However, the presence of exogenous drugs or toxins, especially alcohol, does not exclude the possibility that other factors, particularly head trauma, are also contributing to the clinical state. An ethanol level of 43 mmol/L (200 mg/dL) in nonhabituated patients generally causes impaired mental activity and of >65 mmol/L (300 mg/dL) is associated with stupor. The development of tolerance may allow the chronic alcoholic to remain awake at levels >87 mmol/L (400 mg/dL).

The availability of CT and MRI has focused attention on causes of coma that are radiologically detectable (e.g., hemorrhages, tumors, or hydrocephalus). Resorting primarily to this approach, although at times expedient, is imprudent because most cases of coma (and confusion) are metabolic or toxic in origin. The notion that a normal CT scan excludes anatomic lesions as the cause of coma is also erroneous. Bilateral hemisphere infarction, small brainstem lesions, encephalitis, meningitis, mechanical shearing of axons as a result of closed head trauma, sagittal sinus thrombosis, and subdural hematomas that are isodense to adjacent brain are some of the disorders that may not be detected. Nevertheless, if the source of coma remains unknown, a scan should be obtained.

The EEG is useful in metabolic or drug-induced confusional states but is rarely diagnostic, except when coma is due to clinically unrecognized seizures, to herpesvirus encephalitis, or to Creutzfeldt-Jakob disease. The amount of background slowing of the EEG is a reflection of the severity of any diffuse encephalopathy. Predominant high-voltage slowing (δ or triphasic waves) in the frontal regions is typical of metabolic coma, as from hepatic failure, and widespread fast (β) activity implicates sedative drugs (e.g., diazepines, barbiturates). A special pattern of "α coma," defined by widespread, variable 8- to 12-Hz activity, superficially resembles the normal α rhythm of waking but is unresponsive to environmental stimuli. It results from pontine or diffuse cortical damage and is associated with a poor prognosis. Most importantly, EEG recordings may reveal clinically inapparent epileptic discharges in a patient with coma. Normal α activity on the EEG also alerts the clinician to the locked-in syndrome or to hysteria or catatonia.

Lumbar puncture is performed less frequently than in the past because neuroimaging scans effectively exclude intracerebral and subarachnoid hemorrhages that are severe enough to cause coma. However, examination of the CSF is indispensable in the diagnosis of meningitis and encephalitis. Lumbar puncture should therefore not be deferred if meningitis is a possibility.

DIFFERENTIAL DIAGNOSIS OF COMA (Table 257-1) The causes of coma can be conceptualized in three broad categories: those without focal neurologic signs (e.g., metabolic encephalopathies); meningitis syndromes, characterized by fever or stiff neck and an excess of cells in the spinal fluid (e.g., bacterial meningitis, subarachnoid hemorrhage);

TABLE 257-1 Differential Diagnosis of Coma

1. Diseases that cause no focal or lateralizing neurologic signs, usually with normal brainstem functions; CT scan and cellular content of the CSF are normal
   a. Intoxications: alcohol, sedative drugs, opiates, etc.
   b. Metabolic disturbances: anoxia, hyponatremia, hypernatremia, hypercalcemia, diabetic acidosis, nonketotic hyperosmolar hyperglycemia, hypoglycemia, uremia, hepatic coma, hypercarbia, addisonian crisis, hypo- and hyperthyroid states, profound nutritional deficiency
   c. Severe systemic infections: pneumonia, septicemia, typhoid fever, malaria, Waterhouse-Friderichsen syndrome
   d. Shock from any cause
   e. Postseizure states, status epilepticus, subclinical epilepsy
   f. Hypertensive encephalopathy, eclampsia
   g. Severe hyperthermia, hypothermia
   h. Concussion
   i. Acute hydrocephalus
2. Diseases that cause meningeal irritation with or without fever, and with an excess of WBCs or RBCs in the CSF, usually without focal or lateralizing cerebral or brainstem signs; CT or MRI shows no mass lesion
   a. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, trauma
   b. Acute bacterial meningitis
   c. Viral encephalitis
   d. Miscellaneous: Fat embolism, cholesterol embolism, carcinomatous and lymphomatous meningitis, etc.
3. Diseases that cause focal brainstem or lateralizing cerebral signs, with or without changes in the CSF; CT and MRI are abnormal
   a. Hemispheral hemorrhage (basal ganglionic, thalamic) or infarction (large middle cerebral artery territory) with secondary brainstem compression
   b. Brainstem infarction due to basilar artery thrombosis or embolism
   c. Brain abscess, subdural empyema
   d. Epidural and subdural hemorrhage, brain contusion
   e. Brain tumor with surrounding edema
   f. Cerebellar and pontine hemorrhage and infarction
   g. Widespread traumatic brain injury
   h. Metabolic coma (see above) with preexisting focal damage
   i. Miscellaneous: cortical vein thrombosis, herpes simplex encephalitis, multiple cerebral emboli due to bacterial endocarditis, acute hemorrhagic leukoencephalitis, acute disseminated (postinfectious) encephalomyelitis, thrombotic thrombocytopenic purpura, cerebral vasculitis, gliomatosis cerebri, pituitary apoplexy, intravascular lymphoma, etc.

Note: CT, computed tomography; CSF, cerebrospinal fluid; WBCs, white blood cells; RBCs, red blood cells; MRI, magnetic resonance imaging.

and those with prominent focal signs (e.g., stroke, cerebral hemorrhage). In most instances confusion and coma are part of an obvious medical problem such as drug ingestion, hypoxia, stroke, trauma, or liver or kidney failure. Conditions that cause sudden coma include drug ingestion, cerebral hemorrhage, trauma, cardiac arrest, epilepsy, or basilar artery embolism. Coma that appears subacutely is usually related to a preceding medical or neurologic problem, including the secondary brain swelling of a mass lesion such as tumor or cerebral infarction.

Cerebrovascular diseases cause the greatest difficulty in coma diagnosis (Chap. 349). These may be summarized as follows: (1) basal ganglia and thalamic hemorrhage (acute but not instantaneous onset, vomiting, headache, hemiplegia, and characteristic eye signs); (2) pontine hemorrhage (sudden onset, pinpoint pupils, loss of reflex eye movements and corneal responses, ocular bobbing, posturing, hyperventilation, and excessive sweating); (3) cerebellar hemorrhage (occipital headache, vomiting, gaze paresis, and inability to stand); (4) basilar artery thrombosis (neurologic prodrome or warning spells, diplopia, dysarthria, vomiting, eye movement and corneal response abnormalities, and asymmetric limb paresis); and (5) subarachnoid hemorrhage (precipitous coma after headache and vomiting). The most common stroke, infarction in the territory of the middle cerebral artery, does not cause coma, but edema surrounding large infarcts may expand during the first few days and act as a mass. The syndrome of acute hydrocephalus accompanies many intracranial diseases, particularly subarachnoid hemorrhage. It is characterized by headache and sometimes vomiting that may progress quickly to coma, with extensor posturing of the limbs, bilateral Babinski signs, small nonreactive pupils, and impaired oculocephalic movements in the vertical direction.

If the history and examination do not indicate the cause of coma, then information obtained from CT or MRI may be needed. As mentioned earlier, the majority of medical causes of coma can be established without a neuroimaging study.

BRAIN DEATH This is a state in which there has been cessation of cerebral blood flow; as a result there is global loss of brain function while respiration is maintained by artificial means and the heart continues to pump. It is the only type of brain damage that is recognized as equivalent to death. Many roughly equivalent criteria have been advanced for the diagnosis of brain death, and it is essential to adhere to those standards endorsed by the local medical community. Ideal criteria are simple, can be conducted at the bedside, and allow no chance of diagnostic error. They contain three essential elements: (1) widespread cortical destruction shown by deep coma—unresponsiveness to all forms of stimulation; (2) global brainstem damage demonstrated by absent pupillary light reaction and the loss of oculovestibular and corneal reflexes; and (3) destruction of the medulla manifested by complete apnea. The pulse rate is invariant and unresponsive to atropine. Diabetes insipidus is often present, but may develop hours or days after the other clinical signs of brain death. The pupils are often enlarged but may be mid-sized; they should not be constricted. The absence of deep tendon reflexes is not required because the spinal cord remains functional.

Demonstration that apnea is due to irreversible medullary damage requires that the P_{CO_2} be high enough to stimulate respiration during a test of spontaneous breathing (apnea test). This can be done safely by the use, prior to removing the ventilator, of diffusion oxygenation. This is accomplished by preoxygenation with 100% oxygen, which is then sustained during the test by oxygen administered through a tracheal cannula. CO_2 tension increases approximately 0.3 to 0.4 kPa/min (2 to 3 mmHg/min) during apnea. At the end of the period of observation, typically several minutes in duration, arterial P_{CO_2} should be at least >6.6 to 8.0 kPa (50 to 60 mmHg) for the test to be valid. Complete apnea is considered to be present if no respiratory effort is observed in the presence of a sufficiently elevated P_{CO_2}.

The possibility of profound drug-induced or hypothermic depression of the nervous system should be excluded, and some period of observation, usually 6 to 24 h, is desirable during which this state is shown to be sustained. It is particularly advisable to delay clinical testing for at least 24 h if a cardiac arrest has caused brain death or if the inciting disease is not known. An isoelectric EEG may be used as a confirmatory test for total cerebral damage but is not absolutely necessary. Radionuclide brain scanning, cerebral angiography, or transcranial Doppler measurements may also be used to demonstrate the absence of cerebral blood flow but they have not been extensively correlated with pathologic changes.

There is no compelling reason to embark on the demonstration of brain death except when organ transplantation is involved. Although it is largely accepted in western society that the respirator can be disconnected from a brain-dead patient, problems frequently arise because of poor communication and inadequate preparation of the family by the physician. Reasonable medical practice allows the removal of support or transfer out of an intensive care unit of patients who are not brain dead but whose condition is nonetheless hopeless and are likely to live for only a brief time.

TREATMENT

The immediate goal is prevention of further nervous system damage. Hypotension, hypoglycemia, hypercalcemia, hypoxia, hypercapnia, and hyperthermia should be corrected rapidly. An oropharyngeal airway is adequate to keep the pharynx open in drowsy patients who are breathing normally. Tracheal intubation is indicated if there is apnea, upper airway obstruction, hypoventilation, or emesis, or if the patient is liable to aspirate because of coma. Mechanical ventilation is required if there is hypoventilation or a need to induce hypocapnia in order to lower ICP as described below. Intravenous access is established, and naloxone and dextrose are administered if narcotic overdose or hypoglycemia are even remote possibilities; thiamine is given along with glucose to avoid provoking Wernicke disease in malnourished patients. In cases of suspected basilar thrombosis with brainstem ischemia, intravenous heparin or a thrombolytic agent is often utilized, after cerebral hemorrhage is excluded by a neuroimaging study. Physostigmine may awaken patients with anticholinergic-type drug overdose, but must be used only by experienced physicians and with careful monitoring; many physicians believe that it should only be used to treat anticholinergic overdose–associated cardiac arrhythmias. The use of benzodiazepine antagonists offers some prospect of improvement after overdoses of soporific drugs and has transient benefit in hepatic encephalopathy. Intravenous administration of hypotonic solutions should be monitored carefully in any serious acute brain illness because of the potential for exacerbating brain swelling. Cervical spine injuries must not be overlooked, particularly prior to attempting intubation or evaluating of oculocephalic responses. Headache accompanied by fever and meningismus indicates an urgent need for examination of the CSF to diagnose meningitis. If the lumbar puncture in a case of suspected meningitis is delayed for any reason, an antibiotic such as a third-generation cephalosporin should be administered as soon as possible, preferably after obtaining blood cultures. The management of raised ICP is discussed in Chap. 258.

PROGNOSIS The prediction of the outcome of coma must be considered in reference to long-term care and medical resources. One hopes to avoid the emotionally painful, hopeless outcome of a patient who is left severely disabled or vegetative. The uniformly pessimistic outcome of the persistent vegetative state has already been mentioned. Children and young adults may have ominous early clinical findings such as abnormal brainstem reflexes and yet recover, so that temporization in offering a prognosis in this group of patients is wise. Metabolic comas have a far better prognosis than traumatic comas. All schemes for prognosis in adults should be taken as approximations, and medical judgments must be tempered by factors such as age, underlying systemic disease, and general medical condition. In an attempt to collect prognostic information from large numbers of patients

with head injury, the Glasgow Coma Scale was devised; empirically it has predictive value in cases of brain trauma (Chap. 357). For anoxic and metabolic coma, clinical signs such as the pupillary and motor responses after 1 day, 3 days, and 1 week have been shown to have predictive value (Chap. 258). The absence of the cortical waves of the somatosensory evoked potentials has also proved a strong indicator of poor outcome in coma from any cause.

258 CRITICAL CARE NEUROLOGY

J. Claude Hemphill

Life-threatening neurologic illness may be caused by a primary disorder affecting any region of the neuroaxis or may occur as a consequence of a systemic disorder such as hepatic failure, multisystem organ failure, or cardiac arrest (Table 258-1). Neurologic critical care focuses on preservation of neurologic tissue and prevention of secondary brain injury caused by ischemia, edema, and elevated intracranial pressure (ICP).

PATHOPHYSIOLOGY ■ Brain Edema

Swelling, or edema, of brain tissue occurs with many types of brain injury. The two principal types of edema are vasogenic and cytotoxic. *Vasogenic edema* refers to the influx of fluid and solutes into the brain through an incompetent blood-brain barrier (BBB). In the normal cerebral vasculature, endothelial tight junctions associated with astrocytes create an impermeable barrier (the BBB), through which access into the brain interstitium is dependent upon specific transport mechanisms (Chap. 345). The BBB may be compromised in ischemia, trauma, infection, and metabolic derangements. Typically, vasogenic edema develops rapidly following injury. *Cytotoxic edema* refers to cellular swelling and occurs in a variety of settings including brain ischemia and trauma. Early astrocytic swelling is a hallmark of ischemia. Brain edema that is clinically significant usually represents a combination of vasogenic and cellular components. Edema can lead to increased ICP as well as tissue shifts and brain displacement from focal processes. These tissue shifts can cause injury by mechanical distraction and compression in addition to the ischemia of impaired perfusion consequent to the elevated ICP.

Ischemic Cascade and Cellular Injury

When delivery of substrates, principally oxygen and glucose, is inadequate to sustain cellular function, a series of interrelated biochemical reactions known as the *ischemic cascade* is initiated. The release of excitatory amino acids, especially glutamate, leads to influx of calcium and sodium ions, which disrupt cellular homeostasis. An increased intracellular calcium concentration may activate proteases and lipases, which then lead to lipid peroxidation and free radical–mediated cell membrane injury. Cytoxic edema ensues, and ultimately necrotic cell death and tissue infarction occur. This pathway to irreversible cell death is common to ischemic stroke, global cerebral ischemia, and traumatic brain injury. *Penumbra* refers to ischemic brain tissue that has not yet undergone irreversible infarction, implying that the region is potentially salvagable if ischemia can be reversed. Factors that may exacerbate ischemic

TABLE 258-1 Neurologic Disorders in Critical Illness

Localization Along Neuroaxis	Syndrome
CENTRAL NERVOUS SYSTEM	
Brain: Cerebral hemispheres	Global encephalopathy
	Sepsis
	Organ failure—hepatic, renal
	Medication related
	Sedatives/hypnotics/analgesics
	H_2 blockers, antihypertensives
	Drug overdose
	Electrolyte disturbance—hyponatremia; hypoglycemia
	Hypotension/hypoperfusion
	Hypoxia
	Meningitis
	Subarachnoid hemorrhage
	Wernicke's disease
	Seizure—postictal or nonconvulsive status
	Hypertensive encephalopathy
	Hypothyroidism—myxedema
	Focal deficits
	Ischemic stroke
	Tumor
	Abscess, subdural empyema
	Subdural/epidural hematoma
Brainstem	Mass effect and compression
	Ischemic stroke, intraparenchymal hemorrhage
	Hypoxia
Spinal cord	Mass effect and compression
	Disc herniation
	Epidural hematoma
	Ischemia—hypotension/embolic
	Subdural empyema
	Trauma, central cord syndrome
PERIPHERAL NERVOUS SYSTEM	
Peripheral nerve	
Axonal	Critical illness polyneuropathy
	Possible neuromuscular blocking agent complication
	Metabolic disturbances, uremia—hyperglycemia
	Medication effects—chemotherapeutic, antiretroviral
Demyelinating	Guillian-Barré syndrome
	Chronic inflammatory demyelinating polyneuropathy
Neuromuscular junction	Prolonged effect of neuromuscular blockade
	Medication effects—aminoglycosides
	Myasthenia-gravis, Lambert-Eaton syndrome
Muscle	Septic myopathy
	Cachectic myopathy—with or without disuse atrophy
	Electrolyte disturbances—hypokalemia/hyperkalemia; hypophosphatemia
	Acute quadriplegic myopathy

brain injury include systemic hypotension and hypoxia, which further reduce substrate delivery to vulnerable brain tissue, and fever, seizures, and hyperglycemia, which can increase cellular metabolism outstripping compensatory processes. Clinically, these events are known as *secondary brain insults* because they lead to exacerbation of the primary brain injury. Prevention, identification, and treatment of secondary brain insults are fundamental goals of management.

An alternative pathway of cellular injury is *apoptosis*. This process implies programmed cell death, which may occur in the setting of ischemic stroke, global cerebral ischemia, traumatic brain injury, and possibly intracerebral hemorrhage. Apoptotic cell death can be distinguished histologically from the necrotic cell death of ischemia and is mediated through a different set of biochemical pathways. At present, interventions for prevention and treatment of apoptotic cell death remain less well defined than those for ischemia. →***Excitotoxicity and mechanisms of cell death are discussed in more detail in Chap. 345.***

Cerebral Perfusion and Autoregulation Brain tissue requires constant perfusion in order to ensure adequate delivery of substrate. The hemodynamic response of the brain has the capacity to preserve perfusion across a wide range of systemic blood pressures. Cerebral perfusion pressure (CPP), defined as the mean systemic arterial pressure (MAP) minus the ICP, provides the driving force for circulation across the capillary beds of the brain. *Autoregulation* refers to the physiologic response whereby cerebral blood flow (CBF) remains relatively constant over a wide range of blood pressures as a consequence of alterations of cerebrovascular resistance (Fig. 258-1). If systemic blood pressure drops, cerebral perfusion is preserved through vasodilatation of arterioles in the brain; likewise, arteriolar vasoconstriction occurs at high systemic pressures to prevent hyperperfusion. At the extreme limits of MAP or CPP (high or low), flow becomes directly related to perfusion pressure. These autoregulatory changes occur in the microcirculation and are mediated by vessels below the resolution of those seen on angiography. CBF is also strongly influenced by pH and P_{CO_2}. CBF increases with hypercapnia and acidosis and decreases with hypocapnia and alkalosis. This forms the basis for the use of hyperventilation to lower ICP, and this effect on ICP is mediated through a decrease in intracranial blood volume. Cerebral autoregulation is critical to the normal homeostatic functioning of the brain, and this process may be disordered focally and unpredictably in disease states such as traumatic brain injury and severe focal cerebral ischemia.

Cerebrospinal Fluid and Intracranial Pressure The cranial contents consist essentially of brain, cerebrospinal fluid (CSF), and blood. CSF is produced principally in the choroid plexus of each lateral ventricle, exits the brain via the foramina of Luschka and Magendi, and flows over the cortex to be absorbed into the venous system along the superior sagittal sinus. Approximately 150 mL of CSF are contained within the ventricles and surrounding the brain and spinal cord; the cerebral blood volume is also ~150 mL. The bony skull offers excellent protection for the brain but allows little tolerance for additional volume. Significant increases in volume eventually result in increased ICP. Obstruction of CSF outflow, edema of cerebral tissue, or increases in volume from tumor or hematoma may increase ICP. Elevated ICP diminishes cerebral perfusion and can lead to tissue ischemia. Ischemia in turn may lead to vasodilatation via autoregulatory mechanisms designed to restore cerebral perfusion. However, vasodilatation also increases cerebral blood volume, which in turn then increases ICP, lowers CPP, and provokes further ischemia (Fig. 258-2). This vicious cycle is commonly seen in traumatic brain injury, massive intracerebral hemorrhage, and large hemispheric infarcts with significant tissue shift.

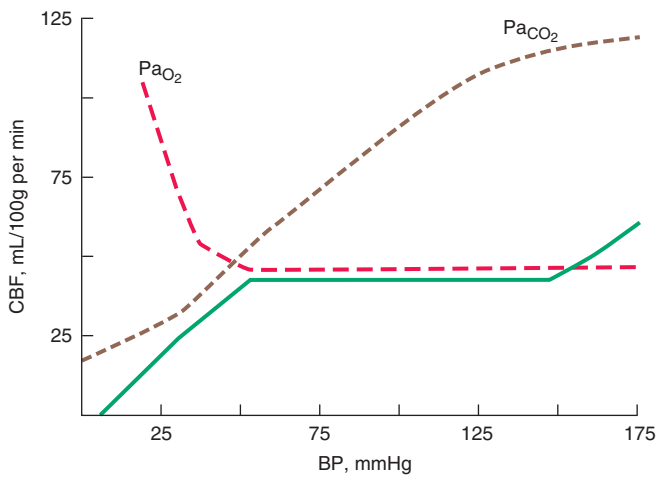

FIGURE 258-1 Autoregulation of cerebral blood flow (solid line). Cerebral perfusion is constant over a wide range of systemic blood pressure. Perfusion is increased in the setting of hypoxia or hypercarbia. BP, blood pressure; CBF, cerebral blood flow. *(Reprinted with permission from Anesthesiology 43:447, 1975. Copyright 1975, Lippincott Company.)*

APPROACH TO THE PATIENT

Critically ill patients with severe central nervous system dysfunction require rapid evaluation and intervention in order to limit primary and secondary brain injury. Initial neurologic evaluation should be performed concurrent with stabilization of basic respiratory, cardiac, and hemodynamic parameters. Significant barriers may exist to neurologic assessment in the critical care unit. Endotracheal intubation and the use of sedative or paralytic agents to facilitate critical care procedures can make clinical assessment challenging.

An impaired level of consciousness is frequent in critically ill patients. The essential first task in assessment is to determine whether the cause of dysfunction is related to a diffuse, usually metabolic, process or whether a focal, usually structural, process is implicated. Examples of diffuse processes include metabolic encephalopathies related to organ failure, drug overdose, or hypoxia-ischemia. Focal processes include ischemic and hemorrhagic stroke and traumatic brain injury, especially with intracranial hematomas. Since these two categories of disorders have fundamentally different causes, treatments, and prognoses, the initial focus is on making this distinction rapidly and accurately. →***The approach to the confused or comatose patient is discussed in Chap. 257; etiologies are listed in Table 257-1.***

Minor focal deficits may be present on the neurologic examination in patients with metabolic encephalopathies. However, the finding of prominent focal signs such as pupillary asymmetry, hemiparesis, gaze palsy, or paraplegia should alert the examiner to the possibility of a structural lesion. All patients with a decreased level of consciousness associated with focal findings should undergo an urgent neuroimaging procedure, as should all patients

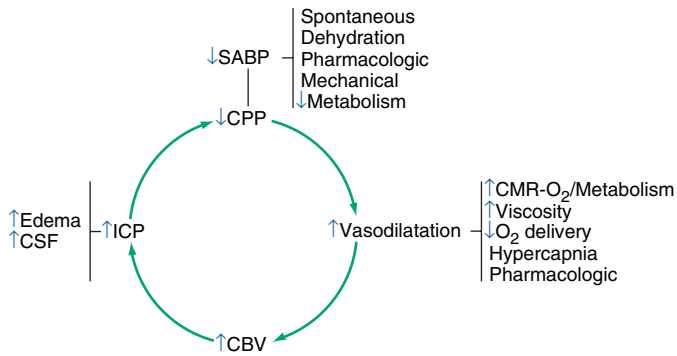

FIGURE 258-2 Ischemia and vasodilatation. Reduced cerebral perfusion pressure (CPP) leads to increased ischemia, vasodilatation, increased intracranial pressure (ICP), and further reductions in CPP, a cycle leading to further neurologic injury. CBV, cerebral blood volume; CMR, cerebral metabolic rate; CSF, cerebrospinal fluid; SABP, systolic arterial blood pressure. *(From MJ Rosner et al: J Neurosurg 83:949, 1995; with permission.)*

with coma of unknown etiology. Computed tomographic (CT) scanning is usually the most appropriate initial study because it can be performed quickly in critically ill patients and demonstrates hemorrhage, hydrocephalus, and intracranial tissue shifts well. Magnetic resonance imaging (MRI) may provide more specific information in some situations, such as acute ischemic stroke (diffusion-weighted imaging, DWI) and cerebral venous sinus thrombosis (magnetic resonance venography, MRV). Any suggestion of trauma from the history or examination should alert the examiner to the possibility of cervical spine injury and prompt an imaging evaluation using plain x-rays, MRI, or CT.

Other diagnostic studies are best utilized in specific circumstances, usually when neuroimaging studies fail to reveal a structural lesion and the etiology of the altered mental state remains uncertain. Electroencephalography (EEG) can be important in the evaluation of critically ill patients with severe brain dysfunction. The EEG of metabolic encephalopathy typically reveals generalized slowing. One of the most important uses of EEG is to help exclude inapparent seizures, especially nonconvulsive status epilepticus. Untreated continuous or frequently recurrent seizures may cause neuronal injury, making the diagnosis and treatment of seizure crucial in this patient group. Lumbar puncture (LP) may be necessary to exclude infectious processes, and an elevated opening pressure may be an important clue to cerebral venous sinus thrombosis. In patients with coma or profound encephalopathy, it is preferable to perform a neuroimaging study prior to LP. If bacterial meningitis is suspected, an LP may be performed first or antibiotics may be empirically administered before the diagnostic studies are completed. Standard laboratory evaluation of critically ill patients should include assessment of serum electrolytes (especially sodium and calcium), glucose, renal and hepatic function, complete blood counts, and coagulation. Serum or urine toxicology screens should be performed in patients with encephalopathy of unknown cause. EEG, LP, and other specific laboratory tests are most useful when the mechanism of the altered level of consciousness is uncertain; they are not routinely performed in clear-cut cases of stroke or traumatic brain injury.

Monitoring of ICP can be an important tool in selected patients. Indications for ICP monitoring, as well as specific types of monitors, vary. In general, patients who should be considered for ICP monitoring are those with primary neurologic disorders, such as stroke or traumatic brain injury, who are at significant risk for secondary brain injury due to elevated ICP and decreased CPP. Such patients include those with severe traumatic brain injury resulting in coma [Glasgow Coma Scale (GCS) score of ≤8 (Table 357-1)]; those with large tissue shifts from supratentorial ischemic or hemorrhagic stroke resulting in decreased consciousness; and those with (or at risk for) hydrocephalus from subarachnoid hemorrhage, intraventricular hemorrhage, or posterior fossa stroke. An additional disorder in which ICP monitoring can add important information is fulminant hepatic failure, in which elevated ICP may be treated with barbiturates or, eventually, liver transplantation. In general, ventriculostomy is preferable to ICP monitoring devices that are placed in brain parenchyma, because ventriculostomy allows CSF drainage as a method of treating elevated ICP. However, parenchymal ICP monitoring is most appropriate for patients with diffuse edema and small ventricles (which may make ventriculostomy placement more difficult) or any degree of coagulopathy (in which ventriculostomy carries a higher risk of hemorrhagic complications).

Treatment of Elevated ICP Elevated ICP may occur in a wide range of disorders including head trauma, intracerebral hemorrhage, subarachnoid hemorrhage with hydrocephalus, and fulminant hepatic failure. Because CSF and blood volume can be redistributed initially, by the time elevated ICP occurs intracranial compliance is severely impaired. At this point, small changes in the volume of CSF, intravascular blood, edema, or a mass lesion may result in significant changes in ICP. Elevated ICP then diminishes cerebral perfusion. This is a fundamental mechanism of secondary ischemic brain injury and constitutes an emergency that requires immediate attention. Specific thresholds of ICP vary, but in general, ICP should be maintained at <20 mmHg and CPP should be maintained at ≥70 mmHg.

A number of different interventions may lower ICP, and ideally the selection of treatment will be based on the underlying mechanism responsible for the elevated ICP (Table 258-2). For example, in hydrocephalus from subarachnoid hemorrhage, the principal cause of elevated ICP is impairment of CSF drainage. In this setting, ventricular drainage of CSF is likely to be sufficient and most appropriate. In head trauma and stroke, cytotoxic edema may be most responsible, and the use of osmotic diuretics such as mannitol becomes an appropriate early step. As described above, elevated ICP may cause tissue ischemia, and, if cerebral autoregulation is intact, the resulting vasodilatation can lead to a cycle of worsening ischemia. Paradoxically, administration of vasopressor agents to increase mean arterial pressure may actually lower ICP by improving perfusion, thereby allowing autoregulatory vasoconstriction as ischemia is relieved and ultimately decreasing intracranial blood volume.

Early signs of elevated ICP include drowsiness and a diminished level of consciousness. Neuroimaging studies may reveal evidence of edema and mass effect. Hypotonic intravenous fluids should be avoided, and elevation of the head of the bed is recommended. Patients must be carefully observed for risk of aspiration and compromise of the airway as the level of alertness declines. Coma and unilateral pupillary changes are late signs and require immediate intervention. Emergent treatment of elevated ICP is most quickly achieved by intubation and hyperventilation, which causes vasoconstriction and reduces cerebral blood volume. Because of the concern of provoking or worsening cerebral ischemia, hyperventilation is best used for short periods of time until a more definitive treatment can be instituted. Furthermore, the effects of continued hyperventilation on ICP are short-lived, often only for several hours because of the buffering capacity of the cerebral interstitium, and rebound elevated ICP may accompany abrupt discontinuation of hyperventilation. As the level of consciousness declines to coma, the ability to follow the neurologic status of the patient by examination deteriorates and measurement of ICP must be considered. If a ventriculostomy device is in place, direct drain-

TABLE 258-2 Stepwise Approach to Treatment of Elevated Intracranial Pressure[a]

Insert ICP monitor—ventriculostomy versus parenchymal device
General goals: maintain ICP < 20 mmHg and CPP > 70 mmHg

For ICP > 20–25 mmHg for >5 min:
1. Drain CSF via ventriculostomy (if in place)
2. Elevate head of the bed
3. Osmotherapy—mannitol 25–100 g q4h as needed (maintain serum osmolality <320 mosmol)
4. Glucocorticoids—dexamethasone 4 mg q6h for vasogenic edema from tumor, abscess (avoid glucocorticoids in head trauma, ischemic and hemorrhagic stroke)
5. Sedation (e.g., morphine, propofol, or midazolam); add neuromuscular paralysis if necessary (patient will require endotracheal intubation and mechanical ventilation at this point, if not before)
6. Hyperventilation—to Pa_{CO_2} 30–35 mmHg
7. Pressor therapy—phenylephrine, dopamine, or norepinephrine to maintain adequate MAP to ensure CPP > 70 mmHg (maintain euvolemia to minimize deleterious systemic effects of pressors)
8. Consider second-tier therapies for refractory elevated ICP
   a. High-dose barbiturate therapy ("pentobarb coma")
   b. Aggressive hyperventilation to Pa_{CO_2} < 30 mmHg
   c. Hemicraniectomy

[a] Throughout ICP treatment algorithm, consider repeat head CT to identify mass lesions amenable to surgical evacuation.

Note: CPP, cerebral perfusion pressure; MAP, mean arterial pressure; Pa_{CO_2}, arterial partial pressure of carbon dioxide.

age of CSF to reduce ICP is possible. Finally, high-dose barbiturates or hypothermia are sometimes used for refractory elevated ICP, although these have significant side effects and have not been shown to improve outcome.

Secondary Brain Insults Patients with primary brain injuries, whether trauma or stroke, are at significant risk for ongoing secondary ischemic brain injury. Because secondary brain injury can be a major determinant of a poor outcome, strategies for minimizing secondary brain insults are an integral part of the critical care of all patients. While elevated ICP may lead to secondary ischemia, most secondary brain injury is mediated through other clinical events that exacerbate the ischemic cascade already initiated by the primary brain injury. Episodes of secondary brain insults are usually not associated with apparent neurologic worsening. Rather, they lead to cumulative injury, which manifests as higher mortality or worsened long-term functional outcome. Thus, clinical strategies involve close monitoring of vital signs and early intervention to prevent secondary ischemia. Avoiding hypotension and hypoxia is critical, as significant hypotensive events (systolic blood pressure < 90 mmHg) as short as 10 min in duration have been shown to adversely influence outcome after traumatic brain injury. Even in patients with stroke or head trauma who do not require ICP monitoring, close attention to adequate cerebral perfusion is warranted. Hypoxia (percutaneous oxygen saturation $< 90\%$), alone or in combination with hypotension, also leads to secondary brain injury. Likewise, fever and hyperglycemia both worsen experimental ischemia and have been associated with worsened clinical outcome after stroke and head trauma. Aggressive control of fever with a goal of normothermia is warranted and can usually be achieved with antipyretic medications and cooling blankets. The use of intravenous insulin infusion is encouraged for control of hyperglycemia as this allows better regulation of serum glucose levels than subcutaneous insulin. A reasonable goal is to maintain the serum glucose level at <160 mg/dL, although some experts believe that even tighter control is appropriate. New cerebral monitoring tools that allow continuous evaluation of brain tissue oxygen tension, CBF, and metabolism (via microdialysis) may further improve the management of secondary brain injury.

CRITICAL CARE DISORDERS OF THE CENTRAL NERVOUS SYSTEM ASSOCIATED WITH SYSTEMIC DISEASE

HYPOXIC-ISCHEMIC ENCEPHALOPATHY This occurs from lack of delivery of oxygen to the brain because of hypotension or respiratory failure. The most common causes are myocardial infarction, cardiac arrest, shock, asphyxiation, paralysis of respiration, and carbon monoxide or cyanide poisoning. In some circumstances, hypoxia may predominate. Carbon monoxide and cyanide poisoning are termed *histotoxic hypoxia* since they cause a direct impairment of the respiratory chain.

Clinical Manifestations Mild degrees of pure hypoxia, such as occur at high altitudes, cause impaired judgment, inattentiveness, motor incoordination, and, at times, euphoria. However, with hypoxia-ischemia, such as occurs with circulatory arrest, consciousness is lost within seconds. If circulation is restored within 3 to 5 min, full recovery may occur, but if hypoxia-ischemia lasts beyond 3 to 5 min, some degree of permanent cerebral damage is the rule. Except in extreme cases, it may be difficult to judge the precise degree of hypoxia-ischemia, and some patients make a relatively full recovery after even 8 to 10 min of global cerebral ischemia. The distinction between pure hypoxia and hypoxia-ischemia is important, since a Pa_{O_2} as low as 20 mmHg (2.7 kPa) can be well tolerated if it develops gradually and normal blood pressure is maintained, but short durations of very low or absent cerebral circulation may result in permanent impairment.

Clinical examination at different time points after a hypoxic-ischemic insult (especially cardiac arrest) is useful in assessing prognosis for long-term neurologic outcome. The prognosis is better for patients with intact brainstem function, as indicated by normal pupillary light responses and intact oculocephalic (doll's-eyes), oculovestibular (caloric), and corneal reflexes (Fig. 258-3). Absence of these reflexes and the presence of persistently dilated pupils that do not react to light are grave prognostic signs. A uniformly dismal prognosis from hypoxic-ischemic coma is conveyed by the clinical findings of absence of pupillary light reflex or absence of a motor response to pain on day 3 following the injury. Electrophysiologically, the finding of bilateral absence of the early cortical somatosensory evoked response (SSEPs) in the first week also conveys a poor prognosis. Whether administration of mild hypothermia after cardiac arrest (see "Treatment") will alter the usefulness of these clinical and electrophysiologic predictors is unknown. Long-term consequences of hypoxic-ischemic encepha-

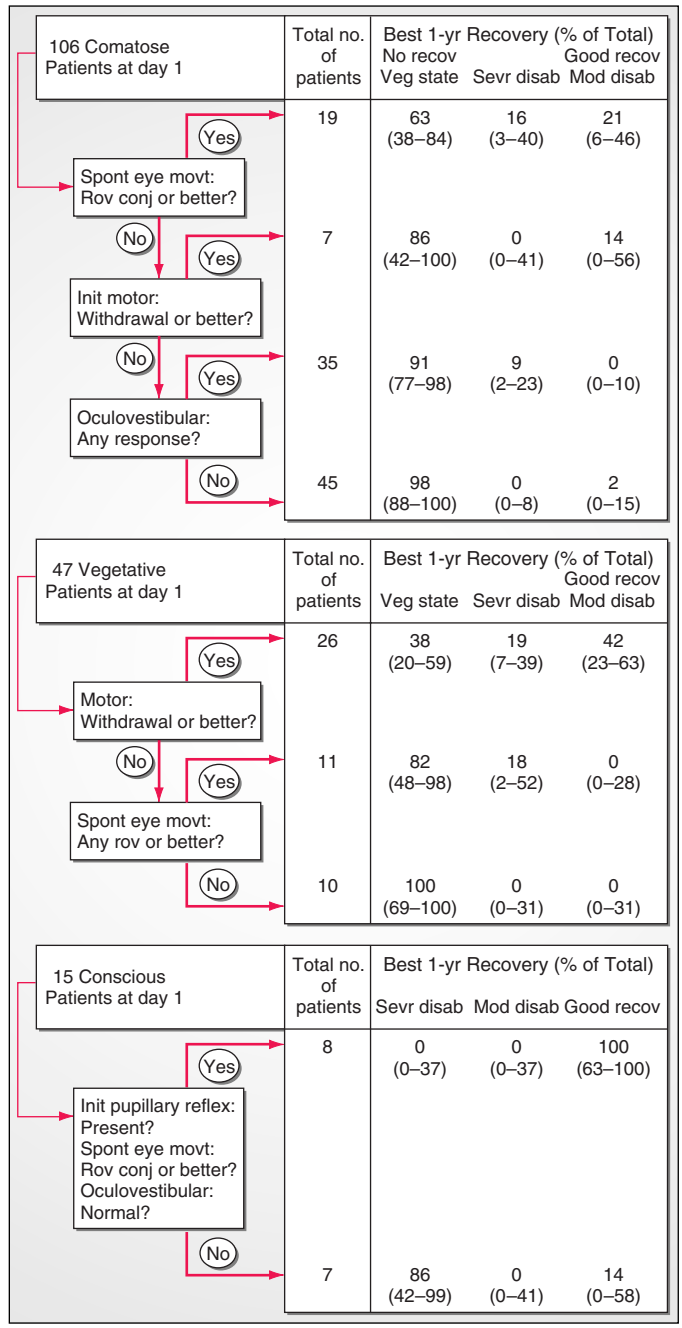

FIGURE 258-3 Clinical examination at day 1 provides useful prognostic information in hypoxic-ischemic encephalopathy. Numbers in parentheses represent 95% confidence intervals. lopathy include persistent coma or vegetative state (Chap. 257), dementia, visual agnosia (Chap. 23), parkinsonism, choreoathetosis, cerebellar ataxia, myoclonus, seizures, and an amnestic state, which may be a consequence of selective damage to the hippocampus.

Pathologic Findings Principal histologic findings are extensive multifocal or diffuse laminar cortical necrosis (Fig. 258-4), with almost invariable involvement of the hippocampus. The hippocampal CA1 neurons (Fig. 350-1) are vulnerable to even brief episodes of hypoxia-ischemia, perhaps explaining why selective persistent memory deficits may occur after brief cardiac arrest. Scattered small areas of infarction or neuronal loss may be present in the basal ganglia, hypothalamus, or brainstem. In some cases, extensive bilateral thalamic scarring may affect pathways that mediate arousal, and this pathology may be responsible for the persistent vegetative state. A specific form of hypoxic-ischemic encephalopathy, so-called watershed infarcts, occurs at the distal territories between the major cerebral arteries and can cause cognitive deficits, including visual agnosia, and weakness that is greater in proximal than in distal muscle groups.

Diagnosis Diagnosis is based upon the history of a hypoxic-ischemic event such as cardiac arrest. Blood pressure <70 mmHg systolic or $Pa_{O_2} < 40$ mmHg is usually necessary, although both absolute levels as well as duration of exposure are important determinants of cellular injury. Occasionally the clinical and radiographic features of a hypoxic-ischemic syndrome are seen without documented profound hypotension or hypoxia. Carbon monoxide intoxication can be confirmed by measurement of carboxyhemoglobin and is suggested by a cherry red color of the skin, although the latter is an inconsistent clinical finding.

TREATMENT

Treatment should be directed at restoration of normal cardiorespiratory function. This includes securing a clear airway, ensuring adequate oxygenation and ventilation, and restoring cerebral perfusion, whether by cardiopulmonary resuscitation, fluid, pressors, or cardiac pacing. Hypothermia may target the neuronal cell injury cascade and has substantial neuroprotective properties in experimental models of brain injury. In two recently reported clinical trials, mild hypothermia (33°C) improved functional outcome in patients who remained comatose after resuscitation from a cardiac arrest. Treatment was initiated within minutes of cardiac resuscitation and continued for 12 h in one study and 24 h in the other. Potential complications of hypothermia treatment include coagulopathy and an increased risk of infection.

Severe carbon monoxide intoxication may be treated with hyperbaric oxygen. Anticonvulsants may be needed to control seizures, although these are not usually given prophylactically. Posthypoxic myoclonus may respond to oral administration of clonazepam at doses of 1.5 to 10 mg daily or valproate at doses of 300 mg to 1200 mg daily in divided doses. Myoclonic status epilepticus after a severe hypoxic-ischemic insult portends a universally poor prognosis, even if seizures are controlled.

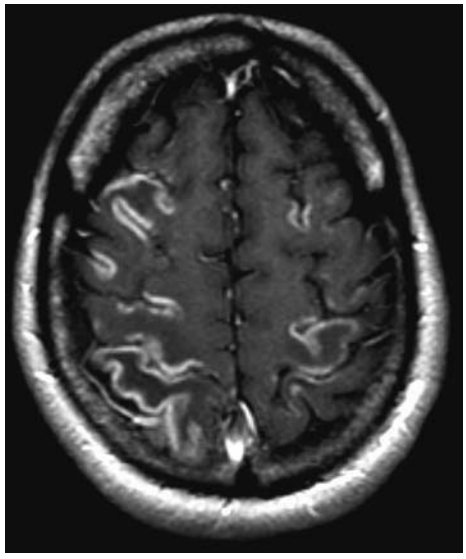

FIGURE 258-4 Cortical laminar necrosis in hypoxic-ischemic encephalopathy. T1-weighted postcontrast magnetic resonance image shows cortical enhancement in a watershed distribution consistent with laminar necrosis.

DELAYED POSTANOXIC ENCEPHALOPATHY Delayed postanoxic encephalopathy is an uncommon phenomenon in which patients appear to make an initial recovery from hypoxic-ischemic insult but then develop a relapse characterized by apathy, confusion, and agitation. Progressive neurologic deficits may include shuffling gait, diffuse rigidity and spasticity, persistent parkinsonism or myoclonus, and, on occasion, coma and death after 1 to 2 weeks. Widespread cerebral demyelination may be present.

Carbon monoxide and cyanide intoxication can also cause a delayed encephalopathy. Little clinical impairment is evident when the patient first regains consciousness, but a parkinsonian syndrome characterized by akinesia and rigidity without tremor may develop. Symptoms can worsen over months, accompanied by increasing evidence of damage in the basal ganglia as seen on both CT and MRI.

METABOLIC ENCEPHALOPATHIES Altered mental states, variously described as confusion, delirium, disorientation, and encephalopathy, are present in many patients with severe illness in an intensive care unit (ICU). Older patients are particularly vulnerable to delirium, a confusional state characterized by disordered perception, frequent hallucinations, delusions, and sleep disturbance. This is often attributed to medication effects, sleep deprivation, pain, and anxiety. The term *ICU psychosis* has been used to describe a mental state with profound agitation occurring in this setting. The presence of family members in the ICU may help to calm and orient agitated patients, and in severe cases, low doses of neuroleptics (e.g., haloperidol 0.5 to 1 mg) can be useful. Ultimately, the psychosis resolves with improvement in the underlying illness and a return to familiar surroundings.

In the ICU setting, several metabolic causes of an altered level of consciousness predominate. Hypercarbic encephalopathy can present with headache, confusion, stupor, or coma. Hypoventilation syndrome occurs most frequently in patients with a history of chronic CO_2 retention who are receiving oxygen therapy for emphysema or chronic pulmonary disease (Chap. 246). The elevated Pa_{CO_2} leading to CO_2 narcosis may have a direct anesthetic effect, and cerebral vasodilatation from increased Pa_{CO_2} can lead to increased ICP. Hepatic encephalopathy is suggested by asterixis and can occur in chronic liver failure or acute fulminant hepatic failure. Both hyperglycemia and hypoglycemia can cause encephalopathy, as can hypernatremia and hyponatremia. Confusion, impairment of eye movements, and gait ataxia are the hallmarks of acute Wernicke's disease (see below).

SEPTIC ENCEPHALOPATHY ■ Pathogenesis In patients with sepsis, the systemic response to infectious agents leads to the release of circulating inflammatory mediators that appear to contribute to encephalopathy. Critical illness, in association with the systemic inflammatory response syndrome (SIRS), can lead to multisystem organ failure. This syndrome can occur in the setting of apparent sepsis, severe burns, or trauma, even without clear identification of an infectious agent. Many patients with critical illness, sepsis, or SIRS develop encephalopathy without obvious explanation. This condition is broadly termed *septic encephalopathy*. While the specific mediators leading to neurologic dysfunction remain uncertain, it is clear that the encephalopathy is not simply the result of metabolic derangements of multiorgan failure. The cytokines tumor necrosis factor α, interleukin (IL) 1, IL-2, and IL-6 are thought to play a role in this syndrome.

Diagnosis Septic encephalopathy presents clinically as a diffuse dysfunction of the brain without prominent focal findings. Confusion, disorientation, agitation, and fluctuations in level of alertness are typ-

ical. In more profound cases, especially with hemodynamic compromise, the decrease in level of alertness can be more prominent, at times resulting in coma. Hyperreflexia and frontal release signs such as a grasp or snout reflex (Chap. 23) can be seen. Abnormal movements such as myoclonus, tremor, or asterixis can occur. Septic encephalopathy is quite common, occurring in the majority of patients with sepsis and multisystem organ failure. Diagnosis is often difficult because of the multiple potential causes of neurologic dysfunction in critically ill patients, and requires exclusion of structural, metabolic, toxic, and infectious (e.g., meningitis or encephalitis) causes. Although the mortality of patients with septic encephalopathy severe enough to produce coma approaches 50%, this reflects the severity of the underlying critical illness and is not a direct result of the septic encephalopathy. Neurologically, successful treatment of the underlying critical illness almost always results in complete resolution of the encephalopathy, without significant residua.

CENTRAL PONTINE MYELINOLYSIS This disorder typically presents in a devastating fashion as quadriplegia and pseudobulbar palsy. Predisposing factors include severe underlying medical illness or nutritional deficiency; most cases are associated with rapid correction of hyponatremia or with hyperosmolar states. The pathology consists of demyelination without inflammation in the base of the pons, with relative sparing of axons and nerve cells. MRI is useful in establishing the diagnosis (Fig. 258-5) and may also identify partial forms that present as confusion, dysarthria, and/or disturbances of conjugate gaze without quadriplegia. Therapeutic guidelines for the restoration of severe hyponatremia should aim for gradual correction, i.e., by $\leq$10 mmol/L (10 meq/L) within 24 h and 20 mmol/L (20 meq/L) within 48 h.

WERNICKE'S DISEASE Wernicke's disease is a common and preventable disorder due to a deficiency of thiamine (Chap. 61). In the United States, alcoholics account for most cases, but patients with malnutrition due to hyperemesis, starvation, renal dialysis, cancer, or AIDS are also at risk. The characteristic clinical triad is that of ophthalmoplegia, ataxia, and global confusion. However, only one-third of patients with acute Wernicke's disease present with the classic clinical triad. Most patients are profoundly disoriented, indifferent, and inattentive, although rarely they have an agitated delirium related to ethanol withdrawal. If the disease is not treated, stupor, coma, and death may ensue. Ocular motor abnormalities include horizontal nystagmus on lateral gaze, lateral rectus palsy (usually bilateral), conjugate gaze palsies, and rarely ptosis. Gait ataxia probably results from a combination of polyneuropathy, cerebellar involvement, and vestibular paresis. The pupils are usually spared, but they may become miotic with advanced disease.

Wernicke's disease is usually associated with other manifestations of nutritional disease, such as polyneuropathy. Rarely, amblyopia or myelopathy occurs. Tachycardia and postural hypotension may be related to impaired function of the autonomic nervous system or to the coexistence of cardiovascular beriberi. Patients who recover show improvement in ocular palsies within hours after the administration of thiamine, but horizontal nystagmus may persist. Ataxia improves more slowly than the ocular motor abnormalities. Approximately half recover incompletely and are left with a slow, shuffling, wide-based gait and an inability to tandem walk. Apathy, drowsiness, and confusion improve more gradually. As these symptoms recede, an amnestic state with impairment in recent memory and learning may become more apparent (*Korsakoff's psychosis*). Korsakoff's psychosis is frequently persistent; the residual mental state is characterized by gaps in memory, confabulation, and disordered temporal sequencing.

Pathology Lesions in the periventricular regions of the diencephalon, midbrain, and brainstem as well as the superior vermis of the cerebellum consist of symmetric discoloration of structures surrounding the third ventricle, aqueduct, and fourth ventricle, with petechial hemorrhages in occasional acute cases and atrophy of the mamillary bodies in most chronic cases. There is frequently endothelial proliferation,

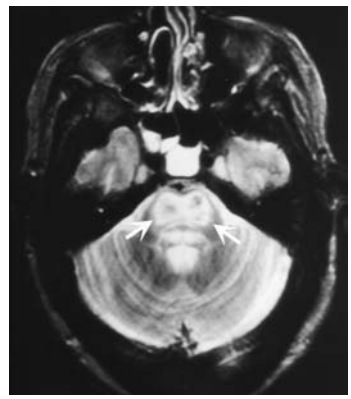

FIGURE 258-5 Central pontine myelinolysis. Axial T2-weighted magnetic resonance scan through the pons reveals a symmetric area of abnormal high signal intensity within the basis pontis (*arrows*).

demyelination, and some neuronal loss. These changes may be detected by MRI scanning (Fig. 258-6). The amnestic defect is related to lesions in the dorsal medial nuclei of the thalamus.

Pathogenesis Thiamine is a cofactor of several enzymes, including transketolase, pyruvate dehydrogenase, and α-ketoglutarate dehydrogenase. Thiamine deficiency produces a diffuse decrease in cerebral glucose utilization and results in mitochondrial damage. Glutamate accumulates owing to impairment of α-ketoglutarate dehydrogenase activity and, in combination with the energy deficiency, may result in excitotoxic cell damage.

TREATMENT

Wernicke's disease is a medical emergency and requires immediate administration of thiamine, in a dose of 100 mg either intravenously or intramuscularly. The dose should be given daily until the patient resumes a normal diet and should be begun prior to treatment with intravenous glucose solutions. Glucose infusions may precipitate Wernicke's disease in a previously unaffected patient or cause a rapid worsening of an early form of the disease. For this reason, thiamine should be administered to all alcoholic patients requiring parenteral glucose.

CRITICAL CARE DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM ASSOCIATED WITH SYSTEMIC DISEASE

Critical illness with disorders of the peripheral nervous system (PNS) arises in two contexts: (1) primary neurologic diseases that require critical care interventions such as intubation and mechanical ventilation, and (2) secondary PNS manifestations of systemic critical illness, often involving multisystem organ failure. The former include acute polyneuropathies such as Guillain-Barré syndrome (Chap. 365), neuromuscular junction disorders including myasthenia gravis (Chap.

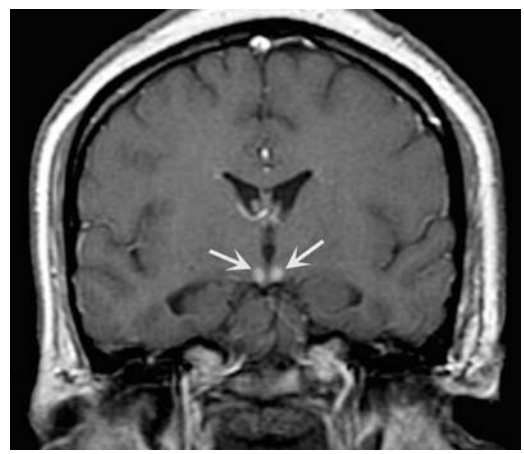

FIGURE 258-6 Wernicke's disease. Coronal T1-weighted postcontrast magnetic resonance image reveals abnormal enhancement of the mammillary bodies (*arrows*), typical of acute Wernicke's encephalopathy.

366) and botulism (Chap. 125), and primary muscle disorders such as polymyositis (Chap. 369). The latter result either from the systemic disease itself or as a consequence of interventions.

General principles of respiratory evaluation in patients with PNS involvement, regardless of cause, include assessment of pulmonary mechanics, such as maximal inspiratory force (MIF) and vital capacity (VC), and evaluation of strength of bulbar muscles. Regardless of the cause of weakness, endotracheal intubation should be considered when the MIF falls to < -25 cmH_2O or the VC is <1 L. Also, patients with severe palatal weakness may require endotracheal intubation in order to prevent acute upper airway obstruction or recurrent aspiration. Arterial blood gases and percutaneous oxygen saturation are used to follow patients with potential respiratory compromise from PNS dysfunction. However, intubation and mechanical ventilation should be undertaken based on clinical assessment rather than waiting until oxygen saturation drops or CO_2 retention develops from hypoventilation. →***Principles of mechanical ventilation are discussed in Chap. 252.***

NEUROPATHY While encephalopathy may be the most obvious neurologic dysfunction in critically ill patients, dysfunction of the PNS is also quite common. It is typically present in patients with prolonged critical illnesses lasting several weeks and involving sepsis; clinical suspicion is aroused when there is failure to wean from mechanical ventilation despite improvement of the underlying sepsis and critical illness. *Critical illness polyneuropathy* refers to the most common PNS complication related to critical illness; it is seen in the setting of prolonged critical illness, sepsis, and multisystem organ failure. Neurologic findings include diffuse weakness, decreased reflexes, and distal sensory loss. Electrophysiologic studies demonstrate a diffuse, symmetric, distal axonal sensorimotor neuropathy, and pathologic studies have confirmed axonal degeneration. The precise mechanism of critical illness polyneuropathy remains unclear, but circulating factors such as cytokines, which are associated with sepsis and SIRS, are thought to play a role. It has been reported that up to 70% of patients with the sepsis syndrome have some degree of neuropathy, although far fewer have a clinical syndrome profound enough to cause severe respiratory muscle weakness requiring prolonged mechanical ventilation or resulting in failure to wean. Treatment is supportive, with specific intervention directed at treating the underlying illness. While spontaneous recovery is usually seen, the time course may extend over weeks to months and necessitate long-term ventilatory support and care even after the underlying critical illness has resolved.

DISORDERS OF NEUROMUSCULAR TRANSMISSION A defect in neuromuscular transmission may be a source of weakness in critically ill patients. Myasthenia gravis may be a consideration; however, persistent weakness secondary to impaired neuromuscular junction transmission is almost always due to administration of drugs. A number of medications impair neuromuscular transmission; these include antibiotics, especially aminoglycosides, and beta-blocking agents. In the ICU, the nondepolarizing neuromuscular blocking agents (nd-NMBAs), also known as muscle relaxants, are most commonly responsible. Included in this group of drugs are such agents as pancuronium, vecuronium, rocuronium, and atracurium. They are often used to facilitate mechanical ventilation or other critical care procedures, but with prolonged use persistent neuromuscular blockade may result in weakness even after discontinuation of these agents hours or days earlier. Risk factors for this prolonged action of neuromuscular blocking agents include female sex, metabolic acidosis, and renal failure.

Prolonged neuromuscular blockade does not appear to produce permanent damage to the PNS. Once the offending medications are discontinued, full strength is restored, although this may take days. In general, the lowest dose of neuromuscular blocking agent should be used to achieve the desired result, and, when these agents are used in the ICU, a peripheral nerve stimulator should be used to monitor neuromuscular junction function.

MYOPATHY Critically ill patients, especially those with sepsis, frequently develop muscle wasting, often in the face of seemingly adequate nutritional support. The assumption has been that this represents a catabolic myopathy brought about as a result of multiple factors, including elevated cortisol and catecholamine release and other circulating factors induced by the SIRS. In this syndrome, known as *cachectic myopathy*, serum creatine kinase levels and electromyography (EMG) are normal. Muscle biopsy shows type II fiber atrophy. Panfascicular muscle fiber necrosis may also occur in the setting of profound sepsis. This so-called *septic myopathy* is characterized clinically by weakness progressing to a profound level over just a few days. There may be associated elevations in serum creatine kinase and urine myoglobin. Both EMG and muscle biopsy may be normal initially but eventually show abnormal spontaneous activity and panfascicular necrosis with an accompanying inflammatory reaction.

Acute quadriplegic myopathy describes a clinical syndrome of severe weakness seen in the setting of glucocorticoid and nd-NMBA use. The most frequent scenario in which this is encountered is the asthmatic patient who requires high-dose glucocorticoids and nd-NMBA to facilitate mechanical ventilation. This muscle disorder is not due to prolonged action of nd-NMBAs at the neuromuscular junction but, rather, is an actual myopathy with muscle damage; it has occasionally been described with high-dose glucocorticoid use alone. Clinically this syndrome is most often recognized when a patient fails to wean from mechanical ventilation despite resolution of the primary pulmonary process. Pathologically, there may be vacuolar changes in both type I and type II muscle fibers with evidence of regeneration. Acute quadriplegic myopathy has a good prognosis. If patients survive their underlying critical illness, the myopathy invariably improves and patients usually return to normal. However, because this syndrome is a result of true muscle damage, not just prolonged blockade at the neuromuscular junction, this process may take weeks or months, and tracheostomy with prolonged ventilatory support may be necessary. At present, it is unclear how to prevent this myopathic complication, except by avoiding use of nd-NMBAs, a strategy not always possible. Monitoring with a peripheral nerve stimulator can help to avoid the overuse of these agents. However, this is more likely to prevent the complication of prolonged neuromuscular junction blockade than it is to prevent this myopathy.

259 ADAPTATION TO RENAL INJURY

Robert M. Brenner, Barry M. Brenner

Near constancy of the internal environment, including the volume, composition, and compartmental distribution of the body fluids, is essential to survival. With normal day-to-day variations in the intake of food and water, preservation of the internal environment requires the excretion in amounts that balance the quantities ingested. While losses from intestines, lungs, and skin contribute, the greatest responsibility for solute and water excretion is borne by the kidneys. This chapter reviews the excretory functions of the kidney and examines how these functions are affected by chronic renal disease.

EFFECTS OF NEPHRON LOSS ON RENAL EXCRETORY MECHANISMS

GLOMERULAR ULTRAFILTRATION Urine production begins at the glomerulus where an ultrafiltrate of plasma is formed. The rate of glomerular ultrafiltration (glomerular filtration rate, GFR) is governed chiefly by forces favoring filtration on the one hand (hydraulic pressure in the glomerular capillaries) and forces opposing filtration on the other (the sum of hydraulic pressure in Bowman's space and colloid osmotic pressure of blood in the glomerular capillaries). The rate of glomerular plasma flow and the total surface area of the glomerular capillaries are also determinants of GFR. Decreased GFR can therefore be expected when (1) glomerular hydraulic pressure is reduced (as in circulatory shock); (2) tubule (hence Bowman's space) hydraulic pressure is elevated, as in urinary tract obstruction; (3) plasma colloid osmotic pressure rises to high levels (hemoconcentration due to severe volume depletion, or myeloma, other dysproteinemias); (4) renal, and hence glomerular, blood flow is reduced (severe hypovolemia, cardiac failure); (5) permeability is reduced (diffuse glomerular disease); or (6) filtration surface area is diminished, through nephron loss in progressive renal failure.

The glomerular capillary wall is specially adapted to allow passage of extremely large volumes of water while retaining all but the smallest solute molecules. Molecules the size of inulin (approximately 5200 mol wt) pass freely across the glomerular filtration barrier, appearing at approximately the same concentration in Bowman's space as in plasma. The passage of solutes across the glomerular barrier decreases progressively with increasing molecular size such that, as the molecular weight of albumin is approached, most of the solute is retained in the plasma. Albumin, a polyanionic molecule in plasma, is further retarded at the glomerular filtration barrier by *electrostatic forces* imparted by negatively charged cell-surface molecules on the epithelial foot processes that form the *filtration slits* and the *slit diaphragms*. With disruption of these structural and electrostatic barriers, as in many forms of glomerular injury (Chap. 264), large quantities of plasma proteins gain access to the glomerular filtrate.

GLOMERULAR ADAPTATIONS TO NEPHRON LOSS With loss of nephron mass, the remaining functional (or least injured) nephrons tend to hypertrophy and take on an increased workload so that the overall loss of function is minimized. For example, a patient with a unilateral nephrectomy loses one-half of the nephron mass, resulting in a 50% reduction in GFR at the time of surgery. However, within several months total GFR may rise to 80% of the preoperative value. This indicates that the GFR of the individual remaining nephrons has increased above normal, a state known as *hyperfiltration*. Increases in single-nephron GFR may be achieved by renal hemodynamic adjustments (increased glomerular plasma flow and increased glomerular capillary hydraulic pressure), which augment the forces driving ultrafiltration, and by glomerular hypertrophy, which increases the maximum surface area available for filtration. These structural adaptations are evident from the enlargement of glomeruli (and tubules) seen on histologic sections from persons with single kidneys. Similar structural changes are observed in kidneys damaged by chronic disease processes; foci of hypertrophied glomeruli and tubules are interspersed with areas of atrophic or scarred parenchyma. Although direct measurements of single-nephron GFR cannot be made in humans, it is reasonable to conclude that focal nephron enlargement as occurs in chronically diseased kidneys generally signifies focally increased single-nephron GFR, and that these dynamic adaptations represent compensatory adjustments for the effects of nephron loss through disease.

GLOMERULOTUBULAR BALANCE The close integration of glomerular and tubular functions (*glomerulotubular balance*) seen in chronic renal failure (CRF) supports the notion that progressive nephron obliteration is the usual mode of GFR reduction in CRF. Preservation of glomerulotubular balance until the terminal stages of CRF is fundamental to the *intact-nephron hypothesis*, which states that as CRF advances, kidney function is supported by a diminishing pool of functioning (or hyperfunctioning) nephrons, rather than relatively constant numbers of nephrons, each with diminishing function. This hypothesis has important implications for the mechanisms of disease progression in CRF. A considerable amount of evidence suggests that nephrons subjected to increased excretory burdens for prolonged periods actually sustain injury as a result of these adaptations: thus the cost of these compensatory adaptations to nephron loss may ultimately be relentless destruction of the remaining nephron pool.

The magnitude of the single-nephron hyperfiltration induced by loss of 50% of the total nephron mass usually has no serious adverse clinical consequences, even when sustained over two to three decades. When more than 50% of the total nephron mass is lost, however, as in renal-sparing surgery for bilateral trauma or neoplasm or from a renal disease whose activity has abated, the remaining nephrons are forced to the limits of their compensatory capacity. While these adaptations achieve remarkable short-term success at offsetting the tendency for GFR to fall, over time, proteinuria and focal and segmental glomerulosclerosis develop, the more so where greater amounts of nephrons are lost or removed. As a result, a progressive decline in GFR ensues. Experimental study of the processes that advance glomerular injury show that the adverse long-term consequences of severe nephron deficits are invariably preceded by increases in glomerular capillary hydraulic pressure (glomerular capillary hypertension), glomerular hyperperfusion, and hypertrophy. Interventions directed against these compensatory and maladaptive responses can greatly ameliorate the subsequent development of renal failure. In particular, drugs (e.g., angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) and other interventions (such as dietary protein restriction) that lower glomerular pressure can slow the rate of progression of experimental and human renal disease. In the absence of such interventions, more and more glomeruli cease to function through advancing glomerulosclerosis and disruption of tubule structure and function, leading eventually to marked or even total loss of GFR (i.e., end-stage renal disease). This *final common pathway* for chronic renal injury helps to explain the observed progressive nature of chronic renal failure resulting from many different kidney diseases.

BIOLOGIC CONSEQUENCES OF SUSTAINED REDUCTIONS IN GFR

Figure 259-1 depicts the major types of response to impaired GFR. The degree of reduction in total GFR is plotted on the abscissa, expressed as a percentage of normal (100%). The renal handling of most solutes normally present in glomerular filtrate conforms to one of three

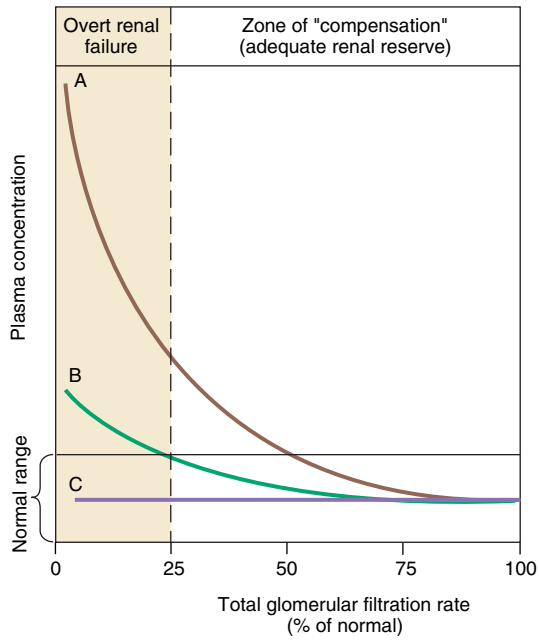

FIGURE 259-1 Representative patterns of adaptation for different types of solutes in body fluids in chronic renal failure. *[After NS Bricker et al, in BM Brenner (ed): Brenner and Rector's The Kidney, 6th ed. Philadelphia, Saunders, 2000.]*

patterns. Curve *A* describes the pattern with substances such as creatinine and urea that normally depend largely on glomerular filtration for urinary excretion, i.e., secretion contributes little to overall excretion. Therefore, as illustrated, gradual reductions in GFR are accompanied by progressive increases in plasma levels of creatinine, urea, and other substances normally excreted primarily by filtration.

The clinical course of CRF usually also approximates the pattern described by curve *A*. Patients with CRF usually pass from a long asymptomatic period of "compensation" to a more accelerated and clinically overt terminal phase. In other words, despite chronic injury leading to destruction of more than 50% of nephrons, plasma elevations of creatinine and urea may still lie within the normal limits for these substances. With further nephron loss and reduction in GFR, however, the limits of renal reserve are exceeded and continued accumulations of curve *A*–type solutes lead to abnormally elevated plasma concentrations (Fig. 259-1). Because some of these retained solutes are thought to exert "toxic" effects on all organ systems, clinical manifestations of CRF may now become apparent.

The accumulation of curve *A*–type solutes with chronic loss of renal function proceeds until external balance is restored, i.e., intake and/or production rates exactly match excretion rates. In the case of creatinine, for example, assuming a constant rate of creatinine production, a 50% reduction in GFR results in an approximate doubling of the plasma creatinine concentration. The latter restores the filtered load of creatinine (i.e., the product of GFR and plasma creatinine concentration) to normal, and the urinary excretion rate once again is equivalent to creatinine production. *In practice, so long as the net rates of acquisition and production (i.e., liver function and muscle mass) remain reasonably constant, the inverse relationship between plasma concentrations of solutes such as creatinine and urea and GFR is sufficiently reliable to serve as clinical indices of GFR.* However, where muscle mass is low, as with severe weight loss, even normal plasma levels of creatinine may belie substantial reductions in GFR.

In contrast to solutes of the curve *A* type, plasma levels of phosphate (PO_4^{3-}), urate, and potassium (K^+) and hydrogen (H^+) ions usually do not rise until the GFR falls to a small percentage of normal. With progressive renal failure this pattern of response (curve *B* in Fig. 259-1) reflects the participation of tubule transport mechanisms in the excretion of these substances. In other words, *as GFR declines, the tubules facilitate greater elimination of these substances, by enhancing secretion and/or by diminishing reabsorption, so that a greater fraction of the filtered load is excreted.* Plasma levels of curve *B*–type solutes, therefore, rise less than those of curve *A* because, with progressive reductions in GFR, *excretion rate per nephron* and therefore *fractional excretion* both increase. Eventually, however, with further loss of GFR, enhanced fractional excretion can no longer mitigate the reduction in net filtered load of these solutes and plasma levels rise (Fig. 259-1). For urate, PO_4^{3-}, and K^+, at least, increased fractional excretion serves to maintain normal plasma levels until GFR falls to less than one-fourth of normal.

Finally, for certain solutes, such as sodium chloride (NaCl), plasma concentrations remain normal throughout the course of CRF, despite unrestricted intake of these substances (curve *C* in Fig. 259-1). The compensatory mechanism required to achieve this represents a fundamental adaptation to chronic renal injury. To illustrate the magnitude of this adaptation, it is useful to compare the excretion of sodium (Na^+) in a normal individual (GFR of 125 mL/min) with that of a patient with advanced renal failure (GFR of 2 mL/min). Both individuals consume a conventional diet containing 7 g/d of salt (120 mmol Na^+). With a serum Na^+ concentration of 140 mmol/L, external Na^+ balance is achieved in the normal subject by excreting approximately 0.5% of the filtered load. By contrast, for external balance to be maintained in the patient with CRF, fractional excretion of Na^+ must rise to 30%. In other words, *to maintain external Na^+ balance*, the same amount of Na^+ must be excreted into the urine each day in the patient with CRF as in the normal individual. Given the drastic reduction in GFR in CRF, external balance can only be maintained by marked adaptations in the reabsorptive processes in surviving tubules. In this manner, a progressively larger fraction of the filtered load escapes reabsorption and appears in the final urine.

ADAPTATIONS IN TUBULE TRANSPORT MECHANISMS IN RESPONSE TO NEPHRON LOSS

Despite progressive nephron loss, many mechanisms that regulate renal solute and water balance differ only quantitatively, and not qualitatively, from those that operate normally. Thus, glomerulotubular balance is maintained. The most important of these mechanisms are considered below.

TUBULAR TRANSPORT OF SODIUM CHLORIDE AND WATER Most of the filtered water and sodium salts are reabsorbed by the tubules, leaving small and variable amounts, equivalent on average to the quantities ingested, to reach the final urine. About two-thirds of the glomerular ultrafiltrate is reabsorbed in the *proximal tubule* with little change in the osmolality or Na^+ concentration of the unreabsorbed fraction (Fig. 259-2). In other words, fluid reabsorption in the proximal tubule is nearly *isosmotic* and is coupled to the active transport of Na^+. Since chloride (Cl^-) and bicarbonate (HCO_3^-) are the primary anions in the extracellular fluid, they constitute the main solutes that accompany Na^+ reabsorption in the renal tubules. In the earliest portion of the proximal tubule, bicarbonate is the principal anion that accompanies the reabsorption of Na^+. This process occurs via a Na^+/H^+ exchanger at the luminal brush border and is dependent on the activity of carbonic anhydrase. Glucose, amino acids, and other organic solutes (e.g., lactate) are also extensively reabsorbed in the proximal tubule by cotransport mechanisms that link the cellular entry of these organic molecules with Na^+.

The coupling of water absorption (i.e., volume) with solute absorption appears to be dependent upon three processes. First, given the remarkably high water permeability of this segment, very small transepithelial osmolality differences, i.e., *luminal hypotonicity* of the order of 2 to 3 mosmol/L produced by solute absorption, could drive water absorption. Second, due to preferential absorption of HCO_3^- and organic solutes in the early portions of the proximal tubule, the concentrations of these substances decrease along the proximal tubule while that of chloride increases. Volume reabsorption would then occur if the diffusion of Na^+ and Cl^- down their respective electrochemical gradients across the proximal tubule epithelium occurred more

easily than the back-diffusion of sodium bicarbonate into the lumen, creating an *effective osmotic pressure gradient*. Finally, *lateral interstitial space hypertonicity* produced by differences in the rates at which solutes are transported into the spaces or exit them by diffusion may also contribute to the coupling of water and solute reabsorption.

Reabsorption of Fluid from Proximal Convoluted Tubules This is sensitive to *Starling forces*, i.e., the hydraulic and colloid osmotic (or oncotic) pressures acting across the walls of the peritubular capillaries. Because the plasma proteins in glomerular capillaries are concentrated by ultrafiltration, oncotic pressure rises along the glomerular capillary network. This step-up in oncotic pressure is transmitted largely unchanged to the first branches of the peritubular capillaries via the efferent arterioles. These resistance vessels cause a substantial drop in hydraulic pressure, however, so that when the plasma reaches the peritubular capillaries, oncotic pressure greatly exceeds hydraulic pressure. The Starling forces are therefore oriented in an *uptake* mode, in contrast to their configuration at the glomerulus where hydraulic pressure exceeds oncotic pressure, favoring *filtration*. The extent to which oncotic pressure exceeds hydraulic pressure in the peritubular capillary network modulates the overall rate of fluid absorption by the peritubular capillaries. Therefore, when peritubular capillary oncotic pressure falls, or hydraulic pressure rises, uptake of fluid by these capillaries is reduced. As a result, fluid is retained in the interstitial space, tending to increase hydraulic pressure, ultimately retarding the egress of fluid from the lateral intercellular channels.

Without an adequate route of drainage, fluid in the intercellular channels leaks back into the tubule lumen, thereby *diminishing net fluid reabsorption* from this tubule segment. The opposite occurs in states where peritubular oncotic pressure is increased (increased filtration fraction) or hydraulic pressure is decreased (enhanced efferent arteriolar tone). Under these circumstances, peritubular capillary uptake of reabsorbate is augmented, leading ultimately to *enhanced net fluid reabsorption* by the proximal tubule. Although physical factors appear to be the major determinants of fluid reabsorption in the proximal tubule, hormones (e.g., angiotensin II) may also modulate fluid reabsorption directly, by enhancing luminal Na^+ entry into proximal tubule cells via an apical Na^+/H^+ exchanger.

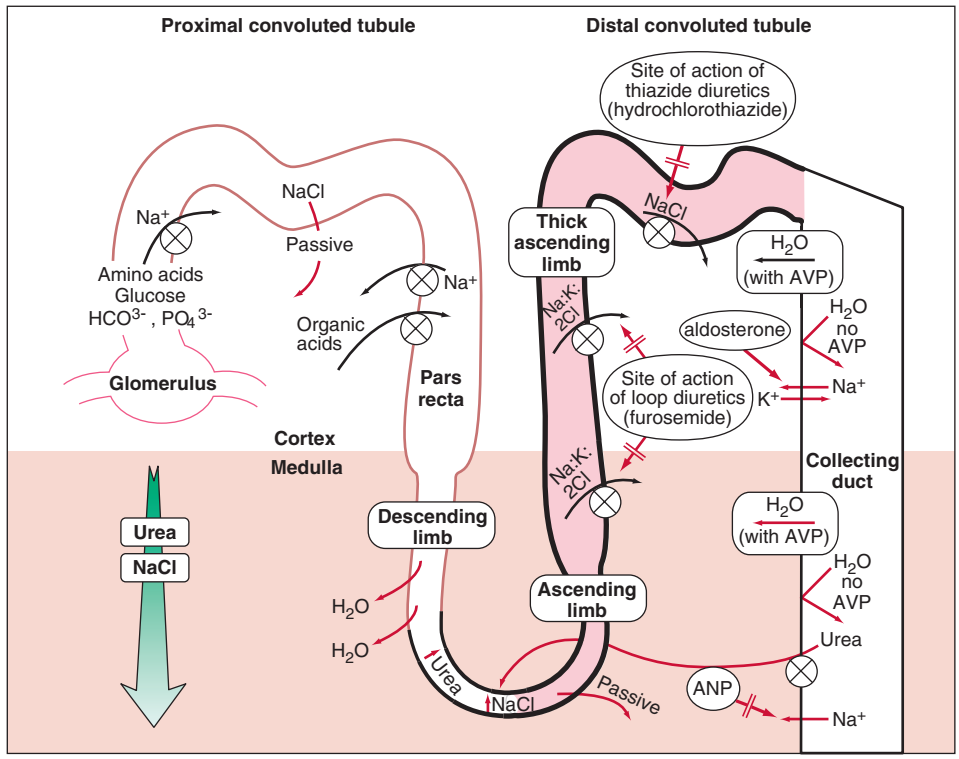

FIGURE 259-2 Transport functions of the various anatomic segments of the mammalian nephron. Fluid reabsorption across the proximal tubule is isosmotic and accounts for reabsorption of approximately two-thirds of the filtered Na^+ and H_2O. The major portions of the filtered HCO_3^-, amino acids, glucose, and phosphate are reabsorbed in the early proximal convoluted tubule. Reabsorption of glucose and amino acids is coupled to Na^+ transport and thereby generates a negative potential difference within the tubule lumen. At the same time, HCO_3^- is reabsorbed by a nonelectrogenic mechanism, via H^+ secretion. The active transport of these solutes results in transepithelial concentration and effective osmotic pressure gradients promoting H_2O flow across the proximal tubule, into the peritubular capillaries. The rise in tubule fluid Cl^- concentration is a necessary reciprocal consequence of the decreased luminal HCO_3^- concentration. The resultant high concentration of Cl^- becomes an important force for the outward passive transport of Cl^- down its concentration gradient, resulting in a lumen-positive potential difference in the late proximal convoluted tubule.

The pars recta of the proximal tubule is capable of active electrogenic transport of Na^+ independent of organic solute transport. Under normal conditions, approximately one-third of the glomerular filtrate enters the descending limb of Henle's loop. This segment is incapable of active outward NaCl transport and is characterized by low permeability to Na^+ but high H_2O permeability, H_2O is abstracted passively as the fluid approaches the bend of Henle's loop. Hypertonic fluid with a greater NaCl concentration but lower urea concentration than the surrounding medullary interstitium thus enters the thin ascending limb of Henle, which is largely impermeable to H_2O and urea but highly permeable to NaCl. This permits passive outward diffusion of NaCl. Active Na:K:2Cl transport across the water-impermeable thick ascending limb of Henle enables tubule fluid to become dilute and the medullary interstitium hypertonic.

Irrespective of the final osmolality of the urine, the fluid that enters the distal convoluted tubule (DCT) is always hypoosmotic. This segment exhibits active Na^+ reabsorption. All but the terminal portion of the DCT is water-impermeable, even in the presence of arginine vasopressin (AVP). Aldosterone exerts its effect in this segment by enhancing Na^+ reabsorption, which is variably coupled to K^+ and H^+ secretion. The cortical and papillary portions of the collecting duct are sites where AVP exerts its principal effect. The permeability of these segments to H_2O in the absence of AVP is very low but can be greatly enhanced in the presence of AVP. These segments are also characterized by active Na^+ reabsorption, which appears to depend on the presence of mineralocorticoid. In the absence of AVP, the collecting tubule is water-impermeable so that hypotonic tubule fluid courses through it. However, in the presence of AVP, water is avidly reabsorbed here, resulting in hypertonic final urine. Sites of action of furosemide and thiazide diuretics and of aldosterone and atrial natriuretic peptide (ANP) are shown.

The Limbs of Henle's Loop In contrast to the proximal tubule, active outward transport of Na^+ has not been established for the *thin descending or ascending limbs of Henle's loop*. However, passive outward salt transport does occur, as indicated in Fig. 259-2. In the next nephron segment, the *medullary thick ascending limb of Henle*, the concentration of NaCl is reduced as fluid traverses this segment. Here Cl^- absorption occurs by an active process involving a Na^+:K^+:2Cl^- cotransport mechanism in the luminal membrane, with one-half of Na^+ absorption proceeding passively, driven by the lumen positive transepithelial voltage difference. This cotransporter is the site of action of the powerful loop diuretics, and mutations give rise to Bartter's syndrome. Since the ascending limb of Henle is impermeable to water, net NaCl reabsorption generates a hypotonic tubule fluid and gives rise to the high NaCl concentration of the outer medullary interstitium (Fig. 259-2).

Distal Tubule The fluid leaving the thick ascending limb of Henle is normally of low NaCl concentration, a characteristic independent of the organism's hydration status. In the *distal tubule*, water reabsorption is variable, depending on the state of hydration or, specifically, on the presence or absence of arginine vasopressin (AVP) in plasma. In the absence of AVP, this and more distal nephron segments are impermeable to water, so that hypotonic fluid entering this segment is excreted as *dilute urine*. Indeed, continued salt reabsorption along the distal convoluted tubule (DCT) and connecting tubule segments, a

process that can be inhibited by thiazide diuretics, results in further dilution of the urine. In the presence of AVP, the permeability of these nephron segments to water increases. This is made possible by the insertion of proteins known as *aquaporins* into the luminal cell membrane of DCT cells. These proteins facilitate water movement from the low-osmolality environment of the DCT lumen into the higher osmolality of the medullary interstitium, thereby contributing to the creation of a concentrated final urine. NaCl continues to be reabsorbed from the tubule lumen against moderately steep chemical and electrical gradients. The reabsorption of NaCl at the collecting tubule is enhanced by *aldosterone*.

Collecting Tubules and Ducts The *cortical collecting tubule* possesses a low permeability to water in the absence of AVP, whereas permeability increases in the presence of this hormone. The sensitivity of this segment to AVP appears to be more pronounced than that of the DCT. As with the DCT, the cortical collecting tubule is capable of active reabsorption of NaCl and its stimulation by aldosterone.

The terminal segment of the distal nephron is the highly branched *papillary collecting duct*. Continued electrolyte transport in this segment results in the large ion concentration differences that normally exist between urine and plasma. As in the cortical collecting tubule, Na^+ transport appears to be active, since reabsorption proceeds against sizeable electrochemical gradients. The rate of Na^+ transport in this segment depends on the load of Na^+ delivered from more proximal segments and is also affected by aldosterone. The permeability to water is also increased markedly in the presence of AVP.

EFFECTS OF NEPHRON LOSS ON SODIUM CHLORIDE TRANSPORT IN SURVIVING NEPHRONS With progressive nephron loss, *maintenance of external balance for NaCl requires that fractional salt excretion increases in concert with the decline in GFR*. Several mechanisms contribute to this adaptive increase in fractional Na^+ excretion. With loss of functioning nephrons, peritubular capillary Starling forces are altered in directions that serve to reduce proximal tubule reabsorption of NaCl and water. For example, a rise in peritubular capillary hydraulic pressure, which tends to inhibit net proximal fluid reabsorption, might be anticipated with systemic hypertension, a common feature of CRF. Similarly, reductions in peritubular capillary oncotic pressures may be anticipated due to reductions in both filtration fraction and hypoalbuminemia.

Several factors that regulate NaCl transport across tubules under normal conditions are also likely to contribute to the enhanced fractional excretion of NaCl in renal insufficiency. Atrial natriuretic peptides are released from the heart in response to elevated cardiac (atrial) filling pressures as seen with increased plasma volume or atrial tachyarrhythmias. These peptides affect natriuresis by reducing net Na^+ reabsorption through complementary actions on Na^+ transport in the collecting duct and by altering Starling forces in the adjacent vasa recta. Other modulators of tubule transport processes may also contribute to increased single-nephron natriuresis in the setting of nephron loss. Vasodilator prostaglandins are present at increased plasma levels in CRF, as are other inhibitors of transport, including inhibitor(s) of the Na^+,K^+-ATPase. Serum and urine from patients with uremia contain retained toxins capable of inhibiting this enzyme.

The obligatory high rate of solute excretion per surviving nephron (so-called osmotic diuresis due to urea and other retained solutes) also contributes to enhancing fractional NaCl excretion, much as occurs in normal individuals after the administration of mannitol or other nonreabsorbable solutes. Finally, certain forms of CRF are associated with unusually large losses of salt in the urine. These *salt-wasting nephropathies* include chronic pyelonephritis and other tubulointerstitial diseases (Chap. 266) as well as polycystic and medullary cystic diseases. These disorders have in common greater destruction of medullary and tubulointerstitial, rather than cortical and glomerular, portions of the renal parenchyma. →***For discussion of clinical derangements that alter renal handling of NaCl in CRF (including hypo- and hypervolemia, hypertension, etc.), see Chap. 261.***

EFFECTS OF NEPHRON LOSS ON WATER REABSORPTION IN SURVIVING NEPHRONS As with NaCl, there is a progressive increase in the fractional excretion of water with advancing renal insufficiency, so that external water balance can be maintained even with a total GFR of 5 mL/min or less. The adaptations of water handling by the diseased kidney are of importance in the defects in urinary concentration and dilution and hence the polyuria, nocturia, and tendency to develop water retention encountered in CRF (Chap. 40). To appreciate the mechanisms involved, the responses of a normal individual and a patient with CRF maintaining external water balance need to be considered. Assuming both individuals have the same dietary and fluid intakes, total solute and volume excretion in both should be identical as well. If the *obligatory solute load* to be excreted by each is 600 mmol/d (600 mosmol/d) and the urine osmolality is 300 mmol/kg water (300 mosmol/kg), a urine volume of 2 L/d will be required to excrete the total solute. If the GFR in normal individuals and the patient with CRF totals 180 and 4 L/d, respectively, urinary volume excretion of 2 L/d represents excretion of slightly more than 1% of the total glomerular filtrate in the normal subject compared with 50% in the patient with CRF. Since the range of urine osmolalities that the diseased kidney can achieve [250 to 350 mmol/kg (250 to 350 mosmol/kg)] is narrower than in the normal kidney [40 to 1200 mmol/kg (40 to 1200 mosmol/kg)], the individual with normal function is able to excrete the obligatory daily solute load of 600 mmol (600 mosmol) in as little as 500 mL urine per day or as much as 15 L/d, compared with the narrower range in CRF, from about 1.7 to 2.4 L/d.

In CRF, the limited capacity to concentrate the urine often correlates with other measures of impaired renal function. Isosthenuria (urine of similar osmolality to plasma) is therefore an almost universal finding when the GFR falls below 25 mL/min. At this level of GFR and below, urine osmolality does not rise even when supraphysiologic doses of AVP are administered, suggesting that the concentrating defect relates to impaired concentrating capacity in surviving nephrons. The associated increased fractional excretion per nephron of a variety of solutes produces an obligatory water loss (solute diuresis) at roughly isotonic proportions. Consequently, formation of a concentrated urine is prevented. Disease-induced abnormalities of the architecture of the renal medulla (loops of Henle, vasa recta), aberrations in medullary blood flow, and defective transport of NaCl in the ascending limb of Henle also contribute to this defect in urine concentration.

Since patients with CRF are unable to excrete concentrated or dilute urine, they must have access to adequate, and to some extent, relatively constant amounts of water per day to ensure that they have adequate water to eliminate total daily solute loads. For this reason, restriction of fluid intake may be hazardous in patients with CRF. Likewise, impairment of diluting capacity may prevent many patients from excreting excess ingested fluid. →***For discussion of the consequences of the abnormal patterns of water excretion, and the attendant susceptibilities to develop hypo- and hypernatremia, see Chaps. 41 and 261.***

TUBULE TRANSPORT OF PHOSPHATE WITH NORMAL AND REDUCED NEPHRON MASS Under normal physiologic conditions, about 80 to 90% of phosphate is reabsorbed, mainly in the proximal tubule. *Parathyroid hormone* (PTH), by augmenting phosphate excretion via inhibition of this proximal reabsorptive process (Chap. 331), plays a central role in phosphate homeostasis. When dietary phosphate intake increases, a *transient* rise in plasma phosphate concentration is usually observed. This results in a similarly transient reduction in the plasma ionized calcium level (due largely to deposition of calcium phosphate in bone), which is sensed by a specific receptor on parathyroid cells, stimulating PTH secretion. By enhancing fractional phosphate excretion, PTH restores external phosphate balance and normophosphatemia. This enables plasma ionized calcium and hence phosphate levels to return to normal, thereby removing the stimulus to PTH release.

With advancing renal failure and constant dietary intake of phosphate, external phosphate balance is achieved by progressive reduction

in fractional phosphate reabsorption. Enhanced PTH secretion is an important determinant of this phosphaturic response. With succeeding decrements in total GFR, the amount of phosphate filtered by surviving glomeruli is reduced, leading to transient phosphate retention and, therefore, a rise (albeit small) in plasma phosphate concentration. This leads to a small, reciprocal decline in plasma levels of ionized calcium and a corresponding increase in PTH secretion. Although the phosphaturic response of surviving tubules to this elevation in circulating PTH restores plasma phosphate and calcium to normal levels (at least in the "compensated" stage of CRF described by curve *B* in Fig. 259-1), the new steady-state conditions are only achieved at the cost of *persistently elevated plasma PTH levels*. With progressive reductions in GFR, the process is repeated, resulting in substantially elevated PTH levels.

Alterations in Vitamin D Metabolism The kidney is normally the major site of *conversion of vitamin D to its active metabolites*. As discussed in Chap. 331, vitamin D, synthesized in skin or acquired in the diet, undergoes initial hydroxylation in the liver to form 25-hydroxyvitamin D [25(OH)D]. The kidney is the site of a second important conversion to 1,25-dihydroxyvitamin D [1,25(OH_2)D]. This active form of vitamin D acts directly on the parathyroid gland to suppress PTH secretion as well as to enhance intestinal absorption of calcium and promote its resorption from bone. With advancing renal disease, nephron loss reduces the renal capacity for vitamin D hydroxylation; phosphate retention also impairs this reaction. Not only are the circulating levels of 1,25(OH_2)D diminished in CRF, but the receptors that mediate its action at the parathyroid gland are also diminished. These two effects remove inhibitory influences on PTH secretion, leading again to increased plasma PTH levels. Reduction in circulating 1,25(OH_2)D levels, by suppressing intestinal calcium absorption, contributes to the development of the hypocalcemia and hyperparathyroidism of CRF (Chap. 261). →***For a discussion of hyperparathyroidism in chronic renal failure, see Chap. 261.***

HYDROGEN AND BICARBONATE TRANSPORT WITH NORMAL AND REDUCED RENAL MASS As discussed in Chap. 42, the pH of extracellular fluid is normally maintained within a narrow range (7.36 to 7.44) despite day-to-day fluctuations in the quantity of acids added to the extracellular fluid from dietary and metabolic sources (approximately 1 mmol H^+ per kilogram of body weight per day). These acids consume buffers from both extracellular and intracellular fluid, of which HCO_3^- is the most important in the intracellular compartment. Such buffering minimizes changes in pH. Long-term effectiveness of the HCO_3^- buffer system, however, requires mechanisms for replenishment, otherwise unrelenting acquisition of nonvolatile acids from dietary and metabolic sources would ultimately exhaust buffering capacity, culminating in fatal acidosis. The kidneys normally function to prevent this eventuality by *regenerating* bicarbonate, thereby maintaining plasma concentrations of HCO_3^-. In addition, the kidneys also *reclaim* HCO_3^- in the glomerular ultrafiltrate.

The *reabsorption* of filtered HCO_3^- occurs by the following mechanism. Filtered bicarbonate combines with H^+ secreted from proximal tubule cells via the Na^+/H^+ exchange, to form carbonic acid (H_2CO_3). Dehydration of carbonic acid under the influence of *luminal* carbonic anhydrase yields H_2O and CO_2, which is free to diffuse from lumen to peritubular blood. In the proximal tubule cell, the OH^- left behind by the H^+ secretion reacts with CO_2, under the influence of *intracellular* carbonic anhydrase, forming HCO_3^-. This ion is transported across the contraluminal proximal tubule cell membrane, via an electrogenic Na/HCO_3^- cotransporter, to reenter the extracellular HCO_3^- pool. The net result is *reclamation of a filtered bicarbonate ion*. Hydrogen ions in the urine are bound to filtered buffers (e.g., phosphate) in amounts equivalent to the amounts of alkali required to titrate the pH of the urine up to the pH of the blood (the so-called titratable acid). It is not usually possible to excrete all the daily acid load in the form of titratable acid due to limits of urinary pH. Metabolism of glutamine by proximal tubule cells to yield ammonium (ammoniagenesis) serves as an additional mechanism for H^+ elimination and bicarbonate regeneration. Glutamine metabolism forms not only NH_4^+ (i.e., NH_3 plus H^+) but also HCO_3^-, which is transported across the proximal tubule (HCO_3^- regeneration). The NH_4^+ must be excreted in the urine for this process to be effective in bicarbonate regeneration. *Ammoniagenesis* is responsive to the acid-base needs of the individual. When faced with an acute acid burden and an increased need for HCO_3^- regeneration, the rate of renal ammonia synthesis increases sharply.

The quantity of hydrogen ions excreted as titratable acid and NH_4^+ is equal to the quantity of HCO_3^- regenerated in tubule cells and added to plasma. Under steady-state conditions, the net quantity of acid excreted into the urine (the sum of titratable acid and NH_4^+ less HCO_3^-) must equal the quantity of acid gained by the extracellular fluid from all sources. Metabolic acidosis and alkalosis result when this delicate balance is perturbed, the former the result of insufficient net acid excretion, and the latter due to excessive acid excretion (Chap. 42).

Progressive loss of renal function usually causes little or no change in arterial pH, plasma bicarbonate concentration, or arterial carbon dioxide tension (P_{CO_2}) until GFR falls below 25% of normal. Thereafter, all three tend to decline as *metabolic acidosis* ensues. In general, the metabolic acidosis of CRF is not due to overproduction of acids but is rather a reflection of nephron loss, which limits the amount of NH_3 (and therefore also HCO_3^-) that can be generated. Although surviving nephrons appear to be capable of generating supranormal amounts of NH_3 *per nephron*, the diminished nephron population causes overall production to be reduced to an extent that is insufficient to permit adequate buffering of H^+ in urine. As a result, although patients with CRF may be able to acidify their urine normally (i.e., urine pH as low as 4.5), the defect in NH_3 production limits daily net acid excretion to 30 to 40 mmol, or one-half to two-thirds the quantity of nonvolatile acid added to the extracellular fluid in the same time period. Metabolic acidosis resulting from this daily positive balance of H^+ is seldom florid in CRF of mild to moderate severity. Relative stability of plasma bicarbonate (albeit at reduced levels of 14 to 18 mmol/L) is maintained at the expense of buffering by bone. Because it contains large reserves of alkaline salts (calcium phosphate and calcium bicarbonate), bone constitutes a major reserve of buffering capacity. Dissolution of these buffers contributes to the osteodystrophy of CRF (see Fig. 261-1).

Although the acidosis of CRF is due to loss of tubule mass, it nevertheless depends to a large part on the level of GFR. When GFR is reduced to only a moderate extent (i.e., to about 50% of normal), retention of anions, principally sulfates and phosphates, is not pronounced. Therefore, as the plasma HCO_3^- falls owing to dysfunction or loss of tubules, retention of Cl^- by the kidneys leads to a *hyperchloremic acidosis*. At this stage *the anion gap is normal*. With further reductions in GFR and progressive azotemia, however, the retention of phosphates, sulfates, and other *unmeasured* anions ensues and plasma Cl^- falls to normal levels despite the reduction in plasma HCO_3^- concentration. *An elevated anion gap therefore develops.*

TUBULE POTASSIUM TRANSPORT WITH NORMAL AND REDUCED NEPHRON MASS As with H^+, the concentration of K^+ in extracellular fluid is normally maintained within a relatively narrow range, 4 to 5 mmol/L. At least 95% of total-body K^+ is in the intracellular compartment, where the intracellular concentration is approximately 160 mmol/L. Normal individuals maintain external K^+ balance by excreting amounts into the urine that equal the intake, less the relatively small losses in stool and sweat. K^+ is freely filtered at the glomerulus, although the amount excreted usually represents no more than about 20% of the quantity filtered. The great bulk of the K^+ filtered is reabsorbed in the early portions of the nephron, about two-thirds in the proximal tubule, and an additional 20 to 25% in the loop of Henle. A *K^+* secretory process operates in the distal tubule and terminal nephron segments. This process is largely dependent on Na^+ reabsorption and the accompanying lumen-negative voltage creating an electrical gradient across the tubule wall, favoring K^+ secretion into the lumen of the distal tubule and collecting duct.

The ability to maintain external K^+ balance and normal plasma K^+ concentration until relatively late in the course of CRF is a consequence primarily of a progressive increase in fractional excretion of K^+. Greatly enhanced rates of K^+ secretion occur in distal portions of surviving tubules. The augmented secretion rate of aldosterone contributes to enhanced tubule secretion of K^+. In addition, both the increased distal tubule flow rates in surviving nephrons, due to the osmotic diuresis, and enhanced luminal electronegativity, created by the increased presence of highly impermeable anions such as phosphate and sulfate, enhance K^+ secretion. Aldosterone also stimulates net entry of K^+ into the lumen of the colon, a mechanism known to be enhanced in CRF. →***For more detailed discussions of abnormal K^+ homeostasis in acute and chronic forms of renal failure, see Chaps. 260 and 261.***

260 ACUTE RENAL FAILURE

Hugh R. Brady, Barry M. Brenner

Acute renal failure (ARF) is a syndrome characterized by rapid decline in glomerular filtration rate (hours to days), retention of nitrogenous waste products, and perturbation of extracellular fluid volume and electrolyte and acid-base homeostasis. ARF complicates approximately 5% of hospital admissions and up to 30% of admissions to intensive care units. Oliguria (urine output < 400 mL/d) is a frequent but not invariable clinical feature (~50%). ARF is usually asymptomatic and diagnosed when biochemical monitoring of hospitalized patients reveals a recent increase in blood urea and creatinine concentrations. It may complicate a wide range of diseases, which for purposes of diagnosis and management are conveniently divided into three categories: (1) diseases that cause renal hypoperfusion without compromising the integrity of renal parenchyma (*prerenal ARF*, prerenal azotemia) (~55%); (2) diseases that directly involve renal parenchyma (*intrinsic renal ARF*, renal azotemia) (~40%); and (3) diseases associated with urinary tract obstruction (*postrenal ARF*, postrenal azotemia) (~5%). Most ARF is reversible, the kidney being relatively unique among major organs in its ability to recover from almost complete loss of function. Nevertheless, ARF is associated with major in-hospital morbidity and mortality, in large part due to the serious nature of the illnesses that precipitate the ARF.

ETIOLOGY AND PATHOPHYSIOLOGY

PRERENAL ARF (PRERENAL AZOTEMIA) Prerenal ARF is the most common form of ARF and represents a physiologic response to mild to moderate renal hypoperfusion. Prerenal ARF is by definition rapidly reversible upon restoration of renal blood flow and glomerular ultrafiltration pressure. Renal parenchymal tissue is not damaged; indeed, kidneys from individuals with prerenal ARF function well when transplanted into recipients with normal cardiovascular function. More severe hypoperfusion may lead to ischemic injury of renal parenchyma and intrinsic renal ARF (see below). Thus, prerenal ARF and intrinsic renal ARF due to ischemia are part of a spectrum of manifestations of renal hypoperfusion. As shown in Table 260-1, prerenal ARF can complicate any disease that induces hypovolemia, low cardiac output, systemic vasodilatation, or selective intrarenal vasoconstriction.

Hypovolemia leads to a fall in mean systemic arterial pressure, which is detected as reduced stretch by arterial (e.g., carotid sinus) and cardiac baroreceptors. Activated baroreceptors trigger a coordinated series of neural and humoral responses designed to restore blood volume and arterial pressure. These include activation of the sympathetic nervous system and renin-angiotensin-aldosterone system and release of arginine vasopressin (AVP; formerly called antidiuretic hormone). Norepinephrine, angiotensin II, and AVP act in concert in an attempt to preserve cardiac and cerebral perfusion by stimulating vasoconstriction in relatively "nonessential" vascular beds, such as the musculocutaneous and splanchnic circulations, by inhibiting salt loss through sweat glands, by stimulating thirst and salt appetite, and by promoting renal salt and water retention. Glomerular perfusion, ultrafiltration pressure, and filtration rate are preserved during mild hypoperfusion through several compensatory mechanisms. Stretch receptors in afferent arterioles, in response to a reduction in perfusion pressure, trigger afferent arteriolar vasodilatation through a local myogenic reflex (autoregulation). Biosynthesis of vasodilator prostaglandins (e.g., prostaglandin E_2 and prostacyclin) is also enhanced, and these compounds preferentially dilate afferent arterioles. In addition, angiotensin II induces preferential constriction of efferent arterioles. As a result, intraglomerular pressure is maintained, the fraction of plasma flowing through glomerular capillaries that is filtered is increased (filtration fraction), and glomerular filtration rate (GFR) is preserved. During states of more severe hypoperfusion, these compensatory responses are overwhelmed and GFR falls, leading to prerenal ARF.

Autoregulatory dilatation of afferent arterioles is maximal at mean systemic arterial blood pressures of ~80 mmHg, and hypotension below this level is associated with a precipitous decline in GFR. Lesser degrees of hypotension may provoke prerenal ARF in the elderly and in patients with diseases affecting the integrity of afferent arterioles (e.g., hypertensive nephrosclerosis, diabetic vasculopathy). In addition, drugs that interfere with adaptive responses in the renal microcirculation may convert compensated renal hypoperfusion into overt prerenal ARF or trigger progression of prerenal ARF to ischemic intrinsic renal ARF (see below). Pharmacologic inhibitors of either renal prostaglandin biosynthesis [*cyclooxygenase inhibitors*; nonsteroidal anti-inflammatory drugs (NSAIDs)] or angiotensin-converting enzyme (ACE) activity (ACE inhibitors) and angiotensin II receptor blockers are the major culprits and should be used judiciously in the setting of suspected renal hypoperfusion. NSAIDs do not compromise GFR in healthy individuals but may precipitate prerenal ARF in patients with volume depletion or in those with chronic renal insufficiency in whom GFR is maintained, in part, through prostaglandin-mediated hyperfiltration by the remaining functional nephrons. ACE inhibitors should be used with special care in patients with bilateral renal artery stenosis or unilateral stenosis in a solitary functioning kidney. In these settings glomerular perfusion and filtration may be exquisitely dependent on the actions of angiotensin II. Angiotensin II preserves glomerular filtration pressure distal to stenoses by elevating systemic arterial pressure and by triggering selective constriction of efferent arterioles. ACE inhibitors blunt these responses and precipitate ARF, usually reversible, in ~30% of these patients.

Hepatorenal Syndrome This is a particularly aggressive form of ARF, with many of the features of prerenal ARF, that frequently complicates hepatic failure due to advanced cirrhosis or other liver diseases, including malignancy, hepatic resection, and biliary obstruction. In full-blown hepatorenal syndrome, ARF progresses even after optimization

TABLE 260-1 Classification and Major Causes of Acute Renal Failure (ARF)

PRERENAL ARF

I. Hypovolemia
  A. Hemorrhage, burns, dehydration
  B. Gastrointestinal fluid loss: vomiting, surgical drainage, diarrhea
  C. Renal fluid loss: diuretics, osmotic diuresis (e.g., diabetes mellitus), hypoadrenalism
  D. Sequestration in extravascular space: pancreatitis, peritonitis, trauma, burns, severe hypoalbuminemia
II. Low cardiac output
  A. Diseases of myocardium, valves, and pericardium; arrhythmias; tamponade
  B. Other: pulmonary hypertension, massive pulmonary embolus, positive pressure mechanical ventilation
III. Altered renal systemic vascular resistance ratio
  A. Systemic vasodilatation: sepsis, antihypertensives, afterload reducers, anesthesia, anaphylaxis
  B. Renal vasoconstriction: hypercalcemia, norepinephrine, epinephrine, cyclosporine, tacrolimus, amphotericin B
  C. Cirrhosis with ascites (hepatorenal syndrome)
IV. Renal hypoperfusion with impairment of renal autoregulatory responses
  Cyclooxygenase inhibitors, angiotensin-converting enzyme inhibitors
V. Hyperviscosity syndrome (rare)
  Multiple myeloma, macroglobulinemia, polycythemia

INTRINSIC RENAL ARF

I. Renovascular obstruction (bilateral or unilateral in the setting of one functioning kidney)
  A. Renal artery obstruction: atherosclerotic plaque, thrombosis, embolism, dissecting aneurysm, vasculitis
  B. Renal vein obstruction: thrombosis, compression
II. Disease of glomeruli or renal microvasculature
  A. Glomerulonephritis and vasculitis
  B. Hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, toxemia of pregnancy, accelerated hypertension, radiation nephritis, systemic lupus erythematosus, scleroderma
III. Acute tubular necrosis
  A. Ischemia: as for prerenal ARF (hypovolemia, low cardiac output, renal vasoconstriction, systemic vasodilatation), obstetric complications (abruptio placentae, postpartum hemorrhage)
  B. Toxins
    1. Exogenous: radiocontrast, cyclosporine, antibiotics (e.g., aminoglycosides), chemotherapy (e.g., cisplatin), organic solvents (e.g., ethylene glycol), acetaminophen, illegal abortifacients
    2. Endogenous: rhabdomyolysis, hemolysis, uric acid, oxalate, plasma cell dyscrasia (e.g., myeloma)
IV. Interstitial nephritis
  A. Allergic: antibiotics (e.g., β-lactams, sulfonamides, trimethoprim, rifampicin), nonsteroidal anti-inflammatory agents, diuretics, captopril
  B. Infection: bacterial (e.g., acute pyelonephritis, leptospirosis), viral (e.g., cytomegalovirus), fungal (e.g., candidiasis)
  C. Infiltration: lymphoma, leukemia, sarcoidosis
  D. Idiopathic
V. Intratubular deposition and obstruction
  Myeloma proteins, uric acid, oxalate, acyclovir, methotrexate, sulphonamides
VI. Renal allograft rejection

POSTRENAL ARF (OBSTRUCTION)

I. Ureteric
  Calculi, blood clot, sloughed papillae, cancer, external compression (e.g., retroperitoneal fibrosis)
II. Bladder neck
  Neurogenic bladder, prostatic hypertrophy, calculi, cancer, blood clot
III. Urethra
  Stricture, congenital valve, phimosis

of systemic hemodynamics and carries a mortality rate of >90%. →***The diagnosis and management of this condition are discussed in Chaps. 289 and 291.***

INTRINSIC RENAL ARF (INTRINSIC RENAL AZOTEMIA) Intrinsic renal ARF can complicate many diverse diseases of the renal parenchyma. From a clinicopathologic viewpoint, it is useful to divide the causes of intrinsic renal ARF into (1) diseases of larger renal vessels, (2) diseases of the renal microcirculation and glomeruli, (3) ischemic and nephrotoxic ARF, and (4) tubulointerstitial inflammation (Table 260-1). Most intrinsic renal ARF is triggered by ischemia (ischemic ARF) or nephrotoxins (nephrotoxic ARF), insults that classically induce acute tubular necrosis (ATN). Accordingly, the terms ARF and ATN are usually used interchangeably in these settings. However, as many as 20 to 30% of patients with ischemic or nephrotoxic ARF do not have clinical (granular or tubular cell urinary casts) or morphologic evidence of tubular necrosis, underscoring the role of sublethal injury to tubular epithelium and injury to other renal cells (e.g., endothelial cells) in the pathophysiology of this syndrome.

Etiology and Pathophysiology of Ischemic ARF Prerenal ARF and ischemic ARF are part of a spectrum of manifestations of renal hypoperfusion. Ischemic ARF differs from prerenal ARF in that the hypoperfusion induces ischemic injury to renal parenchymal cells, particularly tubular epithelium, and recovery typically takes 1 to 2 weeks after normalization of renal perfusion as it requires repair and regeneration of renal cells. In its most extreme form, ischemia leads to bilateral renal cortical necrosis and irreversible renal failure. Ischemic ARF occurs most frequently in patients undergoing major cardiovascular surgery or suffering severe trauma, hemorrhage, sepsis, and/or volume depletion (Table 260-1). Ischemic ARF can also complicate milder forms of true hypovolemia or reduced "effective" arterial blood volume if they occur in the presence of other insults (e.g., nephrotoxins or sepsis) or in patients with compromised autoregulatory defense mechanisms or preexisting renal disease.

The course of ischemic ARF is typically characterized by three phases: the initiation, maintenance, and recovery phases. The *initiation phase* (hours to days) is the initial period of renal hypoperfusion during which ischemic injury is evolving. GFR declines because (1) glomerular ultrafiltration pressure is reduced as a consequence of the fall in renal blood flow, (2) the flow of glomerular filtrate within tubules is obstructed by casts comprised of epithelial cells and necrotic debris derived from ischemic tubule epithelium, and (3) there is backleak of glomerular filtrate through injured tubular epithelium (Fig. 260-1). Ischemic injury is most prominent in the terminal medullary portion of the proximal tubule (S_3 segment, pars recta) and the medullary portion of the thick ascending limb of the loop of Henle. Both segments have high rates of active (ATP-dependent) solute transport and oxygen consumption and are located in a zone of the kidney (the outer medulla) that is relatively ischemic, even under basal conditions, by virtue of the unique countercurrent arrangement of the medullary vasculature. Cellular ischemia results in a series of alterations in energetics, ion transport, and membrane integrity that ultimately lead to cell injury and, if severe, cell apoptosis or necrosis. These alterations include depletion of ATP, inhibition of active sodium transport and transport of other solutes, impairment of cell volume regulation and cell swelling, cytoskeletal disruption and loss of cell polarity, cell-cell and cell-matrix attachment, accumulation of intracellular calcium, altered phospholipid metabolism, oxygen free radical formation, and peroxidation of membrane lipids. Importantly, renal injury can be limited by restoration of renal blood flow during this period.

The initiation phase is followed by a *maintenance phase* (typically 1 to 2 weeks) during which renal cell injury is established, GFR stabilizes at its nadir (typically 5 to 10 mL/min), urine output is lowest, and uremic complications arise (see below). The reasons why the GFR remains low during this phase, despite correction of systemic hemodynamics, are still being defined. Putative mechanisms include persistent intrarenal vasoconstriction and medullary ischemia triggered by dysregulated release of vasoactive mediators from injured endothelial cells (e.g., decreased nitric oxide, increased endothelin-1, adenosine, and platelet-activating factor), congestion of medullary blood vessels, and reperfusion injury induced by reactive oxygen species and other mediators derived from leukocytes or renal parenchymal cells

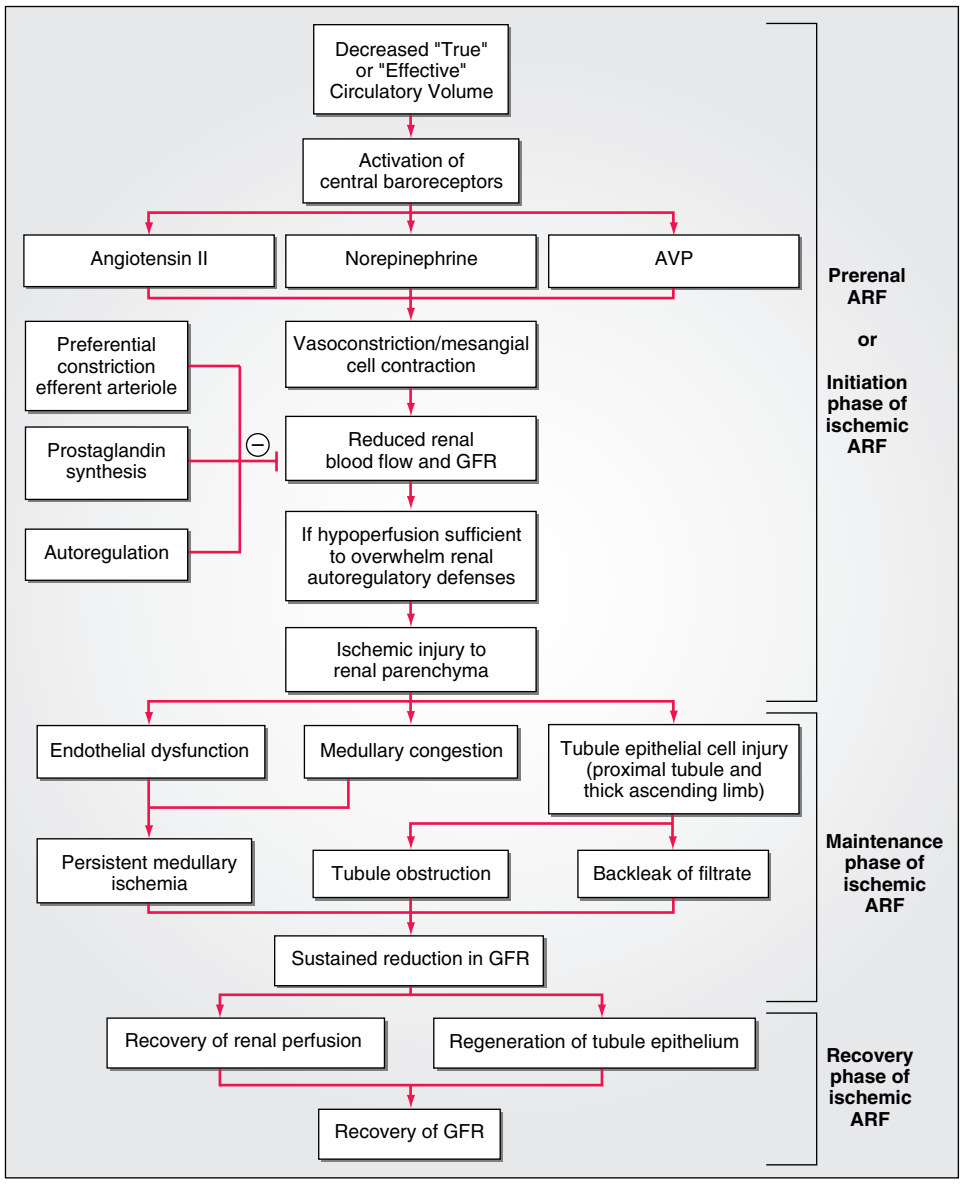

FIGURE 260-1 Overview of the pathophysiology of prerenal ARF and ischemic intrinsic renal ARF: A spectrum of manifestations of renal hypoperfusion. ARF, acute renal failure; AVP, arginine vasopressin; GFR, glomerular filtration rate.

(Fig. 260-1). In addition, epithelial cell injury per se may contribute to persistent intrarenal vasoconstriction by a process termed *tubuloglomerular feedback*. Specialized epithelial cells in the macula densa region of distal tubules detect increases in distal salt (probably chloride) delivery that occur as a consequence of impaired reabsorption by more proximal nephron segments. Macula densa cells in turn stimulate constriction of adjacent afferent arterioles by a poorly defined mechanism and further compromise glomerular perfusion and filtration, thereby contributing to a vicious cycle. A *recovery phase* is characterized by renal parenchymal cell, particularly tubule epithelial cell, repair and regeneration and a gradual return of GFR to or towards premorbid levels. The recovery phase may be complicated by a marked diuretic phase due to excretion of retained salt and water and other solutes, continued use of diuretics, and/or delayed recovery of epithelial cell function (solute and water reabsorption) relative to glomerular filtration (see below).

Etiology and Pathophysiology of Nephrotoxic ARF Acute intrinsic renal ARF can complicate exposure to many structurally diverse pharmacologic agents (Table 260-1). With most nephrotoxins, the incidence of ARF is increased in the elderly and in patients with preexisting chronic renal insufficiency, true or "effective" hypovolemia, or concomitant exposure to other toxins.

Intrarenal vasoconstriction is a pivotal event in ARF that is triggered by *radiocontrast agents* (contrast nephropathy), *cyclosporine*, and *tacrolimus (FK506)*. In keeping with this pathophysiology, both agents induce ARF that shares features with prerenal ARF: namely, an acute fall in renal blood flow and GFR, a relatively benign urine sediment, and a low fractional excretion of sodium (see below). Severe cases may show clinical or pathologic evidence of ATN. Contrast nephropathy classically presents as an acute (onset within 24 to 48 h) but reversible (peak 3 to 5 days, resolution within 1 week) rise in blood urea nitrogen and creatinine and is most common in individuals with preexisting chronic renal insufficiency, diabetes mellitus, congestive heart failure, hypovolemia, or multiple myeloma. The syndrome appears to be dose-related, and its incidence is only slightly reduced in high-risk individuals by use of more expensive low osmolality, nonionic contrast agents.

Direct toxicity to tubule epithelial cells and/or intratubular obstruction are major pathophysiologic events in ARF induced by many antibiotics and anticancer drugs. Frequent offenders are the antimicrobial agents, such as acyclovir, foscarnet, aminoglycosides, amphotericin B, and pentamidine, and chemotherapeutic agents, such as cisplatin, carboplatin, and ifosfamide. ARF complicates 10 to 30% of courses of *aminoglycoside antibiotics*, even in the presence of therapeutic levels. *Amphotericin B* causes dose-related ARF through intrarenal vasoconstriction and direct toxicity to proximal tubule epithelium. Cisplatin and carboplatin, like the aminoglycosides, are accumulated by proximal tubule cells and typically provoke ARF after 7 to 10 days of exposure by inducing mitochondrial injury, inhibition of ATPase activity and solute transport, free radical–mediated injury to cell membranes, apoptosis, and/or necrosis.

The most common endogenous nephrotoxins are calcium, myoglobin, hemoglobin, urate, oxalate, and myeloma light chains. Hypercalcemia can compromise GFR, predominantly by inducing intrarenal vasoconstriction. Calcium phosphate deposition within the kidney may also contribute. Both *rhabdomyolysis* and *hemolysis* can induce ARF, particularly in hypovolemic or acidotic individuals. Myoglobinuric ARF complicates approximately 30% of cases of rhabdomyolysis. Common causes of the latter include traumatic crush injury, acute muscle ischemia, seizures, excessive exercise, heat stroke or malignant hyperthermia, intoxications (e.g., alcohol, cocaine), and infectious or metabolic disorders. ARF due to hemolysis is relatively rare and is observed following massive blood transfusion reactions. It has been postulated that myoglobin and hemoglobin or other compounds released from muscle or red blood cells cause ARF via toxic effects on tubule epithelial cells, by promoting intrarenal oxidative stress and by inducing intratubular cast formation. Hypovolemia or acidosis may contribute to the pathogenesis of ARF in this setting by promoting intratubular cast formation. In addition, both hemoglobin and myoglobin are potent inhibitors of nitric oxide bioactivity and may trigger

intrarenal vasoconstriction and ischemia in patients with borderline renal hypoperfusion. The formation of intratubular casts containing filtered immunoglobulin light chains and other proteins, including Tamm-Horsfall protein produced by thick ascending limb cells, is the major trigger for ARF in patients with *multiple myeloma* (myeloma cast nephropathy). In addition, light chains are directly toxic to tubule epithelial cells. Intratubular obstruction is also an important cause of ARF in patients with severe *hyperuricosuria* or *hyperoxaluria*. Acute uric acid nephropathy typically complicates treatment of lymphoproliferative or myeloproliferative disorders but occasionally occurs in other forms of primary or secondary hyperuricemia if the urine is concentrated.

Pathology of Ischemic and Nephrotoxic ARF The classic pathologic features of ischemic ARF are patchy and focal necrosis of tubule epithelium with detachment from its basement membrane and occlusion of tubule lumens with casts composed of intact or degenerating epithelial cells, cellular debris, Tamm-Horsfall mucoprotein, and pigments. Leukocyte accumulation is frequently observed in vasa recta; however, the morphology of the glomeruli and renal vasculature is characteristically normal. Necrosis is most severe in the straight portion (pars recta) of proximal tubules but may also affect the medullary thick ascending limb of the loop of Henle.

In nephrotoxic ARF, morphologic changes tend to be most prominent in both the convoluted and straight portions of proximal tubules. Tubule cell necrosis is less pronounced than in ischemic ARF.

Other Causes of Intrinsic Renal ARF Patients with advanced atherosclerosis can develop ARF after manipulation of the aorta or renal arteries at surgery or angiography, following trauma, or, rarely, spontaneously due to embolization of cholesterol crystals to the renal vasculature (atheroembolic ARF). Cholesterol crystals lodge in small- and medium-sized arteries and incite a giant cell and fibrotic reaction in the vessel wall with narrowing or obstruction of the vessel lumen. Atheroembolic ARF is frequently irreversible. A myriad of structurally diverse pharmacologic agents induce ARF by triggering allergic interstitial nephritis, a disease characterized by infiltration of the tubulointerstitium by granulocytes (typically but not invariably eosinophils), macrophages, and/or lymphocytes and by interstitial edema. The most common offenders are antibiotics (e.g., penicillins, cephalosporins, trimethoprim, sulfonamides, rifampicin) and NSAIDs (Table 260-1).

POSTRENAL ARF (See also Chap. 270) Urinary tract obstruction accounts for fewer than 5% of cases of ARF. Because one kidney has sufficient clearance capacity to excrete the nitrogenous waste products generated daily, ARF from obstruction requires obstruction to urine flow between the external urethral meatus and bladder neck, bilateral ureteric obstruction, or unilateral ureteric obstruction in a patient with one functioning kidney or with preexisting chronic renal insufficiency. Bladder neck obstruction represents the most common cause of postrenal ARF and is usually due to prostatic disease (e.g., hypertrophy, neoplasia, or infection), neurogenic bladder, or therapy with anticholinergic drugs. Less common causes of acute lower urinary tract obstruction include blood clots, calculi, and urethritis with spasm. Ureteric obstruction may result from intraluminal obstruction (e.g., calculi, blood clots, sloughed renal papillae), infiltration of the ureteric wall (e.g., neoplasia), or external compression (e.g., retroperitoneal fibrosis, neoplasia or abscess, inadvertent surgical ligature). During the early stages of obstruction (hours to days), continued glomerular filtration leads to increased intraluminal pressure upstream to the site of obstruction. As a result there is gradual distention of the proximal ureter, renal pelvis, and calyces and a fall in GFR. Acute obstruction is initially associated with modest increase in renal blood flow, but arteriolar vasoconstriction soon supervenes, leading to a further decline in glomerular filtration.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Patients presenting with renal failure should be assessed initially to determine if the decline in GFR is acute or chronic. An acute process is easily established if a review of laboratory records reveals a recent rise in blood urea and creatinine levels, but previous measurements are not always available. Findings that suggest chronic renal failure (Chap. 261) include anemia, neuropathy, and radiologic evidence of renal osteodystrophy or small scarred kidneys. However, it should be noted that anemia may also complicate ARF (see below), and renal size may be normal or increased in several chronic renal diseases (e.g., diabetic nephropathy, amyloidosis, polycystic kidney disease). Once a diagnosis of ARF has been established, several issues should be addressed promptly: (1) the identification of the cause of ARF, (2) the elimination of the triggering insult (e.g., nephrotoxin) and/or institution of disease-specific therapies, and (3) the prevention and management of uremic complications.

CLINICAL ASSESSMENT Clinical clues to *prerenal* ARF are symptoms of thirst and orthostatic dizziness and physical evidence of orthostatic hypotension and tachycardia, reduced jugular venous pressure, decreased skin turgor, dry mucous membranes, and reduced axillary sweating. Case records should be reviewed for documentation of a progressive fall in urine output and body weight and recent initiation of treatment with NSAIDs, ACE inhibitors, or angiotensin II receptor blockers. Careful clinical examination may reveal stigmata of chronic liver disease and portal hypertension, advanced cardiac failure, sepsis, or other causes of reduced "effective" arterial blood volume (Table 260-1).

Intrinsic renal ARF due to ischemia is likely following severe renal hypoperfusion complicating hypovolemic or septic shock or following major surgery. The likelihood of ischemic ARF is increased further if ARF persists despite normalization of systemic hemodynamics. Diagnosis of nephrotoxic ARF requires careful review of the clinical data and pharmacy, nursing, and radiology records for evidence of recent exposure to nephrotoxic medications or radiocontrast agents or to endogenous toxins (e.g., myoglobin, hemoglobin, uric acid, myeloma protein, or elevated levels of serum calcium).

Although ischemic and nephrotoxic ARF account for more than 90% of cases of intrinsic renal ARF, other renal parenchymal diseases must be considered (Table 260-2). Flank pain may be a prominent symptom following occlusion of a renal artery or vein and with other parenchymal diseases distending the renal capsule (e.g., severe glomerulonephritis or pyelonephritis). Subcutaneous nodules, livedo reticularis, bright orange retinal arteriolar plaques, and digital ischemia, despite palpable pedal pulses, are clues to atheroembolization. ARF in association with oliguria, edema, hypertension, and an "active" urine sediment (nephritic syndrome) suggests acute glomerulonephritis or vasculitis. Malignant hypertension is a likely cause of ARF in patients with severe hypertension and evidence of hypertensive injury to other organs (e.g., left ventricular hypertrophy and failure, hypertensive retinopathy and papilledema, neurologic dysfunction). Fever, arthralgias, and a pruritic erythematous rash following exposure to a new drug suggest allergic interstitial nephritis, although systemic features of hypersensitivity are frequently absent.

Postrenal ARF presents with suprapubic and flank pain due to distention of the bladder and of the renal collecting system and capsule, respectively. Colicky flank pain radiating to the groin suggests acute ureteric obstruction. Prostatic disease is likely if there is a history of nocturia, frequency, and hesitancy and enlargement or induration of the prostate on rectal examination. Neurogenic bladder should be suspected in patients receiving anticholinergic medications or with physical evidence of autonomic dysfunction. Definitive diagnosis of postrenal ARF hinges on judicious use of radiologic investigations and rapid improvement in renal function following relief of obstruction.

URINALYSIS Anuria suggests complete urinary tract obstruction but may complicate severe cases of prerenal or intrinsic renal ARF. Wide fluctuations in urine output raise the possibility of intermittent obstruction, whereas patients with partial urinary tract obstruction can present with polyuria due to impairment of urine concentrating mechanisms.

TABLE 260-2 *Useful Clinical Features, Urinary Findings, and Confirmatory Tests in the Differential Diagnosis of Major Causes of ARF*

Cause of Acute Renal Failure	Suggestive Clinical Features	Typical Urinalysis	Some Confirmatory Tests
I. Prerenal ARF	Evidence of true volume depletion (thirst, postural or absolute hypotension and tachycardia, low jugular venous pressure, dry mucous membranes/axillae, weight loss, fluid output > input) or decreased "effective" circulatory volume (e.g., heart failure, liver failure), treatment with NSAIDs or ACE inhibitors	Hyaline casts FE_{Na} <1% U_{Na} <10 mmol/L SG >1.018	Occasionally requires invasive hemodynamic monitoring; rapid resolution of ARF upon restoration of renal perfusion
II. Intrinsic renal ARF			
A. Diseases involving large renal vessels			
1. Renal artery thrombosis	History of atrial fibrillation or recent myocardial infarct; flank or abdominal pain	Mild proteinuria Occasionally red cells	Elevated LDH with normal transaminases, renal arteriogram
2. Atheroembolism	Age usually > 50 years, recent manipulation of aorta, retinal plaques, subcutaneous nodules, palpable purpura, livedo reticularis, vasculopathy, hypertension, anticoagulation	Often normal, eosinophiluria, rarely casts	Eosinophilia, hypocomplementemia, skin biopsy, renal biopsy
3. Renal vein thrombosis	Evidence of nephrotic syndrome or pulmonary embolism, flank pain	Proteinuria, hematuria	Inferior vena cavagram and selective renal venogram
B. Diseases of small vessels and glomeruli			
1. Glomerulonephritis/vasculitis	Compatible clinical history (e.g., recent infection), sinusitis, lung hemorrhage, skin rash or ulcers, arthralgias, new cardiac murmur, history of hepatitis B or C infection	Red cell or granular casts, red cells, white cells, mild proteinuria	Low C3, ANCA, anti-GBM Ab, ANA, ASO, anti-DNase, cryoglobulins, blood cultures, renal biopsy
2. Hemolytic-uremic syndrome/ thrombotic thrombocytopenic purpura	Compatible clinical history (e.g., recent gastrointestinal infection, cyclosporine, anovulants), fever, pallor, ecchymoses, neurologic abnormalities	May be normal, red cells, mild proteinuria, rarely red cell/ granular casts	Anemia, thrombocytopenia, schistocytes on blood smear, increased LDH, renal biopsy
3. Malignant hypertension	Severe hypertension with headaches, cardiac failure, retinopathy, neurologic dysfunction, papilledema	Red cells, red cell casts, proteinuria	LVH by echocardiography/ECG, resolution of ARF with control of blood pressure
C. ARF mediated by ischemia or toxins (ATN)			
1. Ischemia	Recent hemorrhage, hypotension (e.g., cardiac arrest), surgery	Muddy brown granular or tubular epithelial cell casts FE_{Na} >1% U_{Na} >20 mmol/L SG <1.015	Clinical assessment and urinalysis usually sufficient for diagnosis
2. Exogenous toxins	Recent radiocontrast study, nephrotoxic antibiotics or anticancer agents often coexistent with volume depletion, sepsis, or chronic renal insufficiency	Muddy brown granular or tubular epithelial cell casts FE_{Na} >1% U_{Na} >20 mmol/L SG <1.015	Clinical assessment and urinalysis usually sufficient for diagnosis
3. Endogenous toxins	History suggestive of rhabdomyolysis (seizures, coma, ethanol abuse, trauma)	Urine supernatant positive for heme	Hyperkalemia, hyperphosphatemia, hypocalcemia, increased circulating myoglobin, CPK (MM), and uric acid
	History suggestive of hemolysis (blood transfusion)	Urine supernatant pink and positive for heme	Hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, pink plasma positive for hemoglobin
	History suggestive of tumor lysis (recent chemotherapy), myeloma (bone pain), or ethylene glycol ingestion	Urate crystals, dipstick-negative proteinuria, oxalate crystals, respectively	Hyperuricemia, hyperkalemia, hyperphosphatemia (for tumor lysis); circulating or urinary monoclonal spike (for myeloma); toxicology screen, acidosis, osmolal gap (for ethylene glycol)
D. Acute diseases of the tubulointerstitium			
1. Allergic interstitial nephritis	Recent ingestion of drug, and fever, rash, or arthralgias	White cell casts, white cells (frequently eosinophiluria), red cells, rarely red cell casts, proteinuria (occasionally nephrotic)	Systemic eosinophilia, skin biopsy of rash (leukocytoclastic vasculitis), renal biopsy
2. Acute bilateral pyelonephritis	Flank pain and tenderness, toxic, febrile	Leukocytes, proteinuria, red cells, bacteria	Urine and blood cultures
III. Postrenal ARF	Abdominal or flank pain, palpable bladder	Frequently normal, hematuria if stones, hemorrhage, malignancy, or prostatic hypertrophy	Plain film, renal ultrasound, IVP, retrograde or anterograde pyelography, CT scan

Note: U_{Na}, urine sodium concentration; SG, specific gravity; LDH, lactate dehydrogenase; C3, complement component; ANCA, antineutrophil cytoplasmic autoantibody; anti-GBM Ab, anti-glomerular basement membrane antibody; ANA, antinuclear antibody; ASO, antistreptolysin O; LVH, left ventricular hypertrophy; ECG, electrocardiogram; CK, creatine kinase; IVP, intravenous pyelogram; CT, computed tomography.

In prerenal ARF, the sediment is characteristically acellular and contains transparent hyaline casts ("bland," "benign," "inactive" urine sediment). Hyaline casts are formed in concentrated urine from normal constitutents of urine—principally Tamm-Horsfall protein, which is secreted by epithelial cells of the loop of Henle. Postrenal ARF may also present with an inactive sediment, although hematuria and pyuria are common in patients with intraluminal obstruction or prostatic disease. Pigmented "muddy brown" granular casts and casts containing tubule epithelial cells are characteristic of ATN and suggest ischemic or nephrotoxic ARF. They are usually found in association with microscopic hematuria and mild "tubular" proteinuria (<1 g/d); the latter reflects impaired reabsorption and processing of filtered proteins by injured proximal tubules. Casts are absent, however, in 20 to 30% of patients with ischemic or nephrotoxic ARF and are not a requisite for diagnosis. In general, red blood cell casts indicate glomerular injury or, less often, acute tubulointerstitial nephritis. White cell casts and nonpigmented granular casts suggest interstitial nephritis, whereas broad granular casts are characteristic of chronic renal disease and probably reflect interstitial fibrosis and dilatation of tubules. Eosinophiluria (>5% of urine leukocytes) is a common finding (~90%) in antibiotic-induced allergic interstitial nephritis when studied using Hansel's stain; however, lymphocytes may predominate in allergic interstitial nephritis induced by NSAIDs. Eosinophiluria is also a feature of atheroembolic ARF. Occasional uric acid crystals (pleomorphic in shape) are common in the concentrated urine of prerenal ARF but suggest acute urate nephropathy if seen in abundance. Oxalate (envelope-shaped) and hippurate (needle-shaped) crystals raise the possibility of ethylene glycol ingestion and toxicity.

Proteinuria of >1 g/d suggests injury to the glomerular ultrafiltration barrier ("glomerular proteinuria") or excretion of myeloma light chains. The latter are not detected by conventional dipsticks (which detect albumin) and must be sought by other means (e.g., sulfosalicylic acid test, immunoelectrophoresis). Heavy proteinuria is also a frequent finding (~80%) in patients who develop combined allergic interstitial nephritis and minimal change glomerulopathy when treated with NSAIDs. A similar syndrome can be triggered by ampicillin, rifampicin, or interferon α. Hemoglobinuria or myoglobinuria should be suspected if urine is strongly positive for heme by dipstick, but contains few red cells, and if the supernatant of centrifuged urine is positive for free heme. Bilirubinuria may provide a clue to the presence of hepatorenal syndrome.

RENAL FAILURE INDICES Analysis of urine and blood biochemistry is particularly useful for distinguishing prerenal ARF from ischemic or nephrotoxic intrinsic renal ARF (Table 260-3). The fractional excretion of sodium (FE_{Na}) is most useful in this regard. The FE_{Na} relates sodium clearance to creatinine clearance. Sodium is reabsorbed avidly from glomerular filtrate in patients with prerenal ARF, in an attempt to restore intravascular volume, but not in patients with ischemic or nephrotoxic intrinsic ARF, as a result of tubular epithelial cell injury. In contrast, creatinine is not reabsorbed in either setting. Consequently, patients with prerenal ARF typically have a FE_{Na} of <1.0% (frequently <0.1%), whereas the FE_{Na} in patients with ischemic or nephrotoxic ARF is usually >1.0%. The *renal failure index* (Table 260-3) provides comparable information, since clinical variations in serum sodium concentration are relatively small. *Urine sodium concentration* is a less sensitive index for distinguishing prerenal ARF from ischemic and nephrotoxic ARF as values overlap between groups. Similarly, indices of urinary concentrating ability such as urine specific gravity, urine osmolality, urine-to-plasma urea ratio, and blood urea-to-creatinine ratio are of limited value in differential diagnosis.

Many caveats apply when interpreting biochemical renal failure indices. FE_{Na} may be >1.0% in prerenal ARF if patients are receiving diuretics or have bicarbonaturia (accompanied by sodium to maintain electroneutrality), preexisting chronic renal failure complicated by salt wasting, or adrenal insufficiency. In contrast, the FE_{Na} is <1.0% in approximately 15% of patients with nonoliguric ischemic or nephrotoxic ARF, probably reflecting patchy injury to tubular epithelium with preservation of reabsorptive function in some areas. The FE_{Na} is also often <1.0% in ARF due to urinary tract obstruction, glomerulonephritis, and vascular diseases.

TABLE 260-3 *Urine Diagnostic Indices in Differentiation of Prerenal versus Intrinsic Renal ARF*

	Typical Findings in ARF	
Diagnostic Index	*Prerenal*	*Intrinsic Renal*
Fractional excretion of sodium (%)[a] $\frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100$	<1	>1
Urine sodium concentration (mmol/L)	<10	>20
Urine creatinine to plasma creatinine ratio	>40	<20
Urine urea nitrogen to plasma urea nitrogen ratio	>8	<3
Urine specific gravity	>1.020	~1.010
Urine osmolality (mosmol/kg H_2O)	>500	~300
Plasma BUN/creatinine ratio	>20	<10–15
Renal failure index[a] $\frac{U_{Na}}{U_{Cr}/P_{Cr}}$	<1	>1
Urinary sediment	Hyaline casts	Muddy brown granular casts

[a] Most sensitive indices.
Note: U_{Na}, urine sodium concentration; P_{Cr}, plasma creatinine concentration; P_{Na}, plasma sodium concentration; U_{Cr}, urine creatinine concentration; BUN, blood urea nitrogen.

LABORATORY FINDINGS Serial measurements of serum creatinine can provide useful pointers to the cause of ARF. Prerenal ARF is typified by fluctuating levels that parallel changes in hemodynamic function. Creatinine rises rapidly (within 24 to 48 h) in patients with ARF following renal ischemia, atheroembolization, and radiocontrast exposure. Peak creatinine levels are observed after 3 to 5 days with contrast nephropathy and return to baseline after 5 to 7 days. In contrast, creatinine levels typically peak later (7 to 10 days) in ischemic ARF and atheroembolic disease. The initial rise in serum creatinine is characteristically delayed until the second week of therapy with many tubule epithelial cell toxins (e.g., aminoglycosides, cisplatin) and probably reflects the need for accumulation of these agents within cells before GFR falls.

Hyperkalemia, hyperphosphatemia, hypocalcemia, and elevations in serum uric acid and creatine kinase (MM isoenzyme) levels at presentation suggest a diagnosis of rhabdomyolysis. Hyperuricemia [>890 μmol/L (>15 mg/dL)] in association with hyperkalemia, hyperphosphatemia, and increased circulating levels of intracellular enzymes such as lactate dehydrogenase may indicate acute urate nephropathy and tumor lysis syndrome following cancer chemotherapy. A wide serum anion and osmolal gap (measured serum osmolality minus the serum osmolality calculated from serum sodium, glucose, and urea concentrations) indicate the presence of an unusual anion or osmole in the circulation and are clues to diagnosis of ethylene glycol or methanol ingestion. Severe anemia in the absence of hemorrhage raises the possibility of hemolysis, multiple myeloma, or thrombotic microangiopathy. Systemic eosinophilia suggests allergic interstitial nephritis but is also a feature of atheroembolic disease and polyangiitis nodosa.

RADIOLOGIC FINDINGS Imaging of the urinary tract by ultrasonography is useful to exclude postrenal ARF. Computed tomography and magnetic resonance imaging are alternative imaging modalities. Whereas pelvicalyceal dilatation is usual with urinary tract obstruction (98% sensitivity), dilatation may be absent immediately following obstruc-

tion or in patients with ureteric encasement (e.g., retroperitoneal fibrosis, neoplasia). Retrograde or anterograde pyelography are more definitive investigations in complex cases and provide precise localization of the site of obstruction. A plain film of the abdomen, with tomography if necessary, is a valuable initial screening technique in patients with suspected nephrolithiasis. Doppler ultrasonography and magnetic resonance angiography are useful for assessment of patency of renal arteries and veins in patients with suspected vascular obstruction; however, contrast angiography is usually required for definitive diagnosis.

RENAL BIOPSY Biopsy is reserved for patients in whom prerenal and postrenal ARF have been excluded and the cause of intrinsic renal ARF is unclear. Renal biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. Examples include glomerulonephritis, vasculitis, hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, and allergic interstitial nephritis.

COMPLICATIONS

ARF impairs renal excretion of sodium, potassium, and water and perturbs divalent cation homeostasis and urinary acidification mechanisms. As a result, ARF is frequently complicated by intravascular volume overload, hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, hypermagnesemia, and metabolic acidosis. In addition, patients are unable to excrete nitrogenous waste products and are prone to develop the uremic syndrome (Chap. 261). The speed of development and the severity of these complications reflect the degree of renal impairment and catabolic state of the patient.

Expansion of extracellular fluid volume is an inevitable consequence of diminished salt and water excretion in oliguric or anuric individuals. Whereas milder forms are characterized by weight gain, bibasilar lung rales, raised jugular venous pressure, and dependent edema, continued volume expansion may precipitate life-threatening pulmonary edema. Hypervolemia may be particularly problematic in patients receiving multiple intravenous medications and enteral or parenteral nutrition. Excessive administration of free water either through ingestion and nasogastric administration or as hypotonic saline or isotonic dextrose solutions (dextrose being metabolized) can induce *hypoosmolality* and *hyponatremia*, which, if severe, lead to cerebral edema and neurologic abnormalities, including seizures.

Hyperkalemia is a frequent complication of ARF. Serum potassium typically rises by 0.5 mmol/L per day in oliguric and anuric patients due to impaired excretion of ingested or infused potassium and potassium released from injured tissue. Coexistent metabolic acidosis may exacerbate hyperkalemia by promoting potassium efflux from cells. Hyperkalemia may be particularly severe, even at the time of diagnosis, in patients with rhabdomyolysis, hemolysis, and tumor lysis syndrome. Mild hyperkalemia (<6.0 mmol/L) is usually asymptomatic. Higher levels may trigger electrocardiographic abnormalities and/or arrythmias (Chap. 210).

Metabolism of dietary protein yields between 50 and 100 mmol/d of fixed nonvolatile acids that are normally excreted by the kidneys. Consequently, ARF is typically complicated by *metabolic acidosis*, often with an increased serum anion gap (Chap. 42). Acidosis can be particularly severe when endogenous production of hydrogen ions is increased by other mechanisms (e.g., diabetic or fasting ketoacidosis; lactic acidosis complicating generalized tissue hypoperfusion, liver disease, or sepsis; metabolism of ethylene glycol or methanol).

Mild *hyperphosphatemia* is an almost invariable complication of ARF. Severe hyperphosphatemia may develop in highly catabolic patients or following rhabdomyolysis, hemolysis, or tumor lysis. Metastatic deposition of calcium phosphate can lead to *hypocalcemia*, particularly when the product of serum calcium (mg/dL) and phosphate (mg/dL) concentrations exceeds 70. Other factors that contribute to hypocalcemia include tissue resistance to the actions of parathyroid hormone and reduced levels of 1,25-dihydroxyvitamin D. Hypocalcemia is often asymptomatic but can cause perioral paresthesia, muscle cramps, seizures, hallucinations and confusion, and prolongation of the QT interval and nonspecific T-wave changes on electrocardiography (Chap. 332).

Anemia develops rapidly in ARF and is usually mild and multifactorial in origin. Contributing factors include impaired erythropoiesis, hemolysis, bleeding, hemodilution, and reduced red cell survival time. Prolongation of the *bleeding time* and *leukocytosis* are also common. Common contributors to the bleeding diathesis include mild thrombocytopenia, platelet dysfunction, and/or clotting factor abnormalities (e.g., factor VIII dysfunction), whereas leukocytosis usually reflects sepsis, a stress response, or other concurrent illness. *Infection* is a common and serious complication of ARF, occurring in 50 to 90% of cases and accounting for up to 75% of deaths. It is unclear whether patients with ARF have a clinically significant defect in host immune responses or whether the high incidence of infection reflects repeated breaches of mucocutaneous barriers (e.g., intravenous cannulae, mechanical ventilation, bladder catheterization). *Cardiopulmonary complications* of ARF include arrhythmias, myocardial infarction, pericarditis and pericardial effusion, pulmonary edema, and pulmonary embolism. Mild *gastrointestinal bleeding* is common (10 to 30%) and is usually due to stress ulceration of gastric or small intestinal mucosa.

Protracted periods of severe ARF are invariably associated with the development of the *uremic syndrome* (Chap. 261).

A *vigorous diuresis* can occur during the recovery phase of ARF (see above), which may on occasions be inappropriate and lead to intravascular volume depletion and delayed recovery of GFR by causing secondary prerenal ARF. *Hypernatremia* can also complicate recovery if water losses via hypotonic urine are not replaced or if losses are inappropriately replaced by relatively hypertonic saline solutions. *Hypokalemia*, *hypomagnesemia*, *hypophosphatemia*, and *hypocalcemia* are less common metabolic complications during this period.

TREATMENT

Prevention Because there are no specific therapies for ischemic or nephrotoxic ARF, prevention is of paramount importance. Many cases of ischemic ARF can be avoided by close attention to cardiovascular function and intravascular volume in high-risk patients, such as the elderly and those with preexisting renal insufficiency. Indeed, aggressive restoration of intravascular volume has been shown to reduce dramatically the incidence of ischemic ARF after major surgery or trauma, burns, or cholera. The incidence of nephrotoxic ARF can be reduced by tailoring the dosage of nephrotoxic drugs to body size and GFR; for example, reducing the dose or frequency of administration of drugs in patients with preexisting renal impairment. In this regard, it should be noted that serum creatinine is a relatively insensitive index of GFR and may overestimate GFR considerably in small or elderly patients. For purposes of drug dosing, it is advisable to estimate the GFR using the Cockcroft-Gault formula, which factors in the variables of age and weight (Chap. 40). Adjusting drug dosage according to circulating drug levels also appears to limit renal injury in patients receiving aminoglycoside antibiotics, cyclosporine, or tacrolimus. Diuretics, cyclooxygenase inhibitors, ACE inhibitors, angiotensin II receptor blockers, and other vasodilators should be used with caution in patients with suspected true or "effective" hypovolemia or renovascular disease as they may precipitate prerenal ARF or convert the latter to ischemic ARF. Allopurinol and forced alkaline diuresis are useful prophylactic measures in patients at high risk for acute urate nephropathy (e.g., cancer chemotherapy in hematologic malignancies) to limit uric acid generation and prevent precipitation of urate crystals in renal tubules. Forced alkaline diuresis may also prevent or attenuate ARF in patients receiving high-dose methotrexate or suffering from rhabdomyolysis. *N*-acetylcysteine limits acetaminophen-induced renal injury if given within 24 h of ingestion. Dimercaprol, a chelating agent,

may prevent heavy metal nephrotoxicity. Ethanol inhibits ethylene glycol metabolism to oxalic acid and other toxic metabolites and is an important adjunct to hemodialysis in the emergency management of ethylene glycol intoxication.

Specific Therapies By definition, prerenal ARF is rapidly reversible upon correction of the primary hemodynamic abnormality, and postrenal ARF resolves upon relief of obstruction. To date, there are no specific therapies for established intrinsic renal ARF due to ischemia or nephrotoxicity. Management of these disorders should focus on elimination of the causative hemodynamic abnormality or toxin, avoidance of additional insults, and prevention and treatment of complications. Specific treatment of other causes of intrinsic renal ARF depends on the underlying pathology.

PRERENAL ARF The composition of replacement fluids for treatment of prerenal ARF due to hypovolemia must be tailored according to the composition of the lost fluid. Severe hypovolemia due to hemorrhage should be corrected with packed red cells, whereas isotonic saline is usually appropriate replacement for mild to moderate hemorrhage or plasma loss (e.g., burns, pancreatitis). Urinary and gastrointestinal fluids can vary greatly in composition but are usually hypotonic. Hypotonic solutions (e.g., 0.45% saline) are usually recommended as initial replacement in patients with prerenal ARF due to increased urinary or gastrointestinal fluid losses, although isotonic saline may be more appropriate in severe cases. Subsequent therapy should be based on measurements of the volume and ionic content of excreted or drained fluids. Serum potassium and acid-base status should be monitored carefully, and potassium and bicarbonate supplemented as appropriate. Cardiac failure may require aggressive management with positive inotropes, preload and afterload reducing agents, antiarrhythmic drugs, and mechanical aids such as intraaortic balloon pumps. Invasive hemodynamic monitoring may be required to guide therapy for complications in patients in whom clinical assessment of cardiovascular function and intravascular volume is difficult.

Fluid management may be particularly challenging in patients with cirrhosis complicated by ascites. In this setting, it is important to distinguish between full-blown hepatorenal syndrome (Chap. 289), which carries a grave prognosis, and reversible ARF due to true or "effective" hypovolemia induced by overzealous use of diuretics or sepsis (e.g., spontaneous bacterial peritonitis). The contribution of hypovolemia to ARF can be definitively assessed only by administration of a fluid challenge. Fluids should be administered slowly and titrated against jugular venous pressure and, if necessary, central venous and pulmonary capillary wedge pressure, abdominal girth, and urine output. Patients with a reversible prerenal component typically have an increase in urine output and fall in serum creatinine, whereas patients with hepatorenal syndrome do not and may suffer increased ascites formation and pulmonary compromise if not monitored closely. Large volumes of ascitic fluid can usually be drained by paracentesis without deterioration in renal function if intravenous albumin is administered simultaneously. Indeed, "large-volume paracentesis" may afford an increase in GFR, possibly by lowering intraabdominal pressure and improving flow in renal veins. Shunting of ascitic fluid from the peritoneum to a central vein (peritoneojugular shunt, LeVeen or Denver shunts) is an alternative approach in refractory cases but has not been shown to improve survival in controlled trials. The efficacy of the newer technique of transjugular intrahepatic portosystemic shunting (TIPS procedure) is currently undergoing rigorous clinical assessment. Shunting can also improve GFR and sodium excretion transiently, probably because the increase in central blood volume stimulates release of atrial natriuretic peptides (ANPs) and inhibits secretion of aldosterone and norepinephrine.

INTRINSIC RENAL ARF Many different approaches have been tested for their ability to attenuate injury or hasten recovery in ischemic and nephrotoxic ARF. These include ANP, low-dose dopamine, endothelin antagonists, loop-blocking diuretics, calcium channel blockers, α-adrenoreceptor blockers, prostaglandin analogues, antioxidants, antibodies against leukocyte adhesion molecules, and insulin-like growth factor type I. Whereas many of these are beneficial in experimental models of ischemic or nephrotoxic ARF, they have either failed to confer consistent benefit or proved ineffective in humans.

ARF due to other intrinsic renal diseases such as acute glomerulonephritis or vasculitis may respond to glucocorticoids, alkylating agents, and/or plasmapheresis, depending on the primary pathology. Glucocorticoids also hasten remission in some cases of allergic interstitial nephritis. Aggressive control of systemic arterial pressure is of paramount importance in limiting renal injury in malignant hypertensive nephrosclerosis, toxemia of pregnancy, and other vascular diseases. Hypertension and ARF due to scleroderma may be exquisitely sensitive to treatment with ACE inhibitors.

POSTRENAL ARF Management of postrenal ARF requires close collaboration between nephrologist, urologist, and radiologist. Obstruction of the urethra or bladder neck is usually managed initially by transurethral or suprapubic placement of a bladder catheter, which provides temporary relief while the obstructing lesion is identified and treated definitively. Similarly, ureteric obstruction may be treated initially by percutaneous catheterization of the dilated renal pelvis or ureter. Indeed, obstructing lesions can often be removed percutaneously (e.g., calculus, sloughed papilla) or bypassed by insertion of a ureteric stent (e.g., carcinoma). Most patients experience an appropriate diuresis for several days following relief of obstruction. Approximately 5% of patients develop a transient salt-wasting syndrome that may require administration of intravenous saline to maintain blood pressure.

Supportive Measures (Table 260-4) Following correction of hypovolemia, salt and water intake are tailored to match losses. Hypervolemia can usually be managed by restriction of salt and water intake and diuretics. Indeed, there is, as yet, no proven rationale for administration of diuretics in ARF except to treat this complication. High doses of loop-blocking diuretics such as furosemide (up to 200 to 400 mg intravenously) or bumetanide (up to 10 mg intravenously administered as a bolus or by continuous infusion) may promote diuresis in patients who fail to respond to conventional doses. Despite the fact that subpressor doses of dopamine may transiently promote salt and water excretion by increasing renal blood flow and GFR and by inhibiting tubule sodium reabsorption, subpressor ("low-dose," "renal-dose,") dopamine has proved ineffective in clinical trials, may trigger arrythmias and sudden cardiac death in critically ill patients, and should not be used as a renoprotective agent in this setting. Ultrafiltration or dialysis is used to treat severe hypervolemia when conservative measures fail. Hyponatremia and hypoosmolality can usually be controlled by restriction of free water intake. Conversely, hypernatremia is treated by administration of water or intravenous hypotonic saline or isotonic dextrose-containing solutions. →***The management of hyperkalemia is described in Chap. 41.***

Metabolic acidosis is not usually treated unless serum bicarbonate concentration falls below 15 mmol/L or arterial pH falls below 7.2. More severe acidosis is corrected by oral or intravenous sodium bicarbonate. Initial rates of replacement are guided by estimates of bicarbonate deficit and adjusted thereafter according to serum levels (Chap. 42). Patients are monitored for complications of sodium bicarbonate administration such as hypervolemia, metabolic alkalosis, hypocalcemia, and hypokalemia. From a practical point of view, most patients requiring sodium bicarbonate need emergency dialysis within days. Hyperphosphatemia is usually controlled by restriction of dietary phosphate and by oral aluminum hydroxide or calcium carbonate, which reduce gastrointestinal absorption of phosphate. Hypocalcemia does not usually require treatment unless severe, as may occur with rhabdomyolysis or pancreatitis or following admininstration of bicarbonate. Hyperuricemia is typically mild [$<$890 μmol/L ($<$ 15 mg/dL)] and does not require intervention.

The objective of *nutritional management* during the maintenance phase of ARF is to provide sufficient calories to avoid catabolism and starvation ketoacidosis, while minimizing production of nitrogenous

TABLE 260-4 *Management of Ischemic and Nephrotoxic Acute Renal Failure*[a]

Management Issue	Therapy
REVERSE CAUSATIVE RENAL INSULT	
Ischemic ARF	Restore systemic hemodynamics and renal perfusion
Nephrotoxic ARF	Eliminate nephrotoxins Consider specific measures (e.g., forced alkaline diuresis, chelators: see text)
PREVENTION AND TREATMENT OF COMPLICATIONS	
Intravascular volume overload	Salt (1–2 g/d) and water (usually <1 L/d) restriction Diuretics (usually loop blockers ± thiazide) Ultrafiltration or dialysis
Hyponatremia	Restriction of enteral free water intake (<1 L/d) Avoid hypotonic intravenous solutions (including dextrose solutions)
Hyperkalemia	Restriction of dietary K^+ intake (usually <40 mmol/d) Eliminate K^+ supplements and K^+-sparing diuretics Potassium-binding ion-exchange resins (e.g., sodium polystyrene sulphonate) Glucose (50 mL of 50% dextrose) and insulin (10 units regular) Sodium bicarbonate (usually 50–100 mmol) Calcium gluconate (10 mL of 10% solution over 5 min) Dialysis (with low K^+ dialysate)
Metabolic acidosis	Restriction of dietary protein (usually 0.6 g/kg per day of high biologic value) Sodium bicarbonate (maintain serum bicarbonate >15 mmol/L or arterial pH >7.2) Dialysis
Hyperphosphatemia	Restriction of dietary phosphate intake (usually <800 mg/d) Phosphate binding agents (calcium carbonate, aluminum hydroxide)
Hypocalcemia	Calcium carbonate (if symptomatic or if sodium bicarbonate to be administered) Calcium gluconate (10–20 mL of 10% solution)
Hypermagnesemia	Discontinue Mg^{2+}-containing antacids
Hyperuricemia	Treatment usually not necessary [if <890 μmol/L (<15 mg/dL)]
Nutrition	Restriction of dietary protein (~0.6 g/kg per day) Carbohydrate (~100 g/d) Enteral or parenteral nutrition (if recovery prolonged or patient very catabolic)
Indications for dialysis	Clinical evidence (symptoms or signs) of uremia Intractable intravascular volume overload Hyperkalemia or severe acidosis resistant to conservative measures ?Prophylactic dialysis when urea >100–150 mg/dL or creatinine >8–10 mg/dL
PRESCRIBING OF MEDICATIONS	
Choice of agents	Avoid other nephrotoxins, ACE inhibitors, cyclooxygenase inhibitors, and radiocontrast unless absolute indication and no alternative agent
Drug dosing	Adjust doses and frequency of administration for degree of renal impairment

[a] These are general recommendations and must be tailored to needs of individual patients.

waste. This is best achieved by restricting dietary protein to approximately 0.6 g/kg per day of protein of high biologic value (i.e., rich in essential amino acids) and to provide most calories as carbohydrate (approximately 100 g daily). Nutritional management is easier in nonoliguric patients and following institution of dialysis. Vigorous parenteral hyperalimentation is claimed to improve prognosis; however, convincing benefit has yet to be demonstrated in controlled trials.

Anemia may necessitate blood transfusion if severe or if recovery is delayed. In contrast to chronic renal failure, recombinant human erythropoietin is rarely used in ARF because bone marrow resistance to erythropoietin is common, more immediate treatment of anemia (if any) is required, and renal failure is usually self-limiting. Uremic bleeding usually responds to correction of anemia, administration of desmopressin or estrogens, or dialysis. Regular doses of antacids appear to reduce the incidence of gastrointestinal hemorrhage significantly and may be more effective in this regard than H_2 antagonists or proton pump inhibitors. Meticulous care of intravenous cannulae, bladder catheters, and other invasive devices is mandatory to avoid infections. Unfortunately, prophylactic antibiotics have not been shown to reduce the incidence of infection in these high-risk patients.

INDICATIONS AND MODALITIES OF DIALYSIS (See also Chap. 262) Dialysis replaces renal function until regeneration and repair restore renal function. Hemodialysis and peritoneal dialysis appear equally effective for management of ARF. Thus, the dialysis modality is chosen according to the needs of individual patients (e.g., peritoneal dialysis may be preferable if the patient is hemodynamically unstable, and hemodialysis after abdominal surgery involving the peritoneum), the expertise of the nephrologist, and the facilities of the institution. Vascular access for conventional intermittent hemodialysis is best achieved by insertion of a temporary double-lumen hemodialysis catheter into the internal jugular vein. The subclavian and femoral veins are alternative access sites. Peritoneal dialysis is achieved by insertion of a cuffed catheter into the peritoneal cavity. Absolute indications for dialysis include symptoms or signs of the uremic syndrome and management of refractory hypervolemia, hyperkalemia, or acidosis. Most nephrologists also initiate dialysis empirically for blood urea levels of >100 mg/dL, even in the absence of clinical uremia; however, this approach has yet to be validated in controlled clinical trials. Recent evidence suggests that more intensive hemodialysis (e.g., daily rather than alternate-day intermittent dialysis) is clinically superior and confers improved survival in ARF once dialysis is required. This conclusion may not be as intuitive as it first appears as dialysis itself has been postulated to prolong the period of oliguria in some cases by inducing hypotension and further renal ischemia and through activation of leukocytes on the dialysis membrane, which may then proceed to aggravate renal injury.

Continuous renal replacement therapies (CRRTs) are alternatives to conventional intermittent hemodialysis techniques for treatment of ARF. They are particularly valuable techniques in patients in whom intermittent hemodialysis fails to control hypervolemia or uremia and for those who do not tolerate intermittent hemodialysis and in whom peritoneal dialysis is not possible. Continuous arteriovenous hemodiafiltration (CAVHD) requires both arterial and venous access. The patient's own blood pressure generates an ultrafiltrate of plasma across a porous biocompatible dialysis membrane. A physiologic crystalloid solution is passed along the other side of the membrane to achieve diffusive clearance. Continuous venovenous hemodiafiltration (CVVHD), in contrast, requires only a double-lumen venous catheter as a blood pump generates ultrafiltration pressure across the dialysis membrane. In the more simple techniques of continuous arteriovenous hemofiltration (CAVH) and continuous venovenous hemofiltration (CVVH) the dialysis step is eliminated and an ultrafiltrate of plasma is removed across the dialysis membrane and replaced by a physiologic crystalloid solution. The bulk of evidence to date suggests that intermittent and continuous dialytic therapies are equally effective in the context of ARF. The choice of technique is currently tailored to the specific needs of the patient, the resources of the institution, and the expertise of the physician. Potential disadvantages of continuous hemodialysis techniques are the need for prolonged immobilization in bed, systemic anticoagulation, arterial cannulation (in CAVH), and prolonged exposure of blood to synthetic, albeit relatively biocompatible, dialysis membranes.

OUTCOME AND LONG-TERM PROGNOSIS

The mortality rate among patients with ARF approximates 50% and has changed little over the past 30 years. It should be stressed, however, that patients usually die from sequelae of the primary illness that induced ARF and not from ARF itself. Indeed, the kidney is one of the few organs whose function can be replaced artificially (i.e., by dialysis) for protracted periods of time. In agreement with this interpretation, mortality rates vary greatly depending on the cause of ARF: ~15% in obstetric patients, ~30% in toxin-related ARF, and ~60% following trauma or major surgery. Oliguria (<400 mL/d) at time of presentation and a rise in serum creatinine of >265 μmol/L (>3 mg/dL) are associated with a poor prognosis and probably reflect the severity of renal injury and of the primary illness. Mortality rates are higher in older debilitated patients and in those with multiple organ failure. Most patients who survive an episode of ARF recover sufficient renal function to live normal lives. However, 50% have subclinical impairment of renal function or residual scarring on renal biopsy. Approximately 5% of patients never recover function and require long-term renal replacement with dialysis or transplantation. An additional 5% suffer progressive decline in GFR, following an initial recovery phase, probably due to hemodynamic stress and sclerosis of remnant glomeruli (Chap. 264).

261 CHRONIC RENAL FAILURE

Karl Skorecki, Jacob Green,† Barry M. Brenner

MECHANISMS OF CHRONIC RENAL FAILURE

DEFINITIONS *Chronic renal disease* (CRD) is a pathophysiologic process with multiple etiologies, resulting in the inexorable attrition of nephron number and function and frequently leading to *end-stage renal disease* (ESRD). In turn, ESRD represents a clinical state or condition in which there has been an irreversible loss of endogenous renal function, of a degree sufficient to render the patient permanently dependent upon renal replacement therapy (dialysis or transplantation) in order to avoid life-threatening *uremia*. Uremia is the clinical and laboratory syndrome, reflecting dysfunction of all organ systems as a result of untreated or undertreated acute or chronic renal failure. Given the capacity of the kidneys to regain function following acute injury (Chap. 260), the vast majority (>90%) of patients with ESRD have reached this state as a result of CRD.

PATHOPHYSIOLOGY OF CRD (See also Chap. 259) The pathophysiology of CRD involves initiating mechanisms specific to the underlying etiology as well as a set of progressive mechanisms that are a common consequence following long-term reduction of renal mass, irrespective of etiology. Such reduction of renal mass causes structural and functional hypertrophy of surviving nephrons. This compensatory hypertrophy is mediated by vasoactive molecules, cytokines, and growth factors and is due initially to adaptive hyperfiltration, in turn mediated by increases in glomerular capillary pressure and flow. Eventually, these short-term adaptations prove maladaptive, in that they predispose to sclerosis of the remaining viable nephron population. Increased intrarenal activity of the renin-angiotensin axis appears to contribute both to the initial adaptive hyperfiltration and to the subsequent maladaptive hypertrophy and sclerosis.

The definition of CRD requires that the pathophysiologic process described above last more than 3 months. A recently widely accepted international classification divides CRD into a number of stages (Table 261-1) defined by clinical estimation of the glomerular filtration rate (GFR). These stages help guide clinical diagnostic and management approaches. First, it is important to identify factors that increase the risk for CRD, even in individuals with normal GFR. Such factors include family history of heritable renal disease, hypertension, diabetes, autoimmune disease, older age, past episode of acute renal failure, and current evidence of kidney damage with normal or even increased GFR. Such evidence of kidney damage in the face of normal or increased GFR places affected individuals into stage 1 CRD and includes proteinuria, abnormal urinary sediment, or urinary tract structural abnormalities (e.g., vesicoureteric reflux) evident on imaging studies. Even at this stage, when baseline GFR is normal, there is often a characteristic loss of renal reserve. This early stage is particularly well documented in diabetic nephropathy. Further stages in the pathogenesis of CRD are characterized by a progressive decline in estimated GFR with mild, moderate, and severe stages defined at GFR levels (mL/min per 1.73 m^2) of 60 to 89, 30 to 59, and 15 to 29, respectively. At a GFR < 15 mL/min per 1.73 m^2, renal replacement therapy may be indicated if uremia is present. For purposes of staging CRD, current guidelines recommend estimating GFR using one of the two equations shown in Table 261-2, based on measured plasma creatinine concentration, age, gender, and ethnic origin. The normal annual mean decline in GFR with age beginning at age 20 to 30 years is 1 mL/min per 1.73 m^2, reaching a mean value in males of 70 at age 70. GFR is slightly lower in women than men. By the time plasma creatinine concentration is even mildly elevated, substantial chronic nephron injury has already occurred.

Albuminuria serves as a key adjunctive tool for monitoring nephron injury and response to therapy in many forms of CRD. Current guidelines recommend use of albumin-specific dipstick measurement or quantitation by measurement of albumin-to-creatinine ratio in a spot first morning urine sample. Persistence of >17 mg albumin per gram of creatinine in adult males and 25 mg albumin per gram of creatinine in adult females usually signifies chronic renal damage, irrespective of GFR, and can be followed in monitoring natural history and response to therapy, especially in CRD consequent to diabetes, hypertension, or glomerulonephritis. →***Further considerations in the overall clinical approach to proteinuria are provided in Chap. 40.***

During stages 1 and 2 CRD, patients often remain free of symp-

TABLE 261-1 Stages of Chronic Renal Disease CRD

Stage	Description	GFR, mL/min per 1.73 m^2
	At increased risk	90 (with CRD risk factors)
1	Kidney damage with normal or increased GFR	90
2	Kidney damage with mildly decreased GFR	60–89
3	Moderately decreased GFR	30–59
4	Severely decreased GFR	15–29
5	Renal failure	<15 (or dialysis)

TABLE 261-2 *Recommended Equations for Estimation of Glomerular Filtration Rate (GFR) from Laboratory-Validated Plasma Creatinine Concentration (P_{Cr})*

1. Equation from the Modification of Diet in Renal Disease study[a]
   Estimated GFR (mL/min per 1.73 m^2) = $1.86 \times (P_{Cr})^{-1.154} \times (age)^{-0.203}$
   Multiply by 0.742 for women
   Multiply by 1.21 for African Americans
2. Cockcroft-Gault equation
   Estimated creatinine clearance (mL/min) = $\frac{(140 - age) \times body\ weight\ (kg)}{72 \times P_{Cr}\ (mg/dL)}$
   Multiply by 0.85 for women

[a] Equation is *available* in hand-held calculators and in tabular form.

toms, other than those that might accompany the underlying etiologic process causing renal disease. As the decline in GFR progresses to stages 3 and 4 (GFR < 60 mL/min per 1.73 m^2), clinical and laboratory complications of CRD become progressively more prominent. Virtually all organ systems are affected, but the most evident complications include anemia and loss of energy; decreasing appetite and disturbances in nutritional status; abnormalities in calcium and phosphorus metabolism accompanied by metabolic bone disease; and abnormalities in sodium, water, potassium, and acid-base homeostasis. When GFR falls to <15 mL/min per 1.73 m^2, patients usually experience a severe disturbance in their activities of daily living, sense of well-being, nutritional status, and water and electrolyte homeostasis, eventuating in an overtly uremic state wherein continued survival without renal replacement therapy becomes impossible.

ETIOLOGY AND EPIDEMIOLOGY It has been estimated that at least 6% of the adult U.S. population have chronic renal damage with a GFR > 60 mL/min per 1.73 m^2 (stages 1 and 2 CRD) and hence are at imminent risk of a progressive further decline in GFR. An additional ~4.5% of the U.S. population are in stages 3 and 4 CRD. Diabetic and hypertensive nephropathy are the leading underlying etiologies of both CRD and ESRD. Hypertension is a particularly common cause and consequence of CRD in the elderly, in whom chronic renal ischemia due to renovascular disease may be an underrecognized additional contribution to the pathophysiologic process. It should be noted that cardiovascular mortality precludes most patients with CRD from reaching the stage of ESRD. Identification of CRD as a major risk factor for cardiovascular morbidity and mortality, and the expectation of effective interventions to diminish premature cardiovascular mortality, and increasing longevity overall, will increase the cohort of patients reaching ESRD.

Although the clinical manifestations of the declining GFR per se dominate the clinical presentation in all forms of CRD, in many cases the underlying etiology can be presumed from associated additional clinical information (Table 261-3).

GENETIC CONSIDERATIONS Disorders with clear-cut monogenic inheritance comprise a small but important component among the etiologies of CRD. Among these, autosomal dominant polycystic kidney disease is the most common on a world-wide basis (Chap. 265). Alport's hereditary nephritis (Chap. 264) is a less common cause of both benign hematuria without progression to CRD and more severe nephron injury with progression to ESRD, and it most often displays an X-linked pattern of inheritance. Several genetic loci have been identified that encode important components of the glomerular podocyte-associated filtration barrier, and mutations in these genes cause inherited forms of focal segmental glomerular sclerosis with glucocorticoid nonresponsive nephrotic syndrome and progression to ESRD. Nephronopthisis, medullary cystic kidney disease, and Fabry's disease are among other rare causes of progressive CRD with monogenic inheritance based on well-characterized genetic loci. In contrast, the two most common etiologies of CRD, diabetes mellitus (both types 1 and 2) and essential hypertension, display complex polygenic patterns of inheritance.

TABLE 261-3 *Summary of Clinical Presentations That may Suggest Given Major Categories of Causes of Chronic Renal Disease*

Cause	Clinical Presentation
Diabetic kidney disease	History of diabetes, proteinuria, retinopathy
Hypertension	Elevated blood pressure, normal urinalysis, family history.
Nondiabetic glomerular disease	Nephritic or nephrotic presentations (Chap. 264)
Cystic kidney disease	Urinary tract symptoms, abnormal urinary sediment, radiologic imaging abnormalities
Tubulointerstitial disease	History of urinary tract infections and reflux, chronic medication and drug exposure, abnormalities in urinary tract imaging, tubular syndromes including urine-concentrating defect, abnormal urinalysis

Source: Adapted from Levey, with permission.

The striking interindividual variability in the rate of progression to ESRD has an important heritable component, and a number of genetic loci that contribute to the progression of CRD have been identified. Most extensively studied has been an insertion/deletion polymorphism of the angiotensin-converting enzyme (ACE) gene. The homozygous deletion (D/D) variant is associated with the highest expression of endogenous ACE activity and a greater risk of CRD progression. This finding leads to the prediction that ACE inhibitor therapy might be most effective in patients who are homozygous for the "at-risk" allele. Similar conclusions have been reached with respect to genes encoding other components of the renin-angiotensin axis. More recent studies of genetic association with renal failure progression have focused on a region of human chromosome 10, homologous to a well-characterized rodent renal failure susceptibility gene (R*f*1).

PATHOPHYSIOLOGY AND BIOCHEMISTRY OF UREMIA *Azotemia* refers to the retention of nitrogenous waste products as renal insufficiency develops. *Uremia* refers to the more advanced stages of progressive renal insufficiency when the complex, multiorgan system derangements become clinically manifest.

Although not the major cause of overt uremic toxicity, urea may contribute to some of the clinical abnormalities, including anorexia, malaise, vomiting, and headache. Additional categories of nitrogenous excretory products include guanido compounds, urates and hippurates, end products of nucleic acid metabolism, polyamines, myoinositol, phenols, benzoates, and indoles, among others. Nitrogenous compounds with a molecular mass of 500 to 12,000 Da (so-called middle molecules) are also retained in CRD and similarly are believed to contribute to morbidity and mortality in uremic subjects. However, uremia involves more than renal excretory failure alone. A host of metabolic and endocrine functions normally subserved by the kidney are also impaired, resulting in anemia; malnutrition; impaired metabolism of carbohydrates, fats, and proteins; defective utilization of energy; and metabolic bone disease. Furthermore, plasma levels of many polypeptide hormones, including parathyroid hormone (PTH), insulin, glucagon, luteinizing hormone, and prolactin, rise with renal failure, not only because of impaired renal catabolism but also because of enhanced endocrine secretion, occurring as a secondary consequence of primary excretory or synthetic renal dysfynction. On the other hand, the renal production of erythropoietin (EPO) and 1,25-dihydroxycholecalciferol is impaired. Thus, the pathophysiology of the uremic syndrome can be divided into two sets of abnormalities: (1) those consequent to the accumulation of products of protein metabolism; and (2) those consequent to the loss of other renal functions, such as fluid and electrolyte homeostasis and hormonal abnormalities.

CLINICAL AND LABORATORY MANIFESTATIONS OF CHRONIC RENAL FAILURE AND UREMIA

Uremia leads to disturbances in the function of every organ system. Chronic dialysis (Chap. 262) reduces the incidence and severity of these disturbances, so that, where modern medicine is practiced, the overt and florid manifestations of uremia have largely disappeared. Unfortunately, as indicated in Table 261-4, even optimal dialysis therapy is not a panacea, because some disturbances resulting from impaired renal function fail to respond fully, while others continue to progress.

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS (See also Chaps. 41, 42, and 259) ■ **Sodium and Water Homeostasis** In most patients with stable CRD, the total body contents of Na^+ and H_2O are increased modestly, although this may not be clinically apparent. The underlying etiologic disease process may itself disrupt glomerulotubular balance and promote Na^+ retention (e.g., glomerulonephritis), or excessive Na^+ ingestion may lead to cumulative positive Na^+ balance and attendant extracellular fluid volume (ECFV) expansion. Such ECFV expansion contributes to hypertension, which in turn accelerates further the progression of nephron injury. As long as water intake does not exceed the capacity for free water clearance, the ECFV expansion will be isotonic and the patient will remain normonatremic. Hyponatremia is an uncommon complication in predialysis patients, and water restriction is only necessary when hyponatremia is documented. Weight gain usually associated with volume expansion may be offset in patients with CRD by concomitant loss of lean body mass. In the CRD patient who is not yet on dialysis but has clear evidence of ECFV expansion, administration of loop diuretics coupled with restriction of salt intake are the mainstays of therapy. It should be noted that resistance to loop diuretics in renal failure often mandates use of higher doses than those usually used when GFR is well preserved. The combination of loop diuretics with metalozone, which inhibits the Na^+Cl^- cotransporter of the distal convoluted tubule, can sometimes overcome diuretic resistance. When the GFR falls to <5 to 10 mL/min per 1.73 m^2, even high doses of combination diuretics are ineffective. ECFV expansion under these circumstances usually means that dialysis is indicated.

Patients with CRD also have impaired renal mechanisms for conserving Na^+ and H_2O (Chap. 259). When an *extrarenal* cause for fluid loss is present (e.g., vomiting, diarrhea, sweating, fever), these patients are prone to volume depletion. Depletion of ECFV may compromise residual renal function with resulting signs and symptoms of overt uremia. Because of impaired renal Na^+ and H_2O conservation, the usual indices of prerenal azotemia (oliguria, high urine osmolality, low urinary Na^+ concentration, and low fractional excretion of Na^+) are not useful. Cautious volume repletion, usually with normal saline, returns ECFV to normal and usually restores renal function to prior levels.

Potassium Homeostasis (See also Chap. 41) In CRD, the decline in GFR is not necessarily accompanied by a concomitant and proportionate decline in urinary K^+ excretion. In addition, K^+ excretion in the gastrointestinal tract is augmented in patients with CRD. However, hyperkalemia may be precipitated in a number of clinical situations, including constipation, augmented dietary intake, protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells, metabolic acidosis, and following the exposure to a variety of medications that inhibit K^+ entry into cells or K^+ secretion in the distal nephron. Most commonly encountered medications in this regard are beta blockers, ACE inhibitors and angiotensin receptor blockers, K^+-sparing diuretics (amiloride, triamterene, spironolactone), and nonsteroidal anti-inflammatory drugs (NSAIDs). In addition, certain etiologies of CRD may be associated with earlier and more severe disruption of K^+ secretory mechanisms in the distal nephron, relative to the reduction in GFR. Most important are conditions associated with hyporeninemic hypoaldosteronism (e.g., diabetic nephropathy and certain forms of distal renal tubular acidosis; Chaps. 264 and 265).

Hypokalemia is uncommon in CRD and usually reflects markedly reduced dietary K^+ intake, in association with excessive diuretic therapy or gastrointestinal losses. Hypokalemia occurs as a result of primary renal K^+ wasting in association with other solute transport abnormalities, as in Fanconi's syndrome, renal tubular acidosis, or other forms of hereditary or acquired tubulointerstitial diseases. However, even under these circumstances, as GFR declines, the tendency

[a] Virtually all abnormalities in this table are completely reversed in time by successful renal transplantation. The response of these abnormalities to hemodialysis or peritoneal dialysis therapy is more variable. (I) denotes an abnormality that usually improves with an optimal program of dialysis and related therapy; (P) denotes an abnormality that tends to persist or even progress, despite an optimal program; (D) denotes an abnormality that develops only after initiation of dialysis therapy.
[b] Improves with dialysis and erythropoietin therapy.
Note: Lp(a), lipoprotein A.

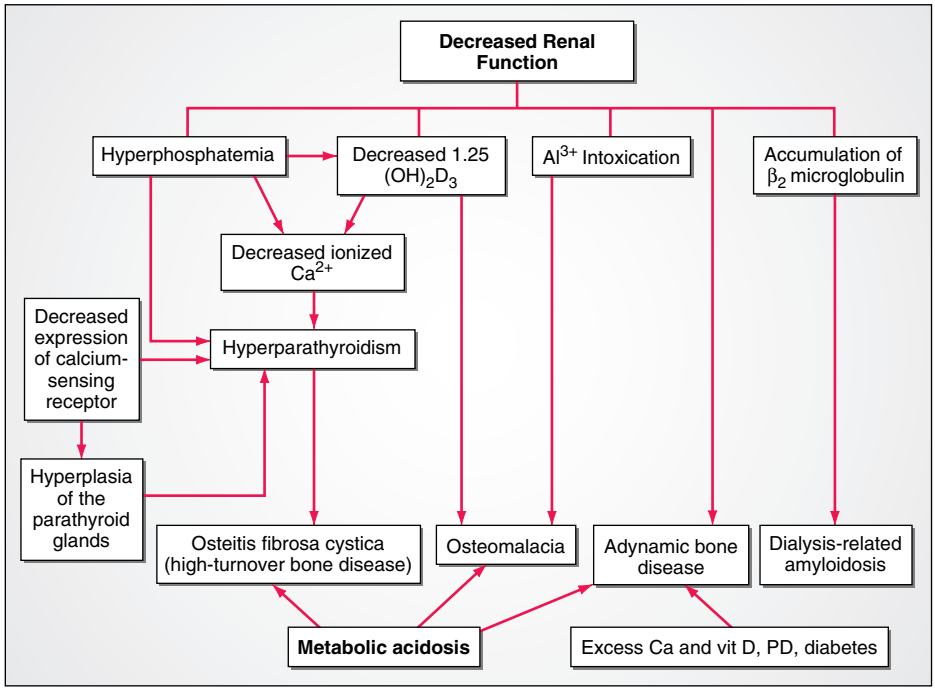

FIGURE 261-1 Flowchart for the development of bone, phosphate, and calcium abnormalities in chronic renal disease. (PD, peritoneal dialysis).

to hypokalemia diminishes and hyperkalemia may supervene. Accordingly, K^+ supplementation and K^+-sparing diuretics should generally be avoided as GFR declines.

Metabolic Acidosis (See also Chap. 42) Acidosis is a common disturbance during the advanced stages of CRD. Although in a majority of patients with CRD the urine can be acidified normally, these patients have a reduced ability to produce ammonia. Hyperkalemia further depresses urinary ammonium excretion. The combination of hyperkalemia and hyperchloremic metabolic acidosis (known as type IV renal tubular acidosis, or hyporeninemic hypoaldosteronism) is most characteristically seen in patients with diabetes or in those with predominantly tubulointerstitial disease. Treatment of the hyperkalemia frequently improves the acidosis as well.

With advancing renal failure, total urinary net daily acid excretion is usually limited to 30 to 40 mmol, and an anion gap of ~20 mmol/L with a reciprocal fall in plasma [HCO_3^-] may develop. In most patients, the metabolic acidosis is mild; the pH is rarely <7.35 and can usually be corrected by treating the patient with 20 to 30 mmol of $NaHCO_3$ or sodium citrate daily. However, the concomitant Na^+ load mandates careful attention to volume status and the potential need for diuretic agents. Also, citrate enhances aluminum absorption in the large bowel, and citrate-containing agents should be avoided if aluminum-containing drugs are also administered. Severe symptomatic manifestations of acid-base imbalance may occur when the patient is challenged with an excessive endogenous or exogenous acid load or loses excessive alkali (e.g., with diarrhea).

TREATMENT

Adjustments in dietary intake and use of loop diuretics, occasionally in combination with metalozone, may be needed to maintain salt and hence extracellular fluid volume balance. In contrast, overzealous salt restriction and diuretic use may cause hypovolemia and precipitate a further decline in GFR. Occasional patients with salt-wasting states need to be given sodium-rich diets or sodium supplements. Water restriction is indicated only if there is a demonstrated propensity to hyponatremia. Intractable ECFV expansion, despite dietary restriction and diuretic use, indicates the need to initiate renal replacement therapy. Hyperkalemia often responds to dietary restriction of potassium, avoidance of potassium-containing or -retaining medications, and to the use of diuretics if they are also indicated for management of sodium balance. Many salt substitutes contain potassium instead of sodium, and patients with CRD seeking to avoid sodium should be cautioned accordingly as part of their dietary counseling. Potassium-binding resins taken with cathartics can promote gastrointestinal potassium losses and thus are useful as temporizing measures in the treatment or avoidance of hyperkalemia in CRD patients. However, the need for such treatment over a prolonged period, in the absence of other reversible causes of hyperkalemia, usually signifies the need to initiate renal replacement therapy.

BONE DISEASE AND DISORDERS OF CALCIUM AND PHOSPHATE METABOLISM (Fig. 261-1; see also Chaps. 331 and 332) The major disorders of bone disease in CRD can be classified into those associated with high bone turnover and high PTH levels (including osteitis fibrosa, the hallmark lesion of secondary hyperparathyroidism) and low bone turnover with low or normal PTH levels (osteomalacia and adynamic bone disease).

The pathophysiology of bone disease due to secondary hyperparathyroidism is related to abnormal mineral metabolism. (1) Decreased GFR leads to reduced inorganic phosphate (PO_4^{3-}) excretion and consequent PO_4^{3-} retention, (2) retained PO_4^{3-} has a direct stimulatory effect on PTH synthesis and on cellular mass of the parathyroid glands, (3) retained PO_4^{3-} also indirectly causes excessive production and secretion of PTH through lowering of ionized Ca^{2+} and by suppression of calcitriol (1,25-dihydroxycholecalciferol) production, and (4) reduced calcitriol production in CRD results both from decreased synthesis due to reduced kidney mass and from hyperphosphatemia. Low calcitriol levels, in turn, lead to hyperparathyroidism via both direct and indirect mechanisms. Calcitriol is known to have a direct suppressive effect on PTH transcription (i.e., a genomic effect), and therefore reduced calcitriol in CRD causes elevated levels of PTH. In addition, reduced calcitriol leads to impaired Ca^{2+} absorption from the gastrointestinal tract, thereby leading to hypocalcemia, which then increases PTH secretion and production. Taken together, hyperphosphatemia, hypocalcemia, and reduced calcitriol synthesis all promote the production of PTH and the proliferation of parathyroid cells, resulting in secondary hyperparathyroidism.

In addition to excessive release of PTH from individual parathyroid cells, the mass of parathyroid cells increases progressively with CRD. Excessive parathyroid gland cellular mass may assume one of the following patterns: (1) diffuse hyperplasia (polyclonal), (2) nodular growth (monoclonal) within diffuse hyperplastic tissue, or (3) diffuse monoclonal hyperplasia ("adenoma" or tertiary autonomous hyperparathyroidism). Patients with monoclonal ("autonomous") hyperplasia are especially prone to develop hypercalcemia following successful kidney transplantation, often necessitating parathyroidectomy. High PTH levels stimulate osteoblasts and result in high bone turnover, which leads to *osteitis fibrosa cystica*. The latter is characterized by irregularly woven abnormal osteoid, fibrosis, and cyst formation, which result in decreased cortical bone and bone strength and an increased risk of fracture.

Low-turnover bone disease can be classified into two categories—osteomalalcia and adynamic bone disease. Both lesions are characterized by a reduced number of osteoclasts and osteoblasts and decreased activity of the latter. In *osteomalacia* there is an accumulation of unmineralized bone matrix, or increased osteoid volume, which may be caused by vitamin D deficiency, excess aluminum deposition, or meta-

bolic acidosis. Adynamic bone disease is now recognized to be as prevalent as the hyperparathyroid bone lesion in patients with CRD and ESRD, and is especially common among diabetic patients. *Adynamic bone disease* is characterized by reduced bone volume and mineralization and may result in part from excessive suppression of PTH production with calcitriol treatment or, currently less common, from aluminium exposure.

Irrespective of the cause for skeletal abnormalities in CRD, bone disease can lead to pain, increased incidence of fractures, and severe incapacity. Bone fractures complicate both the high- and low-turnover types of bone disease, and it is now appreciated that patients with adynamic bone may be more predisposed to fractures than those with osteitis fibrosa cystica. In the latter disorder, however, a PTH-associated proximal myopathy often coexists, giving rise to gait abnormalities and impaired ambulation.

Other Complications of Abnormal Calcium-Phosphate Product Metabolism In addition to abnormalities in bone metabolism, abnormal calcium-phosphate product metabolism may lead to *calciphylaxis*, i.e., extraosseous ("metastatic") calcification of soft tissue and blood vessels. Electron beam computed tomography in patients with CRD has revealed highly elevated coronary calcification scores, which likely represent a major factor in the predisposition to occlusive coronary vascular disease in the CRD and ESRD populations. The pathogenesis remains unclear, but hyperphosphatemia, hypercalcemia, elevated calcium-phosphate product, and increased PTH levels are all thought to contribute to this process. Calciphylaxis represents a severe and systemic form of vascular and soft tissue calcium-phosphate product deposition associated with skin and soft tissue necrosis, which can lead to extremity loss.

TREATMENT

Secondary hyperparathyroidism and osteitis fibrosa are best prevented and treated by reducing the plasma PO_4^{3-} concentration through the use of a phosphate-restricted diet as well as oral phosphate-binding agents. Calcium carbonate and calcium acetate are useful phosphate-binding agents. Sevelamer, a nonabsorbable, non-calcium-containing polymer has been recently added to the phosphate-lowering armamentarium. It has an advantage over the calcium-based phosphate chelating agents in that it does not predispose CRD patients to hypercalcemia and attenuates calcium deposition in the coronary arteries and aorta.

Daily oral calcitriol, or intermittent oral or intravenous pulses, appears to exert a direct suppressive effect on PTH secretion, in addition to the indirect effect mediated through raising plasma Ca^{2+} concentration. The use of calcitriol and calcium preparations in the predialysis population must take into account potential effects of increased PO_4^{3-} and Ca^{2+} on the rate of progression of CRD. The recommended target plasma PO_4^{3-} concentration is approximately 1.4 mmol/L (4.5 mg/dL), with a corresponding plasma Ca^{2+} concentration of approximately 2.5 mmol/L (10 mg/dL) in an attempt to suppress parathyroid hyperplasia, thus avoiding or reversing osteitis fibrosa cystica, osteomalacia, and myopathy. It is particularly important to maintain the calcium-phosphate product in the normal range to avoid metastatic calcification. Recognition of the role of the extracellular calcium–sensing receptor has led to the development of calcimimetic agents that enhance the sensitivity to Ca^{2+}-suppressive effects on PTH secretion. The first-generation calcimimetic agent tested produced a dose-dependent reduction in PTH and plasma Ca^{2+} concentration, and subsequent formulations with improved pharmacokinetic profiles show great promise as effective and safe treatments for secondary hyperparathyroidism. However, since adynamic bone disease is often a consequence of overzealous treatment of secondary hyperparathyroidism, suppression of PTH levels to $<$120 pg/mL in CRD patients may not be desirable.

The incidence of aluminum-induced osteomalacia has been greatly reduced with the recognition of aluminum as the principal culprit. Therapy for this disorder is based on the complete cessation of the use of aluminum combined with the use of a chelating agent such as deferoxamine.

Management of metabolic acidosis should aim to maintain a nearly normal level of plasma bicarbonate with the administration of calcium acetate or calcium carbonate, with the addition of sodium bicarbonate (limited by considerations of sodium load) if necessary. Excessive administration of alkali should be avoided to minimize risk of urinary precipitation of Ca^{2+} phosphate.

CARDIOVASCULAR ABNORMALITIES Cardiovascular disease is the leading cause of morbidity and mortality in patients with CRD at all stages. Estimates of the increase in cardiovascular disease risk attributable to CRD range from 10- to 200-fold, depending on the stage of CRD, other risk factors, and comorbid conditions. Between 30 and 45% of patients reaching ESRD already have advanced cardiovascular complications. Thus the management of patients with CRD should emphasize prevention of cardiovascular complications as well as measures aimed at alleviating the progression and complications of CRD itself.

Ischemic Cardiovascular Disease CRD at all stages constitutes a major risk factor for ischemic cardiovascular disease, including occlusive coronary heart, cerebrovascular, and peripheral vascular diseases. Increased prevalence of coronary heart disease in CRD derives from both traditional ("classic") and CRD-related ("nontraditional") risk factors. The former include hypertension (see below), hypervolemia, dyslipidemia, sympathetic overactivitiy, and hyperhomocysteinemia. The CRD-related risks include anemia, hyperphosphatemia, hyperparathyroidism, and a state of "microinflammation" that can be found at all stages of CRD but is undoubtedly aggravated by dialysis. The inflammatory state elicits a rise in acute-phase reactants such as interleukin 6 and C-reactive protein, which contribute to the coronary occlusive process and are predictors of cardiovascular disease risk. Other abnormalities augment myocardial ischemia. These include reduced myocardial tolerance to ischemia due to left ventricular hypertrophy (see below) and microvascular disease. Also, coronary reserve, defined as the increase in coronary blood flow in response to greater demand, is attenuated. Nitric oxide is an important mediator for vascular dilatation. Its availability in CRD is decreased because of increased concentrations of asymmetric dimethyl-l-arginine, even at early stages of CRD, and also because nitric oxide is scavenged by reactive oxygen species. In addition, coronary arteriolar hypertrophy/hyperplasia limits vasodilatory capacity.

Congestive Heart Failure (See also Chap. 216) Abnormal cardiac function secondary to myocardial ischemic disease and/or left ventricular hypertrophy, together with salt and water retention in uremia, often result in congestive heart failure and/or pulmonary edema. A unique form of pulmonary congestion and edema may occur even in the absence of volume overload and is associated with normal or mildly elevated intracardiac and pulmonary capillary wedge pressures. This entity, characterized radiologically by peripheral vascular congestion giving rise to a "butterfly wing" distribution, is due to increased permeability of alveolar capillary membranes. This "low-pressure" pulmonary edema as well as cardiopulmonary abnormalities associated with circulatory overload usually respond promptly to vigorous dialysis.

Hypertension and Left Ventricular Hypertrophy (See also Chap. 230) Hypertension is the most common complication of CRD and ESRD. It may develop early during the course of CRD and is associated with adverse outcomes—in particular, more rapid loss of renal function and development of cardiovascular disease. Numerous epidemiologic studies and clinical trials have shown a relationship between the level of blood pressure and rate of progression of diabetic and non-diabetic kidney disease (see below).

Administration of EPO (p. 1658) may raise blood pressure and increase the requirement for antihypertensive drugs in CRD patients. Left ventricular hypertrophy and dilated cardiomyopathy are among the most ominous risk factors for excess cardiovascular morbidity and

mortality in patients with CRD and ESRD and are thought to be related primarily to prolonged hypertension and ECFV overload. In addition, anemia and the surgical placement of an arteriovenous anastomosis for future or ongoing dialysis access may generate a high cardiac output state and pulmonary hypertension, which also intensify the burden placed on the left ventricle. *Absence* of hypertension may signify the presence of a salt-wasting form of renal disease (e.g., medullary cystic disease, chronic tubulointerstitial disease, or papillary necrosis), ongoing antihypertensive therapy, volume-depletion due to gastrointestinal causes or diuretic therapy, or reduced cardiac index.

Since volume overload is the major cause of hypertension in uremia, the normotensive state can often be restored by appropriate (not overzealous) use of salt restriction and natriuretic drugs or ultrafiltration in the dialysis setting. Nevertheless, because of hyperreninemia and other disturbances in renal vasoconstrictors and vasodilators, some patients remain hypertensive despite rigorous salt and water restriction and ultrafiltration. Rarely, such patients may develop accelerated or malignant hypertension. Intravenous labetolol, or more recently approved agents such as fenoldopam or urapidil, together with control of ECFV generally control such hypertension. Enalaprilat or other ACE inhibitors may also be considered, but in the face of bilateral renovascular disease they have the potential to further reduce GFR abruptly.

TREATMENT

Management of Hypertension (See also Chap. 230) There are two overall goals: to slow the progression of CRD itself and to prevent the extrarenal complications of hypertension, such as cardiovascular disease and stroke. In all patients with CRD, blood pressure should be controlled to at least the level established in the guidelines of the Sixth Joint National Commission on Hypertension Detection Education and Follow-up Program (130/80 to 85 mmHg). In CRD patients with diabetes or proteinuria >1 g per 24 h, blood pressure should be further reduced to 125/75 mmHg. Volume control with salt restriction and diuretics is the mainstay of therapy. When volume management is not sufficient, the choice of antihypertensive agent is similar to that in the general population, with the added consideration of cardioprotective benefit provided by ACE inhibition, or angiotensin receptor blockade. The choice of antihypertensive agents may come from all the major classes, with careful consideration of comorbid conditions. However, powerful direct-acting vasodilators, such as hydralazine or minoxidil, may perpetuate the tendency to cardiac hypertrophy, despite the lowering of blood pressure. Therefore, prolonged use of such agents should be reserved for those very rare patients in whom severe refractory hypertension persists, despite adequate volume reduction and compliance with all other classes of antihypertensives.

Management of Cardiovascular Disease Hypertension, hyperhomocysteinemia, and lipid abnormalities promote atherosclerosis but are potentially treatable complications of CRD. Ongoing or prior nephrotic syndrome is also associated with hyperlipidemia and hypercoagulability, which increase the risk of occlusive vascular disease. Since diabetes mellitus and hypertension are themselves the two most frequent etiologies of CRD, it is not surprising that cardiovascular disease is the most frequent cause of death in ESRD patients. Therefore, accepted life-style changes and therapeutic measures for cardiac risk reduction (Chap. 225) are especially important in this group of patients. Hyperhomocysteinemia may respond to vitamin therapy, which includes folate supplementation to between 1 and 5 mg/d. Hyperlipidemia in patients with CRD and ESRD should be managed aggressively according to the guidelines of the National Cholesterol Education Program (Chap. 335). If dietary measures are inadequate, the preferred lipid-lowering medications are gemfibrozil and an HMG-CoA reductase inhibitor. However, caution should be exercised in combining these two classes of agents because of an increased risk of myositis and rhabdomyolysis in CRD and ESRD patients.

Pericarditis (See also Chap. 222) With the advent of early initiation of renal replacement therapy, pericarditis is now observed more often in underdialyzed patients than in predialysis CRD patients. Pericardial pain with respiratory accentuation, accompanied by a friction rub, are the hallmarks of uremic pericarditis. The finding of a multicomponent friction rub strongly supports the diagnosis. Classic electrocardiographic abnormalities include PR-interval depression and diffuse ST-segment elevation. Pericarditis may be accompanied by the accumulation of pericardial fluid that is readily detected by echocardiography and that sometimes leads to cardiac tamponade. Pericardial fluid in uremic pericarditis is more often hemorrhagic than in viral pericarditis.

TREATMENT

Uremic pericarditis is an absolute indication for initiation of dialysis or for intensification of the dialysis prescription in those already on dialysis. Because of the propensity to hemorrhagic pericardial fluid, heparin-free dialysis is indicated. Pericardiectomy should be considered only if more conservative measures fail. Nonuremic causes of pericarditis and pericardial effusion include viral, malignant, and tuberculous pericarditis and pericarditis associated with myocardial infarction; these are also more frequent in patients with ESRD and should be managed according to the dictates of the underlying disease process.

HEMATOLOGIC ABNORMALITIES ■ Anemia A normocytic, normochromic anemia attributable to CRD is observed beginning at stage 3 CRD and is almost universal at stage 4. If untreated, the anemia of CRD is associated with a number of physiologic abnormalities, including decreased tissue oxygen delivery and utilization, increased cardiac output, cardiac enlargement, ventricular hypertrophy, angina, congestive heart failure, decreased cognition and mental acuity, altered menstrual cycles, and impaired host defense against infection. In addition, anemia may play a role in growth retardation in children with CRD. The primary cause of anemia in patients with CRD is insufficient production of EPO by the diseased kidneys. Additional factors include iron and folate deficiency, severe hyperparathyroidism, acute and chronic inflammation, aluminum toxicity, shortened red cell survival, and associated comorbid conditions such as hemoglobinopathies. These potential contributing factors should be considered and addressed, especially in EPO-resistant patients.

TREATMENT

The anemia of CRD is due to several factors including chronic blood loss, hemolysis, marrow suppression by retained uremic factors and reduced renal production of EPO. The availability of recombinant human EPO, epoetin alfa, has made possible one of the most significant advances in the care of renal patients since the introduction of dialysis and transplantation. More recently, a novel erythropoiesis-stimulating protein has been introduced for the treatment of anemia in CRD patients. This protein, darbopoetin alfa, is a hyperglycosylated analogue of recombinant human EPO that possesses greater biologic activity and prolonged half-life. Thus, dose intervals can be extended and still effectively correct renal anemia in both predialysis and dialysis patients. Guidelines for using epoetin and darbopoetin alfa for the management of anemia of CRD are provided in Table 261-5.

The iron status of the patient with CRD must be assessed, and adequate iron stores should be available before treatment with EPO is initiated. Iron supplementation is usually essential to ensure an adequate response to EPO in patients with CRD, because the demands for iron by the erythroid marrow frequently exceed the amount of iron that is immediately available for erythropoiesis (as measured by percent transferrin saturation) as well as iron stores (as measured by serum ferritin). In most cases, intravenous iron is required to achieve and/or maintain adequate iron. However, excessive iron therapy may be associated with a number of complications, including hemosiderosis, accelerated atherosclerosis, increased susceptibility to infection, and

possibly an increased propensity to the emergence of malignancies. In addition to iron, an adequate supply of the other major substrates and cofactors for erythrocyte production must be assured, especially vitamin B_{12} and folate. Anemia resistant to recommended doses of EPO in the face of adequate availability of iron and vitamin factors often suggests inadequate dialysis; uncontrolled hyperparathyroidism; aluminum toxicity; chronic blood loss or hemolysis; associated hemoglobinopathy, malnutrition, chronic infection, multiple myeloma, or another malignancy. Blood transfusions may contribute to suppression of erythropoiesis in CRD; because they increase the risk of hepatitis, hemosiderosis, and transplant sensitization, they should be avoided unless the anemia fails to respond to erythropoietin and the patient is symptomatic.

TABLE 261-5 Management Guidelines for Correction of Anemia of Chronic Renal Disease

Erythropoietin	
Starting dosage:	50–150 units/kg per week IV or SC (once, twice, or three times per week)
Target hemoglobin (Hb):	11–12 g/dL
Optimal rate of correction[a]	Increase Hb by 1–2 g/dL over 4-week period
Darbepoetin alfa	
Starting dosage:	0.45 μg/kg administered as a single IV or SC injection once weekly 0.75 μg/kg administered as a single IV or SC injection once every 2 weeks
Target Hb:	≤12 g/dL
Optimal rate of correction	Increase Hb by 1–2 g/dL over 4-week period
Iron	
1. Monitor iron stores by percent transferrin saturation (TSat) and serum ferritin.	
2. If patient is iron-deficient (TSat <20%; serum ferritin <100 μg/L), administer iron, 50–100 mg IV twice per week for 5 weeks; if iron indices are still low, repeat the same course.	
3. If iron indices are normal yet Hb is still inadequate, administer IV iron as outlined above; monitor Hb, TSat, and ferritin.	
4. Withhold iron therapy when TSat > 50% and/or ferritin > 800 ng/mL (>800 μg/L).	

[a] If correction of anemia is inadequate, consider causes for refractoriness as outlined in text. Recent reports of pure red blood cell aplasia, may lead to preferences for IV route for some EPO formulations.

Abnormal Hemostasis This is common in CRD and is associated with prolongation of bleeding time, decreased activity of platelet factor III, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption. Clinical manifestations include an increased tendency to abnormal bleeding and bruising; bleeding from surgical wounds; and spontaneous bleeding into the gastrointestinal tract, pericardial sac, or intracranial vault (in the form of subdural hematoma or intracerebral hemorrhage). Notwithstanding these abnormalities in hemostasis, CRD patients have a greater susceptibility to thromboembolic complications, particularly if their underlying disease was characterized by a nephrotic presentation.

TREATMENT

Abnormal bleeding times and coagulopathy in patients with renal failure may be reversed with desmopressin, cryoprecipitate, conjugated estrogens, and blood transfusions, as well as EPO. On the other hand, patients with CRD should also be viewed as being at greater risk for thromboembolic complications and receive appropriate anticoagulant prophylaxis when indicated. Avoidance or dose adjustment of certain anticoagulants, such as fractionated low-molecular-weight heparin, is necessary in CRD patients.

NEUROMUSCULAR ABNORMALITIES Central, peripheral, and autonomic neuropathy, as well as abnormalities in muscle composition and function, are all common complications in CRD. Retained nitrogenous metabolites and middle molecules as well as PTH all contribute to the pathophysiology of neuromuscular abnormalities. Subtle clinical manifestations of uremic neuromuscular disease usually become evident beginning at stage 3 CRD. Early manifestations of central nervous system complications include mild disturbances in memory and concentration and sleep disturbance. Neuromuscular irritability, including hiccups, cramps, and fasciculations/twitching of muscles, becomes evident at later stages. Asterixis, myoclonus, and chorea are common in terminal uremia, which may also be associated with seizures and coma.

Peripheral neuropathy usually becomes clinically evident when the patient has been at stage 4 CRD for >6 months, although electrophysiologic and histologic evidence of peripheral neuropathy occurs earlier. Initially, sensory nerves are involved more than motor nerves, lower extremities more than upper, and distal portions of the extremities more than proximal. The "restless legs syndrome" is characterized by ill-defined sensations of discomfort in the legs and feet requiring frequent leg movement. If dialysis is not instituted soon after onset of sensory abnormalities, motor involvement follows, including muscle weakness and loss of deep tendon reflexes. Accordingly, evidence of peripheral neuropathy is a firm indication for renal replacement therapy. Some of the central nervous system and neuromuscular complications of advanced uremia resolve with dialysis, although nonspecific electroencephalographic abnormalities may persist. Successful transplantation may reverse residual peripheral neuropathy.

GASTROINTESTINAL AND NUTRITIONAL ABNORMALITIES *Uremic fetor*, a uriniferous odor to the breath, derives from the breakdown of urea to ammonia in saliva and is often associated with an unpleasant metallic taste sensation. Gastritis, peptic disease, and mucosal ulcerations at any level of the gastrointestinal tract occur in uremic patients and can lead to abdominal pain, nausea, vomiting, and blood loss. Other gastrointestinal complications of CRD include an increased incidence of diverticulosis, particularly in patients with polycystic kidney disease, and an increased incidence of pancreatitis. In addition, central nervous system effects of uremia contribute to anorexia, hiccups, nausea, and vomiting. Protein restriction is useful in diminishing nausea and vomiting late in the course of renal failure. However, protein restriction should not be implemented in patients with signs of protein-energy malnutrition, which is a consequence of low protein and caloric intake, resistance to anabolic actions of insulin and other hormones and growth factors, disturbed dietary protein utilization, proinflammatory cytokine activation, and metabolic acidosis. Assessment for protein-energy malnutrition should begin at stage 3 CRD (GFR < 60 mL/min per 1.73 m^2). A number of indices are useful in this assessment and include dietary history, edema-free body weight, measurement of urinary protein nitrogen appearance, and plasma markers, of which albumin is the most useful. Guidelines for calorie and protein intake in patients with CRD are provided below (p. 1661).

ENDOCRINE-METABOLIC DISTURBANCES Disturbances in parathyroid function have already been considered (p. 1656).

Glucose metabolism is impaired in CRD, as evidenced by a slowing of the rate at which blood glucose levels decline after a glucose load. Fasting blood glucose is usually normal or only slightly elevated, and the mild glucose intolerance related to uremia per se, when present, does not require specific therapy. Because the kidney contributes significantly to insulin removal from the circulation, plasma levels of insulin are slightly to moderately elevated in most uremic subjects, both in the fasting and postprandial states. However, the response to insulin and glucose utilization is impaired in CRD. Many hypoglycemic drugs require dose reduction in renal failure, and some, such as metformin, are contraindicated when the GFR has diminished by more than approximately 25 to 50%.

In women, *estrogen levels* are low, and amenorrhea and inability to carry pregnancies to term are common manifestations of uremia. When the GFR has declined by ~30%, pregnancy may hasten the progression of CRD. In men with CRD, including those receiving chronic dialysis, impotence, oligospermia, and germinal cell dysplasia

are common, as are reduced plasma testosterone levels. Like growth, sexual maturation is often impaired in adolescent children with CRD, even among those treated with chronic dialysis. Many of these abnormalities improve or reverse with successful renal transplantation.

DERMATOLOGIC ABNORMALITIES The skin may show evidence of anemia (pallor), defective hemostasis (ecchymoses and hematomas), calcium-phosphate deposition and secondary hyperparathyroidism (pruritus, excoriations), and deposition of pigmented metabolites or *urochromes* (yellow discoloration) or urea itself (uremic frost). Although many of these cutaneous abnormalities improve with dialysis, *uremic pruritus* often remains a problem. The first lines of management are to rule out unrelated skin disorders and to control PO_4^{3-} concentration with avoidance of an elevated calcium-phosphate product. Occasionally, pruritus remains refractory to these measures and to other nonspecific systemic and topical therapies. Skin necrosis can occur as part of the calciphylaxis syndrome, which also includes subcutaneous, vascular, joint, and visceral calcification in patients with poorly controlled calcium-phosphate product.

EVALUATION AND MANAGEMENT OF PATIENTS WITH CRD

INITIAL APPROACH ■ History and Physical Examination Complaints referred to the kidneys themselves are often conspicuously absent in CRD, and this often surprises patients and is a cause of skepticism and denial. Of special importance in establishing the etiology of CRD are a history of hypertension; diabetes; systemic infectious, inflammatory, or metabolic diseases; exposure to drugs and toxins; and a family history of renal and urologic disease. Drugs of particular importance include analgesics (usage frequently underestimated or denied by the patient), NSAIDs, gold, penicillamine, antimicrobials, lithium, and ACE inhibitors. In evaluating the uremic syndrome, questions about appetite, diet, nausea, vomiting, hiccupping, shortness of breath, edema, weight change, muscle cramps, pruritus, mental acuity, and activities of daily living are especially helpful.

On physical examination, particular attention should be paid to blood pressure, fundoscopy, precordial examination, examination of the abdomen for bruits and palpable renal masses, examination for edema, and neurologic examination for the presence of asterixis, muscle weakness, and neuropathy. In addition the evaluation of prostate size in men, and potential pelvic masses in women should be undertaken.

Laboratory Investigations These should also focus on a search for clues to an underlying disease process and its continued activity. Therefore, if the history and physical examination warrant, immunologic tests for systemic lupus erythematosus and vasculitis might be considered. Serum and urinary protein electrophoresis should be undertaken in all patients >40 years with unexplained CRD and anemia, to rule out paraproteinemia. Other tests to determine the stage and chronicity of the disease, including complications of the uremic syndrome, include serial measurements of plasma creatinine and estimation of GFR, urea, electrolytes (including HCO_3^-, Ca^{2+}, and PO_4^{3-}), and alkaline phosphatase to assess metabolic bone disease as well as hemoglobin. Urinalysis may be helpful in assessing the presence of ongoing activity of the underlying inflammatory or proteinuric disease process and, when indicated, should be supplemented by a 24-h urine collection for protein excretion. The latter is particularly helpful in guiding management strategies aimed at ameliorating the progression of CRD. The presence of broad casts on examination of the urinary sediment is a nonspecific finding seen with all underlying etiologies and reflects chronic tubulointerstitial scarring and tubular atrophy with widened tubule diameter, usually signifying an advanced stage of CRD.

Imaging Studies The most useful imaging study is renal ultrasonography. An ultrasound examination of the kidneys can verify the presence of two symmetric kidneys, provide an estimate of kidney size, and rule out renal masses and obstructive uropathy. The documentation of symmetric small kidneys supports the diagnosis of progressive CRD with an irreversible component of scarring. Normal kidney size suggests the possibility of an acute rather than chronic process. However, polycystic kidney disease, amyloidosis, diabetes, and HIV-associated renal disease (Chap. 173) may lead to CRD with normal kidney size. Documentation of asymmetric kidney size suggests either a unilateral developmental abnormality or chronic renovascular disease. In the latter case, a vascular imaging procedure, such as duplex doppler sonography of the renal arteries, radionuclide scintigraphy, or magnetic resonance angiography should be strongly considered if the possibility of revascularization is feasible. A spiral computed tomographic scan without contrast may be useful in assessing kidney stone activity. Voiding cystourethrography to rule out reflux may be indicated in some patients with a history of enuresis or with a family history of reflux. However, in most cases by the time CRD is established, reflux has resolved, and even if present, its repair does not stabilize renal function. In any case, imaging studies should avoid exposure to intravenous radiocontrast dye where possible because of its nephrotoxicity.

Renal Biopsy This procedure should be reserved for patients with near-normal kidney size, in whom a clear-cut diagnosis cannot be made by less invasive means and when the possibility of a reversible underlying disease process remains tenable, such that clarification of the underlying etiology may alter management. The extent of tubulointerstitial scarring on kidney biopsy generally provides the most reliable pathologic correlate indicating prognosis for continued deterioration toward ESRD. Contraindications to renal biopsy include bilateral small kidneys, polycystic kidney disease, uncontrolled hypertension, urinary tract or perinephric infection, bleeding diathesis, respiratory distress, and morbid obesity. Ultrasound-guided percutaneous biopsy is the favored approach, but surgical approaches, including laparoscopic biopsy, may be considered in special circumstances such as biopsy of a solitary kidney.

ESTABLISHING THE DIAGNOSIS AND ETIOLOGY OF CRD The most important initial step in the evaluation of a patient presenting de novo with biochemical or clinical evidence of renal failure is to distinguish newly diagnosed CRD from acute renal failure. Availability of past medical records documenting serial measurements of the plasma urea and/or creatinine concentrations can be of great help in this regard. In the absence of such information, some of the laboratory tests and imaging studies outlined above can be useful. In particular, a urinary sediment that is inactive or reveals proteinuria and broad casts; the demonstration of evidence of chronic metabolic bone disease with hyperphosphatemia, hypocalcemia, elevated PTH levels, and radiologic bone disease; normocytic and normochromic anemia; and the finding of bilaterally reduced kidney size (< 8.5 cm) by imaging studies, strongly favor a long-standing process consistent with CRD. However, these findings do not rule out the superimposition of an acute and reversible exacerbating factor that may have accelerated the decline in GFR (see below).

In the early stages of CRD it is often possible to establish the underlying etiology. Integration of a particular constellation of clinical, laboratory, and imaging findings based on the approach noted above strongly supports a particular presumed underlying etiologic disease process. For example, in a patient with insulin-dependent type 1 diabetes mellitus of 15 to 20 years duration, diabetic retinopathy, and nephrotic-range albuminuria without hematuria, the diagnosis of *diabetic nephropathy* is likely. The diagnosis of *chronic hypertensive nephrosclerosis* requires a history of long-standing hypertension, in the absence of evidence for another renal disease process, and hence it is usually a diagnosis of exclusion. Usually proteinura is mild to moderate (< 3 g/d) and the urine sediment inactive. It should be noted that in many cases of presumed hypertensive nephrosclerosis, renovascular disease not only may be the cause of hypertension but also may cause ischemic renal damage. In this regard, bilateral renovascular ischemic disease may be a greatly underdiagnosed cause of CRD. This is of therapeutic significance from two points of view: (1) documentation of ischemic renal disease secondary to occlusive vascular dis-

ease may prompt revascularization therapy in some subgroups of patients, with occasional stabilization and improvement in renal function; (2) renovascular ischemic disease is a contraindication to ACE inhibitor therapy in most cases. *Analgesic-associated chronic tubulointerstitial nephropathy* is also an underdiagnosed cause of CRD. Imaging studies, including computed tomography, often reveal pathognomonic features such as papillary calcification and necrosis. Under such circumstances, cessation of analgesic exposure may dramatically stabilize renal function.

In the absence of an etiologically suggestive clinical constellation, renal biopsy may be the only recourse to establish etiology in early CRD. However, in advanced stages of CRD, definitively establishing an underlying etiology becomes less feasible and is also of less therapeutic significance.

TREATMENT

Specific treatments aimed at selected underlying etiologies of CRD are provided in the respective chapters describing these disease states. The optimal time for such therapy is usually well before there has been a measurable decline in baseline GFR and usually well before CRD is established. It is of benefit to follow and plot the rate of decline in GFR in all patients. Any acceleration in the rate of decline should prompt a search for superimposed acute processes that may lead to an acute and reversible decline in GFR in patients with CRD. These include superimposed volume depletion, accelerated and uncontrolled hypertension, urinary tract infection, superimposed obstructive uropathy (e.g., due to stone disease, papillary necrosis), nephrotoxic effect of medications (e.g., NSAIDs) and radiocontrast agents, and reactivation or flare of the original underlying etiologic disease process.

SLOWING THE PROGRESSION OF CRD While there is great interindividual variation in the rate of decline of GFR in patients with CRD, a series of therapeutic interventions should be pursued that aim to stabilize the GFR or reduce the annual rate of decline.

Protein Restriction (Table 261-6) A major goal of protein restriction in CRD, beyond ameliorating the complications of uremia, is to slow the rate of nephron injury. This concept is based on clinical and experimental evidence demonstrating the role of protein-mediated hyperfiltration in progressive nephron injury. The effectiveness of protein restriction in slowing the progression of CRD has been shown in controlled clinical trials in patients with both diabetic and nondiabetic renal disease.

Protein restriction should be carried out in the context of an overall dietary program that optimizes nutritional status and avoids malnutrition, especially as patients near dialysis or transplantation. Metabolic and nutritional studies indicate that protein requirements for patients with CRD are similar to those for normal adults and are in the range of 0.6 g/kg per day. However, there is a particular requirement in patients with CRD that the composition of dietary protein be higher in essential amino acids, and that this be combined with an overall energy supply sufficient to mitigate a catabolic state. Energy requirements in the range of 35 kcal/kg per day are recommended. Fortunately, even patients with advanced CRD (GFR ~ 10 to 15 mL/min per 1.73 m^2) are able to activate the same adaptive responses to dietary protein restriction as healthy individuals, i.e., a postprandial suppression of whole-body protein degradation and a marked inhibition of amino acid oxidation. These compensatory responses to dietary protein restriction and nutritional indices are sustained during long-term therapy.

TABLE 261-6 Management Guidelines for Dietary Protein Restriction in CRD

CRD Stage	Protein, g/kg per d	Phosphorus, g/kg per d
Stages 1 and 2	Protein restriction not usually recommended	No restriction
Stage 3	0.6 g/kg per d including ≥0.35 g/kg per d of HBV	≤10
Stages 4 and 5	0.6 g/kg per d including ≥0.35 g/kg per d of HBV *or* 0.3 g/kg per d supplemented with EAA or KA	≤10 ≤9
GFR <60 mL/min per 1.73 m^2 (nephrotic syndrome)	0.8 g/kg per d (plus 1 g protein/g proteinuria) *or* 0.3 g/kg per d supplemented with EAA or KA (plus 1 g protein/g proteinuria)	≤12 ≤9

Note: CRD, chronic renal disease; GFR, glomerular filtration rate; HBV, high biologic value protein; EAA, essential amino acid supplement; KA, ketoanalogue supplement.

Reducing Intraglomerular Hypertension and Proteinuria (See also p. 1657) In addition to reduction of cardiovascular disease risk, antihypertensive therapy in patients with CRD also aims to slow the progression of nephron injury, by ameliorating intraglomerular hypertension and hypertrophy. Progressive renal injury in CRD appears to be most closely related to the height of intraglomerular pressure and/or the extent of glomerular hypertrophy. Control of hypertension is as at least as important as dietary protein restriction in slowing the progression of CRD. Furthermore, the target for pharmacologic therapy is highly dependent on the level of proteinuria. Indeed, proteinuria is now considered a risk factor for both progressive nephron injury as well cardiovascular disease. Elevated blood pressure increases proteinuria due to the transmission to the glomeruli of the elevated systemic pressure. Conversely, the renoprotective effect of antihypertensive medications is evident through the curtailment of proteinuria. Thus, the more effective a given treatment is in lowering proteinuria, the greater the subsequent impact on protection from GFR decline. This is the basis for the treatment guideline establishing 125/75 mmHg as the target blood pressure value in proteinuric CRD patients.

Owing to their unique effect on the glomerular microcirculation (i.e., dilatation of the efferent arteriole), which is related to inhibition of the renin-angiotensin system, ACE inhibitors and angiotensin receptor blockers are now clearly established as effective, antiproteinuric agents. Several multicenter studies have shown that these drugs are effective in slowing the progression of renal failure in patients with both diabetic and nondiabetic renal failure. The slowing in the progression of renal failure by these drugs is strongly related to their proteinuria-lowering effect. In the absence of a significant antiproteinuric response, combined treatment with both an ACE inhibitor and angiotensin receptor blocker can be tried. Contraindications to or adverse effects of the use of these classes of agents (e.g., intractable cough, anaphylaxis, hyperkalemia not controlled by dietary restriction) may prompt the choice of calcium channel blockers as a second-line therapeutic approach. Among the calcium channel blockers, diltiazem and verapamil may exhibit superior antiproteinuric and renal protective effects. Available clinical studies have indicated that calcium antagonists as a group do not adversely affect renal function in patients with nondiabetic renal insufficiency, and also indicate that they may be more effective in preventing or ameliorating progressive renal injury than some other classes of antihypertensive drugs in this group of patients. Thus, it appears that at least two different categories of responses may exist: one in which progression is strongly associated with systemic and intraglomerular hypertension and with proteinuria (e.g., diabetic nephropathy, glomerular diseases) and in which ACE inhibitors and angiotensin receptor blockers are likely to be the first choice; and the second in which proteinuria is mild or absent (e.g., adult polycystic kidney disease), probably with a less prominent role for intraglomerular hypertension, and which might respond as well to calcium entry blockers.

SLOWING DIABETIC RENAL DISEASE (See also Chap. 323) Diabetic nephropathy is now the leading cause of CRD eventuating in ESRD in many parts of the world. Furthermore, the prognosis of diabetic patients on chronic renal replacement therapy is very poor, owing to

accelerated cardiovascular disease. Therefore, it is particularly compelling to search for strategies whose aim is to prevent or slow the progression of this complication of diabetes mellitus.

Glucose Control Although tight glycemic control reduces the risk of kidney disease in patients with type 1 diabetes, there has been prolonged controversy over whether the same is true in patients with type 2 diabetes. The results of recent controlled prospective studies provide incontrovertible evidence that in type 2 diabetes mellitus the risk of the development and progression of albuminuria and CRD can also be substantially reduced by improving glycemic control. The United Kingdom Prospective Diabetes Study showed that the way in which glycemic control was achieved, whether by insulin or oral antihyperglycemic agents such as sulfonylureas or metformin, was far less important than success in achieving control. Achieving a target hemoglobin A_{1C} level of <7.2%, as compared to >9%, is associated with an approximately 50% reduction in the occurrence of indices of progressive nephropathy. As a result of these findings, recommendations for glucose control aim to achieve plasma values for preprandial glucose in the range of 90 to 130 mg/dL, and for average bedtime glucose of 110 to 150 mg/dL and hemoglobin $A_{1C} < 7\%$. Reduction in GFR mandates dose adjustment of many antihyperglycemic agents, and in particular the discontinuation of metformin when the plasma creatinine is >133 μmol/L (1.5 mg/dL).

Control of Blood Pressure and Proteinuria Hypertension or an abnormal circadian blood pressure profile is found in 80% of type 2 diabetic patients at the time of diagnosis. Both of these findings correlate with the presence of albuminuria and are powerful predictors of cardiovascular and renal events. The onset of microalbuminuria precedes the decline in GFR in diabetic patients and heralds renal as well as cardiovascular complications. Therefore, microalbuminuria testing is recommended in all diabetic patients at least annually, and more frequently to follow therapeutic interventions. Antihypertensive treatment reduces albuminuria and diminishes the risk of progression of albuminuria even in normotensive patients with diabetes. There is now compelling evidence that ACE inhibitors and angiotensin receptor blockers have specific renoprotective properties in diabetic patients with microalbuminuria or overt proteinuria. These salutary effects are almost certainly mediated by reducing intraglomerular pressure and inhibition of transforming growth factor β–mediated sclerosing pathways.

MANAGING OTHER COMPLICATIONS OF CHRONIC RENAL FAILURE ■ Impending Uremic Symptomatology Temporary relief of symptoms and signs of impending uremia, such as anorexia, nausea, vomiting, asterixis, lassitude, and other central nervous system manifestations, may be achieved with protein restriction. However, this must be associated with careful monitoring of nutritional status, so as to avoid protein-energy malnutrition, evidence of which serves as a clear-cut indication for initiation of renal replacement therapy.

Medication Dose Adjustment (See also Chap. 3) Although the loading dose of most drugs is not affected by CRD, maintenance doses of many drugs need to be adjusted. For those drugs in which >70% excretion is by a nonrenal (e.g., hepatic or intestinal) route, dosage adjustment may not be needed. Some drugs that should be entirely avoided include meperidine, metformin, and other oral hypoglycemics with a renal route of elimination. Commonly used medications that require either a reduction in dosage or changes in interval include allopurinol, many antibiotics, several antihypertensives, and antiarrhythmics. For a comprehensive detailed and authoritative listing of the recommended dose adjustment for most of the commonly used medications, the reader is referred to the American College of Physicians' handbook "*Drug Prescribing in Renal Failure*" (see *www.acponline.org*). In addition to dose adjustment requirements, many drugs have nephrotoxicity as a prominent side effect, to which patients with CRD are more susceptible. Of particular notoriety in this regard are NSAIDs, because of their widespread availability and usage. These drugs aggravate the tendency to sodium retention, hypertension, hyperkalemia, and hyponatremia and further reduce GFR in patients with CRD. In this regard, there is no advantage to more selective inhibitors of cyclooxygenase-2.

Preparation for Renal Replacement Therapy (See also Chaps. 262 and 263) Over the past 40 years, renal replacement therapy using dialysis and transplantation has prolonged the lives of hundreds of thousands of patients with ESRD. Renal replacement therapy should *not* be initiated when the patient is totally asymptomatic; however, dialysis and/or transplantation should be started sufficiently early to prevent serious complications of the uremic state. Clear indications for initiation of renal replacement therapy include pericarditis, progressive neuropathy attributable to uremia, encephalopathy, muscle irritability, anorexia and nausea that are not ameliorated by reasonable protein restriction, evidence of protein-energy malnutrition, and fluid and electrolyte abnormalities that are refractory to conservative measures. The latter include volume overload unresponsive to diuretic therapy, hyperkalemia unresponsive to dietary potassium restriction, and progressive metabolic acidosis that cannot be managed with alkali therapy. Clinical clues indicating the imminent development of uremic complications are a history of hiccupping, intractable pruritus, morning nausea and vomiting, muscle twitching and cramps, and the presence of asterixis on physical examination. In addition, the patient whose follow-up and compliance with conservative management are questionable should be considered for earlier initiation of renal replacement therapy, lest potentially life-threatening uremic complications or electrolyte disturbances supervene.

Since there is considerable interindividual variability in the severity of uremic symptoms and renal function, it is ill-advised to assign a certain "usual" level of blood urea nitrogen, serum creatinine, or GFR to the need to start dialysis. Nevertheless, in the United States, the Health Care Financing Administration has assigned levels of serum creatinine and creatinine clearance to qualify for reimbursement from Medicare for patients receiving dialysis. Serum creatinine must be ≥700 μmol/L (≥8.0 mg/dL) and the creatinine clearance must be ≤10 mL/min. Recent controlled studies have failed to show a survival advantage for early initiation of renal replacement therapy prior to onset of clinical indications.

Patient Education and Adjustment Social, psychological, and physical preparation for the transition to renal replacement therapy and choice of the optimal initial modality is best accomplished with a gradual approach involving a multidisciplinary team. While conservative measures are being carried out in patients with CRD, it is important to prepare them with an intensive educational program, explaining the likelihood and timing of initiation of renal replacement therapy and the various forms of therapy available. The more knowledgable patients are concerning hemodialysis, peritoneal dialysis, and transplantation, the easier and more appropriate will be their decisions at a later time. Exploration of social service support resources is of great importance. In those who may perform home dialysis or undergo transplantation, early education of family members for selection and preparation as a home dialysis helper or a related donor for transplantation should occur long before the onset of symptomatic renal failure.

Selection of patients to be treated with various modalities of dialysis or transplantation is a matter of some debate, with considerable variation in different parts of the world. In general, in the United States and some other countries, nearly all patients who have reached ESRD are accepted for dialysis if they or their families desire prolongation of life, irrespective of age.

Only kidney transplantation (Chap. 263) offers the potential for nearly complete rehabilitation. This is because dialysis techniques replace only 10 to 15% of normal kidney function at the level of small-solute removal and are even less efficient at the removal of larger solutes. Generally, kidney transplantation follows a prior period of dialysis treatment. All patients in whom an acute reversible component of renal failure has not been completely excluded should be supported

with dialysis first, at least for some period of time, to allow for possible return of renal function before consideration of transplantation. Recovery of endogenous renal function in patients treated with dialysis for >6 months is a rare occurrence. For patients approaching ESRD in whom a reversible component has been excluded, and who have a good antigenic match with a willing donor, consideration should be given to preemptive or primary transplantation without intervening dialysis.

262 DIALYSIS IN THE TREATMENT OF RENAL FAILURE

Ajay K. Singh, Barry M. Brenner

With the widespread availability of dialysis, the lives of hundreds of thousands of patients with end-stage renal disease (ESRD) have been prolonged. In the United States alone, there are now approximately 400,000 patients with ESRD. The overall incidence of ESRD is 260 cases per million population per year. The incident population of patients with ESRD is increasing at approximately 6% each year. The incidence of ESRD is disproportionately higher in African Americans (843 per million population per year) as compared with white Americans (189 per million population per year). In the United States, the leading cause of ESRD is diabetes mellitus, currently accounting for nearly 45% of newly diagnosed cases of ESRD. The second most common cause is hypertension, which is estimated to cause 28% of ESRD cases. Other causes of ESRD include glomerulonephritis, polycystic kidney disease, and obstructive uropathy. The mortality of patients with ESRD is lowest in Europe and Japan but is very high in the developing world because of the limited availability of dialysis. In the United States, the mortality rate of patients on dialysis is approximately 18% per year. Deaths are due mainly to cardiovascular diseases and infections (approximately 50% and 15% of deaths, respectively).

TREATMENT OPTIONS FOR ESRD PATIENTS

Commonly accepted criteria for placing patients on dialysis include the presence of the uremic syndrome; the presence of hyperkalemia unresponsive to conservative measures; extracellular volume expansion; acidosis refractory to medical therapy; a bleeding diathesis; and a creatinine clearance of 10 mL/min per 1.73 m^2. Early referral to a nephrologist for advanced planning and creation of a dialysis access, education about ESRD treatment options, and the aggressive management of the complications of chronic renal failure, including acidosis, anemia, and hyperparathyroidism, are important. In addition to carefully evaluating patients for the onset of uremia (Chap. 261), regular measurement of renal function is important.

Renal function can be assessed indirectly by measurement of serum creatinine and blood urea nitrogen or of creatinine and urea clearance, or directly by measurement of glomerular filtration rate (GFR) using a radioisotope such as iothalamate. Creatinine clearance usually overestimates GFR because a substantial fraction of creatinine excretion in advanced renal failure occurs as a consequence of proximal tubular secretion. On the other hand, urea clearance invariably underestimates GFR because urea is reabsorbed in the distal nephron. Thus, when measurement of GFR by a direct test is not available, the average of the sum of the creatinine and urea clearance, or a cimetidine-blocked creatinine clearance (cimetidine blocks proximal tubular secretion), is recommended. Alternatively, the GFR can be estimated using a prediction equation that computes a calculated value for GFR. Examples of such equations include the Cockcroft-Gault equation and the Modification of Diet in Renal Disease (MDRD) equation.

The treatment options available for patients with renal failure depend on whether it is acute or chronic (Fig. 262-1). In acute renal failure, treatments include hemodialysis, continuous renal replacement therapies (Chap. 260), and peritoneal dialysis. In chronic renal failure (ESRD) the options include hemodialysis (in center or at home); peritoneal dialysis, as either continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD); or transplantation (Chap. 263). Although there are geographic variations, hemodialysis remains the most common therapeutic modality for ESRD (>80% of patients in the United States). The choice between hemodialysis and peritoneal dialysis involves the interplay of various factors that include the patient's age, the presence of comorbid conditions, the ability to perform the procedure, and the patient's own conceptions about the therapy. Peritoneal dialysis is favored in younger patients because of their better manual dexterity and greater visual acuity, and because younger patients prefer the independence and flexibility of home-based peritoneal dialysis treatment. In contrast, larger patients (>80 kg), patients with no residual renal function, and patients who have truncal obesity with or without prior abdominal surgery may be more suited to hemodialysis. Larger patients with no residual renal function are more appropriate for hemodialysis because these patients have a large volume of distribution of urea and require significantly higher amounts of peritoneal dialysis, which may be difficult to achieve because of the limited willingness of patients to perform more than four exchanges each day. In some patients, the inability to obtain vascular access necessitates a switch from hemodialysis to peritoneal dialysis.

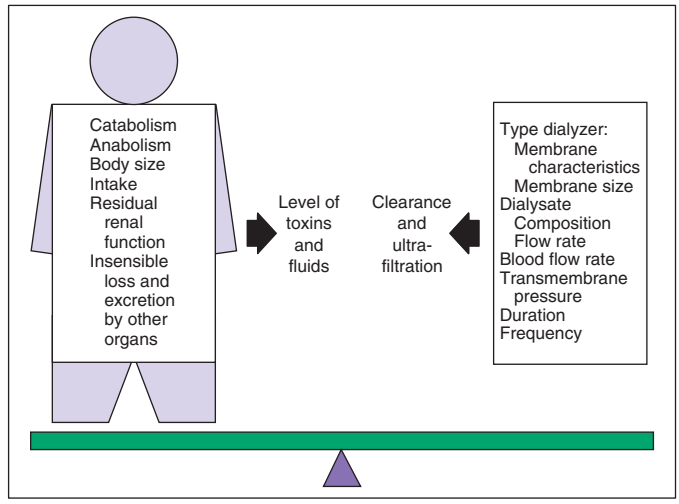

FIGURE 262-1 Factors in the development of the uremic syndrome and considerations in its treatment.

HEMODIALYSIS

Hemodialysis relies on the principles of solute diffusion across a semipermeable membrane. Movement of metabolic waste products takes place down a concentration gradient from the circulation into the dialysate. The rate of diffusive transport increases in response to several factors, including the magnitude of the concentration gradient, the membrane surface area, and the mass transfer coefficient of the membrane. The latter is a function of the porosity and thickness of the membrane, the size of the solute molecule, and the conditions of flow on the two sides of the membrane. According to the laws of diffusion, the larger the molecule, the slower its rate of transfer across the membrane. A small molecule such as urea (60 Da) undergoes substantial clearance, whereas a larger molecule such as creatinine (113 Da) is cleared less efficiently. In addition to diffusive clearance, movement of toxic materials such as urea from the circulation into the dialysate may occur as a result of ultrafiltration. Convective clearance occurs because of solvent drag with solutes getting swept along with water across the semipermeable dialysis membrane.

THE DIALYZER There are three essential components to dialysis: the dialyzer, the composition and delivery of the dialysate, and the blood delivery system (Fig. 262-2). The dialyzer consists of a plastic device with the facility to perfuse blood and dialysate compartments at very high flow rates. The surface area of dialysis membranes in adult patients is usually in the range of 0.8 to 1.2 m^2.

There are currently two geometric configurations for dialyzers: hollow fiber and flat plate. The hollow fiber dialyzer is the most common in use in the United States. These dialyzers are composed of bundles of capillary tubes through which blood circulates while dialysate travels on the outside of the fiber bundle. In contrast, the less frequently utilized flat plate dialyzers are composed of sandwiched sheets of membrane in a parallel plate configuration. The advantage of the hollow fiber construction is the lower priming volume (60 to 90 mL vs 100 to 120 mL for the flat plate) and easier reprocessing of the filter for reuse in future dialysis treatments.

Recent advances have led to the development of many different types of membrane material. Broadly, there are four categories of dialysis membranes: cellulose, substituted cellulose, cellulosynthetic, and synthetic. Over the past two decades, there has been a gradual switch from cellulose-derived to synthetic membranes, because the latter are more biocompatible. Bioincompatibility may be defined as the ability of the membrane to activate the complement cascade. Cellulosic membranes are bioincompatible because of the presence of free hydroxyl groups on the membrane surface. In contrast, with the substituted cellulose membranes (e.g., cellulose acetate) or the cellulosynthetic membranes, the hydroxyl groups are chemically bonded to either acetate or tertiary amino groups, resulting in limited complement activation. Synthetic membranes, such as polysulfone, polymethylmethacrylate, and polyacrylonitrile membranes, are more biocompatible because of the absence of these hydroxyl groups. Polysulfone membranes are now used in over 60% of the dialysis treatments in the United States.

Reprocessing and reuse of hemodialyzers are employed for patients on chronic hemodialysis in nearly 80% of dialysis centers in the United States, in large part because of the expense of individual dialyzers. Evidence also suggests that reuse reduces complement activation, the incidence of anaphylactoid reactions to the membrane (first-use syndrome), and, in some studies, mortality rates among dialysis patients. In most centers, only the dialyzer unit is reprocessed and reused, whereas in the developing world blood lines are also frequently reused. The reprocessing procedure can be either manual or automated. It consists of the sequential rinsing of the blood and dialysate compartments with water, a chemical cleansing step with reverse ultrafiltration from the dialysate to the blood compartment, the testing of the patency of the dialyzer, and, finally, disinfection of the dialyzer. Formaldehyde, peracetic acid–hydrogen peroxide, and glutaraldehyde are the most frequently used reprocessing agents, with peracetic acid–hydrogen peroxide being the most common.

DIALYSATE The composition of dialysate is listed in Table 262-1. Bicarbonate has replaced acetate as the preferred buffer in the United States. This change has resulted in fewer episodes of hypotension dur-

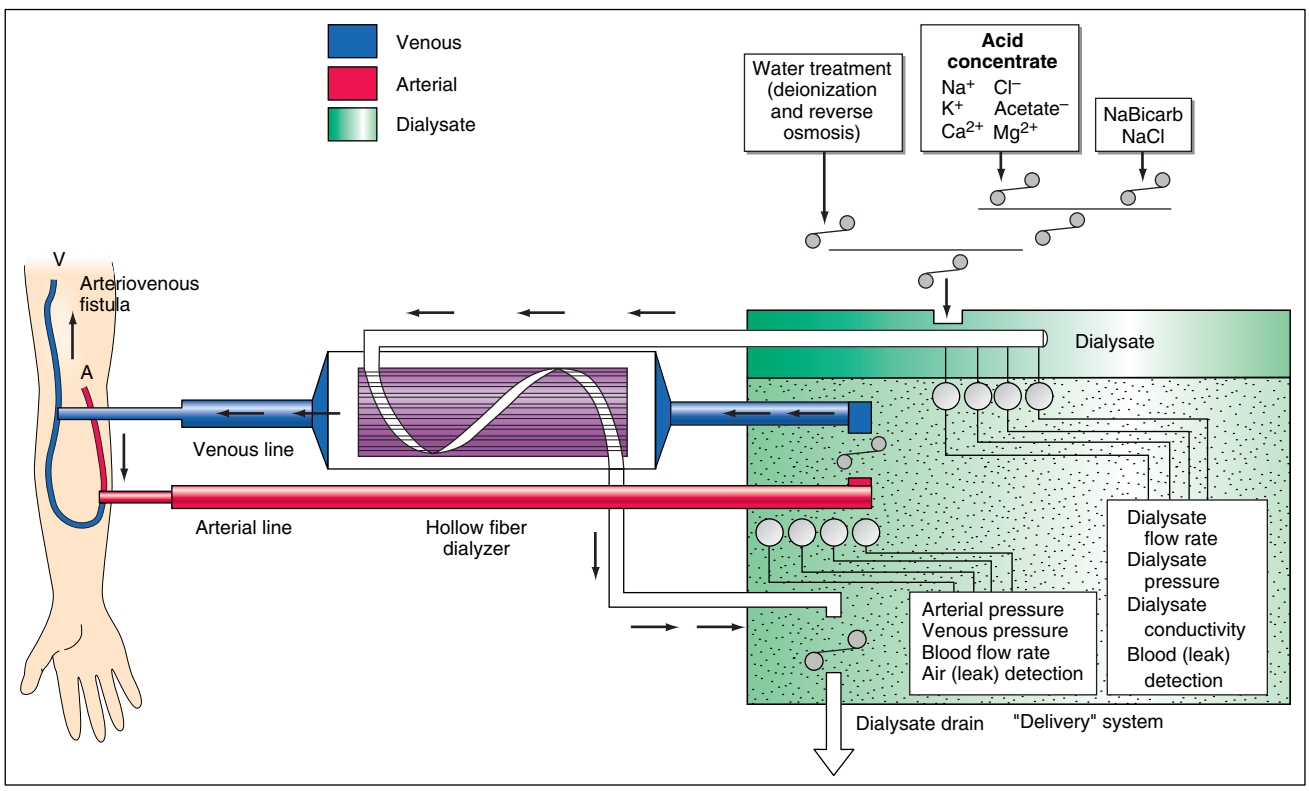

FIGURE 262-2 Schema for hemodialysis.

TABLE 262-1 Composition of Commercial Dialysate for Hemodialysate

Solute	Bicarbonate Dialysate
Sodium (meq/L)	137–143
Potassium (meq/L)	0–4.0
Chloride (meq/L)	100–111
Calcium (meq/L)	0–3.5
Magnesium (meq/L)	0.75–1.5
Acetate (meq/L)	2.0–4.5
Bicarbonate (meq/L)	30–35
Glucose (g/L)	0–0.25

ing dialysis. The potassium concentration of dialysate may be varied from 0 to 4 mmol/L depending on the predialysis plasma potassium concentration. The usual dialysate calcium concentration is 1.25 mmol/L (2.5 meq/L). The usual dialysate sodium concentration is 140 mmol/L. Lower dialysate sodium concentrations are associated with a higher frequency of hypotension, cramping, nausea, vomiting, fatigue, and dizziness. In patients who frequently develop hypotension during their dialysis run, sodium modeling to counterbalance urea-related osmolar gradients is now widely used. In this technique, the dialysate sodium concentration is gradually lowered from the range of 148 to 160 meq/L to isotonic levels (140 meq/L) near the end of the dialysis treatment. A dialysate glucose concentration of 200 mg/dL (11 mmol/L) is used to optimize blood glucose concentrations. Because patients are exposed to approximately 120 L of water during each dialysis treatment, untreated water could expose them to a variety of environmental contaminants. Therefore, in 98% of U.S. dialysis centers, water used for the dialysate is subjected to filtration, softening, deionization, and, ultimately, reverse osmosis. During the reverse osmosis process, water is forced through a semipermeable membrane at very high pressure to remove microbiologic contaminants and more than 90% of dissolved ions.

BLOOD DELIVERY SYSTEM The blood delivery system is composed of the extracorporeal circuit in the dialysis machine and the dialysis access. The dialysis machine consists of a blood pump, dialysis solution delivery system, and various safety monitors. The blood pump, using a roller mechanism, moves blood from the access site, through the dialyzer, and back to the patient. The blood flow rate may range from 250 to 500 mL/min. Negative hydrostatic pressure on the dialysate side can be manipulated to achieve desirable fluid removal: so-called *ultrafiltration*. Dialysis membranes have different ultrafiltration coefficients (i.e., mL removed/min per mmHg) so that along with hydrostatic changes, fluid removal can be varied. The dialysis solution delivery system dilutes the dialysate concentrate with water and monitors the temperature, conductivity, and flow of dialysate. The dialysate may be delivered to the dialyzer from a storage tank or a proportioning system that manufactures dialysate online.

Dialysis Access The fistula, graft, or catheter through which blood is obtained for hemodialysis is often referred to as a *dialysis access*. A native fistula created by the anastomosis of an artery to a vein (e.g., the Cimino-Breschia fistula, in which the cephalic vein is anastomosed to the radial artery) results in arterialization of the vein. This facilitates its subsequent use in the placement of large needles (typically 15 gauge) to access the circulation. Although fistulas have a high patency rate (approximately 60% are patent at 3 years following creation), fistulas are created in only approximately 30% of patients in the United States. In the majority of U.S. dialysis patients, the dialysis access consists of an arteriovenous graft that interposes prosthetic material, such as polytetrafluoroethylene, between an artery and a vein. Reasons for the higher rates of graft placement include the late referral of patients to vascular access surgeons so that by the time surgery is planned, the patient's arm veins have already been obliterated through multiple blood draws; the high prevalence of patients with diabetes mellitus and its associated microvascular disease; and the greater surgical skill required in creating a fistula. However, by 3 years most grafts fail because of thrombosis or infection. Fortunately, grafts may be inserted in one of several locations: the arm (brachial artery to basilic vein), the chest wall (axillary artery to axillary vein), or the leg (femoral artery to femoral vein). The most common access-related complication is thrombosis due to intimal hyperplasia, which results in stenosis 2 to 3 cm proximal to the venous anastomosis.

A double-lumen cuffed catheter is used in approximately 20% of patients on chronic hemodialysis in the United States. These catheters are used as an alternative to either a native arteriovenous fistula or a graft in selected patients in whom dialysis is required relatively urgently, such as patients who manifest delayed recovery from acute renal failure, or where a further permanent access procedure (e.g., arteriovenous fistula or arteriovenous graft) is not feasible for anatomical reasons. Although double-lumen catheters may permit blood flows comparable to a permanent arteriovenous access, these catheters are prone to infection and to occlusion because of thrombosis. Temporary double-lumen catheters in either the femoral vein or the internal jugular or subclavian vein are usually employed in patients with acute renal failure. The jugular is preferred to the subclavian vein because, for unclear reasons, a catheter placed in a subclavian vein appears to be associated with a higher rate of venous stenosis. Temporary access can be used for 2 to 3 weeks. Thrombosis, low blood flow, and infection limit the life of the catheter.

GOALS OF DIALYSIS The hemodialysis procedure is targeted at removing both low- and high-molecular-weight solutes. The procedure consists of pumping heparinized blood through the dialyzer at a flow rate of 300 to 500 mL/min, while dialysate flows in an opposite *countercurrent* direction at 500 to 800 mL/min. The clearance of urea ranges from 200 to 350 mL/min, while the clearance of α_2 microglobulin is more modest and ranges from 20 to 25 mL/min. The efficiency of dialysis is determined by blood and dialysate flow through the dialyzer, as well as dialyzer characteristics (i.e., its efficiency in removing solute). The *dose* of dialysis, which is defined as the magnitude of urea clearance during a single dialysis treatment, is further governed by patient size, residual renal function, dietary protein intake, the degree of anabolism or catabolism, and the presence of comorbid conditions.

Since the landmark studies of Sargent and Gotch relating the measurement of the dose of dialysis using urea concentration with patient outcome, the *delivered* dose of dialysis has been correlated with morbidity and mortality. This has led to the development of two major models for assessing the adequacy of the dialysis dose. Fundamentally, these two widely used measures of the adequacy of dialysis are calculated from the decrease in the blood urea nitrogen concentration during the dialysis treatment—that is, the urea reduction ratio (URR), and KT/V, an index based on the urea clearance rate, K, and the size of the urea pool, represented as the urea distribution volume, V. K, which is the sum of clearance by the dialyzer plus renal clearance, is multiplied by the time spent on dialysis, T. Increasingly, KT/V has become the preferred marker for dialysis adequacy. Currently, a URR of 65% and a KT/V of 1.2 per treatment are minimal standards for adequacy among ESRD patients; lower levels of dialysis treatment are associated with increased morbidity and mortality. The HEMO study examined the effect of dialysis dose and the level of flux of the dialyzer membrane on mortality and morbidity and found that a higher dialysis dose (single pool KT/V of 1.71 ± 0.11) did not confer a benefit over a standard dialysis dose (single pool KT/V of 1.32 ± 0.09). Thus, the study supported the continued use of current US Practice Guidelines, which recommend a KT/V of at least 1.2. Furthermore, since no benefit of a high flux dialyzer was demonstrated in the study, the use of a high flux dialyzer was also not supported.

For the majority of patients with chronic renal failure, between 9 and 12 h of dialysis is required each week, usually divided into three equal sessions. However, the dialysis dose must be individualized. Recently there has been much interest in the possibility that more frequent dialysis may be associated with improved outcomes in pa-

tients with acute or chronic renal failure. Indeed, it has been suggested that among patients with acute renal failure, daily dialysis may better control uremia, reduce hypotensive episodes, more rapidly resolve acute renal failure, and significantly lower mortality. Therefore, the measurement of dialysis adequacy using KT/V or the URR should serve only as a guide; body size, residual renal function, dietary intake, complicating illness, degree of anabolism or catabolism, and the presence of large interdialytic fluid gains should be important factors that are taken into consideration in the dialysis prescription.

COMPLICATIONS DURING HEMODIALYSIS Hypotension is the most common acute complication of hemodialysis, particularly among diabetics. Numerous factors appear to increase the risk of hypotension, including excessive ultrafiltration with inadequate compensatory vascular filling, impaired vasoactive or autonomic responses, osmolar shifts, food ingestion, impaired cardiac reserve, diastolic dysfunction, the use of antihypertensive drugs, anemia, and vasodilation due to the use of warm dialysate. Because of the vasodilatory and cardiodepressive effects of acetate, the use of acetate as the buffer in dialysate was once a common cause of hypotension. Since the introduction of bicarbonate-containing dialysate, dialysis-associated hypotension has become less common. The management of hypotension during dialysis consists of discontinuing ultrafiltration, the administration of 100 to 250 mL of isotonic saline or 10 mL of 23% saturated hypertonic saline, and administration of salt-poor albumin. Hypotension during dialysis can frequently be prevented by careful evaluation of the dry weight, withholding of antihypertensive medications on the day prior to and on the day of dialysis, and avoiding heavy meals during dialysis. Additional maneuvers include ultrafiltration modeling, such that more fluid is ultrafiltered at the beginning rather than the end of the dialysis procedure; the performance of sequential ultrafiltration followed by dialysis; the use of midodrine, a selective α_1-adrenergic pressor agent; and cooling of the dialysate during dialysis treatment.

Muscle cramps during dialysis are also a common complication of the procedure. However, since the introduction of volumetric controls on dialysis machines and sodium modeling, the incidence of cramps has fallen. The etiology of dialysis-associated cramps remains obscure. Changes in muscle perfusion because of excessively aggressive volume removal, particularly below the estimated dry weight, and the use of low-sodium-containing dialysate, have been proposed as precipitants of dialysis-associated cramps. Strategies that may be used to prevent cramps include reducing volume removal during dialysis, the use of higher concentrations of sodium in the dialysate, and the use of quinine sulfate (260 mg 2 h before treatment).

Anaphylactoid reactions to the dialyzer, particularly on its first use, have been reported most frequently with the bioincompatible cellulosic-containing membranes. With the gradual phasing out of cuprophane membranes in the United States, the first-use syndrome has become relatively uncommon. The first-use syndrome consists of either an intermediate hypersensitivity reaction due to an IgE-mediated reaction to ethylene oxide used in the sterilization of new dialyzers, or a symptom complex of nonspecific chest and back pain, which appears to result from complement activation and cytokine release.

The major cause of death in patients with ESRD receiving chronic dialysis is cardiovascular disease. The rate of death from cardiac disease is higher in patients on hemodialysis as compared to patients on peritoneal dialysis and renal transplantation. The underlying cause of cardiovascular disease is unclear but may be related to the inadequate treatment of hypertension; the presence of hyperlipidemia, homocystinemia and anemia; the calcification of coronary arteries in patients with an elevated calcium-phosphorus product; and perhaps alterations in cardiovascular dynamics during the dialysis treatment. Intensive investigation of the mechanisms and potential interventions that could impact on reducing the mortality from cardiovascular causes is currently underway.

CONTINUOUS RENAL REPLACEMENT THERAPY Continuous renal replacement therapies (CRRT) have become increasingly prevalent in the intensive care unit (ICU) setting for management of acute renal failure. The advantages of CRRT over intermittent hemodialysis are that it is usually better tolerated hemodynamically; it facilitates gradual correction of biochemical abnormalities; it is highly effective in removing fluid; and it is technically simple to perform. Clearance of toxic materials (using urea as the marker) can occur with CRRT from convective clearance alone if the ultrafiltration rate is high and with diffusive clearance if dialysis accompanies ultrafiltration. CRRT techniques include continuous arteriovenous hemodiafiltration (CAVH/D) with or without dialysis, and continuous veno-venous hemodiafiltration (CVVH/D) with or without dialysis.

Veno-venous therapies differ fundamentally from arteriovenous therapies in that veno-venous therapies do not require arterial access. This allows obtaining less risky and easier vascular access. However, because there is no systemic arterial pressure to drive hemofiltration, veno-venous therapies require a blood pump in the extracorporeal circuit. Veno-venous therapies such as CVVH provide substantial flexibility because changing the blood flow rate in the pump can change the ultrafiltration and clearance rates. In contrast, arteriovenous therapies such as CAVH are associated with variable efficiency because the systemic blood pressure is frequently low or unstable in patients with acute renal failure. Furthermore, low blood flow with CAVH may also result in clotting of the extracorporeal circuit. CAVH often results in clearance rates as low as 10 to 15 mL/min, whereas CVVH may generate clearances in the range of 30 to 40 mL/min. Thus, in light of these advantages of CVVH, many centers have completely switched from arteriovenous to veno-venous therapies in patients with acute renal failure in the ICU setting.

Vascular access in patients on CVVH is usually achieved by the insertion of a double-lumen catheter into the femoral vein. The blood pump is typically set to deliver approximately 150 to 180 mL/min. In automated systems, (e.g., the Cobe Prisma system), the treatment is volumetrically governed by continuously weighing the effluent and replacement solutions and using a servomechanism to drive the replacement fluid pump at a rate computed either to balance the inflow and loss of fluid or to maintain a predetermined rate of fluid loss. Anticoagulation of the extracorporeal circuit is via a heparin infusion (200 to 1600 U/h) through the inflow side of the circuit. Alternatively, citrate can be used to chelate calcium in the extracorporeal circuit to provide regional anticoagulation in selected patients who cannot undergo systemic heparinization. The replacement solution in continuous therapies is designed specifically to replace calcium, magnesium, and bicarbonate. In place of bicarbonate, lactate or citrate is the buffer in the replacement solution. However, bicarbonate-based replacement fluid is the preferred option in patients with liver failure because of the impaired ability of the liver to metabolize either lactate or acetate into bicarbonate.

PERITONEAL DIALYSIS

Peritoneal dialysis consists of infusing 1 to 3 L of a dextrose-containing solution into the peritoneal cavity and allowing the fluid to dwell for 2 to 4 h. As with hemodialysis, toxic materials are removed through a combination of convective clearance generated through ultrafiltration, and diffusive clearance down a concentration gradient. The clearance of solute and water during a peritoneal dialysis exchange depends on the balance between the movement of solute and water into the peritoneal cavity versus absorption from the peritoneal cavity. The rate of diffusion diminishes with time and eventually stops when equilibration between plasma and dialysate is reached. Absorption of solutes and water from the peritoneal cavity occurs across the peritoneal membrane into the peritoneal capillary circulation and via peritoneal lymphatics into the lymphatic circulation. The rate of peritoneal solute transport varies from patient to patient and may be altered by the presence of infection (peritonitis), drugs such as beta blockers and calcium channel blockers, and physical factors such as position and exercise.

FORMS OF PERITONEAL DIALYSIS Peritoneal dialysis may be carried out as continuous ambulatory peritoneal dialysis (CAPD), continuous cyclic peritoneal dialysis (CCPD), or nocturnal intermittent peritoneal dialysis (NIPD). In CAPD, dialysis solution is manually infused into the peritoneal cavity during the day and exchanged three to four times daily. A nighttime dwell is frequently instilled at bedtime and remains in the peritoneal cavity through the night. The drainage of spent dialysate (effluence) is performed manually with the assistance of gravity to move fluid out of the abdomen. In CCPD, exchanges are performed in an automated fashion, usually at night; the patient is connected to the automated cycler, which then performs four to five exchange cycles while the patient sleeps. Peritoneal dialysis cyclers automatically cycle dialysate in and out of the abdominal cavity. In the morning the patient, with the last exchange remaining in the abdomen, is disconnected from the cycler and goes about his regular daily activities. In NIPD, the patient is given approximately 10 h of cycling each night, with the abdomen left dry during the day.

Peritoneal dialysis solutions are available in various volumes ranging from 0.5 to 3.0 L. The electrolyte composition is shown in Table 262-2. Lactate is the preferred buffer in peritoneal dialysis solutions. Acetate in peritoneal dialysis solutions appears to accelerate peritoneal sclerosis, whereas use of bicarbonate results in precipitation of calcium and caramelization of glucose. The most common additives to peritoneal dialysis solutions are heparin and antibiotics during an episode of acute peritonitis. Insulin may also be added in patients with diabetes mellitus.

ACCESS TO THE PERITONEAL CAVITY This is obtained through a peritoneal catheter. These are either *acute* catheters, used to perform acute continuous peritoneal dialysis, usually in an emergency setting, or *chronic* catheters, which have either one or two Dacron cuffs and are tunneled under the skin into the peritoneal cavity. An acute catheter consists of a straight or slightly curved rigid tube with several holes at its distal end. Catheters can be inserted at the bedside by making a small incision in the anterior abdominal wall; the catheter is inserted with the assistance of a guidewire or stylet. Acute catheters are anchored externally with adhesives or sutures and are usually reserved for temporary use because of the risk of infection, which increases after 72 h of use. In contrast, chronic catheters are flexible and made of silicon rubber with numerous side holes at the distal end. These chronic catheters usually have two Dacron cuffs to promote fibroblast proliferation, granulation, and invasion of the cuff. The scarring that occurs around the cuffs anchors the catheter and seals it from bacteria tracking from the skin surface into the peritoneal cavity; it also prevents the external leakage of fluid from the peritoneal cavity. The cuffs are placed in the preperitoneal plane and approximately 2 cm from the skin surface. The most common chronic peritoneal dialysis catheter in use is the Tenckhoff catheter, which contains two cuffs.

TABLE 262-2 *Composition of Peritoneal Dialysate*

Solute	Dianeal (PD-2)
Sodium (meq/L)	132
Potassium (meq/L)	0
Chloride (meq/L)	96
Calcium (meq/L)	3.5
Magnesium (meq/L)	0.5
D,L-Lactate (meq/L)	40
Glucose (g%)	
1.5	
2.5	
4.25	
pH	5.2

The initial CAPD prescription consists of the infusion of a 2-L volume of a 1.5% dextrose concentration peritoneal dialysis solution into the peritoneal cavity over 10 min and allowing it to dwell for 2.5 h. The effluent solution is then drained over 20 min before the next exchange. Three daytime exchanges are accompanied by a 2-L nighttime dwell as the standard prescription. Because peritoneal membrane characteristics vary from one individual to another, the peritoneal equilibrium test should be employed within 2 months of a patient initiating peritoneal dialysis. This test measures the peritoneal membrane transfer rate for solutes (usually urea and creatinine) based on the ratio of their concentration in dialysate and plasma at specific times during the dialysate dwell. It allows patients to be classified as low, low–average, high–average, and high transporters. Approximately 10 to 17% of patients are high transporters, 50% high–average transporters, 25 to 30% low–average transporters, and 1 to 5% low transporters. Identifying the high transporters early is important, since these patients not only demonstrate excellent solute removal, they also absorb glucose rapidly; maximum ultrafiltration occurs early in the dwell, followed by reabsorption of water back into the circulation over the course of the dwell. Such patients benefit from either NIPD or CAPD without a nighttime dwell.

The dose of peritoneal dialysis required to provide adequate or optimal dialysis as measured by patient outcomes is not known. However, there is emerging consensus that the weekly KT/V should be >2.0 and the creatinine clearance >65 L/week per 1.73 m^2. The most frequently utilized approach to calculating a weekly KT/V and creatinine clearance is to collect the spent dialysate and urine over a 24-h period. The peritoneal dialysis prescription can be tailored to improve suboptimal clearance values by increasing the volume of individual exchanges, increasing the number of exchanges, or combining the CAPD and CCPD techniques. In combining these techniques, the CAPD patient hooks up to a cycler at night and the machine automatically performs one or two nocturnal exchanges, whereas the CCPD patient makes an additional manual daytime exchange.

263 TRANSPLANTATION IN THE TREATMENT OF RENAL FAILURE

Charles B. Carpenter, Edgar L. Milford, Mohamed H. Sayegh

Transplantation of the human kidney is frequently the most effective treatment of advanced chronic renal failure. Worldwide, tens of thousands of such procedures have been performed. When azathioprine and prednisone were initially used as immunosuppressive drugs in the 1960s, the results with properly matched familial donors were superior to those with organs from cadaveric donors, namely, 75 to 90% compared with 50 to 60% graft survival rates at 1 year. During the 1970s and 1980s, the success rate at the 1-year mark for cadaveric transplants rose progressively. By the time cyclosporine was introduced in the early 1980s, cadaveric donor grafts had a 70% 1-year survival and reached the 82% level in the mid-1990s and 88% by 1998 (Fig. 263-1). After the first year, graft survival curves show an exponential decline in numbers of functioning grafts from which a half-life ($t_{1/2}$) in years is calculated; this has increased by 2 years since the 1980s (Fig. 263-1).

Mortality rates after transplantation are highest in the first year and are age-related: 2% for ages 18 to 34 years, 3% for ages 35 to 49 years, and 6.8% for ages over 50 to 60 years. These rates compare favorably to those in the chronic dialysis population, even after risk adjustments for age, diabetes, and cardiovascular status. Occasionally, acute irreversible rejection may occur after many months of good function, especially if the patient neglects to take the immunosuppressive drugs. Most grafts, however, succumb at varying rates to a chronic vascular and interstitial obliterative process termed *chronic rejection*, although its pathogenesis is incompletely understood. Overall, transplantation returns the majority of patients to an improved lifestyle and an improved life expectancy, as compared to patients on dialysis; however, careful prospective cohort studies have yet to be reported.

RECIPIENT SELECTION There are few absolute contraindications to renal transplantation. The transplant procedure is relatively noninvasive, as the organ is placed in the inguinal fossa without entering the peritoneal cavity. Recipients without perioperative complications can often be discharged from the hospital in excellent condition within 5 days of the operation.

Virtually all end-stage renal disease (ESRD) patients who receive a transplant have a higher life expectancy than risk-matched patients who remain on dialysis. Even though diabetics or older candidates have a higher mortality rate than other transplant recipients, their survival is improved with transplantation compared to remaining on dialysis. This global benefit of transplantation as a treatment modality poses substantial ethical issues for policy makers, as the number of cadaveric kidneys available is far from sufficient to meet the current needs of the candidates. Waiting lists continue to grow, and the average wait time for a cadaver kidney is now >4 years in many locales. The current standard of care is that the candidate should have a life expectancy of >5 years to be put on a cadaver organ wait list. Even for living donation, the candidate should have >5 years of life expectancy. This is because the benefits of kidney transplantation over dialysis are only realized after a perioperative period in which the mortality is higher in transplanted patients than in dialysis patients with comparable risk profile.

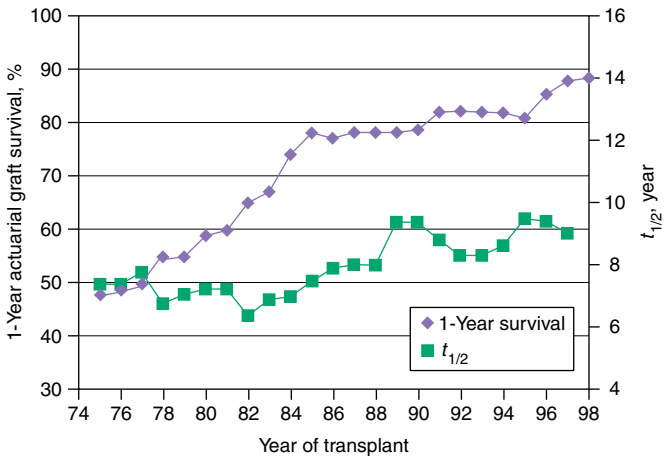

FIGURE 263-1 One-year actuarial graft survival of cohorts of first cadaver kidney transplants performed from 1975 through 1998 is displayed (in purple) along with $t_{1/2}$ or post-year-one half-life of the same cohorts (green). These registry data are derived from the U.S. Renal Data System 2002 Annual Report. The upper curve represents the 1-year actual graft survival, which approaches 90% by 1998. From 1982 to 1985 there was an impressive rise in the 1-year survival, partially attributable to the introduction of cyclosporine. Since 1985, there has been a consistent, slow increase in 1-year survival. The lower curve represents long-term graft survival, expressed as the half-life ($t_{1/2}$), which has been relatively stable over the past decade.

All candidates must have a thorough risk/benefit evaluation prior to being approved for transplantation. In particular, an aggressive approach to diagnosis of correctable coronary artery disease, presence of latent or indolent infection (HIV, hepatitis B or C, tuberculosis), and neoplasm should be a routine part of the candidate workup. Most transplant centers consider overt AIDS and active hepatitis to be an absolute contraindication to transplantation because of the high risk of opportunistic infection. Some centers are now transplanting individuals with hepatitis and even HIV infection under strict protocols to determine whether the risks and benefits favor transplantation over dialysis.

Among the few absolute contraindications to transplantation is the presence of potentially harmful antibody against the donor kidney at the time of the anticipated transplant. Harmful antibodies that can cause very early graft loss include natural antibodies against the ABO blood group antigens and antibodies against HLA-class I (A, B, C) or class II (DR) antigens. These antibodies are routinely excluded by proper pretransplant screening of the candidates, ABO and HLA typing of donor and recipient, and cross-matching of candidate serum with that of the donor.

DONOR SELECTION Donors can be cadavers or volunteer living donors. The latter are usually family members selected to have at least partial compatibility for HLA antigens. Living volunteer donors should be normal on physical examination and of the same major ABO blood group, because crossing major blood group barriers prejudices survival of the allograft. It is possible, however, to transplant a kidney of a type O donor into an A, B, or AB recipient. Selective renal arteriography should be performed on donors to rule out the presence of multiple or abnormal renal arteries, because the surgical procedure is difficult and the ischemic time of the transplanted kidney long when vascular abnormalities exist. Transplant surgeons are now using a laparascopic method to isolate and remove the living donor kidney. This operation has the advantage of less evident surgical scars, and, because there is less tissue trauma, the laparoscopic donors have a substantially shorter hospital stay and less discomfort than those who have the traditional surgery. Cadaveric donors should be free of malignant neoplastic disease, hepatitis, and HIV because of possible transmission to the recipient. Increased risk of graft failure exists when the donor is elderly or has renal failure and when the kidney has a prolonged period of ischemia and storage.

In the United States, there is a coordinated national system of regulations, allocation support, and outcomes analysis for kidney transplantation called the Organ Procurement Transplant Network. It is now possible to remove cadaver kidneys and to maintain them for up to 48 h on cold pulsatile perfusion or simple flushing and cooling. This permits adequate time for typing, cross-matching, transportation, and selection problems to be solved.

TISSUE TYPING AND CLINICAL IMMUNOGENETICS Matching for antigens of the HLA major histocompatibility gene complex (Chap. 296) is an

important criterion for selection of donors for renal allografts. Each mammalian species has a single chromosomal region that encodes the strong, or major, transplantation antigens, and this region on the human sixth chromosome is called *HLA*. HLA antigens have been classically defined by serologic techniques, but methods to define specific nucleotide sequences in genomic DNA are increasingly being used. Other antigens, called "minor," may nevertheless play crucial roles, in addition to the ABH(O) blood groups and endothelial antigens that are not shared with lymphocytes. The Rh system is not expressed on graft tissue. Evidence for designation of HLA as the genetic region encoding major transplantation antigens comes from the success rate in living related donor renal and bone marrow transplantation, with superior results in HLA-identical sibling pairs. Nevertheless, 5% of HLA-identical renal allografts are rejected, often within the first weeks after transplantation. These failures represent states of prior sensitization to non-HLA antigens. Non-HLA minor antigens are relatively weak when initially encountered and are therefore suppressible by conventional immunosuppressive therapy. Once priming has occurred, however, secondary responses are much more refractory to treatment. ABO incompatibilities are hazardous because of the presence of natural anti-A and anti-B antibodies in recipients and the normal expression of A and B blood group substances on endothelium, resulting in immediate vascular injury.

Living Donors When first-degree relatives are donors, graft survival rates at 1 year are 5 to 7% greater than those for cadaver grafts. The 5-year survival rates still favor the partially matched (3/6 HLA mismatched) family donor over a randomly selected cadaver donor (Table 263-1). In addition, living donors provide the advantage of immediate availability. For both living and cadaveric donors, the 5-year outcomes are poor if there is a complete (6/6) HLA mismatch. Waiting lists for cadaveric kidneys have grown faster than the available organ supply, to the point where most new patients with ESRD wait for >4 years. In response to this increasing disparity between cadaver donor supply and patient demand, living unrelated volunteers, usually spouses or close friends, are being accepted as donors in increasing numbers. The survival rate of living unrelated renal allografts is as good or better than that of perfectly HLA matched cadaver renal transplants and comparable to that of kidneys from living relatives. This is likely to be a consequence both of short cold ischemia time and the extra care taken to document that the condition and renal function of the donor are optimal before proceeding with a living unrelated donation (Table 263-1). It is illegal in the United States to purchase organs for transplantation.

Concern has been expressed regarding the potential risk to a volunteer kidney donor of premature renal failure after several years of increased blood flow and hyperfiltration per nephron in the remaining kidney. There are a few reports of the development of hypertension, proteinuria, and even lesions of focal segmental sclerosis in donors under long-term follow-up. Difficulties in donors followed for ≥20 years are unusual, however, and it may be that having a single kidney becomes significant only when another condition, such as hypertension, is superimposed. It is also desirable to consider the risk of development of type 1 diabetes mellitus in a family member who is a potential donor to a diabetic renal failure patient. Anti-insulin and anti-islet antibodies should be measured, and glucose tolerance tests should be performed in such donors to rule out a prediabetic state.

TABLE 263-1 *Effect of HLA-A, -B, -DR Mismatching on Kidney Graft Survival*[a]

Degree of Donor Mismatch	1-Year Survival, %	5-Year Survival, %
Cadaver donor (all)	89.2	61.3
0/6-HLA mismatch	91.3	68.2
3/6-HLA mismatch	90.1	60.8
6/6-HLA mismatch	85.2	55.3
Living related donor (all)	94.7	76.0
0/6-HLA mismatch	96.7	87.0
3/6-HLA mismatch	94.3	73.2
6/6-HLA mismatch	92.7	57.7
Living unrelated donor	95.3	77.4

Note: 0-mismatched related donor transplants are virtually all from HLA-identical siblings, while 3/6-mismatched transplants can be one haplotype mismatched (1-A, 1-B, and 1-DR antigen) from parent, child or sibling; 6/6-HLA-mismatched living related kidneys are derived from siblings or relatives outside of the nuclear family.

HLA Matching and Cadaveric Donors The question of whether matching of HLA antigens in unrelated donor-recipient pairs would approximate the high initial success rates and slow rates of subsequent graft loss with HLA-identical sib pairs could not be answered until the late 1980s when reliable class II histocompatibility (DR) typing became widely available. Now that pooled data on tens of thousands of cadaveric renal transplants from all over the world are available, the HLA-matching effect can be clearly seen, especially in the long-term survival figures. It is shown in Table 263-1 that there is an overall beneficial effect of HLA matching in cadaveric grafts. With increasing numbers of mismatches for cadaveric donors, the 5-year survival drops from 68.2% to 55.3%. The survival rates at the 10-year mark are projected to range from 65 (zero mismatches) to 34% (six mismatches). There is controversy regarding the value of cadaveric organ-sharing rules that are based entirely upon the numbers of HLA mismatches. Giving preference to HLA zero-mismatched candidates (Table 263-1) is a top priority in the United States, however, and 20% of kidneys are transplanted on this basis. Table 263-1 also shows the interaction of HLA matching and graft ischemia on results; namely, kidneys from HLA-incompatible unrelated or spousal donors do better than those from similarly mismatched cadaver donors, suggesting that the additional ischemic injury of organ storage is important. Nevertheless, when such a cadaveric donor is HLA-compatible, the benefit of matching can still be seen.

Presensitization A positive cross match of recipient serum with donor T lymphocytes representing anti-HLA class I is usually predictive of an acute vasculitic event termed *hyperacute rejection*. Patients with anti-HLA antibodies can be safely transplanted if careful cross-matching of donor blood lymphocytes with recipient serum is performed. Patients sustained by dialysis often show fluctuating antibody titers and specificity patterns. At the time of assignment of a cadaveric kidney, cross matches are performed with at least a current serum. Previously analyzed antibody specificities and additional cross matches are performed accordingly. Techniques for cross-matching are not universally standardized; however, at least two techniques are employed in most laboratories. The minimal purpose for the cross match is avoidance of hyperacute rejection mediated by recipient antibodies to donor HLA class I antigens. Sensitive tests, such as the use of flow cytometry, can be useful for avoidance of accelerated, and often untreatable, early graft rejection in patients receiving second or third transplants. Donor T lymphocytes, which express only class I antigens, are used as targets for detection of anti-class I (HLA-A and -B) antibodies. Preformed anti-class II (HLA-DR) antibodies against the donor carry a higher risk of graft loss as well, particularly in recipients who have suffered early loss of a prior kidney transplant. B lymphocytes expressing both class I and class II antigens are used in these assays. Non-HLA antigens restricted in expression to endothelium and sometimes monocytes have been described, but clinical relevance is not well established. A series of minor histocompatibility antigens do not elicit antibodies, and sensitization to these is detectable only by cytotoxic T cells, an assay too cumbersome for routine use.

Blood Transfusions Exposure to leukocyte HLA antigens during transfusions is a major cause of sensitization that limits transplantation access and increases the risk of early graft rejection. In the 1970s, attempts to avoid all blood exposure in dialysed patients paradoxically increased the risk of graft rejection. The beneficial "transfusion effect" was never fully explained, and it almost disappeared in the 1980s as overall management of patients improved with the use of cyclosporine and more effective means of rejection treatment. Currently, with the use of erythropoietin the need for transfusion is much reduced. It has

been noted, however, that nontransfused patients do have more rejection activity.

IMMUNOLOGY OF REJECTION Both cellular and humoral (antibody-mediated) effector mechanisms can play roles in kidney transplant rejection. Antibodies directed against ABO blood group antigens and HLA class I or class II antigens can cause hyperacute rejection within minutes to hours of engraftment if they are present in the recipient at the time of engraftment. Such antibodies bind to vascular endothelium, cause activation of the complement cascade, and direct endothelial damage, platelet aggregation, microvascular thrombi, and in the most severe cases ischemic necrosis of the organ. Antibodies against ABO are naturally found in humans. Anti-HLA antibodies are produced as a consequence of prior blood transfusions, multiple pregnancies, or rejection of a prior HLA-incompatible transplant. Antibodies that bind to cells within the transplant can also initiate a form of antibody-dependent cell death mediated by recipient cells that bear receptors for the Fc portion of immunoglobulin.

Cellular rejection is mediated by lymphocytes that respond to HLA antigens expressed within the organ. The CD4+ lymphocyte responds to class II (HLA-DR) incompatibility by proliferating and releasing proinflammatory cytokines that augment the proliferative response of both CD4+ and CD8+ cells. CD8+ cytotoxic lymphocyte precursors respond primarily to class I (HLA-A, -B) antigens and mature into cytotoxic effector cells. The cytotoxic effector, or "killer" T, cells cause organ damage through direct contact and lysis of donor target cells. The natural role of HLA antigens is to present processed peptide fragments of antigen to T lymphocytes, the fragments residing in a "groove" of the HLA molecule distal to the cell surface. T cells can be directly stimulated by non-self HLA antigen expressed on donor parenchymal cells and residual donor leukocytes residing in the kidney interstitium. In addition, donor HLA molecules can be processed by a variety of donor or recipient cells capable of antigen presentation and then presented to T cells in the same manner as most other antigens. The former mode of stimulation is sometimes called *direct presentation* and the latter mode called *indirect presentation* (Fig. 263-2). There is evidence that non-HLA antigens can also play a role in renal transplant rejection episodes. Recipients who receive a kidney from an HLA-identical sibling can have rejection episodes and require maintenance immunosuppression, while identical twin transplants require no immunosuppression. There are documented non-HLA antigens, such as an endothelial-specific antigen system with limited polymorphism and a tubular antigen, which can be targets of humoral or cellular rejection responses, respectively.

IMMUNOSUPPRESSIVE TREATMENT Immunosuppressive therapy, as presently available, generally suppresses all immune responses, including those to bacteria, fungi, and even malignant tumors. In the 1950s when clinical renal transplantation began, sublethal total-body irradiation was employed. We have now reached the point where sophisticated pharmacologic immunosuppression is available, but it still has the hazard of promoting infection and malignancy. In general, all clinically useful drugs are more selective to primary than to memory immune responses. Agents to suppress the immune response are discussed in the following paragraphs, and those currently in clinical use are listed in Table 263-2.

Drugs *Azathioprine*, an analogue of mercaptopurine, was for two decades the keystone to immunosuppressive therapy in humans. This agent can inhibit synthesis of DNA, RNA, or both. Because cell division and proliferation are a necessary part of the immune response to antigenic stimulation, suppression by this agent may be mediated by the inhibition of mitosis of immunologically competent lymphoid cells, interfering with synthesis of DNA. Alternatively, immunosuppression may be brought about by blocking the synthesis of RNA (possibly messenger RNA), inhibiting processing of antigens prior to lymphocyte stimulation. Therapy with azathioprine in doses of 1.5 to 2.0 mg/kg per day is generally added to cyclosporine as a means of decreasing the requirements for the latter. Because azathioprine is rapidly metabolized by the liver, its dosage need not be varied directly in relation to renal function, even though renal failure results in retention of the metabolites of azathioprine. Reduction in dosage is required because of leukopenia and occasionally thrombocytopenia. Excessive amounts of azathioprine may also cause jaundice, anemia, and alopecia. If it is essential to administer allopurinol concurrently, the azathioprine dose must be reduced, since inhibition of xanthine oxidase delays degradation. This combination is best avoided.

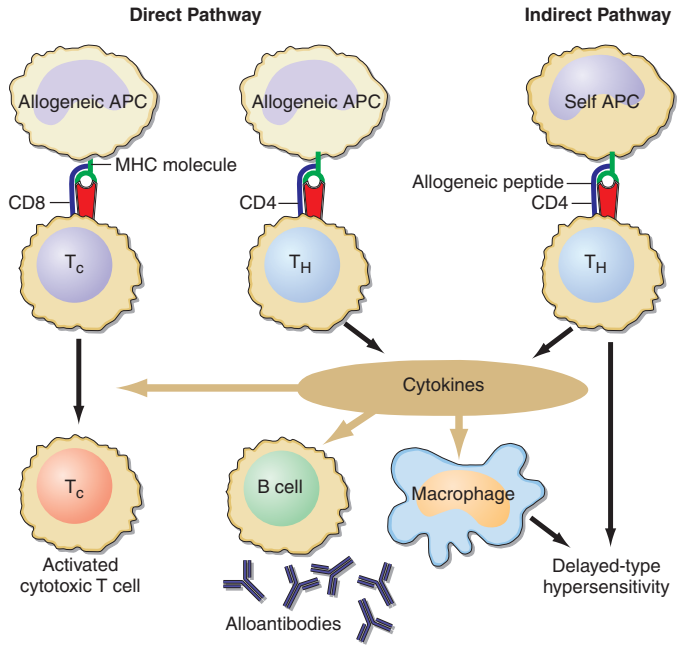

FIGURE 263-2 Recognition pathways for major histocompatibility complex (MHC) antigens. Graft rejection is initiated by CD4 helper T lymphocytes (T_H) having antigen receptors that bind to specific complexes of peptides and MHC class II molecules on antigen-presenting cells (APC). In transplantation, in contrast to other immunologic responses, there are two sets of T cell clones involved in rejection. In the direct pathway the class II MHC of donor allogeneic APCs is recognized by CD4 T_H cells that bind to the intact MHC molecule, and class I MHC allogeneic cells are recognized by CD8 T cells. The latter generally proliferate into cytotoxic cells (T_C). In the indirect pathway, the incompatible MHC molecules are processed into peptides that are presented by the self-APCs of the recipient. The indirect, but not the direct, pathway is the normal physiologic process in T cell recognition of foreign antigens. Once T_H cells are activated, they proliferate, and by secretion of cytokines and direct contact exert strong helper effects on macrophages, T_C, and B cells. *(From Sayegh and Turka, Copyright 1998, Massachusetts Medical Society. All rights reserved.)*

Mycophenolate mofetil is now used in place of azathioprine in many centers. It has a similar mode of action and a mild degree of gastrointestinal toxicity but produces minimal bone marrow suppression. Its advantage is its increased potency in preventing or reversing rejection. Patients with hyperuricemia can be given allopurinol without adjustment of the mycophenylate dose.

Glucocorticoids are important adjuncts to immunosuppressive therapy. Of all the agents employed, prednisone has effects that are easiest to assess, and in large doses it is usually effective for the reversal of rejection. In general, 200 to 300 mg prednisone is given immediately prior to or at the time of transplantation, and the dosage is reduced to 30 mg within a week. The side effects of the glucocorticoids, particularly impairment of wound healing and predisposition to infection, make it desirable to taper the dose as rapidly as possible in the immediate postoperative period. Customarily, methylprednisolone, 0.5 to 1.0 g intravenously, is administered immediately upon diagnosis of beginning rejection and continued once daily for 3 days. When the drug is effective, the results are usually apparent within 96 h. Such "pulse" doses are not effective in chronic rejection. Most patients whose renal function is stable after 6 months or a year do not require

large doses of prednisone; maintenance doses of 10 to 15 mg/d are the rule. Many patients tolerate an alternate-day course of steroids without an increased risk of rejection.

A major effect of steroids is on the monocyte-macrophage system, preventing the release of interleukin (IL) 6 and IL-1. Lymphopenia after large doses of glucocorticoids is primarily due to sequestration of recirculating blood lymphocytes to lymphoid tissue.

Cyclosporine is a fungal peptide with potent immunosuppressive activity. It acts on the calcineurin pathway to block transcription of mRNA for IL-2 and other proinflammatory cytokines, thereby inhibiting T cell proliferation. Although it works alone, cyclosporine is more effective in conjunction with glucocorticoids. Since cyclosporine blocks production of IL-2 by T cells, its combination with steroids is expected to produce a double block in the macrophage → IL-6/IL-1 → T cell → IL-2 sequence. Clinical results with tens of thousands of renal transplants have been impressive. Of its toxic effects (nephrotoxicity, hepatotoxicity, hirsutism, tremor, gingival hyperplasia, diabetes), only nephrotoxicity presents a serious management problem and is further discussed below.

TABLE 263-2 *Maintenance Immunosuppressive Drugs*

Agent	Pharmacology	Mechanisms	Side Effects
Glucocorticoids	Increased bioavailability with hypoalbuminemia and liver disease; prednisone/prednisolone generally used	Binds cytosolic receptors and heat shock proteins. Blocks transcription of IL-1,-2,-3,-6, TNF-α, and IFN-γ	Hypertension, glucose intolerance, dyslipidemia, osteoporosis
Cyclosporine (CsA)	Lipid-soluble polypeptide, variable absorption, microemulsion more predictable	Trimolecular complex with cyclophilin and calcineurin → block in cytokine (e.g., IL-2) production; however, stimulates TGF-β production	Nephrotoxicity, hypertension, dyslipidemia, glucose intolerance, hirsutism/ hyperplasia of gums
Tacrolimus (FK506)	Macrolide, well absorbed	Trimolecular complex with FKBP-12 and calcineurin → block in cytokine (e.g., IL-2) production; may stimulate TGF-β production	Similar to CsA, but hirsutism/hyperplasia of gums unusual, and diabetes more likely
Azathioprine	Mercaptopurine analogue	Hepatic metabolites inhibit purine synthesis	Marrow suppression (WBC > RBC > platelets)
Mycophenolate mofetil (MMF)	Metabolized to mycophenolic acid	Inhibits purine synthesis via inosine monophosphate dehydrogenase	Diarrhea/cramps; dose-related liver and marrow suppression is uncommon
Sirolimus	Macrolide, poor oral bioavailability	Complexes with FKBP-12 and then blocks p70 S6 kinase in the IL-2 receptor pathway for proliferation	Hyperlipidemia, thrombocytopenia

Note: IL, interleukin; TNF, tumor necrosis factor; IFN, interferon; TGF, transforming growth factor; FKBP-12, FK506 binding protein 12; WBC, white blood cells; RBC, red blood cells.

Tacrolimus (FK-506) is a fungal macrolide that has the same mode of action, and a similar side effect profile, as cyclosporine. It does not produce hirsutism or gingival hyperplasia, however. De novo induction of diabetes mellitus is more common with tacrolimus. The drug was first used in liver transplantation and may substitute for cyclosporine entirely or be tried as an alternative in renal patients whose rejections are poorly controlled by cyclosporine.

Sirolimus (previously called rapamycin) is another fungal macrolide but has a different mode of action, i.e., it inhibits T cell growth factor pathways, preventing the response to IL-2 and other cytokines. Sirolimus can be used in conjunction with cyclosporine or tacrolimus as an alternative immunosuppressive regimen. Its use with tacrolimus alone shows promise as a steroid-sparing regimen, especially in patients who would benefit from pancreatic islet transplantation, where steroids have an adverse effect on islet survival.

Antibodies to Lymphocytes When serum from animals made immune to host lymphocytes is injected into the recipient, a marked suppression of cellular immunity to the tissue graft results. The action on cell-mediated immunity is greater than on humoral immunity. A globulin fraction of serum [antilymphocyte globulin (ALG)] is the agent generally employed. For use in humans, peripheral human lymphocytes, thymocytes, or lymphocytes from spleens or thoracic duct fistulas have been injected into horses, rabbits, or goats to produce antilymphocyte serum, from which the globulin fraction is then separated. Monoclonal antibodies against defined lymphocyte subsets offer a more precise and standardized form of therapy. OKT3 is directed to the CD3 molecules that form a portion of the T cell antigen-receptor complex; hence CD3 is expressed on all mature T cells. CD4 or CD8 molecules also form part of the fully activated cluster of molecules, and monoclonal antibodies to these offer the potential for more selective targeting of T cell subsets.

Another approach to more selective therapy is to target the 55-kDa alpha chain of the IL-2 receptor, expressed only on T cells that have been recently activated. The problem with such mouse antibodies is the potential for developing human antimouse antibodies (HAMA), an event that limits the effective period of use. Genetically engineered monoclonal antibodies can solve this problem. Two such antibodies to the IL-2 receptor, in which either a chimeric protein has been made between mouse Fab with human Fc (basiliximab) or "humanized" by splicing the combining sites of the mouse into a molecule that is 90% human IgG (daclizumab), have been approved for prophylaxis of acute rejection in the immediate posttransplant period. They are effective at decreasing the acute rejection rate and have few adverse side effects.

CLINICAL COURSE AND MANAGEMENT OF THE RECIPIENT Adequate hemodialysis should be performed within 48 h of surgery, and care should be taken that the serum potassium level is not markedly elevated so that intraoperative cardiac arrhythmias can be averted. The diuresis that commonly occurs postoperatively must be carefully monitored; in some instances it may be massive, reflecting the inability of ischemic tubules to regulate sodium and water excretion; with large diureses, massive potassium losses may occur. Most chronically uremic patients have some excess of extracellular fluid, and it is useful to maintain an expanded fluid volume in the immediate postoperative period. Acute tubular necrosis (ATN) may cause immediate oliguria or may follow an initial short period of graft function. ATN is most likely when cadaveric donors have been hypotensive or if the interval between cessation of blood flow and organ harvest (warm ischemic time) is more than a few minutes. Recovery usually occurs within 3 weeks, although periods as long as 6 weeks have been reported. Superimposition of rejection on ATN is common, and the differential diagnosis may be difficult without a graft biopsy. Cyclosporine therapy prolongs ATN, and some patients do not diurese until the dose is drastically reduced. Many centers avoid starting cyclosporine for the first several days, using ALG or a monoclonal antibody along with mycophenolate mofetil and prednisone until renal function is established. Fig. 263-3 illustrates an algorithm followed by many transplant centers for early

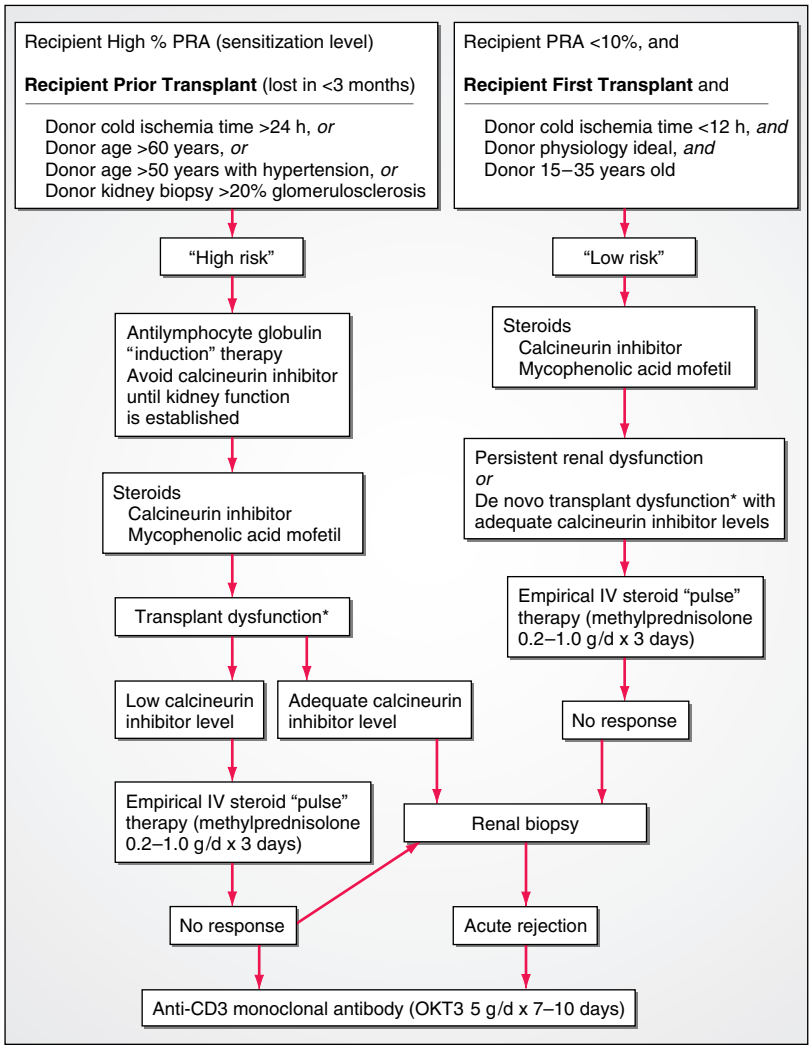

FIGURE 263-3 A typical algorithm for early posttransplant care of the kidney recipient. If any of the recipient or donor "high-risk" factors exist, more aggressive management is called for. Low-risk patients can be treated with a standard immunosuppressive regimen. Patients at higher risk of rejection or early ischemic and nephrotoxic transplant dysfunction are often induced with an antilymphocyte globulin to provide more potent early immunosuppression or to spare calcineurin nephrotoxicity. *When there is early transplant dysfunction, prerenal, obstructive, and vascular causes must be ruled out by ultrasonographic examination. The panel reactive antibody (PRA) is a quantitation of how much antibody is present in a candidate against a panel of cells representing the distribution of antigens in the donor pool.

posttransplant management of recipients at high or low risk of early renal dysfunction.

The Rejection Episode Early diagnosis of rejection allows prompt institution of therapy to preserve renal function and prevent irreversible damage. Clinical evidence of rejection is rarely characterized by fever, swelling, and tenderness over the allograft. Rejection may present only with a rise in serum creatinine, with or without a reduction in urine volume. The focus should be on ruling out other causes of functional deterioration.

Arteriography and radioactive iodohippurate sodium renograms of the transplanted kidney may be useful in ascertaining changes in the renal vasculature and in renal blood flow, even in the absence of urinary flow. Thrombosis of the renal vein occurs rarely; it may be reversible if caused by technical factors and intervention is prompt. Diagnostic ultrasound is the procedure of choice to rule out urinary obstruction or to confirm the presence of perirenal collections of urine, blood, or lymph. When renal function has been good initially, a rise in the serum creatinine level is the most sensitive and reliable indicator of possible rejection and may be the only sign.

Calcineurin inhibitors (cyclosporine or tacrolimus) may cause deterioration in renal function in a manner similar to a rejection episode. In fact, rejection processes tend to be more indolent with these inhibitors, and the only way to make a diagnosis may be by renal biopsy. Calcineurin inhibitors have an afferent arteriolar constrictor effect on the kidney and may produce permanent vascular and interstitial injury after sustained high-dose therapy. Addition of angiotensin-converting enzyme (ACE) inhibitors or nonsteroidal anti-inflammatory drugs are likely to raise serum creatinine levels. The former are generally safe to use after the early months, while the latter are best avoided in all renal transplant patients. There is no universally accepted lesion(s) that makes a diagnosis of calcineurin inhibitor toxicity, although interstitial fibrosis, isometric tubular vacuolization, and thickening of arteriolar walls have been noted by some. Basically, if the biopsy does not reveal moderate and active cellular rejection activity, the serum creatinine will most likely respond to a reduction in dose. Blood levels of drug can be useful if very high or very low but do not correlate precisely with renal function, although serial changes in a patient can be useful. If rejection activity is present in the biopsy, appropriate therapy is indicated. The first rejection episode is usually treated with intravenous administration of methylprednisolone, 500 to 1000 mg daily for 3 days. Failure to respond is indication for antibody therapy, usually with OKT3.

OKT3 monoclonal antibody, given intravenously for 10 to 14 days, is effective in >90% of first rejections but less so if methylprednisolone pulses have failed and in cases of severe recurrent rejection activity. A major problem with OKT3 is that severe systemic reactions may be produced during the first day or two of therapy. Chills, fever, hypotension, and headache are the direct result of the antibody effects on the targeted T cells, most likely related to the known potential of OKT3 to activate T cells nonspecifically with release of cytokines, especially tumor necrosis factor α. If the antibody is administered to overhydrated oliguric patients, pulmonary edema may be induced. These reactions are not characteristic of other monoclonal antibodies, such as those to the IL-2 receptor. Recurrent or rebound rejection activity may require additional therapy. In such circumstances, methylprednisolone may be effective even though it failed initially. Second courses of OKT3 may be given in spite of HAMA generated in response to the first course if the titers are low and the human antibodies are not directed to the combining-site region (idiotype) of the OKT3.

Management Problems The usual clinical manifestations of infection in the posttransplant period are blunted by immunosuppressive therapy. The major toxic effect of azathioprine is bone marrow suppression, which is less likely with mycophenolate mofetil, while calcineurin inhibitors have no marrow effects. All drugs predispose to unusual opportunistic infections, however. The typical times posttransplant when the most common opportunistic infections occur are tabulated in Table 263-3. The signs and symptoms of infection may be masked or distorted. Fever without obvious cause is common and only after days or weeks may it become apparent that it has a viral or fungal origin. Bacterial infections are most common during the first month after transplantation. The importance of blood cultures in such patients cannot be overemphasized, because systemic infection without obvious foci is frequent, although wound infections with or without urinary fistulas are most common. Particularly ominous are rapidly occurring pulmonary lesions, which may result in death within 5 days of onset. When these become apparent, immunosuppressive agents should be discontinued, except for maintenance doses of prednisone.

TABLE 263-3 The Most Common Opportunistic Infections in the Renal Transplant Recipient

Peritransplant (<1 month)	Late (>6 months)
Wound infections	*Aspergillus*
Herpesvirus	*Nocardia*
Oral candidiasis	BK virus (polyoma)
Urinary tract infection	Herpes zoster
Early (1–6 months)	Hepatitis B
Pneumocystis carinii	Hepatitis C
Cytomegalovirus	
Legionella	
Listeria	
Hepatitis B	
Hepatitis C	

Aggressive diagnostic procedures, including transbronchial and open lung biopsy, are frequently indicated. In the case of *Pneumocystis carinii* (Chap. 191) infection, trimethoprim-sulfamethoxazole is the treatment of choice; amphotericin B has been used effectively in systemic fungal infections. Prophylaxis against *P. carinii* with daily or alternate day low-dose trimethoprim-sulfamethoxazole is very effective. Involvement of the oropharynx with *Candida* (Chap. 187) may be treated with local nystatin. Tissue-invasive fungal infections require treatment with systemic agents such as fluconazole. Small doses (a total of 300 mg) of amphotericin given over a period of 2 weeks may be effective in fungal infections refractory to fluconazole. Macrolide antibiotics, especially ketoconazole and erythromycin, and some calcium channel blockers (diltiazem, verapamil) compete with calcineurin inhibitors for P450 catabolism and cause elevated levels of these immunosuppressive drugs. Analeptics, such as phenytoin and carbamazepine, will increase catabolism to result in low levels. *Aspergillus* (Chap. 188), *Nocardia* (Chap. 146), and cytomegalovirus (CMV) (Chap. 166) infections also occur.

CMV is a common and dangerous infection in transplant recipients. It does not generally appear until the end of the first posttransplant month. Active CMV infection is sometimes associated, or occasionally confused, with rejection episodes. Patients at highest risk for severe CMV disease are those without anti-CMV antibodies who receive a graft from a CMV antibody–positive donor (15% mortality). Serial intravenous administration of high-titer CMV immune globulin is effective in reducing this risk. Prophylactic use of ganciclovir is an effective alternative. Valganciclovir is a cost-effective and bioavailable oral form of ganciclovir that has proven effective in both prophylaxis and treatment of CMV disease. Early diagnosis in a febrile patient can be made by detecting CMV antigens in the blood. A rise in IgM antibodies to CMV is also diagnostic. Culture of CMV from blood may be less sensitive. Tissue invasion of CMV is common in the gastrointestinal tract and lungs. CMV retinopathy occurs late in the course, if untreated. Treatment of active CMV disease with valganciclovir is always indicated. Many patients immune to CMV can activate the virus after heavy immunosuppression, such as with OKT3. Concurrent treatment with ganciclovir during OKT3 administration appears to be effective for prophylaxis of CMV activation. The complications of glucocorticoid therapy are well known and include gastrointestinal bleeding, impairment of wound healing, osteoporosis, diabetes mellitus, cataract formation, and hemorrhagic pancreatitis. The treatment of unexplained jaundice in transplant patients should include cessation or reduction of immunosuppressive drugs if hepatitis or drug toxicity is suspected. It is surprising that cessation of azathioprine or calcineurin inhibitor therapy in such circumstances often does not result in rejection of a graft, at least for several weeks. Acyclovir is effective in therapy of herpes simplex virus infections.

Chronic Lesions of the Transplanted Kidney While 1-year transplant survival is excellent, most recipients experience progressive decline in kidney function over time thereafter. The chronic renal transplant dysfunction can be caused by recurrent disease, hypertension, cyclosporine or tacrolimus nephrotoxicity, chronic immunologic rejection, secondary focal glomerulosclerosis, or a combination of these pathophysiologies. Chronic vascular changes with intimal proliferation and medical hypertrophy are commonly found. Control of systemic and intrarenal hypertension with ACE inhibitors is thought to have a beneficial influence on the rate of progression of chronic renal transplant dysfunction. Renal biopsy can distinguish subacute cellular rejection from recurrent disease or secondary focal sclerosis.

Malignancy The incidence of tumors in patients on immunosuppressive therapy is 5 to 6%, or approximately 100 times greater than that in the general population of the same age range. The most common lesions are cancer of the skin and lips and carcinoma in situ of the cervix, as well as lymphomas, such as non-Hodgkin's lymphomas. The risks are increased in proportion to the total immunosuppressive load administered and time elapsed since transplantation. Surveillance for skin and cervical cancers is necessary.

Other Complications *Hypercalcemia* after transplantation may indicate failure of hyperplastic parathyroid glands to regress. Aseptic necrosis of the head of the femur is probably due to preexisting hyperparathyroidism, with aggravation by glucocorticoid treatment. With improved management of calcium and phosphorus metabolism during chronic dialysis, the incidence of parathyroid-related complications has fallen dramatically. Persistent hyperparathyroid activity may require subtotal parathyroidectomy.

Hypertension may be caused by (1) native kidneys; (2) rejection activity in the transplant; (3) renal artery stenosis, if an end-to-end anastomosis was constructed with an iliac artery branch; and (4) renal calcineurin inhibitor toxicity. The latter may improve with reduction in dose. Whereas ACE inhibitors may be useful, calcium channel blockers are more frequently used initially. Amelioration of hypertension to the 120 to 130/70 to 80 mmHg range should be the goal in all patients.

While most transplant patients have a robust production of erythropoietin and normalization of the hemoglobin without exogenous erythropoietin administration, *anemia* is commonly seen in the posttransplant period. Often the anemia is attributable to bone marrow–suppressant immunosuppressive medications such as azathioprine, mycophenolate mofetil, or sirolimus. Gastrointestinal bleeding is a common side effect of high-dose and long-term steroid administration. Many transplant patients have creatinine clearances of 30 to 50 mL/min and can be considered in the same way as other patients with chronic renal insufficiency for anemia management, including supplemental erythropoietin.

Chronic hepatitis, particularly when due to hepatitis B virus, can be a progressive, fatal disease over a decade or so. Patients who are persistently hepatitis B surface antigen–positive are at higher risk, according to some studies, but the presence of hepatitis C virus is also a concern when one embarks on a course of immunosuppression in a transplant recipient.

Both chronic dialysis and renal transplant patients have a higher incidence of death from myocardial infarction and stroke than in the population at large, and this is particularly true in diabetic patients. Contributing factors are the use of glucocorticoids, hypertension, and hypertriglyceridemia. Increased low-density lipoprotein cholesterol and depressed high-density lipoprotein cholesterol concentrations may be exaggerated after transplantation and require treatment, particularly in patients receiving sirolimus. Recipients of renal transplants have a high prevalence of coronary artery and peripheral vascular diseases. The percentage of deaths from these causes has been slowly rising as the numbers of transplanted diabetic patients and the average age of all recipients increase. More than 50% of renal recipient mortality is attributable to cardiovascular disease. In addition to strict control of blood pressure and blood lipid levels, close monitoring of patients for indications of further medical or surgical intervention is an important part of management.

264 GLOMERULAR DISEASES

Hugh R. Brady, Yvonne M. O'Meara, Barry M. Brenner

PATHOGENESIS

The glomerulus is a modified capillary network that delivers an ultrafiltrate of plasma to Bowman's space, the most proximal portion of the renal tubule. Approximately 1.6 million glomeruli are present in two mature kidneys (range 0.5 to 2.4 million) and collectively they produce 120 to 180 L of ultrafiltrate daily. Glomerular filtration rate (GFR) is dependent on glomerular blood flow, ultrafiltration pressure, and the area and composition of the filtration barrier. These parameters are tightly regulated through changes in afferent and efferent arteriolar tone (for blood flow and ultrafiltration pressure) and mesangial cell contractility (for filtration surface area). Arteriolar tone and mesangial cell contractility are, in turn, modulated by neurohumoral factors, local myenteric reflexes, and endothelium-derived vasoactive substances, such as nitric oxide, prostanoids, and endothelins. In health, glomerular endothelium is also antithrombotic and antiadhesive for leukocytes and platelets, thereby preventing inappropriate vascular thrombosis and inflammation during the filtration process. Filtration of most plasma proteins and all blood cells is normally prevented as a consequence of the physiochemical and electrostatic charge characteristics of the glomerular filtration barrier, the latter being composed of fenestrated glomerular endothelium, basement membrane, and the foot processes and slit diaphragms of visceral epithelial cells (podocytes). Parietal epithelium facilitates glomerular filtration by maintaining the integrity of Bowman's space. In keeping with the physiologic functions of the glomerulus outlined above, virtually all glomerular injury results in impairment of glomerular filtration and/or the inappropriate appearance of plasma proteins and blood cells in the urine.

CLINICOPATHOLOGIC CORRELATES IN GLOMERULAR DISEASE The major morphologic patterns of glomerular disease and their clinical features are summarized in Table 264-1. These clinicopathologic entities can be induced by a variety of mechanisms. Prompt diagnosis, optimal management, and accurate prognostication is a multistep process that requires (1) recognition of the presenting clinical syndrome, (2) delineation of the underlying morphologic pattern of glomerular injury, and (3) elucidation of the specific renal-limited or systemic disease that triggered glomerular dysfunction.

Nomenclature The terms *glomerulonephritis* and *glomerulopathy* are usually used interchangeably to denote glomerular injury, although some authorities reserve the former term for injury with evidence of inflammation such as leukocyte infiltration, antibody deposition, and complement activation. Glomerular diseases are classified as *primary* when the pathology is confined to the kidney and any systemic features are a direct consequence of glomerular dysfunction (e.g., pulmonary edema, hypertension, the uremic syndrome). Usually, but not always, the term primary is synonymous with *idiopathic*. Glomerular diseases are classified as *secondary* when part of a multisystem disorder. In general, *acute* refers to glomerular injury occurring over days or weeks, *subacute* or *rapidly progressive* over weeks or a few months, and *chronic* over many months or years. Lesions are classified as *focal* or *diffuse* when they involve the minority (<50%) or majority (≥50%) of glomeruli, respectively. Lesions are termed *segmental* or *global* when they involve part of or almost all of the glomerular tuft, respectively. *Proliferative* is used to describe an increase in glomerular cell number, which can be either true proliferation of resident glomerular cells or glomerular hypercellularity caused by infiltration by leukocytes.

Proliferation of resident glomerular cells is classified as *intracapillary* or *endocapillary* when referring to endothelial or mesangial cells and *extracapillary* when referring to cells in Bowman's space. A *crescent* is a half-moon-shaped collection of cells in Bowman's space, usually composed of proliferating parietal epithelial cells and infiltrating macrophages. Because crescentic glomerulonephritis is often associated with renal failure that progresses rapidly over weeks to months, the clinical term *rapidly progressive glomerulonephritis* and pathologic term *crescentic glomerulonephritis* are often used interchangeably. The description *membranous* is applied to glomerulonephritis dominated by expansion of the glomerular basement membrane (GBM) by immune deposits. *Sclerosis* refers to an increase in the amount of homogeneous nonfibrillar extracellular material of similar composition to GBM and mesangial matrix. This process is distinct from *fibrosis*, which involves deposition of collagens type I and III and is more commonly a consequence of healing of crescents or tubulointerstitial inflammation.

Major Clinicopathologic Entities In the absence of comprehensive knowledge of disease etiology, most glomerulopathies are still classified and named according to their morphologic features (Table 264-1). The major inflammatory glomerulopathies are *focal proliferative glomerulonephritis* (termed *mesangial proliferative glomerulonephritis* if the proliferating cells are predominantly mesangial cells), *diffuse proliferative glomerulonephritis*, and *crescentic glomerulonephritis*. These diseases typically present with a *nephritic-type* "active" urine sediment characterized by the presence of red blood cells, red blood cell casts, leukocytes, and *subnephrotic* proteinuria of <3 g/24 h. The severity of renal insufficiency varies in proportion to the degree of glomerular inflammation.

The major morphologic patterns affecting the glomerular filtration barrier for proteins, namely the GBM and visceral epithelial cells, are *membranous glomerulopathy*, *minimal change disease* (MCD), and *focal and segmental glomerulosclerosis* (FSGS). These entities typically present with *nephrotic-range* proteinuria of ≥3 g/24 h and the presence of relatively few red blood cells, leukocytes, or cellular casts. As a consequence of the heavy proteinuria, nephrotic syndrome is associated with hypoalbuminemia, edema, hyperlipidemia, and lipiduria, and a prothrombotic state. *Membranoproliferative glomerulonephritis*, as the name suggests, is a hybrid lesion that presents with a combination of nephritic and nephrotic features.

The *glomerular deposition diseases* are a group of disorders characterized by prominent extravascular deposition of a paraprotein or fibrillar material. These diseases can trigger either nephritic-type or nephrotic-type responses (or a combination of both) and thus show marked clinical and morphologic overlap with the entities described above.

TABLE 264-1 *Major Clinicopathologic Presentation of Glomerular Disease*

Structural Pattern	Typical Clinical Presentation	Typical Pathology Findings	Most Common Etiologies
Diffuse proliferative GN	Acute nephritic syndrome: Acute renal failure over days to weeks, hypertension, edema, oliguria, active urine sediment, subnephrotic proteinuria	Diffuse increase in cellularity of tufts of most glomeruli due to infiltration by neutrophils and monocytes, and proliferation of glomerular endothelial and mesangial cells	Immune complex GN: idiopathic, postinfectious, SLE, SBE, cryoglobulinemia, HSP Pauci-immune GN and anti-GBM disease (crescentic GN common—see below)
Crescentic GN	Rapidly progressive glomerulonephritis (RPGN): Subacute renal failure over weeks to months, active urine sediment, variable amount of hypertension, edema, oliguria, and proteinuria	Majority of glomeruli contain areas of fibrinoid necrosis and crescents in Bowman's space, composed of proliferating parietal epithelial cells, infiltrating macrophages, and fibrin	Immune complex GN (as above) Pauci-immune GN: Wegener's granulomatosis, microscopic polyarteritis nodosa, renal-limited crescentic GN Anti-GBM disease (Goodpasture's syndrome if lung hemorrhage)
Focal proliferative GN	Mild to moderate glomerular inflammation: Active urine sediment and mild to moderate decline in GFR	Segmental areas of proliferation and necrosis in less than 50% of glomeruli, occasionally with crescent formation	Early and milder forms, or recovery phase of most diseases causing diffuse proliferative and crescentic GN IgA nephropathy/HSP
Mesangial proliferative GN	Chronic glomerular inflammation: Proteinuria, hematuria, hypertension, variable effect on GFR	Proliferation of mesangial cells and matrix	IgA nephropathy/HSP Early and milder forms, or recovery phases of most diseases that cause diffuse proliferative and crescentic GN (see above) In association with minimal change glomerulopathy and FSGS
Membranoproliferative GN	Variable combination of nephritic and nephrotic features: Acute or subacute decline in GFR, active urine sediment, proteinuria often in nephrotic range	Diffuse proliferation of mesangial cells and infiltration of glomeruli by macrophages; increased mesangial matrix and thickening and reduplication of glomerular basement membrane	Immune complex GN (as for diffuse proliferative GN) In association with thrombotic microangiopathies (see below) In association with deposition diseases (see below) Postrenal or -marrow transplantation
Minimal change GN	Nephrotic syndrome: Proteinuria of >3–3.5 g/d, hypoalbuminemia, edema, hyperlipidemia, lipiduria, thrombotic diathesis, slow decline in GFR in 10–30%.	Light microscopy normal, but electron microscopy (EM) shows foot process effacement	Idiopathic In association with drug-induced interstitial nephritis, HIV infection, heroin, Hodgkin's and other lymphomas
Focal segmental glomerulosclerosis	Nephrotic syndrome: Proteinuria of >3–3.5 g/d, hypoalbuminemia, edema, hyperlipidemia, lipiduria, thrombotic diathesis, slow decline in GFR in 10–30%.	Segmental capillary collapse affecting <50% of glomeruli with entrapment of amorphous hyaline material. EM shows foot process effacement	Primary FSGS: idiopathic, HIV, heroin, lysosomal diseases, Charcot-Marie-Tooth Secondary response to reduction in nephron number from any cause (hyperfiltration injury)
Nodular or global sclerosis	Proteinuria and chronic renal failure	Sclerosis of most glomeruli with interstitial fibrosis	Diabetic nephropathy Potential long-term consequence of most glomerulopathies listed above
Membranous GN	Nephrotic syndrome: Proteinuria of >3–3.5 g/d, hypoalbuminemia, edema, hyperlipidemia, lipiduria, thrombotic diathesis, slow decline in GFR in 10–30%	Diffuse thickening of the glomerular basement membrane with subepithelial projections ("spikes") around immune deposits	Idiopathic Infections (e.g., hepatitis B & C, syphilis, schistasomiasis, malaria, leprosy) Drugs (e.g., gold, penicillamine, captopril) Autoimmune diseases (SLE, rheumatoid arthritis) Paraneoplastic
Deposition diseases	Combination of nephritic and nephrotic features: Renal failure over months to years, proteinuria, hematuria, and hypertension.	Mesangial expansion and thickening of glomerular capillary wall; variable cellular proliferation and crescent formation	Amyloid Cryoglobulinemia Light chain deposition disease Fibrillary/immunotactoid GN
Thrombotic microangiopathy	Acute or subacute renal failure: Variable degree of hypertension, edema and proteinuria, urine sediment usually contains red blood cells, but less activity than patients with nephritic syndrome or RPGN	Microthrombi in glomerular capillaries ± endothelial injury	Idiopathic In association with gastrointestinal infections, or drugs such as anovulants, mitomycin C, cyclosporine Other diseases: SLE, scleroderma, toxemia, malignant hypertension
Nonimmune basement membrane abnormalities	Asymptomatic hematuria and variable renal failure	Alport's syndrome—mesangial hypercellularity with focal sclerosis and interstitial fibrosis; splintering of GBM on EM.	Alport's syndrome, Thin basement membrane disease. Nail-patella syndrome, Lecithin–cholesterol acyltransferase deficiency

Note: Diffuse, affecting ≥50% of glomeruli; focal, affecting <50% of glomeruli; global, affecting ≥50% of glomerular tuft; segmental, affecting <50% of glomerular tuft; GN, glomerulonephritis; FSGS, focal segmental glomerulosclerosis; HSP, Henoch-Schönlein purpura; SLE, systemic lupus erythematosus; SBE, subacute bacterial endocarditis; GBM, glomerular basement membrane; GFR, glomerular filtration rate.

TABLE 264-2 *Primary Mechanisms of Glomerular Injury*

Mechanism of Injury	Some Renal Insults/Defects	Glomerular Disease
Immunologic[a]	Immunoglobulin[b]	Immune complex–mediated glomerulonephritis
	Cell-mediated injury[b]	Pauci-immune glomerulonephritis
	Cytokine (or other soluble factor)	Primary focal segmental glomerulosclerosis
	Persistent complement activation	Membranoproliferative glomerulonephritis (type II)
Metabolic[a]	Hyperglycemia[b]	Diabetic nephropathy
	Fabry's disease and sialidosis	Focal segmental glomerulosclerosis
Hemodynamic[a]	Systemic hypertension[b]	Hypertensive nephrosclerosis
	Intraglomerular hypertension[b]	Secondary focal segmental glomerulosclerosis
Toxic	*E. coli*–derived verotoxin	Thrombotic microangiopathy
	Therapeutic drugs (e.g., NSAIDs)	Minimal change disease
	Recreational drugs (heroin)	Focal segmental glomerulosclerosis
Deposition	Amyloid fibrils	Amyloid nephropathy
Infectious	HIV	HIV nephropathy
	Subacute bacterial endocarditis	Immune complex glomerulonephritis
Inherited	Defect in gene for α5 chain of type IV collagen	Alport's syndrome
	Abnormally thin basement membrane	Thin basement membrane disease

[a] Most common categories.
[b] Most common insults within these categories.
Note: NSAIDs, nonsteroidal anti-inflammatory drugs.

The *thrombotic microangiopathies* are a family of diseases in which the pathologic presentation is dominated by coagulation disturbances or endothelial cell injury that result in the formation of thrombi within the renal microvasculature, often leading to renal insufficiency. ***→For further discussion of this category of glomerular diseases see Chap. 267.***

MAJOR DETERMINANTS OF GLOMERULAR INJURY The important determinants of the extent and severity of glomerular injury, and accordingly of the clinical presentation, include (1) the nature of the primary insult and the secondary mediator systems that it invokes; (2) the site of injury within the glomerulus; and (3) the speed of onset, the extent, and intensity of disease.

Primary Insult Glomeruli are susceptible to a variety of inflammatory, metabolic, hemodynamic, toxic, and infectious insults (Table 264-2). Most human glomerular disease is triggered by either immune attack (e.g., most forms of inflammatory glomerulonephritis), metabolic stress (e.g., diabetic nephropathy), or mechanical stress (e.g., hypertension). Diverse insults can induce similar clinicopathologic presentations, suggesting marked overlap among downstream molecular and cellular responses. For example, immune complex deposition triggered by streptococcal pharyngitis and antibody-independent glomerular injury in microscopic polyarteritis can each induce proliferative glomerulonephritis. Similarly, metabolic (e.g., diabetes mellitus) and deposition diseases (e.g., amyloid) can each induce glomerulosclerosis with nephrotic syndrome.

Site of Injury The consequences of injury at different sites within the glomerulus can be predicted from the physiologic functions of the cells within the local milieu. In health the renal endothelium is antiadhesive for leukocytes and antithrombotic and maintains the diameter of the vascular lumen through release of nitric oxide and prostacyclin. The major sequelae of injury to the endothelium and subendothelial aspect of the GBM are (1) recruitment of leukocytes leading to inflammatory glomerulonephritis, or (2) perturbed hemostasis leading to thrombotic microangiopathy. It is usual for one of these phenotypes to dominate; however, hybrid lesions may occur (e.g., in lupus nephritis; see below). Intrarenal vasoconstriction and mesangial cell contraction can complicate each phenotype and thereby contribute to renal failure. Injury localized to the mesangial area typically presents as asymptomatic abnormalities of the urinary sediment and mild renal insufficiency. Proteinuria dominates the clinical presentation of injury to the subepithelial aspect of the GBM and visceral epithelial cells. As with mesangial injury, GFR is often only mildly compromised in this setting unless there is concomitant tubulointerstitial injury. The classic pathologic manifestation of parietal epithelial cell injury is crescent formation, which typically presents with acute or subacute renal failure. Crescents can be the dominant morphologic presentation of glomerular disease or complicate proliferative or membranous lesions.

Speed of Onset, Intensity, and Extent of Injury To illustrate the importance of the speed of onset, extent, and intensity of glomerular injury, it is instructive to compare two forms of immune complex glomerulonephritis, i.e., acute postinfectious glomerulonephritis and IgA nephropathy. Poststreptococcal glomerulonephritis is characterized by rapid deposition of immune complexes throughout the glomerular capillary wall, which often provokes acute diffuse proliferative glomerulonephritis with the classic hallmarks of acute inflammation (i.e., complement activation, leukocyte recruitment, lysosomal enzyme release, free radical generation, and perturbation of vascular tone and permeability) with resultant acute renal failure. In contrast, IgA nephropathy is characterized by slow, but sustained, formation of IgA-containing immune complexes, largely confined to the mesangium; less dramatic activation of complement and other mediator systems; and either stability of GFR or progressive renal insufficiency over decades.

MAJOR MECHANISMS OF GLOMERULAR INJURY

Hereditary defects accounts for a minority of glomerular disease. Most acquired glomerular disease is triggered by immune-mediated injury, metabolic stress, or mechanical stress.

INHERITED GLOMERULAR DISEASES *Alport's syndrome* (hereditary nephritis; p. 1691 and Chap. 342), the prototypical inherited glomerular disease, is usually transmitted as an X-linked dominant trait, although autosomal dominant and recessive forms have been reported. Patients afflicted with the classic X-linked form have a mutation in the COL4A5 gene that encodes the α5 chain of type IV collagen located on the X chromosome. As a result, the GBM is irregular with longitudinal layering, splitting, or thickening, and patients develop hematuria, progressive glomerulosclerosis, and renal failure. Other inherited glomerular diseases include *thin basement membrane disease* (p. 1690), *nail-patella syndrome* (osteoonychodysplasia), *partial lipodystrophy*, and *familial lecithin–cholesterol acyltransferase deficiency*. These will be discussed later in this chapter.

IMMUNOLOGIC GLOMERULAR INJURY Immune-mediated glomerulonephritis accounts for a large fraction of acquired renal disease (Fig. 264-1). The majority of cases are associated with the deposition of antibodies, often autoantibodies, within the glomerular tuft, indicating dysregulation of humoral immunity. Cellular immune mechanisms contribute to the pathogenesis of antibody-mediated glomerulonephritis by modulating antibody production and through antibody-dependent cell cytotoxicity (see below). Cellular immune mechanisms also play a dominant role in the pathophysiology of "pauci-immune" glomerulonephritis, notable for robust glomerular inflammation without immunoglobulin deposition.

Humoral Antibody-Mediated Injury Most antibody-mediated glomerulonephritis in humans is initiated by reactivity of circulating antibodies with glomerular antigens. The major mechanisms of antibody deposition within the glomerulus are (1) reactivity of circulating autoantibodies with intrinsic autoantigens that are components of normal glomerular parenchyma, as occurs in anti-GBM disease (Goodpasture's

syndrome); (2) in situ formation of immune complexes within glomeruli through interaction of circulating antibodies with extrinsic antigens that have been trapped, or "planted," within the glomerulus, as occurs in postinfectious glomerulonephritis; and (3) intraglomerular trapping of immune complexes that have formed in the systemic circulation, as occurs in cryoglobulinemia-associated glomerulonephritis. Circulating autoantibodies against neutrophil cytoplasmic antigens (antineutrophil cytoplasmic antibodies, ANCA) and endothelial antigens (antiendothelial cell antibodies, AECA) may represent additional mechanisms of antibody-mediated glomerular injury in patients without discernible immune complexes in the glomerular parenchyma.

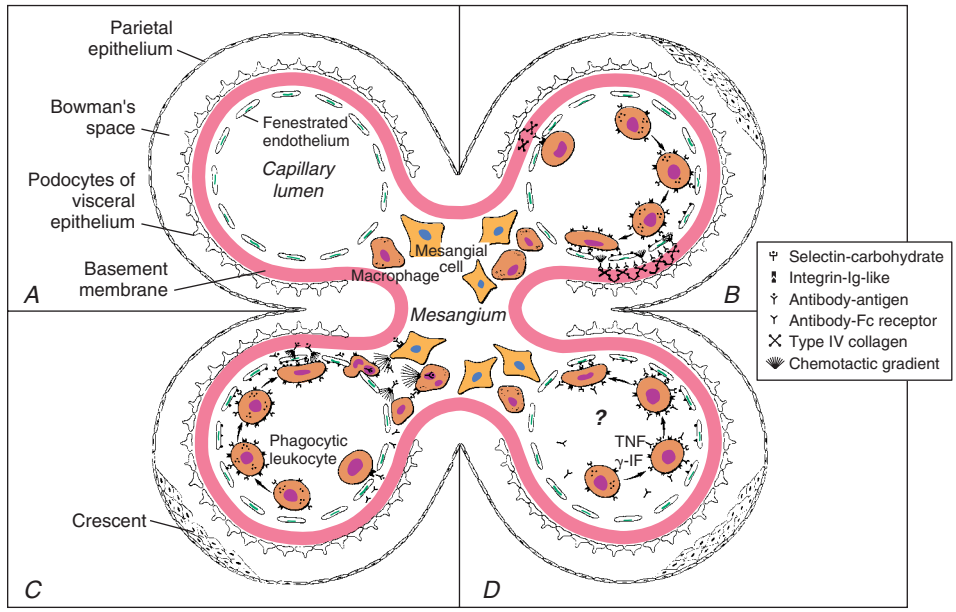

FIGURE 264-1 Major mechanisms of antibody-mediated injury in glomerulonephritis. *A*. Normal glomerulus. Key components of "healthy" glomerular capillary loop. *B*. Antiglomerular basement membrane antibody-mediated glomerulonephritis. Linear deposition of IgG against the Goodpasture antigen. The latter autoantigen is a normal constituent of the noncollagenous domain of $\alpha 3$ chain of type IV collagen, whose "chicken wire"–like structure is essential for maintenance of normal glomerular basement membrane architecture and function. *C*. Immune complex–mediated glomerulonephritis. Immune complexes scattered throughout the glomerular capillary wall, e.g., as can occur in lupus nephritis or postinfectious glomerulonephritis. In mechanisms *B* and *C*, leukocyte chemotaxis is triggered by complement components, chemokines, and other inflammatory mediators. Leukocyte–endothelial cell adhesion is supported by four major classes of adhesion molecules: the selectins and their diverse carbohydrate-bearing ligands, the leukocyte integrins, and immunoglobulin-like molecules such as intercellular adhesion molecule-1. Leukocytes also adhere through binding of their Fc receptors to the Fc domains of immunoglobulin. *D*. Antineutrophil cytoplasmic antibody (ANCA)-associated glomerulonephritis. In diseases such as Wegener's granulomatosis, ANCA are postulated to induce glomerular injury by interacting with neutrophil granule components that have migrated to the cell surface following priming of neutrophils by cytokines, as may occur during a prodromal viral illness. Reactivity of ANCA with neutrophil granule components in vitro triggers neutrophil activation and endothelial cell injury. This mechanism of glomerular injury remains to be established definitively in vivo, however, hence the symbol "?" in the cartoon. Crescents are formed by proliferation of parietal epithelial cells and migration of monocyte-macrophages into the glomerulus from the glomerular capillary lumen and tubulointerstitial space. As they expand, crescents compress the glomerular capillary tuft and are a rich source of mediators that further amplify the inflammatory response. TNF, tumor necrosis factor; γ-IF, interferon γ.

GENERATION OF NEPHRITOGENIC ANTIBODIES Exposure of the host to a foreign antigen (e.g., a prodromal infection) has been implicated as the trigger for the generation of nephritogenic autoantibodies in several forms of glomerulonephritis. Foreign antigens can provoke autoantibody formation through several mechanisms. First, a foreign antigen, whose structure resembles that of a host glomerular antigen, may stimulate the production of autoantibodies that cross-react with the intrinsic glomerular antigen (*molecular mimickry*). Second, the foreign antigen may trigger aberrant expression of major histocompatibility complex (MHC) class II molecules on glomerular cells, which present previously "invisible" autoantigens to T lymphocytes and thereby generate an autoimmune response. Third, the foreign antigen can trigger polyclonal activation of B lymphocytes, some of which generate nephritogenic antibodies. Alternatively, individuals may suffer a breakdown of immune tolerance through other mechanisms (e.g., genetically programmed).

Autoreactive B cells are usually deleted in the thymus during development (*clonal deletion*) or rendered anergic in peripheral lymphoid tissue (*clonal anergy*). Similar tolerogenic mechanisms exist for deleting or anergizing autoreactive T helper cells that modulate immunoglobulin production by autoreactive B cells. Perturbation of these tolerogenic mechanisms could drive immunoglobulin production in some forms of autoimmune glomerulonephritis. Indeed, defective clonal deletion of autoreactive T cells has been demonstrated in experimental lupus nephritis due to defective synthesis of Fas, a cell-surface receptor that modulates T cell deletion through *apoptosis* (programmed cell death) within the thymus.

DEPOSITION OF NEPHRITOGENIC ANTIBODIES WITHIN THE GLOMERULUS (Fig. 264-1) The site of antibody deposition within the glomerulus is a critical determinant of the clinicopathologic presentation and is determined by the avidity, affinity, and quantity of the antibody; the size, charge, and site of the antigen; the size of the immune complexes; the efficiency of the clearance mechanisms for immune complexes; and local hemodynamic factors. Relatively anionic antigens are repelled by the GBM, which is negatively charged, and tend to be trapped in the subendothelial cell space and mesangium. In contrast, relatively cationic antigens tend to permeate the GBM and deposit within the GBM or in the subepithelial space.

Acute deposition of antibody in the subendothelial cell space (e.g., poststreptococcal glomerulonephritis) or mesangium (e.g., Henoch-Schönlein purpura) typically triggers a nephritic-type response characterized by rapid recruitment of leukocytes and platelets, probably because inflammatory mediators generated at these sites are strategically positioned to activate endothelial and hematogenous cells. Leukocyte-derived products, such as reactive oxygen species, lysosomal enzymes and cytokines, complement components, and other toxic moieties generated in the local inflammatory milieu are both injurious to the glomerular vascular wall and filtration barrier and attract subsequent waves of leukocytes from the circulation. Antibody deposition in the subepithelial cell space (e.g., membranous nephropathy) typically induces a nephrotic-type response characterized by proteinuria without a pronounced inflammatory cell infiltrate, probably because the immune complexes are shielded from circulating inflammatory cells by the GBM and because the large fluid flux from blood to Bowman's space minimizes back-diffusion of inflammatory mediators towards the endothelium and vascular lumen. In this setting, complement components such as the membrane attack complex (C5b-9) appear to be the major effectors of glomerular injury.

Cellular Antibody-Independent Glomerular Injury Although cell-mediated injury is, as yet, less well defined than antibody-mediated glomerular injury, T cells have also been implicated as independent mediators of glomerular injury and as modulators of the production of nephritogenic antibodies. T cells may be particularly important as initiators of injury in pauci-immune glomerulonephritis. T cells interact, through their cell-surface T cell receptor/CD3 complex, with antigens presented in

the groove of MHC molecules of resident glomerular endothelial, mesangial, and epithelial cells, a process that is facilitated by cell-cell adhesion and costimulatory molecules. Cytokines and other mediators released by activated T cells are potent stimuli for further leukocyte recruitment, cytotoxicity, and fibrogenesis. CD4 T lymphocytes are important recruiters of macrophages and trigger clonal expansion of autoreactive B cells; they also promote glomerular cell injury by CD8 cytotoxic T lymphocytes and natural killer cells and through antibody-dependent cell cytotoxicity. Soluble factors derived from T cells have also been implicated in the pathogenesis of proteinuria in MCD and primary FSGS. The identity and molecular characterization of these nonimmunoglobulin circulating permeability factors remain to be determined.

Whereas the initiating events in antibody-independent pauci-immune forms of glomerular injury are poorly understood by comparison with antibody-dependent injury, there appears to be marked overlap between the downstream mediator systems that perturb glomerular morphology and function. Thus key pathogenic roles have already been defined in pauci-immune glomerular disease for many of the mediator systems discussed above including leukocyte-derived toxic moieties, such as reactive oxygen species, proteases, cytokines, chemokines, and other inflammatory mediators derived from recruited and resident renal cells.

Cell Proliferation and Accumulation of Extracellular Matrix A hallmark of the nephritic-type proliferative glomerulopathies is an increase in glomerular cell number. Initially, this hypercellularity is due predominantly to infiltration of the glomerular tuft by leukocytes. Subsequently, resident glomerular cells proliferate in response to growth factors [e.g., epidermal growth factor (EGF), platelet-derived growth factor (PDGF)] released into the local inflammatory milieu. The proliferating cells are typically mesangial in mesangioproliferative glomerulonephritis and both endothelial and mesangial cells in diffuse proliferative glomerulonephritis. The visceral epithelial cell is, for the most part, a terminally differentiated cell that does not proliferate rapidly, even when injured.

Whereas acute antibody-mediated glomerulonephritis typically induces acute diffuse proliferative glomerulonephritis and acute renal failure over days to weeks (nephritic syndrome), subacute immune injury often induces the formation of glomerular crescents and renal failure over weeks to months (termed *rapidly progressive glomerulonephritis* (RPGN). As discussed above, crescents are extracapillary proliferations of cells in Bowman's space, composed of infiltrating monocytes, proliferating parietal epithelial cells, and fibrin.

Sustained low-level immune complex deposition over months to years can provoke a marked increase in basement membrane or mesangial matrix production. Mild to moderate accumulation of matrix usually manifests as proteinuria due to disruption of the glomerular filtration barrier; however, in its most severe form, matrix accumulation causes glomerulosclerosis and chronic renal insufficiency.

Determinants of Resolution, Repair, and Scarring Glomerular inflammation can resolve with complete recovery of renal function or with a variable amount of scarring and chronic renal insufficiency. Acute poststreptococcal glomerulonephritis, for example, usually resolves spontaneously and fully in children, whereas adults may be left with residual renal impairment. The resolution process requires cessation of further antibody production and immune complex formation, removal of deposited and circulating immune complexes, inhibition of further recruitment of inflammatory cells, dissipation of the gradients of inflammatory mediators, restoration of normal endothelial adhesiveness and permeability, normalization of vascular tone, and clearance of infiltrating inflammatory cells and proliferating resident glomerular cells. Putative pro-resolution signals in spontaneously resolving glomerular inflammation include the lipoxygenase-derived eicosanoids, the lipoxins, and cytokines such as interleukin (IL)-4, -10, and -13.

Unfortunately, the resolution phase of most inflammatory glomerulopathies in adults terminates in some glomerular scarring. This is particularly true in patients with crescentic glomerulopathies who may be left with end-stage renal failure requiring dialysis or transplantation. Transforming growth factor (TGF) β and connective tissue growth factor (CTGF) stimulate production of extracellular matrix by most glomerular cells, inhibits synthesis of tissue proteases that normally degrade matrix proteins, and appear to be important stimuli for scar formation immediately following glomerular injury.

NONIMMUNOLOGIC GLOMERULAR INJURY While many glomerular diseases are driven by immunologic events, a variety of nonimmunologic metabolic, hemodynamic, and toxic stresses can each induce glomerular pathology, either alone or in concert with immunologic processes.

Metabolic Injury Glomerulopathy complicates a variety of inherited and acquired diseases of carbohydrate and lipid metabolism. Hyperglycemia is a central event in the injury process. The mechanisms by which hyperglycemia perturbs renal function in diabetes are still being appreciated and include (1) the interactions of advanced glycosylation end-products (AGEs) with renal cells; (2) direct effects of high glucose on renal cells mediated through the generation of reactive oxygen species, cell sorbitol accumulation, activation of protein kinase C, and mitogen-activated protein kinases; and (3) high glucose–triggered glomerular hypertension. Important functional consequences of these high glucose–triggered events include mesangial cell hypertrophy, increased mesangial cell matrix production, reduced matrix catabolism, and glomerulosclerosis.

Several rare inherited lysosomal enzyme defects induce focal segmental glomerulosclerosis, probably by allowing accumulation of toxic metabolites in renal cells. *Fabry's disease* (α-galactosidase deficiency) and *sialidosis* (*N*-acetylneuraminic acid hydrolase deficiency) are the major culprits in this regard.

Hemodynamic Glomerular Injury High intraglomerular pressure is a major cause of glomerular injury and can result from systemic hypertension or from local change in glomerular hemodynamics leading to glomerular hypertension.

Systemic Hypertension (See also Chap. 230) Although the kidneys have evolved sophisticated mechanisms for autoregulating glomerular blood flow and pressure, marked or sustained increments in systemic blood pressure can overwhelm these compensatory systems and perturb glomerular morphology and function. In its most dramatic form, namely malignant hypertension, hemodynamic stress causes massive fibrinoid necrosis of afferent arterioles and glomeruli, thrombotic microangiopathy, a nephritic urinary sediment, and acute renal failure. Chronic sustained hypertension typically leads to arteriolar vasoconstriction and sclerosis, which, in turn, cause secondary atrophy and sclerosis of glomeruli and the tubulointerstitium. A variety of molecular signals appear to couple elevations in intravascular pressure to myointimal proliferation and eventually sclerosis of the vessel wall. These include growth factors such as angiotensin II, EGF, PDGF, and CTGF; cytokines such as TGF-β; and activation of stretch-activated ion channels and early response genes.

Glomerular Hypertension As discussed below, glomerular hypertension is also a key factor in the pathogenesis of the progressive glomerulosclerosis and renal failure. Glomerular hypertension is an adaptive response to increased workload in the remaining functioning nephrons following loss of other nephrons from any cause, including chronic allograft failure. While appropriate in the short term, sustained glomerular hypertension is a stimulus for increased mesangial matrix production and glomerulosclerosis. Importantly, glomerular hypertension appears to precede the development of systemic hypertension in many forms of glomerular disease where it is an independent risk factor for glomerular injury.

Miscellaneous Mechanisms of Nonimmunologic Glomerular Injury In addition to the major immune, metabolic, and mechanical mechanisms of glo-

meruli injury described above, glomerulopathy can be precipitated by a variety of infectious and toxic agents; the latter include both exogenous (e.g., drugs) and endogenous (e.g., fibril deposition) toxins.

FINAL COMMON PATHWAYS OF INJURY IN GLOMERULAR DISEASE Two pathologic features dominate most cases of chronic progressive glomerular disease, i.e., focal segmental glomerulosclerosis and tubulointerstitial fibrosis. By elucidating the molecular events that contribute to these final common pathways of injury, it should be possible to design new renoprotective therapies. Indeed, the identification of glomerular hypertension as a major stimulus for secondary focal segmental glomerulosclerosis has already led to the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) as specific renoprotective agents in clinical practice.

Secondary Focal Segmental Glomerulosclerosis Nephron loss, from any cause, is followed by compensatory vasodilation of afferent arterioles, increased glomerular pressure (*glomerular hypertension*), and increased filtration (*glomerular hyperfiltration*) in the remaining functional glomeruli. This adaptive response is appropriate in the short term and maintains GFR. Over years, however, sustained glomerular hypertension and hyperfiltration induce focal and segmental glomerulosclerosis and eventually global sclerosis, which manifests clinically as proteinuria, hypertension, and progressive renal insufficiency. Glomerular hypertension, in particular, has been implicated as a major stimulus for glomerulosclerosis in this setting. Increased glomerular blood flow and ultrafiltration pressure are early findings in remnant nephrons in most experimental models in which the function of >50% of nephron mass has been lost through surgical ablation, immunologic or toxic injury, or other mechanisms.

Sustained glomerular hypertension is thought to stimulate the accumulation of extracellular matrix by perturbing the function of visceral epithelial and mesangial cells, either directly or by increasing the flux of circulating macromolecules through the glomerular capillary wall. As with most forms of glomerulosclerosis, TGF-β may be an important regulator of matrix accumulation in remnant nephrons. Angiotensin II, PDGF, CTGF, and endothelins are other potential modulators of this process. Maneuvers that lower intraglomerular pressure, such as a low-protein diet or treatment with ACE inhibitors or ARBs, slow the development of glomerulosclerosis and renal failure. Glomerular hypertrophy, intracapillary microthrombi, recruited macrophages, and hyperlipidemia are other potential stimuli for glomerulosclerosis. Indeed, glomerular capillary hypertension and hypertrophy appear to be independent risk factors that could act synergistically to cause progressive renal insufficiency. Intriguingly, angiotensin II may trigger TGF-β production, and engagement of angiotensin II receptors may trigger activation of growth factor receptor signaling pathways (so-called *receptor transactivation*) in remnant nephrons, suggesting that ACE inhibitors and ARBs may be renoprotective through complementary effects on glomerular hemodynamics and matrix production.

Tubulointerstitial Inflammation and Fibrosis Downstream from Glomerular Injury Moderate-to-severe glomerulonephritis is usually associated with a variable degree of tubulointerstitial inflammation and scarring in addition to glomerular injury. Indeed, the severity of tubulointerstitial injury usually correlates closely with long-term impairment of renal function. The pathogenesis of tubulointerstitial inflammation in this setting is unclear. Potential mechanisms include: (1) primary involvement of both the glomeruli and the tubulointerstitium in autoimmune disease; (2) induction of tubulointerstitial inflammation by mediators generated by diseased glomeruli, which then diffuse into the tubulointerstitium via blood, tubular fluid, or the interstitial space; (3) injury to tubule epithelial cells by excessive filtered proteins ("protein overload" hypothesis); and (4) ischemia to areas of the tubulointerstitium downstream to areas of vigorous glomerular inflammation or severe glomerulosclerosis.

CLINICAL PRESENTATIONS

ACUTE NEPHRITIC SYNDROME AND RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

CLINICAL FEATURES AND CLINICOPATHOLOGIC CORRELATES The *acute nephritic syndrome* is the clinical correlate of acute glomerular inflammation. In its most dramatic form, the acute nephritic syndrome is characterized by sudden onset (i.e., over days to weeks) of acute renal failure and oliguria (400 mL/day of urine). Renal blood flow and GFR fall as a result of obstruction of the glomerular capillary lumen by infiltrating inflammatory cells and proliferating resident glomerular cells. Renal blood flow and GFR are further compromised by intrarenal vasoconstriction and mesangial cell contraction that result from local imbalances of vasoconstrictor (e.g., leukotrienes, platelet-activating factor, thromboxanes, endothelins) and vasodilator substances (e.g., nitric oxide, prostacyclin) within the renal microcirculation. Extracellular fluid volume expansion, edema, and hypertension develop because of impaired GFR and enhanced tubular reabsorption of salt and water. As a result of injury to the glomerular capillary wall, urinalysis typically reveals red blood cell casts, dysmorphic red blood cells, leukocytes, and subnephrotic proteinuria of <3.0 g per 24 h ("nephritic urinary sediment"). Hematuria is often macroscopic.

The classic pathologic correlate of the nephritic syndrome is *proliferative glomerulonephritis*. The proliferation of glomerular cells is due initially to infiltration of the glomerular tuft by neutrophils and monocytes and subsequently to true proliferation of resident glomerular endothelial and mesangial cells (endocapillary proliferation). In its most severe form, the nephritic syndrome is associated with acute inflammation of most glomeruli, i.e., *acute diffuse proliferative glomerulonephritis*. When less vigorous, <50% of glomeruli may be involved, i.e., *focal proliferative glomerulonephritis*. In milder forms of nephritic injury, cellular proliferation may be confined to the mesangium, i.e., *mesangioproliferative glomerulonephritis*.

RPGN is the clinical correlate of more subacute glomerular inflammation. Patients develop renal failure over weeks to months in association with a nephritic urinary sediment, subnephrotic proteinuria and variable oliguria, hypervolemia, edema, and hypertension. The classic pathologic correlate of RPGN is crescent formation involving most glomeruli (*crescentic glomerulonephritis*). In practice, the clinical term *rapidly progressive glomerulonephritis* and the pathologic term *crescentic glomerulonephritis* are often used interchangeably. In addition to classic crescentic glomerulonephritis, in which crescents dominate the glomerular pathology, crescents can also develop concomitantly with proliferative glomerulonephritis or as a complication of membranous glomerulopathy and other more indolent forms of glomerular inflammation.

The acute nephritic syndrome and RPGN are part of a spectrum of presentations of immunologically mediated proliferative glomerulonephritis. Studies of experimental models suggest that nephritic syndrome and diffuse proliferative glomerulonephritis represent an acute immune response to a sudden large antigen load, whereas RPGN and crescentic glomerulonephritis represent a more subacute immune response to a smaller antigen load in presensitized individuals. At the other end of the spectrum, chronic low-grade immune injury presents with slowly progressive renal insufficiency or asymptomatic hematuria in association with focal proliferative or mesangioproliferative glomerulonephritis. These more indolent forms of immune-mediated glomerulonephritis are discussed later in this chapter.

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS Acute nephritic syndrome and RPGN can result from renal-limited *primary* glomerulopathy or from *secondary* glomerulopathy complicating systemic disease. Figure 264-2 highlights the histopathologic and serologic features that help distinguish among the major causes of nephritic syndrome and RPGN. In general, rapid diagnosis and prompt treatment are critical to avoid

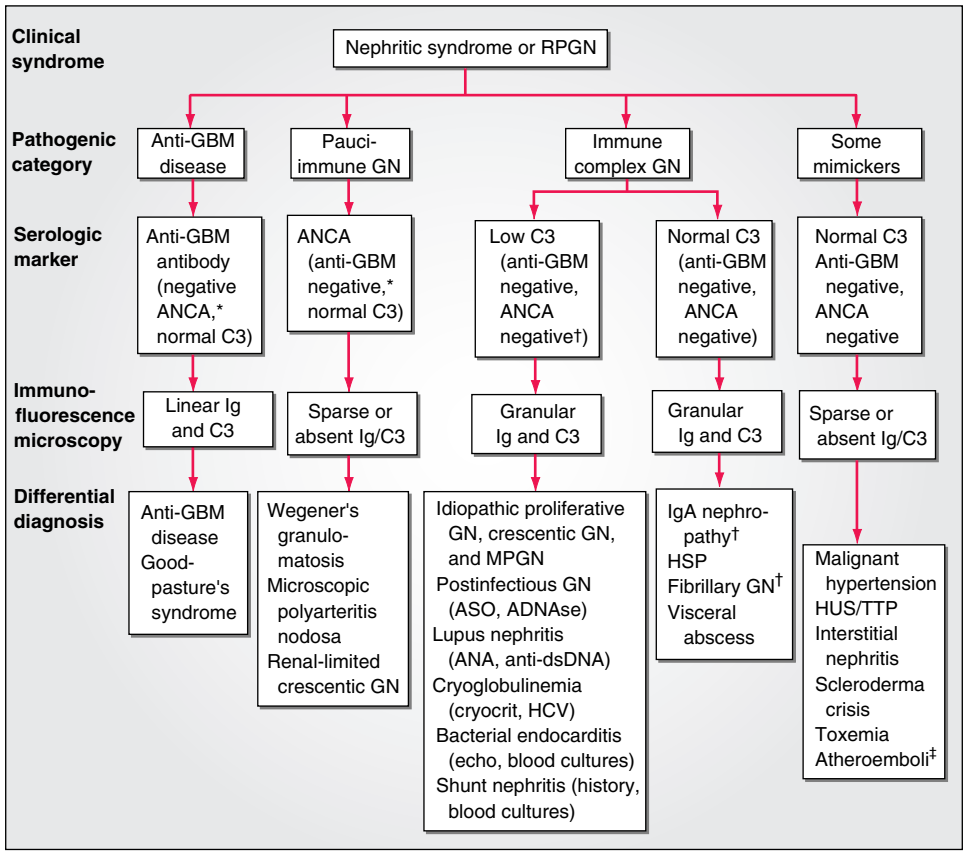

FIGURE 264-2 Differential diagnosis of nephritic syndrome and rapidly progressive glomerulonephritis. Abbreviations: GN, glomerulonephritis; RPGN, rapidly progressive glomerulonephritis; MPGN, membranoproliferative glomerulonephritis; GBM, glomerular basement membrane; ANCA, antineutrophil cytoplasmic antibodies; Ig, immunoglobulin; C3, third component of complement; ASO, antistreptolysin O antibody titer; ADNAse, anti-deoxyribonuclease antibody titer; ANA, antinuclear antibody; anti-dsDNA, anti-double-stranded DNA antibody; HCV, hepatitis C virus; echo, echocardiogram; HSP, Henoch-Schönlein purpura; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura. *Approximately 20% of patients with anti-GBM disease have ANCA, which may portend a better prognosis. †Nephritic syndrome and RPGN are unusual presentations of IgA nephropathy and fibrillary GN. ‡Atheroembolic renal disease may cause transient hypocomplementemia.

the development of irreversible renal failure. Renal biopsy remains the "gold standard" for diagnosis. *Immunofluorescence microscopy* is particularly helpful and identifies three major patterns of deposition of immunoglobulin that define three broad diagnostic categories: (1) scattered *granular* deposits of immunoglobulin, a hallmark of *immune-complex glomerulonephritis*; (2) more discrete *linear* deposition of immunoglobulin along the GBM, characteristic of *anti-GBM disease*; and (3) paucity or absence of immunoglobulin—*pauci-immune glomerulonephritis* (Figs. 264-1 and 264-3). Most patients (≥70%) with full-blown acute nephritic syndrome have immune-complex glomerulonephritis. Pauci-immune glomerulonephritis is less common in this setting (<30%), and anti-GBM disease is rare (<1%). Among patients with RPGN, immune-complex glomerulonephritis and pauci-immune glomerulonephritis are equally prevalent (~45% each), whereas anti-GBM disease again accounts for a minority of cases (<10%).

Three *serologic markers* often predict the immunofluorescence microscopy findings in nephritic syndrome and RPGN and may obviate the need for renal biopsy in classic cases. They are the serum C3 level and titers of anti-GBM antibody and ANCA. As discussed in previous sections, the kidney is host to immune attack in immune-complex glomerulonephritis, most cases being initiated either by in situ formation of immune complexes or less commonly by glomerular trapping of circulating immune complexes. These patients typically have hypocomplementemia (low C3 in 90%) and negative anti-GBM and ANCA serology, the major exception being IgA nephropathy/Henoch Schönlein purpura where complement levels are typically normal. The glomerulus is the direct target of immune attack in anti-GBM disease, glomerular inflammation being initiated by an autoantibody directed at a 28-kDa autoantigen on the α3 chain of type IV collagen. Approximately 90 to 95% of patients with anti-GBM disease have circulating anti-GBM autoantibodies detectable by immunoassay; serum complement levels are typically normal, and ANCA are usually not detected. The pathogenesis of pauci-immune glomerulonephritis is still being defined; however, most patients have circulating ANCA. Serum complement levels are typically normal, and anti-GBM titers are usually negative in ANCA-associated renal disease. It should be noted, however, that there may be some serologic overlap, with as many as 20% of patients with immune complex or anti-GBM glomerulonephritis also having at least low levels of circulating ANCA.

NEPHRITIC SYNDROME AND RPGN DUE TO IMMUNE-COMPLEX GLOMERULONEPHRITIS

Nephritic syndrome induced by immune-complex glomerulonephritis may be (1) be idiopathic, (2) represent a response to a known antigenic stimulus (e.g., glomerulonephritis triggered by bacterial endocarditis or streptococcal infection, or hepatitis B or C infection in cryoglobulinemic glomerulonephritis), or (3) form part of a multisystem immune-complex disorder (e.g., lupus nephritis, Henoch-Schönlein purpura; Table 264-1, Figs. 264-1 to 264-3).

INFECTION-ASSOCIATED GLOMERULONEPHRITIS INCLUDING GLOMERULONEPHRITIS ASSOCIATED WITH STREPTOCOCCAL INFECTION AND INFECTIVE ENDOCARDITIS A variety of infections can precipitate immune-complex glomerulonephritis. The most common clinicopathologic lesion in this setting is acute diffuse proliferative glomerulonephritis presenting as the acute nephritic syndrome; however, depending on the speed of onset and site and extent of immune complex formation, infection-associated immune complex formation can trigger mesangioproliferative, focal proliferative, membranoproliferative, or membranous glomerulopathy.

Poststreptococcal glomerulonephritis is the prototypical *postinfectious glomerulonephritis* and a leading cause of acute nephritic syndrome. Most cases are sporadic, though the disease can occur as an epidemic. Glomerulonephritis develops, on average, 10 days after pharyngitis or 2 weeks after a skin infection (impetigo) with a nephritogenic strain of group A β-hemolytic streptococcus. The known nephritic strains include M types 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60. Immunity to these strains is type-specific and long-lasting, and repeated infection and nephritis are rare. Epidemic poststreptococcal glomerulonephritis is most commonly encountered in children of 2 to 6 years of age with pharyngitis during the winter months. This entity appears to be decreasing in frequency, possibly due to more widespread and prompt use of antibiotics. Poststreptococcal glomerulonephritis in association with cutaneous infections usually occurs in a setting of poor personal hygiene or streptococcal superinfection of another skin disease.

The classic clinical presentation of poststreptococcal glomerulonephritis is full-blown nephritic syndrome with oliguric acute renal failure; however, most patients have milder disease. Indeed, subclinical cases outnumber overt cases by four- to tenfold during epidemics. Patients with overt disease present with gross hematuria (red or

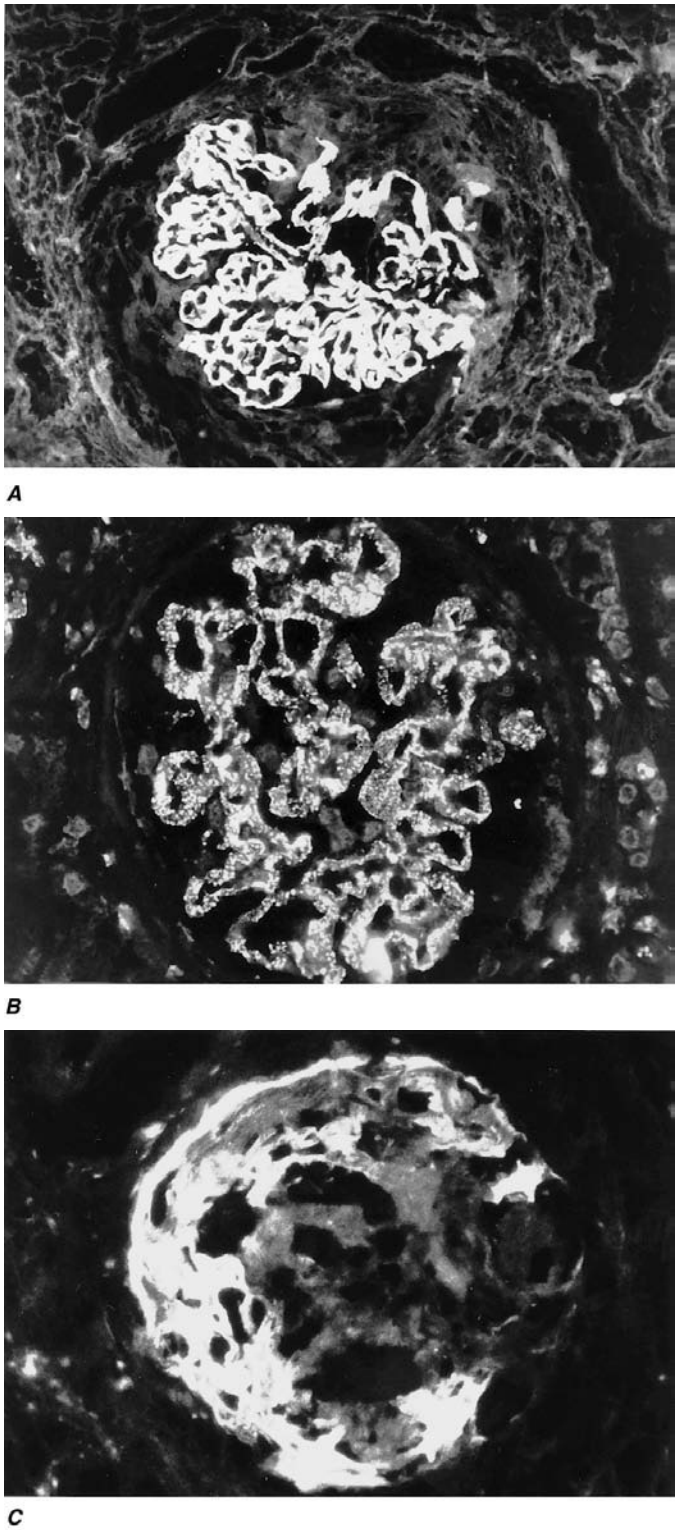

FIGURE 264-3 Typical findings on immunofluorescence microscopy of renal biopsy specimens from patients with anti-glomerular basement membrane antibody disease, immune complex–mediated glomerulonephritis, and pauci-immune glomerulonephritis. Specimens in the upper and middle panels were stained for immunoglobulin and show the classic linear "ribbon-like" pattern of anti-GBM disease (*A*) and granular pattern of immune complex–mediated glomerulonephritis (*B*). Immunoglobulin is sparse or absent in patients with pauci-immune glomerulonephritis (not shown); however, abundant fibrin is detected in crescents (*C*). *(Micrographs courtesy of Dr. Helmut Rennke.)*

"smoky" urine), headache, and generalized symptoms such as anorexia, nausea, vomiting, and malaise. Swelling of the renal capsule can cause flank or back pain. Physical examination reveals hypervolemia, edema, and hypertension. The urinary sediment is nephritic, with dysmorphic red blood cells, red cell casts, leukocytes, occasionally leukocyte casts, and subnephrotic proteinuria. Fewer than 5% of patients develop nephrotic-range proteinuria. The latter may only manifest as acute nephritis resolves and renal blood flow and GFR recover. Coexistent rheumatic fever is extremely rare.

The serum creatinine is often mildly elevated at presentation. Serum C3 levels and CH_{50} are depressed within 2 weeks in ~90% of cases. C4 levels are characteristically normal, indicating activation of the alternate pathway of complement. Complement levels usually return to normal within 6 to 8 weeks. Persistently depressed levels after this period should suggest another cause, such as the presence of a C3 nephritic factor (see "Membranoproliferative Glomerulonephritis," p. 1687). The majority of patients (>75%) have transient hypergammaglobulinemia and mixed cryoglobulinemia. The antecedent streptococcal infection may still be evident or may have resolved either spontaneously or in response to antibiotic therapy. Most patients (>90%) have circulating antibodies against streptococcal exoenzymes such as antistreptolysin O (ASO), anti-deoxyribonuclease B (anti-DNAse B), antistreptokinase (ASKase), anti-nicotinyl adenine dinucleotidase (anti-NADase), and antihyaluronidase (AHase).

Acute poststreptococcal glomerulonephritis is usually diagnosed on clinical and serologic grounds, without resort to renal biopsy, especially in children with a typical antecedent history. The characteristic lesion on light microscopy is diffuse proliferative glomerulonephritis. Crescents are uncommon, and extraglomerular involvement is usually mild. Immunofluorescence microscopy reveals diffuse granular deposition of IgG and C3, giving rise to a "starry sky" appearance (Figs. 264-1 and 264-3). The characteristic finding on electron microscopy is the presence of large electron-dense immune deposits in the subendothelial, subepithelial, and mesangial areas.

In addition to poststreptococcal glomerulonephritis, the nephritic syndrome and RPGN can complicate acute immune-complex glomerulonephritis due to other viral, bacterial, fungal, and parasitic infections. Diffuse proliferative immune-complex glomerulonephritis is a well-described complication of acute and *subacute infective endocarditis* and is usually associated with hypocomplementemia. The glomerular lesion typically resolves following eradication of the cardiac infection.

TREATMENT

Treatment of poststreptococcal glomerulonephritis focuses on eliminating the streptococcal infection with antibiotics and providing supportive therapy until spontaneous resolution of glomerular inflammation occurs. Patients are usually confined to bed during the acute inflammatory phase. Diuretics and antihypertensive agents are employed to control extracellular fluid volume and blood pressure. Dialysis is rarely needed to control hypervolemia or the uremic syndrome. Poststreptococcal glomerulonephritis carries an excellent prognosis and rarely causes end-stage renal disease (ESRD). Whereas spontaneous resolution of the glomerular lesion and nephritic syndrome is the norm in children within 6 to 8 weeks, >20% of adults may have some degree of persistent proteinuria and/or compromise of GFR 1 year after presentation. As with poststreptoccal glomerulonephritis, treatment of immune complex glomerulonephritis in association with bacterial endocarditis and other forms of infection is supportive until the causative infection is eliminated.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) (LUPUS NEPHRITIS) (See also Chap. 300) Renal involvement is clinically evident in 40 to 85% of patients with SLE; it varies from isolated abnormalities of the urinary sediment to full-blown nephritic or nephrotic syndrome or chronic renal failure. Most glomerular injury is triggered by the formation of immune complexes within the glomerular capillary wall; however, thrombotic microangiopathy may be the dominant reason for renal dysfunction in a small subset of patients with the antiphospholipid antibody syndrome. Renal biopsy has proven very useful for identifying the different pat-

terns of immune-complex glomerulonephritis in SLE, which are diverse, portend different prognoses, and do not necessarily correlate with the clinical findings. Indeed, clinically silent lupus nephritis is well described as having a urinalysis virtually normal but renal biopsy demonstrating varying degrees of injury.

Patients with active lupus nephritis have a range of serologic abnormalities. Hypocomplementemia is present in 75 to 90% of patients and is most striking with diffuse proliferative glomerulonephritis. Antinuclear antibodies (ANA) are usually detected (95 to 99%), although not specific for SLE. ANA titers tend to fall with treatment, and ANA may not be detected during remissions. Anti-double-stranded DNA (dsDNA) antibodies are highly specific for SLE, and changes in their titers correlate with the activity of lupus nephritis.

Patients with the lupus-related antiphospholipid antibody syndrome can develop a variable degree of renal impairment due to thrombotic microangiopathy. The latter typically affects the interlobular arteries, arterioles, and glomerular capillaries and is characterized by intravascular microthrombi and swelling of endothelial cells. Decreased levels of tissue plasminogen activator and increased levels of α_2-antiplasmin, both of which would tend to promote thrombosis, have been described in this syndrome.

TREATMENT

The treatment of lupus nephritis is controversial and based largely on the class of injury and disease activity. Because there is relatively poor correlation between clinical features (urinalysis findings, serum creatinine) and histologic class, the renal biopsy findings are an important guide to therapy. Treatment is not indicated for those with a normal biopsy or only mesangial deposits of immunoglobulins, as these histologic patterns portend an excellent prognosis (100% and 90% 5-year survival rates, respectively). Extrarenal manifestations may warrant treatment with glucocorticoids, salicylates, or antimalarials. Glucocorticoids and cyclophosphamide are the mainstays of therapy for patients with proliferative nephritis. High-dose steroids given as intravenous boluses (pulse therapy) are usually effective at rapidly controlling acute glomerular inflammation. Cyclophosphamide and azathioprine are important adjuncts to steroid therapy and appear to afford better long-term preservation of renal function than steroids alone. Intravenous pulse cyclophosphamide is as efficacious as oral therapy and appears to be less toxic. An initial regimen of monthly intravenous boluses of cyclophosphamide for 6 months should be administered. Subsequent therapy is tailored to disease activity and typically involves dosing every 3 to 6 months for a total treatment period of 12 to 24 months.

The initial dose of cyclophosphamide is 0.5 g/m^2, and the dose is increased gradually to a maximum of 1 g/m^2 unless patients develop leukopenia or other side effects. Steroids are usually started simultaneously at 1 mg/kg per day and are tapered over the first 6 months to a maintenance dose of 5 to 10 mg/d for the duration of cyclophosphamide therapy. Cyclophosphamide may be stopped after 6 months and replaced with either azathioprine or mycophenolate provided that partial or complete remission has been achieved. Five-year renal survival rates of 60 to 90% have been obtained with these regimens. Mycophenolate mofetil has also been used as a therapeutic option in patients resistant to cyclophosphamide. A large randomized, prospective trial indicated that plasmapheresis does not offer additional benefit in patients with severe proliferative lupus nephritis.

The management of membranous lupus nephritis (see "Nephrotic Syndrome," below) is less well defined. As with idiopathic membranous glomerulopathy, the incidence of spontaneous remission approaches 50% in membranous lupus nephritis, and the course of the disease is generally indolent, with a 70 to 90% renal survival rate at 5 years. Some authorities advocate steroids at the time of diagnosis, whereas others reserve them for patients with progressive renal insufficiency or severe nephrotic syndrome. Useful parameters for monitoring the response to therapy and predicting relapse include the activity of the urine sediment, proteinuria, GFR, serum complement levels, and anti-dsDNA titers. As in other proteinuric renal diseases, ACE inhibitors or ARBs are usually prescribed as adjunctive treatment. Despite maximal immunosuppressive therapy, about 20% of patients with aggressive lupus nephritis develop ESRD requiring dialysis. SLE tends to become quiescent with advanced uremia, and patients rarely develop systemic flares once they commence dialysis. Recurrence of nephritis and systemic flares are also very uncommon after renal transplantation, and allograft survival rates are comparable to those in patients with other causes of ESRD.

In patients with thrombotic microangiopathy due to lupus-related antiphospholipid antibody syndrome, anticoagulation to maintain the Internalized Normal Ratio (INR) at 3.0 may be beneficial in reducing the incidence of recurrent thromboses. There are uncontrolled reports of a benefit of plasmapheresis in the setting of acute renal failure secondary to thrombotic microangiopathy.

CRYOGLOBULINEMIA GLOMERULOPATHY (See also Chap. 306) Renal involvement is most common with the mixed cryoglobulinemias (types II and III), which are more common in females and usually begin in the sixth decade. Most patients present with a variable combination of leukocytoclastic vasculitis, skin ulcerations, arthralgias, fatigue, and Raynaud's phenomenon. Renal disease is a complication in 50% of patients and usually develops after 12 to 24 months. The typical clinical renal manifestations are nephrotic-range proteinuria, microscopic hematuria, and hypertension. Acute nephritic syndrome occurs in 20 to 30%, and oliguric acute renal failure in about 5% of patients with renal disease.

Circulating levels of C3, C4, and CH50 are depressed in about 80% of patients with renal involvement, and a transient ANA (speckled pattern) is sometimes detected. Hepatitis C virus (HCV) RNA has been isolated from the serum of patients with essential mixed cryoglobulinemia (EMC).

TREATMENT

Traditionally, glucocorticoids, with or without cyclophosphamide, and plasmapheresis were the standard treatment for EMC, with poor results. With the recognition that many cases are triggered by HCV infection, interferon α has been employed to successfully control viral replication and stabilize renal function in most HCV-positive patients. Unfortunately, relapse is common when interferon α is discontinued, a major problem given the cost of this agent. In general, patient and renal survival are good in EMC, with 75% of patients being alive at 10 years.

IGA NEPHROPATHY AND HENOCH-SCHÖNLEIN PURPURA IgA nephropathy (Berger's disease) is a renal-limited form of glomerulonephritis characterized by deposition of IgA-containing immune deposits in the glomerular mesangium (p. 1690). Henoch-Schönlein purpura (Chap. 306) is a systemic disease characterized by a petechial rash on the extremities, arthropathy, abdominal pain, and glomerulonephritis. Because the glomerular lesion is identical to that found in IgA nephropathy, Henoch-Schönlein nephritis and IgA nephropathy may be part of a spectrum of manifestations of a single disease. Nephritis is present in 80% of patients and manifests as a nephritic urine sediment and moderate proteinuria. Macroscopic hematuria and nephrotic-range proteinuria are uncommon. Light-microscopic appears can vary from mild mesangial proliferation and expansion to diffuse proliferation with glomerular crescents. The sine qua non for diagnosis is the presence of mesangial IgA deposition on immunofluorescence microscopy. IgG and C3 are also detected. Electron microscopy reveals mesangial immune deposits. Immune complexes may also be present in the peripheral glomerular capillary wall and paramesangial areas. Biopsy of involved skin reveals dermal IgA deposition and leukocytoclastic vasculitis. IgA deposition is also seen in areas of uninvolved skin.

TREATMENT

Since there is no proven therapy for Henoch-Schönlein nephritis, treatment is supportive. Steroids and/or cytotoxic agents are often tried in patients with severe disease, but without compelling scientific evidence to support their use. The disease typically undergoes clinical exacerbations and remissions in the first year and then enters long-term remission. The prognosis is generally excellent; chronic renal failure and persistent hypertension occur in <10% of patients. The treatment of IgA nephropathy will be discussed later.

NEPHRITIC SYNDROME AND RPGN DUE TO ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE (GOODPASTURE'S SYNDROME) Anti-GBM disease is an autoimmune disease in which autoantibodies directed against type IV collagen induce RPGN and crescentic glomerulonephritis (Figs. 264-1 to 264-3). Acute nephritic syndrome is rare. Between 50 and 70% of patients have lung hemorrhage; the clinical complex of anti-GBM nephritis and lung hemorrhage is referred to as *Goodpasture's syndrome*. Patients with this syndrome are typically young males (5 to 40 years; male-female ratio of 6:1). In contrast, patients presenting during the second peak in the sixth decade rarely suffer lung hemorrhage and have an almost equal sex distribution. The target antigen is a component of the noncollagenous (NCI) domain of the α3 chain of type IV collagen, the α3 chain being preferentially expressed in glomerular and pulmonary alveolar basement membrane.

Anti-GBM disease commonly presents with hematuria, nephritic urinary sediment, subnephrotic proteinuria, and rapidly progressive renal failure over weeks, with or without pulmonary hemorrhage. When pulmonary hemorrhage occurs, it usually predates nephritis by weeks or months. Hemoptysis can vary from fluffy pulmonary infiltrates on chest x-ray and mild dyspnea on exertion to life-threatening pulmonary hemorrhage; hypertension is unusual.

The diagnostic serologic marker is circulating anti-GBM antibodies with a specificity for the NCI domain of the α3 chain of type IV collagen. Anti-GBM antibodies are detected in the serum of >90% of patients with anti-GBM nephritis by specific immunoassay. Renal biopsy is the gold standard for diagnosis of anti-GBM nephritis. The typical morphologic pattern on light microscopy is diffuse proliferative glomerulonephritis, with focal necrotizing lesions and crescents in >50% of glomeruli (crescentic glomerulonephritis). Immunofluorescence microscopy reveals linear ribbon-like deposition of IgG along the GBM (Fig. 264-3).

TREATMENT

Prior to the introduction of immunosuppressive therapy, >80% of patients with anti-GBM nephritis developed ESRD within 1 year, and many patients died from pulmonary hemorrhage or complications of uremia. With early and aggressive use of plasmapheresis, glucocorticoids, cyclophosphamide, and azathioprine, renal and patient survival have improved dramatically. In general, emergency plasmapheresis is performed daily or on alternate days until anti-GBM antibodies are not detected in the circulation (usually 1 to 2 weeks). Prednisone (1 mg/kg per day) is started simultaneously, in combination with either cyclophosphamide (2 to 3 mg/kg per day) or azathioprine (1 to 2 mg/kg per day) to suppress new synthesis of anti-GBM antibodies. The speed of initiation of therapy is a critical determinant of outcome. One-year renal survival approaches 90% if treatment is started before serum creatinine exceeds 442 μmol/L (5 mg/dL) and falls to about 10% if renal failure is more advanced. Patients who require dialysis at presentation rarely recover renal function. Serial anti-GBM titers are monitored to gauge response to therapy. Relapses are not unusual and are often heralded by rising antibody titers. In patients with ESRD, renal transplantation is a viable treatment option. Recurrence of anti-GBM nephritis in the allograft is extremely unusual provided that anti-GBM antibody titers have been consistently negative for 6 to 12 months prior to transplantation. However, in occasional patients with Alport's syndrome, when the allograft presents normal GBM components to the immune system of the recipient for the first time, anti-GBM nephritis can occur de novo in renal allografts.

NEPHRITIC SYNDROME AND RPGN DUE TO PAUCI-IMMUNE GLOMERULONEPHRITIS The major pauci-immune glomerulonephritides are *idiopathic renal-limited crescentic glomerulonephritis*, *microscopic polyangiitis nodosa* (PAN), and *Wegener's granulomatosis* (Figs. 264-1 to 264-3). Significant glomerular disease may also complicate the Churg-Strauss syndrome and classic forms of PAN, albeit less frequently than the aforementioned three conditions. RPGN is a more common clinical presentation than acute nephritic syndrome, and the usual pathology is necrotizing glomerulonephritis with crescents affecting 50% of glomeruli (crescentic glomerulonephritis). The marked overlap of clinical features and glomerular histopathology, and the presence of circulating ANCA in most patients, suggest that these entities are a spectrum of a single disease. Indeed this group of diseases is frequently categorized under the all-encompassing term *ANCA-associated small vessel vasculitis*. They are more common in whites and older patients (mean age 57 years) and typically present with nonspecific constitutional symptoms and signs such as lethargy, malaise, anorexia, weight loss, fever, arthralgias, and myalgias. Nonspecific laboratory abnormalities include a rapid sedimentation rate, elevated C-reactive protein, leukocytosis, thrombocytosis, and normochromic, normocytic anemia. Serum complement levels are typically normal.

ANCA-Associated Renal Disease Patients with ANCA-associated renal disease usually present with a nephritic urine sediment and subnephrotic proteinuria. Renal dysfunction can vary from a mild decrement in GFR to RPGN. Renal biopsy typically reveals focal, segmental, necrotizing glomerulonephritis with crescent formation. Immunofluorescence and electron microscopy are remarkable for the paucity or absence of immunoglobulin, complement, and immune deposits: hence the term *pauci-immune glomerulonephritis*.

Idiopathic Renal-Limited Crescentic Glomerulonephritis This is more common in middle-aged and older patients and shows a slight male preponderance. Patients typically present with RPGN, nephritic syndrome being rare. ANCA, usually a perinuclear ANCA IgG with specificity for myeloperoxidase, are detected in 70 to 90% of patients. The erythrocyte sedimentation rate and C-reactive protein levels may be elevated; however, C3 levels are typically normal, and circulating immune complexes, cryoglobulins, and anti-GBM antibodies are not detected. Most patients have crescents on light microscopy, often associated with necrotizing glomerulonephritis. Immune deposits are scanty or absent. Immunofluorescence microscopy reveals abundant fibrin deposits within crescents (Fig. 264-3).

Wegener's Granulomatosis (See also Chap. 306) Renal injury occurs in 80% of patients with Wegener's granulomatosis and varies from indolent smoldering inflammation to rapidly progressive renal failure. Cytoplasmic ANCA are detected at presentation in 80% of patients with renal disease and in 10% more on follow-up. Renal biopsy typically reveals focal, segmental, necrotizing pauci-immune glomerulonephritis with crescent formation. In contrast to the lung, granulomas are rarely seen in the kidney.

Microscopic Polyangiitis Nodosa (See also Chap. 306) Microscopic PAN is a systemic disease characterized by leukocytoclastic vasculitis involving multiple organ systems including the lungs, skin, joints, and kidneys. Clinical renal disease ranges from a nephritic urinary sediment with mild impairment of GFR to RPGN. The usual histopathologic lesion is pauci-immune focal segmental necrotizing and crescentic glomerulonephritis. Circulating ANCA are detected in 70 to 80% of patients at presentation, with cANCA or pANCA being equally prevalent.

Churg-Strauss Syndrome (See also Chap. 306) Clinical renal involvement in Churg-Strauss syndrome is relatively infrequent and usually limited to mild proteinuria and hematuria. Evolution to chronic renal

failure is rare. Renal biopsy most frequently reveals extraglomerular pathology, with involvement of the renal vasculature and tubulointerstitium by granulomatous vasculitis. Focal segmental glomerulonephritis with crescents is also seen. A minority of patients have focal segmental necrotizing glomerulonephritis.

CLASSIC POLYANGIITIS NODOSA AND LARGE VESSEL VASCULITIDES (See also Chap. 306) In contrast to the small vessel vasculitides discussed above, it is unusual to detect ANCA in classic PAN and the major large-vessel vasculitides. The typical glomerular lesion in classic PAN is ischemic collapse and obsolescence. Characteristic clinical and serologic features are hypertension, a bland urine sediment with subnephrotic proteinuria, slowly progressive renal insufficiency, normal serum complement levels, and absence of ANCA. Glomerular involvement is exceedingly rare in the major large vessel vasculitides such as Takayasu's disease and giant cell arteritis.

TREATMENT

Glucocorticoids and cyclophosphamide are the mainstays of treatment and dramatically ameliorate glomerular injury in pauci-immune glomerulonephritis. Steroids are usually administered initially by pulse intravenous therapy on three consecutive days, followed by a daily oral dose of about 1 mg/kg body weight tapered to a maintenance doses of 5 to 10 mg every day or alternate day over 3 to 6 months. Cyclophosphamide is typically administered orally at a daily dose of 1 to 2 mg/kg or as six monthly intravenous pulses of 1 g/m^2 of body surface area followed by pulses every 3 months for a maximum of 1 to 2 years. Alternatively, patients are switched from cyclophosphamide to either azathioprine or mycophenolate after 6 months in an effort to avoid cyclophosphamide toxicity and treatment is continued for a total duration of at least 1 year. Plasmapheresis may be a useful adjunct in patients with severe nephritis requiring dialysis. As many as 30% of patients relapse after treatment-induced remission. As with all patients receiving potent immunosuppressive therapy, the benefits of immunosuppression must be balanced against the risk of toxicity, and factors such as patient age co-morbidity, and the intensity of the vasculitic process must be taken into account. A persistently elevated or rising ANCA titer may predict relapse in individual patients; however, this relationship is not strong enough to justify treatment based on titers alone. Recent studies demonstrate that administration of trimethoprim-sulfamethoxazole reduces the relapse rate, possibly by eradicating nasal carriage of *Staphylococcus aureus*. Dialysis and renal transplantation afford excellent survival in patients with ESRD. Recurrence of Wegener's granulomatosis in the allograft is rare. ACE inhibitors may help to slow the progression to end-stage renal failure.

NEPHROTIC SYNDROME

Proteinuria >150 mg per 24 h is abnormal and can result from a number of mechanisms. *Glomerular proteinuria* results from leakage of plasma proteins through a perturbed glomerular filtration barrier; *tubular proteinuria* results from failure of tubular reabsorption of low-molecular-weight plasma proteins that are normally filtered and then reabsorbed and metabolized by tubular epithelium; *overflow proteinuria* results from filtration of proteins, usually immunoglobulin light chains, that are present in excess in the circulation. Tubular proteinuria virtually never exceeds 2 g per 24 h and thus, by definition, never causes nephrotic syndrome. Overflow proteinuria should be suspected in patients with clinical or laboratory evidence of multiple myeloma or other lymphoproliferative malignancy. Suspicion is heightened when there is a discrepancy between proteinuria detected by dipstick, the latter being sensitive to albumin but not light chains, and the sulfosalicylic acid precipitation method, which detects both.

DEFINITION The *nephrotic syndrome* is a clinical complex characterized by a number of renal and extrarenal features, the most prominent of which are proteinuria of >3.5 g per 1.73 m^2 per 24 h (in practice, >3.0 to 3.5 g per 24 h), hypoalbuminemia, edema, hyperlipidemia, lipiduria, and hypercoagulability. Nephrotic syndrome can complicate any disease that perturbs the negative electrostatic charge or architecture of the GBM and the podocytes and their slit diaphragms. Recent attention has focused on several key molecules that mediate GBM-podocyte-slit diaphragm interactions such as nephrin, podocin, and alpha-actinin-4. Six entities account for >90% of cases of nephrotic syndrome in adults: minimal change disease (MCD), focal and segmental glomerulosclerosis (FSGS), membranous glomerulopathy, membranoproliferative glomerulonephritis (MPGN), diabetic nephropathy, and amyloidosis. *Renal biopsy* is a valuable tool in adults with nephrotic syndrome for establishing a definitive diagnosis, guiding therapy, and assessing prognosis. Renal biopsy is not required in the majority of children with nephrotic syndrome as most cases are due to MCD and respond to empirical treatment with glucocorticoids.

It should be stressed that the key component of nephrotic syndrome is *proteinuria*, which results from altered permeability of the glomerular filtration barrier for protein, namely the GBM and the podocytes and their slit diaphragms. The other components of the nephrotic syndrome and the ensuing metabolic complications are all secondary to urine protein loss and can occur with lesser degrees of proteinuria or may be absent even in patients with massive proteinuria.

PATHOPHYSIOLOGY In general, the greater the proteinuria, the lower the serum albumin level. *Hypoalbuminemia* is compounded further by increased renal catabolism and inadequate, albeit usually increased, hepatic synthesis of albumin. The pathophysiology of *edema* formation in nephrotic syndrome is poorly understood. The *underfilling hypothesis* postulates that hypoalbuminemia results in decreased intravascular oncotic pressure, leading to leakage of extracellular fluid from blood to the interstitium. Intravascular volume falls, thereby stimulating activation of the renin-angiotensin-aldosterone axis and the sympathetic nervous system and release of vasopressin (antidiuretic hormone), and suppressing atrial natriuretic peptide release. These neural and hormonal responses promote renal salt and water retention, thereby restoring intravascular volume and triggering further leakage of fluid to the interstitium. This hypothesis does not, however, explain the occurrence of edema in many patients in whom plasma volume is expanded and the renin-angiotensin-aldosterone axis is suppressed. The latter finding suggests that *primary renal salt and water retention* may also contribute to edema formation in some cases.

Hyperlipidemia is believed to be a consequence of increased hepatic lipoprotein synthesis that is triggered by reduced oncotic pressure and may be compounded by increased urinary loss of proteins that regulate lipid homeostasis. Defective lipid catabolism is also thought to play an important role. Low-density lipoproteins and cholesterol are increased in the majority of patients, whereas very low density lipoproteins and triglycerides tend to rise in patients with severe disease. Although not proven conclusively, hyperlipidemia may accelerate atherosclerosis and progression of renal disease.

Hypercoagulability is probably multifactorial in origin and is caused, at least in part, by increased urinary loss of antithrombin III, altered levels and/or activity of proteins C and S, hyperfibrinogenemia due to increased hepatic synthesis, impaired fibrinolysis, and increased platelet aggregability. As a consequence of these perturbations, patients can develop spontaneous *peripheral arterial or venous thrombosis*, *renal vein thrombosis*, and *pulmonary embolism*. Clinical features that suggest acute renal vein thrombosis include sudden onset of flank or abdominal pain, gross hematuria, a left-sided varicocele (the left testicular vein drains into the renal vein), increased proteinuria, and an acute decline in GFR. Chronic renal vein thrombosis is usually asymptomatic. Renal vein thrombosis is particularly common (up to 40%) in patients with nephrotic syndrome due to membranous glomerulopathy, membranoproliferative glomerulonephritis, and amyloidosis.

Other metabolic complications of nephrotic syndrome include *protein malnutrition* and iron-resistant *microcytic hypochromic anemia* due to transferrin loss. *Hypocalcemia* and secondary hyperparathyroidism can occur as a consequence of vitamin D deficiency due to

enhanced urinary excretion of cholecalciferol-binding protein, whereas loss of thyroxine-binding globulin can result in *depressed thyroxine levels*. An increased *susceptibility to infection* may reflect low levels of IgG that result from urinary loss and increased catabolism. In addition, patients are prone to unpredictable changes in the *pharmacokinetics* of therapeutic agents that are normally bound to plasma proteins.

TREATMENT

GENERAL MANAGEMENT OF NEPHROTIC SYNDROME AND COMPLICATIONS The treatment of nephrotic syndrome involves (1) specific treatment of the underlying morphologic entity and, when possible, causative disease (see above); (2) general measures to control proteinuria if remission is not achieved through immunosuppressive therapy and other specific measures; and (3) general measures to control nephrotic complications.

General measures may be warranted to control proteinuria in nephrotic syndrome if patients do not respond to immunosuppressive therapy and other specific measures and suffer progressive renal failure or severe nephrotic complications. Nonspecific measures that may reduce proteinuria include ACE inhibitors, ARBs, and nonsteroidal anti-inflammatory drugs (NSAIDs). ACE inhibitors and ARBs reduce proteinuria and slow the rate of progression of renal failure by lowering intraglomerular pressure and preventing the development of hemodynamically mediated focal segmental glomerulosclerosis. There is conclusive evidence that these drugs are renoprotective in human diabetic nephropathy and many other proteinuric glomerulopathies, including secondary FSGS. NSAIDs also reduce proteinuria in some patients with nephrotic syndrome, probably by altering glomerular hemodynamics and GBM permeability characteristics. This potential benefit must be balanced against the risk of inducing acute renal failure, hyperkalemia, salt and water retention, and other side effects.

Complications of nephrotic syndrome that may require treatment include edema, hyperlipidemia, thromboembolism, malnutrition, and vitamin D deficiency. Edema should be managed cautiously by moderate *salt restriction*, usually 1 to 2 g per day, and the judicious use of *loop diuretics*. It is unwise to remove >1.0 kg of edema per day without close monitoring as more aggressive diuresis may precipitate intravascular volume depletion and prerenal azotemia. Administration of salt-poor albumin is not recommended as most is excreted within 24 to 48 h. Whereas many nephrologists advocate lowering low-density lipoproteins and cholesterol levels with *lipid-lowering drugs*, specifically HMG CoA reductase inhibitors to prevent accelerated atherosclerosis and possibly slow the rate of decline of GFR, the value of such interventions in this setting has not been conclusively shown.

Anticoagulation is indicated for patients with deep venous thrombosis, arterial thrombosis, and pulmonary embolism. Patients may be relatively resistant to heparin as a consequence of antithrombin III deficiency. Renal vein and vena caval angiography are probably indicated only when embolization occurs on anticoagulation and insertion of a caval filter is contemplated. There is no consensus regarding the optimal *diet* for patients with nephrotic syndrome. High-protein diets to prevent protein malnutrition are now in disfavor, since protein supplements have little, if any, effect on serum albumin levels and may hasten the progression of renal disease by increasing urinary protein excretion. The potential value of dietary protein restriction for reducing proteinuria must be balanced against the risk of contributing to malnutrition. *Vitamin D* supplementation is advisable in patients with clinical or biochemical evidence of vitamin D deficiency.

MINIMAL CHANGE DISEASE (MINIMAL CHANGE GLOMERULOPATHY) MCD accounts for about 80% of nephrotic syndrome in children younger than 16 years and 20% in adults (Table 264-3). The peak incidence is between 6 and 8 years. Patients typically present with nephrotic syndrome and benign urinary sediment. Microscopic hematuria is present in 20 to 30%. Hypertension and renal insufficiency are very rare.

MCD (also called nil disease, lipoid nephrosis, or foot process disease) is so named because glomerular size and architecture are normal by light microscopy. Immunofluorescence studies are typically negative for immunoglobulin and C3. The findings of mesangial hypercellularity and sparse deposits of C3 and IgM portend a worse prognosis. Electron microscopy reveals characteristic *diffuse effacement of the foot processes of visceral epithelial cells* (Fig. 264-4). This morphologic finding is referred to as foot process fusion in the older literature.

TABLE 264-3 Major Causes of Minimal Change Disease (Nil Disease, Lipoid Nephrosis)

Idiopathic (majority)
In association with systemic diseases or drugs
Drug-induced interstitial nephritis induced by NSAIDs, rifampin, interferon α
Hodgkin's disease and other lymphoproliferative malignancy
HIV infection

Note: NSAIDs, nonsteroidal anti-inflammatory drugs.

The etiology of MCD is unknown, and the vast majority of cases are idiopathic (Table 264-3). MCD occasionally develops after upper respiratory tract infection, immunizations, and atopic attacks. Patients with atopy and MCD have an increased incidence of HLA-B12, suggesting a genetic predisposition. MCD, often in association with interstitial nephritis, is a rare side effect of NSAIDs, rifampin, and interferon α. The occasional association with lymphoproliferative malignancies (such as Hodgkin's lymphoma), the tendency for idiopathic MCD to remit during intercurrent viral infection such as measles, and the good response of idiopathic forms to immunosuppressive agents (see below) suggest an immune etiology. In children, the urine contains albumin principally and minimal amounts of higher molecular weight proteins such as IgG and α_2-macroglobulin. This *selective proteinuria* in conjunction with foot process effacement suggests injury to podocytes and loss of the fixed *negative charge* in the glomerular filtration barrier for protein. Proteinuria is typically nonselective in adults, suggesting more extensive perturbation of membrane permeability. Mutations in nephrin, α-actinin-4, and podocin, molecules that pay central roles in the anchoring of podocytes together through their slit diaphragms and to the GBM, cause proteinuria and glomerular morphologic changes that are virtually identical to those observed with acquired MCD and FSGS. There is increasing evidence that the expression and/or function of these and related molecules is also perturbed in acquired MCD and FSGS.

TREATMENT

MCD is highly steroid-responsive and carries an excellent prognosis. Spontaneous remission occurs in 30 to 40% of childhood cases but is less common in adults. Approximately 90% of children and 50% of adults enter remission following 8 weeks of high-dose oral glucocorticoids. In a typical regimen using prednisone, children receive 60 mg/m^2 of body surface area daily for 4 weeks, followed by 40 mg/m^2 on alternate days for an additional 4 weeks; adults receive 1 to 1.5 mg/kg body weight per day for 4 weeks, followed by 1 mg/kg per day on alternate days for 4 weeks. Up to 90% of adults enter remission if therapy is extended for 20 to 24 weeks. Nephrotic syndrome relapses in over >50% of cases following withdrawal of glucocorticoids. Alkylating agents are reserved for the small number of patients who fail to achieve lasting remission. These include patients who relapse during or shortly after withdrawal of steroids (steroid-dependent) and those who relapse more than three times per year (frequently relapsing). In these settings, cyclophosphamide (2 to 3 mg/kg per day) or chlorambucil (0.1 to 0.2 mg/kg per day) is started after steroid-induced remission and continued for 8 to 12 weeks. Cytotoxic agents may also induce remission in occasional steroid-resistant cases. These benefits must be balanced against the risk of infertility, cystitis, alopecia, infection, and secondary malignancies, particularly in children and young adults. Azathioprine has not been proven to be a useful adjunct to steroid therapy. Cyclosporine induces remission in 60 to 80% of patients; it is an alternative to cytotoxic agents and an option in patients who are resistant to cytotoxic agents. Unfortunately, relapse is usual

C

FIGURE 264-4 Typical findings on electron microscopy of renal biopsy specimens from patients with minimal change glomerulopathy, membranous glomerulopathy, and membranoproliferative glomerulonephritis. The pathognomonic feature of minimal change glomerulopathy (*A*) is effacement of foot processes of visceral epithelial cells (podocytes), giving the impression of foot process fusion. Foot process effacement is also evident in focal and segmental glomerulosclerosis (not shown here); in addition, there is typically detachment of podocytes from basement membrane, areas of glomerular capillary collapse, deposits of hyaline material, and sclerosis. Membranous nephropathy (*B*) is characterized by immune complexes in the subepithelial space. These electron-dense immune deposits stimulate production of new GBM, which eventually surrounds and incorporates the immune deposits into the GBM. The hallmarks of type I membranoproliferative glomerulonephritis (*C*) are increased mesangial cellularity and matrix and thickening and reduplication of the GBM. The latter is initiated by formation of electron-dense immune complexes on the subendothelial aspect of the GBM, which are subsequently covered by a new layer of GBM, probably produced by regenerating endothelial cells. *(Micrographs courtesy of Dr. Helmut Rennke.)*

when cyclosporine is withdrawn, and long-term therapy carries the risk of nephrotoxicity and other side effects. Long-term renal and patient survival is excellent in MCD.

FOCAL AND SEGMENTAL GLOMERULOSCLEROSIS The pathognomonic morphologic lesion in FSGS is sclerosis with hyalinosis involving portions (segmental) of fewer than 50% (focal) of glomeruli on a tissue section. The incidence of idiopathic (primary) FSGS has increased over the past two decades so that it now accounts for about one-third of cases of nephrotic syndrome in adults and as many as one-half of cases of nephrotic syndrome in blacks. Secondary FSGS can complicate a number of systemic diseases and sustained glomerular capillary hypertension following nephron loss from any cause (Table 264-4).

Idiopathic FSGS typically presents as nephrotic syndrome (~66%) or subnephrotic proteinuria (~33%) in association with hypertension, mild renal insufficiency, and an abnormal urine sediment that contains red blood cells and leukocytes. Proteinuria is nonselective in most cases.

Light microscopy of renal biopsy tissue reveals FSGS with entrapment of amorphous hyaline material, a process that shows a predilection for juxtamedullary glomeruli. Electron microscopy reveals evidence of damage to visceral epithelial cell.

The etiology of primary FSGS is unclear, but appears to be, at least in part, immunologic. There is evidence that a circulating nonimmunoglobulin permeability factor, possibly a lymphokine, triggers FSGS in at least a subgroup of patients. Plasmapharesis has been employed with variable success to control the nephrotic syndrome in this group. Secondary FSGS is a potential long-term consequence of nephron loss from any cause. It can complicate congenital renal diseases such as congenital oligomeganephronia, in which both kidneys have a reduced complement of nephrons, and congenital unilateral agenesis. In addition, FSGS may develop following acquired loss of nephrons from extensive surgical ablation of renal mass; reflux nephropathy; glomerulonephritis; interstitial nephritis; sickle cell disease; and the combined effects of ischemia, cyclosporine nephrotoxicity, and rejection on renal allograft function (Table 264-4). It appears that >50% of nephrons must be lost for development of secondary FSGS.

TABLE 264-4 Etiology of Focal and Segmental Glomerulosclerosis

Idiopathic (majority)
In association with systemic diseases or drugs
HIV infection
Diabetes mellitus
Fabry's disease
Sialidosis
Charcot-Marie-Tooth disease
As consequence of sustained glomerular capillary hypertension
Congenital oligonephropathies
Unilateral renal agenesis
Oligomeganephronia
Acquired nephron loss
Surgical resection
Reflux nephropathy
Glomerulonephritis or tubulointerstitial nephritis
Other adaptive responses
Sickle cell nephropathy
Obesity with sleep apnea syndrome
Familial dysautonomia
Miscellaneous
Heroin use

TREATMENT

Spontaneous remission of primary FSGS is rare and renal prognosis is relatively poor. Proteinuria remits in only 20 to 40% of patients treated with glucocorticoids for 8 weeks. Uncontrolled studies suggest that up to 70% respond when steroid therapy is prolonged for 16 to 24 weeks. Cyclophosphamide and cyclosporine, when used at doses described above for MCD, induce partial or complete remission in 50 to 60% of steroid-responsive patients but are generally ineffective in steroid-resistant cases. Mycophenolate mofetil is another option in resistant cases. Poor prognostic factors at presentation include hypertension, abnormal renal function, black race, and persistent heavy proteinuria. Renal transplantation is complicated by recurrence of FSGS in the allograft in about 50% of cases and graft loss in about 10%. Factors associated with an increased risk of recurrence include a short time interval between the onset of the FSGS and ESRD, young age at onset, and possibly the presence of mesangial hypercellularity on renal biopsy.

MEMBRANOUS GLOMERULOPATHY (MEMBRANOUS NEPHROPATHY) This morphologic lesion is a leading cause of idiopathic nephrotic syndrome in adults (30 to 40%) and a rare cause in children (<5%). It has a peak incidence between the ages of 30 to 50 years and a male-female ratio of 2:1 (Fig. 264-4 and Table 264-5). Membranous glomerulopathy derives its name from the characteristic light-microscopic appearance on renal biopsy, namely diffuse thickening of the GBM, which is most apparent upon staining with periodic acid–Schiff (PAS). Most patients (>80%) present with nephrotic syndrome, proteinuria usually being nonselective. Microscopic hematuria is present in up to 50% of cases. Hypertension is documented in only 10 to 30% of patients at the outset but is common later in patients with progressive renal failure. Serologic tests such as antinuclear antibody, ANCA, anti-GBM antibody, cryoglobulin titers, and complement levels are normal in the idiopathic form.

Light microscopy of renal biopsy sections reveals diffuse thickening of the GBM without evidence of inflammation or cellular proliferation. Immunofluorescence reveals granular deposition of IgG, C3, and the terminal components of complement (C5b–9) along the glomerular capillary wall.

The pathogenesis of idiopathic human membranous glomerulopathy is incompletely understood. The presence of electron-dense immune deposits that contain IgG and C3 suggest an immune process. About one-third of adult membranous nephropathy occurs in association with systemic diseases such as SLE, infections such as hepatitis B, malignancy, and drug therapy with gold and penicillamine (Table 264-5).

TABLE 264-5 Conditions Associated with Membranous Glomerulopathy

Idiopathic (majority)
In association with systemic diseases or drugs
Infection
Hepatitis B and C, secondary and congenital syphilis, malaria, schistosomiasis, leprosy, hydatid disease, filariasis, enterococcal endocarditis
Systemic autoimmune diseases
SLE, rheumatoid disease, Sjögren's syndrome, Hashimoto's disease, Graves' disease, mixed connective tissue disease, primary biliary cirrhosis, ankylosing spondylitis, dermatitis herpetiformis, bullous pemphigoid, myasthenia gravis
Neoplasia
Carcinoma of the breast, lung, colon, stomach, and esophagus; melanoma; renal cell carcinoma; neuroblastoma; carotid body tumor
Drugs
Gold, penicillamine, captopril, NSAIDs, probenecid, trimethadione, chlormethiazole, mercury
Miscellaneous
Sarcoidosis, diabetes mellitus, sickle cell disease, Crohn's disease, Guillain-Barré syndrome, Weber-Christian disease, Fanconi's syndrome, α_1 antitrypsin deficiency, angiofollicular lymph node hyperplasia

Note: SLE, systemic lupus erythematosus; NSAIDs, nonsteroidal anti-inflammatory drugs.

Nephrotic syndrome remits spontaneously and completely in up to 40% of patients. The natural history of another 30 to 40% is characterized by repeated relapses and remissions. The final 10 to 20% suffer a slow progressive decline in GFR that typically culminates in ESRD after 10 to 15 years. Presenting features that predict a poor prognosis include male gender, older age, hypertension, severe proteinuria and hyperlipidemia, and impaired renal function. Controlled trials of glucocorticoids have failed to show consistent improvement in proteinuria or renal protection. Cyclophosphamide, chlorambucil, and cyclosporine have each been shown to reduce proteinuria and/or slow the decline in GFR in patients with progressive disease in small or uncontrolled studies. These observations need to be confirmed in controlled prospective studies. Transplantation is a successful treatment option for patients who reach ESRD.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS This morphologic entity, also known as mesangiocapillary glomerulonephritis, is characterized by thickening of the GBM and proliferative changes on light microscopy (Fig. 264-4 and Table 264-6). Two major types are identified; both are characterized by a diffuse increase in mesangial cellularity and matrix, and by thickening and reduplication of the GBM such that the lobular pattern of the glomerular tuft is exaggerated. The hallmark of type I MPGN is the presence of subendothelial and mesangial deposits on electron microscopy that contain C3 and IgG or IgM; rarely, IgA deposits are demonstrated by immunofluorescence microscopy. The hallmark of type II MPGN (dense deposit disease) is the presence of electron-dense deposits within the GBM and other renal basement membranes (shown by electron microscopy) that stain for C3, but little or no immunoglobulin.

Most patients with type I MPGN present with heavy proteinuria or nephrotic syndrome, active urinary sediment, and normal or mildly impaired GFR. C3 levels are usually depressed, and C1q and C4 levels are borderline or low. Type I MPGN is an immune-complex glomerulonephritis and can be associated with a variety of chronic infections (e.g., bacterial endocarditis, HIV, hepatitis B and C), systemic immune-complex diseases (e.g., SLE, cryoglobulinemia), and malignancies (e.g., leukemias, lymphomas). Type I MPGN usually has a protracted course, and as many as 50% of patients reach ESRD by 10 years. There is no proven therapy for patients with progressive disease beyond eradicating the underlying infection, malignancy, or systemic disease, when possible. The incidence of type I MPGN appears to be falling, possibly because the overall incidence of HCV infection has fallen dramatically in western society over the past decade.

TABLE 264-6 Causes of Membranoproliferative (Mesangiocapillary) Glomerulonephritis (MPGN)

Idiopathic	
Type I	With subendothelial and mesangial immune deposits
Type II	With intramembranous dense deposits containing sparse or no Ig; associated with C3 nephritic factor
Type III	Features of type I MPGN and membranous nephropathy
In association with systemic diseases or drugs[a]	
Systemic immune-complex disease	SLE, mixed cryoglobulinemia, Sjögren's syndrome
Chronic infections	Hepatitis B and C, HIV, bacterial endocarditis, ventriculoatrial shunts, visceral abscess
Malignancy	Leukemias, lymphomas
Liver disease	Chronic active hepatitis and cirrhosis (usually associated with hepatitis B or C)
Miscellaneous	Partial lipodystrophy, heroin use, sarcoidosis, inherited C2 deficiency, thrombotic microangiopathies

[a] Usual with morphologic features of idiopathic type I MPGN (see above).
Note: SLE, systemic lupus erythematosus.

Type II MPGN can also present with proteinuria and nephrotic syndrome; however, some patients present with nephritic syndrome, RPGN, or recurrent macroscopic hematuria. Type II MPGN is an autoimmune disease in which patients have an IgG autoantibody, termed *C3 nephritic factor*, that binds to C3 convertase, the enzyme that metabolizes C3, and renders it resistant to inactivation. Type II MPGN runs a variable course; the GFR remains stable in some patients and declines gradually to ESRD over 5 to 10 years in others. There is no effective therapy for this disease, which may be associated with partial lipodystrophy, although corticosteroids are sometimes used.

A third, rarer form of MPGN is associated with subepithelial immune deposits. It should be noted that a membranoproliferative pattern of glomerular injury may also complicate thrombotic microangiopathies (e.g., antiphospholipid antibody syndrome, chronic allograft rejection, healing phase of hemolytic-uremic syndrome, or thrombotic thrombocytopenic purpura) and glomerular deposition disease (e.g., fibrillary glomerulopathy—see below).

MESANGIOPROLIFERATIVE GLOMERULONEPHRITIS In 5 to 10% of patients with idiopathic nephrotic syndrome, renal biopsy reveals a diffuse increase in glomerular cellularity, predominantly due to proliferation of mesangial and endothelial cells, and infiltration by monocytes. Findings on immunofluorescence microscopy vary and include deposits of IgA, IgG, IgM, and/or complement, or absence of immune reactants. It is likely that this morphologic entity is, in fact, a heterogeneous group of diseases that includes atypical forms of MCD and FSGS and milder or resolving forms of the immune-complex and pauci-immune glomerulopathies described above under nephritic syndrome and RPGN. In keeping with the heterogeneity of this diagnosis, the prognosis is variable. In general, persistent nephrotic-range proteinuria signals a poor prognosis, with many patients progressing to ESRD over 10 to 20 years despite immunosuppressive therapy.

DIABETIC NEPHROPATHY (See also Chap. 323) Diabetic nephropathy is the leading cause of ESRD in western societies and accounts for 30 to 35% of patients on renal replacement therapy in North America. Type 1 diabetes mellitus (DM; formerly, insulin-dependent diabetes mellitus) and type 2 DM (formerly, non-insulin-dependent diabetes mellitus) affect approximately 0.5 and 4% of the population, respectively. Nephropathy complicates 30% of cases of type 1 DM and approximately 20% of cases of type 2 DM. However, most diabetic patients with ESRD have type 2 DM because of the greater prevalence of type 2 DM worldwide (90% of all individuals with diabetes). Risk factors for the development of diabetic nephropathy include hyperglycemia, systemic hypertension, glomerular hypertension and hyperfiltration, proteinuria, and possibly cigarette smoking, hyperlipidemia, and gene polymorphisms affecting the activity of the renin-angiotensin-aldosterone axis. For reasons that are unclear, ESRD from diabetic nephropathy is more common in blacks with type 2 DM than in whites (4:1 ratio), whereas the reverse is true for type 1 DM.

Pathophysiology The pathophysiology, clinical features, and morphology of diabetic nephropathy appears similar in type 1 and type 2 DM, although the true incidence and precise time course of nephropathy in type 2 DM is still debated. Glomerular hypertension and hyperfiltration are the earliest renal abnormalities in experimental and human diabetes and are observed within days to weeks of diagnosis. Microalbuminuria, so named because the abnormal albumin excretion of 30 to 300 mg/24 h is below the limits of detection of standard dipsticks, develops after approximately 5 years of sustained glomerular hypertension and hyperfiltration in type 1 DM.

Microalbuminuria is the first manifestation of injury to the glomerular filtration barrier and predicts the development of overt nephropathy. Dipstick-positive proteinuria, ultimately reaching nephrotic levels, typically develops 5 to 10 years after the onset of microalbuminuria (i.e., 10 to 15 years after the onset of diabetes) and is associated with hypertension and progressive loss of renal function. In addition, patients can display features of tubulointerstitial disease such as hyperkalemia and type IV renal tubular acidosis. ESRD typically develops 5 to 10 years after the development of overt nephropathy. As noted above, the course of diabetic nephropathy may be shorter in type 2 DM, and many patients present with established nephropathy and hypertension. Diabetic nephropathy is usually diagnosed on clinical grounds without a renal biopsy. Supportive clues are the presence of normal sized or enlarged kidneys, evidence of proliferative diabetic retinopathy, and a bland urinary sediment. Retinopathy is found in 90% and 60% of patients with type 1 and type 2 DM, respectively, who develop nephropathy.

Pathologic Changes The earliest morphologic abnormalities in diabetic nephropathy are thickening of the GBM and expansion of the mesangium due to accumulation of extracellular matrix. With time, matrix accumulation becomes diffuse and is evident as eosinophilic, PAS-positive glomerulosclerosis on renal biopsy. Prominent areas of nodular matrix expansion (nodular glomerulosclerosis, the classic Kimmelsteil-Wilson lesion) are often superimposed on this background. The glomeruli and kidneys are typically normal or increased in size, distinguishing diabetic nephropathy from most other forms of chronic renal insufficiency (renal amyloidosis and polycystic kidney disease being other important exceptions). Immunofluorescence microscopy may reveal deposition of IgG along the GBM in a linear pattern, but this does not appear to be immunopathogenetic as in anti-GBM disease. Immune deposits are not seen. The renal vasculature typically displays evidence of atherosclerosis, as a consequence of hyperlipidemia, and hypertensive arteriosclerosis.

Factors implicated as triggers for increased matrix production in DM include glomerular hypertension; the direct effects of hyperglycemia on mesangial cells; advanced glycosylation end-products; growth factors such as growth hormone, insulin-like growth factor 1, angiotensin II, CTGF; cytokines such as TGF-β; hyperlipidemia; and cell sorbitol accumulation. Complementary clinical and laboratory approaches suggest an important role for hemodynamic factors. Glomerular hydrostatic pressure and GFR increase within months of the development of hyperglycemia. The mechanism by which DM induces glomerular hypertension is still being defined and appears to involve circulating factors such as atrial natriuretic peptide acting in concert with the direct effects of high glucose on the actin cytoskeleton of renal mesangial and vascular smooth-muscle cells.

In this framework, glycosuria triggers increased reabsorption of glucose coupled to sodium in the proximal tubule, thereby increasing total-body sodium and extracellular fluid volume. As a compensatory response, atrial natriuretic peptide is released from cardiac myocytes and induces natriuresis in part by triggering afferent arteriolar dilatation and thereby increasing intraglomerular pressure and GFR. Whereas this compensatory response is appropriate in the short term, sustained glomerular hypertension provokes thickening of the GBM, increased mesangial matrix production, and glomerulosclerosis and disruption of barrier function. Exposure of mesangial cells and vascular smooth-muscle cells to high glucose in vitro and in vivo results in disruption of the actin cytoskeleton, possibly through the action of reactive oxygen species, rendering the cells relatively unresponsive to vasoconstrictors and further contributing to afferent arteriolar vasodilatation and glomerular hypertension. In keeping with a central role for intraglomerular pressure in the pathogenesis of diabetic nephropathy, ACE inhibitors and ARBs, which lower intraglomerular pressure, slow the progression of diabetic nephropathy, even in normotensive patients.

It remains to be determined why DM and glomerular hypertension induce glomerulosclerosis in some but not all individuals. Epidemiologic studies and studies of disease concordance in identical twins suggest that important, but as yet unidentified, genetic factors may play a role. It is likely that hemodynamic and metabolic factors act in concert to generate the final glomerulosclerotic phenotype in genetically predisposed patients.

TREATMENT

Therapy is aimed at retarding the progression of nephropathy through control of blood sugar, systemic blood pressure, and glomerular capillary pressure. Glycemic control is achieved through regulation of diet and administration of oral hypoglycemic agents and insulin. ACE inhibitors and ARBs are the drugs of choice as they control both systemic hypertension and intraglomerular hypertension by inhibiting the actions of angiotensin II on the systemic vasculature and renal efferent arterioles. In addition, these agents also attenuate the stimulatory effect of angiotensin II on glomerular cell growth and matrix production. Because ACE inhibitors conclusively delayed the time to ESRD by 50% in patients with type 1 DM in several randomized controlled trials and probably delay progression in type 2 DM, it is recommended that all patients with diabetes over the age of 12 should be screened annually for microalbuminuria and should receive an ACE inhibitor on the development of microalbuminuria, even in the absence of systemic hypertension. ARBs slowed the rate of progression of diabetic nephropathy in patients with type 2 DM in two recent randomized controlled trials and are an alternative to ACE inhibitors for renoprotection. Approximately 80% of patients with DM require more than one drug to control systemic hypertension, and aggressive lowering of blood pressure in these patients retards the rate of progression of nephropathy and other diabetic complications.

Diabetic nephropathy is the most common cause of ESRD requiring renal replacement therapy, and patients with DM have the highest annual mortality rate (20 to 30%) of any group on dialysis, in large part as a result of accelerated atherosclerosis. The survival rates of younger patients undergoing either peritoneal dialysis or hemodialysis are comparable; however, older patients with DM appear to have a higher mortality rate on peritoneal dialysis. Renal transplantation, with or without pancreas transplantation, is the preferred mode of renal replacement therapy in patients who are otherwise medically suitable.

GLOMERULAR DEPOSITION DISEASES The glomerular deposition diseases are characterized by deposition of abnormal proteins, usually immunoglobulins or fragments thereof, within the glomerulus. They include amyloidosis, light and heavy chain deposition disease, cryoglobulinemia, and fibrillary/immunotactoid glomerulonephritis below.

Renal Amyloidosis Amyloidosis is classified according to the major component of its fibrils (Chap. 310). There is substantial overlap in the renal clinicopathologic presentations of amyloid (AL) and amyloid A (AA) disease. Glomeruli are involved in 75 to 90% of patients, usually in association with involvement of other organs. The clinical correlate of glomerular amyloid deposition is nephrotic-range proteinuria. In addition, >50% of patients have impaired glomerular filtration at diagnosis. Hypertension is present in about 20 to 25%. Renal size is usually normal or slightly enlarged. A minority of patients present with renal failure due to amyloid deposition in the renal vasculature or with Fanconi's syndrome, nephrogenic diabetes insipidus, or renal tubular acidosis due to involvement of the tubulointerstitium. Rectal biopsy and abdominal fat pad biopsy reveal amyloid deposits in about 70% of patients and may obviate the need for renal biopsy.

Renal biopsy gives a very high yield if there is clinical evidence of renal involvement. The earliest pathologic changes are mesangial expansion by amorphous hyaline material and thickening of the GBM. Further amyloid deposition results in the development of large nodular eosinophilic masses. When stained with Congo red, these deposits show apple-green birefringence under polarized light. Electron microscopy reveals the characteristic nonbranching extracellular amyloid fibrils of 7.5 to 10 nm in diameter. Tubulointerstitial and vascular deposits of amyloid are also seen and may occasionally be more prominent than glomerular deposits.

TREATMENT

Most patients with renal involvement by AL amyloidosis develop ESRD within 2 to 5 years. No treatment has been shown consistently to improve this prognosis; however, some success has been reported with a combination of melphalan and prednisone. Preliminary studies have reported a benefit of high-dose melphalan with autologous stem cell transplantation. Colchicine delays the onset of nephropathy in patients with familial Mediterranean fever but has not proved useful in patients with established disease or with other forms of amyloid. Remissions may be achieved in AA amyloidosis by eradication of the underlying cause. Renal replacement therapy is offered to patients who reach ESRD; however, the 1-year survival rate on dialysis is low (~66%) by comparison with other causes of ESRD. Most patients die from extrarenal complications, particularly cardiovascular disease. Renal transplantation is a viable option in patients with AA amyloidosis whose primary disease has been eradicated. Transplantation is also an option for patients with AL amyloidosis, although a poor prognosis because of extrarenal organ involvement may preclude them as candidates. Here again, the survival rate is lower by comparison with other causes of ESRD; most of the excess mortality is due to infectious and cardiovascular complications. Recurrence of amyloidosis in the allograft is common but rarely leads to graft loss.

LIGHT CHAIN DEPOSITION DISEASE (LCDD) (See also Chap. 98) Renal involvement is a complication in 90% of patients with LCDD and is often the dominant feature. Nephrotic syndrome and renal impairment are the usual presenting features. Microscopic hematuria occurs in about 20% of patients. Defective hydrogen ion and potassium excretion and urinary concentration may be evident if light chains are deposited predominantly in the tubules. The most common pathologic lesion on renal biopsy is ribbon-like thickening of the tubular basement membrane due to light chain deposition. Mesangial expansion and nodular glomerulosclerosis are found in about 33% of patients. This light-microscopic appearance resembles that of idiopathic membranoproliferative glomerulonephritis and diabetic nephropathy. Superimposed crescentic change is occasionally seen. Immunofluorescence studies are strongly positive for monoclonal light chains, in contrast to AL amyloid, because the constant region of the immunoglobulin is typically deposited. The tissue deposits in LCDD are granular rather than fibrillar on electron microscopy, appear more amorphous in character, do not stain with Congo red, and seem to have a greater affinity for basement membranes.

The prognosis of LCDD is poor when it is associated with multiple myeloma, and most patients progress rapidly to ESRD. Treatment with melphalan and prednisone has been reported to reduce proteinuria and stabilize renal function in uncontrolled studies. In the absence of myeloma, the prognosis is somewhat more variable, and several patients have undergone successful renal transplantation.

WALDENSTRÖM'S MACROGLOBULINEMIA (See also Chap. 98) This disorder is characterized by monoclonal proliferation of an IgM-secreting clone of plasma cells. The circulating IgM paraprotein frequently gives rise to the hyperviscosity syndrome, which may compromise renal blood flow and GFR. Direct renal involvement is rare and, when present, involves deposition of large amorphous deposits of eosinophilic material in the glomerular capillaries. Renal amyloidosis can also occur.

FIBRILLARY-IMMUNOTACTOID GLOMERULOPATHY This emerging clinicopathologic entity accounts for 1% of diagnoses in most large renal biopsy series. Virtually all patients present with proteinuria, and ~50% have nephrotic syndrome. The majority of patients also have hematuria, hypertension, and renal insufficiency. The light-microscopic appearances vary from mesangial expansion and basement membrane thickening with PAS-positive material to proliferative and crescentic glomerulonephritis. On electron microscopy, this PAS-pos-

itive material is observed to be composed of randomly arranged (fibrillary glomerulopathy) or organized bundles (immunotactoid glomerulopathy) of microfibrils and microtubules, the composition of which has yet to be defined. The etiology of fibrillary-immunotactoid glomerulopathy remains to be determined. Patients with the immunotactoid variant have an increased incidence of lymphoproliferative malignancy. There is no proven therapy for fibrillary-immunotactoid glomerulopathy, and many patients progress to ESRD over 1 to 10 years. Transplantation appears to be a viable option in the latter setting.

ASYMPTOMATIC ABNORMALITIES OF THE URINARY SEDIMENT

Many cases of glomerular disease are diagnosed when asymptomatic hematuria or proteinuria are detected on routine examination of the urinary sediment as part of preemployment or insurance-related medical assessments.

HEMATURIA Most asymptomatic glomerular hematuria is due to IgA nephropathy (Berger's disease) or thin basement membrane (TBM) disease (benign hematuria). A rarer but more ominous cause of isolated hematuria is Alport's syndrome (p. 1691). The latter is the most common form of hereditary nephritis, is usually transmitted as an X-linked dominant trait, and is associated with sensorineural deafness, ophthalmologic abnormalities, and progressive renal insufficiency. TBM disease is sometimes familial but, in contrast to Alport's syndrome, is usually a benign disorder. Asymptomatic hematuria may also be the presenting feature of indolent forms of most other primary and secondary proliferative glomerulopathies. Glomerular hematuria must be distinguished from a variety of renal parenchymal and extrarenal causes of hematuria. It is particularly important to exclude malignancy of the kidney or urinary tract, particularly in older male patients. Other potential diagnoses include vascular, cystic, and tubulointerstitial diseases; papillary necrosis; hypercalciuria and hyperuricosuria; benign prostatic hypertrophy; and renal calculi. Important clues to the presence of glomerular hematuria are the presence of urinary red blood cell casts; dysmorphic urinary red blood cells; proteinuria >2.0 g per 24 h; and clinical or serologic evidence of nephritic syndrome, RPGN, or a compatible systemic disease.

IGA NEPHROPATHY (BERGER'S DISEASE) IgA nephropathy is the most common glomerulopathy worldwide and accounts for 10 to 40% of glomerulonephritis in most series (Table 264-7). The disease is particularly common in southern Europe and Asia and appears to be more common in blacks than whites. Familial clustering has been reported but is rare. Most cases are idiopathic. The renal and serologic abnormalities in IgA nephropathy and Henoch-Schönlein purpura are indistinguishable, and most authorities consider these to be a spectrum of a single disease. Less commonly, IgA nephropathy is found in association with systemic diseases, including chronic liver disease, Crohn's disease, gastrointestinal adenocarcinoma, chronic obstructive bronchiolitis, idiopathic interstitial pneumonia, dermatitis herpetiformis, mycosis fungoides, leprosy, ankylosing spondylitis, relapsing polychondritis, and Sjögren's syndrome. In many of these conditions, IgA is deposited in the glomerulus without inducing inflammation, and this may be a clinically insignificant consequence of perturbed IgA homeostasis.

Patients with IgA nephropathy typically present with gross hematuria, often 24 to 48 h after a pharyngeal or gastrointestinal infection, vaccination, or strenuous exercise. Other cases are diagnosed upon detection of microscopic hematuria during routine physical examinations. Hypertension (20 to 30%) and nephrotic syndrome (~10%) are unusual at presentation. Light microscopy of renal biopsy specimens typically shows mesangial expansion by increased matrix and cells. Diffuse proliferation, cellular crescents, interstitial inflammation, and areas of glomerulosclerosis may be evident in severe cases. The diagnostic finding, for which the disease is named, is mesangial deposition of IgA, detected by immunofluorescence microscopy. C3 is usually detected in the area of immune deposits, and IgG is observed in 50% of cases. Electron microscopy reveals electron-dense deposits in the mesangium and, in severe cases, these extend into the paramesangial subendothelial space. The pathogenesis of IgA nephropathy is incompletely understood. Among the major abnormalities in IgA metabolism described in this setting are increased IgA production, abnormal IgA glycosylation, and impaired IgA clearance. Although IgA nephropathy is associated with altered mucosal immunity, most IgA deposited in the kidney appears to be derived from bone marrow cells.

TABLE 264-7 Diseases Associated with IgA Nephropathy

Idiopathic (majority)	
Renal-limited or as component of Henoch-Schönlein purpura	
In association with systemic diseases or drugs[a]	
Liver	Chronic liver disease with involvement of biliary tree
Gastrointestinal	Celiac disease, Crohn's disease, adenocarcinoma
Respiratory	Idiopathic interstitial pneumonitis, obstructive bronchiolitis, adenocarcinoma
Skin	Dermatitis herpetiformis, mycosis fungoides, leprosy
Eyes	Episcleritis, anterior uveitis
Miscellaneous	Ankylosing spondylitis, relapsing polychondritis, Sjögren's syndrome, monoclonal IgA gammopathy, schistosomiasis

[a] Although prominent deposition of IgA has been reported with each of these conditions, significant glomerular inflammation and dysfunction are rare.

TREATMENT

The optimal treatment of IgA nephropathy is a subject of ongoing debate and controversy. Most authorities advise observation only in patients whose GFR is not compromised and whose proteinuria is <1 g/day. ACE inhibitors are usually prescribed for their renoprotective effect in patients with more severe disease. One trial has suggested a role for prolonged (6 months) high-dose glucocorticoids in patients presenting with impaired GFR and >1 g of proteinuria. Randomized controlled trials evaluating the efficacy of daily fish oils have yielded conflicting results. The case for other immunosuppressive agents such as cyclophosphamide and mycophenolate mofetil is unproven, and such agents are usually reserved for the minority of patients presenting with nephritic syndrome or RPGN, and with aggressive crescent formation and marked glomerular inflammation on renal biopsy.

IgA nephropathy typically smolders for decades, with patients often suffering exacerbations of hematuria and renal impairment during intercurrent infections. As many as 20 to 50% of patients develop ESRD within 20 years. Clinical predictors of a poor prognosis include older age, male sex, hypertension, nephrotic-range proteinuria, and renal insufficiency at presentation. Histologic features that predict an aggressive course include diffuse severe disease, extracapillary proliferation (crescents), extension of immune attack into the paramesangial subendothelial space, glomerulosclerosis, interstitial fibrosis, and arteriolar hyalinosis.

THIN BASEMENT MEMBRANE DISEASE (BENIGN HEMATURIA) This disorder can be heredofamilial or sporadic and is as common as IgA nephropathy in some series of asymptomatic hematuria. When familial, it is usually inherited as an autosomal dominant trait and is due to a defect in the gene encoding the α4 chain of type IV collagen. The molecular basis for the sporadic form of TBM disease has not been determined. TBM disease typically manifests in childhood as persistent hematuria. Intermittent hematuria and exacerbation of hematuria during upper respiratory tract infections have also been reported. The kidney is normal on light and immunofluorescence microscopy. The GBM is thin by comparison with normal subjects. TBM disease is usually a benign condition, and progressive renal impairment or proteinuria should prompt a search for an alternative diagnosis. A small proportion of patients do, however, appear to develop hypertension and focal glom-

erulosclerosis upon long-term follow-up, and ACE inhibitors are usually prescribed in this group in an effort to attenuate renal injury.

ALPORT'S SYNDROME (HEREDITARY NEPHRITIS) Alport's syndrome is the most common hereditary nephritis and is usually transmitted as an X-linked dominant trait. The genetic defect resides in the gene for the $\alpha 5$ chain of type IV collagen located on the long arm of the X chromosome; type IV collagen is a major structural component of the GBM. Numerous genetic mutations have been detected (Chap. 342).

Typical light-microscopic features on renal biopsy include mesangial hypercellularity, focal and segmental glomerulosclerosis, chronic tubulointerstitial fibrosis, atrophy, and accumulation of foam cells. Electron microscopy reveals thickening, fragmentation, and lamellation of the lamina densa of the GBM.

Males with the disease tend to progress to ESRD and are suitable candidates for dialysis and transplantation. ACE inhibitors are typically prescribed in the predialysis phase in an effort to slow the decline in GFR. About 5% of transplant recipients develop anti-GBM disease in the renal allograft; their immune system recognizes normal GBM of the transplanted kidney as a foreign antigen. These patients can have antibodies against the $\alpha 3$ (Goodpasture antigen) or $\alpha 5$ chains of type IV collagen, probably because defective synthesis of the $\alpha 5$ chain results in defective incorporation or orientation of the $\alpha 3$ chain in the GBM. In the majority of patients this posttransplant anti-GBM disease does not significantly compromise GFR.

PROTEINURIA Between 0.5 and 10% of the population have isolated proteinuria, defined as proteinuria in the presence of an otherwise normal urinary sediment, a radiologically normal urinary tract, and the absence of known renal disease. The majority of these patients excrete <2 g of protein per day, and more than 80% have an excellent prognosis (*benign isolated proteinuria*). A minority (10 to 25%) are found to have persistent proteinuria (*persistent isolated proteinuria*), some of whom develop progressive renal insufficiency over 10 to 20 years.

Benign Isolated Proteinuria The major categories of benign isolated proteinuria are idiopathic transient proteinuria, functional proteinuria, intermittent proteinuria, and postural proteinuria. *Idiopathic transient proteinuria* is usually observed in young adults and refers to dipstick-positive proteinuria in an otherwise healthy individual that disappears spontaneously by the next clinic visit. *Functional proteinuria* refers to transient proteinuria during fever, exposure to cold, emotional stress, congestive cardiac failure, or obstructive sleep apnea. This phenomenon is presumed to be mediated through changes in glomerular ultrafiltration pressure and/or membrane permeability. Patients with *intermittent proteinuria* have proteinuria in approximately half of their urine samples in the absence of other renal or systemic abnormalities. *Postural proteinuria* is proteinuria (usually <2.0 g per 24 h) that is evident only in the upright position. This disorder affects 2 to 5% of adolescents and may be transient ($\sim$80%) or fixed ($\sim$20%). Fixed postural proteinuria resolves within 10 to 20 years in most cases. In each of these conditions, renal biopsy reveals either normal renal parenchyma or mild and nonspecific changes involving podocytes or the mesangium. All carry an excellent prognosis.

Persistent Isolated Proteinuria Isolated proteinuria detected on multiple ambulatory clinic visits in both the recumbent and upright position usually signals a structural renal lesion. Virtually all glomerulopathies that induce nephrotic syndrome (see above) can cause persistent isolated proteinuria. The most common lesion on renal biopsy is mild mesangial proliferative glomerulonephritis with or without focal and segmental glomerulosclerosis (30 to 70%), followed by focal or diffuse proliferative glomerulonephritis ($\sim$15%) and interstitial nephritis ($\sim$5%). Although this clinical entity carries a worse prognosis than benign isolated proteinuria, the prognosis is still relatively good, with only 20 to 40% of patients developing renal insufficiency after 20 years. Furthermore, progression to ESRD is extremely rare. It is wise to exclude monoclonal gammopathy by urinary electrophoresis in older patients.

CHRONIC GLOMERULONEPHRITIS AND OTHER GLOMERULAR ABNORMALITIES

This syndrome is characterized by persistent proteinuria and/or hematuria and renal insufficiency that progresses slowly over years. Chronic glomerulonephritis usually comes to light either (1) upon routine urinalysis, (2) when routine blood tests reveal unexplained anemia or elevated blood urea nitrogen and creatinine, (3) following discovery of bilateral small kidneys on abdominal imaging, (4) during evaluation for secondary causes of hypertension, or (5) during a clinical exacerbation of glomerulonephritis triggered by pharyngitis (synpharyngitic) or other infections. Chronic glomerulonephritis can be a manifestation of virtually all of the major glomerulopathies. While renal biopsy may reveal the causative glomerular lesion, glomerular scarring and sclerosis are frequently so advanced by the time patients present that it may be impossible to define the primary diagnosis. Tubulointerstitial inflammation and scarring are frequent additional findings and portend a poor prognosis. Glomerular hypertension and hyperfiltration through remnant functioning nephrons can hasten progression to ESRD. Treatment is directed at lowering systemic and glomerular hypertension, usually with an ACE inhibitor or ARB, and controlling extracellular fluid volume, anemia, metabolic abnormalities, and the uremic syndrome through judicious use of diuretics, erythropoietin, and dietary modification. Some patients develop ESRD and require renal replacement therapy with dialysis or transplantation.

GLOMERULAR DISEASES IN SPECIFIC CLINICAL SITUATIONS

When considering the clinical approach to patients presenting with abnormalities of the urinary sediment, it is worth considering several specific clinical scenarios: (1) patients whose presentation or family history suggests a hereditary disease, (2) patients on therapeutic or recreational drugs, (3) glomerular disease in the setting of a systemic infection, (4) glomerular disease in a patient with neoplasia, and (5) glomerular disease in patients with arthritis and connective tissue diseases.

HEREDITARY DISEASE WITH GLOMERULAR INVOLVEMENT Although relatively rare, hereditary glomerular diseases are an important category of glomerular disease because of their propensity to cause progressive loss of renal function and for transmission down the generations. Furthermore, studies into the pathogenesis of these disorders have shed important new insights on renal physiology and pathophysiology that are relevant to a wider group of glomerulopathies.

Alport's Syndrome Alport's syndrome is the most common form of hereditary glomerular disease (Chap. 342).

Sickle Cell Disease (See also Chap. 91) Glomerular disease is common (15 to 30%) in homozygotes for sickle cell disease. Glomerular hyperfiltration and hypertrophy occur within the first 5 years of life. Approximately 15 to 30% of patients develop proteinuria in the first three decades, and 5% develop ESRD. The glomerular pathology is usually focal segmental glomerulosclerosis, probably due to sustained glomerular capillary hypertension. MPGN is also seen on occasion. Predictors of chronic renal failure are worsening anemia, proteinuria, nephrotic syndrome, and hypertension. ACE inhibitors and ARBs may slow the progression of renal disease by lowering systemic and glomerular capillary hypertension.

Fabry's Disease (See also Chap. 340) In patients with Fabry's disease, renal biopsy reveals accumulation of neutral glycosphingolipids with terminal α-galactosyl moieties in lysosomes of glomerular, tubular, vascular, and interstitial cells. Focal and global glomerulosclerosis are later features. Electron microscopy reveals stacked, concentric lamellar profiles known as "myeloid" bodies, which are characteristic. Renal disease manifests in the late teens to early twenties with lipiduria, proteinuria with minimal hematuria, nephrotic syndrome, hypertension, and progressive renal insufficiency. The renal lesion is progressive, and these patients often tolerate hemodynamic changes during

dialysis poorly because of progressive vascular disease. Significant slowing of disease progression has been demonstrated in early trials of enzyme replacement with recombinant human α-galactosidase A. Successful renal transplantation has been reported despite recurrence in the allograft.

Nail-Patella Syndrome The nail-patella syndrome is a rare hereditary disorder transmitted as an autosomal dominant trait. The abnormal gene is located on the long arm of chromosome 9 and encodes transcription factor of the LIM-homeodomain type, namely LMX1B. The phenotype is characterized by multiple osseous abnormalities, primarily affecting the elbows and knees, and nail dysplasia. About 50% of patients have clinically evident nephropathy. The light-microscopic features on renal biopsy include local GBM thickening, tubular atrophy, interstitial fibrosis, and varying degrees of glomerular sclerosis. The disease usually manifests clinically as asymptomatic hematuria and proteinuria, occasionally in the nephrotic range, but it may be silent. The renal lesion is relatively benign, and progression to ESRD occurs in 10 to 30% of patients.

Lipodystrophy MPGN type II (dense deposit disease) is the most frequent glomerular lesion in patients with lipodystrophy (80%), whereas MPGN type I affects the remainder (20%). The disease occurs mostly in females between the ages of 5 and 15 years, and the clinical presentation and course are similar to those of idiopathic MPGN, namely nephrotic-range proteinuria and progressive renal insufficiency. Low C3 levels are common in association with C3 nephritic factor (p. 1680).

Lecithin-Cholesterol Acyltransferase Deficiency (See also Chap. 335) Renal manifestations of this disease include proteinuria, microscopic hematuria, and progressive renal insufficiency. Renal biopsy typically reveals focal and segmental glomerulosclerosis. Endothelial cell detachment is also evident, and capillary lumens may be occluded by vacuolated foam cells. Recurrence of the disease has been documented in the renal allograft but without marked impairment of graft function.

DRUG-INDUCED GLOMERULAR DISEASE A variety of drugs damage the glomerular filtration barrier and induce proteinuria and nephrotic syndrome (Table 264-8). In contrast, drug-induced proliferative glomerulonephritis is rare. The more common drug-induced glomerulopathies are discussed here.

NSAIDs have a variety of renal side effects, including hemodynamically mediated acute renal failure, salt and water retention, hyponatremia, hyperkalemia, papillary necrosis, acute interstitial nephritis, nephrotic syndrome, and ESRD. Nephrotic syndrome and acute renal failure frequently coexist due to a combination of acute interstitial nephritis and a glomerular lesion that is identical to that of MCD. This entity occurs most commonly in patients on propionic acid derivatives such as fenoprofen, ibuprofen, and naproxen but can occur with other NSAIDs, ampicillin, rifampin, and interferon α. Withdrawal of the drug usually results in resolution of renal disease. Membranous nephropathy is also described as an idiosyncratic reaction to NSAIDs. While the more selective inhibitors of cyclooxygenase (COX)-2 appear to have less renal toxicity, many of the renal syndromes described for NSAIDs have also been reported with COX-2 inhibitors.

Gold therapy, administered by injection or orally, induces proteinuria in 5 to 25% of patients with rheumatoid arthritis. Proteinuria develops after 4 to 6 months of therapy, and up to 33% of patients develop full-blown nephrotic syndrome. Renal biopsy typically reveals membranous glomerulopathy, though MCD or mesangial proliferative lesions have also been described. Progressive renal impairment is rare. Nephrotic syndrome is more common in patients who are HLA-B8/DR3 positive, suggesting a genetic susceptibility. Withdrawal of the drug leads to gradual resolution of the proteinuria.

Penicillamine also induces proteinuria in 5 to 30% of patients. As with gold, the underlying glomerular lesion is usually membranous glomerulopathy, and proteinuria gradually resolves after withdrawal of the drug. Acute renal failure secondary to crescentic glomerulonephritis with immune deposits has also been described.

Intravenous heroin use is associated with an increased incidence of focal and segmental glomerulosclerosis (heroin-associated nephropathy). It is not clear whether the nephrotoxin in this setting is heroin itself or a contaminant. Heroin-associated nephropathy occurs predominantly in blacks and is characterized by nephrotic syndrome, hypertension, and a gradual progression to ESRD over a period of 3 to 5 years. The pathologic features are similar to those of idiopathic FSGS, although mesangial deposition of IgM and C3 may be more prominent. The incidence of this disease appears to be declining steadily. Potential reasons for the decline include increased purity of street heroin and a bias to attribute FSGS to HIV infection when both risk factors coexist. Intravenous *amphetamine* abuse is a rare cause of systemic necrotizing vasculitis.

TABLE 264-8 Drug-Induced Glomerular Disease

Morphologic Lesion	Causative Agent
Minimal change diseases (usually with interstitial nephritis)	Nonsteroidal anti-inflammatory agents Recombinant interferon α Rifampin Ampicillin
Membranous nephropathy	Penicillamine Gold Mercury Trimethadione Captopril Chlormethiazole
Focal segmental glomerulosclerosis	Heroin
Pauci-immune necrotizing GN	Ciprofloxacin Hydralazine
Proliferative GN with vasculitis	Allopurinol Penicillin Sulfonamides Thiazides Intravenous amphetamines
RPGN	Rifampin Warfarin Carbimazole Amoxicillin Penicillamine

Note: GN, glomerulonephritis; RPGN, rapidly progressive glomerulonephritis.

GLOMERULAR LESIONS ASSOCIATED WITH INFECTIOUS DISEASES Infectious organisms can induce glomerular disease through several different mechanisms: (1) by direct infection of renal cells, (2) by elaborating nephrotoxins such as *Escherichia coli*–derived verotoxin, (3) by inciting intraglomerular deposition of immune complexes (e.g., postinfectious glomerulonephritis) or cryoglobulins (e.g., hepatitis B or C), and (4) by providing a chronic stimulus for amyloid fibril formation, as in AA amyloidosis. Direct infection of glomerular cells is a relatively rare mechanism of injury but has been implicated in the pathogenesis of nephropathy associated with HIV (Chap. 173 and below).

Viral Infections ■ *HEPATITIS B VIRUS (HBV) INFECTION* (See also Chap. 285) Infectious HBV, HCV, and HIV are strongly associated with glomerular disease. Glomerular lesions associated with HBV infection include membranous glomerulopathy, MPGN, IgA nephropathy, essential mixed cryoglobulinemia, and polyarteritis nodosa. Membranous glomerulopathy is most common. In endemic areas, such as Asia and Africa, 80 to 100% of children and 30 to 45% of adults with membranous glomerulopathy have HBV surface antigenemia. HBV antigens have been identified in renal immune deposits, suggesting in situ immune-complex formation after planting of HBV antigens or trapping of circulating immune complexes containing HBV antigens. Pa-

tients typically present with nephrotic syndrome and microscopic hematuria. Hypertension and renal impairment are rare. The most common associated hepatic lesion is chronic persistent or chronic active hepatitis. In nonendemic areas there is a male preponderance, and many patients are intravenous drug users or have other risk factor for acquisition of HBV. The asymptomatic carrier state of HBV is frequently associated with MPGN in endemic areas. Hypertension and azotemia are more common with this morphologic pattern than with membranous glomerulopathy. Children with HBV-associated membranous glomerulonephritis have a good prognosis, and almost two-thirds enter spontaneous remission within 3 years. ESRD is rare. In contrast, 30% of adults develop progressive renal failure within 5 years, with 10% reaching ESRD. Steroids and cytotoxic agents are contraindicated as they may lead to increased viral replication and worsening of liver disease. Interferon α may reduce proteinuria and stabilize renal function in patients with progressive disease.

HEPATITIS C VIRUS INFECTION (See also Chap. 285) This should be considered in all patients with cryoglobulinemic proliferative glomerulonephritis, MPGN, and membranous glomerulopathy. These three clinicopathologic entities may represent a spectrum of morphologic manifestations of the same pathogenetic process, namely HCV-induced immune-complex disease. Up to 30% of patients with chronic HCV infection have an abnormal urinary sediment. HCV infection accounts for 10 to 20% of type I MPGN and is a major cause of essential mixed cryoglobulinemia. Renal biopsy reveals typical features of type I MPGN and IgG, IgM, C3, and/or cryoglobulin deposits. Most patients present with nephrotic syndrome and microscopic hematuria and may have red blood cell casts. Liver function tests are usually abnormal, and C3 levels are typically depressed. Anti-HCV antibodies are detected in most patients, and viral RNA has been documented in blood and cryoglobulins. Various treatments have been reported to be useful in HCV-induced renal disease including steroids, cytotoxic agents, and plasmapheresis; however, controlled trials to support their use are lacking. Interferon α has been demonstrated to clear antigenemia, lower cryoglobulin levels, and stabilize renal disease. Unfortunately, relapse is usual once the drug is discontinued.

HIV INFECTION (See also Chap. 173) This condition has been associated with focal segmental glomerulosclerosis, acute diffuse proliferative glomerulonephritis, and mesangioproliferative glomerulonephritis, including IgA nephropathy, MPGN, and membranous glomerulopathy. The classic and most common HIV-associated glomerulopathy is an aggressive form of focal segmental glomerulosclerosis, an entity that is termed *HIV-associated nephropathy* (HIVAN). This disease may be the first manifestation of infection in otherwise asymptomatic patients. HIVAN is more common in blacks than in other ethnic groups and is more frequent in intravenous drug abusers with HIV infection than in homosexuals. The disease has been described in all high-risk groups, however, including infants of HIV-positive mothers. Renal biopsy typically reveals visceral epithelial cell swelling, collapse of the glomerular capillary tuft, severe tubulointerstitial inflammation, and microcystic dilatation of renal tubules. The presence of tubuloreticular inclusions and the aggressive clinical course distinguish HIVAN from idiopathic focal segmental glomerulosclerosis. The mechanisms of renal cell injury are still being defined. Viral DNA has been demonstrated in the renal epithelia of HIV-infected patients with and without nephropathy, suggesting that pathogenetic factors, other than infection of cells, are required for induction of disease. The typical clinical correlates of HIVAN are severe nephrotic syndrome and rapid progression to ESRD, occurring in weeks to months. Despite early reports of poor survival of patients on dialysis, more recent studies indicate improved survival for both asymptomatic patients with HIV and patients with full-blown AIDS.

There is no proven therapy for HIVAN. The initial experience with combined highly active antiretroviral therapy (triple therapy) suggests that these regimens have reduced the incidence of nephropathy in HIV-infected patients and improved prognosis in patients with established nephropathy. A number of retrospective studies of glucocorticoids alone or in combination with triple therapy have demonstrated a reduction in proteinuria and slowing of renal progression in some patients with established nephropathy. The precise role of steroids requires further study. ACE inhibitors may confer renoprotection as in other proteinuric renal diseases.

Bacterial Infections Immune-complex glomerulonephritis is a relatively frequent complication of *infective endocarditis* (Chap. 109). Other mechanisms of renal injury in bacterial endocarditis include embolic renal infarction, septic abscesses, acute tubular necrosis secondary to septicemia and drug therapy, disseminated intravascular coagulation, and antibiotic-induced acute interstitial nephritis. Patients typically present with microscopic hematuria, urinary red blood cell casts, pyuria and modest proteinuria (nephrotic range in 25% of patients), and variable degrees of renal failure. Rheumatoid factor is present in 10 to 70%, and circulating immune complexes in 90%. Serum complement levels are usually depressed. Renal biopsy reveals mild focal proliferative glomerulonephritis with mesangial and capillary wall deposition of IgG and C3 by immunofluorescence microscopy and subendothelial, mesangial, and subepithelial electron-dense deposits by electron microscopy. Occasional patients develop diffuse necrotizing glomerulonephritis with crescent formation and present with nephritic syndrome or RPGN. Endocarditis-associated glomerulonephritis typically has a good prognosis and resolves with eradication of the underlying infection.

Suppurative infections such as intrathoracic and intraabdominal abscesses, osteomyelitis, and dental abscesses have been associated with glomerulonephritis. The usual presentation is hematuria, urinary red blood cell casts, proteinuria, and acute renal failure. Oliguria and hypertension are common. Pathologic renal lesions include mesangial proliferative, membranoproliferative, and diffuse proliferative glomerulonephritis with crescents. Immunofluorescence reveals mesangial and capillary wall deposition predominantly of C3, although IgG and IgM may also be seen.

Nephrotic syndrome is a complication in 0.3% of patients with secondary *syphilis* and 8% of patients with congenital syphilis. The usual pathology is membranous glomerulopathy.

Leprosy most commonly causes AA amyloidosis; however, a syndrome resembling acute poststreptococcal glomerulonephritis has also been described.

Protozoan and Parasitic Infections Transient proteinuria (50% of patients) and nephrotic syndrome (<1% of patients) are complications of infection with *Plasmodium falciparum*. Membranoproliferative glomerulonephritis is the usual pathologic lesion and may respond to eradication of infection. *P. malariae* has been associated with diffuse or focal proliferative glomerulonephritis, membranous glomerulopathy, and minimal change disease. Eradication of the malarial infection does not consistently induce remission of the nephrotic syndrome. *Schistosoma mansoni* causes nephrotic syndrome in 5 to 10% of patients, and progression to ESRD is common. The usual pathology is MPGN or mesangial proliferative glomerulonephritis, although membranous glomerulonephritis and amyloidosis are occasionally seen. *Filariasis* can trigger membranous glomerulonephritis (*Loa loa*) and occasionally induces proliferative glomerulonephritis (*Onchocerca volvulus*). *Congenital toxoplasmosis* infection occasionally induces immune-complex glomerulonephritis characterized by mesangial and subendothelial immune deposits that contain *Toxoplasma* antigens. Membranous glomerulopathy and proliferative glomerulonephritis are occasional complications of *hydatid disease* and *trichinosis*, respectively.

GLOMERULAR LESIONS ASSOCIATED WITH NEOPLASIA Infectious glomerulopathies associated with neoplasia include membranous glomerulopathy, MCD, FSGS, immune-complex glomerulonephritis, fibrillary/immunotactoid glomerulonephritis, LCDD, and amyloidosis. Mild proteinuria is common in patients with *solid tumors*, but overt glomerulonephritis is rare. Occasional patients with solid tumors of the lung, gastrointestinal tract, breast, kidney, and ovary develop full-

blown nephrotic syndrome, usually due to a membranous glomerulopathy. Estimates of the incidence of occult malignancy in patients presenting with membranous glomerulopathy range from 0.1 to 10%. Most authorities agree that an extensive search for malignancy is not indicated, unless there are other suggestive clinical features. As many as 35% of patients with renal cell carcinoma have mesangial deposition of IgG and C3 visible on immunofluorescence; however, morphologic abnormalities are detected in only 50% of these patients, and clinically significant glomerulopathy is rare. Glomerular amyloidosis has also been described in association with this tumor.

An array of glomerular disease has been reported in patients with lymphoproliferative malignancy. Nephrotic syndrome is a recognized complication of *Hodgkin's lymphoma*, with 70% of cases due to MCD. The latter may occur concurrently with (40 to 45%), precede (10 to 15%), or follow (40 to 50%) diagnosis of the malignancy. It is postulated that a lymphokine or other mediator released by malignant T lymphocytes perturbs podocyte function and alters glomerular permeability in this setting. Nephrotic syndrome typically resolves with successful treatment and relapses with recurrence of disease. Less frequent associations with Hodgkin's lymphoma include FSGS, membranous glomerulopathy, MPGN, proliferative glomerulonephritis, and crescentic glomerulonephritis. MCD, membranous glomerulopathy, MPGN, and crescentic glomerulonephritis have also been reported in patients with *non-Hodgkin's lymphoma*. Glomerulopathy in the context of leukemia is rare. MPGN can complicate *chronic lymphatic leukemia* and related *B cell lymphomas*, particularly when associated with cryoglobulinemia. Other glomerular lesions associated with *paraproteinemia* include primary amyloid, LCDD, proliferative glomerulonephritis induced by cryoglobulinemia, and fibrillary/immunotactoid glomerulopathy. Here again, the renal lesion frequently improves or resolves with successful treatment of the underlying malignancy.

GLOMERULAR LESIONS ASSOCIATED WITH ARTHRITIS AND OTHER FORMS OF CONNECTIVE TISSUE DISEASE Although extraarticular manifestations are present in 35% of patients with rheumatoid arthritis, direct involvement of the kidney by rheumatoid disease is rare, and glomerular injury is usually secondary to AA amyloidosis or a side effect of drug therapy. AA amyloidosis is a complication experienced by 10 to 20% of patients with rheumatoid arthritis, and renal involvement is evident clinically in 3 to 10% of these patients (nephrotic syndrome, renal insufficiency). Amyloidosis is more frequent in patients with rheumatoid arthritis of long duration (>10 years), with circulating rheumatoid factor, and with destructive arthropathy. Less frequent glomerular lesions include mesangial proliferative glomerulonephritis and basement membrane thickening by subepithelial immune deposits. Gold and penicillamine may cause nephrotic syndrome by inducing membranous glomerulopathy, whereas NSAIDs can trigger the nephrotic syndrome by inducing minimal change nephropathy, usually in association with acute interstitial nephritis (see above). Tubulointerstitial injury is the most common form of renal involvement in Sjögren's syndrome and usually presents as either Fanconi's syndrome, distal renal tubular acidosis, or impairment of renal concentrating ability. Glomerulonephritis is relatively rare and should prompt a search for other causes. Membranous glomerulopathy and MPGN are the most common lesions. Anecdotal reports describe successful therapy with glucocorticoids and cytotoxic agents. Occasional cases of focal mesangial proliferative glomerulonephritis with mesangial deposition of IgG and complement have been described in polymyositis/dermatomyositis. Membranous glomerulopathy has also been reported, particularly when polymyositis/dermatomyositis is associated with malignancy. Mixed connective tissue disease is a syndrome that includes features of SLE, scleroderma, and polymyositis and is associated with high titers of anti-ribonucleoprotein antibodies and negative anti-smooth-muscle antibodies. Renal involvement occurs in fewer than 15% of patients and manifests as hematuria and subnephrotic proteinuria. The usual pathologic lesion is membranous glomerulopathy or MPGN. The prognosis is usually excellent, and steroid therapy may be useful in rare patients with progressive renal disease.

265 TUBULAR DISORDERS

John R. Asplin, Fredric L. Coe

The renal tubular disorders and their morphologic and functional abnormalities, mode of inheritance, and associated abnormalities are summarized in Table 265-1. The individual disorders are discussed in detail below.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Etiology and Pathology Autosomal dominant polycystic kidney disease (ADPKD) has a prevalence of 1:300 to 1:1000 and accounts for ~4% of end-stage renal disease (ESRD) in the United States. Some 90% of cases are inherited as an autosomal dominant trait, and ~10% are spontaneous mutations.

GENETIC CONSIDERATIONS Three forms of ADPKD have been identified. ADPKD-1 accounts for 85% of cases, and the gene has been mapped to chromosome 16p13.3. The gene for ADPKD-2 has been mapped to chromosome 4q21-23. The protein products of the two genes form the polycystin complex, which may regulate cell-cell or cell-matrix interactions. A defect in either of these proteins interrupts the normal function of the polycystin complex, resulting in the same phenotype for two distinct genetic abnormalities. ADPKD-2 appears to have a later age of onset of symptoms and renal failure than ADPKD-1. A rare third form has been described but has not been mapped to a gene at this point.

The kidneys are grossly enlarged, with multiple cysts studding the surface of the kidney. The cysts contain straw-colored fluid that may become hemorrhagic. The cysts are spherical, vary in size from a few millimeters to centimeters, and are distributed evenly throughout the cortex and medulla. Only 1 to 5% of nephrons will develop cysts. Cysts form when a "second hit" causes a somatic mutation in the normal allele of a tubule cell, leading to monoclonal proliferation of the tubular epithelium. The remaining renal parenchyma reveals varying degrees of tubular atrophy, interstitial fibrosis, and nephrosclerosis.

TABLE 265-1 *Renal Tubule Defects*

Disease	Renal Morphologic Abnormalities	Renal Functional Abnormalities	Mode of Inheritance	Associated Abnormalities
Autosomal dominant polycystic disease	Cortical and medullary cysts	Chronic renal failure, >20 yr	AD	Hepatic cysts, intracranial aneurysms, colonic diverticula
Autosomal recessive polycystic disease	Distal tubule and collecting duct cysts	Chronic renal failure, <20 yr	AR	Congenital hepatic fibrosis
Tuberous sclerosis	Renal cysts and angiomyolipomas	None	AD, S	Skin lesions, hamartomas of the central nervous system
Von Hippel–Lindau disease	Renal cysts, increased risk of renal cell cancer	None	AD	Hemangioblastoma of the retina and central nervous system
Medullary sponge kidney	Dilated collecting ducts	Nephrocalcinosis, hematuria	AD, S	None
Nephronophthisis	Medullary cysts, small kidneys	Chronic renal failure, <20 yr polyuria, salt wasting	AR	Hepatic fibrosis, retinal abnormalities
Medullary cystic disease	Medullary cysts, small kidneys	Chronic renal failure, >20 yr polyuria, salt wasting	AD	None
Liddle's syndrome	None	Hypokalemia, alkalosis, low aldosterone levels	AD	Hypertension
Bartter's syndrome	Juxtaglomerular apparatus hyperplasia	Hypokalemia, alkalosis, high aldosterone levels	AR	None
Gitelman's syndrome	Juxtaglomerular apparatus hypertrophy	Hypokalemia, alkalosis, hypocalciuria	AR	None
Congenital nephrogenic diabetes insipidus	None	Vasopressin renal concentrating defect	XL, AR	None
Renal tubular acidosis, type 1	Nephrocalcinosis	Impaired proton secretion in distal tubule, non-anion-gap metabolic acidosis	AD, AR, S, ACQ	Rickets, osteomalacia, nephrolithiasis
Renal tubular acidosis, type 2	None	Reduced bicarbonate reabsorption, non-anion-gap metabolic acidosis	AR, AD, ACQ	Fanconi syndrome, rickets
Renal tubular acidosis, type 4	Chronic renal insufficiency	Reduced proton and potassium secretion	ACQ	Renal insufficiency
X-linked hypophosphatemia	None	Reduced phosphate reabsorption	XL	Rickets, osteomalacia, normal serum $1,25(OH)_2D_3$
Autosomal dominant hypophosphatemic rickets	None	Reduced phosphate reabsorption	AD	Rickets, osteomalacia
Vitamin D–dependent rickets, type 1	None	Defective renal $1,25(OH)_2D_3$ production	AR	Rickets, osteomalacia, low serum $1,25(OH)_2D_3$
Vitamin D–dependent rickets, type 2	None	Renal resistance to $1,25(OH)_2D_3$	AR, S	Rickets, osteomalacia, high serum $1,25(OH)_2D_3$
Oncogenic osteomalacia	None	Reduced phosphate reabsorption	ACQ	Osteomalacia, mesenchymal tumors
Dent's disease	Interstitial fibrosis, medullary calcifications	Hypercalciuria, low-molecular-weight proteinuria	XL	Renal failure
Isolated hyperuricemia	None	Reduced urate reabsorption	AR	Variable hypercalciuria
Hartnup disorder	None	Reduced reabsorption of neutral amino acids	AR	Dermatitis, diarrhea, dementia
Cystinuria	Cystine stones	Reduced reabsorption of dibasic amino acids	AR	Short stature
Iminoglycinuria	None	Reduced reabsorption of proline, hydroxyproline, and glycine	AR	None
Fanconi syndrome	Swan neck deformity of proximal tubule	Reduced reabsorption of bicarbonate, glucose, phosphate, uric acid, and amino acids	AR	Rickets, osteomalacia, hypokalemia, metabolic acidosis

Note: AD, autosomal dominant; AR, autosomal recessive; S, sporadic; XL, X-linked; ACQ, acquired

Clinical Features The disease may present at any age but most frequently causes symptoms in the third or fourth decade. Patients may develop chronic flank pain from the mass effect of the enlarged kidneys. Acute pain indicates infection, urinary tract obstruction by clot or stone, or sudden hemorrhage into a cyst. Gross and microscopic hematuria are common, and impaired renal concentrating ability frequently leads to nocturia. Nephrolithiasis occurs in 15 to 20% of patients, calcium oxalate and uric acid stones being most common. Low urine pH, low urine citrate, and urinary stasis from distortion of the collecting system by cysts all play a role in stone formation. Hypertension is found in 20 to 30% of children and up to 75% of adults. It is secondary to intrarenal ischemia from distortion of the renal architecture, leading to activation of the renin-angiotensin system. Patients with hypertension have a much more rapid progression to ESRD. Urinary tract infection is common and may involve the bladder or renal interstitium (pyelonephritis) or infect a cyst (pyocyst). Pyocysts can be difficult to diagnose but are more likely to be present if the patient has positive blood cultures, new renal pain, or failed to improve clinically after a standard course of antibiotic therapy.

Progressive decline in renal function is common, with ~50% of patients developing ESRD by age 60. However, there is considerable variation in age of onset of renal failure, even within the same family. Hypertension, recurrent infections, male sex, and early age of diagnosis are related to early onset renal failure. Renal failure usually progresses slowly; if a sudden decrement in kidney function occurs, ureteral obstruction from stone, clot, or compression by a cyst are likely

causes. Patients usually have high hematocrits for their level of renal function, as erythropoietin production is high. Fluid overload is uncommon because of a tendency for renal salt wasting.

Extrarenal manifestations of this disease are frequent and underscore the systemic nature of the defect. Hepatic cysts occur in 50 to 70% of patients. Cysts are generally asymptomatic, and liver function is normal, though women may develop massive hepatic cystic disease on occasion. Cyst formation has also been observed in the spleen, pancreas, and ovaries. Intracranial aneurysms are present in 5 to 10% of asymptomatic patients, with potential for permanent neurologic injury or death from subarachnoid hemorrhage. Screening of all ADPKD patients for aneurysms is not recommended, but patients with a family history of subarachnoid hemorrhage should be studied noninvasively with magnetic resonance imaging angiography. Colonic diverticular disease is common, and patients are more likely to develop perforation than the general population with colonic diverticula. Mitral valve prolapse is found in 25% of patients, and the prevalence of aortic and tricuspid valve insufficiency is increased.

Diagnosis Ultrasound is the preferred technique for diagnosis of symptomatic patients and for screening asymptomatic family members. The ability to detect cysts increases with the subject's age: 80 to 90% of ADPKD patients over the age of 20 will have detectable cysts, and almost 100% over the age of 30 will have cysts. At least three to five cysts in each kidney is the standard diagnostic criteria for ADPKD. Computed tomography (CT) scan may be more sensitive than ultrasound in detection of small cysts. Genetic linkage analysis is now available for diagnosis of ADPKD but is reserved for cases where radiographic imaging is negative and the need for definitive diagnosis critical, such as screening family members for potential kidney donation.

TREATMENT

The goals of treatment are to slow the rate of progression of renal disease and minimize symptoms. Hypertension and renal infection should be treated aggressively to maintain renal function. Converting enzyme inhibitors are effective antihypertensive agents, though patients should be closely monitored as some develop renal insufficiency and hyperkalemia. Urinary infection is treated in a standard manner unless a pyocyst is suspected, in which case antibiotics that penetrate cysts should be used, such as trimethoprim-sulfamethoxazole, ciprofloxacin, and chloramphenicol. Chronic pain from cysts can be managed by cyst puncture and sclerosis with ethanol.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

GENETIC CONSIDERATIONS Autosomal recessive polycystic kidney disease (ARPKD) is a rare genetic disease with an incidence of 1:20,000 births. The gene for ARPKD has been localized to chromosome 6p21 and encodes a large novel protein whose function has not yet been determined. In the past, ARPKD was categorized as being of neonatal, infantile, or juvenile form depending on the age of onset and the relative degree of involvement of the kidneys and liver. However, variable clinical presentations within siblings in the same family, as well as the localization of the disease to chromosome 6 in multiple families, support the premise that this is a single genetic disease with variable phenotypic presentation.

At birth the kidneys are enlarged with a smooth external surface. The distal tubules and collecting ducts are dilated into elongated cysts that are arranged in a radial fashion. As the patient ages, the cysts may become more spherical and the disease can be confused with ADPKD. Interstitial fibrosis is also seen as renal function deteriorates. Liver involvement includes proliferation and dilation of intrahepatic bile ducts as well as periportal fibrosis.

Clinical Features The majority of cases are diagnosed in the first year of life, presenting as bilateral abdominal masses. Death in the neonatal period is most commonly due to pulmonary hypoplasia. Hypertension and impaired urinary concentrating ability are common. The time course to ESRD is variable, though many children maintain adequate kidney function for years. Older children present with complications secondary to congenital hepatic fibrosis and generally have less severe kidney disease. Hepatosplenomegaly, portal hypertension, and esophageal varices are frequent complications of ARPKD.

Diagnosis Ultrasound is the most common technique used to diagnose ARPKD, prenatally and in childhood. Ultrasound examination reveals enlarged kidneys with increased echogenicity. At times spherical cysts may be seen, potentially leading to an incorrect diagnosis of ADPKD. A thorough family history and imaging the kidneys of the parents aids in differentiation from other cystic diseases. Hepatic fibrosis seen on imaging studies in association with cystic kidneys supports the diagnosis of ARPKD.

TREATMENT

Aggressive treatment of hypertension and urinary tract infection are the major goals of therapy in order to maintain native renal function as long as possible. Dialysis and transplant are appropriate when kidney failure occurs. Hepatic fibrosis may lead to life-threatening variceal hemorrhage, requiring sclerotherapy or portosystemic shunts.

TUBEROUS SCLEROSIS

Patients with this multisystem disease most commonly present with skin lesions and benign tumors of the central nervous system (Chap. 358). Renal involvement is common; angiomyolipomas are the most frequent abnormality and are usually bilateral. Renal cysts may be present as well and can give an appearance similar to that of ADPKD. Histologically, the cysts are unique—the cyst lining cells are large with an eosinophilic staining cytoplasm and may form hyperplastic nodules that can fill the cyst space.

GENETIC CONSIDERATIONS One-third of cases are inherited as an autosomal dominant trait, the rest are due to sporadic mutations. Mutations of tumor-suppression genes have been identified on chromosomes 9q34 (*TSCI*) and 16p13 (*TSC2*). Mutations of *TSC2* account for the majority of cases and are more likely to be associated with mental retardation and polycystic kidneys. Tuberous sclerosis may be confused with ADPKD if extrarenal manifestations are minimal.

VON HIPPEL–LINDAU DISEASE

This autosomal dominant disease is characterized by hemangioblastomas of the retina and the central nervous system (Chap. 358). Renal cysts occur in the majority of cases and are usually bilateral. The *VHL* gene, located on chromosome 3p25, is a tumor-suppressor gene that regulates hypoxia-induced transcription factors. It is the same gene that is mutated in sporadic renal cell carcinoma. Renal cell carcinoma may be found in 40 to 70% of patients with von Hippel–Lindau disease and is frequently multifocal. Yearly screening of adults using CT scans has been recommended in an attempt to diagnose renal cell cancers at an early stage.

MEDULLARY SPONGE KIDNEY

Etiology and Pathology Medullary sponge kidney (MSK) is a congenital disorder. Although some cases have apparent autosomal dominant inheritance, most are sporadic. It is found in 0.5 to 1% of all intravenous pyelograms. Males and females are affected equally. The pathologic lesion is cystic dilation of the inner medullary and papillary collecting ducts. Bilateral renal involvement is present in 70% of cases, but not all papillae are equally affected. The dilated ducts are lined by cuboidal epithelium with areas of pseudostratified and stratified squamous epithelium. Calculi are frequently found in the dilated collecting ducts.

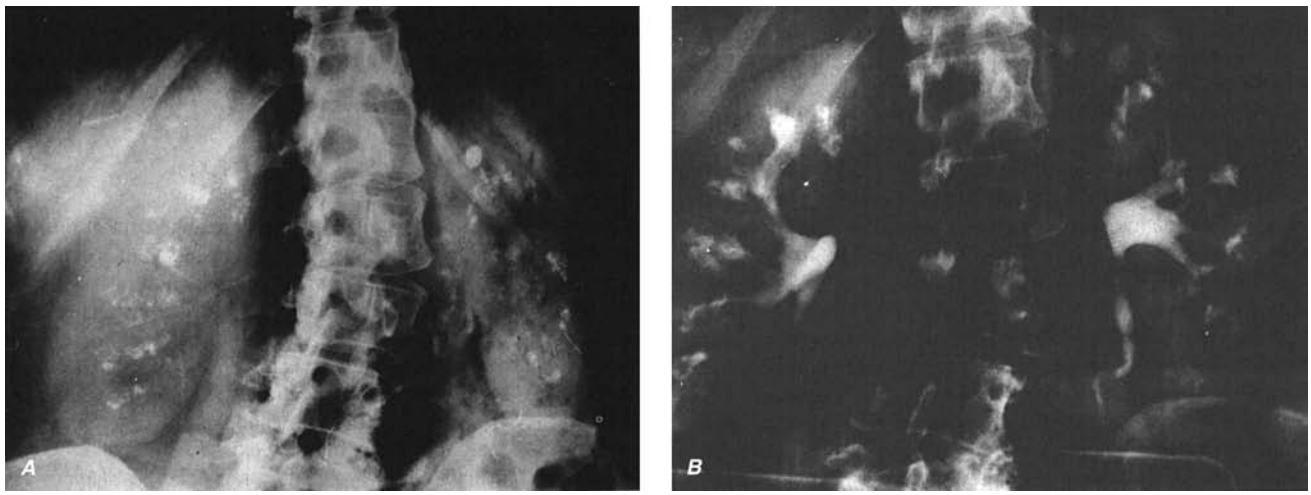

FIGURE 265-1 *A*. Radiographic appearance of medullary sponge kidney. Abdominal flat plate reveals multiple bilateral calcifications. *B*. Radiographic contrast material accumulates in the dilated and cystic terminal collecting ducts and obscures the calcifications.

Clinical Features Patients generally present in the third or fourth decade with kidney stones, infection, or recurrent hematuria. The disease is most commonly diagnosed by intravenous pyelogram, which shows linear striations radiating into the renal papillae or small cystic collections of contrast in the dilated ducts (Fig. 265-1). Approximately 60% of patients with MSK have stones, and 12% of all stone formers will have MSK. Hypercalciuria occurs with the same frequency in MSK as it does in random stone formers. Papillary nephrocalcinosis occurs more frequently in patients with MSK than in the random stone former. Proteinuria is minimal, if present at all, and renal function is normally preserved unless there is renal damage from recurrent infection or severe stone disease.

TREATMENT

Asymptomatic patients require no specific therapy except to maintain high fluid intake to reduce the risk of nephrolithiasis. If stones are present, standard laboratory evaluation should be done and metabolic abnormalities treated as in any stone former (Chap. 268). Infection should be treated aggressively, and instrumentation of the urinary tract should be minimized to avoid introducing infection.

NEPHRONOPHTHISIS/MEDULLARY CYSTIC DISEASE

GENETIC CONSIDERATIONS Nephronophthisis (NPH) and medullary cystic disease (MCD) have similar pathologic findings but differ in inheritance pattern and age of onset. NPH is inherited as an autosomal recessive disease. Three forms have been identified, the most common is juvenile (NPH1), which maps to a gene on chromosome 2q13. The infantile form (NPH2) maps to chromosome 9, and the adolescent form (NPH3) maps to chromosome 3. MCD is an autosomal dominant disease. Two loci have been associated with MCD, one on chromosome 1q21 and the other on 16p12. In both NPH and MCD the kidneys tend to be small, with cysts throughout the medulla; the cortex and papilla rarely have cysts. The cysts originate in the collecting ducts, distal convoluted tubules, and loops of Henle and range in size from 1 to 10 mm. Sclerotic glomeruli, tubule atrophy, and interstitial fibrosis are frequent findings on biopsy.

Clinical Features Patients with NPH present during childhood with symptoms of polyuria, growth retardation, anemia, and progressive renal insufficiency. ESRD develops at an average age of 2 years in NPH2, 13 years in NPH1, and 19 years in NPH3. NPH accounts for 2 to 10% of renal failure in children. Hepatic fibrosis and cerebellar ataxia have been reported in association with NPH. MCD presents in the third or fourth decade, though some cases may be diagnosed in the elderly population. Presenting symptoms in MCD are the same as in NPH except for growth retardation. In addition, MCD does not have extrarenal abnormalities. Severe salt wasting can be seen, though this is usually a transient phase that resolves as the disease progresses to ESRD. Other features of tubule damage are often found, including hyperkalemia and hyperchloremic metabolic acidosis. Proteinuria is mild, and hematuria is rare.

Diagnosis The diagnosis is suggested by a family history of renal disease. The pattern of inheritance and age of onset aid in distinguishing NPH/MCD from other inherited diseases. Radiographic studies show small kidneys, loss of the corticomedullary junction, and multiple cysts in the medulla. CT scan is more sensitive than ultrasound in making the diagnosis. The majority of cases of NPH can be diagnosed using molecular genetics techniques. Open renal biopsy, including medullary tissue, may be required for diagnosis in some cases.

TREATMENT

Treatment is mainly supportive, as there is no specific therapy to prevent loss of renal function. Patients with salt wasting require a large oral intake of salt and water to maintain adequate extracellular volume. Alkali replacement and erythropoietin are required for acidosis and anemia, respectively. Renal transplantation has been performed in numerous patients, and the disease does not recur.

LIDDLE'S SYNDROME

Liddle's syndrome is a rare autosomal dominant disorder with a clinical presentation of hyperaldosteronism, consisting of hypertension, hypokalemia, and metabolic alkalosis. However, aldosterone levels are undetectable and renin levels are suppressed. The syndrome is caused by activating mutations in the amiloride-sensitive sodium channel, which leads to increased distal tubule sodium reabsorption and potassium wasting. Potassium-sparing diuretics that block the sodium channel, such as amiloride and triamterene, used in conjunction with a low-sodium diet, are effective in treating the hypertension and electrolyte abnormalities. Spironolactone is ineffective, since the disease is not mediated via the aldosterone receptor.

BARTTER'S SYNDROME

Clinical Features Hypokalemia secondary to renal potassium wasting, metabolic alkalosis, and normal to low blood pressure are the clinical features of Bartter's syndrome. Two variants of Bartter's syndrome have been described. *Antenatal Bartter's syndrome* (also known as *hyperprostaglandin E syndrome*) is characterized by polyhydramnios and premature delivery. During infancy, episodes of fever and dehydration are common and can lead to growth retardation. Nephrocal-

cinosis secondary to hypercalciuria is frequent. Prostaglandin E production is very high. Most cases of *classic Bartter's syndrome* present during childhood. Symptoms such as weakness and cramps are secondary to the hypokalemia. Polyuria and nocturia are common due to the hypokalemia-induced nephrogenic diabetes insipidus. Nephrocalcinosis is less common than in the antenatal form. Both forms are inherited as autosomal recessive traits. Although rarely required for diagnosis, renal biopsy reveals hyperplasia of the juxtaglomerular apparatus and prominence of medullary interstitial cells, with variable degrees of interstitial fibrosis, though these are not pathognomonic for the syndrome.

GENETIC CONSIDERATIONS Abnormalities in three renal tubule transport proteins have been shown to cause Bartter's syndrome. Mutations in either the bumetanide-sensitive Na-K-2Cl cotransporter or the apical K^+ channel (ROMK) have been described in antenatal Bartter's. Mutations of a basolateral chloride channel (CLC-Kb) are found in patients with classic Bartter's syndrome. All of these mutations lead to a loss of Na^+ and Cl^- reabsorption in the loop of Henle. The resultant volume depletion activates the renin-angiotensin system. Distal delivery of NaCl and water are high in the presence of high aldosterone, promoting secretion of K^+ and H^+ ions. Prostaglandin overproduction is mediated by volume depletion, hypokalemia, and high angiotensin II and kallikrein levels. Increased prostaglandin production contributes to the severity of disease by inducing resistance to the pressor effects of angiotensin II and reducing reabsorption in the thick ascending limb of the loop of Henle.

Diagnosis Hypokalemia, metabolic alkalosis, and normal to low blood pressure are the clinical findings characteristic of Bartter's syndrome. The differential diagnosis includes vomiting, surreptitious diuretic abuse, and magnesium deficiency. Chronic vomiting can be diagnosed by a low urine Cl^- concentration. Magnesium deficiency causes kaluresis and alkalosis, simulating Bartter's syndrome. Serum and urine magnesium will be low in such cases. Diuretic abuse produces metabolic abnormalities indistinguishable from Bartter's syndrome. Urine should be screened for diuretics multiple times before the diagnosis of Bartter's is made in a patient without a family history of the disorder.

TREATMENT

Dietary intake of sodium and potassium should be liberal. Potassium supplements are usually required. Spironolactone will reduce potassium wasting. Nonsteroidal antiinflammatory drugs (NSAIDs) are useful, particularly in patients with antenatal Bartter's syndrome, since they reduce prostaglandin production. Angiotensin-converting enzyme (ACE) inhibitors may be beneficial in some patients.

GITELMAN'S SYNDROME

Gitelman's syndrome shares many features with Bartter's syndrome including hypokalemia, metabolic alkalosis, salt wasting, elevated renin and aldosterone levels, and normal blood pressure. Clinically it is distinguished from Bartter's by hypomagnesemia and hypocalciuria. Gitelman's syndrome is usually diagnosed during adolescence or adulthood, with weakness, fatigue, muscle cramps, and nocturia being the most common symptoms. The syndrome is inherited as an autosomal recessive trait and is due to mutations in the thiazide-sensitive Na-Cl transporter. The reduced Na^+ reabsorption in the distal convoluted tubule leads to volume depletion and hypokalemia. Loss of activity of the thiazide-sensitive transporter increases tubule calcium reabsorption, leading to the classic finding of hypocalciuria in Gitelman's syndrome. Treatment consists of liberal dietary sodium intake, potassium and magnesium supplements, and potassium sparing diuretics. Unlike in Bartter's syndrome, NSAIDs and ACE inhibitors are not effective.

CONGENITAL NEPHROGENIC DIABETES INSIPIDUS

GENETIC CONSIDERATIONS This rare genetic disorder is most commonly inherited as an X-linked disease, with full expression in males and variable penetrance in females. Vasopressin acts through two receptors; type 1 receptors are located in the vasculature, while type 2 receptors are found in the collecting ducts of the kidney. In X-linked nephrogenic diabetes insipidus (NDI), only the actions requiring type 2 receptors are abnormal. Mutations of the type 2 vasopressin receptor lead to misfolding and trapping of the receptor in the endoplasmic reticulum, with no receptor present on the cell surface. Less frequently, NDI may be inherited as an autosomal trait, either recessive or dominant, in which mutations in the gene for the water channels in collecting duct cells (aquaporin 2) lead to abnormal cell routing of aquaporin 2.

Clinical Features The clinical presentation is that of persistent polyuria, dehydration, and hypotonic urine in the presence of hypernatremia. Vasopressin levels are appropriately elevated in the hypertonic state, but renal response is lacking. About 90% of cases are diagnosed in the first 2.5 years of life. Recurrent hypernatremia may lead to seizures or mental retardation. Once old enough to satisfy their thirst, children will be clinically stable though in a chronic state of polyuria and polydypsia. Renal function is normal, and radiographic studies of the urinary system reveal dilated ureters and bladder secondary to the chronically high urine flow. Since the most common form of the disease is X-linked, most patients are male. Heterozygous females generally have mild concentrating defects, though a few have phenotypic expression similar to males due to skewed X-chromosome inactivation.

TREATMENT

Treatment is aimed at maintaining adequate hydration. In the infant, low-solute feedings and high water intake are generally adequate. Addition of a thiazide diuretic reduces urine flow by inhibiting sodium reabsorption in the distal convoluted tubule. This lowers free water production and, by causing extracellular volume contraction, increases proximal salt and water reabsorption, reducing delivery to the distal nephron. Amiloride or indomethacin are frequently used to potentiate the effects of thiazide diuretics. Administration of vasopressin and its analogues has no role in the management of this disorder.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA) is a disorder of renal acidification out of proportion to the reduction in glomerular filtration rate. RTA is characterized by hyperchloremic metabolic acidosis with a normal serum anion gap $[Na^+ - (Cl^- + HCO_3^-)]$. There are multiple forms of RTA, depending on which aspects of renal acid handling have been affected. Defective bicarbonate reabsorption in the proximal tubule, suppressed renal ammoniagenesis, and inadequate distal tubule proton secretion are the abnormalities that produce RTA. Three major forms of RTA exist (Table 265-2). Types 1 and 2 may be inherited or acquired. Type 4 is usually acquired and is associated with either hypoaldosteronism or tubular hyporesponsiveness to mineralocorticoids. *Type 3 is a very rare form of RTA with features of both type 1 and type 2 RTA*. It is due to deficiency carbonic anhydrase II, an enzyme present in both the proximal and distal tubules. It is an autosomal recessive disease associated with osteopetrosis and mental retardation.

TYPE 1 (DISTAL) RTA In this disorder the distal nephron does not lower urine pH normally, either because the collecting ducts permit excessive back-diffusion of hydrogen ions from lumen to blood or because there is inadequate transport of hydrogen ions. Excretion of titratable acid is low, as inadequate proton secretion prevents titration of urinary buffers such as phosphate. Urine ammonium excretion is inappropriately low for the level of acidosis, as the defect in acidification reduces the ion trapping required for ammonium excretion. Urinary concentration and potassium conservation also tend to be impaired.

Chronic acidosis lowers tubule reabsorption of calcium, causing renal hypercalciuria and mild secondary hyperparathyroidism. Buffering of bone by the daily metabolic acid load contributes to hypercalciuria. Urine citrate excretion is low, as acidosis and hypokalemia stimulate proximal tubule reabsorption of citrate. The hypercalciuria, alkaline urine, and low levels of urine citrate cause calcium phosphate stones and nephrocalcinosis. Growth retardation is common and improves with correction of the acidosis by alkali. In both children and adults, bone diseases may result, in part, from acidosis-induced loss of bone material and inadequate production of 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$]. Since the kidney does not conserve potassium or concentrate the urine normally, polyuria and hypokalemia occur. With the stress of an intercurrent illness, acidosis and hypokalemia can be life-threatening.

TABLE 265-2 *Comparison of Normal Anion-Gap Acidoses*

Finding	Type 1 RTA	Type 2 RTA	Type 4 RTA	GI Bicarbonate Loss
Normal anion-gap acidosis	Yes	Yes	Yes	Yes
Minimum urine pH	>5.5	<5.5	<5.5	5 to 6
% Filtered bicarbonate excreted	<10	>15	<10	<10
Serum potassium	Low	Low	High	Low
Fanconi syndrome	No	Yes	No	No
Stones/nephrocalcinosis	Yes	No	No	No
Daily acid excretion	Low	Normal	Low	High
Urine anion gap	Positive	Negative	Positive	Negative
Daily bicarbonate replacement needs	<4 mmol/kg	>4 mmol/kg	<4 mmol/kg	Variable

Note: RTA, renal tubular acidosis.

GENETIC CONSIDERATIONS Type 1 RTA can be familial, with autosomal dominant as the most common mode of inheritance. Autosomal recessive and sporadic cases have been reported. Mutations in the basolateral chloride-bicarbonate exchanger (*AE1*) of intercalated cells have been identified in the autosomal dominant form. The autosomal recessive form has been associated with mutations in the H^+-ATPase in some families. Sensorineural deafness frequently accompanies the H^+-ATPase mutation. Other hereditary diseases that cause type 1 RTA include galactosemia, Ehler-Danlos syndrome, Fabry's disease, MSK, Wilson's disease, and hereditary elliptocytosis. The majority of cases of type 1 RTA are secondary to a systemic disorder such as Sjögren's syndrome, hypergammaglobulinemia, chronic active hepatitis, or lupus.

Diagnosis The diagnosis of type 1 RTA is suggested by a normal anion gap metabolic acidosis with a simultaneous urine pH > 5.5. Calcium phosphate stones or nephrocalcinosis support the diagnosis, though they are not present in all cases. Bicarbonaturia is not present, which distinguishes this disorder from type 2 RTA. If acidosis is not severe and urine pH is equivocal, an oral ammonium chloride loading test may confirm the diagnosis. As systemic acidosis worsens with ammonium chloride, urine pH does not fall below 5.5 in patients with type I RTA.

Chronic diarrheal states cause normal anion gap acidosis and hypokalemia; urine pH may be >5.5 if ammonium production is very high. The urine anion gap ($Na^+ + K^+ - Cl^-$) can be used to estimate renal ammonium production and distinguish RTA from gastrointestinal bicarbonate loss. Normally the urine anion gap is positive, as unmeasured anions exceed unmeasured cations. If urine ammonium levels are high, urine chloride concentration increases to balance the charge. Unmeasured cation (predominantly ammonium) now exceeds unmeasured anion, and the urine anion gap is negative. During metabolic acidosis, a negative urine anion gap suggests an extrarenal cause of acidosis, whereas a positive urine anion gap suggests RTA. The urine anion gap cannot be used if there are large amounts of unmeasured anions, such as bicarbonate or ketones, in the urine.

TREATMENT

Alkali supplements are the standard therapy. Enough alkali is prescribed to titrate the daily metabolic acid production, usually in the range of 0.5 to 2.0 mmol/kg body weight in four to six divided doses per day. Sodium bicarbonate and Shohl's solution are common treatments. Potassium alkali salts can be used if hypokalemia is a persistent problem. Citrate requires less frequent dosing than bicarbonate salts as it is metabolized to bicarbonate after absorption. The dose of alkali should be raised until acidosis and hypercalciuria are both eliminated. Requirements for alkali may rise during intercurrent illnesses but are <4 mmol/kg body weight per day. The relatives of patients with idiopathic type 1 RTA should be screened for this disorder, as timely treatment can prevent growth retardation in children. Incomplete RTA secondary to idiopathic hypercalciuria is best treated using thiazide diuretics in conjunction with potassium citrate (Chap. 268).

TYPE 2 (PROXIMAL) RTA Type 2 RTA usually occurs as part of a generalized disorder of proximal tubule function, presenting as hyperchloremic acidosis with other features of Fanconi syndrome. Bicarbonate reabsorption in the proximal tubule is defective. At normal concentrations of plasma bicarbonate, large amounts of bicarbonate are delivered to the distal tubule, overwhelming the absorptive capacity of the distal tubule and resulting in bicarbonaturia. As plasma bicarbonate levels fall, the lower filtered load of bicarbonate can be reabsorbed by the proximal tubule, resulting in normal distal delivery of bicarbonate. At this point the distal nephron can acidify the urine normally, resulting in normal excretion of daily metabolic acid production, albeit at a low serum bicarbonate level. Hypophosphatemia and low calcitriol levels are common and may lead to rickets or osteomalacia. Hypercalciuria occurs, but stone formation is unusual since urine citrate levels are normal or high because of reduced proximal tubule citrate reabsorption. Type 2 RTA without Fanconi syndrome may be inherited as an autosomal dominant or recessive disorder. Mutations in the Na^+-HCO_3^- cotransporter (NBC-1) have been reported in some families with the autosomal recessive form. Type 2 RTA may be acquired in association with other diseases (see "Fanconi Syndrome," below) or be secondary to drugs that inhibit carbonic anhydrase activity, such as acetazolamide.

Type 2 RTA may be distinguished from type 1 RTA by the ability to normally acidify urine during spontaneous or ammonium chloride–induced acidosis. Correction of acidosis with bicarbonate will result in bicarbonaturia in type 2 RTA but not in type 1 RTA. Fractional excretion of bicarbonate is >15% at normal or near-normal serum bicarbonate levels. In distal RTA it is <10%. It is unusual for serum bicarbonate levels to fall below 15 mmol/L in proximal RTA. The urine anion gap will be positive, as ammonium excretion is normal to handle daily acid production but is not elevated as in nonrenal causes of acidosis.

TREATMENT

Children should be treated to prevent growth retardation. Alkali must be given in large amounts daily, 5 to 15 mmol/kg body weight per day, because bicarbonate is rapidly excreted in the urine. A thiazide diuretic can be used in conjunction with a low-salt diet to reduce the amount of bicarbonate required. Potassium requirements increase during alkali therapy due to increased renal loss of potassium from bicarbonaturia.

TYPE 4 RTA In type 4 RTA, also called *hyperkalemic distal RTA*, distal tubule secretion of both potassium and hydrogen ions is abnormal, resulting in hyperchloremic acidosis with hyperkalemia. Type 4 RTA is an acquired disorder; a moderate degree of renal insufficiency is

present in the majority of patients. Patients with type 4 RTA can be differentiated from patients with type 1 since they have an acid urine (pH $<$ 5.5) during periods of acidosis (Table 265-2) and hyperkalemia. They differ from type 2 patients by having a fractional excretion of bicarbonate $<$10% and a daily bicarbonate requirement of 1 to 3 mmol/kg body weight per day. Because potassium and hydrogen ion excretion are abnormal, such patients are considered to have generalized distal nephron dysfunction due to either insufficient aldosterone production or intrinsic renal disease causing aldosterone resistance. The resulting hyperkalemia reduces proximal tubule ammonia production, in addition to the inadequate proton secretion, leading to inadequate excretion of the daily metabolic proton load. These patients have an acid urine despite reduced proton secretion because there is inadequate ammonia to buffer protons in the distal tubule. If buffer delivery to the distal nephron is increased, urine pH will rise despite persistent acidosis.

Type 4 RTA due to inadequate aldosterone production has multiple etiologies. Hyporeninemic hypoaldosteronism is the most common cause of type 4 RTA and is usually associated with diabetic nephropathy. Plasma levels of renin and aldosterone are subnormal, even during extracellular volume depletion. NSAIDs, ACE inhibitors, trimethoprim, and heparin can reduce aldosterone production and produce a type 4 RTA. Drug-induced type 4 RTA is usually seen in patients with preexisting renal insufficiency. Reduced aldosterone production may be due to adrenal disease, occurring as either an isolated defect or as part of a more generalized adrenal disorder (Chap. 321). Renin levels are normal to high in adrenal disorders.

Patients with tubular resistance to aldosterone present with the same clinical features as those with hyporeninemic hypoaldosteronism. A tubulointerstitial process damages the distal tubule, restricting potassium and hydrogen ion excretion, despite adequate aldosterone levels. Obstructive uropathy and sickle cell disease are the most common causes of acquired tubular resistance to aldosterone. Hyporeninemic hypoaldosteronism can be found in addition to tubular aldosterone resistance in many patients. Potassium-sparing diuretics can cause a type 4 RTA by producing an aldosterone resistant state.

TREATMENT

The main goal of therapy is to reduce serum potassium, as acidosis will usually improve once the hyperkalemic block of ammonium production is removed. All patients should be placed on a low-potassium diet. Any drug that suppresses aldosterone production or blocks aldosterone effect should be discontinued. Mineralocorticoid supplementation with fludrocortisone, 0.1 to 0.2 mg/d, will improve hyperkalemia and acidosis; however, the patients who also have a partial tubule resistance to mineralocorticoid will require a higher dose. Mineralocorticoid replacement may not be appropriate for patients with hypertension or a history of heart failure. In such situations, a loop diuretic with a liberal sodium intake can usually promote adequate potassium excretion. Exchange resins will reduce potassium levels but are usually not tolerated well enough to be used for long-term treatment.

PSEUDOHYPOALDOSTERONISM

GENETIC CONSIDERATIONS Type I pseudohypoaldosteronism is transmitted as either an autosomal dominant or recessive trait. The autosomal dominant form is caused by mutations in the mineralocorticoid receptor gene; the autosomal recessive disease is caused by inactivating mutations in the amiloride-sensitive epithelial sodium channel. The aldosterone resistance leads to hyperkalemia, metabolic acidosis, salt wasting, and volume depletion, which present during childhood. Plasma renin and aldosterone levels are elevated. Treatment includes salt supplements, alkali, and potassium restriction.

Type II pseudohypoaldosteronism (also known as *Gordon syndrome*) presents as hypertension, hyperkalemia, and metabolic acidosis with normal renal function. The disease is inherited as an autosomal dominant trait and appears to be secondary to overactivity of the thiazide sensitive Na-Cl cotransporter. Two genes have been linked to the disease and both encode WNK kinases that are expressed in the distal tubule. Thiazide diuretics control the hypertension and correct the electrolyte disorders.

VITAMIN D DISORDERS

X-LINKED HYPOPHOSPHATEMIC RICKETS (See also Chap. 331) This disorder is an X-linked dominant disorder characterized by hypophosphatemia with renal phosphate wasting, rickets, and short stature. Hypophosphatemia is present soon after birth; rachitic bowing of the legs develops when the child begins to walk. Children have growth retardation, which is limited almost entirely to the lower extremities. Dentition is delayed, and skull abnormalities are common. Presentation in adults ranges from disabling bone pain to no active symptoms, but generally some physical sign of childhood disease, such as short stature or bowed legs, is present. Overgrowth of bone at joints or sites of muscle attachment may reduce the mobility of the joint or cause nerve entrapment.

Hypophosphatemia secondary to reduced renal phosphate reabsorption is the hallmark of the disease. Serum calcium levels are usually normal, with low intestinal absorption and renal excretion of calcium. Serum alkaline phosphatase and osteocalcin levels are elevated. Parathyroid hormone levels are normal, as would be expected with normal serum calcium. $1,25(OH)_2D_3$ levels are usually normal, though in the setting of hypophosphatemia $1,25(OH)_2D_3$ levels should be elevated. The disease is caused by inactivating mutations in the PHEX gene, located on chromosome Xp22.1, which codes for a membrane-bound endopeptidase. Circulating humoral factors, phosphatonins, that are normally inactivated by the PHEX endopeptidase accumulate in the serum and reduce proximal tubule phosphate reabsorption and $1,25(OH)_2D_3$ production.

TREATMENT

The goal of therapy is to raise serum phosphorous to normal or near-normal levels to improve bone mineralization. Oral neutral phosphate, 1 to 4 g/d in four to six doses, combined with calcitriol is an effective therapy that improves growth rate, reduces bone pain, and leads to radiographically evident improvement of the bone disease. Patients should be closely monitored during therapy as they may develop nephrocalcinosis and renal insufficiency.

AUTOSOMAL DOMINANT HYPOPHOSPHATEMIC RICKETS This disorder usually presents during childhood with low serum phosphate from renal phosphate wasting, rickets, and dental abnormalities. There is significant phenotypic variability with some subjects not presenting until adulthood and other cases spontaneously correcting metabolic abnormalities after puberty. The disorder has been linked to a locus on chromosome 12p13, and mutations have been identified in the gene product, fibroblast growth factor (FGF-23). FGF-23 may act as a phosphatonin and promote renal phosphate wasting.

VITAMIN D–DEPENDENT RICKETS TYPE I

GENETIC CONSIDERATIONS This is an autosomal recessive disorder in which $1,25(OH)_2D_3$ levels are very low but 25-hydroxyvitamin D levels are normal. The disease is caused by inactivating mutations in the gene encoding the 1α-hydroxylase enzyme, leading to a clinical syndrome of vitamin D deficiency.

Symptoms usually appear before the age of 2, including rickets and growth retardation. Levels of serum calcium and phosphorous are low, but that of alkaline phosphatase is elevated. Intestinal calcium absorption and urinary calcium excretion are low. Parathyroid hormone is elevated in response to the hypocalcemia, resulting in increased urinary phosphate losses.

TREATMENT

Calcitriol (0.5 to 1 μg/d) leads to rapid correction of the biochemical abnormalities and resolution of the bone disease. Calcium and phosphorous supplementation are usually not required.

VITAMIN D–DEPENDENT RICKETS TYPE II (See also Chap. 331) End-organ resistance to $1,25(OH)_2D_3$ is the pathogenesis of this disorder. Serum calcium and phosphate levels are low, secondary hyperparathyroidism is present, and $1,25(OH)_2D_3$ levels are elevated. Inheritance is usually autosomal recessive, though sporadic cases have been reported. Most patients present during childhood with rickets, though some have a milder form of disease not recognized until adulthood. Alopecia is common and tends to be associated with the more severe childhood form of the disease. Mutations in the vitamin D receptor reduce tissue response to $1,25(OH)_2D_3$. Pharmacologic doses of calcitriol (5 to 30 μg/d) along with mineral supplementation will improve the biochemical disorders and bone disease, though some patients have no response to massive doses of calcitriol.

ONCOGENIC OSTEOMALACIA This syndrome generally occurs in adults with highly vascular mesenchymal tumors. Patients present with bone pain and muscle weakness. Symptoms may be present for years before the correct diagnosis is made. Over 90% of the tumors are benign, and most are found in the extremities or maxillofacial region. Hypophosphatemia secondary to renal phosphate wasting and low levels of $1,25(OH)_2D_3$ are the major biochemical abnormalities. Serum calcium and parathyroid hormone levels are normal. The tumors produce humoral agents, phosphatonins, that reduce proximal tubule phosphate reabsorption and 1α-hydroxylase activity. FGF-23 is a fibroblast growth factor that has been identified as a potential phosphatonin. Removal of the tumor leads to rapid resolution of the disease. Octreotide therapy reduces secretion of phosphatonins and improves serum phosphorus in some patients with oncogenic osteomalacia.

DENT'S DISEASE

This disorder presents as hypercalciuria, low-molecular-weight proteinuria, calcium nephrolithiasis, and nephrocalcinosis in male children. Progression to renal failure is common. Phosphaturia, glycosuria, aminoaciduria, and other features of Fanconi's syndrome may be present. Females carrying the gene are asymptomatic except for low-molecular-weight proteinuria. Kidney biopsy reveals tubular atrophy, interstitial fibrosis, and medullary calcifications. The gene has been mapped to the short arm of the X chromosome and encodes a voltage-gated chloride channel (CLC-5). Treatment with thiazide diuretics improves the hypercalciuria, but whether thiazides help preserve renal function is not known.

ISOLATED HYPOURICEMIA (See also Chap. 338)

This disorder is generally inherited as an autosomal recessive trait. Most commonly there is deficient urate reabsorption in the proximal tubule, though some patients have been demonstrated to oversecrete urate. Serum uric acid is usually <120 μmol/L (2 mg/dL) and hyperuricosuria is common, possibly due to decreased intestinal urate excretion. Hypouricemia is usually an incidental finding, as patients with this disorder are asymptomatic except for an increased risk of nephrolithiasis. Other disorders associated with hypouricemia include Fanconi syndrome, Wilson's disease, Hodgkin's disease, and Hartnup disease. No treatment is required except for high fluid intake to prevent kidney stones. Alkali and allopurinol may be used to prevent stones if fluids alone are not sufficient.

SELECTED DISORDERS OF AMINO ACID TRANSPORT

HARTNUP DISEASE This disorder is characterized by reduced intestinal absorption and renal reabsorption of neutral amino acids. The defect involves an amino acid transporter on the brush border of the jejunum and the proximal tubule. Intestinal absorption of free amino acids is reduced, though the neutral amino acids can be absorbed when present in di- and tripeptides. Degradation of unabsorbed tryptophan by intestinal bacteria produces indolic acids that are absorbed and subsequently excreted at high levels in the urine of these patients. The disorder is inherited as an autosomal recessive trait with an estimated incidence of 1 in 24,000 live births. Linkage analysis suggests a locus on chromosome 5.

The majority of individuals with this disorder are asymptomatic. Approximately 10 to 20% present with clinical symptoms similar to those seen in pellagra, including a photosensitive erythematous scaly rash, intermittent cerebral ataxia, delirium, and diarrhea. Short stature is noted in some patients. The symptoms are thought to be due to deficiency in the essential amino acid tryptophan and resultant inadequate synthesis of nicotinamide. Though the inheritance of the disorder is autosomal recessive, the development of symptomatic disease appears to be multifactorial. Diet, environment, and polygenic traits controlling plasma amino acid levels all contribute to development of symptoms.

Clinically affected patients can be differentiated from patients with pellagra by dietary history and the presence of aminoaciduria. Diagnosis is made by the characteristic finding of large amounts of neutral amino acids in the urine. It can easily be distinguished from generalized aminoaciduria by the normal excretion of proline. There are no other renal tubule defects as in Fanconi syndrome. Heterozygotes have normal urinary amino acid excretion.

TREATMENT

Symptomatic individuals should receive oral nicotinamide, 40 to 200 mg/d, and a high-protein diet to compensate for the poor amino acid absorption. Some patients who do not respond to nicotinamide may improve with tryptophan ethyl ester, which is lipid soluble and can be absorbed without an active transport system.

FANCONI SYNDROME

GENETIC CONSIDERATIONS Fanconi syndrome is a generalized defect in proximal tubule transport involving amino acids, glucose, phosphate, uric acid, sodium, potassium, bicarbonate, and proteins. Idiopathic Fanconi syndrome may be inherited as an autosomal dominant, autosomal recessive, or X-linked trait. The autosomal dominant form has been mapped to chromosome 15. Sporadic cases are also seen. A variety of inherited systemic disorders are also associated with Fanconi syndrome including Wilson's disease, galactosemia, tyrosinemia, cystinosis, fructose intolerance, and Lowe's oculocerebral syndrome. The syndrome may be acquired in multiple myeloma, amyloid, heavy metal toxicity, and from chemotherapeutic drugs.

The patients may present with a wide array of laboratory abnormalities including proximal renal tubular acidosis, glucosuria with a normal serum glucose, hypophosphatemia, hypouricemia, hypokalemia, generalized aminoaciduria, and low-molecular-weight proteinuria. Some patients do not have abnormalities in all proximal tubule transporters and may present with only a few of the laboratory findings. Rickets and osteomalacia are common findings secondary to the hypophosphatemia; production of calcitriol may also be abnormal. Metabolic acidosis also contributes to the bone disease. Polyuria, salt wasting, and hypokalemia may be quite severe.

TREATMENT

Treatment includes phosphate supplements and calcitriol to heal the bone lesions, alkali for the acidosis, and liberal intake of salt and water. Alkali in the form of potassium salts may be particularly useful in the patient with RTA and hypokalemia. Aminoaciduria, glucosuria, hypouricemia, and low-molecular-weight proteinuria do not require treatment.

266 TUBULOINTERSTITIAL DISEASES OF THE KIDNEY

Alan S. L. Yu, Barry M. Brenner

Primary tubulointerstitial diseases of the kidney, as distinct from the disorders considered in Chaps. 264 and 267, are characterized by histologic and functional abnormalities that involve the tubules and interstitium to a greater degree than the glomeruli and renal vasculature (Table 266-1). Secondary tubulointerstitial disease occurs as a consequence of progressive glomerular or vascular injury. Morphologically, acute forms of these disorders are characterized by interstitial edema, often associated with cortical and medullary infiltration by both mononuclear cells and polymorphonuclear leukocytes, and patchy areas of tubule cell necrosis. In more chronic forms, interstitial fibrosis predominates, inflammatory cells are typically mononuclear, and abnormalities of the tubules tend to be more widespread, as evidenced by atrophy, luminal dilatation, and thickening of tubule basement membranes. Because of the nonspecific nature of the histology, particularly in chronic tubulointerstitial diseases, biopsy specimens rarely provide a specific diagnosis. The urine sediment is also unlikely to be diagnostic, except in allergic forms of acute tubulointerstitial disease, in which eosinophils may predominate in the urinary sediment.

Defects in renal function often accompany these alterations of tubule and interstitial structure (Table 266-2). Proximal tubule dysfunction may be manifested as selective reabsorptive defects leading to hypokalemia, aminoaciduria, glycosuria, phosphaturia, uricosuria, or bicarbonaturia [proximal or type II renal tubular acidosis (RTA); Chap. 265]. In combination, these defects constitute the *Fanconi syndrome*. Proteinuria, predominantly of low-molecular-weight proteins, is usually modest, rarely exceeding 2 g/d.

Defects in urinary acidification and concentrating ability often represent the most troublesome of the tubule dysfunctions encountered in patients with tubulointerstitial disease. Hyperchloremic metabolic acidosis often develops at a relatively early stage in the course. Patients with this finding generally elaborate urine of maximal acidity (pH $\leq$ 5.3). In such patients the defect in acid excretion is usually caused by a reduced capacity to generate and excrete ammonia due to the reduction in renal mass. Preferential damage to the collecting ducts, as in amyloidosis or chronic obstructive uropathy, may also predispose to distal or type I RTA, characterized by high urine pH ($\geq$5.5) during spontaneous or NH_4Cl-induced metabolic acidosis. Patients with tubulointerstitial diseases affecting predominantly medullary and papillary structures may also exhibit concentrating defects, with resultant nocturia and polyuria. Analgesic nephropathy and sickle cell disease are prototypes of this form of injury.

TABLE 266-1 Principal Causes of Tubulointerstitial Disease of the Kidney

ACUTE INTERSTITIAL NEPHRITIS
Drugs[a]
Antibiotics (β-lactams, sulfonamides, quinolones, vancomycin, erythromycin, minocycline, rifampin, ethambutol, acyclovir)
Nonsteroidal anti-inflammatory drugs
Diuretics (thiazides, furosemide, triamterene)
Anticonvulsants (phenytoin, phenobarbital, carbamazepine, valproic acid)
Miscellaneous (captopril, H_2 receptor blockers, omeprazole, mesalazine, indinavir, allopurinol)
Infection
Bacteria (*Streptococcus*, *Staphylococcus*, *Legionella*, *Salmonella*, *Brucella*, *Yersinia*, *Corynebacterium diphtheriae*)
Viruses (Epstein-Barr virus, cytomegalovirus, Hantavirus, HIV)
Miscellaneous (*Leptospira*, *Rickettsia*, *Mycoplasma*)
Idiopathic
Tubulointerstitial nephritis–uveitis syndrome
Anti-tubule basement membrane disease
Sarcoidosis
CHRONIC TUBULOINTERSTITIAL DISEASES
Hereditary renal diseases
Polycystic kidney disease[a] (Chap. 276)
Medullary cystic disease (Chap. 276)
Medullary sponge kidney (Chap. 276)
Exogenous toxins
Analgesic nephropathy[a]
Lead nephropathy
Miscellaneous nephrotoxins (e.g. lithium[a], cyclosporine[a], heavy metals, slimming regimens with Chinese herbs)
Metabolic toxins
Hyperuricemia[a]
Hypercalcemia
Miscellaneous metabolic toxins (e.g., hypokalemia, hyperoxaluria, cystinosis, Fabry's disease)
Autoimmune disorders
Sjögren's syndrome
Neoplastic disorders
Leukemia
Lymphoma
Multiple myeloma[a]
Miscellaneous disorders
Sickle cell nephropathy
Chronic pyelonephritis
Chronic urinary tract obstruction
Vesicoureteral reflux[a]
Radiation nephritis
Balkan nephropathy
Tubulointerstitial disease secondary to glomerular and vascular disease

[a] Common

TOXINS

Although the kidney is vulnerable to toxic injury, renal damage by a variety of nephrotoxins often goes unrecognized because the manifestations of such injury are usually nonspecific in nature and insidious in onset. Diagnosis largely depends on a history of exposure to a certain toxin. Particular attention should be paid to the occupational history, as well as to an assessment of exposure—current and remote—to drugs, especially antibiotics and analgesics, and to dietary supplements or herbal remedies. The recognition of a potential association between a patient's renal disease and exposure to a nephrotoxin is crucial, because, unlike many other forms of renal disease, progression of the functional and morphologic abnormalities associated with toxin-induced nephropathies may be prevented, and even reversed, by eliminating additional exposure.

TABLE 266-2 *Functional Consequences of Tubulointerstitial Disease*

Defect	Cause(s)
Reduced glomerular filtration rate[a]	Obliteration of microvasculature and obstruction of tubules
Fanconi syndrome	Damage to proximal tubular reabsorption of glucose, amino acids, phosphate, and bicarbonate
Hyperchloremic acidosis[a]	1. Reduced ammonia production 2. Inability to acidify the collecting duct fluid (distal renal tubular acidosis) 3. Proximal bicarbonate wasting
Tubular or small-molecular-weight proteinuria[a]	Failure of proximal tubule protein reabsorption
Polyuria, isothenuria[a]	Damage to medullary tubules and vasculature
Hyperkalemia[a]	Potassium secretory defects including aldosterone resistance
Salt wasting	Distal tubular damage with impaired sodium reabsorption

[a] Common

EXOGENOUS TOXINS ■ Analgesic Nephropathy A distinct clinicopathologic syndrome has been described in heavy users of analgesic mixtures containing phenacetin in combination with aspirin, acetaminophen, or caffeine. Morphologically, analgesic nephropathy is characterized by papillary necrosis and tubulointerstitial inflammation. At an early stage, damage to the vascular supply of the inner medulla (vasa recta) leads to a local interstitial inflammatory reaction and, eventually, to papillary ischemia, necrosis, fibrosis, and calcification. The susceptibility of the renal papillae to damage by phenacetin is believed to be related to the establishment of a renal gradient for its acetaminophen metabolite, resulting in papillary tip concentrations tenfold higher than those in renal cortex. Aspirin in these analgesic compounds contributes to renal injury by uncoupling oxidative phosphorylation in renal mitochondria and by inhibiting the synthesis of renal prostaglandins, which are potent endogenous renal vasodilator hormones.

In analgesic nephropathy, renal function usually declines gradually. Occasionally, papillary necrosis may be associated with hematuria and even renal colic owing to obstruction of a ureter by necrotic tissue. More than half of patients with analgesic nephropathy have pyuria, which, if persistently associated with sterile urine, provides an important clue to the diagnosis. Nonetheless, active pyelonephritis may coexist in patients with analgesic nephropathy. Proteinuria, if present, is typically mild (< 1 g/d). Patients with analgesic nephropathy are usually unable to generate maximally concentrated urine, reflecting the underlying medullary and papillary damage. An acquired form of distal RTA (Chap. 265) may contribute to the development of *nephrocalcinosis*. The occurrence of anemia out of proportion to the degree of azotemia may also provide a clue to the diagnosis of analgesic nephropathy. When analgesic nephropathy has progressed to renal insufficiency, the kidneys usually appear bilaterally shrunken on intravenous pyelography, and the calyces are deformed. A "ring sign" on the pyelogram is pathognomonic of papillary necrosis and represents the radiolucent sloughed papilla surrounded by the radiodense contrast material in the calyx. Computed tomography may reveal papillary calcifications surrounding the central sinus complex in a "garland" pattern. Transitional cell carcinoma may develop in the urinary pelvis or ureters as a late complication of analgesic abuse.

Whether non-phenacetin analgesics, alone or in combination, cause renal disease is controversial. A recent cohort study of men with normal baseline renal function found no association between moderate analgesic use and subsequent renal dysfunction, suggesting that the risk, if any, is low. Until conclusive evidence is available, however, physicians should consider screening heavy users of acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) for evidence of renal disease, and discouraging their use of these drugs.

Lead Nephropathy (See also Chap. 376) Lead intoxication may produce a chronic tubulointerstitial renal disease. Children who repeatedly ingest lead-based paints (pica) may develop kidney disease as adults. Significant occupational exposure may occur in workplaces where lead-containing metals or paints are heated to high temperatures, such as battery factories, smelters, salvage yards, and weapon firing ranges. Alcohol, illegally distilled in an apparatus constructed from automobile radiators (so-called moonshine), is another cause of lead poisoning. Environmental lead exposure, particularly in industrial regions, may be great enough to produce changes in renal function.

Tubule transport processes enhance the accumulation of lead within renal cells, particularly in the proximal convoluted tubule, leading to cell degeneration, mitochondrial swelling, and eosinophilic intranuclear inclusion bodies rich in lead. In addition, lead nephropathy is associated with ischemic changes in the glomeruli, fibrosis of the adventitia of small renal arterioles, and focal areas of cortical scarring. Eventually, the kidneys become atrophic. Urinary excretion of lead, porphyrin precursors such as δ-aminolevulinic acid and coproporphyrin, and urobilinogen may be increased. Patients with chronic lead nephropathy are characteristically *hyperuricemic*, a consequence of enhanced reabsorption of filtered urate. Acute gouty arthritis (so-called saturnine gout) develops in about 50% of patients with lead nephropathy, in striking contrast to other forms of chronic renal failure in which de novo gout is rare (Chap. 338). Hypertension is also a complication. Therefore, in any patient with slowly progressive renal failure, atrophic kidneys, gout, and hypertension, the diagnosis of lead intoxication should be considered. Features of acute lead intoxication (abdominal colic, anemia, peripheral neuropathy, and encephalopathy) are usually absent.

The diagnosis may be suspected by finding elevated serum levels of lead. However, because blood levels may not be elevated even in the presence of a toxic total-body burden of lead, the quantitation of lead excretion following infusion of the chelating agent calcium disodium edetate is a more reliable indicator of serious lead exposure. While urinary excretion of more than 0.6 mg/d of lead is generally considered to be indicative of overt or potential toxicity, recent evidence suggests that even lead burdens of 0.15 to 0.6 mg/d may cause progressive loss of renal function.

TREATMENT

Treatment includes removing the patient from the source of exposure and augmenting lead excretion with a chelating agent such as calcium disodium edetate.

Lithium Use of lithium salts for bipolar disorder (Chap. 371) is associated with chronic tubulointerstitial nephropathy, generally manifest as the insidious development of chonic renal insufficiency. Nephrogenic diabetes insipidus, which may occur alone or in association with the renal insufficiency, is common. It manifests as polyuria and polydipsia, and is due to lithium-induced downregulation of the vasopressin-regulated water channels in the collecting duct. Mild proteinuria can occur. The predominant finding on renal biopsy is tubular atrophy and interstitial fibrosis out of proportion to the extent of glomerular or vascular disease. Tubular cysts are common, and concomitant focal segmental glomerulosclerosis can be observed.

Renal function should be followed in patients taking this drug, and caution should be exercised if lithium is employed in patients with underlying renal disease. Once renal impairment occurs, lithium therapy should be stopped and an alternative agent substituted. Despite discontinuation of lithium, chronic renal disease in such patients is often irreversible and can progress to end-stage renal failure.

Miscellaneous Nephrotoxins The immunosuppressant *cyclosporine* causes both acute and chronic renal injury. The acute injury and the use of cyclosporine in transplantation are discussed in Chap. 263. The chronic injury results in an irreversible reduction in glomerular filtra-

tion rate (GFR), with mild proteinuria and arterial hypertension. Hyperkalemia is a relatively common complication and results in part from tubule resistance to aldosterone. The histologic changes in renal tissue include patchy interstitial fibrosis and tubular atrophy. In addition, the intrarenal vasculature often demonstrates hyalinosis, and focal segmental glomerular sclerosis can be present as well. Fibrosis may be the result of a cyclosporine-induced increase in renal collagen production. Vasoconstrictive mediators, such as angiotensin II, may also play a role in chronic cyclosporine toxicity. In patients receiving this drug for renal transplantation (Chap. 263), chronic graft dysfunction and recurrence of the primary disease may coincide with chronic cyclosporine injury, and on clinical grounds, distinction among these may be difficult. Cyclosporine nephrotoxicity is also seen in patients undergoing heart or lung transplantation, as well as in patients receiving cyclosporine as an immunosuppressant in a variety of inflammatory and autoimmune disorders. Dose reduction appears to mitigate cyclosporine-associated renal fibrosis but may increase the risk of rejection and graft loss. Treatment of any associated arterial hypertension may lessen renal injury.

Chinese herbs nephropathy is characterized by rapidly progressive interstitial renal fibrosis in young women due to ingestion of slimming pills containing Chinese herbs. At least one of the culprit ingredients is aristolochic acid. Clinically, patients present with progressive chronic renal insufficiency with sterile pyuria and anemia that is disproportionately severe relative to the level of renal function. The pathologic findings are interstitial fibrosis and tubular atrophy that affects the cortex in preference to the medulla, fibrous intimal thickening of the interlobular arteries, and a relative paucity of cellular infiltrates.

Many agents that commonly lead to acute renal failure are also capable of producing tubulointerstitial injury (Chap. 260). These include antibiotics (e.g., aminoglycosides, amphotericin B), radiographic contrast agents, various hydrocarbons (e.g., carbon tetrachloride), and heavy metals (e.g., mercury, cadmium, and bismuth).

METABOLIC TOXINS ■ Acute Uric Acid Nephropathy (See also Chap. 313) Acute overproduction of uric acid and extreme hyperuricemia often lead to a rapidly progressive renal insufficiency, so-called acute uric acid nephropathy. This tubulointerstitial disease is usually seen as part of the tumor lysis syndrome in patients given cytotoxic drugs for the treatment of lymphoproliferative or myeloproliferative disorders but may also occur in these patients before such treatment is begun. The pathologic changes are largely the result of deposition of uric acid crystals in the kidneys and their collecting systems, leading to partial or complete obstruction of collecting ducts, renal pelvis, or ureter. Since obstruction is often bilateral, patients typically follow the clinical course of acute renal failure, characterized by oliguria and rapidly rising serum creatinine concentration. In the early phase uric acid crystals can be found in urine, usually in association with microscopic or gross hematuria. Hyperuricemia can also be a consequence of renal failure of any etiology. The finding of a urine/uric acid creatinine ratio greater than 1 mg/mg (0.7 mol/mol) distinguishes acute uric acid nephropathy from other causes of renal failure.

Prevention of hyperuricemia in patients at risk by treatment with allopurinol in doses of 200 to 800 mg/d prior to cytotoxic therapy reduces the danger of acute uric acid nephropathy. Once hyperuricemia develops, however, efforts should be directed to preventing deposition of uric acid within the urinary tract. Increasing urine volume with potent diuretics (furosemide or mannitol) effectively lowers intratubular uric acid concentrations, and alkalinization of the urine to pH 7 or greater with sodium bicarbonate and/or a carbonic anhydrase inhibitor (acetazolamide) enhances uric acid solubility. If these efforts, together with allopurinol therapy, are ineffective in preventing acute renal failure, dialysis should be instituted to lower the serum uric acid concentration as well as to treat the acute manifestations of uremia.

Gouty Nephropathy (See also Chap. 313) Patients with less severe but prolonged forms of hyperuricemia are predisposed to a more chronic tubulointerstitial disorder, often referred to as *gouty nephropathy*. The severity of renal involvement correlates with the duration and magnitude of the elevation of the serum uric acid concentration. Histologically, the distinctive feature of gouty nephropathy is the presence of crystalline deposits of uric acid and monosodium urate salts in kidney parenchyma. These deposits not only cause intrarenal obstruction but also incite an inflammatory response, leading to lymphocytic infiltration, foreign-body giant cell reaction, and eventual fibrosis, especially of medullary and papillary regions of the kidney. Bacteriuria and pyelonephritis occur in about one-fourth of cases, presumably as complications of intrarenal urinary stasis. Since patients with gout frequently suffer from hypertension and hyperlipidemia, degenerative changes of the renal arterioles may constitute a striking feature of the histologic abnormality, often out of proportion to other morphologic defects. Clinically, gouty nephropathy is an insidious cause of renal insufficiency. Early in its course, GFR may be near normal, often despite focal morphologic changes in medullary and cortical interstitium, proteinuria, and diminished urinary concentrating ability. Whether reducing serum uric acid levels with allopurinol exerts a beneficial effect on the kidney remains to be demonstrated. Although such undesirable consequences of hyperuricemia as gout and uric acid stones respond well to allopurinol, use of this drug in asymptomatic hyperuricemia has not been shown to improve renal function consistently. On the other hand, uricosuric agents such as probenecid, which may increase uric acid stone production, clearly have no role in the treatment of renal disease associated with hyperuricemia.

Hypercalcemic Nephropathy (See also Chap. 332) Chronic hypercalcemia, as occurs in primary hyperparathyroidism, sarcoidosis, multiple myeloma, vitamin D intoxication, or metastatic bone disease, can cause tubulointerstitial damage and progressive renal insufficiency. The earliest lesion is a focal degenerative change in renal epithelia, primarily in collecting ducts, distal convoluted tubules, and loops of Henle. Tubule cell necrosis leads to nephron obstruction and stasis of intrarenal urine, favoring local precipitation of calcium salts and infection. Dilatation and atrophy of tubules eventually occur, as do interstitial fibrosis, mononuclear leukocyte infiltration, and interstitial calcium deposition (nephrocalcinosis). Calcium deposition may also occur in glomeruli and the walls of renal arterioles.

Clinically, the most striking defect is an inability to concentrate the urine maximally, resulting in polyuria and nocturia. Reduced collecting duct responsiveness to vasopressin and defective transport of NaCl in the ascending limb of Henle's loop are responsible for this concentrating defect. Reductions in GFR and renal blood flow also occur, both in acute severe hypercalcemia and with prolonged hypercalcemia of lesser severity. Distal RTA and sodium and potassium wasting have also been described in these chronic states. Eventually, uncontrolled hypercalcemia leads to severe tubulointerstitial damage and overt renal failure. Abdominal x-rays may demonstrate nephrocalcinosis as well as nephrolithiasis, the latter due to the hypercalciuria that often accompanies hypercalcemia.

TREATMENT

This consists of reducing the serum calcium concentration toward normal and correcting the primary abnormality of calcium metabolism. The management of hypercalcemia is discussed in Chap. 332. Prognosis for recovery of renal function depends on the severity of the renal lesion at the time hypercalcemia is corrected. Renal dysfunction of acute hypercalcemia may be completely reversible. Gradual, progressive renal insufficiency related to chronic hypercalcemia, however, may not improve with correction of the calcium disorder. Nonetheless, every effort should be made to return serum calcium concentration to normal to minimize further loss of renal function.

RENAL PARENCHYMAL DISEASE ASSOCIATED WITH EXTRARENAL NEOPLASM

Except for the glomerulopathies associated with lymphomas and several solid tumors (Chap. 264), the renal manifestations of primary ex-

trarenal neoplastic processes are confined mainly to the interstitium and tubules. Although metastatic renal involvement by solid tumors is unusual, the kidneys are often invaded by neoplastic cells in hematologic malignancies. In postmortem studies of patients with *lymphoma* and *leukemia*, renal involvement is found in approximately half. Diffuse infiltration of the renal parenchyma with malignant cells is seen most commonly. There may be flank pain, and x-rays may show enlargement of one or both kidneys. Renal insufficiency occurs in a minority of cases, and overt uremia is rare. Treatment of the primary disease may improve renal function in these cases.

PLASMA CELL DYSCRASIAS Several glomerular and tubulointerstitial disorders may occur in association with plasma cell dyscrasias (Chap. 98). Infiltration of the kidneys with myeloma cells is infrequent. When it occurs, the process is usually focal, so renal insufficiency from this cause is also uncommon. The more usual lesion is *myeloma kidney*, characterized histologically by atrophic tubules, many with eosinophilic intraluminal casts, and numerous multinucleated giant cells within tubule walls and in the interstitium. The frequent occurrence of myeloma kidney in patients with Bence Jones proteinuria has suggested a causal relation. Bence Jones proteins are thought to cause myeloma kidney through direct toxicity to renal tubule cells. In addition, Bence Jones proteins may precipitate within the distal nephron where the high concentrations of these proteins and the acid composition of the tubule fluid favor intraluminal cast formation and intrarenal obstruction. Occasionally, acute renal failure occurs after intravenous pyelography in patients with multiple myeloma and is believed to result from the further precipitation of Bence Jones proteins induced by dehydration prior to radiographic study. Dehydration of the patient with myeloma in preparation for intravenous pyelography should therefore be avoided. Multiple myeloma may also affect the kidneys indirectly. Hypercalcemia or hyperuricemia may lead to the nephropathies described above. Proximal tubule disorders are also seen occasionally, including type II proximal RTA and the Fanconi syndrome.

AMYLOIDOSIS (See also Chaps. 264 and 310) Glomerular pathology usually predominates and leads to heavy proteinuria and azotemia. However, tubule function may also be deranged, giving rise to a nephrogenic diabetes insipidus and to distal (type I) RTA. In several cases these functional abnormalities correlated with peritubular deposition of amyloid, particularly in areas surrounding vasa rectae, loops of Henle, and collecting ducts. Bilateral enlargement of the kidneys, especially in a patient with massive proteinuria and tubule dysfunction, should raise the possibility of amyloid renal disease.

IMMUNE DISORDERS

ALLERGIC INTERSTITIAL NEPHRITIS An acute diffuse tubulointerstitial reaction may result from hypersensitivity to a number of drugs, including sulfonamides, many penicillins and cephalosporins, the fluoroquinolone antibiotics ciprofloxacin and norfloxacin, and the antituberculous drugs isoniazid and rifampin. Acute tubulointerstitial damage has also occurred after use of thiazide and loop diuretics, antiulcer medications (cimetidine, ranitidine, and omeprazole), allopurinol, and NSAIDs. Of note, the tubulointerstitial nephropathy that develops in some patients taking NSAIDs may be associated with nephrotic-range proteinuria and histologic evidence of either minimal change or membranous glomerulopathy. The use of mesalazine for the treatment of inflammatory bowel disease is associated with a more subacute disorder in which a severe indolent interstitial nephritis occurs several months after the initiation of the drug. Grossly, the kidneys are usually enlarged. Histologically, the glomeruli appear normal. The principal pathologic abnormalities are in the interstitium of the kidney, which reveals pronounced edema and infiltration with polymorphonuclear leukocytes, lymphocytes, plasma cells, and, in some cases, large numbers of eosinophils. If the process is severe, tubule cell necrosis and regeneration may also be apparent. Immunofluorescence studies have either been unrevealing or demonstrated a linear pattern of immunoglobulin and complement deposition along tubule basement membranes.

Most patients require several weeks of drug exposure before developing evidence of renal injury. Rare cases have occurred after only a few doses or after a year or more of use. Azotemia is usually present; a diagnostic triad of fever, skin rash, and peripheral blood eosinophilia is highly suggestive of acute tubulointerstitial nephritis but is often absent. Examination of the urine sediment reveals hematuria and often pyuria; occasionally, eosinophils may be present. Proteinuria is usually mild to moderate, except in cases of NSAID-induced tubulointerstitial nephritis with minimal change glomerulopathy. The clinical picture may be confused with acute glomerulonephritis, but when acute azotemia and hematuria are accompanied by eosinophilia, skin rash, and a history of drug exposure, a hypersensitivity reaction leading to acute tubulointerstitial nephritis should be regarded as the leading diagnostic possibility. Discontinuation of the drug usually results in complete reversal of the renal injury; rarely, renal damage may be irreversible. Glucocorticoids may accelerate renal recovery, but their value has not been definitively established.

SJÖGREN'S SYNDROME (See also Chap. 304) When the kidneys are involved in this disorder, the predominant histologic findings are those of chronic tubulointerstitial disease. Interstitial infiltrates are composed primarily of lymphocytes, causing the histology of the renal parenchyma in these patients to resemble that of the salivary and lacrimal glands. Renal functional defects include diminished urinary concentrating ability and distal (type I) RTA. Urinalysis may show pyuria (predominantly lymphocyturia) and mild proteinuria.

TUBULOINTERSTITIAL ABNORMALITIES ASSOCIATED WITH GLOMERULONEPHRITIS Primary glomerulopathies are often associated with damage to tubules and the interstitium. Occasionally, the primary disorder may affect glomeruli and tubules directly. For example, in more than half of patients with the nephropathy of systemic lupus erythematosus, deposits of immune complexes can be identified in tubule basement membranes, usually accompanied by an interstitial mononuclear inflammatory reaction. Similarly, in many patients with glomerulonephritis associated with anti-glomerular basement membrane antibody, the same antibody is reactive against tubule basement membranes as well. More frequently, tubulointerstitial damage is a secondary consequence of glomerular dysfunction. The extent of tubulointerstitial fibrosis correlates closely with the degree of renal impairment. Potential mechanisms by which glomerular disease might cause tubulointerstitial injury include glomerular leak of plasma proteins toxic to epithelial cells, activation of tubule epithelial cells by glomerulus-derived cytokines, reduced peritubular blood flow leading to downstream tubulointerstitial ischemia, and hyperfunction of remnant tubules.

MISCELLANEOUS DISORDERS

VESICOURETERAL REFLUX (See also Chap. 270) When the function of the ureterovesical junction is impaired, urine may reflux into the ureters due to the high intravesical pressure that develops during voiding. Clinically, reflux is often detected on the voiding and postvoiding films obtained during intravenous pyelography, although voiding cystourethrography may be required for definitive diagnosis. Bladder infection may ascend the urinary tract to the kidneys through incompetent ureterovesical sphincters. Not surprisingly, therefore, reflux is often discovered in patients with acute and/or chronic urinary tract infections. With more severe degrees of reflux, characterized by dilatation of ureters and renal pelves, progressive renal damage often appears, and although active infection may also be present, uncertainty exists as to the necessity of infection in producing the scarred kidney of reflux nephropathy. Substantial proteinuria is often present, and glomerular lesions similar to those of idiopathic focal glomerulosclerosis (Chap. 264) are often found in addition to the changes of chronic tubulointerstitial disease. Surgical correction of reflux is usually necessary only with the more severe degrees of reflux since renal damage correlates with the extent of reflux. Obviously, if extensive glomerulosclerosis already exists, urologic repair may no longer be warranted.

RADIATION NEPHRITIS Renal dysfunction can be expected to occur if 23 Gy (2300 rad) or more of x-ray irradiation is administered to both kidneys during a period of 5 weeks or less. Histologic examination of the kidneys reveals hyalinized glomeruli, atrophic tubules, extensive interstitial fibrosis, and hyalinization of the media of renal arterioles. Radiation-induced renal ischemia is believed to be the main pathogenic factor responsible for the tubulointerstitial damage, which may not become evident clinically for months after completion of radiation. The presentation of acute radiation nephritis includes rapidly progressive azotemia, moderate to malignant hypertension, anemia, and proteinuria that may reach the nephrotic range. More than 50% progress to chronic renal failure. A more insidious form is characterized by slower development of azotemia, anemia, and nephrotic syndrome. Malignant hypertension may follow unilateral renal irradiation and resolve with ipsilateral nephrectomy. Radiation nephritis has all but vanished because of heightened awareness of its pathogenesis by radiotherapists.

267 VASCULAR INJURY TO THE KIDNEY

Kamal F. Badr, Barry M. Brenner

Adequate delivery of blood to the glomerular capillary network is crucial for glomerular filtration and overall salt and water balance. Thus, in addition to the threat to the viability of renal tissue, vascular injury to the kidney may compromise the maintenance of body fluid volume and composition. Involvement of the renal vessels by atherosclerotic, hypertensive, embolic, inflammatory, and hematologic disorders is usually a manifestation of generalized vascular pathology. The morphologic and clinical responses to these insults are considered in this chapter.

THROMBOEMBOLIC DISEASES OF THE RENAL ARTERIES

Thrombosis of the major renal arteries or their branches is an important cause of deterioration of renal function, especially in the elderly. It is often difficult to diagnose and therefore requires a high index of suspicion. Thrombosis may occur as a result of intrinsic pathology in the renal vessels (posttraumatic, atherosclerotic, or inflammatory) or as a result of emboli originating in distant vessels, most commonly fat emboli, emboli originating in the left heart (mural thrombi following myocardial infarction, bacterial endocarditis, or aseptic vegetations), or "paradoxical" emboli passing from the right side of the circulation via a patent foramen ovale or atrial septal defect. Renal emboli are bilateral in 15 to 30% of cases.

The clinical presentation is variable, depending on the time course and the extent of the occlusive event. Acute thrombosis and infarction, such as follows embolization, may result in sudden onset of flank pain and tenderness, fever, hematuria, leukocytosis, nausea, and vomiting. If infarction occurs, renal enzymes may be elevated, namely aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and alkaline phosphatase, which rise and fall in the order listed. Urinary LDH and alkaline phosphatase may also increase after infarction. Renal function deteriorates acutely, leading in bilateral thrombosis to acute oliguric renal failure. More gradual (i.e., atherosclerotic) occlusion of a single renal artery may go undetected. A spectrum of clinical presentations lies between these two extremes. Hypertension usually follows renal infarction and results from renin release in the peri-infarction zone. Hypertension is usually transient but may be persistent. Diagnosis is established by renal arteriography.

Rx TREATMENT

Management of *acute* renal arterial thrombosis includes surgical intervention, anticoagulant therapy, conservative and supportive therapy, and control of hypertension. The choice of treatment depends mainly on (1) the condition of the patient, in particular the patient's ability to withstand major surgery, and (2) the extent of renovascular occlusion and amount of renal mass at risk of infarction. In general, supportive care and anticoagulant therapy are indicated in unilateral disease. In *acute* bilateral thrombosis, medical and surgical therapies yield comparable results. Twenty-five percent of patients die during the acute episode, usually from extrarenal complications. In *chronic* ischemic renal disease, surgical revascularization is more likely to preserve and improve renal function (see below).

ATHEROEMBOLIC DISEASE OF THE RENAL ARTERIES

Atheroembolic renal disease is part of a systemic syndrome characterized by cholesterol crystal embolization. Renal damage results from embolization of cholesterol crystals from atherosclerotic plaques present in large arteries, such as the aorta, to small arteries in the renal vasculature. Atheroembolic renal disease is an increasingly common and often underdiagnosed cause of renal insufficiency in the elderly. A review of 372 autopsies identified cholesterol emboli in 2.4% of renal tissue samples. Male gender, older age, hypertension, and diabetes mellitus are important predisposing factors, present in 85% of cases. Patients with cholesterol embolization syndrome also often have a history of ischemic cardiovascular disease, aortic aneurysm, cerebrovascular disease, congestive heart failure, or renal insufficiency. A significant association is present between renal artery stenosis and atheroembolic renal disease. Inciting events, which include vascular surgery, arteriography, angioplasty, anticoagulation with heparin, and thrombolytic therapy, can be identified in about 50% of cases. Arteriographic procedures constitute the most common cause of cholesterol embolization.

Clinical manifestations usually appear 1 to 14 days after an inciting event, but their onset can be more insidious. Systemic manifestations occur in fewer than half of the patients and include fever, myalgias, headaches, and weight loss. Cutaneous manifestations such as livedo reticularis, "purple" toes, and toe gangrene occur in 50 to 90% of patients and constitute the most common extrarenal findings. Other targets of cholesterol embolization include the retina, musculoskeletal system, nervous system, and gut. Accelerated or labile hypertension is present in one-half of patients. Malignant hypertension has been described. Renal insufficiency is usually subacute and advances in a stepwise fashion over a period of several weeks. Renal failure, however, can be acute and oliguric. Uremic signs and symptoms requiring dialytic therapy develop in 40% of patients, only half of whom recover sufficient renal function to stop dialysis after 1 year. More recent data suggest less inexorable deterioration with a possibility of recovery of renal function in about one-third of patients after variable periods of dialytic support. Renal infarction secondary to cholesterol embolization is rare. Cholesterol embolic disease in renal allografts has been reported and can be of donor or of recipient origin.

Antemortem diagnosis of atherosclerotic renal emboli is difficult. The demonstration of cholesterol emboli in the retina is helpful, but a

firm diagnosis is established only by demonstration of cholesterol crystals in the smaller arteries and arterioles on renal biopsy. These may also be seen in asymptomatic skeletal muscle or skin. Atheroembolic renal disease is associated with a 64 to 81% mortality rate.

TREATMENT

No effective therapy for atheroembolic renal disease is available. Withdrawal of anticoagulation may be beneficial. In some patients, kidney function improved even after a prolonged period of renal insufficiency. Cholesterol-lowering agents may also improve outcome. An aggressive therapeutic approach with patient-tailored supportive measures may be associated with more favorable clinical outcome.

RENAL VEIN THROMBOSIS (RVT)

Thrombosis of one or both main renal veins occurs in a variety of settings (Table 267-1). Nephrotic syndrome accompanying membranous glomerulopathy and certain carcinomas seems to predispose to the development of RVT, which occurs in 10 to 50% of patients with these disorders. RVT may exacerbate preexisting proteinuria but is infrequently the cause of the nephrotic syndrome.

The clinical manifestations depend on the severity and abruptness of its occurrence. Acute cases occur typically in children and are characterized by sudden loss of renal function, often accompanied by fever, chills, lumbar tenderness (with kidney enlargement), leukocytosis, and hematuria. Hemorrhagic infarction and renal rupture may lead to hypovolemic shock. In young adults RVT is usually suspected from an unexpected and relatively acute or subacute deterioration of renal function and/or exacerbation of proteinuria and hematuria in the appropriate clinical setting. In cases of gradual thrombosis, usually occurring in the elderly, the only manifestation may be recurrent pulmonary emboli or development of hypertension. A Fanconi-like syndrome and proximal renal tubular acidosis have been described.

The definitive diagnosis can only be established through selective renal venography with visualization of the occluding thrombus. Short of angiography, Doppler ultrasound, contrast-enhanced computed tomography (CT), and magnetic resonance imaging (MRI) often provides definitive evidence of thrombus.

TREATMENT

Treatment consists of anticoagulation, the main purpose of which is prevention of pulmonary embolization, although some authors have also claimed improvement in renal function and proteinuria. Encouraging reports have appeared concerning the use of streptokinase. Spontaneous recanalization with clinical improvement has also been observed. Anticoagulant therapy is more rewarding in the acute thrombosis seen in younger individuals. Nephrectomy is advocated in infants with life-threatening renal infarction. Thrombectomy is effective in some cases.

RENAL ARTERY STENOSIS (RAS)/ISCHEMIC RENAL DISEASE

Ischemic renal disease underlies end-stage renal disease in 15 to 20% of uremic patients over 50 years of age. Stenosis of the main renal artery and/or its major branches is causative in 2 to 5% of patients with hypertension (Chap. 230). The common cause in the middle-aged and elderly is an atheromatous plaque at the origin of the renal artery. In a large unselected autopsy series, stenosis producing >50% renal artery diameter reduction was found in 18% of those between 65 and 74 years of age and in 42% of those older than 75 years. Bilateral involvement is present in half of the affected cases in both age groups. It should be considered seriously in elderly individuals, particularly in those with evidence of hypertension, diabetes, and atherosclerotic arterial disease elsewhere. In this population, the incidence of renal arterial stenosis can be as high as 40%. Established plaques progress in >50% of cases over 5 years (15% to total occlusion). Renal hypertrophy is detectable in 20% of affected kidneys. In younger women, stenosis is due to intrinsic structural abnormalities of the arterial wall caused by a heterogeneous group of lesions termed *fibromuscular dysplasia*. Clinical settings in which RAS should be considered are listed in Table 267-2.

TABLE 267-1 Conditions Associated with Renal Vein Thrombosis

Trauma
Extrinsic compression (lymph nodes, aortic aneurysm, tumor)
Invasion by renal cell carcinoma
Dehydration (infants)
Nephrotic syndrome
Pregnancy or oral contraceptives

DIAGNOSIS Diagnostic evaluation for significant RAS should begin with noninvasive approaches. An initial screening test is Doppler ultrasonography, which provides information on blood-flow velocity and pressure waveforms in the renal arteries and, when positive, is helpful. Its limitations, however, include significant operator dependence, technical difficulty in obese patients, and poor sensitivity in the presence of multiple renal arteries, distal stenoses, and total occlusion. Measurement of the intrarenal resistance index (RI) by Doppler ultrasonography provides valuable information on the extent of parenchymal tissue loss in stenosed and nonstenosed kidneys and hence on the prognosis for functional recovery following revascularization procedures.

Absence of compensatory hypertrophy in the contralateral kidney should raise the suspicion of bilateral stensosis or superimposed parenchymal renal disease, most commonly hypertensive or diabetic nephropathy. Because angiotensin-converting enzyme (ACE) inhibitors magnify the impairment in renal blood flow and glomerular filtration rate (GFR) caused by functionally significant renal artery stenosis, use of these drugs in association with ^{99m}Tc-labeled pentetic acid (DTPA) or ^{99m}Tc-labeled mertiatide (MAG_3) renography enhances diagnostic precision and is of additional predictive value. Gadolinium-enhanced three-dimensional magnetic resonance angiography (MRA) has replaced previous modalities as the most sensitive (>90%) and specific (95%) test for the diagnosis of RAS. The most definitive diagnostic procedure is contrast-enhanced arteriography. Intraarterial digital subtraction techniques minimize the requirements for contrast, reducing the risk of renal toxicity.

TREATMENT

Interventional therapy RAS (i.e., surgery or angioplasty) is superior to medical therapy. Success rates with conventional percutaneous transluminal angioplasty in young patients with fibromuscular dysplasia are 50% cure and improvement in blood pressure control in another

TABLE 267-2 Clinical Findings Associated with Renal Artery Stenosis

Hypertension
Abrupt onset of hypertension before the age of 50 years (suggestive of fibromuscular dysplasia)
Abrupt onset of hypertension at or after the age of 50 years (suggestive of atherosclerotic renal artery stenosis)
Accelerated or malignant hypertension
Refractory hypertension (not responsive to therapy with ⩾3 drugs)
Renal abnormalities
Unexplained azotemia (suggestive of atherosclerotic renal artery stenosis)
Azotemia induced by treatment with an angiotensin-converting enzyme inhibitor
Unilateral small kidney
Unexplained hypokalemia
Other findings
Abdominal bruit, flank bruit, or both
Severe retinopathy
Carotid, coronary, or peripheral vascular disease
Unexplained congestive heart failure or acute pulmonary edema

30%. For atherosclerotic lesions, conventional balloon angioplasty is associated with high restenosis rates (up to 47%) and either stent placement or surgery is recommended. About half of those with reduced renal function as a result of RAS improve following angioplasty or surgery, even when preintervention arteriography shows little evidence of cortical perfusion. In the presence of unilateral RAS and normal overall GFR, the decision for angiographic or surgical revascularization may depend on the results of fractional flow and filtration rate studies to each kidney with ^{99m}TC-DTPA or ^{99m}Tc-MAG$_3$. These techniques can also be used to assess the response to revascularization. Three-year survival is influenced by baseline renal function, being 94% in the presence of normal baseline renal function and falling to 52% in patients with serum creatinine >177 μmol/L (>2.0 mg/dL). Renal parenchymal damage, as reflected in noninvasive imaging and degree of proteinuria, is the major predictor of functional outcome and should be used for risk stratification. Rapid decline in renal function is associated with a favorable response to intervention.

Despite the risks associated with surgery, long-term follow-up studies demonstrate an advantage of surgery over angioplasty both with regard to the incidence of restenosis and to the preservation or improvement in GFR. Surgery, however, is restricted to those patients in whom angioplasty and stenting are not feasible. As with coronary angioplasty, stenting of renal arteries following balloon angioplasty is being used increasingly. Results are highly encouraging, with restenosis rates <15% at 1 year. Renal functional recovery or stabilization of renal function is seen in approximately 70% of patients. An illustrative example of renal artery stenting is shown in Fig. 267-1.

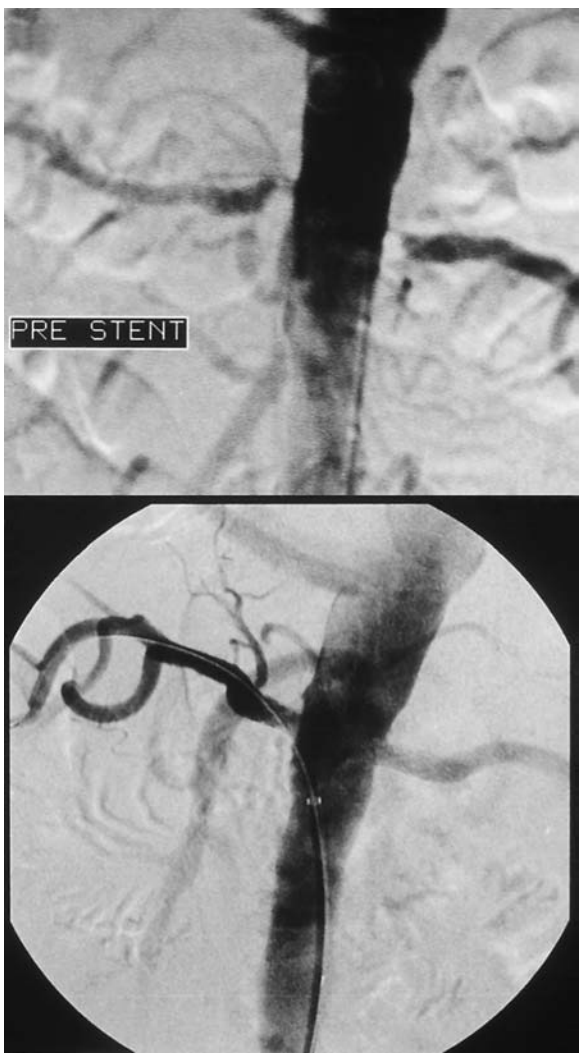

FIGURE 267-1 Bilateral severe ostial renal artery stenosis prior to and following balloon dilatation and stent placement in a patient with severe hypertension and renal insufficiency.

HEMOLYTIC UREMIC SYNDROME (HUS) AND THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) (See also Chap. 101)

HUS and TTP, consumptive coagulopathies characterized by microangiopathic hemolytic anemia and thrombocytopenia, have a particular predilection for the kidney and the central nervous system, the latter especially in TTP. The kidneys of patients with HUS or TTP often exhibit a "flea-bitten" appearance, the result of multiple cortical hemorrhagic infarcts. The major sites of pathology are the small renal arteries and afferent arterioles, which are nearly occluded as a result of marked intimal hyperplasia (particularly in TTP) and fibrin deposits in the subintimal regions. When the vasoocclusive process is extensive, bilateral cortical necrosis may occur. In addition, arteriolar microaneurysms, glomerular infarction, or nonspecific focal changes may be seen. In keeping with the focal nature of the vascular lesions, patchy areas of interstitial edema, tubular necrosis, and, eventually, fibrosis occur. By immunofluorescence staining, complement components and immunoglobulins may be demonstrated in the arterioles, and fibrinogen deposits are present in arteries, arterioles, and glomerular capillary loops.

Endothelial cell injury appears to be the initiating pathophysiologic event in HUS/TTP. Injurious agents include bacterial toxins (Shiga toxin–like) mostly from specific *Escherichia coli* genotypes, endotoxin (lipopolysaccharides, LPS), bacterial neuraminidases, immune complexes, and drugs. Among the latter, most commonly associated with HUS/TTP are chemotherapeutic agents, cyclosporine, clopidogrel, and quinine. Also implicated in endothelial cell injury are intrinsic abnormalities of the complement sytem and the von Willebrand factor pathways, which may account for the genetic predisposition observed in familial forms of the disease.

Renal failure is common in both HUS and TTP, usually manifested by azotemia, mild proteinuria, and microscopic and/or gross hematuria. Patients with HUS have more severe renal failure, often marked by oligoanuria and hypertension and commonly progressing to chronic renal failure. The prognosis in HUS is better in children than in adults. In TTP, the course of which may span days to months, renal failure is usually less severe.

℞ TREATMENT

In TTP, high-dose glucocorticoids and plasma exchange often provide complete remission or cure. Plasma exchange should be initiated as early as possible, and the treatment cycles can be repeated if thrombocytopenia recurs. Splenectomy and antiplatelet therapy have also been used with varying degrees of success. The success of plasma exchange in adult HUS is less well established than in TTP.

ARTERIOLAR NEPHROSCLEROSIS (See also Chaps. 224 and 230)

Whether hypertension is "essential" or of known etiology, persistent exposure of the renal circulation to elevated intraluminal pressures results in development of intrinsic lesions of the renal arterioles (hyaline arteriolosclerosis) that eventually lead to loss of function (nephrosclerosis). Nephrosclerosis is divided into two distinct entities: "benign" and "malignant" (or accelerated).

BENIGN ARTERIOLAR NEPHROSCLEROSIS Benign arteriolar nephrosclerosis is seen in patients who are hypertensive for an extended period of time (blood pressure >150/90 mmHg) but whose hypertension has not progressed to a malignant form (described below). Such patients, usually in the older age group, are often discovered to be hypertensive on routine physical examination or as a result of nonspecific symptomatology (e.g., headaches, weakness, palpitations).

Kidney size is normal to reduced, with loss of cortical mass leading to a fine granularity. Although the larger arteries may show atherosclerotic changes, the characteristic pathology is in the afferent arterioles, which have thickened walls due to deposition of homogeneous

eosinophilic material (hyaline arteriolosclerosis). Narrowing of vascular lumina results, with consequent ischemic injury to glomeruli and tubules.

Nephrosclerosis accompanying long-standing systemic arterial hypertension is only one manifestation of a generalized process affecting the cardiovascular system. Physical examination, therefore, may reveal changes in retinal vessels (arteriolar narrowing and/or flame-shaped hemorrhages), cardiac hypertrophy, and possibly signs of congestive heart failure. Renal disease may manifest as a mild to moderate elevation of serum creatinine concentration and/or mild proteinuria. In general, clinical evaluation does not reveal significant renal abnormalities. More specialized examination may disclose elevated urinary albumin excretion, tapering and loss of caliber of intrarenal vessels on arteriography, and an exaggerated natriuresis in response to a fluid challenge. Patients with benign nephrosclerosis generally maintain a near-normal GFR despite a reduction in renal blood flow.

MALIGNANT ARTERIOLAR NEPHROSCLEROSIS Patients with long-standing benign hypertension or patients not previously known to be hypertensive may develop malignant hypertension characterized by a sudden (accelerated) elevation of blood pressure (diastolic often >130 mmHg) accompanied by papilledema, central nervous system manifestations, cardiac decompensation, and acute progressive deterioration of renal function. The absence of papilledema does not rule out the diagnosis in a patient with markedly elevated blood pressure and rapidly declining renal function. The kidneys are characterized by a flea-bitten appearance resulting from hemorrhages in surface capillaries. Histologically, two distinct vascular lesions can be seen. The first, affecting arterioles, is fibrinoid necrosis, i.e., infiltration of arteriolar walls with eosinophilic material including fibrin, thickening of vessel walls and, occasionally, an inflammatory infiltrate (necrotizing arteriolitis). The second lesion, involving the interlobular arteries, is a concentric hyperplastic proliferation of the cellular elements of the vascular wall with deposition of collagen to form a hyperplastic arteriolitis (onion-skin lesion). Fibrinoid necrosis occasionally extends into the glomeruli, which may also undergo proliferative changes or total necrosis. Most glomerular and tubular changes are secondary to ischemia and infarction. The sequence of events leading to the development of malignant hypertension is poorly defined. Two pathophysiologic alterations appear central in its initiation and/or perpetuation: (1) increased permeability of vessel walls to invasion by plasma components, particularly fibrin, which activates clotting mechanisms leading to a microangiopathic hemolytic anemia, thus perpetuating the vascular pathology; and (2) activation of the renin-angiotensin-aldosterone system at some point in the disease process, which contributes to the acceleration and maintenance of blood pressure elevation and, in turn, to vascular injury.

Malignant hypertension is most likely to develop in a previously hypertensive individual, usually in the third or fourth decade of life. There is a higher incidence among men, particularly black men. The presenting symptoms are usually neurologic (dizziness, headache, blurring of vision, altered states of consciousness, and focal or generalized seizures). Cardiac decompensation and renal failure appear thereafter. Renal abnormalities include a rapid rise in serum creatinine, hematuria (at times macroscopic), proteinuria, and red and white blood cell casts in the sediment. Nephrotic syndrome may be present. Elevated plasma aldosterone levels cause hypokalemic metabolic alkalosis in the early phase. Uremic acidosis and hyperkalemia eventually obscure these early findings. Hematologic indices of microangiopathic hemolytic anemia (i.e., schistocytes) are often seen.

Rx TREATMENT

Control of hypertension is the principal goal of therapy for both benign and malignant forms. The time of initiation of therapy, its effectiveness, and patient compliance are crucial factors in arresting the progression of benign nephrosclerosis. Untreated, most of these patients succumb to the extrarenal complications of hypertension. In contrast, malignant hypertension is a medical emergency; its natural course includes a death rate of 80 to 90% within 1 year of onset, almost always due to uremia. Supportive measures should be instituted to control the neurologic, cardiac, and other complications of acute renal failure, but the mainstay of therapy is prompt and aggressive reduction of blood pressure, which, if successful, can reverse all complications in the majority of patients. Presently, 5-year survival is 50%, and some patients have evidence of partial reversal of the vascular lesions and a return of renal function to near-normal levels.

SCLERODERMA (PROGRESSIVE SYSTEMIC SCLEROSIS)

(See also Chap. 303)

Renal involvement can present in one of two ways, depending on whether malignant hypertension is superimposed on the renal pathology: (1) *Persistent urinary abnormalities* with or without hypertension tend to follow an indolent course with mild proteinuria, occasional casts, cellular elements in the urinary sediment, and a propensity for development of hypertension. Azotemia is absent initially, but when it develops, dialysis is required within 1 year. (2) *Scleroderma renal crisis* (SRC) is a rapid deterioration in renal function, usually accompanied by malignant hypertension, oliguria, fluid retention, microangiopathic hemolytic anemia, and central nervous system involvement. It occurs in 5 to 15% of patients, most commonly in the first 5 years following diagnosis, particularly in patients with diffuse cutaneous involvement. SRC may occur in patients with previously undemonstrable or slowly progressive renal disease. Untreated, it leads to chronic renal failure within days to months.

Rx TREATMENT

The prognosis of scleroderma renal disease is generally poor, particularly following the onset of azotemia. Aggressive antihypertensive therapy may be effective in delaying the progression of renal failure. In SRC, prompt treatment with ACE inhibitors may reverse acute renal failure. Recently, a prospective study on short- and long-term outcomes of SRC in patients who received ACE inhibitors showed that 61% of patients had favorable outcomes (no dialysis or temporary dialysis) with a survival rate at 8 years of 80 to 85%, similar to that of patients with diffuse scleroderma who did not have renal crisis. Moreover, more than half of patients with SRC who initially required dialysis and were treated aggressively with ACE inhibitors were able to discontinue dialysis 3 to 18 months later, suggesting that patients should continue to take ACE inhibitors even after beginning dialysis, in hope of discontinuing it. A significant association exists between antecedent high-dose glucocorticoid therapy and the development of SRC.

SICKLE CELL NEPHROPATHY (See also Chap. 91)

Sickle cell disease causes renal complications that arise mainly as a result of sickling of red blood cells in the microvasculature. The hypertonic and relatively hypoxic environment of the renal medulla, coupled with the slow blood flow in the vasa recta, favors the sickling of red blood cells, with resultant local infarction (papillary necrosis). Functional tubule defects in patients with sickle cell disease are likely the result of partial ischemic injury to the renal tubules.

In addition to the intrarenal microvascular pathology described above, young patients with sickle cell disease are characterized by renal hyperperfusion, glomerular hypertrophy, and hyperfiltration. Many of these individuals eventually develop a glomerulopathy leading to glomerular proteinuria (present in as many as 30%) and, in some, the nephrotic syndrome. Co-inheritance of microdeletions in the α-globin gene (α thalassemia) appear to protect against the development of nephropathy, associated with lower mean arterial pressure and less proteinuria.

Mild azotemia and hyperuricemia can also develop. Advanced renal failure and uremia occur in 4 to 18% of cases. Pathologic examination reveals the typical lesion of "hyperfiltration nephropathy,"

namely, focal segmental glomerular sclerosis. This finding has led to the suggestion that anemia-induced hyperfiltration in childhood is the principal cause of the adult glomerulopathy. Nephron loss secondary to ischemic injury also contributes to the development of azotemia in these patients.

In addition to the glomerulopathy described above, renal complications of sickle cell disease include the following: *Cortical infarcts* can cause loss of function, persistent hematuria, and perinephric hematomas. *Papillary infarcts*, demonstrated radiographically in 50% of patients with sickle trait, lead to an increased risk of bacterial infection in the scarred renal tissues and functional tubule abnormalities. Painless gross hematuria occurs with a higher frequency in sickle trait than in sickle cell disease and likely results from infarctive episodes in the renal medulla. *Functional tubule abnormalities* such as nephrogenic diabetes insipidus result from marked reduction in vasa recta blood flow, combined with ischemic tubule injury. This concentrating defect places these patients at increased risk of dehydration and, hence, sickling crises. The concentrating defect also occurs in individuals with sickle trait. Other tubule defects involve potassium and hydrogen ion excretion, occasionally leading to hyperkalemic metabolic acidosis and a defect in uric acid excretion which, combined with increased purine synthesis in the bone marrow, results in hyperuricemia.

Management of sickle nephropathy is not separate from that of overall patient management (Chap. 91). In addition, however, the use of ACE inhibitors has been associated with improvement of the hyperfiltration glomerulopathy. Three-year graft and patient survival in renal transplant recipients with sickle nephropathy is diminished as compared to those with other causes of end-stage renal disease.

TOXEMIAS OF PREGNANCY See also Chap. 6

BILATERAL CORTICAL NECROSIS

Acute bilateral cortical necrosis is associated with septic abortions, abruptio placentae, and preeclampsia. Coagulation in cortical vessels and arterioles leads to renal tissue necrosis. Anuria and renal failure ensue and may be irreversible. In other cases, renal function returns partially, but on long-term follow-up most patients slowly progress to uremia.

268 NEPHROLITHIASIS

John R. Asplin, Fredric L. Coe, Murray J. Favus

TYPES OF STONES

Calcium salts, uric acid, cystine, and struvite ($MgNH_4PO_4$) are the basic constituents of most kidney stones in the western hemisphere. Calcium oxalate and calcium phosphate stones make up 75 to 85% of the total (Table 268-1) and may be admixed in the same stone. Calcium phosphate in stones is usually hydroxyapatite [$Ca_5(PO_4)_3OH$] or, less commonly, brushite ($CaHPO_4H_2O$).

Calcium stones are more common in men; the average age of onset is the third to fourth decade. Approximately 50% of people who form a single calcium stone eventually form another within the next 10 years. The average rate of new stone formation in recurrent stone formers is about one stone every 2 or 3 years. Calcium stone disease is frequently familial. *Uric acid stones* are radiolucent and are also more common in men. Half of patients with uric acid stones have gout; uric acid lithiasis is usually familial whether or not gout is present. *Cystine stones* are uncommon; their radiopacity is due to the sulfur content. Cystine crystals appear in the urine as flat, hexagonal plates. *Struvite stones* are common and potentially dangerous. These stones occur mainly in women or patients who require chronic bladder catheterization and result from urinary tract infection with urease-producing bacteria, usually *Proteus* species. The stones can grow to a large size and fill the renal pelvis and calyces to produce a "staghorn" appearance. They are radiopaque and have a variable internal density. In urine, struvite crystals are rectangular prisms said to resemble coffin lids.

MANIFESTATIONS OF STONES

As stones grow on the surfaces of the renal papillae or within the collecting system, they need not produce symptoms. Asymptomatic stones may be discovered during the course of radiographic studies undertaken for unrelated reasons. Stones rank, along with benign and malignant neoplasms, and renal cysts, among the common causes of isolated hematuria. Much of the time, however, stones break loose and enter the ureter or occlude the ureteropelvic junction, causing pain and obstruction.

STONE PASSAGE A stone can traverse the ureter without symptoms, but passage usually produces pain and bleeding. The pain begins gradually, usually in the flank, but increases over the next 20 to 60 min to become so severe that narcotic drugs may be needed for its control. The pain may remain in the flank or spread downward and anteriorly toward the ipsilateral loin, testis, or vulva. Pain that migrates downward indicates that the stone has passed to the lower third of the ureter, but if the pain does not migrate, the position of the stone cannot be predicted. A stone in the portion of the ureter within the bladder wall causes frequency, urgency, and dysuria that may be confused with urinary tract infection. The vast majority of ureteral stones less than 0.5 cm in diameter will pass spontaneously.

It has been standard practice to diagnose acute renal colic by intravenous pyelography; however, helical computed tomography (CT) scan without radiocontrast enhancement is now the preferred proce-

TABLE 268-1 *Major Causes of Renal Stones*

Stone Type and Causes	Percent of all Stones[a]	Percent Occurrence of Specific Causes[a]	Ratio of Males to Females	Etiology	Diagnosis	Treatment
Calcium stones	75–85		2:1 to 3:1			
Idiopathic hypercalciuria		50–55	2:1	Hereditary (?)	Normocalcemia, unexplained hypercalciuria[b]	Thiazide diuretic agents
Hyperuricosuria		20	4:1	Diet	Urine uric acid >750 mg per 24 h (women), >800 mg per 24 h (men)	Allopurinol or diet
Primary hyperparathyroidism		5	3:10	Neoplasia	Unexplained hypercalcemia	Surgery
Distal renal tubular acidosis		Rare	1:1	Hereditary	Hyperchloremic acidosis, minimum urine pH >5.5	Alkali replacement
Dietary hyperoxaluria		10–30	1:1	High oxalate diet or low calcium diet	Urine oxalate >50 mg per 24 h	Low oxalate diet
Enteric hyperoxaluria		~1–2	1:1	Bowel surgery	Urine oxalate >75 mg per 24 h	Cholestyramine or oral calcium loading
Hereditary hyperoxaluria		Rare	1:1	Hereditary	Urine oxalate and glycolic or l-glyceric acid increased	Fluids and pyridoxine
Hypocitraturia		15–60	2:1 to 5:1	Hereditary (?), diet	Urine citrate <320 mg per 24 h	Alkali supplements
Idiopathic stone disease		20	2:1	Unknown	None of the above present	Oral phosphate, fluids
Uric acid stones	5–8					
Gout		~50	3:1 to 4:1	Hereditary	Clinical diagnosis	Alkali and allopurinol
Idiopathic		~50	1:1	Hereditary (?)	Uric acid stones, no gout	Alkali and allopurinol if daily urine uric acid above 1000 mg
Dehydration		?	1:1	Intestinal, habit	History, intestinal fluid loss	Alkali, fluids, reversal of cause
Lesch-Nyhan syndrome		Rare	Males only	Hereditary	Reduced hypoxanthine-guanine phosphoribosyltransferase level	Allopurinol
Malignant tumors		Rare	1:1	Neoplasia	Clinical diagnosis	Allopurinol
Cystine stones	1		1:1	Hereditary	Stone type; elevated cystine excretion	Massive fluids, alkali, D-penicillamine if needed
Struvite stones	10–15		2:10	Infection	Stone type	Antimicrobial agents and judicious surgery

[a] Values are percent of patients who form a particular type of stone and who display each specific cause of stones.

[b] Urine calcium above 300 mg/24 h (men), 250 mg/24 h (women), or 4 mg/kg per 24 h either sex. Hyperthyroidism, Cushing syndrome, sarcoidosis, malignant tumors, immobilization, vitamin D intoxication, rapidly progressive bone disease, and Paget's disease all cause hypercalciuria and must be excluded in diagnosis of idiopathic hypercalciuria.

dure. The advantages of CT include detection of uric acid stones in addition to the traditional radiopaque stones, no exposure to the risk of radiocontrast agents, and possible diagnosis of other causes of abdominal pain in a patient suspected of having renal colic from stones. Ultrasound is not as sensitive as CT in detecting renal or ureteral stones.

OTHER SYNDROMES ■ Staghorn Calculi Struvite, cystine, and uric acid stones often grow too large to enter the ureter. They gradually fill the renal pelvis and may extend outward through the infundibula to the calyces themselves.

Nephrocalcinosis Calcium stones grow on the papillae. Most break loose and cause colic, but they may remain in place so that multiple papillary calcifications are found by x-ray, a condition termed *nephrocalcinosis*. Papillary nephrocalcinosis is common in hereditary distal renal tubular acidosis (RTA) and in other types of severe hypercalciuria. In medullary sponge kidney disease (Chap. 265), calcification may occur in dilated distal collecting ducts.

Sludge Sufficient uric acid or cystine in the urine may plug both ureters with precipitate. Calcium oxalate crystals do not do this because less than 100 mg oxalate usually is excreted daily in the urine even in severe hyperoxaluric states, compared with 1000 mg uric acid in patients with hyperuricosuria and 400 to 800 mg cystine in patients with cystinuria. Calcium phosphate crystals can render the urine milky but do not plug the urinary tract.

INFECTION Although urinary tract infection is not a direct consequence of stone disease, it can occur after instrumentation and surgery of the urinary tract, which are frequent in the treatment of stone disease. Stone disease and urinary tract infection can enhance their respective seriousness and interfere with treatment. Obstruction of an infected kidney by a stone may lead to sepsis and extensive damage of renal tissue, since it converts the urinary tract proximal to the obstruction into a closed, or partially closed, space that can become an abscess. Stones may harbor bacteria in the stone matrix, leading to recurrent urinary tract infection. On the other hand, infection due to bacteria that possess the enzyme urease can cause stones composed of struvite.

ACTIVITY OF STONE DISEASE Active disease means that new stones are forming or that preformed stones are growing. Sequential radiographs of the renal areas are needed to document the growth or appearance of new stones and to ensure that passed stones are actually newly formed, not preexistent ones.

PATHOGENESIS OF STONES

Urinary stones usually arise because of the breakdown of a delicate balance. The kidneys must conserve water, but they must excrete materials that have a low solubility. These two opposing requirements must be balanced during adaptation to diet, climate, and activity. The problem is mitigated to some extent by the fact that urine contains substances that inhibit crystallization of calcium salts and others that bind calcium in soluble complexes. These protective mechanisms are

less than perfect. When the urine becomes supersaturated with insoluble materials, because excretion rates are excessive and/or because water conservation is extreme, crystals form and may grow and aggregate to form a stone.

SUPERSATURATION In a solution in equilibrium with crystals of calcium oxalate, the product of the chemical activities of the calcium and oxalate ions in the solution is termed the *equilibrium solubility product*. If crystals are removed, and if either calcium or oxalate ions are added to the solution, the activity product increases, but no new crystals form. Such a solution is *metastably supersaturated*. If new calcium oxalate seed crystals are now added, they will grow in size. Ultimately, as calcium or oxalate are added to the solution, the activity product reaches a critical value at which a solid phase begins to develop spontaneously. This value is called the *upper limit of metastability*. Stone growth in the urinary tract requires a urine that, on average, is above the equilibrium solubility product. Excessive supersaturation is common in stone formation.

Calcium, oxalate, and phosphate form many stable soluble complexes among themselves and with other substances in urine, such as citrate. As a result, their free ion activities are below their chemical concentrations and can be measured only by indirect techniques. Reduction in ligands such as citrate can increase ion activity, and therefore supersaturation, without changing total urinary calcium. Urine supersaturation can be increased by dehydration or by overexcretion of calcium, oxalate, phosphate, cystine, or uric acid. Urine pH is also important; phosphate and uric acid are weak acids that dissociate readily over the physiologic range of urine pH. Alkaline urine contains more dibasic phosphate, favoring deposits of brushite and apatite. Below a urine pH of 5.5, uric acid crystals (pK 5.47) predominate, whereas phosphate crystals are rare. The solubility of calcium oxalate, on the other hand, is not influenced by changes in urine pH. Measurements of supersaturation in a pooled 24-h urine sample probably underestimate the risk of precipitation. Transient dehydration, variation of urine pH, and postprandial bursts of overexcretion may cause values considerably above average.

NUCLEATION In urine that is supersaturated with respect to calcium oxalate, these two ions form clusters. Most small clusters eventually disperse because the internal forces that hold them together are too weak to overcome the random tendency of ions to move away. Large ion clusters can remain stable because attractive forces balance surface losses. Once they are stable, nuclei can grow at levels of supersaturation below that needed for their creation. Cell debris, calcifications on the renal papillae, and other urinary crystals can serve as templates for crystal formation, a process known as *heterogeneous nucleation*. Heterogeneous nucleation lowers the level of supersaturation required for crystal formation and is likely the mechanism by which stones form in human urine.

INHIBITORS OF CRYSTAL FORMATION Stable nuclei must grow and aggregate to produce a stone of clinical significance. Urine contains potent inhibitors of nucleation, growth, and aggregation for calcium oxalate and calcium phosphate but not for uric acid, cystine, or struvite. Inorganic pyrophosphate is a potent inhibitor that appears to affect calcium phosphate more than calcium oxalate crystals. Citrate inhibits crystal growth and nucleation, though most of the stone inhibitory activity of citrate is due to lowering urine supersaturation via complexation of calcium. Other urine components such as glycoproteins inhibit all three processes of calcium oxalate stone formation. As a consequence of the presence of these inhibitors, crystal growth in urine is slow compared with growth in simple salt solutions, and the upper limit of metastability is higher.

EVALUATION AND TREATMENT OF PATIENTS WITH NEPHROLITHIASIS

Most patients with nephrolithiasis have remediable metabolic disorders that cause stones and can be detected by chemical analyses of serum and urine. Adults with recurrent kidney stones and children with even a single kidney stone should be evaluated. A practical outpatient evaluation consists of two or three 24-h urine collections, with a corresponding blood sample; measurements of serum and urine calcium, uric acid, electrolytes, and creatinine, and urine pH, volume, oxalate, and citrate should be made. Since stone risks vary with diet, activity, and environment, at least one urine collection should be made on a weekend when the patient is at home and another on a work day. When possible, the composition of kidney stones should be determined because treatment depends on stone type (Table 268-1). No matter what disorders are found, every patient should be counseled to avoid dehydration and to drink copious amounts of water. The efficacy of high fluid intake was confirmed in a prospective study of first-time stone formers. Increasing urine volume to 2.5 L per day resulted in a 50% reduction of stone recurrence compared to the control group. Because treatment is prolonged, the use of medications must be justified by the activity and severity of stone disease and the importance of protection against new stones.

℞ TREATMENT

The management of stones already present in the kidneys or urinary tract requires a combined medical and surgical approach. The specific treatment depends on the location of the stone, the extent of obstruction, the function of the affected and unaffected kidney, the presence or absence of urinary tract infection, the progress of stone passage, and the risks of operation or anesthesia given the clinical state of the patient. In general, severe obstruction, infection, intractable pain, and serious bleeding are indications for removal of a stone.

In the past, stones were removed by operation or by passing a flexible basket retrograde up the ureter from the bladder during cystoscopy. There are now three alternatives. *Extracorporeal lithotripsy* causes the in situ fragmentation of stones in the kidney, renal pelvis, or ureter by exposing them to shock waves. The kidney stone is centered at a focal point of parabolic reflectors, and high-intensity shock waves are created by high-voltage discharge. The waves are transmitted to the patient using water as a conduction medium, either by placing the patient in a water tank or by placing water-filled cushions between the patient and the shock wave generators. After multiple discharges, most stones are reduced to powder that moves through the ureter into the bladder. *Percutaneous nephrolithotomy* requires the passage of a cystoscope-like instrument into the renal pelvis through a small incision in the flank. Stones are then disrupted by a small ultrasound transducer or holmium laser. The last method is *lithotripsy via a ureteroscope* for removal of ureteral stones. These various forms of lithotripsy have largely replaced pyelolithotomy and ureterolithotomy.

CALCIUM STONES ■ Idiopathic Hypercalciuria (See also Chap. 332) This condition appears to be hereditary, and its diagnosis is straightforward (Table 268-1). In some patients, primary intestinal hyperabsorption of calcium causes transient postprandial hypercalcemia that suppresses secretion of parathyroid hormone. The renal tubules are deprived of the normal stimulus to reabsorb calcium at the same time that the filtered load of calcium is increased. In other patients, reabsorption of calcium by the renal tubules appears to be defective, and secondary hyperparathyroidism is evoked by urinary losses of calcium. Renal synthesis of 1,25-dihydroxyvitamin D is increased, enhancing intestinal absorption of calcium. In the past, the separation of "absorptive" and "renal" forms of hypercalciuria was used to guide treatment. However, these may not be distinct entities but the extremes of a continuum of behavior. Vitamin D overactivity, either through high calcitriol levels or excess vitamin D receptor, is a likely explanation for the hypercalciuria in many of these patients. Hypercalciuria contributes to stone formation by raising urine saturation with respect to calcium oxalate and calcium phosphate.

℞ TREATMENT

For many years the standard therapy for hypercalciuria was dietary calcium restriction. However, recent studies have shown that low-cal-

cium diets increase the risk of incident stone formation. In addition, hypercalciuric stone formers have reduced bone mineral density and an increased risk of fracture compared to the non-stone-forming population. Low calcium intake likely contributes to the low bone mineral density. A recent prospective trial compared the efficacy of a low-calcium diet to a low-protein, low-sodium, normal-calcium diet in preventing stone recurrence in male calcium stone formers. The group on the low-calcium diet had a significantly greater rate of stone relapse. As a whole, low-calcium diets do not appear to be efficacious and carry a long-term risk of bone disease in the stone-forming population. Low-sodium and low-protein diets are a superior option in stone formers. If diet therapy is not sufficient to prevent stones, then thiazide diuretics may be used. Thiazide diuretics lower urine calcium and are effective in preventing the formation of stones. Three 3-year randomized trials have shown a 50% decrease in stone formation in the thiazide-treated groups as compared to the placebo-treated controls. The drug effect requires slight contraction of the extracellular fluid volume, and massive use of NaCl reduces its therapeutic effect. Thiazide-induced hypokalemia should be aggressively treated since hypokalemia will reduce urine citrate, increasing urine calcium ion levels.

Hyperuricosuria About 20% of calcium oxalate stone formers are hyperuricosuric, primarily because of an excessive intake of purine from meat, fish, and poultry. The mechanism of stone formation is probably due to salting out calcium oxalate by urate. A low-purine diet is desirable but difficult for many patients to achieve. The alternative is allopurinol, which has been shown to be effective in a randomized, controlled trial. A dose of 100 mg bid is usually sufficient.

Primary Hyperparathyroidism (See also Chap. 332) The diagnosis of this condition is established by documenting that hypercalcemia that cannot be otherwise explained is accompanied by inappropriately elevated serum concentrations of parathyroid hormone. Hypercalciuria, usually present, raises the urine supersaturation of calcium phosphate and/or calcium oxalate (Table 268-1). Prompt diagnosis is important because parathyroidectomy should be carried out before renal damage or bone disease occurs.

Distal Renal Tubular Acidosis (See also Chap. 265) The defect in this condition seems to reside in the distal nephron, which cannot establish a normal pH gradient between urine and blood, leading to hyperchloremic acidosis. The diagnosis is suggested by a minimum urine pH above 5.5 in the presence of systemic acidosis. If the diagnosis is in doubt because metabolic abnormalities are mild, oral challenge with NH_4Cl, 1.9 mmol/kg of body weight, will not lower urine pH below 5.5 in patients with distal RTA. Hypercalciuria, an alkaline urine, and a low urine citrate level cause supersaturation with respect to calcium phosphate. Calcium phosphate stones form, nephrocalcinosis is common, and osteomalacia or rickets may occur. Renal damage is frequent, and glomerular filtration rate falls gradually.

Treatment with supplemental alkali reverses hypercalciuria and limits the production of new stones. The usual dose of sodium bicarbonate is 0.5 to 2.0 mmol/kg of body weight per day in four to six divided doses. An alternative is potassium citrate supplementation, given at the same dose per day but needing to be given only three to four times per day. In incomplete distal RTA, systemic acidosis is absent, but urine pH cannot be lowered below 5.5 after an exogenous acid load such as ammonium chloride. Incomplete RTA may develop in some patients who form calcium oxalate stones because of idiopathic hypercalciuria; the importance of RTA in producing stones in this situation is uncertain, and thiazide treatment is a reasonable alternative. Some patients with incomplete RTA form calcium phosphate stones because of low urine citrate and an alkaline urine and are best treated with alkali as if RTA were complete. When treating patients with alkali it is prudent to monitor changes in urine citrate and pH. If urine pH increases without an increase in citrate then calcium phosphate supersaturation will increase and stone disease may worsen.

Hyperoxaluria Oxalate is a metabolic end product in humans. Urine oxalate comes from diet and endogenous metabolic production, with approximately 40 to 50% originating from dietary sources. The upper limit of normal for oxalate excretion is generally considered to be 40 to 50 mg per day. Mild hyperoxaluria (50 to 80 mg/d) is usually caused by excessive intake of high-oxalate foods such as spinach, nuts, and chocolate. In addition, low-calcium diets may promote hyperoxaluria as there is less calcium binding oxalate in the intestine, increasing the amount of oxalate available for absorption. Enteric hyperoxaluria is a consequence of small bowel disease resulting in fat malabsorption. Oxalate excretion is often over 100 mg per day. Enteric hyperoxaluria may be caused by jejunoileal bypass for obesity, bacterial overgrowth syndromes, pancreatic insufficiency, or extensive small intestine involvement from Crohn's disease. With fat malabsorption, calcium in the bowel lumen is bound by fatty acids instead of oxalate, which is left free for absorption in the colon. Delivery of unabsorbed fatty acids and bile salts to the colon may injure the colonic mucosa and enhance oxalate absorption. Hereditary hyperoxaluria states are rare causes of severe hyperoxaluria, often greater than 150 mg per day. Patients usually present with recurrent calcium oxalate stones during childhood. Type I hereditary hyperoxaluria is inherited as an autosomal recessive trait and is due to a deficiency in the peroxisomal enzyme alanine: glyoxylate aminotransferase. Type II is due to a deficiency of D-glyceric dehydrogenase. Severe hyperoxaluria from any cause can produce tubulointerstitial nephropathy (Chap. 266) and lead to stone formation.

℞ TREATMENT

Patients with mild to moderate hyperoxaluria should be treated with a diet low in oxalate and with a normal intake of calcium and magnesium to reduce oxalate absorption. Enteric hyperoxaluria can be treated with the oxalate-binding resin cholestyramine at a dose of 8 to 16 g/d, correction of fat malabsorption, and a low-fat, low-oxalate diet. Calcium supplements, given with meals, precipitate oxalate in the gut lumen, providing an additional form of therapy. Treatment for hereditary hyperoxaluria includes a high fluid intake, neutral phosphate, and pyridoxine (25 to 200 mg/d). Citrate supplementation may also have some benefit. Even with aggressive therapy, irreversible renal failure secondary to recurrent stone formation often occurs. Segmental liver transplant, to correct the enzyme defect, combined with a kidney transplant has been successfully utilized in patients with hereditary hyperoxaluria.

Hypocitraturia Urine citrate prevents calcium stone formation by creating a soluble complex with calcium, effectively reducing free urine calcium. Hypocitraturia is found in 15 to 60% of stone formers, either as a single disorder or in combination with other metabolic abnormalities. It can be secondary to systemic disorders, such as RTA, chronic diarrheal illness, or hypokalemia, or it may be a primary disorder, in which case it is called *idiopathic hypocitraturia*.

℞ TREATMENT

Treatment is with alkali, which increases urine citrate excretion; generally bicarbonate or citrate salts are used. Potassium salts are preferred as sodium loading increases urinary excretion of calcium, reducing the effectiveness of treatment. Two randomized, placebo-controlled trials have demonstrated the effectiveness of citrate supplements in calcium oxalate stone formers.

Idiopathic Calcium Lithiasis Some patients have no metabolic cause for stones despite a thorough metabolic evaluation (Table 268-1). The best treatment appears to be high fluid intake so that the urine specific gravity remains at 1.005 or below throughout the day and night. Thiazide diuretics, allopurinol, and citrate therapy may help reduce crystallization of calcium salts, but there are no prospective trials in this patient population. Oral phosphate at a dose of 2 g phosphorus daily may lower urine calcium and increase urine pyrophosphate and thereby

reduce the rate of recurrence. Orthophosphate causes mild nausea and diarrhea, but tolerance may improve with continued intake.

URIC ACID STONES These stones form because the urine becomes supersaturated with undissociated uric acid that is protonated at its N-9 position. In gout, idiopathic uric acid lithiasis, and dehydration, the average pH is usually below 5.4 and often below 5.0. Undissociated uric acid therefore predominates and is soluble in urine only in concentrations of 100 mg/L. Concentrations above this level represent supersaturation that causes crystals and stones to form. Hyperuricosuria, when present, increases supersaturation, but urine of low pH can be supersaturated with undissociated uric acid even though the daily excretion rate is normal. Myeloproliferative syndromes, chemotherapy of malignant tumors, and Lesch-Nyhan syndrome cause such massive production of uric acid and consequent hyperuricosuria that stones and uric acid sludge form even at a normal urine pH. Plugging of the renal collecting tubules by uric acid crystals can cause acute renal failure.

TREATMENT

The two goals of treatment are to raise urine pH and to lower excessive urine uric acid excretion to less than 1 g/d. Supplemental alkali, 1 to 3 mmol/kg of body weight per day, should be given in three or four evenly spaced, divided doses, one of which should be given at bedtime. The form of the alkali may be important. Potassium citrate may reduce the risk of calcium salts crystallizing when urine pH is increased, whereas sodium citrate or sodium bicarbonate may increase the risk. If the overnight urine pH is below 5.5, the evening dose of alkali may be raised or 250 mg acetazolamide added at bedtime. A low-purine diet should be instituted in those uric acid stone formers with hyperuricosuria. Patients who continue to form uric acid stones despite treatment with fluids, alkali, and a low-purine diet should have allopurinol added to their regimen. If hypercalciuria is also present, it should be specifically treated, as alkali alone could lead to calcium phosphate stone formation.

CYSTINURIA AND CYSTINE STONES (See also Chap. 343) In this autosomal recessive disorder, proximal tubular and jejunal transport of the dibasic amino acids cystine, lysine, arginine, and ornithine are defective, and excessive amounts are lost in the urine. Clinical disease is due solely to the insolubility of cystine, which forms stones.

Pathogenesis Cystinuria occurs because of defective transport of dibasic amino acids by the brush borders of renal tubule and intestinal epithelial cells. The disease classically has been broken into three types based on differences in intestinal and renal amino acid handling in families. However, genomic studies suggest type II and type III cystinuria are due to defects in the same protein. Disease-causing mutations have been identified in both the heavy and light chain of a heteromeric amino acid transporter found in the proximal tubule of the kidney. A gene located on chromosome 2 and designated *SLC3A1* encodes the heavy chain of the transporter and has been found to be abnormal in type I cystinuria. Non-type-I cystinuria is due to mutations in the *SLC7A9* gene on chromosome 19, which encodes the light chain of the heteromeric transporter.

Diagnosis Cystine stones are formed only by patients with cystinuria, but 10% of stones in cystinuric patients do not contain cystine; therefore, every stone former should be screened for the disease. The sediment from a first morning urine specimen in many patients with homozygous cystinuria reveals typical flat, hexagonal, platelike cystine crystals. Cystinuria also can be detected using the urine sodium nitroprusside test. Because the test is sensitive, it is positive in many asymptomatic heterozygotes for cystinuria. A positive nitroprusside test or the finding of cystine crystals in the urine sediment should be evaluated by measurement of daily cystine excretion. Normal adults excrete 40 to 60 mg cystine per gram of creatinine, heterozygotes usually excrete less than 300 mg/g, and homozygotes almost always excrete greater than 250 mg/g.

TREATMENT

High fluid intake, even at night, is the cornerstone of therapy. Daily urine volume should exceed 3 L. Raising urine pH with alkali is helpful, provided the urine pH exceeds 7.5. A low-salt diet (100 mmol/d) can reduce cystine excretion up to 40%. Because side effects are frequent, drugs such as penicillamine and tiopronin, which form the soluble disulfide cysteine-drug complexes, should be used only when fluid loading, salt reduction, and alkali therapy are ineffective. Captopril, which has a free sulfhydryl group to bind cysteine, has been used in a limited number of patients with some success. Low-methionine diets have not proved to be practical for clinical use, but patients should avoid protein gluttony.

STRUVITE STONES These stones are a result of urinary infection with bacteria, usually *Proteus* species, which possess urease, an enzyme that degrades urea to NH_3 and CO_2. The NH_3 hydrolyzes to NH_4^+ and raises urine pH to 8 or 9. The CO_2 hydrates to H_2CO_3 and then dissociates to CO_3^{2-} that precipitates with calcium as $CaCO_3$. The NH_4^+ precipitates PO_4^{3-} and Mg^{2+} to form $MgNH_4PO_4$ (struvite). The result is a stone of calcium carbonate admixed with struvite. Struvite does not form in urine in the absence of infection, because NH_4^+ concentration is low in urine that is alkaline in response to physiologic stimuli. Chronic *Proteus* infection can occur because of impaired urinary drainage, urologic instrumentation or surgery, and especially with chronic antibiotic treatment, which can favor the dominance of *Proteus* in the urinary tract.

TREATMENT

Complete removal of the stone with subsequent sterilization of the urinary tract is the treatment of choice for patients who can tolerate the procedures. Open surgery is successful in debulking the stone and improving renal function if obstruction is present; however, there is recurrence of stone in 25% of the patients. Irrigation of the renal pelvis and calyces with hemiacidrin, a solution that dissolves struvite, can reduce recurrence after surgery. Newer procedures such as lithotripsy and percutaneous nephrolithotomy, alone or in combination, have largely replaced open surgery. Stone-free rates of 50 to 90% have been reported after these procedures. Antimicrobial treatment is best reserved for dealing with acute infection and for maintenance of a sterile urine after surgery. Urine cultures and culture of stone fragments removed at surgery should guide the choice of antibiotic. For patients who are not candidates for surgical removal of stone, acetohydroxamic acid, an inhibitor of urease, can be used. Though effective in treating the stones, acetohydroxamic acid has many side effects, such as headache, tremor, and thrombophlebitis, that limit its use.

269 URINARY TRACT INFECTIONS AND PYELONEPHRITIS

Walter E. Stamm

DEFINITIONS Acute infections of the urinary tract can be subdivided into two general anatomic categories: lower tract infection (urethritis and cystitis) and upper tract infection (acute pyelonephritis, prostatitis, and intrarenal and perinephric abscesses). Infections at these various sites may occur together or independently and may either be asymptomatic or present as one of the clinical syndromes described below. Infections of the urethra and bladder are often considered superficial (or mucosal) infections, while prostatitis, pyelonephritis, and renal suppuration signify tissue invasion.

From a microbiologic perspective, urinary tract infection (UTI) exists when pathogenic microorganisms are detected in the urine, urethra, bladder, kidney, or prostate. In most instances, growth of $>10^5$ organisms per milliliter from a properly collected midstream "clean-catch" urine sample indicates infection. However, significant bacteriuria is lacking in some cases of true UTI. Especially in symptomatic patients, a smaller number of bacteria (10^2 to 10^4/mL) may signify infection. In urine specimens obtained by suprapubic aspiration or "in-and-out" catheterization and in samples from a patient with an indwelling catheter, colony counts of 10^2 to 10^4/mL generally indicate infection. Conversely, colony counts of $>10^5$/mL of midstream urine are occasionally due to specimen contamination, which is especially likely when multiple bacterial species are found.

Infections that recur after antibiotic therapy can be due to the persistence of the originally infecting strain (as judged by species, antibiogram, serotype, and molecular type) or to reinfection with a new strain. "Same-strain" recurrent infections that become evident within 2 weeks of cessation of therapy can be the result of unresolved renal or prostatic infection (termed *relapse*) or of persistent vaginal or intestinal colonization leading to rapid reinfection of the bladder.

Symptoms of dysuria, urgency, and frequency that are unaccompanied by significant bacteriuria have been termed the *acute urethral syndrome*. Although widely used, this term lacks anatomic precision because many cases so designated are actually bladder infections. Moreover, since the causative agent can usually be identified in these patients, the term *syndrome*—implying unknown causation—is inappropriate.

Chronic pyelonephritis refers to chronic interstitial nephritis believed to result from bacterial infection of the kidney (Chap. 266). Many noninfectious diseases also cause an interstitial nephritis that is indistinguishable pathologically from chronic pyelonephritis.

ACUTE UTIs: URETHRITIS, CYSTITIS, AND PYELONEPHRITIS

EPIDEMIOLOGY Epidemiologically, UTIs are subdivided into catheter-associated (or nosocomial) infections and non-catheter-associated (or community-acquired) infections. Infections in either category may be symptomatic or asymptomatic. Acute community-acquired infections are very common and account for more than 7 million office visits annually in the United States. These infections occur in 1 to 3% of schoolgirls and then increase markedly in incidence with the onset of sexual activity in adolescence. The vast majority of acute symptomatic infections involve young women; a prospective study demonstrated an annual incidence of 0.5 to 0.7 infections per patient-year in this group. Acute symptomatic UTIs are unusual in men under the age of 50. The development of asymptomatic bacteriuria parallels that of symptomatic infection and is rare among men under 50 but common among women between 20 and 50. Asymptomatic bacteriuria is more common among elderly men and women, with rates as high as 40 to 50% in some studies.

ETIOLOGY Many different microorganisms can infect the urinary tract, but by far the most common agents are the gram-negative bacilli. *Escherichia coli* causes ~80% of acute infections in patients without catheters, urologic abnormalities, or calculi. Other gram-negative rods, especially *Proteus* and *Klebsiella* and occasionally *Enterobacter*, account for a smaller proportion of uncomplicated infections. These organisms, plus *Serratia* and *Pseudomonas*, assume increasing importance in recurrent infections and in infections associated with urologic manipulation, calculi, or obstruction. They play a major role in nosocomial, catheter-associated infections (see below). *Proteus* spp., by virtue of urease production, and *Klebsiella* spp., through the production of extracellular slime and polysaccharides, predispose to stone formation and are isolated more frequently from patients with calculi.

Gram-positive cocci play a lesser role in UTIs. However, *Staphylococcus saprophyticus*—a novobiocin-resistant, coagulase-negative species—accounts for 10 to 15% of acute symptomatic UTIs in young females. Enterococci occasionally cause acute uncomplicated cystitis in women. More commonly, enterococci and *Staphylococcus aureus* cause infections in patients with renal stones or previous instrumentation or surgery. Isolation of *S. aureus* from the urine should arouse suspicion of bacteremic infection of the kidney.

About one-third of women with dysuria and frequency have either an insignificant number of bacteria in midstream urine cultures or completely sterile cultures and have been previously defined as having the urethral syndrome. About three-quarters of these women have pyuria, while one-quarter have no pyuria and little objective evidence of infection. In the women with pyuria, two groups of pathogens account for most infections. Low counts (10^2 to 10^4/mL) of typical bacterial uropathogens such as *E. coli*, *S. saprophyticus*, *Klebsiella*, or *Proteus* are found in midstream urine specimens from most of these women. These bacteria are probably the causative agents in these infections because they can usually be isolated from a suprapubic aspirate, are associated with pyuria, and respond to appropriate antimicrobial therapy. In other women with acute urinary symptoms, pyuria, and urine that is sterile (even when obtained by suprapubic aspiration), sexually transmitted urethritis-producing agents such as *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus are etiologically important. These agents are found most frequently in young, sexually active women with new sexual partners.

The causative role of several more unusual bacterial and nonbacterial pathogens in UTIs remains poorly defined. *Ureaplasma urealyticum* has frequently been isolated from the urethra and urine of patients with acute dysuria and frequency but is also found in specimens from many patients without urinary symptoms. Ureaplasmas probably account for some cases of urethritis and cystitis. *U. urealyticum* and *Mycoplasma hominis* have been isolated from prostatic and renal tissues of patients with acute prostatitis and pyelonephritis, respectively, and are probably responsible for some of these infections as well. Adenoviruses cause acute hemorrhagic cystitis in children and in some young adults, often in epidemics. Although other viruses can be isolated from urine (e.g., cytomegalovirus), they are thought not to cause acute UTI. Colonization of the urine of catheterized or diabetic patients by *Candida* and other fungal species is common and sometimes progresses to symptomatic invasive infection (Chap. 187). →***Mycobacterial infection of the genitourinary tract is discussed in Chap. 150.***

PATHOGENESIS AND SOURCES OF INFECTION The urinary tract should be viewed as a single anatomic unit that is united by a continuous column of urine extending from the urethra to the kidney. In the vast majority of UTIs, bacteria gain access to the bladder via the urethra. Ascent of bacteria from the bladder may follow and is probably the pathway for most renal parenchymal infections.

The vaginal introitus and distal urethra are normally colonized by diphtheroids, streptococcal species, lactobacilli, and staphylococcal species but not by the enteric gram-negative bacilli that commonly cause UTIs. In females prone to the development of cystitis, however, enteric gram-negative organisms residing in the bowel colonize the

introitus, the periurethral skin, and the distal urethra before and during episodes of bacteriuria. The factors that predispose to periurethral colonization with gram-negative bacilli remain poorly understood, but alteration of the normal vaginal flora by antibiotics, other genital infections, or contraceptives (especially spermicide) appears to play an important role. Loss of the normally dominant H_2O_2-producing lactobacilli in the vaginal flora appears to facilitate colonization by *E. coli*. Small numbers of periurethral bacteria probably gain entry to the bladder frequently, a process that is facilitated in some cases by urethral massage during intercourse. Whether bladder infection ensues depends on interacting effects of the pathogenicity of the strain, the inoculum size, and the local and systemic host defense mechanisms.

Under normal circumstances, bacteria placed in the bladder are rapidly cleared, partly through the flushing and dilutional effects of voiding but also as a result of the antibacterial properties of urine and the bladder mucosa. Owing mostly to a high urea concentration and high osmolarity, the bladder urine of many normal persons inhibits or kills bacteria. Prostatic secretions possess antibacterial properties as well. Polymorphonuclear leukocytes enter the bladder epithelium and the urine soon after infection arises and play a role in clearing bacteriuria. The role of locally produced antibody remains unclear.

Hematogenous pyelonephritis occurs most often in debilitated patients who are either chronically ill or receiving immunosuppressive therapy. Metastatic staphylococcal or candidal infections of the kidney may follow bacteremia or fungemia, spreading from distant foci of infection in the bone, skin, vasculature, or elsewhere.

CONDITIONS AFFECTING PATHOGENESIS ■ Gender and Sexual Activity The female urethra appears to be particularly prone to colonization with colonic gram-negative bacilli because of its proximity to the anus, its short length (~4 cm), and its termination beneath the labia. Sexual intercourse causes the introduction of bacteria into the bladder and is temporally associated with the onset of cystitis; it thus appears to be important in the pathogenesis of UTIs in younger women. Voiding after intercourse reduces the risk of cystitis, probably because it promotes the clearance of bacteria introduced during intercourse. Use of spermicidal compounds with a diaphragm or cervical cap or use of spermicide-coated condoms dramatically alters the normal introital bacterial flora and has been associated with marked increases in vaginal colonization with *E. coli* and in the risk of UTI.

In males who are <50 years old and who have no history of heterosexual or homosexual rectal intercourse, UTI is exceedingly uncommon, and this diagnosis should be questioned in the absence of clear documentation. An important factor predisposing to bacteriuria in men is urethral obstruction due to prostatic hypertrophy. Insertive rectal intercourse is also associated with an increased risk of cystitis in men. Men (and women) who are infected with HIV and who have CD4+ T cell counts of $<200/\mu L$ are at increased risk of both bacteriuria and symptomatic UTI. Finally, lack of circumcision has been identified as a risk factor for UTI in both neonates and young men.

Pregnancy UTIs are detected in 2 to 8% of pregnant women. Symptomatic upper tract infections, in particular, are unusually common during pregnancy; fully 20 to 30% of pregnant women with asymptomatic bacteriuria subsequently develop pyelonephritis. This predisposition to upper tract infection during pregnancy results from decreased ureteral tone, decreased ureteral peristalsis, and temporary incompetence of the vesicoureteral valves. Bladder catheterization during or after delivery causes additional infections. Increased incidences of low-birth-weight infants, premature delivery, and newborn mortality result from UTIs during pregnancy, particularly those infections involving the upper tract.

Obstruction Any impediment to the free flow of urine—tumor, stricture, stone, or prostatic hypertrophy—results in hydronephrosis and a greatly increased frequency of UTI. Infection superimposed on urinary tract obstruction may lead to rapid destruction of renal tissue. It is of utmost importance, therefore, when infection is present, to identify and repair obstructive lesions. On the other hand, when an obstruction is minor and is not progressive or associated with infection, great caution should be exercised in attempting surgical correction. The introduction of infection in such cases may be more damaging than an uncorrected minor obstruction that does not significantly impair renal function.

Neurogenic Bladder Dysfunction Interference with bladder enervation, as in spinal cord injury, tabes dorsalis, multiple sclerosis, diabetes, and other diseases, may be associated with UTI. The infection may be initiated by the use of catheters for bladder drainage and is favored by the prolonged stasis of urine in the bladder. An additional factor often operative in these cases is bone demineralization due to immobilization, which causes hypercalciuria, calculus formation, and obstructive uropathy.

Vesicoureteral Reflux Defined as reflux of urine from the bladder cavity up into the ureters and sometimes into the renal pelvis, vesicoureteral reflux occurs during voiding or with elevation of pressure in the bladder. In practice, this condition is demonstrated by the finding of retrograde movement of radiopaque or radioactive material during a voiding cystourethrogram. An anatomically impaired vesicoureteral junction facilitates reflux of bacteria and thus upper tract infection. However, since a fluid connection between the bladder and the kidney always exists, even in the normal urinary system, some retrograde movement of bacteria probably takes place during infection but is not detected by radiologic techniques.

Vesicoureteral reflux is common among children with anatomic abnormalities of the urinary tract as well as among children with anatomically normal but infected urinary tracts. In the latter group, reflux disappears with advancing age and is probably attributable to factors other than UTI. Long-term follow-up of children with UTI who have reflux has established that renal damage correlates with marked reflux, not with infection.

The routine search for reflux would be aided by the development of noninvasive tests applicable to young children, in whom the need for an effective technique is greatest. In the meantime, it appears reasonable to search for reflux in anyone with unexplained failure of renal growth or with renal scarring, because UTI per se is an insufficient explanation for these abnormalities. On the other hand, it is doubtful that all children who have recurrent UTIs but whose urinary tract appears normal on pyelography should be subjected to voiding cystoureterography merely for the detection of the rare patient with marked reflux not revealed by the intravenous pyelogram.

Bacterial Virulence Factors Not all strains of *E. coli* are equally capable of infecting the intact urinary tract. Bacterial virulence factors markedly influence the likelihood that a given strain, once introduced into the bladder, will cause UTI. Most *E. coli* strains that cause symptomatic UTIs in noncatheterized patients belong to a small number of specific O, K, and H serogroups. These uropathogenic clones have accumulated a number of virulence genes that are often closely linked on the bacterial chromosome in "virulence islands." Adherence of bacteria to uroepithelial cells is a critical first step in the initiation of infection. For both *E. coli* and *Proteus*, fimbriae (hairlike proteinaceous surface appendages) mediate the attachment of bacteria to specific receptors on epithelial cells. The attachment of bacteria to uroepithelial cells initiates a number of important events in the mucosal epithelial cell, including secretion of interleukin (IL) 6 and IL-8 (with subsequent chemotaxis of leukocytes to the bladder mucosa) and induction of apoptosis and epithelial cell desquamation. Besides fimbriae, uropathogenic *E. coli* strains usually produce hemolysin and aerobactin (a siderophore for scavenging iron) and are resistant to the bactericidal action of human serum. Nearly all *E. coli* strains causing acute pyelonephritis and most of those causing acute cystitis are uropathogenic. In contrast, infections in patients with structural or functional abnormalities of the urinary tract are generally caused by bacterial strains that lack these uropathogenic properties; the implication is that these properties are not needed for infection of the compromised urinary tract.

Genetic Factors Increasing evidence suggests that host genetic factors influence susceptibility to UTI. A maternal history of UTI is more often found among women who have experienced recurrent UTIs than among controls. The number and type of receptors on uroepithelial cells to which bacteria may attach are at least in part genetically determined. Many of these structures are components of blood group antigens and are present on both erythrocytes and uroepithelial cells. For example, P fimbriae mediate attachment of *E. coli* to P-positive erythrocytes and are found on nearly all strains causing acute uncomplicated pyelonephritis. Conversely, P blood group–negative individuals, who lack these receptors, have a decreased likelihood of pyelonephritis. It has also been demonstrated that nonsecretors of blood group antigens are at increased risk of recurrent UTI; this predisposition may relate to a different profile of genetically determined glycolipids on uroepithelial cells. Mutations in host genes integral to the immune response (interferon γ receptors and others) may also affect susceptibility to UTI.

LOCALIZATION OF INFECTION Unfortunately, currently available methods of distinguishing renal parenchymal infection from cystitis are neither reliable nor convenient enough for routine clinical use. Fever or an elevated level of C-reactive protein often accompanies acute pyelonephritis and is found in rare cases of cystitis but also occurs in infections other than pyelonephritis.

CLINICAL PRESENTATION ■ Cystitis Patients with cystitis usually report dysuria, frequency, urgency, and suprapubic pain. The urine often becomes grossly cloudy and malodorous, and it is bloody in ~30% of cases. White cells and bacteria can be detected by examination of unspun urine in most cases. However, some women with cystitis have only 10^2 to 10^4 bacteria per milliliter of urine, and in these instances bacteria cannot be seen in a Gram-stained preparation of unspun urine. Physical examination generally reveals only tenderness of the urethra or the suprapubic area. If a genital lesion or a vaginal discharge is evident, especially in conjunction with $<10^5$ bacteria per milliliter on urine culture, then pathogens that may cause urethritis, vaginitis, or cervicitis, such as *C. trachomatis*, *N. gonorrhoeae*, *Trichomonas*, *Candida*, and herpes simplex virus, should be considered. Prominent systemic manifestations, such as a temperature of >38.3°C (>101°F), nausea, and vomiting, usually indicate concomitant renal infection, as does costovertebral angle tenderness. However, the absence of these findings does not ensure that infection is limited to the bladder and urethra.

Acute Pyelonephritis Symptoms of acute pyelonephritis generally develop rapidly over a few hours or a day and include a fever, shaking chills, nausea, vomiting, and diarrhea. Symptoms of cystitis may or may not be present. Besides fever, tachycardia, and generalized muscle tenderness, physical examination reveals marked tenderness on deep pressure in one or both costovertebral angles or on deep abdominal palpation. In some patients, signs and symptoms of gram-negative sepsis predominate. Most patients have significant leukocytosis and bacteria detectable in Gram-stained unspun urine. Leukocyte casts are present in the urine of some patients, and the detection of these casts is pathognomonic. Hematuria may be demonstrated during the acute phase of the disease; if it persists after acute manifestations of infection have subsided, a stone, a tumor, or tuberculosis should be considered.

Except in individuals with papillary necrosis, abscess formation, or urinary obstruction, the manifestations of acute pyelonephritis usually respond to therapy within 48 to 72 h. However, despite the absence of symptoms, bacteriuria or pyuria may persist. In severe pyelonephritis, fever subsides more slowly and may not disappear for several days, even after appropriate antibiotic treatment has been instituted.

Urethritis Approximately 30% of women with acute dysuria, frequency, and pyuria have midstream urine cultures that show either no growth or insignificant bacterial growth. Clinically, these women cannot always be readily distinguished from those with cystitis. In this situation, a distinction should be made between women infected with sexually transmitted pathogens, such as *C. trachomatis*, *N. gonorrhoeae*, or herpes simplex virus, and those with low-count *E. coli* or staphylococcal infection of the urethra and bladder. Chlamydial or gonococcal infection should be suspected in women with a gradual onset of illness, no hematuria, no suprapubic pain, and >7 days of symptoms. The additional history of a recent sex-partner change, especially if the patient's partner has recently had chlamydial or gonococcal urethritis, should heighten the suspicion of a sexually transmitted infection, as should the finding of mucopurulent cervicitis (Chap. 115). Gross hematuria, suprapubic pain, an abrupt onset of illness, a duration of illness of <3 days, and a history of UTIs favor the diagnosis of *E. coli* UTI.

Catheter-Associated UTIs (See also Chap. 116) Bacteriuria develops in at least 10 to 15% of hospitalized patients with indwelling urethral catheters. The risk of infection is ~3 to 5% per day of catheterization. *E. coli*, *Proteus*, *Pseudomonas*, *Klebsiella*, *Serratia*, staphylococci, enterococci, and *Candida* usually cause these infections. Many infecting strains display markedly greater antimicrobial resistance than organisms that cause community-acquired UTIs. Factors associated with an increased risk of catheter-associated UTI include female sex, prolonged catheterization, severe underlying illness, disconnection of the catheter and drainage tube, other types of faulty catheter care, and lack of systemic antimicrobial therapy.

Infection occurs when bacteria reach the bladder by one of two routes: by migrating through the column of urine in the catheter lumen (intraluminal route) or by moving up the mucous sheath outside the catheter (periurethral route). Hospital-acquired pathogens reach the patient's catheter or urine-collecting system on the hands of hospital personnel, in contaminated solutions or irrigants, and via contaminated instruments or disinfectants. Bacteria usually enter the catheter system at the catheter–collecting tube junction or at the drainage bag portal. The organisms then ascend intraluminally into the bladder within 24 to 72 h. Alternatively, the patient's own bowel flora may colonize the perineal skin and periurethral area and reach the bladder via the external surface of the catheter. This route is particularly common in women. Studies have demonstrated the importance of the attachment and growth of bacteria on the surfaces of the catheter in the pathogenesis of catheter-associated UTI. Such bacteria growing in biofilms on the catheter eventually produce encrustations consisting of bacteria, bacterial glycocalyces, host urinary proteins, and urinary salts. These encrustations provide a refuge for bacteria and may protect them from antimicrobial agents and phagocytes.

Clinically, most catheter-associated infections cause minimal symptoms and no fever and often resolve after withdrawal of the catheter. The frequency of upper tract infection associated with catheter-induced bacteriuria is unknown. Gram-negative bacteremia, which follows catheter-associated bacteriuria in 1 to 2% of cases, is the most significant recognized complication of catheter-induced UTIs. The catheterized urinary tract has repeatedly been demonstrated to be the most common source of gram-negative bacteremia in hospitalized patients, generally accounting for ~30% of cases.

Catheter-associated UTIs can sometimes be prevented in patients catheterized for <2 weeks by use of a sterile closed collecting system, by attention to aseptic technique during insertion and care of the catheter, and by measures to minimize cross-infection. Other preventive approaches, including short courses of systemic antimicrobial therapy, topical application of periurethral antimicrobial ointments, use of preconnected catheter–drainage tube units, use of catheters impregnated with antimicrobial agents, and addition of antimicrobial drugs to the drainage bag, have all been protective in at least one controlled trial but are not recommended for general use. Despite precautions, the majority of patients catheterized for >2 weeks eventually develop bacteriuria. For example, because of spinal cord injury, incontinence, or other factors, some patients in hospitals or nursing homes require long-term or semipermanent bladder catheterization. Measures intended to

prevent infection have been largely unsuccessful, and essentially all such chronically catheterized patients develop bacteriuria. If feasible, intermittent catheterization by a nurse or by the patient appears to reduce the incidence of bacteriuria and associated complications in such patients. Treatment should be provided when symptomatic infections arise, but treatment of asymptomatic bacteriuria in such patients has no apparent benefit.

DIAGNOSTIC TESTING Determination of the number and type of bacteria in the urine is an extremely important diagnostic procedure. In symptomatic patients, bacteria are usually present in the urine in large numbers ($\geq 10^5$/mL). In asymptomatic patients, two consecutive urine specimens should be examined bacteriologically before therapy is instituted, and $\geq 10^5$ bacteria of a single species per milliliter should be demonstrable in both specimens. Since the large number of bacteria in the bladder urine is due in part to bacterial multiplication during residence in the bladder cavity, samples of urine from the ureters or renal pelvis may contain $< 10^5$ bacteria per milliliter and yet indicate infection. Similarly, the presence of bacteriuria of any degree in suprapubic aspirates or of $\geq 10^2$ bacteria per milliliter of urine obtained by catheterization usually indicates infection. In some circumstances (antibiotic treatment, high urea concentration, high osmolarity, low pH), urine inhibits bacterial multiplication, resulting in relatively low bacterial colony counts despite infection. For this reason, antiseptic solutions should not be used in washing the periurethral area before collection of the urine specimen. Water diuresis or recent voiding also reduces bacterial counts in urine.

Microscopy of urine from symptomatic patients can be of great diagnostic value. Microscopic bacteriuria, which is best assessed with Gram-stained uncentrifuged urine, is found in >90% of specimens from patients whose infections are associated with colony counts of at least 10^5/mL, and this finding is very specific. However, bacteria cannot usually be detected microscopically in infections with lower colony counts (10^2 to 10^4/mL). The detection of bacteria by urinary microscopy thus constitutes firm evidence of infection, but the absence of microscopically detectable bacteria does not exclude the diagnosis. When carefully sought by means of chamber-count microscopy, pyuria is a highly sensitive indicator of UTI in symptomatic patients. Pyuria is demonstrated in nearly all acute bacterial UTIs, and its absence calls the diagnosis into question. The leukocyte esterase "dipstick" method is less sensitive than microscopy in identifying pyuria but is a useful alternative where microscopy is not feasible. Pyuria in the absence of bacteriuria (sterile pyuria) may indicate infection with unusual bacterial agents such as *C. trachomatis*, *U. urealyticum*, and *Mycobacterium tuberculosis* or with fungi. Alternatively, sterile pyuria may be demonstrated in noninfectious urologic conditions such as calculi, anatomic abnormality, nephrocalcinosis, vesicoureteral reflux, interstitial nephritis, or polycystic disease.

Although many authorities have recommended that urine culture and antimicrobial susceptibility testing be performed for any patient with a suspected UTI, it may be more practical and cost-effective to manage women who have symptoms characteristic of acute uncomplicated cystitis without an initial urine culture. Two approaches to presumptive therapy have generally been used. In the first, treatment is initiated solely on the basis of a typical history and/or typical findings on physical examination. In the second, women with symptoms and signs of acute cystitis and without complicating factors are managed with urinary microscopy (or, alternatively, with a leukocyte esterase test). A positive result for pyuria and/or bacteriuria provides enough evidence of infection to indicate that urine culture and susceptibility testing can be omitted and the patient treated empirically. Urine should be cultured, however, when a woman's symptoms and urine-examination findings leave the diagnosis of cystitis in question. Pretherapy cultures and susceptibility testing are also essential in the management of all patients with suspected upper tract infections and of those with complicating factors, as in these situations any of a variety of pathogens may be involved and antibiotic therapy is best tailored to the individual organism.

TREATMENT

The following principles underlie the treatment of UTIs:

1. Except in acute uncomplicated cystitis in women, a quantitative urine culture or a comparable alternative diagnostic test should be performed to confirm infection before empirical treatment is begun. When culture results become available, antimicrobial sensitivity testing should be used to further direct therapy.
2. Factors predisposing to infection, such as obstruction and calculi, should be identified and corrected if possible.
3. Relief of clinical symptoms does not always indicate bacteriologic cure.
4. Each course of treatment should be classified after its completion as a failure (symptoms and/or bacteriuria not eradicated during therapy or in the immediate posttreatment culture) or a cure (resolution of symptoms and elimination of bacteriuria). Recurrent infections should be classified as same-strain or different-strain and as early (occurring within 2 weeks of the end of therapy) or late.
5. In general, uncomplicated infections confined to the lower urinary tract respond to short courses of therapy, while upper tract infections require longer treatment. After therapy, early recurrences due to the same strain may result from an unresolved upper tract focus of infection but often (especially after short-course therapy for cystitis) result from persistent vaginal colonization. Recurrences >2 weeks after the cessation of therapy nearly always represent reinfection with a new strain or with the previously infecting strain that has persisted in the vaginal and rectal flora.
6. Despite increasing resistance, community-acquired infections, especially initial infections, are usually due to more antibiotic-sensitive strains.
7. In patients with repeated infections, instrumentation, or recent hospitalization, the presence of antibiotic-resistant strains should be suspected. Although many antimicrobial agents reach high concentrations in urine, in vitro resistance usually predicts a substantially higher failure rate.

The anatomic location of a UTI greatly influences the success or failure of a therapeutic regimen. Bladder bacteriuria (cystitis) can usually be eliminated with nearly any antimicrobial agent to which the infecting strain is sensitive; in the past, it was demonstrated that as little as a single dose of 500 mg of intramuscular kanamycin eliminated bladder bacteriuria in most cases. With upper tract infections, however, single-dose therapy fails in the majority of cases, and even a 7-day course is unsuccessful in many instances. Longer periods of treatment (2 to 6 weeks) aimed at eradicating a persistent focus of infection may be necessary in some cases.

In *acute uncomplicated cystitis*, more than 90 to 95% of infections are due to one of two organisms: *E. coli* or *S. saprophyticus*. Although resistance patterns vary geographically and resistance has increased in many areas, most strains are sensitive to many antibiotics. In most parts of the United States, more than one-quarter of *E. coli* strains causing acute cystitis are resistant to amoxicillin, sulfa drugs, and cephalexin; resistance to trimethoprim (TMP) and trimethoprim-sulfamethoxazole (TMP-SMX) is now approaching these levels as well in many areas. Substantially higher rates of resistance to TMP-SMX have been documented in some other countries, as has resistance to fluoroquinolones.

Many have advocated single-dose treatment for acute cystitis. The advantages of single-dose therapy include less expense, ensured compliance, fewer side effects, and perhaps less intense pressure favoring the selection of resistant organisms in the intestinal, vaginal, or perineal flora. However, more frequent recurrences develop shortly after single-dose therapy than after 3-day treatment, and single-dose therapy does not eradicate vaginal colonization with *E. coli* as effectively as do longer regimens. A 3-day course of therapy with TMP-SMX, TMP,

norfloxacin, ciprofloxacin, or ofloxacin appears to preserve the low rate of side effects of single-dose therapy while improving efficacy (Table 269-1); thus 3-day regimens are currently preferred for acute cystitis. In areas where TMP-SMX resistance exceeds 20%, either a fluoroquinolone or nitrofurantoin can be used (Table 269-1). Neither single-dose nor 3-day therapy should be used for women with symptoms or signs of pyelonephritis, urologic abnormalities or stones, or previous infections due to antibiotic-resistant organisms. Males with UTI often have urologic abnormalities or prostatic involvement and hence are not candidates for single-dose or 3-day therapy. For empirical therapy, they should generally receive a 7- to 14-day course of a fluoroquinolone (Table 269-1).

The choice of treatment for women with acute urethritis depends on the etiologic agent involved. In chlamydial infection, azithromycin (1 g in a single oral dose) or doxycycline (100 mg twice daily by mouth for 7 days) should be used. Women with acute dysuria and frequency, negative urine cultures, and no pyuria usually do not respond to antimicrobial agents.

In women, *acute uncomplicated pyelonephritis* without accompanying clinical evidence of calculi or urologic disease is due to *E. coli* in most cases. Although the optimal route and duration of therapy have not been established, a 7- to 14-day course of a fluoroquinolone, an aminoglycoside, or a third-generation cephalosporin is usually adequate. Neither ampicillin nor TMP-SMX should be used as initial therapy because >25% of strains of *E. coli* causing pyelonephritis are now resistant to these drugs in vitro. For at least the first few days of treatment, antibiotics should probably be given intravenously to most patients, but patients with mild symptoms can be treated for 7 to 14 days with an oral antibiotic (usually ciprofloxacin or ofloxacin), with or without an initial single parenteral dose (Table 269-1). Patients who fail to respond to treatment within 72 h or who relapse after therapy should be evaluated for unrecognized suppurative foci, calculi, or urologic disease.

Complicated UTIs (those arising in a setting of catheterization, instrumentation, urologic anatomic or functional abnormalities, stones, obstruction, immunosuppression, renal disease, or diabetes) are typically due to hospital-acquired bacteria, including *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, *Pseudomonas*, enterococci, and staphylococci. Many of the infecting strains are antibiotic-resistant. Empirical antibiotic therapy ideally provides broad-spectrum coverage against these pathogens. In patients with minimal or mild symptoms, oral therapy with a fluoroquinolone, such as ciprofloxacin or ofloxacin, can be administered until culture results and antibiotic sensitivities are known. In patients with more severe illness, including acute pyelonephritis or suspected urosepsis, hospitalization and parenteral therapy should be undertaken. Commonly used empirical regimens include imipenem alone, a penicillin or cephalosporin plus an aminoglycoside, and (when the involvement of enterococci is unlikely) ceftriaxone or ceftazidime. When information on the antimicrobial sensitivity pattern of the infecting strain becomes available, a more specific antimicrobial regimen can be selected. Therapy should generally be administered for 10 to 21 days, with the exact duration depending on the severity of the infection and the susceptibility of the infecting strain. Follow-up cultures 2 to 4 weeks after cessation of therapy should be performed to demonstrate cure.

The need for treatment as well as the optimal type and duration of treatment for *catheterized patients with asymptomatic bacteriuria* have not been established. Removal of the catheter in conjunction with a

TABLE 269-1 *Treatment Regimens for Bacterial Urinary Tract Infections*

Condition	Characteristic Pathogens	Mitigating Circumstances	Recommended Empirical Treatment[a]
Acute uncomplicated cystitis in women	*Escherichia coli*, *Staphylococcus saprophyticus*, *Proteus mirabilis*, *Klebsiella pneumoniae*	None	3-Day regimens: oral TMP-SMX, TMP, quinolone; 7-day regimen: macrocrystalline nitrofurantoin[b]
		Diabetes, symptoms for >7 d, recent UTI, use of diaphragm, age >65 years	Consider 7-day regimen: oral TMP-SMX, TMP, quinolone[b]
		Pregnancy	Consider 7-day regimen: oral amoxicillin, macrocrystalline nitrofurantoin, cefpodoxime proxetil, or TMP-SMX[b]
Acute uncomplicated pyelonephritis in women	*E. coli*, *P. mirabilis*, *S. saprophyticus*	Mild to moderate illness, no nausea or vomiting; outpatient therapy	Oral[c] quinolone for 7–14 d (initial dose given IV if desired); or single-dose ceftriaxone (1 g) or gentamicin (3–5 mg/kg) IV followed by oral TMP-SMX[b] for 14 d
		Severe illness or possible urosepsis: hospitalization required	Parenteral[d] quinolone, gentamicin (± ampicillin), ceftriaxone, or aztreonam until defervescence; then oral[c] quinolone, cephalosporin, or TMP-SMX for 14 d
Complicated UTI in men and women	*E. coli*, *Proteus*, *Klebsiella*, *Pseudomonas*, *Serratia*, enterococci, staphylococci	Mild to moderate illness, no nausea or vomiting: outpatient therapy	Oral[c] quinolone for 10–14 d
		Severe illness or possible urosepsis: hospitalization required	Parenteral[d] ampicillin and gentamicin, quinolone, ceftriaxone, aztreonam, ticarcillin/clavulanate, or imipenem-cilastatin until defervescence; then oral[c] quinolone or TMP-SMX for 10–21 d

[a] Treatments listed are those to be prescribed before the etiologic agent is known; Gram's staining can be helpful in the selection of empirical therapy. Such therapy can be modified once the infecting agent has been identified. Fluoroquinolones should not be used in pregnancy. TMP-SMX, although not approved for use in pregnancy, has been widely used. Gentamicin should be used with caution in pregnancy because of its possible toxicity to eighth-nerve development in the fetus.

[b] Multiday oral regimens for cystitis are as follows: TMP-SMX, 160/800 mg q12h; TMP, 100 mg q12h; norfloxacin, 400 mg q12h; ciprofloxacin, 250 mg q12h; ofloxacin, 200 mg q12h; levofloxacin, 250 mg/d; gatifloxacin, 200 or 400 mg/d; moxifloxacin, 400 mg/d; lomefloxacin, 400 mg/d; enoxacin, 400 mg q12h; macrocrystalline nitrofurantoin, 100 mg qid; amoxicillin, 250 mg q8h; cefpodoxime proxetil, 100 mg q12h.

[c] Oral regimens for pyelonephritis and complicated UTI are as follows: TMP-SMX, 160/800 mg q12h; ciprofloxacin, 500 mg q12h; ofloxacin, 200–300 mg q12h; lomefloxacin, 400 mg/d; enoxacin, 400 mg q12h; gatifloxacin, 400 mg/d; levofloxacin, 200 mg q12h; moxifloxacin, 400 mg/d; amoxicillin, 500 mg q8h; cefpodoxime proxetil, 200 mg q12h.

[d] Parenteral regimens are as follows: ciprofloxacin, 400 mg q12h; ofloxacin, 400 mg q12h; gatifloxacin, 400 mg/d; levofloxacin, 500 mg/d; gentamicin, 1 mg/kg q8h; ceftriaxone, 1–2 g/d; ampicillin, 1 g q6h; imipenem-cilastatin, 250–500 mg q6–8h; ticarcillin/clavulanate, 3.2 g q8h; aztreonam, 1 g q8–12h.

Note: UTI, urinary tract infection; TMP, trimethoprim; TMP-SMX, trimethoprim-sulfamethoxazole.

short course of antibiotics to which the organism is susceptible probably constitutes the best course of action and nearly always eradicates bacteriuria. Treatment of asymptomatic catheter-associated bacteriuria may be of greatest benefit to elderly women, who most often develop symptoms if left untreated. If the catheter cannot be removed, antibiotic therapy usually proves to be unsuccessful and may in fact result in infection with a more resistant strain. In this situation, the bacteriuria should be ignored unless the patient develops symptoms or is at high risk of developing bacteremia. In these cases, use of systemic antibiotics or urinary bladder antiseptics may reduce the degree of bacteriuria and the likelihood of bacteremia.

In *pregnancy*, acute cystitis can be managed with 7 days of treatment with amoxicillin, nitrofurantoin, or a cephalosporin. All pregnant women should be screened for asymptomatic bacteriuria during the first trimester and, if bacteriuric, should be treated with one of the regimens listed in Table 269-1. After treatment, a culture should be performed to ensure cure, and cultures should be repeated monthly thereafter until delivery. Acute pyelonephritis in pregnancy should be managed with hospitalization and parenteral antibiotic therapy, generally with a cephalosporin or an extended-spectrum penicillin. Continuous low-dose prophylaxis with nitrofurantoin should be given to women who have recurrent infections during pregnancy.

Asymptomatic bacteriuria in noncatheterized patients is common, especially among elderly patients, but has not been linked to adverse outcomes in most circumstances other than pregnancy. Thus antimicrobial therapy is unnecessary and may in fact promote the emergence of resistant strains in most patients with asymptomatic bacteriuria. High-risk patients with neutropenia, renal transplants, obstruction, or other complicating conditions may require treatment when asymptomatic bacteriuria occurs. Seven days of therapy with an oral agent to which the organism is sensitive should be given initially. If bacteriuria persists, it can be monitored without further treatment in most patients. Longer-term therapy (4 to 6 weeks) may be necessary in high-risk patients with persistent asymptomatic bacteriuria.

UROLOGIC EVALUATION Very few women with recurrent UTIs have correctable lesions discovered at cystoscopy or upon intravenous pyelography, and these procedures should not be undertaken routinely in such cases. Urologic evaluation should be performed in selected instances—namely, in women with relapsing infection, a history of childhood infections, stones or painless hematuria, or recurrent pyelonephritis. Most males with UTI should be considered to have complicated infection and thus should be evaluated urologically. Possible exceptions include young men who have cystitis associated with sexual activity, who are uncircumcised, or who have AIDS. Men or women presenting with acute infection and signs or symptoms suggestive of an obstruction or stones should undergo prompt urologic evaluation, generally by means of ultrasound.

PROGNOSIS In patients with uncomplicated cystitis or pyelonephritis, treatment ordinarily results in complete resolution of symptoms. Lower tract infections in women are of concern mainly because they cause discomfort, morbidity, loss of time from work, and substantial health care costs. Cystitis may also result in upper tract infection or in bacteremia (especially during instrumentation), but little evidence suggests that renal impairment follows. When repeated episodes of cystitis occur, they are more commonly reinfections rather than relapses.

Acute uncomplicated pyelonephritis in adults rarely progresses to renal functional impairment and chronic renal disease. Repeated upper tract infections often represent relapse rather than reinfection, and a vigorous search for renal calculi or an underlying urologic abnormality should be undertaken. If neither is found, 6 weeks of chemotherapy may be useful in eradicating an unresolved focus of infection.

Repeated symptomatic UTIs in children and in adults with obstructive uropathy, neurogenic bladder, structural renal disease, or diabetes progress to chronic renal disease with unusual frequency. Asymptomatic bacteriuria in these groups as well as in adults without urologic disease or obstruction predisposes to increased numbers of episodes of symptomatic infection but does not result in renal impairment in most instances.

PREVENTION Women who experience frequent symptomatic UTIs ($\geq$3 per year on average) are candidates for long-term administration of low-dose antibiotics directed at preventing recurrences. Such women should be advised to avoid spermicide use and to void soon after intercourse. Daily or thrice-weekly administration of a single dose of TMP-SMX (80/400 mg), TMP alone (100 mg), or nitrofurantoin (50 mg) has been particularly effective. Norfloxacin and other fluoroquinolones have also been used for prophylaxis. Prophylaxis should be initiated only after bacteriuria has been eradicated with a full-dose treatment regimen. The same prophylactic regimens can be used after sexual intercourse to prevent episodes of symptomatic infection in women in whom UTIs are temporally related to intercourse. Other patients for whom prophylaxis appears to have some merit include men with chronic prostatitis; patients undergoing prostatectomy, both during the operation and in the postoperative period; and pregnant women with asymptomatic bacteriuria. All pregnant women should be screened for bacteriuria in the first trimester and should be treated if bacteriuria is demonstrated.

PAPILLARY NECROSIS

When infection of the renal pyramids develops in association with vascular diseases of the kidney or with urinary tract obstruction, renal papillary necrosis is likely to result. Patients with diabetes, sickle cell disease, chronic alcoholism, and vascular disease seem peculiarly susceptible to this complication. Hematuria, pain in the flank or abdomen, and chills and fever are the most common presenting symptoms. Acute renal failure with oliguria or anuria sometimes develops. Rarely, sloughing of a pyramid may take place without symptoms in a patient with chronic UTI, and the diagnosis is made when the necrotic tissue is passed in the urine or identified as a "ring shadow" on pyelography. If renal function deteriorates suddenly in a diabetic individual or a patient with chronic obstruction, the diagnosis of renal papillary necrosis should be entertained, even in the absence of fever or pain. Renal papillary necrosis is often bilateral; when it is unilateral, however, nephrectomy may be a life-saving approach to the management of overwhelming infection.

EMPHYSEMATOUS PYELONEPHRITIS AND CYSTITIS

These unusual clinical entities almost always occur in diabetic patients, often in concert with urinary obstruction and chronic infection. Emphysematous pyelonephritis is usually characterized by a rapidly progressive clinical course, with high fever, leukocytosis, renal parenchymal necrosis, and accumulation of fermentative gases in the kidney and perinephric tissues. Most patients also have pyuria and glucosuria. *E. coli* causes most cases, but occasionally other Enterobacteriaceae are isolated. Gas in tissues can often be seen on plain films and can best be confirmed and localized by computed tomography. Surgical resection of the involved tissue in addition to systemic antimicrobial therapy is usually needed to prevent a fatal outcome in emphysematous pyelonephritis.

Emphysematous cystitis also occurs primarily in diabetic patients, usually in association with *E. coli* or other facultative gram-negative rods and often in relation to bladder outlet obstruction. Patients with this condition are generally less severely ill and have less rapidly progressive disease than those with emphysematous pyelonephritis. The patient typically reports abdominal pain, dysuria, frequency, and (in some cases) pneumaturia. Computed tomography shows gas within both the bladder lumen and the bladder wall. Generally, conservative therapy with systemic antimicrobial agents and relief of outlet obstruction are effective, but some patients do not respond to these measures and require cystectomy.

RENAL AND PERINEPHRIC ABSCESS

See Chap. 112.

PROSTATITIS

The term *prostatitis* has been used for various inflammatory conditions affecting the prostate, including acute and chronic infections with specific bacteria and, more commonly, instances in which signs and symptoms of prostatic inflammation are present but no specific organisms can be detected. Patients with acute bacterial prostatitis can usually be readily identified on the basis of typical symptoms and signs, pyuria, and bacteriuria. To classify a patient with suspected chronic prostatitis correctly, first-void and midstream urine specimens, a prostatic expressate, and a postmassage urine specimen should be quantitatively cultured and evaluated for numbers of leukocytes. On the basis of the results of these studies and other considerations, a panel of the National Institutes of Health has recommended that patients with suspected chronic prostatitis be categorized as having chronic bacterial prostatitis, chronic pelvic pain syndrome, or asymptomatic inflammatory prostatitis. Each of these groups is discussed below.

ACUTE BACTERIAL PROSTATITIS When it occurs spontaneously, this disease generally affects young men; however, it may also be associated with an indwelling urethral catheter in older men. It is characterized by fever, chills, dysuria, and a tense or boggy, extremely tender prostate. Although prostatic massage usually produces purulent secretions with a large number of bacteria on culture, bacteremia may result from manipulation of the inflamed gland. For this reason and because the etiologic agent can usually be identified by Gram's staining and culture of urine, vigorous prostatic massage should be avoided. In non-catheter-associated cases, the infection is generally due to common gram-negative urinary tract pathogens (*E. coli* or *Klebsiella*). Initially, an intravenous fluoroquinolone, third-generation cephalosporin, or aminoglycoside can be administered. The response to antibiotics in acute bacterial prostatitis is usually prompt, perhaps because drugs penetrate more readily into the acutely inflamed prostate. In catheter-associated cases, the spectrum of etiologic agents is broader, including hospital-acquired gram-negative rods and enterococci. The urinary Gram stain may be particularly helpful in such cases. Imipenem, an aminoglycoside, a fluoroquinolone, or a third-generation cephalosporin should be used for initial therapy until the organism has been isolated and its susceptibilities have been determined. The long-term prognosis is good, although in some instances acute infection may result in abscess formation, epididymoorchitis, seminal vesiculitis, septicemia, and residual chronic bacterial prostatitis. Since the advent of antibiotics, the frequency of acute bacterial prostatitis has diminished markedly.

CHRONIC BACTERIAL PROSTATITIS This entity is now infrequent but should be considered in men with a history of recurrent bacteriuria. Symptoms are often lacking between episodes, and the prostate usually feels normal on palpation. Obstructive symptoms or perineal pain develops in some patients. Intermittently, infection spreads to the bladder, producing frequency, urgency, and dysuria. A pattern of relapsing infection in a middle-aged man strongly suggests chronic bacterial prostatitis. Classically, the diagnosis is established by culture of *E. coli*, *Klebsiella*, *Proteus*, or other uropathogenic bacteria from the expressed prostatic secretion or postmassage urine in higher quantities than are found in first-void or midstream urine. Antibiotics promptly relieve the symptoms associated with acute exacerbations but have been less effective in eradicating the focus of chronic infection in the prostate. The relative ineffectiveness of antimicrobial agents in achieving long-term cure has in part been due to the poor penetration into the prostate by most of these drugs. Fluoroquinolones have been considerably more successful than other antimicrobials, but even they must generally be given for at least 12 weeks to be effective. Patients with frequent episodes of acute cystitis in whom attempts at curative therapy fail can be managed with prolonged courses of low-dose antimicrobial agents (usually a sulfonamide, TMP, or nitrofurantoin), with a view toward suppressing symptoms and keeping the bladder urine sterile. Total prostatectomy obviously results in the cure of chronic prostatitis but is associated with considerable morbidity. Transurethral prostatectomy is safer but cures only one-third of patients.

CHRONIC PELVIC PAIN SYNDROME (FORMERLY NONBACTERIAL PROSTATITIS) Patients who present with symptoms of prostatitis (intermittent perineal and low-back pain, obstructive voiding symptoms), few signs on examination, no bacterial growth in cultures, and no history of recurrent episodes of bacterial prostatitis are classified as having chronic pelvic pain syndrome (CPPS). Patients with CPPS are divided into inflammatory and noninflammatory subgroups based on the presence or absence of prostatic inflammation. Prostatic inflammation can be considered present when the expressed prostatic secretion and postmassage urine contain at least tenfold more leukocytes than the first-void and midstream urine specimens or when the expressed prostatic secretion contains $\geq$1000 leukocytes per microliter.

The likely etiology of CPPS associated with inflammation would be an infectious agent, but the agent has not yet been identified. Evidence for a causative role of both *U. urealyticum* and *C. trachomatis* has been presented but is not conclusive. Since most cases of inflammatory CPPS occur in young, sexually active men and since many cases follow an episode of nonspecific urethritis, the causative agent may well be sexually transmitted. The effectiveness of antimicrobial agents in this condition remains uncertain. Some patients benefit from a 4- to 6-week course of treatment with erythromycin, doxycycline, TMP-SMX, or a fluoroquinolone, but controlled trials are lacking. Patients who have symptoms and signs of prostatitis but who have no evidence of prostatic inflammation (normal leukocyte counts) and negative urine cultures are classified as having noninflammatory CPPS. Despite their symptoms, these patients most likely do not have prostatic infection and should not be given antimicrobial agents.

270 URINARY TRACT OBSTRUCTION

Julian L. Seifter, Barry M. Brenner

Obstruction to the flow of urine, with attendant stasis and elevation in urinary tract pressure, impairs renal and urinary conduit functions and is a common cause of acute and chronic renal failure. With early relief of obstruction, the defects in function usually disappear completely. However, chronic obstruction may produce permanent loss of renal mass (renal atrophy) and excretory capability, as well as enhanced susceptibility to local infection and stone formation. Early diagnosis and prompt therapy are therefore essential to minimize the otherwise devastating effects of obstruction on kidney structure and function.

ETIOLOGY Obstruction to urine flow can result from *intrinsic* or *extrinsic mechanical blockade* as well as from *functional defects* not associated with fixed occlusion of the urinary drainage system. Mechanical obstruction can occur at any level of the urinary tract, from the renal calyces to the external urethral meatus. Normal points of narrowing, such as the ureteropelvic and ureterovesical junctions, bladder neck, and urethral meatus, are common sites of obstruction. When blockage is above the level of the bladder, unilateral dilatation of the ureter (*hydroureter*) and renal pyelocalyceal system (*hydronephrosis*) occur; lesions at or below the level of the bladder cause bilateral involvement.

Common forms of obstruction are listed in Table 270-1. Childhood causes include *congenital malformations* such as narrowing of the ureteropelvic junction and anomalous (retrocaval) location of the ureter. Posterior urethral valves are the most common cause of bilateral hydronephrosis in boys. Bladder dysfunction may be secondary to congenital urethral stricture, urethral meatal stenosis, or bladder neck obstruction. In adults, urinary tract obstruction is due mainly to *acquired defects*. Pelvic tumors, calculi, and urethral stricture predominate. Ligation of, or injury to, the ureter during pelvic or colonic surgery can lead to hydronephrosis which, if unilateral, may remain relatively silent and undetected. *Schistosoma haematobium* and genitourinary tuberculosis are infectious causes of ureteral obstruction. Obstructive uropathy may also result from extrinsic neoplastic (carcinoma of cervix or colon) or inflammatory disorders. Retroperitoneal fibrosis, an inflammatory condition in middle-aged men, must be distinguished from other retroperitoneal causes of ureteral obstruction, particularly lymphomas and pelvic neoplasms.

Functional impairment of urine flow usually results from disorders that involve both the ureter and bladder. Causes include neurogenic bladder, often with adynamic ureter, and vesicoureteral reflux. Reflux of urine from bladder to ureter(s) is more common in children, may result in severe unilateral or bilateral hydroureter and hydronephrosis. Abnormal insertion of the ureter into the bladder is the most common cause. Vesicoureteral reflux in the absence of urinary tract infection or bladder neck obstruction usually does not lead to renal parenchymal damage and often resolves with age. Reinsertion of the ureter into the bladder is indicated if reflux is severe and unlikely to improve spontaneously, if renal function deteriorates, or if urinary tract infections recur despite chronic antimicrobial therapy. Hydronephrosis is common in pregnancy, due both to ureteral compression by the enlarged uterus and to functional effects of progesterone.

CLINICAL FEATURES The pathophysiology and clinical features of urinary tract obstruction are summarized in Table 270-2. *Pain*, the symptom that most commonly leads to medical attention, is due to distention of the collecting system or renal capsule. Pain severity is influenced more by the rate at which distention develops than by the degree of distention. Acute supravesical obstruction, as from a stone lodged in a ureter (Chap. 268), is associated with excruciatingly severe pain, usually called *renal colic*. This pain is relatively steady and continuous, with little fluctuation in intensity, and often radiates to the lower abdomen, testes, or labia. By contrast, more insidious causes of obstruction, such as chronic narrowing of the ureteropelvic junction, may produce little or no pain yet result in total destruction of the affected kidney. Flank pain that occurs only with micturition is pathognomonic of vesicoureteral reflux.

Azotemia develops when overall excretory function is impaired, often in the setting of bladder outlet obstruction, bilateral renal pelvic or ureteric obstruction, or unilateral disease in a patient with a solitary functioning kidney. Complete bilateral obstruction should be suspected when acute renal failure is accompanied by anuria. Any patient with renal failure otherwise unexplained, or with a history of nephrolithiasis, hematuria, diabetes mellitus, prostatic enlargement, pelvic surgery, trauma, or tumor should be evaluated for urinary tract obstruction.

In the acute setting, bilateral obstruction may mimic prerenal azotemia. However, with more prolonged obstruction, symptoms of *polyuria* and *nocturia* commonly accompany partial urinary tract obstruction and result from impaired renal concentrating ability. This defect usually does not improve with administration of vasopressin and is therefore a form of acquired nephrogenic diabetes insipidus. Disturbances in sodium chloride transport in the ascending limb of Henle and, in azotemic patients, the osmotic (urea) diuresis per nephron lead to decreased medullary hypertonicity and hence a concentrating defect. Partial obstruction, therefore, may be associated with increased rather than decreased urine output. Indeed, wide fluctuations in urine output in a patient with azotemia should always raise the possibility of intermittent or partial urinary tract obstruction. If fluid intake is inadequate, severe dehydration and hypernatremia may develop. Hesitancy and straining to initiate the urinary

stream, postvoid dribbling, urinary frequency, and incontinence are common with obstruction at or below the level of the bladder.

Partial bilateral urinary tract obstruction often results in *acquired distal renal tubular acidosis*, *hyperkalemia*, and *renal salt wasting*. These defects in tubule function are often accompanied by renal tubulointerstitial damage. Initially the interstitium becomes edematous and infiltrated with mononuclear inflammatory cells. Later, interstitial fibrosis and atrophy of the papillae and medulla occur and precede these processes in the cortex.

Urinary tract obstruction must always be considered in patients with urinary tract infections or urolithiasis. Urinary stasis encourages the growth of organisms. Urea-splitting bacteria are associated with magnesium ammonium phosphate (struvite) calculi. *Hypertension* is frequent in acute and subacute unilateral obstruction and is usually a consequence of increased release of renin by the involved kidney. Chronic hydronephrosis, in the presence of extracellular volume expansion, may result in significant hypertension. *Erythrocytosis*, an infrequent complication of obstructive uropathy, is probably secondary to increased erythropoietin production.

TABLE 270-2 *Pathophysiology of Bilateral Ureteral Obstruction*

Hemodynamic Effects	*Tubule Effects*	*Clinical Features*
ACUTE

RELEASE OF OBSTRUCTION		
Slow ↑ in GFR (variable)	↓Tubule pressure ↑Solute load per nephron (urea, NaCl) Natriuretic factors present	Postobstructive diuresis Potential for volume depletion and electrolyte imbalance due to losses of Na^+, K^+, PO_4^{3-}, Mg^{2+}, and water

Note: GFR, glomerular filtration rate.

DIAGNOSIS A history of difficulty in voiding, pain, infection, or changes in urinary volume is common. Evidence for distention of the kidney or urinary bladder can often be obtained by palpation and percussion of the abdomen. A careful rectal examination may reveal enlargement or nodularity of the prostate, abnormal rectal sphincter tone, or a rectal or pelvic mass. The penis should be inspected for evidence of meatal stenosis or phimosis. In the female, vaginal, uterine, and rectal lesions responsible for urinary tract obstruction are usually revealed by inspection and palpation.

Urinalysis may reveal hematuria, pyuria, and bacteriuria. The urine sediment is often normal, even when obstruction leads to marked azotemia and extensive structural damage. An abdominal scout film may detect nephrocalcinosis or a radiopaque stone. As indicated in Fig. 270-1, if urinary tract obstruction is suspected, a bladder catheter should be inserted. If diuresis does not follow, then abdominal ultrasonography should be performed to evaluate renal and bladder size, as well as pyelocalyceal contour. Ultrasonography is approximately 90% specific and sensitive for detection of hydronephrosis. False-positive results are associated with diuresis, renal cysts, or presence of an extrarenal pelvis, a normal congenital variant. Hydronephrosis may be absent on ultrasound when obstruction is associated with volume contraction, staghorn calculi, retroperitoneal fibrosis, or infiltrative renal disease.

In some cases, the intravenous urogram may define the site of obstruction. In the presence of obstruction, the appearance time of the nephrogram is delayed. Eventually the renal image becomes more dense than normal because of slow tubular fluid flow rate, which results in greater concentration of contrast medium. The kidney involved by an acute obstructive process is usually slightly enlarged, and there is dilatation of the calyces, renal pelvis, and ureter above the obstruction. The ureter is not tortuous as in chronic obstruction. In comparison with the nephrogram, the urogram may be faint, especially if the dilated renal pelvis is voluminous, causing dilution of the contrast medium. The radiographic study should be continued until the site of obstruction is determined or the contrast medium is excreted. Radionuclide scans, though sensitive for the detection of obstruction, define less anatomic detail than intravenous urography and, like the urogram, are of limited value when renal function is poor. They have a role in patients at high risk for reaction to intravenous contrast. Patients suspected of having intermittent ureteropelvic obstruction should have radiologic evaluation while in pain, since a normal urogram is commonly seen during asymptomatic periods. Hydration often helps to provoke a symptomatic attack.

To facilitate visualization of a suspected lesion in a ureter or renal pelvis, *retrograde* or *antegrade urography* should be attempted. These diagnostic studies may be preferable to the intravenous urogram in the azotemic patient, in whom poor excretory function precludes adequate visualization of the collecting system. Furthermore, intravenous urography carries the risk of contrast-induced acute renal failure in patients with proteinuria, renal insufficiency, diabetes mellitus, or mul-

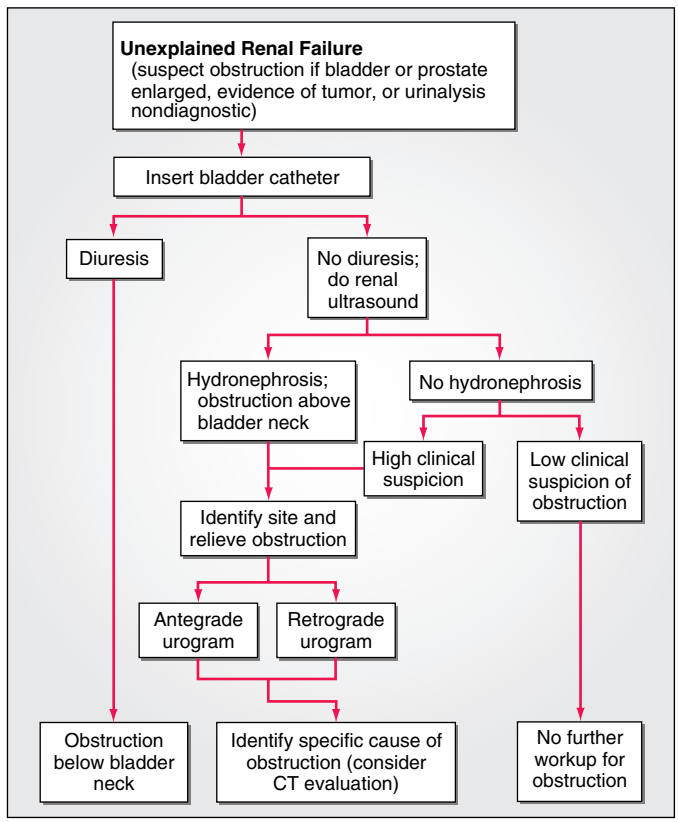

FIGURE 270-1 Diagnostic approach for urinary tract obstruction in unexplained renal failure. CT, computed tomography.

tiple myeloma, particularly if they are dehydrated. The retrograde approach involves catheterization of the involved ureter under cystoscopic control, while the antegrade technique necessitates placement of a catheter into the renal pelvis via a needle inserted percutaneously under ultrasonic or fluoroscopic guidance. While the antegrade approach may provide immediate decompression of a unilateral obstructing lesion, many urologists initially attempt the retrograde approach unless the catheterization is unsuccessful or general anesthesia is contraindicated.

Voiding cystourethrography is of value in the diagnosis of vesicoureteral reflux and bladder neck and urethral obstructions. Patients with obstruction at or below the level of the bladder exhibit thickening, trabeculation, and diverticula of the bladder wall. Postvoiding films reveal residual urine. If these radiographic studies fail to provide adequate information for diagnosis, endoscopic visualization by the urologist often permits precise identification of lesions involving the urethra, prostate, bladder, and ureteral orifices.

Computed tomography (CT) is useful in the diagnosis of specific intraabdominal and retroperitoneal causes of obstruction. The spiral CT is the preferred study to image urinary calculi. Magnetic resonance imaging may also be useful in the identification of specific obstructive causes.

Rx TREATMENT

Urinary tract obstruction complicated by infection requires relief of obstruction as soon as possible to prevent development of generalized sepsis and progressive renal damage. On a temporary basis, drainage is often satisfactorily achieved by nephrostomy, ureterostomy, or ureteral, urethral, or suprapubic catheterization. The patient with acute urinary tract infection and obstruction should be given appropriate antibiotics based on in vitro bacterial sensitivity and the ability of the drug to concentrate in the urine. Treatment may be required for 3 to 4 weeks. Chronic or recurrent infections in an obstructed kidney with poor intrinsic function may necessitate nephrectomy. When infection is not present, immediate surgery often is not required, even in the presence of complete obstruction and anuria because of the availability of dialysis, until acid-base, fluid and electrolyte, and cardiovascular status are restored. Nevertheless, the site of obstruction should be ascertained as soon as feasible, in part because of the possibility that sepsis may occur and this complication necessitates prompt urologic intervention. Elective relief of obstruction is usually recommended in patients with urinary retention, recurrent urinary tract infections, persistent pain, or progressive loss of renal function. Infrequently, mechanical obstruction can be alleviated by nonsurgical means, as with radiation therapy for retroperitoneal lymphoma. Likewise, functional obstruction secondary to neurogenic bladder may be decreased with the combination of frequent voiding and cholinergic drugs. →***The approach to obstruction secondary to renal stones is discussed in Chap. 268.***

PROGNOSIS With relief of obstruction, the prognosis regarding return of renal function depends largely on whether irreversible renal damage has occurred. When obstruction is not relieved, the course will depend mainly on whether the obstruction is complete or incomplete, bilateral or unilateral, and whether urinary tract infection is also present. Complete obstruction with infection can lead to total destruction of the kidney within days. Partial return of glomerular filtration rate may follow relief of complete obstruction of 1 and 2 weeks' duration but after 8 weeks of obstruction, recovery is unlikely. In the absence of definitive evidence of irreversibility, every effort should be made to decompress the obstruction in the hope of restoring renal function at least partially. A renal radionuclide scan, performed after a prolonged period of decompression, may be used to predict reversible renal function.

POSTOBSTRUCTIVE DIURESIS Relief of bilateral, but not unilateral, complete obstruction commonly results in polyuria, which may be massive. The urine is usually hypotonic and may contain large amounts of sodium chloride, potassium, and magnesium. The natriuresis is due in part to the excretion of retained urea (osmotic diuresis). The increase in intratubular pressure very likely also contributes to the impairment in net sodium chloride reabsorption, especially in the terminal nephron segments. Natriuretic factors may also accumulate during uremia and depress salt and water reabsorption when urine flow is reestablished. In the majority of patients this diuresis results in the *appropriate* excretion of the excesses of retained salt and water. When extracellular volume and composition return to normal, the diuresis usually abates spontaneously. Therefore, replacement of urinary losses should only be done in the setting of hypovolemia, hypotension, or disturbances in serum electrolyte concentrations. Occasionally, iatrogenic expansion of extracellular volume is responsible for, or sustains, the diuresis observed in the postobstructive period. Replacement of no more than two-thirds of urinary volume losses per day is usually effective in avoiding this complication. The loss of electrolyte-free water with urea may result in hypernatremia. Serum and urine sodium and osmolal concentrations should guide the use of appropriate intravenous replacement. Often replacement with 0.45% saline is required. In a rare patient, relief of obstruction may be followed by urinary salt and water losses severe enough to provoke profound dehydration and vascular collapse. In these patients, an intrinsic defect in tubule reabsorptive function is probably responsible for the marked diuresis. Appropriate therapy in such patients includes intravenous administration of salt-containing solutions to replace sodium and volume deficits.

271 APPROACH TO THE PATIENT WITH GASTROINTESTINAL DISEASE

William L. Hasler, Chung Owyang

ANATOMIC CONSIDERATIONS

The gastrointestinal (GI) tract extends from the mouth to the anus and comprises several organs with distinct functions. The organs are separated by specialized independently controlled thickened sphincters that assist in gut compartmentalization. The gut wall is organized into well-defined layers that contribute to the functional activities in each region. The mucosa serves as a barrier to luminal contents or as a site for transfer of fluids or nutrients. Gut smooth muscle mediates propulsion from one region to the next. Many GI organs possess a serosal layer that not only provides a supportive foundation but also permits external input.

Interactions with other organ systems serve the needs both of the gut and the body. Pancreaticobiliary conduits deliver bile and enzymes into the duodenum. A rich vascular supply is modulated by GI tract activity. Lymphatic channels assist in gut immune activities. Intrinsic gut wall nerves provide the basic controls for propulsion and fluid regulation. Extrinsic neural input provides volitional or involuntary control to degrees that are specific for each gut region.

FUNCTIONS OF THE GASTROINTESTINAL TRACT

The GI tract serves two main functions—assimilation of nutrients and elimination of waste. The gut anatomy is organized to serve these functions. In the mouth, food is processed, mixed with salivary amylase, and delivered to the luminal GI tract. The esophagus propels the bolus into the stomach, and the lower esophageal sphincter prevents oral reflux of gastric contents. The esophageal mucosa has a protective squamous histology that does not permit significant diffusion or absorption. The propulsive activities of the esophagus are exclusively aboral and are coordinated with relaxation of the upper and lower esophageal sphincters upon swallowing.

The stomach furthers food preparation by triturating and mixing the bolus with pepsin and acid. Gastric acid also sterilizes the upper gut. Gastric motor activities exhibit regional variability: (1) the proximal stomach serves a storage function by relaxing to accommodate the meal; (2) the distal stomach exhibits phasic contractions that propel solid food residue against the pylorus, where it is repeatedly propelled proximally for further mixing before it is emptied into the duodenum; and (3) finally, the stomach secretes intrinsic factor for vitamin B_{12} absorption.

The small intestine serves most of the nutrient absorptive function of the gut. The intestinal mucosa exhibits villous architecture to provide maximal surface area for absorption and is endowed with specialized enzymes and transporters. Triturated food from the stomach is mixed with pancreatic juice and bile in the proximal duodenum to facilitate digestion. Pancreatic juice contains the main enzymes for carbohydrate, protein, and fat digestion as well as bicarbonate to optimize the pH for activation of these enzymes. Bile secreted by the liver and stored in the gallbladder is essential for intestinal lipid digestion. The proximal intestine is optimized for rapid absorption of nutrient breakdown products and most minerals, while the ileum is better suited for absorption of vitamin B_{12} and bile acids. The small intestine also aids in waste elimination. Bile contains byproducts of erythrocyte degradation, toxins, metabolized and unmetabolized medications, and cholesterol. Motor function of the small intestine delivers indigestible food residue and sloughed enterocytes into the colon for further processing. The small intestine terminates in the ileocecal junction, a sphincteric structure that prevents coloileal reflux and maintains small-intestinal sterility.

The colon prepares the waste material for controlled evacuation. The colonic mucosa dehydrates the stool, decreasing daily fecal volumes from the 1000 to 1500 mL delivered from the ileum to the 100 to 200 mL expelled from the rectum. The colonic lumen possesses a dense bacterial colonization that ferments undigested carbohydrates and short-chain fatty acids. Whereas transit times in the esophagus are on the order of seconds and times in the stomach and small intestine range from minutes to a few hours, propagation through the colon takes >1 day in most individuals. Colonic motor patterns exhibit a to-and-fro character that facilitates slow fecal desiccation. The proximal colon serves to mix and absorb fluid, while the distal colon exhibits peristaltic contractions and mass actions that function to expel the stool. The colon terminates in the anus, a structure with volitional and involuntary controls to permit retention of the fecal bolus until it can be released in a socially convenient setting.

EXTRINSIC MODULATION OF GUT FUNCTION

GI function is modified by influences outside of the gut. Unlike other organ systems, the gut is in physical continuity with the outside environment. Thus, protective mechanisms are vigilant against the deleterious effects of consumed foods, medications, toxins, and infectious organisms. Mucosal immune mechanisms include a lymphocyte and plasma cell population that resides in the epithelial layer and lamina propria backed up by lymph node chains to prevent noxious agents from entering the circulation. All substances absorbed into the bloodstream are filtered through the liver via the portal venous circulation. In the liver, many drugs and toxins are detoxified by a variety of mechanisms. Although intrinsic nerves control most basic gut activities, extrinsic neural input modulates a number of functions. The two activities under voluntary control are swallowing and defecation. Many normal GI reflexes involve extrinsic vagus or splanchnic nerve pathways. An active brain-gut axis further alters function in regions not under volitional regulation. As an example, stress alters GI transit as well as gut immune function.

OVERVIEW OF GASTROINTESTINAL DISEASES

GI diseases develop as a consequence of abnormalities within or outside of the gut and range in severity from those that produce mild symptoms and no long-term morbidity to those with intractable symptoms or an adverse outcome. Diseases may be localized to a single organ or exhibit diffuse involvement at a number of sites.

CLASSIFICATION OF GI DISEASES

GI diseases are manifestations of alterations in nutrient assimilation or waste evacuation or in the activities supporting these main functions.

Impaired Digestion and Absorption Diseases of the stomach, intestine, biliary tree, and pancreas can disrupt nutrient digestion and absorption. Gastric hypersecretory conditions such as Zollinger-Ellison syndrome damage the intestinal mucosa and accelerate transit due to excess gastric acid. The most common intestinal maldigestion syndrome, lactase deficiency, produces flatus and diarrhea after dairy product ingestion and has no other adverse outcomes. Other intestinal enzyme deficiencies produce similar symptoms with ingestion of other simple sugars. Conversely, celiac disease, bacterial overgrowth, infectious enteritis, Crohn's ileitis, and radiation damage produce anemia, dehydration,

electrolyte disorders, or malnutrition. Biliary obstruction from stricture or neoplasm may impair fat digestion. Impaired release of pancreatic enzymes in chronic pancreatitis or pancreatic cancer decreases intraluminal digestion and can lead to profound malnutrition.

Altered Secretion Selected GI diseases result from dysregulation of gut secretion. Gastric acid hypersecretion occurs in Zollinger-Ellison syndrome, G-cell hyperplasia, retained antrum syndrome, and in some individuals with duodenal ulcer disease. Conversely, patients with atrophic gastritis or pernicious anemia release little or no gastric acid. Inflammatory and infectious small-intestinal and colonic diseases produce fluid loss through impaired absorption or enhanced secretion but do not usually cause malnutrition. Common intestinal and colonic hypersecretory conditions include acute viral infection, chronic *Giardia* or cryptosporidia infections, small-intestinal bacterial overgrowth, microscopic colitis, diabetic diarrhea, and abuse of certain laxatives. Less common causes include large colonic villous adenomas and endocrine neoplasias with tumor overproduction of secretagogue transmitters such as vasoactive intestinal polypeptide.

Altered Gut Transit Alterations in gut transit are commonly secondary to mechanical obstruction. Esophageal occlusion often results from acid-induced stricture or neoplasm. Gastric outlet obstruction develops from peptic ulcer disease or gastric cancer. Small-intestinal obstruction most commonly results from adhesions but may also occur with Crohn's disease, radiation- or drug-induced strictures, and, less likely, malignancy. The most common cause of colonic obstruction is colon cancer, although inflammatory strictures develop in patients with inflammatory bowel disease, after certain infections, or with some drugs.

Retardation of propulsion also develops from disordered gut motor function. *Achalasia* is characterized by impaired esophageal body peristalsis and incomplete lower esophageal sphincter relaxation. *Gastroparesis* is the symptomatic delay in gastric emptying of solid or liquid meals. Intestinal pseudoobstruction causes marked delays in small-bowel transit due to injury to enteric nerves or intestinal smooth muscle. Slow transit constipation is produced by diffusely impaired colonic propulsion. Constipation is also produced by outlet abnormalities such as rectal prolapse, intussusception, or failure of anal relaxation upon attempted defecation.

Disorders of rapid propulsion are less common than those with delayed transit. Rapid gastric emptying occurs in postvagotomy dumping syndrome and with gastric hypersecretion. Exaggerated intestinal or colonic motor patterns are minor factors in symptoms with selected diarrheal conditions. Accelerated transit with hyperdefecation is noted in hyperthyroidism.

Immune Dysregulation Many inflammatory GI conditions are consequences of altered gut immune function. The mucosal inflammation of *celiac disease* results from dietary ingestion of gluten-containing grains. Some patients with food allergy also exhibit altered immune populations. *Eosinophilic gastroenteritis* is an inflammatory condition with prominent mucosal eosinophils. *Ulcerative colitis* and *Crohn's disease* are disorders of uncertain etiology that produce mucosal injury primarily in the lower gut. The microscopic colitides, lymphocytic and collagenous colitis, exhibit colonic subepithelial infiltrates without visible mucosal damage. Bacterial, viral, and protozoal organisms may produce ileitis or colitis in selected patient populations.

Impaired Gut Blood Flow Different GI regions are at variable risk for ischemic damage from impaired blood flow. Rare cases of gastroparesis result from blockage of the celiac and superior mesenteric arteries. More commonly encountered are intestinal and colonic ischemia, which are consequences of arterial embolus; arterial thrombosis; venous thrombosis; or hypoperfusion from dehydration, sepsis, hemorrhage, or reduced cardiac output. These may produce mucosal injury, hemorrhage, or even perforation. Some cases of radiation enterocolitis exhibit reduced mucosal blood flow.

Neoplastic Degeneration All GI regions are susceptible to malignant degeneration to varying degrees. In the United States, colorectal cancer is most common and typically presents after age 50. Worldwide, gastric cancer is especially prevalent in certain Asian regions. Esophageal cancer develops with chronic acid reflux or in those with an extensive alcohol or tobacco use history. Small-intestinal neoplasms are rare and occur with underlying inflammatory disease. Anal cancers may arise with prior anal infection or inflammation. Pancreatic and biliary cancers elicit severe pain, weight loss, and jaundice and have poor prognoses. Hepatocellular carcinoma usually arises in the setting of chronic viral hepatitis or cirrhosis secondary to other causes. Most GI cancers are epithelial-derived; however, lymphomas and other cell types are also observed.

Disorders without Obvious Organic Abnormalities The most common GI disorders show no abnormalities on biochemical or structural testing and include irritable bowel syndrome (IBS), functional dyspepsia, noncardiac chest pain, and functional heartburn. These functional bowel disorders exhibit altered gut motor function; however, the pathogenic relevance of these abnormalities is uncertain. Exaggerated visceral sensory responses to noxious stimulation may cause discomfort in these disorders. Symptoms in some patients result from altered processing of visceral pain sensations in the central nervous system. Patients with functional bowel abnormalities with severe symptoms may exhibit significant emotional disturbances on psychometric testing.

Genetic Influences Although many GI diseases result from environmental factors, others exhibit hereditary components. Family members of inflammatory bowel disease (IBD) patients show a genetic predisposition to disease development themselves. Colonic and esophageal malignancies arise in certain inherited disorders. Hereditary pancreatitis is caused by mutation in the cationic trypsinogen gene. Rare genetic dysmotility syndromes are described. Familial clustering is even observed in the functional bowel disorders, although this may be secondary to learned familial illness behavior rather than a true hereditary factor.

SYMPTOMS OF GASTROINTESTINAL DISEASE

The most common GI symptoms are abdominal pain, heartburn, nausea and vomiting, altered bowel habits, GI bleeding, and jaundice (Table 271-1). Others are dysphagia, anorexia, weight loss, fatigue, and extraintestinal symptoms.

Abdominal Pain Abdominal pain results from GI disease and extraintestinal conditions involving the genitourinary tract, abdominal wall, thorax, or spine. Visceral pain is generally midline in location and vague in character, while parietal pain is localized and precisely described. Common inflammatory diseases with pain include peptic ulcer, appendicitis, diverticulitis, IBD, and infectious enterocolitis. Other intraabdominal causes of pain include gallstone disease and pancreatitis. Noninflammatory visceral sources include mesenteric ischemia and neoplasia. The most common causes of abdominal pain are IBS and functional dyspepsia.

Heartburn Heartburn, a burning substernal sensation, is reported intermittently by at least 40% of the population. Classically, heartburn is felt to result from excess gastroesophageal reflux of acid. However, some cases exhibit normal esophageal acid exposure and may result from heightened sensitivity of esophageal mucosal nerves.

Nausea and Vomiting Nausea and vomiting are caused by GI diseases, medications, toxins, acute and chronic infection, endocrine disorders, labyrinthine conditions, and central nervous system disease. The best-characterized GI etiologies relate to mechanical obstruction of the upper gut; however, disorders of propulsion including gastroparesis and intestinal pseudoobstruction also elicit prominent symptoms. As with abdominal pain, IBS and functional dyspepsia commonly present with nausea and vomiting.

Altered Bowel Habits Altered bowel habits are common complaints of patients with GI disease. Constipation is reported as infrequent defecation, straining with defecation, passage of hard stools, or a sense of

TABLE 271-1 *Common Causes of Common GI Symptoms*

Abdominal Pain	*Nausea and Vomiting*	*Diarrhea*	*GI Bleeding*	*Obstructive Jaundice*
Appendicitis	Medications	Infection	Ulcer disease	Bile duct stones
Gallstone disease	GI obstruction	Poorly absorbed sugars	Esophagitis	Cholangiocarcinoma

Vascular disease		Endocrine tumor	Infectious colitis	
Gynecologic causes				
Renal stone				

incomplete fecal evacuation. Causes of constipation include obstruction, motor disorders of the colon, medications, and endocrine diseases such as hypothyroidism and hyperparathyroidism. Diarrhea is reported as frequent defecation, passage of loose or watery stools, fecal urgency, or a similar sense of incomplete evacuation. The differential diagnosis of diarrhea is broad and includes infections, inflammatory causes, malabsorption, and medications. IBS produces constipation, diarrhea, or an alternating bowel pattern. Fecal mucus is common in IBS, while pus characterizes inflammatory disease. Steatorrhea develops with malabsorption.

GI Bleeding Hemorrhage may develop from any gut organ. Most commonly, upper GI bleeding presents with melena or hematemesis, whereas lower GI bleeding produces passage of bright red or maroon stools. However, briskly bleeding upper sites can elicit voluminous red rectal bleeding, while slowly bleeding ascending colon sites may produce melena. Chronic slow GI bleeding may present with iron-deficiency anemia. The most common upper GI causes of bleeding are ulcer disease, gastroduodenitis, and esophagitis. Other etiologies include portal hypertensive causes, malignancy, tears across the gastroesophageal junction, and vascular lesions. The most prevalent lower GI sources of hemorrhage include hemorrhoids, anal fissures, diverticula, and arteriovenous malformations. Other causes include neoplasm, IBD, ischemia, infectious colitis, and other vascular lesions.

Jaundice Jaundice results from prehepatic, intrahepatic, or posthepatic disease. Posthepatic causes of jaundice include biliary diseases such as choledocholithiasis, cholangitis, stricture, and neoplasm and pancreatic disorders such as acute and chronic pancreatitis, stricture, and malignancy.

Other Symptoms Other symptoms are manifestations of GI disease. Dysphagia, odynophagia, and unexplained chest pain suggest esophageal disease. A globus sensation is reported with esophagopharyngeal conditions but also occurs with functional GI disorders. Weight loss, anorexia, and fatigue are nonspecific symptoms of neoplastic, inflammatory, gut motor, pancreatic, small bowel mucosal, and psychiatric conditions. Fever is reported with inflammatory illness, but malignancies also evoke febrile responses. GI disorders also produce extraintestinal symptoms. IBD is associated with hepatobiliary dysfunction, skin and eye lesions, and arthritis. Celiac disease may present with dermatitis herpetiformis. Jaundice can produce pruritus. Conversely, systemic diseases can have GI consequences. Systemic lupus may cause gut ischemia, presenting with pain or bleeding. Overwhelming stress or severe burns may lead to gastric ulcer formation.

EVALUATION OF THE PATIENT WITH GASTROINTESTINAL DISEASE

Evaluation of the patient with GI disease begins with a careful history and physical examination. Subsequent investigation with a variety of tools designed to test the structure or function of the gut are indicated in selected cases. Some patients exhibit normal findings on diagnostic testing. In these individuals, validated symptom profiles are employed for confident diagnosis of a functional bowel disorder.

HISTORY The history of the patient with suspected GI disease has several components. Symptom timing can suggest specific etiologies. Symptoms of short duration commonly result from acute infection, toxin exposure, or abrupt inflammation or ischemia. Long-standing symptoms point to an underlying chronic inflammatory or neoplastic condition or a functional bowel disorder. Symptoms from mechanical obstruction, ischemia, IBD, and functional bowel disorders are worsened by meal ingestion. Conversely, ulcer symptoms may be relieved by eating or antacids. The symptom pattern and duration may suggest underlying etiologies. Ulcer pain occurs at intermittent intervals lasting weeks to months, whereas biliary colic has a sudden onset and lasts up to several hours. Pain from acute inflammation, as with acute pancreatitis, is severe and persists for days to weeks. Meals elicit diarrhea in some cases of IBD and IBS, while defecation relieves discomfort in these conditions. Functional bowel disorders are exacerbated by stress. Sudden awakening from sleep suggests organic disease rather than a functional bowel disorder. Diarrhea from malabsorption usually improves with fasting, while secretory diarrhea persists without oral intake.

Symptom relation to other factors narrows the list of diagnostic possibilities. Obstructive symptoms with prior abdominal surgery raise concern for adhesions, whereas loose stools after gastrectomy or gallbladder excision suggest dumping syndrome or post-cholecystectomy diarrhea. Symptom onset after travel prompts a search for enteric infection. Medications produce pain, altered bowel habits, or GI bleeding. Lower GI bleeding likely results from neoplasm, diverticula, or vascular lesions in an older person and anorectal abnormalities or IBD in a younger individual. Celiac disease is prevalent in people of Irish descent, whereas IBD is more common in certain Jewish populations. A sexual history may raise concern for sexually transmitted diseases or immunodeficiency.

Over the past two decades, working groups have been convened to devise symptom criteria to improve the confident diagnosis of the functional bowel disorders and to minimize the number of unnecessary diagnostic tests performed. The most widely accepted symptom-based criteria are the *Rome criteria*. When tested against findings of structural investigations, the Rome criteria exhibit diagnostic specificities >90% for many of the functional bowel disorders.

PHYSICAL EXAMINATION The physical examination complements information from the history. Abnormal vital signs provide diagnostic clues and determine the need for acute intervention. Fever suggests inflammation or neoplasm. Orthostasis is found with significant blood loss, dehydration, sepsis, or autonomic neuropathy. Skin, eye, or joint findings may point to specific diagnoses. Neck examination with swallowing assessment evaluates dysphagia. Cardiopulmonary disease may present with abdominal pain or nausea; thus lung and cardiac examinations are important. Pelvic examination tests for a gynecologic source of abdominal pain. Rectal examination may detect blood, indicating gut mucosal injury or neoplasm, or a palpable inflammatory mass in appendicitis. Metabolic conditions and gut motor disorders have associated peripheral neuropathy.

Inspection of the abdomen may reveal distention from obstruction, tumor, or ascites or vascular abnormalities with liver disease. Ecchymoses develop with severe pancreatitis. Auscultation can detect bruits or friction rubs from vascular disease or hepatic tumors. Loss of bowel sounds signifies ileus, while high-pitched, hyperactive sounds characterize intestinal obstruction. Percussion assesses liver size and can detect shifting dullness from ascites. Palpation assesses for hepatosplenomegaly as well as neoplastic or inflammatory masses. Abdominal examination is helpful in evaluating unexplained pain. Intestinal ischemia elicits severe pain but little tenderness. Patients with visceral pain may exhibit generalized discomfort, while those with parietal pain or peritonitis have directed pain often with involuntary guarding, rigidity, or rebound. Patients with musculoskeletal abdominal wall pain may note tenderness exacerbated by Valsalva or straight leg lift maneuvers.

TOOLS FOR PATIENT EVALUATION Laboratory, radiographic, and scintigraphic tests can assist in diagnosis of suspected GI disease. The GI tract is also amenable to internal evaluation with upper and lower endoscopy and to examination of luminal contents. Histopathologic examinations of gastrointestinal tissues complement these tests.

Laboratory Selected laboratory tests facilitate the diagnosis of GI disease. Iron-deficiency anemia suggests mucosal blood loss, whereas vitamin B_{12} deficiency results from small-intestinal, gastric, or pancreatic disease. Either can also result from inadequate oral intake. Leukocytosis and increased erythrocyte sedimentation rates are found in inflammatory conditions, while leukopenia is seen in viremic illness. Severe vomiting or diarrhea elicits electrolyte disturbances, acid-base abnormalities, and elevated blood urea nitrogen. Pancreaticobiliary or liver disease is suggested by elevated pancreatic or liver chemistries. Thyroid chemistries, cortisol, and calcium levels are obtained to exclude endocrinologic causes of GI symptoms. Pregnancy testing is considered for young women with unexplained nausea. Serologic tests are available for rheumatologic diseases such as systemic lupus erythematosus or scleroderma. Hormone levels are obtained for suspected endocrine neoplasia. Intraabdominal malignancies produce tumor markers including carcinoembryonic antigen, while paraneoplastic dysmotility is associated with antineuronal antibodies. Other body fluids are sampled under certain circumstances. Ascitic fluid is analyzed for infection, malignancy, or findings of portal hypertension. Cerebrospinal fluid is obtained for suspected central nervous system causes of vomiting. Urine samples screen for carcinoid, porphyria, and heavy metal intoxication.

Luminal Contents Luminal contents can be examined for diagnostic clues. Stool samples are cultured for bacterial pathogens or examined for leukocytes or parasites. Duodenal aspirates can be examined for parasites or cultured for bacterial overgrowth. Fecal fat is quantified in possible malabsorption. Stool electrolytes and osmolarity can be measured in diarrheal conditions. A stool osmotic gap >100 mosmol/L indicates osmotic diarrhea. Laxative screens are done when laxative abuse is suspected. Gastric acid is quantified to rule out Zollinger-Ellison syndrome. Esophageal pH testing is done for refractory symptoms of acid reflux. Pancreatic juice is analyzed for enzyme or bicarbonate content to exclude pancreatic exocrine insufficiency.

Endoscopy The gut is accessible by means of endoscopy, which can provide the diagnosis of the causes of bleeding, pain, nausea and vomiting, weight loss, altered bowel function, and fever. Table 271-2 lists the most common indications for the major endoscopic procedures. Upper endoscopy evaluates the esophagus, stomach, and duodenum, while colonoscopy assesses the colon and distal ileum. Upper endoscopy is advocated as the initial structural test performed in patients with upper GI bleeding, suspected ulcer disease, esophagitis, neoplasm, malabsorption, and Barrett's metaplasia because of its ability both to visualize the abnormality directly and to biopsy it. Colonoscopy is the procedure of choice for colon cancer screening and surveillance; diagnosis of colitis secondary to infection, ischemia, radiation, and IBD; and characterization of causes of lower GI bleeding. Sigmoidoscopy examines the colon up to the splenic flexure and is currently used to exclude distal colonic inflammation or obstruction in young patients not at significant risk for colon cancer. For elusive GI bleeding secondary to arteriovenous malformations or superficial ulcers, small-intestinal examination is performed with push enteroscopy or capsule endoscopy. Endoscopic retrograde cholangiopancreaticography (ERCP) provides diagnoses of pancreatic and biliary disease. Endoscopic ultrasound is useful for evaluating the extent of disease in GI malignancy as well as exclusion of choledocholithiasis, evaluation of pancreatitis, drainage of pancreatic pseudocysts, and assessment of anal continuity.

Radiography/Nuclear Medicine Radiographic tests evaluate diseases of the gut and extraluminal structures. Oral or rectal contrast agents such as barium provide mucosal definition from the esophagus to the rectum. Contrast radiography also assesses gut transit and pelvic floor dysfunction. Barium swallow is the initial procedure for evaluation of dysphagia to exclude subtle rings or strictures and assess for achalasia, whereas small-bowel contrast radiology reliably diagnoses intestinal tumors and Crohn's ileitis. Contrast enemas are performed when colonoscopy is unsuccessful or contraindicated. Ultrasound and computed tomography (CT) evaluate regions not accessible by endoscopy or contrast studies, including the liver, pancreas, gallbladder, kidneys, and retroperitoneum. These tests are useful for diagnosis of mass lesions, fluid collections, and organ enlargement. Ultrasound is the initial test to evaluate for gallstone disease. Virtual CT colonoscopy is being evaluated as a method of colon cancer screening. Magnetic res-

TABLE 271-2 *Common Indications for Endoscopy*

Upper Endoscopy	*Colonoscopy*	*Endoscopic Retrograde Cholangiopancreatography*	*Endoscopic Ultrasound*
Dyspepsia despite treatment	Cancer screening	Jaundice	Staging of malignancy
Dyspepsia with signs of organic disease	Lower bleeding	Postbiliary surgery complaints	Characterize and biopsy submucosal mass
Refractory vomiting	Anemia	Cholangitis	Bile duct stones
Dysphagia	Diarrhea	Gallstone pancreatitis	Chronic pancreatitis
Upper bleeding	Polypectomy	Pancreatic/biliary/ampullary tumor	Drain pseudocyst
Anemia	Obstruction	Unexplained pancreatitis	Large gastric folds
Weight loss	Biopsy radiologic abnormality	Pancreatitis with unrelenting pain	Anal continuity
Malabsorption	Cancer surveillance:	Fistulas	
Biopsy radiologic abnormality	Family history, prior polyp/cancer, colitis	Biopsy radiologic abnormality	
Polypectomy	Palliate neoplasm	Pancreaticobiliary drainage	
Place gastrostomy	Remove foreign body	Sample bile	
Barrett's metaplasia surveillance		Sphincter of Oddi manometry	
Palliate neoplasm			
Sample duodenal tissue/fluid			
Remove foreign body			

onance imaging assesses the mesenteric circulation to screen for arterial exclusion; the pancreaticobiliary ducts to exclude neoplasm, stones, and sclerosing cholangitis; and the liver to characterize benign and malignant tumors. Angiography excludes mesenteric ischemia and determines spread of malignancy. Angiographic techniques also access the biliary tree in obstructive jaundice. Positron emission tomography may become useful in distinguishing malignant from benign pancreatic disease.

Scintigraphy both evaluates structural abnormalities and quantifies luminal transit. Radionuclide bleeding scans localize bleeding sites in patients with brisk hemorrhage so that therapy with endoscopy, angiography, or surgery may be directed. Radiolabeled leukocyte scans can search for intraabdominal abscesses not visualized on CT. Biliary scintigraphy is complementary to ultrasound in the assessment of cholecystitis. Scintigraphy to quantify esophageal and gastric emptying are well established, while techniques to measure small-intestinal or colonic transit are less widely used.

Histopathology Gut mucosal biopsies obtained at endoscopy evaluate for inflammatory, infectious, and neoplastic disease. Deep rectal biopsies assist with diagnosis of Hirschsprung's disease or amyloid. Liver biopsy is indicated in cases with abnormal liver chemistries, unexplained jaundice, following liver transplant to exclude rejection, and to characterize the degree of inflammation in patients with chronic viral hepatitis prior to initiating antiviral therapy. Biopsies obtained during CT or ultrasound can evaluate for other intraabdominal conditions not accessible by endoscopy.

Functional Testing Tests of gut function provide important data when structural testing is nondiagnostic. In addition to gastric acid and pancreatic function testing, functional testing of motor activity is provided by regional manometric techniques. Esophageal manometry is useful for suspected achalasia, whereas small-intestinal manometry tests for pseudoobstruction. Anorectal manometry is employed for unexplained incontinence or constipation from outlet dysfunction. Biliary manometry tests for sphincter of Oddi dysfunction with unexplained biliary pain. Electrogastrography measures gastric electrical activity in individuals with nausea and vomiting, whereas electromyography assesses anal function in fecal incontinence.

Rx TREATMENT

Management options for the patient with GI disease depend on the cause of symptoms. Available treatments include modifications in dietary intake, medications, interventional endoscopy or radiology techniques, surgery, and therapies directed to external influences.

Nutritional Manipulation Dietary modifications for GI disease include treatments that only reduce symptoms, therapies that correct pathologic defects, and measures that replace normal food intake with enteral or parenteral formulations. Changes that improve symptoms but do not reverse an organic abnormality include lactose restriction for lactase deficiency, liquid meals in gastroparesis, carbohydrate restrictions in dumping syndrome, and high-fiber diets in IBS. The gluten-free diet for celiac disease exemplifies a modification that serves as primary therapy to reduce mucosal inflammation. Enteral medium-chain triglycerides replace normal fats in patients with short-gut syndrome or severe ileal disease. Perfusion of liquid meals through a gastrostomy is performed in those who cannot swallow safely. Enteral feeding through a jejunostomy is considered for gastric dysmotility syndromes that preclude feeding into the stomach. Intravenous hyperalimentation is employed for individuals with generalized gut malfunction who cannot tolerate or who cannot be sustained with enteral nutrition.

Pharmacotherapy Several medications are available to treat GI diseases. Considerable health care resources are expended on over-the-counter (OTC) remedies. Many prescription drug classes are offered as short-term or continuous therapy of GI illness. A plethora of alternative treatments have gained popularity in GI conditions for which traditional therapies provide incomplete relief.

OVER-THE-COUNTER AGENTS OTC agents are reserved for mild GI symptoms. Antacids and histamine H_2 antagonists decrease symptoms in gastroesophageal reflux and dyspepsia, whereas antiflatulents and adsorbents reduce gaseous symptoms. Fiber supplements, stool softeners, enemas, and laxatives are used for constipation. Laxatives are categorized as stimulants, saline cathartics, and poorly absorbed sugars. Nonprescription antidiarrheal agents include kaolin-pectin combinations and loperamide. Supplemental enzymes include lactase pills for lactose intolerance and bacterial α-galactosidase to treat excess gas. In general, use of a nonprescription drug for more than a short time should be supervised by a health care provider.

PRESCRIPTION DRUGS Prescription drugs for GI diseases are a major focus of attention from pharmaceutical companies. Potent acid suppressants, including drugs that inhibit the proton pump, are advocated for acid reflux when OTC preparations are inadequate. Cytoprotective agents are sometimes used for upper gut ulcers. Prokinetic drugs stimulate GI propulsion in gastroparesis, pseudoobstruction, and constipation as well as the functional bowel disorders. Isotonic solutions containing polyethylene glycol are prescribed for constipation refractory to other agents. Prescription antidiarrheals include opiate drugs, anticholinergic antispasmodics, tricyclics, bile acid binders, and serotonin antagonists. Antispasmodics, tricyclic antidepressants, and selective serotonin reuptake inhibitors are also useful for functional abdominal pain and IBS, whereas narcotics are used for organic conditions such as disseminated malignancy and chronic pancreatitis. Antiemetics in several classes reduce nausea and vomiting. Potent pancreatic enzymes decrease malabsorption and pain from pancreatic disease. Antisecretory drugs such as somatostatin analogue, octreotide, treat hypersecretory states. Antibiotics treat ulcer disease secondary to *Helicobacter pylori*, infectious diarrhea, diverticulitis, intestinal bacterial overgrowth, and Crohn's disease. Anti-inflammatory and immunosuppressive drugs are used in ulcerative colitis, Crohn's disease, microscopic colitis, and refractory celiac disease. Chemotherapy with or without radiotherapy is offered for GI malignancies. Most GI carcinomas respond poorly to therapy, whereas lymphomas may be cured with appropriate intervention.

ALTERNATIVE THERAPIES Alternative treatments are marketed to treat selected GI symptoms. Ginger, acupressure, and acustimulation have been advocated for nausea, while pyridoxine has been investigated for nausea of first trimester pregnancy. Probiotics containing active bacterial cultures are used as adjuncts in some cases of refractory infectious diarrhea and have been used as primary therapy of IBS. Low-potency pancreatic enzyme preparations are sold as general digestive aids but have little evidence to support their efficacy.

Enteric Therapies/Interventional Endoscopy and Radiology Simple luminal interventions are commonly performed for GI diseases. Nasogastric tube suction decompresses the upper gut in ileus or mechanical obstruction. Nasogastric lavage using saline or water in the patient with upper GI hemorrhage determines the rate of bleeding and helps evacuate blood prior to endoscopy. Enteral feedings can be initiated through a nasogastric or nasoenteric tube. Enemas relieve fecal impaction or assist in gas evacuation in acute colonic pseudoobstruction. A rectal tube can be left in place to vent the distal colon.

In addition to its diagnostic role, endoscopy has therapeutic capabilities in certain settings. Cautery techniques can stop hemorrhage from ulcers, vascular malformations, and tumors. Injection with vasoconstrictor substances or sclerosants is used for bleeding ulcers, vascular malformations, varices, and hemorrhoids. Endoscopic encirclement of varices and hemorrhoids with constricting bands stops hemorrhage from these sites. Endoscopy can remove polyps or debulk lumen-narrowing malignancies. Endoscopic sphincterotomy of the ampulla of Vater relieves symptoms of choledocholithiasis. Obstructions of the gut lumen and pancreaticobiliary tree are relieved by endoscopic dilation or placement of plastic or expandable metal stents. In cases of acute colonic pseudoobstruction, colonoscopy is employed

to withdraw luminal gas. Finally, endoscopy is commonly used to insert feeding tubes.

Radiologic measures are also useful in GI disease. Angiographic embolization or vasoconstriction decreases bleeding from sites not amenable to endoscopic intervention. Dilation or stenting with fluoroscopic guidance relieves luminal strictures. Contrast enemas can reduce volvulus and evacuate air in acute colonic pseudoobstruction. CT and ultrasound help drain abdominal fluid collections, in many cases obviating the need for surgery. Percutaneous transhepatic cholangiography relieves biliary obstruction when ERCP is contraindicated. Lithotripsy can fragment gallstones in patients who are not candidates for surgery. In some instances, radiologic approaches offer advantages over endoscopy for gastrostomy placement. Finally, central venous catheters for parenteral nutrition may be placed using radiographic techniques.

Surgery Surgery is performed to cure GI disease, control symptoms without cure, maintain nutrition, or palliate unresectable neoplasm. Medication-unresponsive ulcerative colitis, diverticulitis, cholecystitis, appendicitis, and intraabdominal abscess are curable with surgery, whereas only symptom control without cure is possible with Crohn's disease. Surgery is mandated for ulcer complications such as bleeding, obstruction, or perforation and intestinal obstructions that do not resolve with conservative care. Fundoplication of the gastroesophageal junction is performed for presentations ranging from ulcerative esophagitis to drug-refractory symptoms of acid reflux. Achalasia responds to operations to relieve lower esophageal sphincter pressure. Surgery may be needed to place a jejunostomy for long-term enteral feedings. The threshold for performing surgery depends on the clinical setting. In all cases, the benefits of operation must be weighed against the potential for post-operative complications.

Therapy Directed to External Influences In some conditions, GI symptoms respond to treatments directed outside the gut. Systemic anti-inflammatory or immunosuppressive drugs decrease GI manifestations of gut vasculitis. Plasma expanders may improve gut perfusion in bowel ischemia secondary to hypoperfusion. Finally, psychological therapies including psychotherapy, behavior modification, hypnosis, and biofeedback have shown efficacy in functional bowel disorders. Patients with significant psychological dysfunction and those with little response to treatments targeting the gut are likely to benefit from this form of therapy.

272 GASTROINTESTINAL ENDOSCOPY

Mark Topazian

Gastrointestinal endoscopy has been attempted for over 200 years, but the introduction of semi-rigid gastroscopes in the middle of the twentieth century marked the dawn of the modern endoscopic era. Since then, rapid advances in endoscopic technology have led to dramatic changes in the diagnosis and treatment of many digestive diseases. Innovative endoscopic devices and new endoscopic treatment modalities continue to expand the use of endoscopy in patient care.

Flexible endoscopes provide either an optical image (transmitted over fiberoptic bundles) or an electronic video image (generated by a charge-coupled device in the tip of the endoscope). Operator controls permit deflection of the endoscope tip; fiberoptic bundles bring light to the tip of the endoscope; and working channels allow washing, suctioning, and the passage of instruments. Progressive changes in the diameter and stiffness of endoscopes have improved the ease and patient tolerance of endoscopy.

ENDOSCOPIC PROCEDURES

Upper Endoscopy Upper endoscopy, also referred to as esophagogastroduodenoscopy (EGD), is performed by passing a flexible endoscope through the mouth into the esophagus (Figs. 272-1 to 272-5), stomach (Figs. 272-6 to 272-10), bulb (Figs. 272-11, -12), and second duodenum. The procedure is the best method of examining the upper gastrointestinal mucosa. While the upper gastrointestinal radiographic series has similar accuracy for diagnosis of duodenal ulcer, EGD is superior for detection of gastric ulcers, detects flat mucosal lesions such as those of Barrett's esophagus, and permits directed biopsy and endoscopic therapy, if needed. Topical pharyngeal anesthesia is used, and intravenous conscious sedation is given to most patients in the United States to ease the anxiety and discomfort of the procedure, although in many countries EGD is routinely performed without sedation. Patient tolerance of unsedated EGD is improved by the use of an ultrathin, 5-mm diameter endoscope.

Colonoscopy Colonoscopy is performed by passing a flexible colonoscope through the anal canal into the rectum and colon. The cecum is reached in >95% of cases, and the terminal ileum can often be examined. Colonoscopy is the "gold standard" for diagnosis of colonic mucosal disease (Figs. 272-13 to 272-21). Barium enema is more accurate for evaluation of diverticula and for accurate measurement of colonic strictures, but colonoscopy has greater sensitivity for colitis, polyps, and cancers. Conscious sedation is usually given before colonoscopy in the United States, although a willing patient and a skilled examiner can complete the procedure without sedation in many cases.

Flexible Sigmoidoscopy Flexible sigmoidoscopy is similar to colonoscopy but visualizes only the rectum and a variable portion of the left colon, typically to 60 cm from the anal verge. This procedure causes abdominal cramping, but it is brief and is almost always performed without sedation. Flexible sigmoidoscopy is used for colorectal cancer screening and for evaluation of diarrhea and hematochezia.

Small-Bowel Enteroscopy Two techniques are currently used to evaluate the small intestine, most often in patients with unexplained small-bowel bleeding. *Push enteroscopy* is performed with a long endoscope similar in design to an upper endoscope. The enteroscope is pushed down the small bowel with the help of a stiffening overtube that extends from the mouth to the duodenum. The mid-jejunum is usually reached, and the endoscope's instrument channel allows for biopsies or endoscopic therapy.

Capsule endoscopy involves the patient swallowing a disposable capsule containing a charge-coupled device chip. Color still images (Fig. 272-22) are transmitted wirelessly to an external receiver at fixed intervals until the capsule's battery is exhausted or it is passed into the toilet. Much of the jejunal and ileal mucosa is usually visualized.

Endoscopic Retrograde Cholangiopancreatography (ERCP) During ERCP, a side-viewing endoscope is passed through the mouth to the duodenum, the ampulla of Vater is identified and cannulated with a thin plastic catheter, and radiographic contrast material is injected into the bile duct and pancreatic duct under fluoroscopic guidance (Fig. 272-23 to 272-25). When indicated, the sphincter of Oddi can be opened using the technique of endoscopic sphincterotomy (Fig. 272-26). Stones can be retrieved from the ducts, and strictures of the ducts can be biopsied, dilated, and stented. ERCP is often performed for therapy but remains important in diagnosis, especially for bile duct stones.

FIGURE 272-9

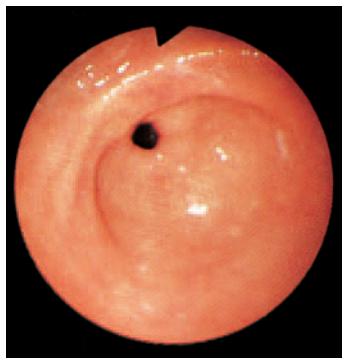

FIGURE 272-10

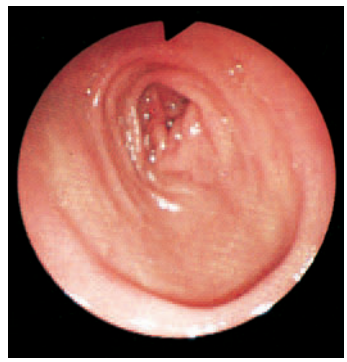

FIGURE 272-11

FIGURE 272-12

FIGURES 272-1 Normal esophagus where fine vasculature can be seen. **272-2** Linear red streaks with a central white streak extend up the esophagus in a peptic regurgitant esophagitis. **272-3** Ulcerated squamous cell carcinoma, with a depressed center, involving one wall of the esophagus. **272-4** Moniliasis of the esophagus—a white exudate is seen with underlying erythematous mucosa. **272-5** Barrett's metaplasia of the esophagus with an adenocarcinoma. The squamocolumnar junction is noted in the proximal esophagus. A mucosal irregularity in the center of the photograph was an adenocarcinoma. **272-6** Normal body of the stomach with rugal folds. **272-7** Large, benign, lesser curve gastric ulcer—the folds end at the ulcer margin. **272-8** The histologic type of this gastric polyp must be determined by excision and pathologic examination. **272-9** An arteriovenus malformation of the gastric mucosa. **272-10** A normal pylorus. Note the absence of gastric rugal folds in the antrum proximal to the pylorus. **272-11** A normal duodenal bulb. **272-12** A typical duodenal ulcer with a clean base is seen on the anterior surface of the duodenal bulb.

Endoscopic Ultrasound (EUS) EUS utilizes high-frequency ultrasound transducers incorporated into the tip of a flexible endoscope. Ultrasound images are obtained of the gut wall and adjacent organs, vessels, and lymph nodes. By sacrificing depth of ultrasound penetration and bringing the ultrasound transducer close to the area of interest via endoscopy, very high resolution images are obtained. EUS provides the most accurate preoperative local staging of esophageal, pancreatic, and rectal malignancies, although it does not detect most distant metastases. Examples of EUS tumor staging are shown in Fig. 272-27. EUS is also highly sensitive for diagnosis of bile duct stones, gallbladder disease, submucosal gastrointestinal lesions, and chronic pancreatitis. Fine-needle aspiration of masses and lymph nodes in the posterior mediastinum, abdomen, and pelvis can be performed under EUS guidance (Fig. 272-28).

RISKS OF ENDOSCOPY

All endoscopic procedures carry some risk of bleeding and gastrointestinal perforation. These risks are quite low with diagnostic upper endoscopy and colonoscopy (<1:1000 procedures), although the risk is as high as 2:100 when therapeutic procedures such as polypectomy, control of hemorrhage, or stricture dilation are performed. Bleeding and perforation are rare with flexible sigmoidoscopy. The risks for diagnostic EUS (without needle aspiration) are similar to the risks for diagnostic upper endoscopy.

Infectious complications are unusual with most endoscopic procedures. Some procedures carry a higher incidence of postprocedure bacteremia, and prophylactic antibiotics may be indicated for these procedures in some patients (Table 272-1).

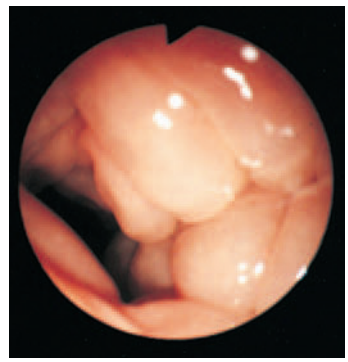

FIGURE 272-20

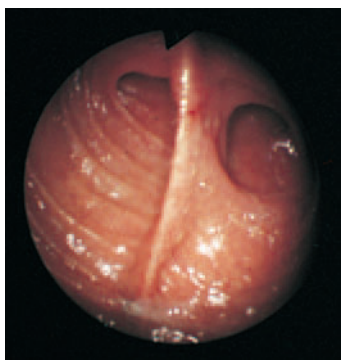

FIGURE 272-21

FIGURE 272-22

FIGURE 272-23

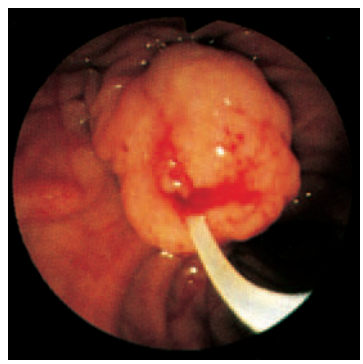

FIGURE 272-24

FIGURES 272-13 Typical folds and vascular pattern can be seen in a normal colon. **272-14** This colonic adenomatous polyp is erythematous; a stalk is seen covered with normal mucosa. **272-15** Multiple, small, colonic adenomatous polyps in a case of familial polyposis coli. This colon was removed to prevent the development of cancer. **272-16** Colon adenocarcinoma—the cancer is multilobed and growing into the lumen. **272-17** Crohn's colitis with linear, serpiginous, white-based ulcers surrounded by colonic mucosa which is relatively normal. **272-18** Severe ulcerative colitis with diffuse ulceration, bleeding, and exudation. **272-19** Kaposi's sarcoma involving the colon in a patient with AIDS. The erythematous lesions involve most of the colonic mucosa in the photograph. **272-20** In this case of colonic varices, multiple, serpiginous, subephithelial structures impinge on the colonic lumen. **272-21** The mucosa appears normal in this pouch reconstructed from ileum to provide a reservoir after total proctocolectomy and ileoanal anastomosis. **272-22** Capsule endoscopy image of a jejunal vascular ectasia. (*Courtesy of Dr. Blair Lewis.*) **272-23** Normal papilla of Vater—bile is seen adjacent to the papilla. **272-24** Periampullary carcinoma—the mass at the papilla of Vater has been catheterized during ERCP.

ERCP carries additional risks. Pancreatitis occurs in about 5% of patients undergoing ERCP and is seen in up to 25% of patients with sphincter of Oddi dysfunction. Young anicteric patients with normal ducts are at increased risk. Post-ERCP pancreatitis is usually mild and self-limited but may infrequently result in prolonged hospitalization, surgery, diabetes, or death. Bleeding occurs after 1% of endoscopic sphincterotomies. Ascending cholangitis, pseudocyst infection, and retroperitoneal perforation and abscess may all occur as a result of ERCP.

The conscious sedation administered during endoscopy may cause respiratory depression or allergic reactions. Percutaneous gastrostomy tube placement during EGD is associated with a 10 to 15% incidence of complications, most often wound infections. Fasciitis, pneumonia, bleeding, and colonic injury may result from gastrostomy placement.

URGENT ENDOSCOPY

ACUTE GASTROINTESTINAL HEMORRHAGE Endoscopy is an important diagnostic and therapeutic technique for patients with acute gastrointestinal hemorrhage. Although most gastrointestinal bleeding stops spontaneously, a minority of patients will have persistent or recurrent hemorrhage that may be life-threatening. Clinical predictors of rebleeding help identify patients most likely to benefit from urgent endoscopy and endoscopic, angiographic, or surgical hemostasis.

Initial Evaluation The initial evaluation of the bleeding patient focuses on the magnitude of hemorrhage as reflected by the postural vital signs, the frequency of hematemesis or melena, and (in some cases) findings on nasogastric lavage. Decreases in hematocrit and hemoglobin lag the clinical course and are not reliable gauges of the magnitude of

acute bleeding. This initial evaluation, completed well before the bleeding source is confidently identified, guides immediate supportive care of the patient and helps determine the timing of endoscopy. The magnitude of the initial hemorrhage is probably the most important indication for urgent endoscopy, since a large initial bleed increases the likelihood of ongoing or recurrent bleeding. Patients with resting hypotension, repeated hematemesis, nasogastric aspirate that does not clear with large volume lavage, orthostatic change in vital signs, or those requiring blood transfusions should be considered for urgent endoscopy. In addition, patients with cirrhosis, coagulopathy, or respiratory or renal failure and those over 70 years are more likely to have significant rebleeding.

Bedside evaluation also suggests an upper or lower gastrointestinal source of bleeding in most patients. Over 95% of patients with melena are bleeding proximal to the ligament of Treitz, and about 90% of patients with hematochezia are bleeding from the colon. Melena can result from bleeding in the small bowel or right colon, especially in older patients with slow colonic transit. Conversely, some patients with massive hematochezia are bleeding from a duodenal ulcer, with rapid intestinal transit. Early upper endoscopy should be considered in such patients.

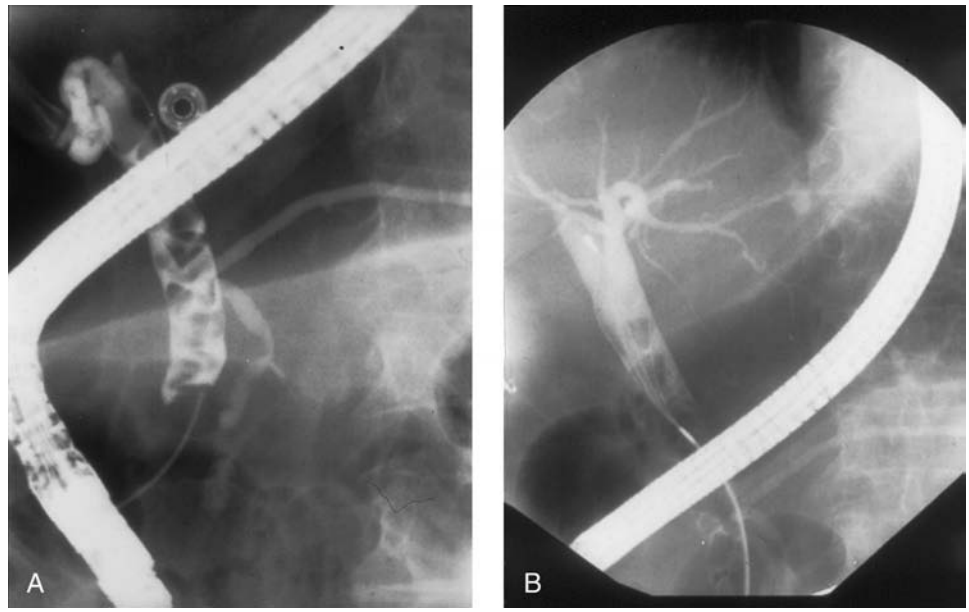

FIGURE 272-25 Endoscopic retrograde cholangiopancreatography (ERCP) for bile duct stones with cholangitis. *A*. Faceted bile duct stones are demonstrated in the common bile duct. *B*. After endoscopic sphincterotomy, the stones are extracted with a Dormia basket. A small abscess communicates with the left intrahepatic duct.

Endoscopy should be performed after the patient has been resuscitated with intravenous fluids and transfusions as necessary. Marked coagulopathy or thrombocytopenia is usually treated before endoscopy, since correction of these abnormalities may lead to resolution of bleeding, and techniques for endoscopic hemostasis are limited in such patients. Metabolic derangements should also be addressed. Tracheal intubation for airway protection should be considered before upper endoscopy in patients with repeated hematemesis and suspected variceal hemorrhage.

Most patients with impressive hematochezia can undergo colonoscopy after a rapid colonic purge with a polyethylene glycol solution; the preparation fluid is often administered via a nasogastric tube. Colonoscopy has a higher diagnostic yield than angiography in lower gastrointestinal bleeding, and endoscopic therapy is appropriate in some cases. In a small minority of cases, persistent bleeding and recurrent hemodynamic instability prevent endoscopic visualization of the colonic mucosa, and other techniques (such as bleeding scans, angiography, or emergency subtotal colectomy) must be employed. Even in these cases, the anal and rectal mucosa should be visualized endoscopically early in the course, since bleeding lesions in or close to the anal canal are often amenable to surgical transanal hemostatic techniques.

Peptic Ulcer The endoscopic appearance of peptic ulcers provides useful prognostic information in patients with acute hemorrhage. When a platelet plug is seen protruding from a vessel wall in the base of an ulcer (a so-called sentinel clot or visible vessel), risk of major rebleeding from the ulcer is 40%. This finding often leads to local endoscopic therapy to decrease the rebleeding rate. A clean-based ulcer is associated with low (3 to 5%) risk of rebleeding; patients with melena and a clean-based duodenal ulcer are often discharged home from the emergency room or endoscopy suite if they are young, reliable, and otherwise healthy. Other findings have an intermediate risk of rebleeding: flat red or purple spots in the ulcer base have a 10% risk, and large adherent clots covering the ulcer base have a 20% risk. Occasionally, active spurting from an ulcer is seen (with >90% risk of ongoing bleeding). Examples of endoscopic stigmata of recent hemorrhage are shown in Fig. 272-29.

Patients with a visible vessel or active bleeding are usually treated endoscopically, decreasing rebleeding rates by about half. Hemostatic techniques include "coaptive coagulation" of the vessel in the base of the ulcer, using a thermal probe that is pressed against the site of bleeding, or injection of epinephrine or sclerosant into and around the vessel.

Varices Two complementary strategies guide therapy of bleeding varices: local treatment of the bleeding vessel and treatment of underlying portal hypertension. Local therapies (including endoscopic sclerotherapy, endoscopic band ligation, and balloon tamponade with a Sengstaken-Blakemore tube) effectively control acute hemorrhage in most patients and are the mainstay of acute treatment, although therapies that decrease portal pressures (pharmacologic treatment, surgical

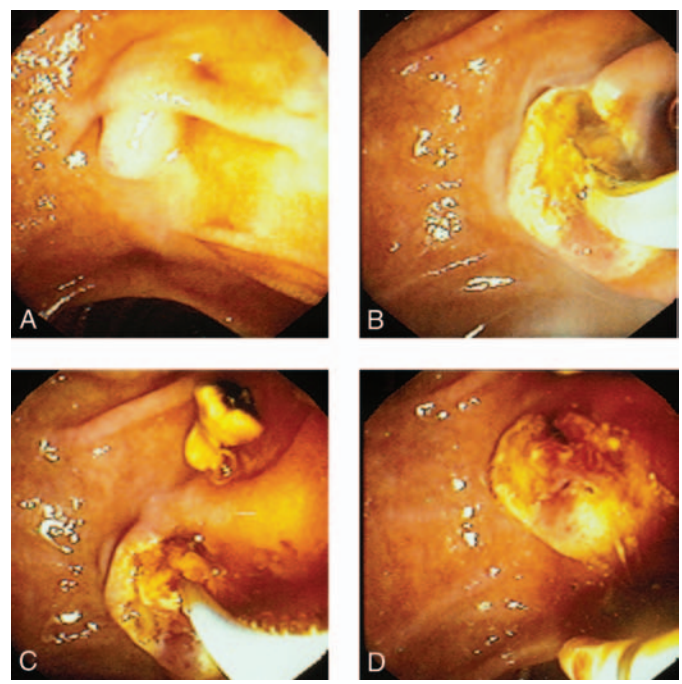

FIGURE 272-26 Endoscopic sphincterotomy. *A*. A normal-appearing ampulla of Vater. *B*. Sphincterotomy is performed with electrocautery. *C*. Bile duct stones are extracted with a balloon catheter. *D*. Final appearance of the sphincterotomy.

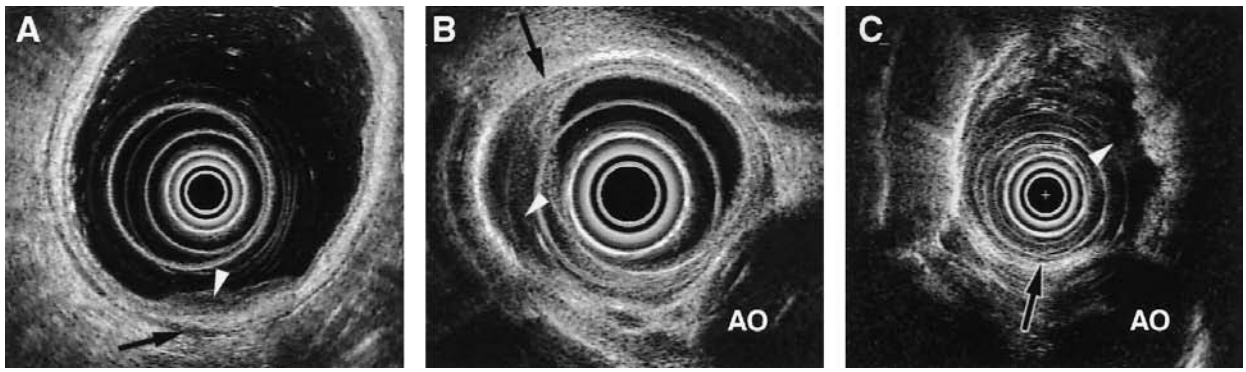

FIGURE 272-27 Local staging of gastrointestinal cancers with endoscopic ultrasound. In each example the white arrowhead marks the primary tumor and the black arrow indicates the muscularis propria (mp) of the intestinal wall. "AO" indicates aorta. *A*. T1 gastric cancer. The tumor does not invade the mp. *B*. T2 esophageal cancer. The tumor invades the mp. *C*. T3 esophageal cancer. The tumor extends through the mp into the surrounding tissue, and focally abuts the aorta.

shunts, or radiologically placed intrahepatic shunts) also play an important role.

Endoscopic band ligation is the preferred local therapy for bleeding esophageal varices. In this technique a varix is suctioned into a cap fitted on the end of the endoscope, and a rubber band is then released from the cap, ligating the varix. Acute hemorrhage can be controlled in up to 90% of patients, and complications (such as sepsis, symptomatic esophageal ulceration, or esophageal stenosis) are uncommon. Endoscopic sclerotherapy is another technique in which a sclerosing, thrombogenic solution is injected into or next to esophageal varices. Sclerotherapy also controls acute hemorrhage in most patients but has higher complication rates. These techniques are used when varices are actively bleeding during endoscopy or (more commonly) when varices are the only identifiable cause of acute hemorrhage.

After treatment of the acute hemorrhage, an elective course of endoscopic therapy can be undertaken with the goal of eradicating esophageal varices and preventing rebleeding months to years later. This chronic therapy is less successful, preventing long-term rebleeding in ~50% of patients. Pharmacologic therapies that decrease portal pressure have similar efficacy, and the two modalities may be combined.

Gastric varices are less amenable to endoscopic therapy and are best treated with a portal decompressive procedure (surgical portosystemic shunt or radiologic transjugular portosystemic shunt). Endoscopic therapy of gastric varices is usually reserved for actively bleeding varices or for patients with thrombosis of the portal venous system.

Dieulafoy's Lesion This lesion, also called *persistent caliber artery*, is a large-caliber arteriole that runs immediately beneath the gastrointestinal mucosa and bleeds through a pinpoint mucosal erosion. Dieulafoy's lesion is seen most commonly on the lesser curvature of the proximal stomach, causes impressive arterial hemorrhage, and is difficult to diagnose; it is often recognized only after repeated endoscopy for recurrent bleeding. Endoscopic therapy with a thermal probe usually controls acute bleeding and successfully ablates the underlying vessel once the bleeding site has been identified. Embolization or surgical oversewing are sometimes required.

Mallory-Weiss Tear A Mallory-Weiss tear is a linear mucosal rent near or across the gastroesophageal junction that is often associated with retching or vomiting. When the tear disrupts a submucosal arteriole, brisk hemorrhage may result. Endoscopy is the best method of diagnosis, and an actively bleeding tear can be treated endoscopically with coaptive coagulation using a thermal probe or by injection of dilute epinephrine. Since Mallory-Weiss tears only rarely rebleed, a sentinel clot in the base of the tear is usually not treated endoscopically.

Vascular Ectasias Vascular ectasias are flat mucosal vascular anomalies best diagnosed by endoscopy. They usually cause slow intestinal blood loss and have several characteristic distributions in the gastrointestinal tract. When limited to the cecum, where they occur as senile lesions, or the gastric antrum (gastric antral vascular ectasias, or "watermelon stomach"), ectasias are often responsive to local endoscopic ablative therapy. Patients with diffuse small-bowel vascular ectasias (associated with chronic renal failure and with hereditary hemorrhagic telangiectasia) often continue to bleed despite endoscopic treatment of accessible lesions and may benefit from octreotide or estrogen/progesterone therapy.

Colonic Diverticula Diverticula form where nutrient arteries penetrate the muscular wall of the colon en route to the colonic mucosa. The artery found in the base of a diverticulum may bleed, causing painless and impressive hematochezia. Colonoscopy is indicated in patients with hematochezia and suspected diverticular hemorrhage, since other causes of bleeding (such as vascular ectasias, colitis, and colonic cancer) must be excluded. In addition, an actively bleeding diverticulum is occasionally seen and treated during colonoscopy.

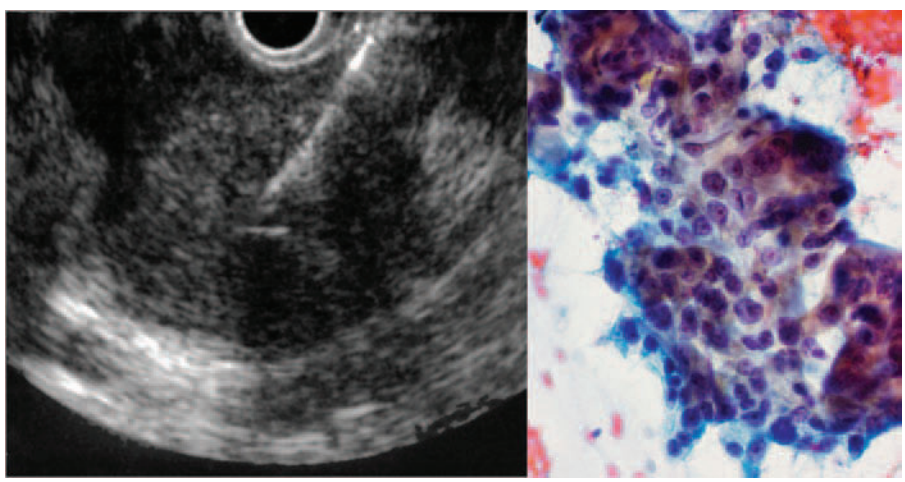

FIGURE 272-28 Endoscopic ultrasound (EUS)–guided needle aspiration. *A*. Ultrasound image of a 22-gauge needle passed through the duodenal wall and positioned in a hypoechoic pancreatic head mass. *B*. Micrograph of aspirated malignant cells. (*Image B courtesy of Dr. Mary Chacho.*)

GASTROINTESTINAL OBSTRUCTION AND PSEUDOOBSTRUCTION Endoscopy is useful for evaluation and treatment of some forms of gastrointestinal obstruction. An important exception is small-bowel obstruction, which is generally not diagnosed by endoscopy or amenable to endoscopic therapy. Esophageal, gastroduodenal, and colonic obstruction or pseudoobstruction can all be diagnosed and often managed endoscopically.

Acute Esophageal Obstruction Esophageal obstruction by impacted food or an ingested foreign body is a potentially life-threatening

TABLE 272-1 *Antibiotic Prophylaxis for Selected Endoscopic Procedures*

Patient Condition	Procedure Contemplated	Antibiotic Prophylaxis[a]
Prosthetic valve, history of endocarditis, systemic-pulmonary shunt, synthetic vascular graft (<1 year old)	High risk[b]	Recommended
	Low risk[c]	Optional[d] (insufficient data)
Rheumatic valvular disease, mitral valve prolapse with insufficiency, congenital cardiac malformations, hypertrophic cardiomyopathy	High risk	Optional[d] (insufficient data)
	Low risk	Not recommended[d]
Pacemakers, implantable defibrillators, prior coronary artery bypass grafts; prosthetic joints	High or low risk	Not recommended

[a] Acceptable antibiotic regimens for esophageal procedures include amoxicillin, 2 g PO, 1 h before, or ampicillin, 2 g IV, 30 min before upper endoscopy; clindamycin, 600 mg PO, may be substituted in penicillin-allergic patients. Acceptable regimens for colonic procedures in high-risk patients include gentamicin, 1.5 mg/kg (not to exceed 120 mg), and ampicillin, 2 g IV, within 30 min of colonoscopy, with or without amoxicillin, 1 g orally, 6 h later; vancomycin, 1 g IV, may be substituted for penicillins in penicillin-allergic patients. For colonic procedures in moderate-risk patients, amoxicillin, 2 g PO, 1 h before the procedure or vancomycin, 1 g IV, are sufficient.

[b] High-risk endoscopic procedures: stricture dilation, variceal sclerosis, endoscopic ultrasound with fine-needle aspiration, endoscopic retrograde cholangiopancreatography with an obstructed biliary tree.

[c] Low-risk endoscopic procedures: esophagogastroduodenoscopy and colonoscopy with or without biopsy and polyp removal, variceal ligation.

[d] Controversy exists and recommendations vary. For more detailed discussion, see Dajani AS et al: Clin Infect Dis 25:1448, 1997.

Source: Adapted from *Antibiotic Prophylaxis for Endoscopic Procedures*, American Society for Gastrointestinal Endoscopy, 1998.

event. Left untreated, the patient may develop esophageal ulceration, ischemia, and perforation. Patients with persistent esophageal obstruction often have hypersalivation and are usually unable to swallow water; endoscopy is generally the best initial test in such patients, since endoscopic removal of the obstructing material is usually possible, and the presence of an underlying esophageal stricture can often be determined. Radiographs of the chest and neck should be considered before endoscopy in patients with fever, obstruction for ≥24 h, or ingestion of a sharp object such as a fishbone. Radiographic contrast studies interfere with subsequent endoscopy and are not advisable in most patients with a clinical picture of esophageal obstruction. Occasionally, sublingual nifedipine or nitrates, or intravenous glucagon, may resolve an esophageal food impaction, but in most patients an underlying web, ring, or stricture is present and endoscopic removal of the obstructing food bolus is necessary.

Gastric Outlet Obstruction Obstruction of the gastric outlet is commonly caused by malignancy of the prepyloric gastric antrum or chronic peptic ulceration with stenosis of the pylorus. Patients vomit partially digested food many hours after eating. Gastric decompression with a nasogastric tube and subsequent lavage for removal of retained material is the first step in treatment. The diagnosis can then be confirmed with a saline load test, if desired. Endoscopy is useful for diagnosis and treatment. Patients with pyloric stenosis may be treated with endoscopic balloon dilation of the pylorus, and a course of endoscopic dilation results in long-term relief of symptoms in about 50% of patients. Malignant pyloric obstruction can be treated with endoscopically placed expandable stents if the patient is deemed a poor surgical candidate.

Colonic Obstruction and Pseudoobstruction These both present with abdominal distention and discomfort; tympany; and a dilated, air-filled colon on plain abdominal radiography. Both conditions may lead to colonic perforation if untreated. Acute colonic pseudoobstruction is a form of colonic ileus that is usually attributable to electrolyte disorders, narcotic and anticholinergic medications, immobility (as after surgery), and retroperitoneal hemorrhage or mass. Multiple causative factors are often present. Either colonoscopy or a water-soluble contrast enema may be used to look for an obstructing lesion and differentiate obstruction from pseudoobstruction. One of these diagnostic studies should be strongly considered if the patient does not have clear risk factors for pseudoobstruction, if radiographs do not show air in the rectum, or if the patient fails to improve when the underlying causes of pseudoobstruction have been addressed. The risk of cecal perforation in pseudoobstruction rises when the cecal diameter exceeds 12 cm, and in such patients decompression of the colon may be achieved using intravenous neostigmine, colonoscopic decompression, or placement of a cecostomy tube. Most patients should receive a trial of conservative therapy (with correction of electrolyte disorders, removal of offending medications, and increased mobilization) before undergoing an invasive decompressive procedure.

Colonic obstruction is an indication for urgent intervention. Emergency diverting colostomy is often performed with a subsequent operation after bowel preparation to address the underlying cause. Colonscopic placement of an expandable stent is an alternative that can relieve malignant obstruction without emergency surgery and permit bowel preparation for elective surgery.

ACUTE BILIARY OBSTRUCTION The steady, severe pain that occurs when a gallstone acutely obstructs the common bile duct often brings patients to a hospital. The diagnosis of a ductal stone is suspected when the patient is jaundiced or when serum liver tests or pancreatic enzyme levels are elevated, and confirmed by direct cholangiography (performed endoscopically, percutaneously, or during surgery). ERCP is currently the primary means of diagnosing and treating common bile duct stones in most hospitals in the United States.

Bile Duct Imaging While transabdominal ultrasound and biliary scintigraphy are not sufficiently accurate for reliable diagnosis of bile duct stones, newer imaging modalities such as spiral computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), and EUS are more accurate and have an emerging role in diagnosis. Ex-

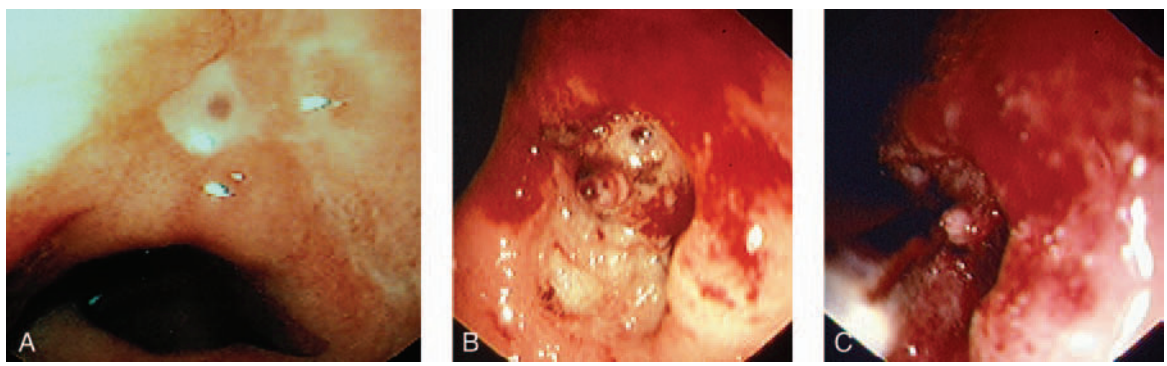

FIGURE 272-29 Endoscopic stigmata of recent bleeding in peptic ulcers. *A*. A flat red spot in an ulcer base. *B*. A sentinel clot protruding from an ulcer base. *C*. Coagulation of the sentinel clot shown in (*B*) with a thermal probe. (*Courtesy of American Society for Gastrointestinal Endoscopy.*)

amples of these modalities are shown in Fig. 272-30. During MRCP, images are obtained that demonstrate stagnant or slowly flowing fluid and subtract all other tissue. The resulting images of the right upper quadrant are strikingly similar to a direct cholangiogram, although with less resolution. MRCP can be performed rapidly without sedation and does not require any radiographic contrast. When an echo-endoscope is passed into the duodenum, detailed EUS views of the adjacent bile duct are readily obtained. While this procedure requires intravenous sedation, it has a very low incidence of complications, in contradistinction to ERCP. Spiral CT has a sensitivity of 85% for diagnosis of bile duct stones, MRCP has a sensitivity of 85 to 95%, and EUS has a sensitivity of 88 to 98%. EUS is more accurate than ERCP in some hands.

When a bile duct stone is highly likely and urgent treatment is required (as in a patient with jaundice and biliary sepsis), ERCP is the procedure of choice, since it remains the gold standard for diagnosis and provides immediate treatment. When a persistent bile duct stone is relatively unlikely (as in a patient with gallstone pancreatitis), less-invasive imaging techniques may supplant ERCP or intraoperative cholangiography.

Ascending Cholangitis Charcot's triad of jaundice, abdominal pain, and fever is present in about 70% of patients with ascending cholangitis and biliary sepsis. Initially, such patients are managed with fluid resuscitation and intravenous antibiotics. Abdominal ultrasound is often done to look for gallbladder stones and bile duct dilation. The bile duct may not be dilated early in the course of acute biliary obstruction, however. Medical management usually improves the patient's clinical status, providing a window of approximately 24 h during which biliary drainage should be established, typically by ERCP. Undue delay can result in recrudescence of overt sepsis and increased morbidity. If, in addition to Charcot's triad, shock and confusion are present (Reynolds's pentad), urgent attempts to restore biliary drainage are usually indicated.

Gallstone Pancreatitis Gallstones may cause acute pancreatitis as they pass through the ampulla of Vater. The occurrence of gallstone pancreatitis usually implies passage of a stone into the duodenum, and only about 20% of patients harbor a persistent stone in the ampulla or the common bile duct. Retained stones are more common in patients with jaundice, severe pancreatitis, or superimposed ascending cholangitis.

Urgent ERCP decreases the morbidity of gallstone pancreatitis in some subsets of patients. It remains unclear whether the benefit of ERCP is mainly attributable to treatment and prevention of ascending cholangitis or to relief of pancreatic duct obstruction. ERCP is warranted early in the course of gallstone pancreatitis if ascending cholangitis is also suspected, especially in a jaundiced patient. Urgent ERCP appears to benefit patients predicted to have severe pancreatitis using a clinical index of severity (such as the Glasgow or Ranson score).

ELECTIVE ENDOSCOPY

Dyspepsia and Reflux Dyspepsia is a chronic or recurrent burning discomfort or pain in the upper abdomen that may be caused by diverse processes such as gastroesophageal reflux, peptic ulcer disease, and "nonulcer dyspepsia," a heterogeneous category that includes disorders of motility, sensation, and somatization. Gastric and esophageal malignancies are less common causes of dyspepsia. Careful history-taking allows accurate differential diagnosis of dyspepsia in only about half of patients. In the remainder, endoscopy can be a useful diagnostic tool, especially in those patients whose symptoms are not resolved by an empirical trial of symptomatic treatment.

Gastroesophageal Reflux Disease (GERD) When classic symptoms of gastroesophageal reflux are present, such as water brash and substernal heartburn, presumptive diagnosis and empirical treatment are often sufficient. Although endoscopy is sensitive for diagnosis of esophagitis, it can miss cases of reflux, since some patients have symptomatic reflux without esophagitis. The most sensitive test for diagnosis of GERD is 24-h ambulatory pH monitoring. Endoscopy is indicated in patients with resistant reflux symptoms and in those with recurrent dyspepsia after treatment that is not clearly due to reflux on clinical grounds alone, to assess the esophagus and exclude other diseases. Endoscopy is also advised in a patient with reflux and dysphagia, to look for a stricture or malignancy. Endoscopy may be indicated in patients with long-standing ($\geq$10 years) frequent heartburn, who are at sixfold increased risk of Barrett's esophagus compared to a patient with $<$1 year of reflux symptoms. Patients with Barrett's esophagus usually enter a program of periodic endoscopy with biopsies, to detect dysplasia or early carcinoma.

Peptic Ulcer Peptic ulcer classically causes epigastric gnawing or burning, often occurring nocturnally and promptly relieved by food or antacids. Although endoscopy is the most sensitive diagnostic test for peptic ulcer, immediate endoscopy is not a cost-effective strategy in young patients with ulcer-like dyspeptic symptoms unless endoscopy is available at low cost. Patients with suspected peptic ulcer should be evaluated for *Helicobacter pylori* infection. Serology (past or present infection), urea breath testing (current infection), and stool tests are less invasive and costly than endoscopy with biopsy. Patients with ulcer-like symptoms despite treatment should undergo endoscopy to exclude gastric malignancy, and patients with "alarm symptoms" (weight loss, anemia, bleeding) should also undergo endoscopy.

Nonulcer Dyspepsia This may be associated with bloating and, unlike peptic ulcer, tends not to remit and recur. Most patients do not respond

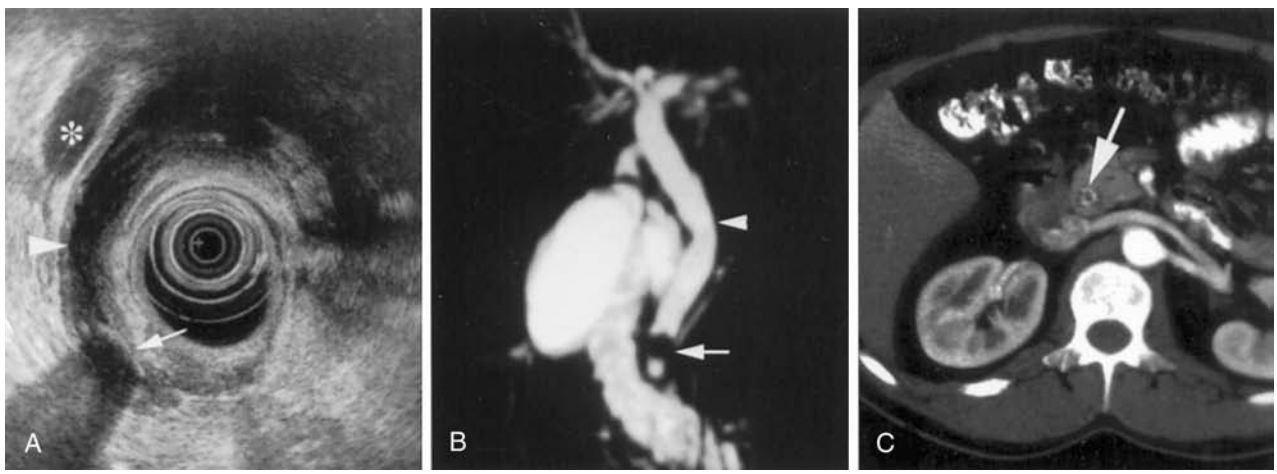

FIGURE 272-30 Methods of bile duct imaging. Arrows mark bile duct stones. Arrowheads indicate the common bile duct, and the asterisk marks the portal vein. *A.* Endoscopic ultrasonography (EUS). *B.* Magnetic resonance cholangiography (MRCP). *C.* Helical computed tomography.

to acid-reducing, prokinetic, or anti-*Helicobacter* therapy and are referred for endoscopy to exclude a refractory ulcer. While endoscopy usefully excludes other diagnoses, it generally does little to improve the treatment of patients with nonulcer dyspepsia.

Dysphagia About 50% of patients with difficulty swallowing have a mechanical obstruction; the remainder have a motor disorder. Careful history-taking often suggests a diagnosis and leads to the appropriate use of diagnostic tests. Esophageal strictures typically cause progressive dysphagia, first for solids, then liquids; motor disorders often cause intermittent dysphagia for both solids and liquids. Some underlying disorders have characteristic historic features: Schatzki's ring causes episodic dysphagia for solids, typically at the beginning of a meal; pharyngeal motor disorders are associated with difficulty initiating deglutition ("transfer dysphagia") and nasal reflux with swallowing; and achalasia may cause nocturnal regurgitation of undigested food.

When mechanical obstruction is suspected, endoscopy is a useful initial diagnostic test, since it permits immediate biopsy and dilation of strictures, masses, or rings. Blind or forceful passage of an endoscope may lead to perforation in a patient with stenosis of the cervical esophagus or a Zencker's diverticulum, but gentle passage of an endoscope under direct visual guidance is reasonably safe. Endoscopy can miss a subtle stricture or ring in some patients.

When a motor disorder is suspected, esophageal radiography is the best initial diagnostic test. The pharyngeal swallowing mechanism, esophageal peristalsis, and the lower esophageal sphincter can all be assessed. In some disorders, subsequent esophageal manometry may also be important for diagnosis.

Anemia and Occult Blood in the Stool Iron-deficiency anemia may be attributed to poor iron absorption (as in celiac sprue) or, more commonly, chronic blood loss. Intestinal bleeding should be strongly suspected in men and postmenopausal women with iron-deficiency anemia, and colonoscopy is indicated in such patients, even in the absence of detectable occult blood in the stool. Some 30% will have large colonic polyps, 10% will have colorectal cancer, and additional patients will have colonic vascular lesions. When a convincing source of blood loss is not found in the colon, upper gastrointestinal endoscopy should also be performed; if no lesion is found, duodenal biopsies should be obtained to exclude sprue. Small-bowel evaluation may be appropriate if both EGD and colonoscopy are unrevealing.

Tests for occult blood in the stool detect hemoglobin or the heme moiety and are most sensitive for colonic blood loss, although they will also detect larger amounts of upper gastrointestinal bleeding. Patients over 50 with occult blood in normal-appearing stool should undergo colonoscopy to diagnose or exclude colorectal neoplasia. The diagnostic yield is lower than in iron-deficiency anemia. Whether upper endoscopy is also indicated largely depends on the patient's symptoms.

The small intestine may be the source of chronic intestinal bleeding, especially if colonoscopy and upper endoscopy are not diagnostic. The utility of small-bowel evaluation varies with the clinical setting and is most important in patients whose bleeding causes chronic or recurrent anemia. While small-bowel radiography is usually normal, capsule endoscopy yields a specific diagnosis in about 50% of such patients. The most common finding is mucosal vascular ectasias.

Colorectal Cancer Screening Most colon cancers develop from preexisting colonic adenomas, and colorectal cancer can be largely prevented by the detection and removal of adenomatous polyps. Screening for polyps and early, asymptomatic cancers can be accomplished both by testing stool specimens for occult blood and by directly examining the colonic mucosa. Since tests for occult blood are insensitive, detecting only about one-fourth of colon cancers and large polyps, visualization of at least a part of the colon is an important component of colorectal cancer screening.

The choice of screening strategy for an asymptomatic patient depends in part on their personal and family history. Patients at increased risk for colon cancer include those with a past history of inflammatory bowel disease, colorectal polyps, a family history of first-degree family members with adenomatous polyps or cancer, or certain familial cancer syndromes. These considerations alter screening recommendations. An individual without these factors is generally considered at average risk.

Screening strategies are summarized in Table 272-2. Either sigmoidoscopy or colonoscopy may be used for cancer screening in asymptomatic average-risk patients. Use of sigmoidoscopy was based on the historic finding that the majority of colorectal cancers occurred in the rectum and left colon, and that patients with right-sided colon cancers had left-sided polyps. Over the past several decades, however, the distribution of colon cancers has changed, with proportionally fewer rectal and left-sided cancers than in the past. Large studies of colonoscopy for screening of average-risk individuals show that cancers are roughly equally distributed between left and right colon and half of patients with right-sided lesions have no polyps in the left colon. In addition, the new imaging technique of "virtual colonoscopy" holds considerable promise. This modality uses data from helical CT to generate a graphic display of a "flight" down the colonic lumen.

TABLE 272-2 *Colorectal Cancer Screening Strategies*

	Recommendation
AVERAGE-RISK PATIENTS	
Asymptomatic individuals ≥ 50 years of age	Colonscopy every 10 years, *or* Annual fecal occult blood test and flexible sigmoidoscopy every 5 years, or Double-contrast barium enema every 5 to 10 years
HIGH-RISK PATIENTS[a]	
Personal history	
History of colon cancer	Evaluate entire colon around the time of resection, then colonoscopy every 3 to 5 years
History of colonic adenomas	Colonoscopy every 3 to 5 years
Ulcerative pancolitis of 8 years' duration, left-sided colitis >15 years' duration	Colonoscopy with biopsies every 1 to 3 years
Family history	
Familial adenomatous polyposis	Consider genetic testing Annual sigmoidoscopy beginning at age 10 to 12; consider colectomy when polyps develop; if no polyps, annual sigmoidoscopy until age 40, then every 3 to 5 years
Hereditary nonpolyposis colorectal cancer (HNPCC)	Consider genetic testing Colonoscopy every 2 years beginning at 25 or when 5 years younger than the youngest affected relative; annual colonoscopy after age 40
Two first-degree relatives with colorectal cancer or adenomas	Colonoscopy every 3 to 5 years, beginning when 10 years younger than the youngest affected relative
One first-degree relative with sporadic colorectal cancer or adenoma before age 60	Same as above

[a] High-risk patients: Past history of inflammatory bowel disease, colorectal adenomatous polyps, or colorectal cancer; family history of colorectal adenomatous polyps, colorectal cancer, or certain familial cancer syndromes.

Source: Adapted from *Recommendations for Colorectal Cancer Screening and Surveillance in People at Average and at Increased Risk*, American Medical Association Council on Scientific Affairs, 2001; and *Screening and Surveillance Colonoscopy in Individuals at Increased Risk for Colorectal Cancer*, American Society for Gastrointestinal Endoscopy, 1998.

This technique is not yet sufficiently sensitive for routine clinical use, but further refinement may result in a useful noninvasive screening method.

Diarrhea Most cases of diarrhea are acute, self-limited, and due to infections or medication. Chronic diarrhea (lasting >6 weeks) is more often due to a primary inflammatory or malabsorptive disorder, is less likely to resolve spontaneously, and generally requires diagnostic evaluation. Patients with chronic diarrhea or severe, unexplained acute diarrhea often undergo endoscopy if stool tests for pathogens are unrevealing. The choice of endoscopic test depends on the clinical setting.

Patients with colonic symptoms and findings such as bloody diarrhea, tenesmus, fever, or leukocytes in stool generally undergo sigmoidoscopy or colonoscopy to look for colitis. Sigmoidoscopy is often adequate and is the best initial test in most such patients. On the other hand, patients with symptoms and findings suggesting small-bowel disease such as large-volume watery stools, substantial weight loss, and malabsorption of iron, calcium, or fat may undergo upper endoscopy with duodenal biopsies.

Many patients with chronic diarrhea do not fit either of these patterns. When there is a long-standing history of alternating constipation and diarrhea dating to early adulthood, without findings such as blood in the stool or anemia, a diagnosis of irritable bowel syndrome may be made without direct visualization of the bowel. Steatorrhea and upper abdominal pain may prompt evaluation of the pancreas rather than the gut. Patients whose chronic diarrhea is not easily categorized often undergo initial colonoscopy to examine the entire colon (and terminal ileum) for inflammatory or neoplastic disease.

Minor Hematochezia Bright red blood passed with or on formed brown stool usually has a rectal, anal, or distal sigmoid source. Patients with even trivial amounts of hematochezia should be investigated with flexible sigmoidoscopy to exclude large polyps or cancers in the distal bowel. Patients who report red blood on the toilet tissue only, without blood in the toilet or on the stool, are bleeding from a lesion in the anal canal, and careful external and digital examinations and anoscopy are sufficient for diagnosis in most cases.

Unexplained Pancreatitis About 20% of patients with pancreatitis have no identified cause after routine clinical investigation (including a review of medication and alcohol use, measurement of serum triglyceride and calcium levels, abdominal ultrasonography, and CT). Endoscopic techniques lead to a specific diagnosis in the majority of such patients, often altering clinical management. Endoscopic investigation is particularly appropriate if the patient has had more than one episode of pancreatitis.

Microlithiasis, or the presence of microscopic crystals in bile, is a leading cause of previously unexplained acute pancreatitis and is sometimes seen during abdominal ultrasonography as layering sludge or flecks of floating, echogenic material in the gallbladder. Gallbladder bile can be obtained for microscopic analysis by administering a cholecystokinin analogue during endoscopy, causing contraction of the gallbladder. Bile is suctioned from the duodenum as it drains from the papilla, and the darkest fraction is examined for cholesterol crystals or bilirubinate granules. Combined EUS of the gallbladder and bile microscopy is probably the most sensitive means of diagnosing microlithiasis.

Previously undetected chronic pancreatitis, pancreatic malignancy, or pancreas divisum may be diagnosed by either ERCP or EUS. Sphincter of Oddi dysfunction probably causes some cases of pancreatitis and can be diagnosed by manometric studies performed during ERCP.

Cancer Staging Local staging of esophageal, gastric, pancreatic, bile duct, and rectal cancers can be obtained with EUS. EUS with fine-needle aspiration (Fig. 272-28) currently provides the most accurate preoperative assessment of local tumor and nodal staging, but it does not detect distant metastases. Details of the local tumor stage can guide treatment decisions including resectability and need for neoadjuvant therapy. EUS with transesophageal needle biopsy may also be used to assess the presence of non-small cell lung cancer in mediastinal nodes.

OPEN-ACCESS ENDOSCOPY

While gastroenterologists have traditionally seen patients in consultation before arranging an endoscopic procedure, direct scheduling of endoscopic procedures by primary care physicians, or *open-access endoscopy*, is an increasingly common practice. When the indications for endoscopy are clear cut and appropriate, the procedural risks are low, and the patient understands what to expect, open-access endoscopy streamlines patient care and decreases costs.

Patients referred for open-access endoscopy should have a recent history, physical examination, and medication review. A copy of such an evaluation should be available when the patient comes to the endoscopy suite. Patients with unstable cardiovascular or respiratory conditions should not be referred directly for open-access endoscopy. Patients with selected cardiac conditions undergoing certain procedures should be prescribed prophylactic antibiotics prior to endoscopy, as described in Table 272-1. In addition, patients taking anticoagulants may need changes in treatment before endoscopy, as detailed in Table 272-3. While many endoscopists recommend discontinuing aspirin for 5 days before elective endoscopic procedures, most evidence suggests that in the absence of a preexisting bleeding disorder it is safe to perform endoscopic procedures in patients taking aspirin and nonsteroidal anti-inflammatory drugs.

Common indications for open-access EGD include dyspepsia resistant to a trial of appropriate therapy; gastrointestinal bleeding; and persistent anorexia, or early satiety. Open-access colonoscopy is often requested in men or postmenopausal women with iron-deficiency anemia, patients over age 50 with occult blood in the stool, patients with a previous history of colorectal adenomatous polyps or cancer, and for colorectal cancer screening. Flexible sigmoidoscopy is commonly performed as an open-access procedure.

When patients are referred for open-access colonoscopy, the primary care provider may need to choose a colonic preparation. Commonly used oral preparations include polyethelene glycol lavage solution and sodium phosphate. Sodium phosphate may cause fluid and electrolyte abnormalities, especially in patients with renal failure, congestive heart failure, and patients over 70 years of age.

TABLE 272-3 *Management of Anticoagulation before Endoscopic Procedures*

	High Patient Risk of Thromboembolism[a]	*Low Patient Risk of Thromboembolism*[b]
High-risk procedure[c]	Stop warfarin 3–5 days before the procedure; consider heparin when INR is below the therapeutic range	Stop warfarin 3–5 days before the procedure; restart warfarin after the procedure
Low-risk procedure[d]	No change in anticoagulation; elective procedures should be delayed while INR is above the therapeutic range	No change in anticoagulation; elective procedures should be delayed while INR is above the therapeutic range

[a] High-risk conditions: atrial fibrillation associated with valvular heart disease, mechanical valve in the mitral position, mechanical valve and prior thromboembolic event.
[b] Low-risk conditions: Uncomplicated or paroxysmal nonvalvular atrial fibrillation, mechanical valve in the aortic position, bioprosthetic valve, deep vein thrombosis.
[c] High-risk procedures: Polypectomy, stricture dilation, treatment of varices, gastrostomy placement, biliary sphincterotomy, endoscopic ultrasound with needle aspiration.
[d] Low-risk procedures: Diagnostic upper endoscopy, colonoscopy, sigmoidoscopy with or without biopsy, diagnostic endoscopic retrograde cholangiopancreatography, endoscopic ultrasound without needle aspiration.
Note: INR, international normalized ratio.

273 DISEASES OF THE ESOPHAGUS

Raj K. Goyal

The two major functions of the esophagus are the transport of the food bolus from the mouth to the stomach and the prevention of retrograde flow of gastrointestinal contents. The transport function is achieved by peristaltic contractions in the pharynx and esophagus associated with relaxation of upper and lower esophageal sphincters (Chap. 33). Retrograde flow is prevented by the two esophageal sphincters, which remain closed between swallows. The upper esophageal sphincter (UES) consists of the cricopharyngeus and inferior pharyngeal constrictor muscles, both of which are striated muscles innervated by excitatory somatic lower motor neurons. These muscles exhibit no myogenic tone and receive no inhibitory innervation. The UES remains closed owing to the elastic properties of its wall and to neurogenic tonic contraction of the sphincter muscles. Inhibition in the central nervous system opens the sphincter muscles in concert with forward displacement of the larynx by the suprahyoid muscles. In contrast, the lower esophageal sphincter (LES) is composed of smooth muscle and is innervated by parallel sets of parasympathetic excitatory and inhibitory pathways. It remains closed because of its intrinsic myogenic tone, which is modulated by the excitatory and inhibitory nerves. It opens in response to the activity of the inhibitory nerves. The neurotransmitters of the excitatory nerves are acetylcholine and substance P, and those of the inhibitory nerves are vasoactive intestinal peptide (VIP) and nitric oxide. The function of the LES is supplemented by the striated muscle of the diaphragmatic crura, which surrounds the LES and acts as an external LES. Relaxation of the LES without esophageal contraction occurs during belching and gastric distention. Gastric distention–evoked transient lower esophageal sphincter relaxation (tLESR) is a vasovagal reflex. Fatty meals, smoking, and beverages with a high xanthine content (tea, coffee, cola) also cause a reduction in sphincter pressure. Many hormones and neurotransmitters can modify LES pressure. Muscarinic M_2 and M_3 receptor agonists, α-adrenergic agonists, gastrin, substance P, and prostaglandin $F_{2\alpha}$ cause contraction. Nicotine, β-adrenergic agonists, dopamine, cholecystokinin, secretin, VIP, calcitonin gene–related peptide (CGRP), adenosine, prostaglandin E, and nitric oxide donors such as nitrates reduce sphincter pressure.

SYMPTOMS

DYSPHAGIA See Chap. 33

ESOPHAGEAL PAIN *Heartburn*, or pyrosis, is characterized by burning retrosternal discomfort that may move up and down the chest like a wave. When severe, it may radiate to the sides of the chest, the neck, and the angles of the jaw. Heartburn is a characteristic symptom of reflux esophagitis and may be associated with regurgitation or a feeling of warm fluid climbing up the throat. It is aggravated by bending forward, straining, or lying recumbent and is worse after meals. It is relieved by an upright posture, by the swallowing of saliva or water, and, more reliably, by antacids. Heartburn is produced by heightened mucosal sensitivity and can be reproduced by infusion of dilute (0.1 *N*) hydrochloric acid (Bernstein test) or neutral hyperosmolar solutions into the esophagus.

Odynophagia, or painful swallowing, is characteristic of nonreflux esophagitis, particularly monilial and herpes esophagitis. Odynophagia may occur with peptic ulcer of the esophagus (Barrett's ulcer), carcinoma with periesophageal involvement, caustic damage of the esophagus, and esophageal perforation. Odynophagia is unusual in uncomplicated reflux esophagitis. Crampy chest pain associated with impaction of a food bolus should be distinguished from odynophagia.

Atypical chest pain other than heartburn and odynophagia occurs in reflux esophagitis or esophageal motility disorders such as diffuse esophageal spasm. Spasm may occur spontaneously or during a meal. Chest pain due to periesophageal involvement with carcinoma or peptic ulcer may be constant and agonizing. Sometimes different types of esophageal pains exist together in the same patient, and frequently patients are not able to describe the pain accurately enough to allow its classification. Coronary artery disease should always be excluded before the esophagus is considered as the cause of atypical chest pain. The most frequent esophageal cause of chest pain is reflux esophagitis. Some patients with atypical chest pain have nonspecific esophageal motor abnormalities of uncertain significance. Many of these patients have behavioral abnormalities, psychosomatic disorders, depression, anxiety, panic reactions, and other psychological disorders.

REGURGITATION *Regurgitation* is the effortless appearance of gastric or esophageal contents in the mouth. In distal esophageal obstruction and stasis, as in achalasia or the presence of a large diverticulum, the regurgitated material consists of tasteless mucoid fluid or undigested food. Regurgitation of sour or bitter-tasting material occurs in severe gastroesophageal reflux and is associated with incompetence of both the UES and the LES. Regurgitation may result in laryngeal aspiration, with spells of coughing and choking that awaken the patient from sleep, and in aspiration pneumonia. Water brash is reflex salivary hypersecretion that occurs in response to peptic esophagitis and should not be confused with regurgitation.

DIAGNOSTIC TESTS

RADIOLOGIC STUDIES Barium swallow with fluoroscopy and an esophagogram is a widely used test for the diagnosis of esophageal disease and can be used to evaluate both structural and motor disorders. Spontaneous reflux of barium from the stomach into the esophagus suggests gastroesophageal reflux. Esophageal peristalsis is best studied in the recumbent position, because in the upright position barium passage occurs largely by gravity alone. A double-contrast esophagogram, obtained by coating the esophageal mucosa with barium and distending the esophageal lumen with air using effervescent granules, is particularly useful in demonstrating mucosal ulcers and early cancers. A barium-soaked piece of bread or a 13-mm barium tablet is sometimes used to demonstrate an obstructive lesion. Figures 273-1 and 273-2 illustrate the radiographic appearance of some esophageal disorders. Since the oropharyngeal phase of swallowing lasts no more than a second, videofluoroscopy is necessary to permit detection and analysis of abnormalities of oral and pharyngeal function. The pharynx is examined to detect stasis of barium in the valleculae and piriform sinuses and regurgitation of barium into the nose and tracheobronchial tree.

ESOPHAGOSCOPY Esophagoscopy is the direct method of establishing the cause of mechanical dysphagia and of identifying mucosal lesions that may not be identified by the usual barium swallow. If the lumen is markedly narrowed, use of a smaller-caliber endoscope may be needed; on occasion a stricture must be dilated before the examination can be completed. Endoscopic biopsies are useful in diagnosing car-

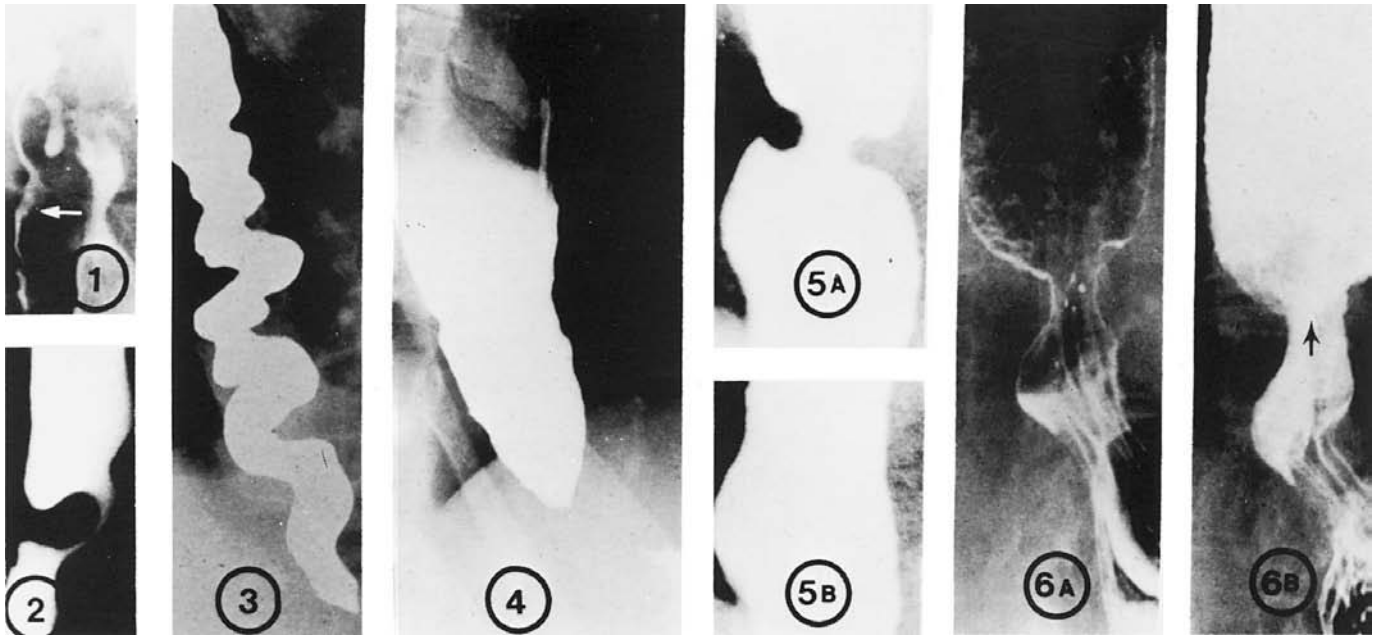

FIGURE 273-1 Radiographic appearance of some motor disorders of the pharynx and esophagus. (1) Pharyngeal paralysis with tracheal aspiration (*arrow*). (2) Cricopharyngeal achalasia. Note the prominent cricopharyngeus, which is recognized by its smoothness and location in the posterior wall. (3) Diffuse esophageal spasm. Note the typical corkscrew appearance of the lower part of the esophagus. (4) Achalasia, showing a dilated esophageal body with an air-fluid level and a closed lower esophageal sphincter. (5) Muscular (contractile) lower esophageal ring. The asymmetric contraction visible in (5A) has disappeared in (5B), obtained during the same examination. (6) Scleroderma esophagus showing dilated esophagus with a stricture (6A) and reflux of barium from the stomach into the esophagus (6B). (Courtesy of Dr. Harvey Goldstein.)

cinoma, reflux esophagitis, and other mucosal diseases. Cells obtained by a cytology balloon or brushing the mucosa can be evaluated for carcinoma. Endoscopic ultrasonography permits evaluation of intramural masses and staging of esophageal cancer.

ESOPHAGEAL MOTILITY The study of esophageal motility entails simultaneous recording of pressures from different sites in the esophageal lumen with an assembly of pressure sensors positioned 5 cm apart. The UES and LES appear as zones of high pressure that relax on swallowing. The pharynx and esophagus normally show peristaltic waves with each swallow.

Esophageal motility studies are helpful in the diagnosis of esophageal motor disorders (achalasia, spasm, scleroderma) (Fig. 273-3) but are of little value in the diagnosis of mechanical dysphagia. In patients with reflux esophagitis, esophageal manometry is useful in quantitating lower esophageal competence and providing information on the status of the esophageal body motor activity. Manometry provides quantitative data that cannot be obtained by barium swallow or endoscopy. Tests for reflux esophagitis are described later.

MOTOR DISORDERS

STRIATED MUSCLE ■ Oropharyngeal Paralysis Paralysis of oral muscles leads to difficulty initiating swallowing and drooling of food out of the mouth. Pharyngeal paralysis, characterized by dysphagia, nasal regurgitation, and aspiration during swallowing, occurs in a variety of

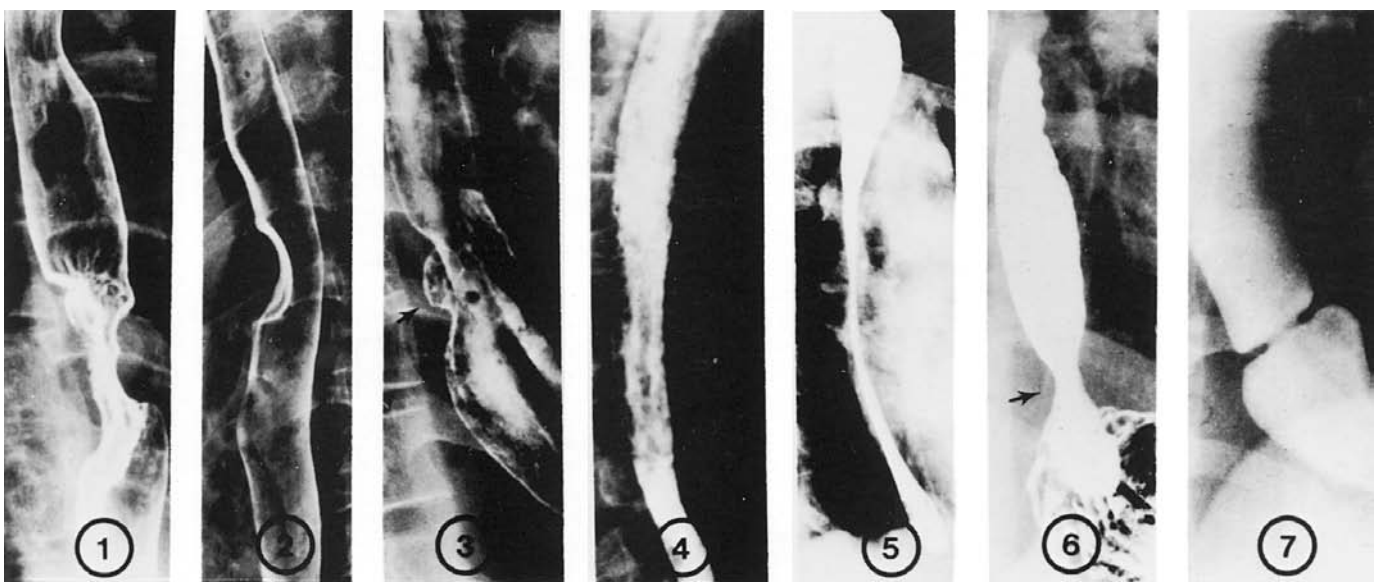

FIGURE 273-2 Selected structural lesions of the esophagus. (1) Carcinoma of the esophagus, with typical annular narrowing with overhanging margins and destruction of the mucosa. (2) Leiomyoma of the esophagus, with a smooth filling defect and right angles of origin from the esophageal wall. (3) Esophageal ulcer in columnar cell–lined esophagus (Barrett's esophagus). (4) Monilial esophagitis, with irregular plaquelike filling defects. (5) Long stricture secondary to lye ingestion. (6) Peptic stricture, short and tubular, with associated hiatal hernia. (7) Lower esophageal mucosal (Schatzki) ring. A thin, weblike annular constriction at the esophagogastric junction is associated with a small hiatal hernia. (Courtesy of Dr. Harvey Goldstein.)

neuromuscular disorders (see Table 33-1). Some of these disorders also involve laryngeal muscles, causing hoarseness. When the suprahyoid muscles are paralyzed, the UES does not open with swallowing, leading to paralytic achalasia of the UES and severe dysphagia.

Videofluoroscopy with barium of various consistencies may reveal difficulties in the oral phase of swallowing. The test may show stasis of barium in the valleculae and piriform sinuses, nasal and tracheal aspiration, failure of the upper sphincter to open, and/or abnormal movement of the hyoid bone and the larynx with a swallow (Fig. 273-1 panel 1). Motility studies demonstrate a reduced amplitude of pharyngeal and upper esophageal contractions and reduced basal upper esophageal sphincter pressure without further relaxation on swallowing (Fig. 273-3). Patients with myasthenia gravis (Chap. 366) and polymyositis (Chap. 369) respond to treatment. Dysphagia resulting from a cerebrovascular accident improves with time, although often not completely. Treatment consists of maneuvers to reduce pharyngeal stasis and enhance airway protection under the direction of a trained swallow therapist. Feeding by a nasogastric tube or an endoscopically placed gastrostomy tube may be necessary for nutritional support; however, these maneuvers do not provide protection against aspiration of salivary secretions. Cricopharyngeal myotomy is sometimes performed, but its usefulness is unproven. Extensive operative procedures to prevent aspiration are rarely needed. Death is often due to pulmonary complications.

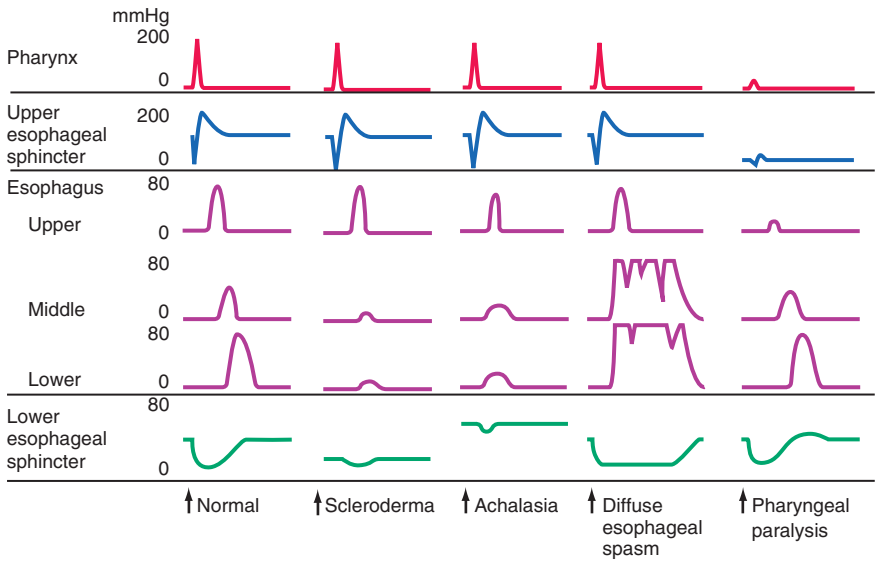

FIGURE 273-3 Motility patterns in selected esophageal and pharyngeal disorders. In normal individuals, the upper and lower esophageal sphincters (UES and LES) appear as zones of high pressure. With a swallow (indicated by ↑), pressure in the sphincters falls and a contraction wave starts in the pharynx and progresses down the esophagus. In scleroderma, the lower part of the esophagus (smooth muscle) shows a reduced amplitude of contractions, which may be peristaltic or simultaneous in onset, and hypotension of the LES. In achalasia, the lower part of the esophagus shows contractions that are reduced in amplitude and simultaneous in onset. In contrast to scleroderma, the LES in achalasia is hypertensive and fails to relax in response to a swallow. In diffuse esophageal spasm, the lower part of the esophagus shows simultaneous-onset, large-amplitude, prolonged, repetitive contractions. In pharyngeal paralysis, the smooth-muscle part of the esophagus is normal. The skeletal muscle part shows a reduced amplitude of contractions. The UES is hypotensive and may not relax normally on swallowing due to associated weakness of the suprahyoid muscles.

Cricopharyngeal Bar Failure of the cricopharyngeus to relax on swallowing appears as a prominent bar on the posterior wall of the pharynx on barium swallow (Fig. 273-1 panel 2). A transient cricopharyngeal bar is seen in up to 5% of individuals without dysphagia undergoing upper gastrointestinal studies; it can be produced in normal individuals during a Valsalva maneuver. A persistent cricopharyngeal bar may be caused by fibrosis in the cricopharyngeus. Some of these patients complain of food sticking in their throats. Cricopharyngeal myotomy may be helpful but is contraindicated in the presence of gastroesophageal reflux because it may lead to pharyngeal and pulmonary aspiration.

Globus Pharyngeus A sensation of a constant lump in the throat, but no difficulty in swallowing, occurs especially in individuals with emotional disorders, particularly women. Results of barium studies and manometry are normal. Treatment consists primarily of reassurance. Some patients with globus pharyngeus have associated reflux esophagitis, and they may respond to treatment of the esophagitis.

SMOOTH MUSCLE ■ Achalasia Achalasia is a motor disorder of the esophageal smooth muscle in which the LES does not relax normally with swallowing, and the esophageal body undergoes nonperistaltic contractions.

PATHOPHYSIOLOGY The underlying abnormality is the loss of intramural neurons. Inhibitory neurons containing VIP and nitric oxide synthase are predominantly involved, but cholinergic neurons are also affected in advanced disease. Primary idiopathic achalasia accounts for most of the patients seen in the United States. Secondary achalasia may be caused by gastric carcinoma that infiltrates the esophagus, lymphoma, Chagas' disease, certain viral infections, eosinophilic gastroenteritis, and neurodegenerative disorders.

CLINICAL FEATURES Achalasia affects patients of all ages and both sexes. Dysphagia, chest pain, and regurgitation are the main symptoms. Dysphagia appears early, occurs with both liquids and solids, and is worsened by emotional stress and hurried eating. Various maneuvers designed to increase intraesophageal pressure, including the Valsalva maneuver, may aid the passage of the bolus into the stomach. Regurgitation and pulmonary aspiration occur because of retention of large volumes of saliva and ingested food in the esophagus. Patients may complain of difficulty belching. The presence of gastroesophageal reflux argues against achalasia; in patients with long-standing heartburn, cessation of heartburn and appearance of dysphagia suggest development of achalasia on top of reflux esophagitis. The course is usually chronic, with progressive dysphagia and weight loss over months to years. Achalasia associated with carcinoma is characterized by severe weight loss and a rapid downhill course if untreated.

DIAGNOSIS A chest x-ray shows absence of the gastric air bubble and sometimes a tubular mediastinal mass beside the aorta. An air-fluid level in the mediastinum in the upright position represents retained food in the esophagus. Barium swallow shows esophageal dilation, and in advanced cases the esophagus may become sigmoid. On fluoroscopy, normal peristalsis is lost in the lower two-thirds of the esophagus. The terminal part of the esophagus shows a persistent beaklike narrowing representing the nonrelaxing LES (Fig. 273-1 panel 4).

Manometry shows the basal LES pressure to be normal or elevated, and swallow-induced relaxation either does not occur or is reduced in degree, duration, and consistency. The esophageal body shows an elevated resting pressure. In response to swallows, primary peristaltic waves are replaced by simultaneous-onset contractions (Fig. 273-3). These contractions may be of poor amplitude (classic achalasia) or of large amplitude and long duration (vigorous achalasia). Cholecystokinin (CCK), which normally causes a fall in the sphincter pressure, paradoxically causes contraction of the LES (the CCK test). This paradoxical response occurs because, in achalasia, the neurally transmitted inhibitory effect of CCK is absent owing to the loss of inhibitory neurons. Endoscopy is helpful in excluding the secondary causes of achalasia, particularly gastric carcinoma.

℞ TREATMENT

Treatment with soft foods, sedatives, and anticholinergic drugs is usually unsatisfactory. Nitrates and calcium channel blockers provide short-term benefit, but their use may be limited by side effects. Nitro-

glycerin, 0.3 to 0.6 mg, is used sublingually before meals and as needed for chest pain. Isosorbide dinitrate, 2.5 to 5 mg sublingually or 10 to 20 mg orally, is used before meals. Nitrates are associated with headache and postural hypotension. The calcium channel blocker nifedipine, 10 to 20 mg orally or sublingually before meals, is also effective. Endoscopic intrasphincteric injection of botulinum toxin is effective over a short period in some patients. Repeated injections may lead to fibrosis, complicating further operative therapy. Botulinum toxin acts by blocking cholinergic excitatory nerves in the sphincter. Balloon dilatation reduces the basal LES pressure by tearing muscle fibers. In experienced hands, this technique is effective in ~85% of patients. Perforation and bleeding are potential complications. Heller's extramucosal myotomy of the LES, in which the circular muscle layer is incised, is equally effective. Laparoscopic myotomy is the procedure of choice. Reflux esophagitis and peptic stricture may follow successful treatment (more often with myotomy than with balloon dilatation).

Diffuse Esophageal Spasm and Related Motor Disorders These disorders present with clinical symptoms of chest pain and dysphagia and are recognized by their manometric features. In pure form, they all show normal relaxation to swallows. Diffuse esophageal spasm is characterized by nonperistaltic contractions, usually of large amplitude and long duration. An esophageal motility pattern showing hypertensive but peristaltic contractions has been called "nutcracker esophagus."

PATHOPHYSIOLOGY Nonperistaltic contractions are due to dysfunction of inhibitory nerves. Histopathologic studies show patchy neural degeneration localized to nerve processes, rather than the prominent degeneration of nerve cell bodies seen in achalasia. Diffuse esophageal spasm may progress to achalasia. Hypertensive peristaltic contractions and hypertensive or hypercontracting LES may represent cholinergic or myogenic hyperactivity.

CLINICAL FEATURES Diffuse spasm and related motor disorders (hypertensive peristaltic contraction, hypertensive LES, and hypercontracting LES) cannot be distinguished clinically. They all present with chest pain, dysphagia, or both. Chest pain is particularly marked in patients with esophageal contractions of large amplitude and long duration. Chest pain usually occurs at rest but may be brought on by swallowing or by emotional stress. The pain is retrosternal; it may radiate to the back, the sides of the chest, both arms, or the sides of the jaw and may last from a few seconds to several minutes. Pain may be acute and severe, mimicking the pain of myocardial ischemia. Dysphagia for solids and liquids may occur with or without chest pain and is correlated with simultaneous-onset contractions.

Diffuse esophageal spasm and related esophageal motor disorders must be differentiated from other causes of chest pain, particularly ischemic heart disease with atypical angina. A complete cardiac workup should be done before a noncardiac etiology is considered seriously. The presence of dysphagia in association with pain should point to the esophagus as the site of disease. Esophageal motility disorders are an uncommon cause of noncardiac chest pain, which is more commonly due to reflux esophagitis or visceral hypersensitivity.

DIAGNOSIS In diffuse esophageal spasm, barium swallow shows that normal sequential peristalsis below the aortic arch is replaced by uncoordinated simultaneous contractions that produce the appearance of curling or multiple ripples in the wall, sacculations, and pseudodiverticula—the "corkscrew" esophagus (Fig. 273-1 panel 3). Sometimes an esophageal contraction obliterates the lumen, and barium is pushed away in both directions. The barium swallow is frequently normal in diffuse esophageal spasm and mostly normal in the related disorders.

Diffuse esophageal spasm (Fig. 273-3) and related motor disorders are manometric diagnoses. Because these abnormalities may be episodic, the results of manometry may be normal at the time of the study. Several techniques are used to provoke esophageal spasm. Cold swallows produce chest pain but do not produce spasm on manometric studies. Solid boluses and pharmacologic agents, particularly edrophonium, induce both chest pain and motor abnormalities. However, correlation between induction of pain and motility changes is poor. The usefulness of pharmacologic provocative tests is limited.

Rx TREATMENT

Anticholinergics are usually of limited value. Agents that relax smooth muscle, such as sublingual nitroglycerin (0.3 to 0.6 mg) or longer-acting agents such as isosorbide dinitrate (10 to 30 mg orally before meals) and nifedipine (10 to 20 mg orally before meals), are helpful. Sublingual forms of these agents can also be used. Reassurance and tranquilizers are helpful in allaying apprehension.

SCLERODERMA ESOPHAGUS The esophageal lesions in systemic sclerosis consist of atrophy of smooth muscle, manifested by weakness in the lower two-thirds of the esophageal body and incompetence of the LES. The esophageal wall is thin and atrophic and may exhibit areas of patchy fibrosis. Patients usually present with dysphagia to solids. Liquids may cause dysphagia when the patient is recumbent. These patients usually also complain of heartburn, regurgitation, and other symptoms of gastroesophageal reflux disease (GERD). Barium swallow shows dilation and loss of peristaltic contractions in the middle and distal portions of the esophagus. The LES is patulous, and gastroesophageal reflux may occur freely (Fig. 273-1 panel 6). Mucosal changes due to esophageal ulceration and esophageal stricture may be present. Motility studies show a marked reduction in the amplitude of smooth-muscle contractions, which may be peristaltic or nonperistaltic. The resting pressure of the LES is subnormal, but sphincter relaxation is normal (Fig. 273-3). Similar esophageal motor abnormalities are found in other collagen vascular diseases and in Raynaud's syndrome alone. Dietary adjustments with the use of soft foods are helpful in management. GERD and its complications should be treated aggressively.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is one of the most prevalent gastrointestinal disorders. Population-based studies show that up to 15% of individuals have heartburn and/or regurgitation at least once a week and 7% have symptoms daily. Symptoms are caused by backflow of gastric acid and other gastric contents into the esophagus due to incompetent barriers at the gastroesophageal junction.

Pathophysiology The normal antireflux mechanisms consist of the LES, the crural diaphragm, and the anatomical location of the gastroesophageal junction below the diaphragmatic hiatus. Reflux occurs only when the gradient of pressure between the LES and the stomach is lost. It can be caused by a sustained or transient decrease in LES tone. A sustained hypotension of the LES may be due to muscle weakness that is often without apparent cause. Secondary causes of sustained LES incompetence include scleroderma-like diseases, myopathy associated with chronic intestinal pseudo-obstruction, pregnancy, smoking, anticholinergic drugs, smooth-muscle relaxants [β-adrenergic agents, aminophylline, nitrates, calcium channel blockers, phosphodiesterase inhibitors that increase cyclic AMP or cyclic GMP (including sildenafil)], surgical damage to the LES, and esophagitis. tLESR without associated esophageal contraction is due to a vagal reflex in which LES relaxation is elicited by gastric distention. Increased episodes of tLESR are associated with GERD. A similar reflex operates during belching. Apart from incompetent barriers, gastric contents are most likely to reflux (1) when gastric volume is increased (after meals, in pyloric obstruction, in gastric stasis, during acid hypersecretion states), (2) when gastric contents are near the gastroesophageal junction (in recumbency, bending down, hiatal hernia), and (3) when gastric pressure is increased (obesity, pregnancy, ascites, tight clothes). Incompetence of the diaphragmatic crural muscle, which surrounds the esophageal hiatus in the diaphragm and functions as an external LES, also predisposes to GERD.

Exposure of the esophagus to refluxed acid correlates with potential for mucosal damage. Exposure depends on the amount of refluxed

material per episode, frequency of episodes, and rate of clearing the esophagus by gravity and peristaltic contractions. When peristaltic contractions are impaired, esophageal clearance is impaired. Acid refluxed into the esophagus is neutralized by saliva. Thus, impaired salivary secretion also increases esophageal exposure time. If the refluxed material extends to the cervical esophagus and breaches the upper sphincter, it can enter the pharynx, larynx, and trachea.

Reflux esophagitis is a complication of reflux and develops when mucosal defenses are unable to counteract the damage done by acid, pepsin, and bile. *Mild esophagitis* involves microscopic changes of mucosal infiltration with granulocytes or eosinophils, hyperplasia of basal cells, and elongation of dermal pegs. In nonerosive reflux disease, endoscopic appearance may be normal or show mild erythema. *Erosive esophagitis* shows endoscopically apparent mucosal damage, redness, friability, bleeding, superficial linear ulcers, and exudates. Histology shows polymorphic infiltrates and granulation tissue. *Peptic stricture* results from fibrosis that causes luminal constriction. These strictures occur in ~10% of patients with untreated GERD. Short strictures caused by spontaneous reflux are usually 1 to 3 cm long and are present in the distal esophagus near the squamocolumnar junction (Fig. 273-2 panel 6). Long, tubular peptic strictures can result from persistent vomiting or prolonged nasogastric intubation. Erosive esophagitis may heal by intestinal metaplasia (*Barrett's esophagus*), which is a risk factor for adenocarcinoma.

Clinical Features Regurgitation of sour material in the mouth and heartburn are the characteristic symptoms of GERD. Reflux into the pharynx, larynx, and tracheobronchial tree can cause chronic cough, bronchoconstriction, pharyngitis, laryngitis, bronchitis, or pneumonia. Morning hoarseness may be noted. Recurrent pulmonary aspiration can cause aspiration pneumonia, pulmonary fibrosis, or chronic asthma. Heartburn is produced by the contact of refluxed material with the sensitized or ulcerated esophageal mucosa. Angina-like or atypical chest pain occurs in some patients, while others experience no heartburn or chest pain. Persistent dysphagia suggests development of a peptic stricture. Most patients with peptic stricture have a history of several years of heartburn preceding dysphagia. However, in one-third of patients, dysphagia is the presenting symptom. Rapidly progressive dysphagia and weight loss may indicate the development of adenocarcinoma in Barrett's esophagus. Bleeding occurs due to mucosal erosions or Barrett's ulcer. Many patients with GERD remain asymptomatic or self-treated and do not seek attention until severe complications occur.

Diagnosis The diagnosis is easily made by history alone. Diagnostic studies are indicated in patients with persistent symptoms or complications or those who do not respond to therapy. The diagnostic approach to GERD can be divided into three categories:

1. documentation of mucosal injury,
2. documentation and quantitation of reflux, and
3. definition of the pathophysiology.

Mucosal damage is documented by the use of barium swallow, esophagoscopy, and mucosal biopsy. The results of barium swallow are usually normal in uncomplicated esophagitis but may reveal a stricture or ulcer. A high esophageal peptic stricture, a deep ulcer, or adenocarcinoma suggest Barrett's esophagus. Esophagoscopy may reveal the presence of erosive esophagitis, distal peptic stricture, or columnar cell–lined lower esophagus with or without a proximally located peptic stricture, ulcer, or adenocarcinoma. Results of esophagoscopy are normal in patients with nonerosive esophagitis; in such patients, mucosal biopsies and the Bernstein test are helpful. The mucosal biopsies should be performed at least 5 cm above the LES, as the esophageal mucosal changes of chronic esophagitis are quite frequent in the most distal esophagus in otherwise normal individuals. The Bernstein test involves the infusion of solutions of 0.1 *N* HCl or normal saline into the esophagus. In patients with symptomatic esophagitis, infusion of acid, but not of saline, reproduces the symptoms of heartburn. Infusion of acid in normal individuals usually produces no symptoms. Supraesophageal manifestations are diagnosed by careful otolaryngologic exam.

A therapeutic trial with a proton pump inhibitor (PPI) (such as omeprazole, 40 mg bid) for 1 week provides strong support for the diagnosis of GERD.

Documentation and quantitation of reflux, when necessary, can be done by ambulatory long-term (24-h) esophageal pH recording. For evaluation of pharyngeal reflux, a system of recording simultaneously from pharyngeal and esophageal sites may be useful. The pH recordings are helpful only in the evaluation of acid reflux. Documentation of reflux is necessary only when the role of reflux in the symptom complex is unclear, particularly in evaluation of supraesophageal symptoms and chest pain without endoscopic evidence of esophagitis.

Definition of pathophysiologic factors in GERD is sometimes indicated for management decisions such as antireflux surgery. Esophageal motility studies may provide useful quantitative information on the competence of the LES and on esophageal motor function.

TREATMENT

The goals of treatment are to provide symptom relief, heal erosive esophagitis, and prevent complications. The management of mild cases includes weight reduction, sleeping with the head of the bed elevated by about 4 to 6 in. with blocks, and elimination of factors that increase abdominal pressure. Patients should not smoke and should avoid consuming fatty foods, coffee, chocolate, alcohol, mint, orange juice, and certain medications (such as anticholinergic drugs, calcium channel blockers, and other smooth-muscle relaxants). They should also avoid ingesting large quantities of fluids with meals. In mild cases, lifestyle changes and over-the-counter antisecretory agents may be adequate. H_2 receptor blocking agents (cimetidine, 300 mg; ranitidine, 150 mg bid; famotidine, 20 mg bid; nizatidine, 150 mg bid) are effective in symptom relief. PPIs are more effective in symptom relief and more commonly used.

The PPIs are comparably effective: omeprazole (20 mg/d), lansoprazole (30 mg/d), pantoprazole (40 mg/d), esomeprazole (40 mg/d), or rabeprazole (20 mg/d) for 8 weeks can heal erosive esophagitis in up to 90% of patients. The drug is taken 15 to 30 min before breakfast and can be maintained indefinitely. Refractory patients can double the dose and administer it twice a day before meals. Side effects are minimal. Aggressive acid suppression causes hypergastrinemia but does not increase the risk for carcinoid tumors or gastrinomas. Vitamin B_{12} absorption is compromised by the treatment. Patients who have Barrett's esophagus with concomitant esophagitis should be similarly treated; however, acid suppression does not lead to resolution of the Barrett's metaplasia or cancer prevention. Patients who have an associated peptic stricture are treated with dilators to relieve dysphagia, and such patients are provided with vigorous treatment for reflux. Esophagoscopy should be performed in patients suspected of complications such as bleeding, stricture, or development of cancer.

Antireflux surgery, in which the gastric fundus is wrapped around the esophagus (fundoplication), increases the LES pressure and should be considered as an alternative for patients who require long-term, high-dose PPIs. Laparoscopic fundoplication is the surgery of choice. Ideal candidates for fundoplication are those in whom motility studies show persistently inadequate LES pressure but normal peristaltic contractions in the esophageal body.

Patients with alkaline esophagitis are treated with general antireflux measures and neutralization of bile salts with cholestyramine, aluminum hydroxide, or sucralfate. Sucralfate is particularly useful in these cases, as it also serves as a mucosal protector.

BARRETT'S ESOPHAGUS The metaplasia of esophageal squamous epithelium to columnar epithelium (Barrett's esophagus) is a complication of severe reflux esophagitis, and it is a risk factor for esophageal adenocarcinoma (Chap. 77). Metaplastic columnar epithelium develops during healing of erosive esophagitis with continued acid reflux

because columnar epithelium is more resistant to acid-pepsin damage than is squamous epithelium. The metaplastic epithelium is a mosaic of different epithelial types including goblet cells and columnar cells that have features of both secretory and absorptive cells (incomplete or type III metaplasia). Barrett's esophagus is arbitrarily divided into long-segment (>2–3 cm) or short-segment (<2–3 cm) groups; long-segment disease is present in 0.5% of the population and short-segment disease may occur in up to 15%.

Barrett's epithelium progresses through a dysplastic stage before developing into adenocarcinoma. The rate of cancer development is 0.5% per year; those with long-segment disease have a risk of developing esophageal cancer that is 30 to 125 times the risk of the general population. Barrett's esophagus can also lead to chronic peptic ulcer of the esophagus with high (midesophageal) and long strictures.

Given the natural history, erosive esophagitis should be aggressively treated. The prevalence of intestinal metaplasia is estimated at 4 to 10% of patients with significant heartburn. Barrett's esophagus is more common in men, particularly white men, and prevalence increases with age. A one-time esophagoscopy is recommended in patients with persistent GERD symptoms at age 50 to identify patients with Barrett's esophagus. Established metaplasia does not regress with treatment; thus, acid suppression and fundoplication are indicated only when active esophagitis is also present.

The need and frequency of surveillance endoscopies in patients with established Barrett's esophagus are debated. The risk of developing esophageal adenocarcinoma is related to the length of involved esophageal mucosa. People with short segments of Barrett's esophagus (distal 2 to 3 cm) account for up to 25% of unselected patients undergoing endoscopy with or without GERD symptoms and appear to be at low risk. They are not routinely surveyed. However, those with long-segment Barrett's esophagus are advised to have endoscopic surveillance at 1-year intervals for 2 years and then every 2 to 3 years. The frequency is increased if dysplasia is detected independent of the length of the metaplasia. Optical methods of recognizing dysplasia during the endoscopy (laser-induced fluorescence spectroscopy, optical coherence tomography) are being developed. Once high-grade dysplasia is detected, treatment of choice is esophagectomy of the Barrett's segment. Photodynamic laser or thermocoagulative mucosal ablation and endoscopic mucosal resection are being evaluated as alternatives.

INFLAMMATORY DISORDERS

INFECTIOUS ESOPHAGITIS Infectious esophagitis can be due to viral, bacterial, fungal, or parasitic organisms. In severely immunocompromised patients, multiple organisms may coexist.

Viral Esophagitis *Herpes simplex virus* (HSV) type 1 occasionally causes esophagitis in immunocompetent individuals, but either HSV type 1 or HSV type 2 may afflict patients who are immunosuppressed (Chap. 163). Patients complain of an acute onset of chest pain, odynophagia, and dysphagia. Bleeding may occur in severe cases; tracheoesophageal fistula and food impaction have been noted. Systemic manifestations such as nausea, vomiting, fever, chills, and mild leukocytosis may be present. Herpetic vesicles on the nose and lips may provide a clue to the diagnosis. Barium swallow is inadequate to detect early lesions and cannot reliably distinguish HSV infection from other types of infections. Endoscopy shows vesicles and small, discrete, punched-out ("volcano-like") superficial ulcerations with or without a fibrinous exudate. In later stages, a diffuse erosive esophagitis develops from enlargement and coalescence of the ulcers. Mucosal cells from a biopsy sample taken at the edge of an ulcer or from a cytologic smear show ballooning degeneration, ground-glass changes in the nuclei with eosinophilic intranuclear inclusions (Cowdry type A), and giant cell formation on routine stains. Culture for HSV becomes positive within days and is helpful in diagnosis and to identify acyclovir-resistant virus. Acyclovir (400 mg 5 times a day for 14 to 21 days) is effective. In patients with severe odynophagia, intravenous acyclovir, 5 mg/kg every 8 h for 7 to 14 days is used. Symptoms usually resolve in 1 week, but large ulcerations may take longer to heal. Foscarnet (90 mg/kg intravenously bid for 2 to 4 weeks) is used if resistance to acyclovir occurs.

Varicella-zoster virus (VZV) (Chap. 164) sometimes produces esophagitis in children with chickenpox and adults with herpes zoster. Esophageal VZV also can be the source of disseminated VZV infection without skin involvement. In an immunocompromised host, VZV esophagitis causes vesicles and confluent ulcers and usually resolves spontaneously, but it may cause necrotizing esophagitis in a severely compromised host. On routine histologic examination of mucosal biopsy samples or cytology specimens, VZV is difficult to distinguish from HSV, but the distinction can be made immunohistologically or by culture. Acyclovir reduces the duration of symptoms in VZV esophagitis.

Cytomegalovirus (CMV) infections (Chap. 166) occur only in immunocompromised patients. CMV is usually activated from a latent stage or may be acquired from blood product transfusions. CMV lesions initially appear as serpiginous ulcers in an otherwise normal mucosa. These may coalesce to form giant ulcers, particularly in the distal esophagus.

Patients present with odynophagia, persistent and focal chest pain, hematemesis, nausea, and vomiting. Diagnosis requires endoscopy and biopsies of the ulcer. Mucosal brushings are not useful. Routine histologic examination shows intranuclear and small intracytoplasmic inclusions in large fibroblasts and endothelial cells. Immunohistology with monoclonal antibodies to CMV and in situ hybridization of CMV DNA on centrifugation culture and are useful for early diagnosis. Ganciclovir, 5 mg/kg every 12 h intravenously, is the treatment of choice. Valganciclovir (900 mg bid) is an oral formulation of ganciclovir. Foscarnet (90 mg/kg every 12 h intravenously) is used in resistant cases. Therapy is continued until healing occurs, which may take 2 to 4 weeks.

HIV (Chap. 173) may be associated with a self-limited syndrome of acute esophageal ulceration associated with oral ulcers and a maculopapular skin rash, which occurs at the time of HIV seroconversion. Some patients with advanced disease have deep, persistent esophageal ulcers requiring treatment with oral glucocorticoids or thalidomide. Some ulcers respond to local steroid injection.

Bacterial and Fungal Esophagitis *Bacterial esophagitis* is unusual, but esophagitis caused by *Lactobacillus* and β-hemolytic streptococci can occur in the immunocompromised host. In patients with profound granulocytopenia and patients with cancer, bacterial esophagitis is often overlooked because it is commonly present with other organisms, including viruses and fungi. In patients with AIDS, infection with *Cryptosporidium* or *Pneumocystis carinii* may cause nonspecific inflammation, and *Mycobacterium tuberculosis* infection may cause deep ulcerations of the distal esophagus. Very rarely, other types of fungi may cause esophagitis.

CANDIDA ESOPHAGITIS

Candida species are normal commensals in the throat but become pathogenic and produce esophagitis in immunodeficiency states. Candida esophagitis can occur without any predisposing factors. Patients may be asymptomatic or complain of odynophagia and dysphagia. Oral thrush or other evidence of mucocutaneous candidiasis may be absent. Rarely, Candida esophagitis is complicated by esophageal bleeding, perforation, and stricture or by systemic invasion. Barium swallow may be normal or show multiple nodular filling defects of various sizes (Fig. 273-2 panel 4). Large nodular defects may resemble grape clusters. Endoscopy shows small, yellow-white raised plaques with surrounding erythema in mild disease. Confluent linear and nodular plaques reflect extensive disease. Diagnosis is made by demonstration of yeast or hyphal forms in plaque smears and exudate stained with periodic acid–Schiff or Gomori silver stains. Histologic examination is often negative. Culture is not useful in diagnosis but may

define the species and the drug sensitivities of the yeast; *Candida albicans* is most common (Chap. 187). Empirical therapy with fluconazole for 7 days is appropriate for suspected cases. Oral fluconazole (200 mg on the first day, followed by 100 mg daily) is the preferred treatment. Patients refractory to fluconazole often respond to itraconazole. Patients who respond poorly or cannot swallow oral medications are treated with amphotericin B (10 to 15 mg as an intravenous infusion for 6 h daily to a total dose of 300 to 500 mg) or intravenous fluconazole. Nystatin oral suspension (100,000 units per mL) in doses of 10 to 20 mL every 6 h is effective for oral thrush. In resistant cases, amphotericin lozenges are used for 7 to 10 days followed by nystatin or fluconazole for as long as the host resistance remains low.

OTHER TYPES OF ESOPHAGITIS *Radiation esophagitis* is a common occurrence during radiation treatment for thoracic cancers. The frequency and severity of esophagitis increase with the amount of radiation delivered and may be enhanced by radiosensitizing drugs like doxorubicin, bleomycin, cyclophosphamide, and cisplatin. Dysphagia and odynophagia may last several weeks to several months after therapy. The esophageal mucosa becomes erythematous, edematous, and friable. Superficial erosions coalesce to form larger superficial ulcers. Submucosal fibrosis and degenerative changes in the blood vessels, muscles, and myenteric neurons may occur. The treatment is relief of pain with viscous lidocaine during the acute phase; indomethacin treatment may reduce radiation damage. Esophageal stricture may develop.

Corrosive esophagitis is caused by the ingestion of caustic agents, such as strong alkali or acid. Severe corrosive injury may lead to esophageal perforation, bleeding, and death. Glucocorticoids are not useful in acute corrosive esophagitis. Healing is usually associated with stricture formation. Caustic strictures are usually long and rigid (Fig. 273-2 panel 5) and generally require dilatation with dilators passed over a guidewire through the stricture. *Pill-induced esophagitis* is associated with the ingestion of certain types of pills and occurs most often in bedridden patients. Antibiotics such as doxycycline, tetracycline, oxytetracycline, minocycline, penicillin, and clindamycin account for more than half the cases. Nonsteroidal anti-inflammatory agents such as aspirin, indomethacin, and ibuprofen may cause injury. Other commonly prescribed pills that cause esophageal injury include potassium chloride, ferrous sulfate or succinate, quinidine, alprenolol, theophylline, ascorbic acid, and pinaverium bromide. Bisphosphonates, particularly alendronate and pamidronate, are more common offenders. Pill esophagitis can be prevented by avoiding the offending agents or by having patients take pills in the upright position and wash them down with copious amounts of fluids.

Sclerotherapy for bleeding esophageal varices usually produces transient retrosternal chest pain and dysphagia; esophageal ulcer, stricture, hematoma, or perforation may occur. Variceal banding causes similar complications but less frequently. *Esophagitis* associated with mucocutaneous and systemic diseases is usually associated with blister and bulla formation, epithelial desquamation, and thin, weblike, or dense esophageal strictures. Pemphigus vulgaris and bullous pemphigoid form intraepithelial and subepithelial bullae, respectively, and can be distinguished by specific immunohistology; both are characterized by sloughing of epithelium or the presence of esophageal casts. Glucocorticoid treatment is usually effective. Cicatricial pemphigoid, Stevens-Johnson syndrome, and toxic epidermolysis bullosa can produce esophageal bullous lesions and strictures requiring gentle dilatation. Graft-versus-host disease occurs in patients who have received allogeneic bone marrow transplants and is associated with generalized desquamation and esophageal strictures. Behçet's disease and eosinophilic gastroenteritis may involve the esophagus and may respond to glucocorticoid therapy. An erosive lichen planus also can involve the esophagus. Crohn's disease may cause inflammatory strictures, sinus tracts, filiform polyps, and fistulas in the esophagus.

OTHER ESOPHAGEAL DISORDERS

DIVERTICULA Diverticula are outpouchings of the wall of the esophagus. A *Zenker's diverticulum* appears in the natural zone of weakness in the posterior hypopharyngeal wall (Killian's triangle) and causes halitosis and regurgitation of saliva and food particles consumed several days previously. When it becomes large and filled with food, such a diverticulum can compress the esophagus and cause dysphagia or complete obstruction. Nasogastric intubation and endoscopy should be performed with utmost care in these patients, since they may cause perforation of the diverticulum. A *midesophageal diverticulum* may be caused by traction from old adhesions or by propulsion associated with esophageal motor abnormalities. An *epiphrenic diverticulum* may be associated with achalasia. Small or medium-sized diverticula and midesophageal and epiphrenic diverticula are usually asymptomatic. *Diffuse intramural diverticulosis* of the esophagus is due to dilation of the deep esophageal glands and may lead to chronic candidiasis or to the development of a stricture high up in the esophagus. These patients may present with dysphagia. Symptomatic Zenker's diverticula are treated by cricopharyngeal myotomy with or without diverticulectomy. Large symptomatic esophageal diverticula are removed surgically. When they are associated with motor abnormalities, distal myotomy is performed. Strictures associated with diffuse intramural diverticulosis are treated with rubber dilators.

WEBS AND RINGS Weblike constrictions of the esophagus are usually congenital or inflammatory in origin. Asymptomatic hypopharyngeal webs are demonstrated in $<10\%$ of normal individuals. When concentric, they cause intermittent dysphagia to solids. The combination of symptomatic hypopharyngeal webs and iron-deficiency anemia in middle-aged women constitutes *Plummer-Vinson syndrome*. The clinical importance of this syndrome is uncertain. Midesophageal webs are rare. A *lower esophageal mucosal ring* (Schatzki ring) is a thin, weblike constriction located at the squamocolumnar mucosal junction at or near the border of the LES (Fig. 273-2 panel 7). It invariably produces dysphagia when the lumen diameter is <1.3 cm. Dysphagia to solids is the only symptom, and it is usually episodic. Asymptomatic rings may be present in $\sim 10\%$ of normal individuals. A lower esophageal ring is one of the common causes of dysphagia. Symptomatic webs and mucosal lower esophageal rings are easily treated by dilatation. A *lower esophageal muscular ring* (contractile ring) is located proximal to the site of mucosal rings and may represent an abnormal uppermost segment of the LES. These rings can be recognized by the fact that they are not constant in size and shape. They also may cause dysphagia and should be differentiated from peptic strictures, achalasia, and lower esophageal mucosal rings. Muscular rings do not respond well to dilatation.

HIATAL HERNIA A *hiatal hernia* is a herniation of part of the stomach into the thoracic cavity through the esophageal hiatus in the diaphragm. A *sliding hiatal hernia* is one in which the gastroesophageal junction and fundus of the stomach slide upward. A sliding hernia may result from weakening of the anchors of the gastroesophageal junction to the diaphragm, from longitudinal contraction of the esophagus, or from increased intra-abdominal pressure. Small sliding hernias can be demonstrated commonly during barium studies if intra-abdominal pressure is increased. Incidence increases with age; in individuals in the sixth decade of life, the prevalence of such hernias is $\sim 60\%$. Small sliding hiatal hernias alone probably produce no symptoms but can contribute to reflux esophagitis. A *paraesophageal hernia* is one in which the esophagogastric junction remains fixed in its normal location and a pouch of stomach is herniated beside the gastroesophageal junction through the esophageal hiatus. A paraesophageal or mixed paraesophageal and sliding hernia may become incarcerated and strangulate, leading to acute chest pain, dysphagia, and a mediastinal mass and requiring surgery. A herniated gastric pouch may cause dysphagia, develop gastritis, or ulcerate, causing chronic blood loss. Large paraesophageal hernias should be surgically repaired.

MECHANICAL TRAUMA *Esophageal rupture* may be caused by (1) iatrogenic damage from instrumentation of the esophagus or external trauma, (2) increased intraesophageal pressure associated with forceful

vomiting or retching (*spontaneous rupture* or *Boerhaave's syndrome*), or (3) diseases of the esophagus such as corrosive esophagitis, esophageal ulcer, and neoplasm. The site of perforation depends on the cause. Instrumental perforation usually occurs in the pharynx or lower esophagus, just above the diaphragm in the posterolateral wall. Esophageal perforation causes severe retrosternal chest pain, which may be worsened by swallowing and breathing. Free air enters the mediastinum and spreads to neighboring structures, causing palpable subcutaneous emphysema in the neck, mediastinal crackling sounds on auscultation, and pneumothorax. With time, secondary infection supervenes, and mediastinal abscess may develop. Esophageal perforation associated with vomiting usually deposits gastric contents in the mediastinum and causes severe mediastinal complications. By contrast, instrumental perforation may be clinically mild and free of severe complications. Spontaneous rupture of the esophagus may mimic myocardial infarction, pancreatitis, or rupture of an abdominal viscus. Symptoms of chest pain may be mild, particularly in the elderly. Mediastinal emphysema may develop late. An x-ray of the chest shows abnormalities in most patients, but computed tomography (CT) of the chest is more sensitive in detecting mediastinal air. Fluid from pleural effusions may have a high content of (salivary) amylase. The diagnosis is confirmed by swallow of radiopaque contrast material. Gastrografin is used initially, and if no leak is found, a small amount of thin barium is used to confirm the diagnosis. Treatment includes esophageal and gastric suction and parenteral broad-spectrum antibiotics. Surgical drainage and repair of the laceration should be performed as soon as possible. In patients with terminal carcinoma, surgical repair may not be feasible, and patients with minor instrumental perforation can be treated conservatively. Extensive corrosive damage may require esophageal diversion and excision of the damaged portion.

Mucosal Tear (Mallory-Weiss Syndrome) This tear is usually caused by vomiting, retching, or vigorous coughing. The tear usually involves the gastric mucosa near the squamocolumnar mucosal junction. Patients present with upper gastrointestinal bleeding, which may be severe. In most patients bleeding ceases spontaneously; continued bleeding may respond to vasopressin therapy or angiographic embolization. Surgery is rarely needed.

Intramural Hematoma Emetogenic injury, particularly in patients with bleeding abnormalities, can cause bleeding between the mucosal and muscle layers of the esophagus. The patients develop sudden dysphagia. The diagnosis is made by barium swallow and CT. Resolution is usually spontaneous.

FOREIGN BODIES Foreign bodies may lodge in the cervical esophagus just beyond the UES, near the aortic arch, or above the LES. Impaction of a bolus of food, particularly a piece of meat or bread, may occur when the esophageal lumen is narrowed due to stricture, carcinoma, or a lower esophageal ring. Acute impaction causes a complete inability to swallow and severe chest pain. Both foreign bodies and food boluses may be removed endoscopically. Use of a meat tenderizer to facilitate passage of a meat bolus is discouraged because of potential esophageal perforation and aspiration pneumonia.

274 PEPTIC ULCER DISEASE AND RELATED DISORDERS

John Del Valle

PEPTIC ULCER DISEASE

Burning epigastric pain exacerbated by fasting and improved with meals is a symptom complex associated with peptic ulcer disease (PUD). An *ulcer* is defined as disruption of the mucosal integrity of the stomach and/or duodenum leading to a local defect or excavation due to active inflammation. Ulcers occur within the stomach and/or duodenum and are often chronic in nature. Acid peptic disorders are very common in the United States, with 4 million individuals (new cases and recurrences) affected per year. Lifetime prevalence of PUD in the United States is ~12% in men and 10% in women. Moreover, an estimated 15,000 deaths per year occur as a consequence of complicated PUD. The financial impact of these common disorders has been substantial, with an estimated burden on direct and indirect health care costs of ~$10 billion per year in the United States.

GASTRIC PHYSIOLOGY Despite the constant attack on the gastroduodenal mucosa by a host of noxious agents (acid, pepsin, bile acids, pancreatic enzymes, drugs, and bacteria), integrity is maintained by an intricate system that provides mucosal defense and repair.

Gastric Anatomy The gastric epithelial lining consists of rugae that contain microscopic gastric pits, each branching into four or five gastric glands made up of highly specialized epithelial cells. The makeup of gastric glands varies with their anatomic location. Glands within the gastric cardia comprise <5% of the gastric gland area and contain mucous and endocrine cells. The majority of gastric glands (75%) are found within the oxyntic mucosa and contain mucous neck, parietal, chief, endocrine, and enterochromaffin cells (Fig. 274-1). Pyloric glands contain mucous and endocrine cells (including gastrin cells) and are found in the antrum.

The parietal cell, also known as the oxyntic cell, is usually found in the neck, or isthmus, or the oxyntic gland. The resting, or unstimulated, parietal cell has prominent cytoplasmic tubulovesicles and intracellular canaliculi containing short microvilli along its apical surface (Fig. 274-2). H^+, K^+-ATPase is expressed in the tubulovesicle membrane; upon cell stimulation, this membrane, along with apical membranes, transforms into a dense network of apical intracellular canaliculi containing long microvilli. Acid secretion, a process requiring high energy, occurs at the apical canalicular surface. Numerous mitochondria (30 to 40% of total cell volume) generate the energy required for secretion.

Gastroduodenal Mucosal Defense The gastric epithelium is under a constant assault by a series of endogenous noxious factors including HCl, pepsinogen/pepsin, and bile salts. In addition, a steady flow of exogenous substances such as medications, alcohol, and bacteria encounter the gastric mucosa. A highly intricate biologic system is in place to provide defense from mucosal injury and to repair any injury that may occur.

The mucosal defense system can be envisioned as a three-level barrier, composed of preepithelial, epithelial, and subepithelial elements (Fig. 274-3). The first line of defense is a mucus-bicarbonate

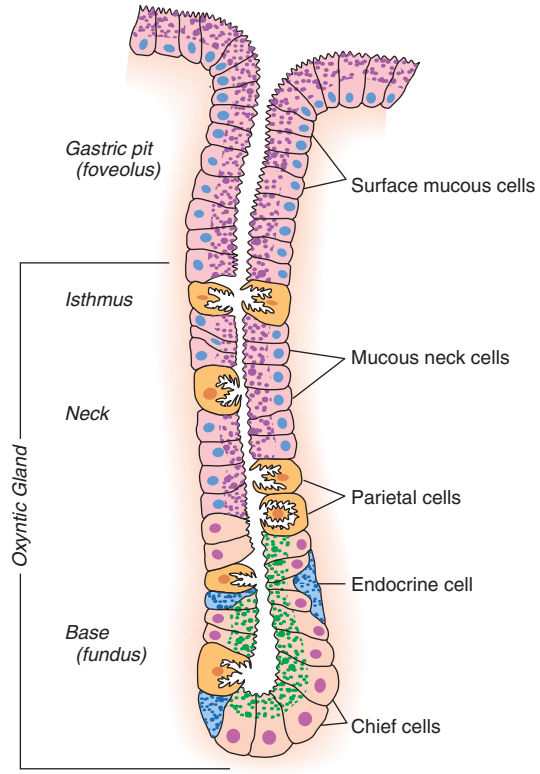

FIGURE 274-1 Diagramatic representation of the oxyntic gastric gland. *(Adapted from S Ito, RJ Winchester: Cell Biol 16:541, 1963.)*

layer, which serves as a physicochemical barrier to multiple molecules including hydrogen ions. Mucus is secreted in a regulated fashion by gastroduodenal surface epithelial cells. It consists primarily of water (95%) and a mixture of lipids and glycoproteins. Mucin is the constituent glycoprotein that, in combination with phospholipids (also secreted by gastric mucous cells), forms a hydrophobic surface with fatty acids that extend into the lumen from the cell membrane. The mucous gel functions as a nonstirred water layer impeding diffusion of ions and molecules such as pepsin. Bicarbonate, secreted by surface epithelial cells of the gastroduodenal mucosa into the mucous gel, forms a pH gradient ranging from 1 to 2 at the gastric luminal surface and reaching 6 to 7 along the epithelial cell surface. Bicarbonate secretion is stimulated by calcium, prostaglandins, cholinergic input, and luminal acidification.

Surface epithelial cells provide the next line of defense through several factors, including mucus production, epithelial cell ionic transporters that maintain intracellular pH and bicarbonate production, and intracellular tight junctions. If the preepithelial barrier were breached,

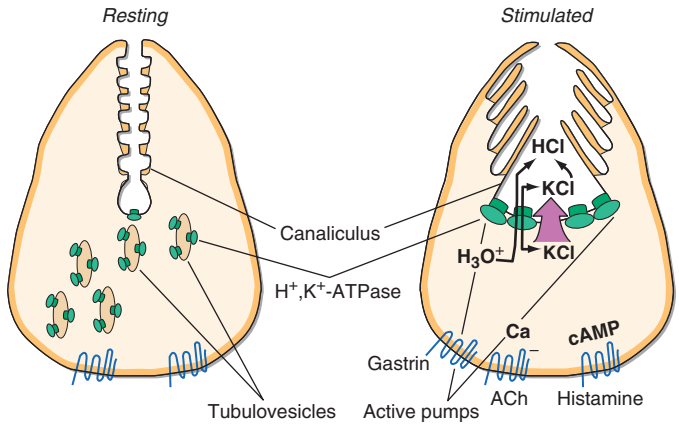

FIGURE 274-2 Gastric parietal cell undergoing transformation after secretagogue-mediated stimulation. *(Adapted from SJ Hersey, G Sachs: Physiol Rev 75:155, 1995.)*

gastric epithelial cells bordering a site of injury can migrate to restore a damaged region (*restitution*). This process occurs independent of cell division and requires uninterrupted blood flow and an alkaline pH in the surrounding environment. Several growth factors including epidermal growth factor (EGF), transforming growth factor (TGF) α, and basic fibroblast growth factor (FGF) modulate the process of restitution. Larger defects that are not effectively repaired by restitution require cell proliferation. Epithelial cell regeneration is regulated by prostaglandins and growth factors such as EGF and TGF-α. In tandem with epithelial cell renewal, formation of new vessels (*angiogenesis*) within the injured microvascular bed occurs. Both FGF and vascular endothelial growth factor (VEGF) are important in regulating angiogenesis in the gastric mucosa.

An elaborate microvascular system within the gastric submucosal layer is the key component of the subepithelial defense/repair system. A rich submucosal circulatory bed provides HCO_3^-, which neutralizes the acid generated by parietal cell secretion of HCl. Moreover, this microcirculatory bed provides an adequate supply of micronutrients and oxygen while removing toxic metabolic by-products.

Prostaglandins play a central role in gastric epithelial defense/repair (Fig. 274-4). The gastric mucosa contains abundant levels of prostaglandins. These metabolites of arachidonic acid regulate the release of mucosal bicarbonate and mucus, inhibit parietal cell secretion, and are important in maintaining mucosal blood flow and epithelial cell restitution. Prostaglandins are derived from esterified arachidonic acid, which is formed from phospholipids (cell membrane) by the action of phospholipase A_2. A key enzyme that controls the rate-limiting step in prostaglandin synthesis is cyclooxygenase (COX), which is present in two isoforms (COX-1, COX-2), each having distinct characteristics regarding structure, tissue distribution, and expression. COX-1 is expressed in a host of tissues including the stomach, platelets, kidneys, and endothelial cells. This isoform is expressed in a constitutive manner and plays an important role in maintaining the integrity of renal function, platelet aggregation, and gastrointestinal mucosal integrity. In contrast, the expression of COX-2 is inducible by inflammatory stimuli, and it is expressed in macrophages, leukocytes, fibroblasts, and synovial cells. The beneficial effects of nonsteroidal anti-inflammatory drugs (NSAIDs) on tissue inflammation are due to inhibition of COX-2; the toxicity of these drugs (e.g., gastrointestinal mucosal ulceration and renal dysfunction) is related to inhibition of the COX-1 isoform. The highly COX-2-selective NSAIDs have the potential to provide the beneficial effect of decreasing tissue inflammation while minimizing toxicity in the gastrointestinal tract.

Physiology of Gastric Secretion Hydrochloric acid and pepsinogen are the two principal gastric secretory products capable of inducing mucosal injury. Acid secretion should be viewed as occurring under basal and stimulated conditions. Basal acid production occurs in a circadian pattern, with highest levels occurring during the night and lowest levels during the morning hours. Cholinergic input via the vagus nerve and histaminergic input from local gastric sources are the principal contributors to basal acid secretion. Stimulated gastric acid secretion occurs primarily in three phases based on the site where the signal originates (cephalic, gastric, and intestinal). Sight, smell, and taste of food are the components of the cephalic phase, which stimulates gastric secretion via the vagus nerve. The gastric phase is activated once food enters the stomach. This component of secretion is driven by nutrients (amino acids and amines) that directly stimulate the G cell to release gastrin, which in turn activates the parietal cell via direct and indirect mechanisms. Distention of the stomach wall also leads to gastrin release and acid production. The last phase of gastric acid secretion is initiated as food enters the intestine and is mediated by luminal distention and nutrient assimilation. A series of pathways that inhibit gastric acid production are also set into motion during these phases. The gastrointestinal hormone somatostatin is released from endocrine cells found in the gastric mucosa (D cells) in response to HCl. Somatostatin can inhibit acid production by both direct (parietal

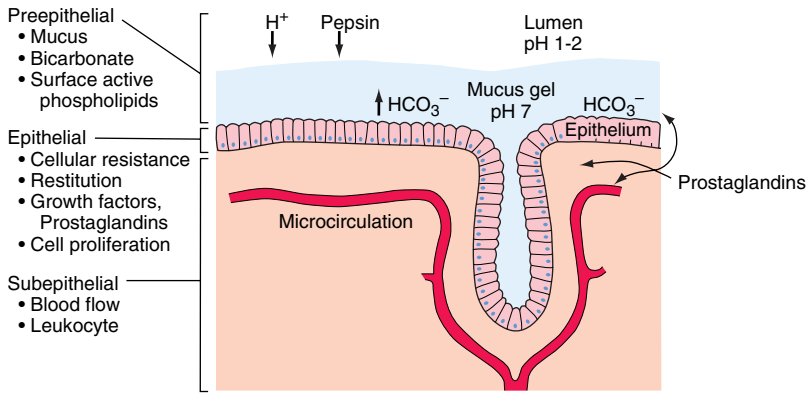

FIGURE 274-3 Components involved in providing gastroduodenal mucosal defense and repair.

cell) and indirect mechanisms [decreased histamine release from enterochromaffin-like (ECL) cells and gastrin release from G cells. Additional neural (central and peripheral) and hormonal (secretin, cholecystokinin) factors play a role in counterbalancing acid secretion. Under physiologic circumstances, these phases are occurring simultaneously.

The acid-secreting parietal cell is located in the oxyntic gland, adjacent to other cellular elements (ECL cell, D cell) important in the gastric secretory process (Fig. 274-5). This unique cell also secretes intrinsic factor (IF). The parietal cell expresses receptors for several stimulants of acid secretion including histamine (H_2), gastrin (cholecystokinin B/gastrin receptor), and acetylcholine (muscarinic, M_3). Each of these are G protein–linked, seven transmembrane–spanning receptors. Binding of histamine to the H_2 receptor leads to activation of adenylate cyclase and an increase in cyclic AMP. Activation of the gastrin and muscarinic receptors results in activation of the protein kinase C/phosphoinositide signaling pathway. Each of these signaling pathways in turn regulates a series of downstream kinase cascades, which control the acid-secreting pump, H^+, K^+-ATPase. The discovery that different ligands and their corresponding receptors lead to activation of different signaling pathways explains the potentiation of acid secretion that occurs when histamine and gastrin or acetylcholine are combined. More importantly, this observation explains why blocking one receptor type (H_2) decreases acid secretion stimulated by agents that activate a different pathway (gastrin, acetylcholine). Parietal cells also express receptors for ligands that inhibit acid production (prostaglandins, somatostatin, and EGF).

The enzyme H^+, K^+-ATPase is responsible for generating the large concentration of H^+. It is a membrane-bound protein that consists of two subunits, α and β. The active catalytic site is found within the α subunit; the function of the β subunit is unclear. This enzyme uses the chemical energy of ATP to transfer H^+ ions from parietal cell cytoplasm to the secretory canaliculi in exchange for K^+. The H^+,K^+-ATPase is located within the secretory canaliculus and in nonsecretory cytoplasmic tubulovesicles. The tubulovesicles are impermeable to K^+, which leads to an inactive pump in this location. The distribution of pumps between the nonsecretory vesicles and the secretory canaliculus varies according to parietal cell activity (Fig. 274-2). Under resting conditions, only 5% of pumps are within the secretory canaliculus, whereas upon parietal cell stimulation, tubulovesicles are immediately transferred to the secretory canalicular membrane, where 60 to 70% of the pumps are activated. Proton pumps are recycled back to the inactive state in cytoplasmic vesicles once parietal cell activation ceases.

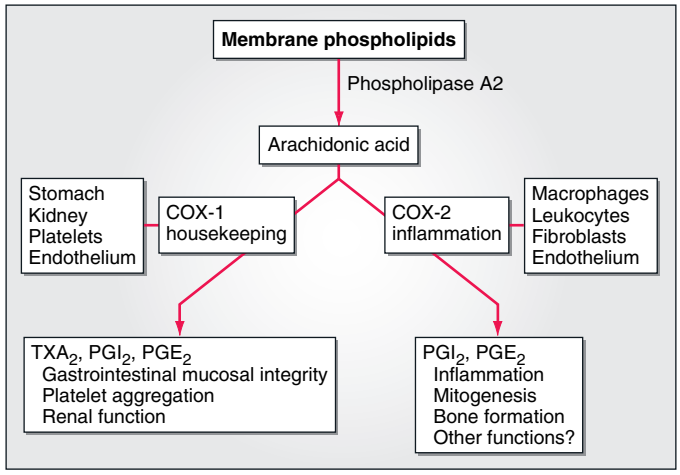

FIGURE 274-4 Schematic representation of the steps involved in synthesis of prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2). Characteristics and distribution of the cyclooxgenase (COX) enzymes 1 and 2 are also shown. TXA_2, thromboxane A_2.

The chief cell, found primarily in the gastric fundus, synthesizes and secretes pepsinogen, the inactive precursor of the proteolytic enzyme pepsin. The acid environment within the stomach leads to cleavage of the inactive precursor to pepsin and provides the low pH (<2.0) required for pepsin activity. Pepsin activity is significantly diminished at a pH of 4 and irreversibly inactivated and denatured at a pH of ≥7. Many of the secretagogues that stimulate acid secretion also stimulate pepsinogen release. The precise role of pepsin in the pathogenesis of PUD remains to be established.

PATHOPHYSIOLOGIC BASIS OF PEPTIC ULCER DISEASE PUD encompasses both gastric and duodenal ulcers. Ulcers are defined as a break in the mucosal surface >5 mm in size, with depth to the submucosa. Duodenal ulcers (DUs) and gastric ulcers (GUs); share many common features in terms of pathogenesis, diagnosis, and treatment, but several factors distinguish them from one another.

Epidemiology ■ *DUODENAL ULCERS* DUs are estimated to occur in 6 to 15% of the western population. The incidence of DUs declined steadily from 1960 to 1980 and has remained stable since then. The death rates, need for surgery, and physician visits have decreased by >50% over the past 30 years. The reason for the reduction in the frequency of DUs is likely related to the decreasing frequency of *Helicobacter pylori*. Before the discovery of *H. pylori*, the natural history of DUs was typified by frequent recurrences after initial therapy. Eradication of *H. pylori* has greatly reduced these recurrence rates.

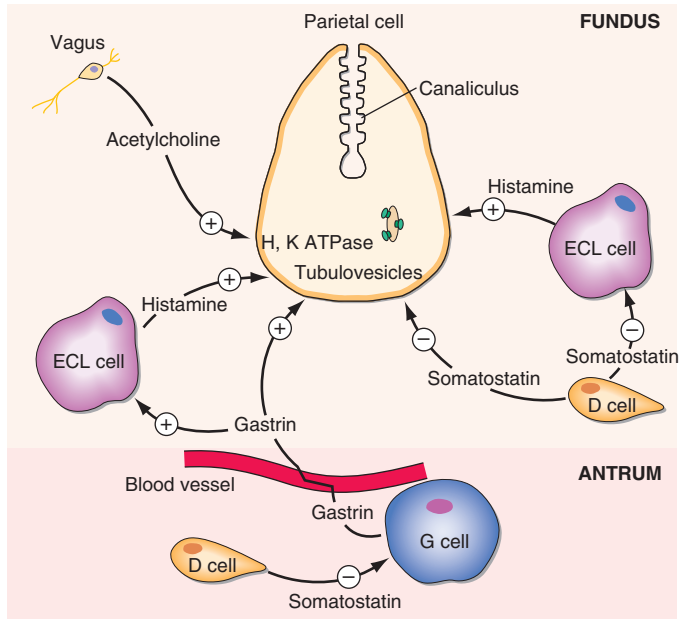

FIGURE 274-5 Regulation of gastric acid secretion at the cellular level. ECL cell, enterochromaffin-like cell.

GASTRIC ULCERS GUs tend to occur later in life than duodenal lesions, with a peak incidence reported in the sixth decade. More than half of GUs occur in males and are less common than DUs, perhaps due to the higher likelihood of GUs being silent and presenting only after a complication develops. Autopsy studies suggest a similar incidence of DUs and GUs.

Pathology ■ *DUODENAL ULCERS* DUs occur most often in the first portion of duodenum (>95%), with ~90% located within 3 cm of the pylorus. They are usually ≤1 cm in diameter but can occasionally reach 3 to 6 cm (giant ulcer). Ulcers are sharply demarcated, with depth at times reaching the muscularis propria. The base of the ulcer often consists of a zone of eosinophilic necrosis with surrounding fibrosis. Malignant duodenal ulcers are extremely rare.

GASTRIC ULCERS In contrast to DUs, GUs can represent a malignancy. Benign GUs are most often found distal to the junction between the antrum and the acid secretory mucosa. This junction is variable, but in general the antral mucosa extends about two-thirds of the distance of the lesser curvature and one-third the way up the greater curvature. Benign GUs are quite rare in the gastric fundus and are histologically similar to DUs. Benign GUs associated with *H. pylori* are associated with antral gastritis. In contrast, NSAID-related GUs are not accompanied by chronic active gastritis but may instead have evidence of a chemical gastropathy.

Pathophysiology It is now clear that *H. pylori* and NSAID-induced injury account for the majority of DUs. Gastric acid contributes to mucosal injury but does not play a primary role.

DUODENAL ULCERS Many acid secretory abnormalities have been described in DU patients. Of these, average basal and nocturnal gastric acid secretion appear to be increased in DU patients as compared to control; however, the level of overlap between DU patients and control subjects is substantial. The reason for this altered secretory process is unclear, but *H. pylori* infection may contribute to this finding. Accelerated gastric emptying of liquids has been noted in some DU patients but is not consistently observed; its role in DU formation, if any, is unclear. Bicarbonate secretion is significantly decreased in the duodenal bulb of patients with an active DU as compared to control subjects. *H. pylori* infection may also play a role in this process.

GASTRIC ULCERS As in DUs, the majority of GUs can be attributed to either *H. pylori* or NSAID-induced mucosal damage. GUs that occur in the prepyloric area or those in the body associated with a DU or a duodenal scar are similar in pathogenesis to DUs. Gastric acid output (basal and stimulated) tends to be normal or decreased in GU patients. When GUs develop in the presence of minimal acid levels, impairment of mucosal defense factors may be present.

Abnormalities in resting and stimulated pyloric sphincter pressure with a concomitant increase in duodenal gastric reflux have been implicated in some GU patients. Although bile acids, lysolecithin, and pancreatic enzymes may injure gastric mucosa, a definite role for these in GU pathogenesis has not been established. Delayed gastric emptying of solids has been described in GU patients but has not been reported consistently. The observation that patients who have undergone disruption of the normal pyloric barrier (pyloroplasty, gastroenterostomy) often have superficial gastritis without frank ulceration decreases enthusiasm for duodenal gastric reflux as an explanation for GU pathogenesis.

H. PYLORI AND ACID PEPTIC DISORDERS Gastric infection with the bacterium *H. pylori* accounts for the majority of PUD. This organism also plays a role in the development of gastric mucosal-associated lymphoid tissue (MALT) lymphoma and gastric adenocarcinoma. Although the entire genome of *H. pylori* has been sequenced, it is still not clear how this organism, which is in the stomach, causes ulceration in the duodenum, or whether its eradication will lead to a decrease in gastric cancer.

The Bacterium The bacterium, initially named *Campylobacter pyloridis*, is a gram-negative microaerophilic rod found most commonly in the deeper portions of the mucous gel coating the gastric mucosa or between the mucous layer and the gastric epithelium. It may attach to gastric epithelium but under normal circumstances does not appear to invade cells. It is strategically designed to live within the aggressive environment of the stomach. It is S-shaped (~0.5 × 3 μm in size) and contains multiple sheathed flagella. Initially, *H. pylori* resides in the antrum but, over time, migrates toward the more proximal segments of the stomach. The organism is capable of transforming into a coccoid form, which represents a dormant state that may facilitate survival in adverse conditions. The genome of *H. pylori* has been sequenced (1.65 million base pairs) and encodes ~1500 proteins. Amongst this multitude of proteins there are factors that are essential determinants of *H. pylori*–mediated pathogenesis and colonization such as the outer membrane protein (Hop proteins), urease, and the vacuolating cytotoxin (Vac A). Moreover, the majority of *H. pylori* strains contain a genomic fragment, which encodes the cag pathogenicity island (cag-PAI). Several of the genes that make up cag-PAI encode components of a type IV secretion island that translocates Cag A into host cells. Once in the cell, Cag A activates a series of cellular events important in cell growth and cytokine production. The first step in infection by *H. pylori* is dependent on the bacteria's motility and its ability to produce urease. Urease produces ammonia from urea, an essential step in alkalinizing the surrounding pH. Additional bacterial factors include catalase, lipase, adhesins, platelet-activating factor, and pic B (induces cytokines). Multiple strains of *H. pylori* exist and are characterized by their ability to express several of these factors (Cag A, Vac A, etc.). It is possible that the different diseases related to *H. pylori* infection can be attributed to different strains of the organism with distinct pathogenic features.

Epidemiology The prevalence of *H. pylori* varies throughout the world and depends to a great extent on the overall standard of living in the region. In developing parts of the world, 80% of the population may be infected by the age of 20, whereas the prevalence is 20 to 50% in industrialized countries. In contrast, in the United States, this organism is rare in childhood. The overall prevalence of *H. pylori* in the United States is ~30%, with individuals born before 1950 having a higher rate of infection than those born later. About 10% of Americans <30 are colonized with the bacteria. The rate of infection with *H. pylori* in industrialized countries has decreased substantially in recent decades. The steady increase in the prevalence of *H. pylori* noted with increasing age is due primarily to a cohort effect, reflecting higher transmission during a period in which the earlier cohorts were children. It has been calculated, through mathematical models, that improved sanitation during the latter half of the nineteenth century dramatically decreased transmission of *H. pylori*. Moreover, with the present rate of intervention, it is predicted that the organism will be ultimately eliminated from the United States. Two factors that predispose to higher colonization rates include poor socioeconomic status and less education. These factors, not race, are responsible for the rate of *H. pylori* infection in blacks and Hispanic Americans being double the rate seen in whites of comparable age. Other risk factors for *H. pylori* infection are (1) birth or residence in a developing country, (2) domestic crowding, (3) unsanitary living conditions, (4) unclean food or water, and (5) exposure to gastric contents of an infected individual.

Transmission of *H. pylori* occurs from person to person, following an oral-oral or fecal-oral route. The risk of *H. pylori* infection is declining in developing countries. The rate of infection in the United States has fallen by >50% when compared to 30 years ago.

Pathophysiology *H. pylori* infection is virtually always associated with a chronic active gastritis, but only 10 to 15% of infected individuals develop frank peptic ulceration. The basis for this difference is unknown. Initial studies suggested that >90% of all DUs were associated with *H. pylori*, but *H. pylori* is present in only 30 to 60% of individuals with GUs and 70% of patients with DUs. The pathophysiology of ulcers not associated with *H. pylori* or NSAID ingestion [or the rare Zollinger-Ellison syndrome (ZES)] is unclear.

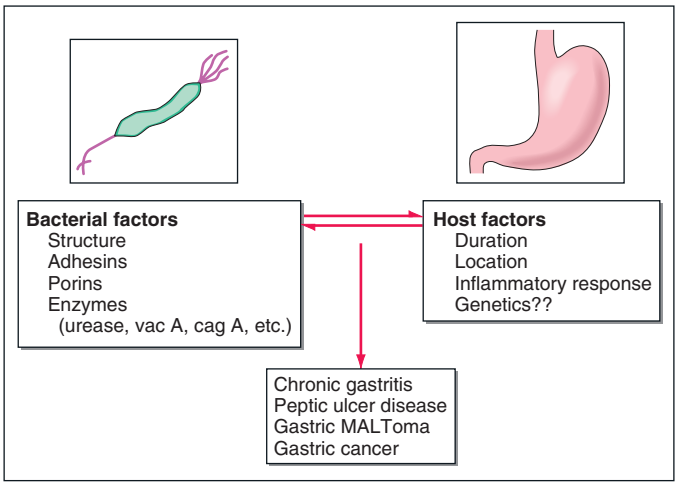

FIGURE 274-6 Outline of the bacterial and host factors important in determining *H. pylori*–induced gastrointestinal disease. MALT, mucosal-associated lymphoid tissue.

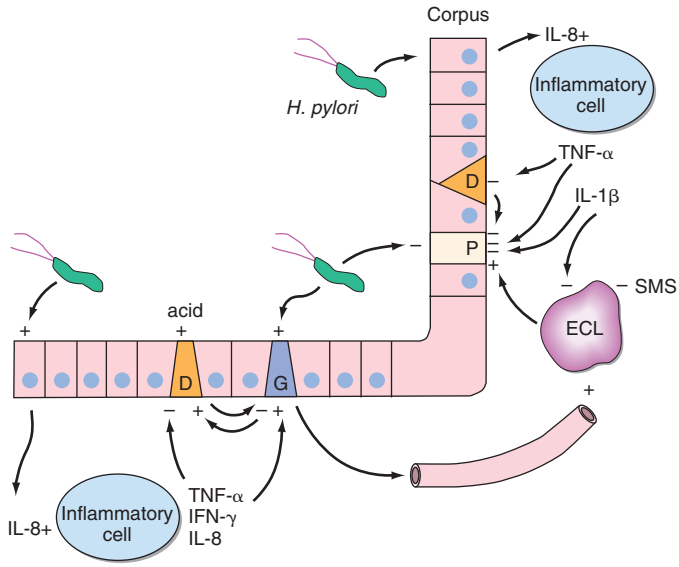

FIGURE 274-7 Summary of potential mechanisms by which *H. pylori* may lead to gastric secretory abnormalities. D, somatostatin cell; ECL, enterochromaffin-like; G, G cell; IFN, interferon; IL, interleukin; P, parietal cell; SMS, somatostatin; TNF, tumor necrosis factor. *(Adapted from J Calam et al: Gastroenterology 113:543, 1997.)*

The particular end result of *H. pylori* infection (gastritis, PUD, gastric MALT lymphoma, gastric cancer) is determined by a complex interplay between bacterial and host factors (Fig. 274-6).

1. *Bacterial factors*: *H. pylori* is able to facilitate gastric residence, induce mucosal injury, and avoid host defense. Different strains of *H. pylori* produce different virulence factors. A specific region of the bacterial genome, the pathogenicity island, encodes the virulence factors Cag A and pic B. Vac A also contributes to pathogenicity, though it is not encoded within the pathogenicity island. These virulence factors, in conjunction with additional bacterial constituents, can cause mucosal damage. Urease, which allows the bacteria to reside in the acidic stomach, generates NH_3, which can damage epithelial cells. The bacteria produce surface factors that are chemotactic for neutrophils and monocytes, which in turn contribute to epithelial cell injury (see below). *H. pylori* makes proteases and phospholipases that break down the glycoprotein lipid complex of the mucous gel, thus reducing the efficacy of this first line of mucosal defense. *H. pylori* expresses adhesins, which facilitate attachment of the bacteria to gastric epithelial cells. Although lipopolysaccharide (LPS) of gram-negative bacteria often plays an important role in the infection, *H. pylori* LPS has low immunologic activity compared to that of other organisms. It may promote a smoldering chronic inflammation.

2. *Host factors*: The inflammatory response to *H. pylori* includes recruitment of neutrophils, lymphocytes (T and B), macrophages, and plasma cells. The pathogen leads to local injury by binding to class II MHC molecules expressed on gastric epithelial cells leading to cell death (*apoptosis*). Moreover, bacterial strains that encode cag-PAI can introduce Cag A into the host cells, leading to further cell injury and activation of cellular pathways involved in cytokine production. Elevated concentrations of multiple cytokines are found in the gastric epithelium of *H. pylori*–infected individuals, including interleukin (IL) 1α/β, IL-2, IL-6, IL-8, tumor necrosis factor (TNF) α and interferon (IFN) γ. *H. pylori* infection also leads to both a mucosal and systemic humoral response, which does not lead to eradication of the bacteria but further compounds epithelial cell injury. Additional mechanisms by which *H. pylori* may cause epithelial cell injury include: activated neutrophil-mediated production of reactive oxygen or nitrogen species and enhanced epithelial cell turnover and apoptosis related to interaction with T cells (T helper 1, or T_H1, cells) and interferon-γ.

The reason for *H. pylori*–mediated duodenal ulceration remains unclear. One potential explanation is that gastric metaplasia in the duodenum of DU patients permits *H. pylori* to bind to it and produce local injury secondary to the host response. Another hypothesis is that *H. pylori* antral infection could lead to increased acid production, increased duodenal acid, and mucosal injury. Basal and stimulated [meal, gastrin-releasing peptide (GRP)] gastrin release are increased in *H. pylori*–infected individuals, and somatostatin-secreting D cells may be decreased. *H. pylori* infection might induce increased acid secretion through both direct and indirect actions of *H. pylori* and proinflammatory cytokines (IL-8, TNF, and IL-1) on G, D, and parietal cells (Fig. 274-7). *H. pylori* infection has also been associated with decreased duodenal mucosal bicarbonate production. Data supporting and contradicting each of these interesting theories have been demonstrated. Thus, the mechanism by which *H. pylori* infection of the stomach leads to duodenal ulceration remains to be established.

In summary, the final effect of *H. pylori* on the gastrointestinal tract is variable and determined by microbial and host factors. The type and distribution of gastritis correlate with the ultimate gastric and duodenal pathology observed. Specifically, the presence of antral-predominant gastritis is associated with DU formation; gastritis involving primarily the corpus predisposes to the development of GUs, gastric atrophy, and ultimately gastric carcinoma (Figure 274-8).

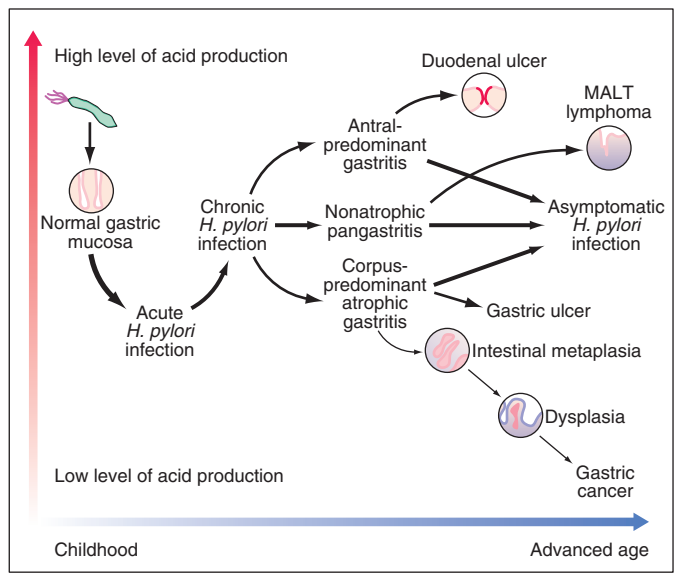

FIGURE 274-8 Natural history of *H. pylori* infection. *(Used with permission from Suerbaum and Michetti.)*

NSAIDS-INDUCED DISEASE ■ ***Epidemiology*** NSAIDs represent one of the most commonly used medications in the United States. More than 30 billion over-the-counter tablets and 70 million prescriptions are sold yearly in the United States alone. In fact, after the introduction of COX-2 inhibitors in the year 2000, the number of prescriptions written for NSAIDs was >111 million at a cost of $4.8 billion. The spectrum of NSAID-induced morbidity ranges from nausea and dyspepsia (prevalence reported as high as 50 to 60%) to a serious gastrointestinal complication such as frank peptic ulceration (3 to 4%) complicated by bleeding or perforation in as many as 1.5% of users per year. About 20,000 patients die each year from serious gastrointestinal complications from NSAIDs. Unfortunately, dyspeptic symptoms do not correlate with NSAID-induced pathology. Over 80% of patients with serious NSAID-related complications did not have preceding dyspepsia. In view of the lack of warning signs, it is important to identify patients who are at increased risk for morbidity and mortality related to NSAID usage. Even 75 mg/d of aspirin may lead to serious gastrointestinal ulceration, thus no dose of NSAID is completely safe. Established risk factors include advanced age, history of ulcer, concomitant use of glucocorticoids, high dose NSAIDs, multiple NSAIDs, concomitant use of anticoagulants, and serious or multisystem disease. Possible risk factors include concomitant infection with *H. pylori*, cigarette smoking, and alcohol consumption.

Pathophysiology Prostaglandins play a critical role in maintaining gastroduodenal mucosal integrity and repair. It therefore follows that interruption of prostaglandin synthesis can impair mucosal defense and repair, thus facilitating mucosal injury via a systemic mechanism. A summary of the pathogenetic pathways by which systemically administered NSAIDs may lead to mucosal injury is shown in Fig. 274-9.

Injury to the mucosa also occurs as a result of the topical encounter with NSAIDs. Aspirin and many NSAIDs are weak acids that remain in a nonionized lipophilic form when found within the acid environment of the stomach. Under these conditions, NSAIDs migrate across lipid membranes of epithelial cells, leading to cell injury once trapped intracellularly in an ionized form. Topical NSAIDs can also alter the surface mucous layer, permitting back diffusion of H^+ and pepsin, leading to further epithelial cell damage. Moreover, enteric-coated or buffered preparations are also associated with risk of peptic ulceration.

MISCELLANEOUS PATHOGENETIC FACTORS IN ACID PEPTIC DISEASE Cigarette smoking has been implicated in the pathogenesis of PUD. Not only have smokers been found to have ulcers more frequently than do nonsmokers, but smoking appears to decrease healing rates, impair response to therapy, and increase ulcer-related complications such as perforation. The mechanism responsible for increased ulcer diathesis in smokers is unknown. Theories have included altered gastric emptying, decreased proximal duodenal bicarbonate production, increased risk for *H. pylori* infection, and cigarette-induced generation of noxious mucosal free radicals. Acid secretion is not abnormal in smokers. Despite these interesting theories, a unifying mechanism for cigarette-induced peptic ulcer diathesis has not been established.

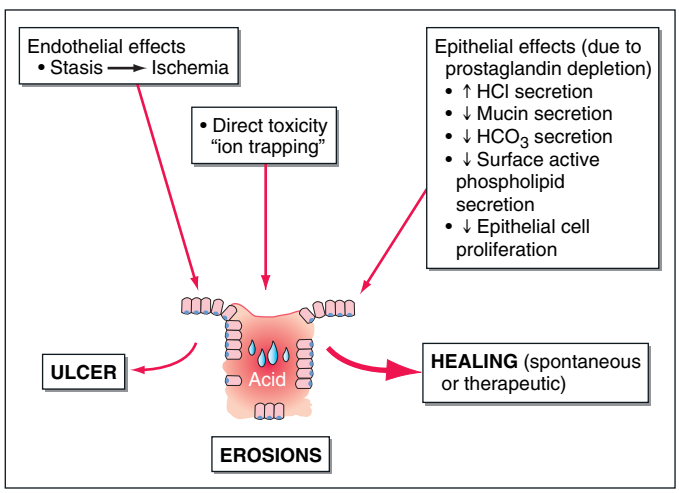

FIGURE 274-9 Mechanisms by which NSAIDs may induce mucosal injury. *(Adapted from J Scheiman et al: J Clin Outcomes Management 3:23, 1996.)*

Genetic predisposition has also been considered to play a role in ulcer development. First-degree relatives of DU patients are three times as likely to develop an ulcer; however, the potential role of *H. pylori* infection in contacts is a major consideration. Increased frequency of blood group O and of the nonsecretor status have also been implicated as genetic risk factors for peptic diathesis. However, *H. pylori* preferentially binds to group O antigens. Therefore, the role of genetic predisposition in common PUD has not been established.

Psychological stress has been thought to contribute to PUD, but studies examining the role of psychological factors in its pathogenesis have generated conflicting results. Although PUD is associated with certain personality traits (neuroticism), these same traits are also present in individuals with nonulcer dyspepsia (NUD) and other functional and organic disorders. Although more work in this area is needed, no typical PUD personality has been found.

Diet has also been thought to play a role in peptic diseases. Certain foods can cause dyspepsia, but no convincing studies indicate an association between ulcer formation and a specific diet. This is also true for beverages containing alcohol and caffeine. Specific chronic disorders have been associated with PUD. Those with a strong association are (1) systemic mastocytosis, (2) chronic pulmonary disease, (3) chronic renal failure, (4) cirrhosis, (5) nephrolithiasis, and (6) α_1-antitrypsin deficiency. Those with a possible association are (1) hyperparathyroidism, (2) coronary artery disease, (3) polycythemia vera, and (4) chronic pancreatitis.

Multiple factors play a role in the pathogenesis of PUD. The two predominant causes are *H. pylori* infection and NSAID ingestion. PUD not related to *H. pylori* or NSAIDs may be increasing. Independent of the inciting or injurious agent, peptic ulcers develop as a result of an imbalance between mucosal protection/repair and aggressive factors. Gastric acid plays an essential role in mucosal injury.

CLINICAL FEATURES ■ **History** Abdominal pain is common to many gastrointestinal disorders, including DU and GU, but has a poor predictive value for the presence of either DU or GU. Up to 10% of patients with NSAID-induced mucosal disease can present with a complication (bleeding, perforation, and obstruction) without antecedent symptoms. Despite this poor correlation, a careful history and physical examination are essential components of the approach to a patient suspected of having peptic ulcers.

Epigastric pain described as a burning or gnawing discomfort can be present in both DU and GU. The discomfort is also described as an ill-defined, aching sensation or as hunger pain. The typical pain pattern in DU occurs 90 min to 3 h after a meal and is frequently relieved by antacids or food. Pain that awakes the patient from sleep (between midnight and 3 A.M.) is the most discriminating symptom, with two-thirds of DU patients describing this complaint. Unfortunately, this symptom is also present in one-third of patients with NUD. The pain pattern in GU patients may be different from that in DU patients, where discomfort may actually be precipitated by food. Nausea and weight loss occur more commonly in GU patients. In the United States, endoscopy detects ulcers in <30% of patients who have dyspepsia. Despite this, 40% of these individuals with typical ulcer symptoms had an ulcer crater, and 40% had gastroduodenitis on endoscopic examination.

The mechanism for development of abdominal pain in ulcer patients is unknown. Several possible explanations include acid-induced activation of chemical receptors in the duodenum, enhanced duodenal sensitivity to bile acids and pepsin, or altered gastroduodenal motility.

Variation in the intensity or distribution of the abdominal pain, as well as the onset of associated symptoms such as nausea and/or vomiting, may be indicative of an ulcer complication. Dyspepsia that be-

comes constant, is no longer relieved by food or antacids, or radiates to the back may indicate a penetrating ulcer (pancreas). Sudden onset of severe, generalized abdominal pain may indicate perforation. Pain worsening with meals, nausea, and vomiting of undigested food suggest gastric outlet obstruction. Tarry stools or coffee ground emesis indicate bleeding.

Physical Examination Epigastric tenderness is the most frequent finding in patients with GU or DU. Pain may be found to the right of the midline in 20% of patients. Unfortunately, the predictive value of this finding is rather low. Physical examination is critically important for discovering evidence of ulcer complication. Tachycardia and orthostasis suggest dehydration secondary to vomiting or active gastrointestinal blood loss. A severely tender, boardlike abdomen suggests a perforation. Presence of a succussion splash indicates retained fluid in the stomach, suggesting gastric outlet obstruction.

PUD-Related Complications ■ *GASTROINTESTINAL BLEEDING* Gastrointestinal bleeding is the most common complication observed in PUD. It occurs in ~15% of patients and more often in individuals >60 years old. The higher incidence in the elderly is likely due to the increased use of NSAIDs in this group. As many as 20% of patients with ulcer-related hemorrhage bleed without any preceding warning signs or symptoms.

PERFORATION The second most common ulcer-related complication is perforation, being reported in as many as 6 to 7% of PUD patients. As in the case of bleeding, the incidence of perforation in the elderly appears to be increasing secondary to increased use of NSAIDs. Penetration is a form of perforation in which the ulcer bed tunnels into an adjacent organ. DUs tend to penetrate posteriorly into the pancreas, leading to pancreatitis, whereas GUs tend to penetrate into the left hepatic lobe. Gastrocolic fistulas associated with GUs have also been described.

GASTRIC OUTLET OBSTRUCTION Gastric outlet obstruction is the least common ulcer-related complication, occurring in 1 to 2% of patients. A patient may have relative obstruction secondary to ulcer-related inflammation and edema in the peripyloric region. This process often resolves with ulcer healing. A fixed, mechanical obstruction secondary to scar formation in the peripyloric areas is also possible. The latter requires endoscopic (balloon dilation) or surgical intervention. Signs and symptoms relative to mechanical obstruction may develop insidiously. New onset of early satiety, nausea, vomiting, increase of postprandial abdominal pain, and weight loss should make gastric outlet obstruction a possible diagnosis.

Differential Diagnosis The list of gastrointestinal and nongastrointestinal disorders that can mimic ulceration of the stomach or duodenum is quite extensive. The most commonly encountered diagnosis among patients seen for upper abdominal discomfort is NUD. NUD, also known as *functional dyspepsia* or *essential dyspepsia*, refers to a group of heterogeneous disorders typified by upper abdominal pain without the presence of an ulcer. Dyspepsia has been reported to occur in up to 30% of the U.S. population. Up to 60% of patients seeking medical care for dyspepsia have a negative diagnostic evaluation. The etiology of NUD is not established, and the potential role of *H. pylori* in NUD remains controversial.

Several additional disease processes that may present with "ulcer-like" symptoms include proximal gastrointestinal tumors, gastroesophageal reflux, vascular disease, pancreaticobiliary disease (biliary colic, chronic pancreatitis), and gastroduodenal Crohn's disease.

Diagnostic Evaluation In view of the poor predictive value of abdominal pain for the presence of a gastroduodenal ulcer and the multiple disease processes that can mimic this disease, the clinician is often confronted with having to establish the presence of an ulcer. Documentation of an ulcer requires either a radiographic (barium study) or an endoscopic procedure. However, a large percentage of patients with symptoms suggestive of an ulcer have NUD; empirical therapy is appropriate for individuals who are otherwise healthy and <45, before embarking on a diagnostic evaluation (Chap. 34).

Barium studies of the proximal gastrointestinal tract are still commonly used as a first test for documenting an ulcer. The sensitivity of older single-contrast barium meals for detecting a DU is as high as 80%, with a double-contrast study providing detection rates as high as 90%. Sensitivity for detection is decreased in small ulcers (<0.5 cm), presence of previous scarring, or in postoperative patients. A DU appears as a well-demarcated crater, most often seen in the bulb. A GU may represent benign or malignant disease. Typically, a benign GU also appears as a discrete crater with radiating mucosal folds originating from the ulcer margin. Ulcers >3 cm in size or those associated with a mass are more often malignant. Unfortunately, up to 8% of GUs that appear to be benign by radiographic appearance are malignant by endoscopy or surgery. Radiographic studies that show a GU must be followed by endoscopy and biopsy.

Endoscopy provides the most sensitive and specific approach for examining the upper gastrointestinal tract. In addition to permitting direct visualization of the mucosa, endoscopy facilitates photographic documentation of a mucosal defect and tissue biopsy to rule out malignancy (GU) or *H. pylori*. Endoscopic examination is particularly helpful in identifying lesions too small to detect by radiographic examination, for evaluation of atypical radiographic abnormalities, or to determine if an ulcer is a source of blood loss.

Although the methods for diagnosing *H. pylori* are outlined in Chap. 135, a brief summary will be included here (Table 274-1). Several biopsy urease tests have been developed (PyloriTek, Clotest, Hpfast, Pronto Dry) and have a sensitivity and specificity of >90 to 95%. Several noninvasive methods for detecting this organism have been developed. Three types of studies routinely used include serologic testing, the ^{13}C- or ^{14}C-urea breath test (UBT), and the fecal *H. pylori* antigen test.

Occasionally, specialized testing such as serum gastrin and gastric acid analysis or sham feeding may be needed in individuals with complicated or refractory PUD (see "Zollinger-Ellison Syndrome," below). Screening for aspirin or NSAIDS (blood or urine) may also be necessary in refractory *H. pylori*–negative PUD patients.

TREATMENT

Before the discovery of *H. pylori*, the therapy of PUD disease was centered on the old dictum by Schwartz of "no acid, no ulcer." Al-

TABLE 274-1 *Tests for Detection of H. pylori*

Test	Sensitivity/ Specificity, %	Comments
INVASIVE (ENDOSCOPY/BIOPSY REQUIRED)		
Rapid urease	80–95/95–100	Simple, false negative with recent use of PPIs, antibiotics, or bismuth compounds
Histology	80–90/>95	Requires pathology processing and staining; provides histologic information
Culture	—/—	Time-consuming, expensive, dependent on experience; allows determination of antibiotic susceptibility
NON-INVASIVE		
Serology	>80/>90	Inexpensive, convenient; not useful for early follow-up
Urea breath test	>90/>90	Simple, rapid; useful for early follow-up; false negatives with recent therapy (see rapid urease test); exposure to low-dose radiation with ^{14}C test
Stool antigen	>90/>90	Inexpensive, convenient; not established for eradication but promising

Note: PPIs, proton pump inhibitors.

though acid secretion is still important in the pathogenesis of PUD, eradication of *H. pylori* and therapy/prevention of NSAID-induced disease is the mainstay. A summary of commonly used drugs for treatment of acid peptic disorders is shown in Table 274-2.

Acid Neutralizing/Inhibitory Drugs ■ *ANTACIDS* Before we understood the important role of histamine in stimulating parietal cell activity, neutralization of secreted acid with antacids constituted the main form of therapy for peptic ulcers. They are now rarely, if ever, used as the primary therapeutic agent but instead are often used by patients for symptomatic relief of dyspepsia. The most commonly used agents are mixtures of aluminum hydroxide and magnesium hydroxide. Aluminum hydroxide can produce constipation and phosphate depletion; magnesium hydroxide may cause loose stools. Many of the commonly used antacids (e.g., Maalox, Mylanta) have a combination of both aluminum and magnesium hydroxide in order to avoid these side effects. The magnesium-containing preparation should not be used in chronic renal failure patients because of possible hypermagnesemia, and aluminum may cause chronic neurotoxicity in these patients.

Calcium carbonate and sodium bicarbonate are potent antacids with varying levels of potential problems. The long-term use of calcium carbonate (converts to calcium chloride in the stomach) can lead to milk-alkali syndrome (hypercalcemia, hyperphosphatemia with possible renal calcinosis and progression to renal insufficiency). Sodium bicarbonate may induce systemic alkalosis.

H_2 RECEPTOR ANTAGONISTS Four of these agents are presently available (cimetidine, ranitidine, famotidine, and nizatidine), and their structures share homology with histamine. Although each has different potency, all will significantly inhibit basal and stimulated acid secretion to comparable levels when used at therapeutic doses. Moreover, similar ulcer-healing rates are achieved with each drug when used at the correct dosage. Presently, this class of drug is often used for treatment of active ulcers (4 to 6 weeks) in combination with antibiotics directed at eradicating *H. pylori* (see below).

Cimetidine was the first H_2 receptor antagonist used for the treatment of acid peptic disorders. The initial recommended dosing profile for cimetidine was 300 mg four times per day. Subsequent studies have documented the efficacy of using 800 mg at bedtime for treatment of active ulcer, with healing rates approaching 80% at 4 weeks. Cimetidine may have weak antiandrogenic side effects resulting in reversible gynecomastia and impotence, primarily in patients receiving high doses for prolonged periods of time (months to years, as in ZES). In view of cimetidine's ability to inhibit cytochrome P450, careful monitoring of drugs such as warfarin, phenytoin, and theophylline is indicated with long-term usage. Other rare reversible adverse effects reported with cimetidine include confusion and elevated levels of serum aminotransferases, creatinine, and serum prolactin. Ranitidine, famotidine, and nizatidine are more potent H_2 receptor antagonists than cimetidine. Each can be used once a day at bedtime. Comparable nighttime dosing regimens are ranitidine, 300 mg, famotidine, 40 mg, and nizatidine, 300 mg.

Additional rare, reversible systemic toxicities reported with H_2 receptor antagonists include pancytopenia, neutropenia, anemia, and thrombocytopenia, with a prevalence rate varying from 0.01 to 0.2%. Cimetidine and rantidine (to a lesser extent) can bind to hepatic cytochrome P450; famotidine and nizatidine do not.

PROTON PUMP (H^+,K^+-ATPASE) INHIBITORS Omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole are substituted benzimidazole derivatives that covalently bind and irreversibly inhibit H^+,K^+-ATPase. Esomeprazole, the newest member of this drug class, is the S-enantiomer of omeprazole, which is a racemic mixture of both S- and R-optical isomers. These are the most potent acid inhibitory agents available. Omeprazole and lansoprazole are the proton pump inhibitors (PPIs) that have been used for the longest time. Both are acid labile and are administered as enteric-coated granules in a sustained-release capsule that dissolves within the small intestine at a pH of 6. Pantoprazole and rabeprazole are available as enteric-coated tablets. Pantoprazole is also available as a parenteral formulation for intravenous use. These agents are lipophilic compounds; upon entering the parietal cell, they are protonated and trapped within the acid environment of the tubulovesicular and canalicular system. These agents potently inhibit all phases of gastric acid secretion. Onset of action is rapid, with a maximum acid inhibitory effect between 2 and 6 h after administration and duration of inhibition lasting up to 72 to 96 h. With repeated daily dosing, progressive acid inhibitory effects are observed, with basal and secretagogue-stimulated acid production being inhibited by >95% after 1 week of therapy. The half-life of PPIs is ~18 h; thus it can take between 2 and 5 days for gastric acid secretion to return to normal levels once these drugs have been discontinued. Because the pumps need to be activated for these agents to be effective, their efficacy is maximized if they are administered before a meal (e.g., in the morning before breakfast). Standard dosing for omeprazole and lansoprazole is 20 mg and 30 mg once per day, respectively. Mild to moderate hypergastrinemia has been observed in patients taking these drugs. Carcinoid tumors developed in some animals given the drugs preclinically; however, extensive experience has failed to demonstrate gastric carcinoid tumor development in humans. Serum gastrin levels return to normal levels within 1 to 2 weeks after drug cessation. As with any agent that leads to significant hypochlorhydria, PPIs may interfere with absorption of drugs such as ketoconazole, ampicillin, iron, and digoxin. Hepatic cytochrome P450 can be inhibited by the earlier PPIs (omeprazole, lansoprazole). Rabeprazole, pantoprazole, and esomeprazole do not appear to interact significantly with drugs metabolized by the cytochrome P450 system. The overall clinical significance of this observation is not definitely established. Caution should be taken when using warfarin, diazepam, and phenytoin concomitantly with PPIs.

Cytoprotective Agents ■ *SUCRALFATE* Sucralfate is a complex sucrose salt in which the hydroxyl groups have been substituted by aluminum hydroxide and sulfate. This compound is insoluble in water and becomes a viscous paste within the stomach and duodenum, binding primarily to sites of active ulceration. Sucralfate may act by several mechanisms. In the gastric environment, aluminum hydroxide dissociates, leaving the polar sulfate anion, which can bind to positively charged tissue proteins found within the ulcer bed, and providing a physicochemical barrier impeding further tissue injury by acid and pepsin. Sucralfate may also induce a trophic effect by binding growth factors such as EGF, enhance prostaglandin synthesis, stimulate mucous and bicarbonate secretion, and enhance mucosal defense and repair. Toxicity from this drug is rare, with constipation being the most common one reported (2 to 3%). It should be avoided in patients with chronic renal

TABLE 274-2 *Drugs Used in the Treatment of Peptic Ulcer Disease*

Drug Type/Mechanism	Examples	Dose
Acid-suppressing drugs		
Antacids	Mylanta, Maalox, Tums, Gaviscon	100–140 meq/L 1 and 3 h after meals and hs
H_2 receptor antagonists	Cimetidine	400 mg bid
	Ranitidine	300 mg hs
	Famotidine	40 mg hs
	Nizatidine	300 mg hs
Proton pump inhibitors	Omeprazole	20 mg/d
	Lansoprazole	30 mg/d
	Rabeprazole	20 mg/d
	Pantoprazole	40 mg/d
	Esomeprazole	20 mg/d
Mucosal protective agents		
Sucralfate	Sucralfate	1 g qid
Prostaglandin analogue	Misoprostol	200 μg qid
Bismuth-containing compounds	Bismuth subsalicylate (BSS)	See anti-*H. pylori* regimens (Table 274-3)

insufficiency to prevent aluminum-induced neurotoxicity. Hypophosphatemia and gastric bezoar formation have also been rarely reported. Standard dosing of sucralfate is 1 g four times per day.

BISMUTH-CONTAINING PREPARATIONS Sir William Osler considered bismuth-containing compounds the drug of choice for treating PUD. The resurgence in the use of these agents is due to their effect against *H. pylori*. Colloidal bismuth subcitrate (CBS) and bismuth subsalicylate (BSS, Pepto-Bismol) are the most widely used preparations. The mechanism by which these agents induce ulcer healing is unclear. Potential mechanisms include ulcer coating; prevention of further pepsin/HCl-induced damage; binding of pepsin; and stimulation of prostaglandins, bicarbonate, and mucous secretion. Adverse effects with short-term usage are rare with bismuth compounds. Long-term usage with high doses, especially with the avidly absorbed CBS, may lead to neurotoxicity. These compounds are commonly used as one of the agents in an anti-*H. pylori* regimen (see below).

PROSTAGLANDIN ANALOGUES In view of their central role in maintaining mucosal integrity and repair, stable prostaglandin analogues were developed for the treatment of PUD. The prostaglandin E_1 derivative misoprostal is the only agent of this class approved by the U.S. Food and Drug Administration for clinical use in the prevention of NSAID-induced gastroduodenal mucosal injury (see below). The mechanism by which this rapidly absorbed drug provides its therapeutic effect is through enhancement of mucosal defense and repair. Prostaglandin analogues enhance mucous bicarbonate secretion, stimulate mucosal blood flow, and decrease mucosal cell turnover. The most common toxicity noted with this drug is diarrhea (10 to 30% incidence). Other major toxicities include uterine bleeding and contractions; misoprostal is contraindicated in women who may be pregnant, and women of childbearing age must be made clearly aware of this potential drug toxicity. The standard therapeutic dose is 200 μg four times per day.

MISCELLANEOUS DRUGS A number of drugs aimed at treating acid peptic disorders have been developed over the years. In view of their limited utilization in the United States, if any, they will only be listed briefly. Anticholinergics, designed to inhibit activation of the muscarinic receptor in parietal cells, met with limited success due to their relatively weak acid-inhibiting effect and significant side effects (dry eyes, dry mouth, urinary retention). Tricyclic antidepressants have been suggested by some, but again the toxicity of these agents in comparison to the safe, effective drugs already described precludes their utility. Finally, the licorice extract carbenoxolone has aldosterone-like side effects with fluid retention and hypokalemia, making it an undesirable therapeutic option.

Therapy of *H. pylori* Extensive effort has been placed into determining who of the many individuals with *H. pylori* infection should be treated. The common conclusion arrived at by multiple consensus conferences (National Institutes of Health Consensus Development, American Digestive Health Foundation International Update Conference, European Maastricht Consensus, and Asia Pacific Consensus Conference) is that *H. pylori* should be eradicated in patients with documented PUD. This holds true independent of time of presentation (first episode or not), severity of symptoms, presence of confounding factors such as ingestion of NSAIDs, or whether the ulcer is in remission. Some have advocated treating patients with a history of documented PUD who are found to be *H. pylori*–positive by serology or breath testing. Over half of patients with gastric MALT lymphoma experience complete remission of the tumor in response to *H. pylori* eradication. Treating patients with NUD to prevent gastric cancer or patients with gastroesophageal reflux disease requiring long-term acid suppression remains controversial.

Multiple drugs have been evaluated in the therapy of *H. pylori*. No single agent is effective in eradicating the organism. Combination therapy for 14 days provides the greatest efficacy. A short-time course administration (7 to 10 days), although attractive, has not proved as successful as the 14-day regimens. The agents used with the greatest frequency include amoxicillin, metronidazole, tetracycline, clarithromycin, and bismuth compounds.

The physician's goal in treating PUD is to provide relief of symptoms (pain or dyspepsia), promote ulcer healing, and ultimately prevent ulcer recurrence and complications. The greatest impact of understanding the role of *H. pylori* in peptic disease has been the ability to prevent recurrence of what was often a recurring disease. Documented eradication of *H. pylori* in patients with PUD is associated with a dramatic decrease in ulcer recurrence to 4% (as compared to 59%) in GU patients and 6% (compared to 67%) in DU patients. Eradication of the organism may lead to diminished recurrent ulcer bleeding. The impact of its eradication on ulcer perforation is unclear.

Suggested treatment regimens for *H. pylori* are outlined in Table 274-3. Choice of a particular regimen will be influenced by several factors including efficacy, patient tolerance, existing antibiotic resistance, and cost of the drugs. The aim for initial eradication rates should be 85 to 90%. Dual therapy [PPI plus amoxicillin, PPI plus clarithromycin, ranitidine bismuth citrate (Tritec) plus clarithromycin] are not recommended in view of studies demonstrating eradication rates of <80 to 85%. The combination of bismuth, metronidazole, and tetracycline was the first triple regimen found effective against *H. pylori*. The combination of two antibiotics plus either a PPI, H_2 blocker, or bismuth compound has comparable success rates. Addition of acid suppression assists in providing early symptom relief and may enhance bacterial eradication.

Triple therapy, although effective, has several drawbacks, including the potential for poor patient compliance and drug-induced side effects. Compliance is being addressed somewhat by simplifying the regimens so that patients can take the medications twice a day. Simpler (dual therapy) and shorter regimens (7 and 10 days) are not as effective as triple therapy for 14 days. Two anti-*H. pylori* regimens are available in prepackaged formulation: Prevpac (lansoprazole, clarithromycin, and amoxicillin) and Helidac (bismuth subsalicylate, tetracycline, and metronidazole). The contents of the Prevpac are to be taken twice per day for 14 days, whereas Helidac constituents are taken four times per day with an antisecretory agent (PPI or H_2 blocker), also taken for at least 14 days.

Side effects have been reported in up to 20 to 30% of patients on triple therapy. Bismuth may cause black stools, constipation, or darkening of the tongue. The most feared complication with amoxicillin is pseudomembranous colitis, but this occurs in <1 to 2% of patients. Amoxicillin can also lead to antibiotic-associated diarrhea, nausea, vomiting, skin rash, and allergic reaction. Tetracycline has been reported to cause rashes and very rarely hepatotoxicity and anaphylaxis.

TABLE 274-3 *Regimens Recommended for Eradication of H. pylori Infection*

Drug	Dose
TRIPLE THERAPY	
1. Bismuth subsalicylate *plus*	2 tablets qid
Metronidazole *plus*	250 mg qid
Tetracycline[a]	500 mg qid
2. Ranitidine bismuth citrate *plus*	400 mg bid
Tetracycline *plus*	500 mg bid
Clarithromycin or metronidazole	500 mg bid
3. Omeprazole (lansoprazole) *plus*	20 mg bid (30 mg bid)
Clarithromycin *plus*	250 or 500 mg bid
Metronidazole[b] *or*	500 mg bid
Amoxicillin[c]	1 gr bid
QUADRUPLE THERAPY	
Omeprazole (lansoprazole)	20 mg (30 mg) daily
Bismuth subsalicylate	2 tablets qid
Metronidazole	250 mg qid
Tetracycline	500 mg qid

[a] Alternative: use prepacked Helidac (see text).
[b] Alternative: use prepacked Prevpac (see text).
[c] Use either metronidazole or amoxicillin, not both.

One important concern with treating patients who may not need treatment is the potential for development of antibiotic-resistant strains. The incidence and type of antibiotic-resistant *H. pylori* strains vary worldwide. Strains resistant to metronidazole, clarithromycin, amoxicillin, and tetracycline have been described, with the latter two being uncommon. Antibiotic-resistant strains are the most common cause for treatment failure in compliant patients. Unfortunately, in vitro resistance does not predict outcome in patients. Culture and sensitivity testing of *H. pylori* is not performed routinely. Although resistance to metronidazole has been found in as many as 30% and 95% of isolates in North America and Asia, respectively, triple therapy is effective in eradicating the organism in >50% of patients infected with a resistant strain. Clarithromycin resistance is seen in about 10% of persons in the United States.

Failure of *H. pylori* eradication with triple therapy is usually due to infection with a resistant organism. Quadruple therapy (Table 274-3), where clarithromycin is substituted for metronidazole (or vice versa), should be the next step. The combination of pantoprazole, amoxicillin, and rifabutin for 10 days has also been used successfully (86% cure rate) in patients infected with resistant strains. If eradication is still not achieved in a compliant patient, then culture and sensitivity of the organism should be considered.

Reinfection after successful eradication of *H. pylori* is rare in the United States (<1%/year). If recurrent infection occurs within the first 6 months after completing therapy, the most likely explanation is recrudescence as opposed to reinfection, which occurs later in time.

Therapy of NSAID-Related Gastric or Duodenal Injury Medical intervention for NSAID-related mucosal injury includes treatment of an active ulcer and prevention of future injury. Recommendations for the treatment and prevention of NSAID-related mucosal injury are in Table 274-4. Ideally the injurious agent should be stopped as the first step in the therapy of an active NSAID-induced ulcer. If that is possible, then treatment with one of the acid inhibitory agents (H_2 blockers, PPIs) is indicated. Cessation of NSAIDs is not always possible because of the patient's severe underlying disease. Only PPIs can heal GUs or DUs, independent of whether NSAIDs are discontinued.

Prevention of NSAID-induced ulceration can be accomplished by misoprostol (200 μg qid) or a PPI. High-dose H_2 blockers (famotidine, 40 mg bid) have also shown some promise, although PPIs are superior. The use of COX-2-selective NSAIDs may also reduce injury to gastric mucosa. Two highly selective COX-2 inhibitors, celecoxib and rofecoxib, are 100 times more selective inhibitors of COX-2 than standard NSAIDs, leading to gastric or duodenal mucosal injury that is comparable to placebo. However, several issues regarding the safety of these selective COX-2 inhibitors require clarification. Specifically, the CLASS study demonstrates that the advantage of celecoxib in preventing gastrointestinal complications was offset when low-dose aspirin was used simultaneously. Therefore, gastric protection therapy is required in individuals taking COX-2 inhibitors and aspirin prophylaxis. In addition, COX-2 inhibitors delay experimental ulcer healing in animal models and may promote cardiovascular thrombosis. Finally, much of the work performed demonstrating the benefit of COX-2 inhibitors and PPIs on gastrointestinal injury has been performed in individuals of average risk; it is unclear if the same level of benefit will be achieved in high-risk patients.

Approach and Therapy: Summary Controversy continues regarding the best approach to the patient who presents with dyspepsia (Chap. 34). The discovery of *H. pylori* and its role in pathogenesis of ulcers has added a new variable to the equation. Previously, if a patient <50 presented with dyspepsia and without alarming signs or symptoms suggestive of an ulcer complication or malignancy, an empirical therapeutic trial with acid suppression was commonly recommended. Although this approach is practiced by some today, an approach presently gaining approval for the treatment of patients with dyspepsia is outlined in Fig. 274-10. The referral to a gastroenterologist is for the potential need of endoscopy and subsequent evaluation and treatment if the endoscopy is negative.

TABLE 274-4 *Recommendations for Treatment of NSAID-Related Mucosal Injury*

Clinical Setting	*Recommendation*
Active ulcer	
NSAID discontinued	H_2 receptor antagonist or PPI
NSAID continued	PPI
Prophylactic therapy	Misoprostol
	PPI
	Selective COX-2 inhibitor
H. pylori infection	Eradication if active ulcer present or there is a past history of peptic ulcer disease

Note: PPI, proton pump inhibitor; COX-2, isoenzyme of cyclooxygenase.

Once an ulcer (GU or DU) is documented, then the main issue at stake is whether *H. pylori* or an NSAID is involved. With *H. pylori* present, independent of the NSAID status, triple therapy is recommended for 14 days, followed by continued acid-suppressing drugs (H_2 receptor antagonist or PPIs) for a total of 4 to 6 weeks. Selection of patients for documentation of *H. pylori* eradication (organisms gone at least 4 weeks after completing antibiotics) is an area of some debate. The test of choice for documenting eradication is the UBT. The stool antigen study may also hold promise for this purpose, but the data have not been as clear cut as in the case of using the stool antigen test for primary diagnosis. Further studies are warranted, but if the UBT is not available, a stool antigen should be considered to document eradication. Serologic testing is not useful for the purpose of documenting eradication since antibody titers fall slowly and often do not become undetectable. Two approaches toward documentation of eradication exist: (1) test for eradication only in individuals with a complicated course or in individuals who are frail or with multisystem disease who would do poorly with an ulcer recurrence, and (2) test all patients for successful eradication. Some recommend that patients with complicated ulcer disease or who are frail should be treated with long-term acid suppression, thus making documentation of *H. pylori* eradication a moot point. In view of this discrepancy in practice, it would be best to discuss with the patient the different options available.

Several issues differentiate the approach to a GU versus a DU. GUs,

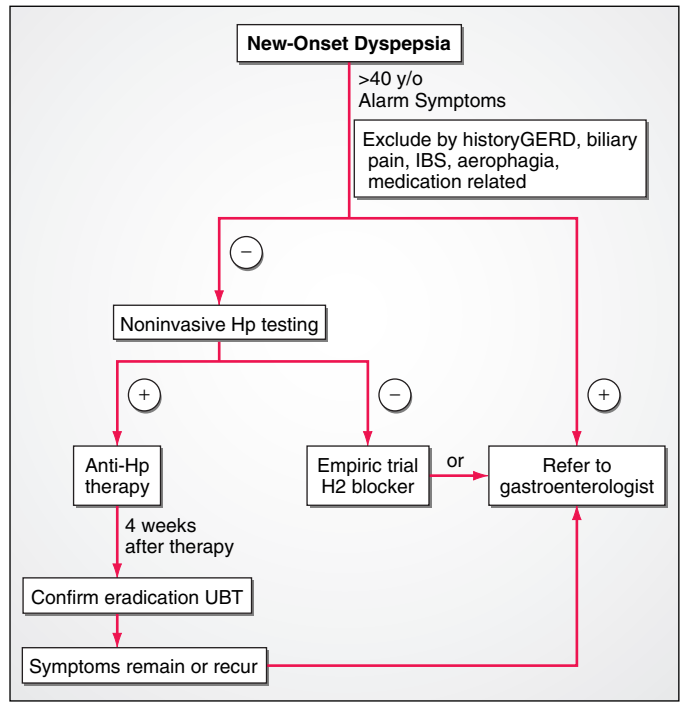

FIGURE 274-10 Overview of new-onset dyspepsia. Hp, *H. pylori*; UBT, urea breath test; IBS, irritable bowel syndrome. *(Adapted from BS Anand and DY Graham: Endoscopy 31:215, 1999.)*

especially of the body and fundus, have the potential of being malignant. Multiple biopsies of a GU should be taken initially; even if these are negative for neoplasm, repeat endoscopy to document healing at 8 to 12 weeks should be performed, with biopsy if the ulcer is still present. About 70% of GUs eventually found to be malignant undergo significant (usually incomplete) healing.

The majority (>90%) of GUs and DUs heal with the conventional therapy outlined above. A GU that fails to heal after 12 weeks and a DU that does not heal after 8 weeks of therapy should be considered refractory. Once poor compliance and persistent *H. pylori* infection have been excluded, NSAID use, either inadvertent or surreptitious, must be excluded. In addition, cigarette smoking must be eliminated. For a GU, malignancy must be meticulously excluded. Next, consideration should be given to a gastric hypersecretory state, which can be excluded with gastric acid analysis. Although a subset of patients have gastric acid hypersecretion of unclear etiology as a contributing factor to refractory ulcers, ZES should be excluded with a fasting gastrin or secretin stimulation test (see below). More than 90% of refractory ulcers (either DUs or GUs) heal after 8 weeks of treatment with higher doses of PPI (omeprazole, 40 mg/d; lansoprazole 30 to 60 mg/d). This higher dose is also effective in maintaining remission. Surgical intervention may be a consideration at this point; however, other rare causes of refractory ulcers must be excluded before recommending surgery. Rare etiologies of refractory ulcers that may be diagnosed by gastric or duodenal biopsies include: ischemia, Crohn's disease, amyloidosis, sarcoidosis, lymphoma, eosinophilic gastroenteritis, or infection [cytomegalovirus (CMV), tuberculosis, or syphilis].

Surgical Therapy Surgical intervention in PUD can be viewed as being either elective, for treatment of medically refractory disease, or as urgent/emergent, for the treatment of an ulcer-related complication. The development of pharmacologic and endoscopic approaches for the treatment of peptic disease has led to a substantial decrease in the number operations needed for this disorder. Refractory ulcers are an exceedingly rare occurrence. Surgery is more often required for treatment of an ulcer-related complication. Gastrointestinal bleeding (Chap. 37), perforation, and gastric outlet obstruction are the three complications that may require surgical intervention.

Hemorrhage is the most common ulcer-related complication, occurring in ~15 to 25% of patients. Bleeding may occur in any age group but is most often seen in older patients (sixth decade or beyond). The majority of patients stop bleeding spontaneously, but in some, endoscopic therapy (Chap. 272) is necessary. Parenterally administered PPIs also decrease ulcer rebleeding. Patients unresponsive or refractory to endoscopic intervention will require surgery (~5% of transfusion-requiring patients).

Free peritoneal perforation occurs in ~2 to 3% of DU patients. As in the case of bleeding, up to 10% of these patients will not have antecedent ulcer symptoms. Concomitant bleeding may occur in up to 10% of patients with perforation, with mortality being increased substantially. Peptic ulcer can also penetrate into adjacent organs, especially with a posterior DU, which can penetrate into the pancreas, colon, liver, or biliary tree.

Pyloric channel ulcers or DUs can lead to gastric outlet obstruction in ~2 to 3% of patients. This can result from chronic scarring or from impaired motility due to inflammation and/or edema with pylorospasm. Patients may present with early satiety, nausea, vomiting of undigested food, and weight loss. Conservative management with nasogastric suction, intravenous hydration/nutrition, and antisecretory agents is indicated for 7 to 10 days with the hope that a functional obstruction will reverse. If a mechanical obstruction persists, endoscopic intervention with balloon dilation may be effective. Surgery should be considered if all else fails.

Specific Operations for Duodenal Ulcers Surgical treatment is designed to decrease gastric acid secretion. Operations most commonly performed include (1) vagotomy and drainage (by pyloroplasty, gastroduodenostomy, or gastrojejunostomy), (2) highly selective vagotomy (which does not require a drainage procedure), and (3) vagotomy with antrectomy. The specific procedure performed is dictated by the underlying circumstances: elective vs. emergency, the degree and extent of duodenal ulceration, and the expertise of the surgeon.

Vagotomy is a component of each of these procedures and is aimed at decreasing acid secretion through ablating cholinergic input to the stomach. Unfortunately, both truncal and selective vagotomy (preserves the celiac and hepatic branches) result in gastric atony despite successful reduction of both basal acid output (BAO, decreased by 85%) and maximal acid output (MAO, decreased by 50%). Drainage through pyloroplasty or gastroduodenostomy is required in an effort to compensate for the vagotomy-induced gastric motility disorder. This procedure has an intermediate complication rate and a 10% ulcer recurrence rate. To minimize gastric dysmotility, highly selective vagotomy (also known as parietal cell, super selective, and proximal vagotomy) was developed. Only the vagal fibers innervating the portion of the stomach that contains parietal cells is transected, thus leaving fibers important for regulating gastric motility intact. Although this procedure leads to an immediate decrease in both BAO and stimulated acid output, acid secretion recovers over time. By the end of the first postoperative year, basal and stimulated acid output are ~30 and 50%, respectively, of preoperative levels. Ulcer recurrence rates are higher with highly selective vagotomy (≥10%), although the overall complication rates are the lowest of the three procedures.

The procedure that provides the lowest rates of ulcer recurrence (1%) but has the highest complication rate is vagotomy (truncal or selective) in combination with antrectomy. Antrectomy is aimed at eliminating an additional stimulant of gastric acid secretion, gastrin. Gastrin originates from G cells found in the antrum. Two principal types of reanastomoses are used after antrectomy, gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II) (Fig. 274-11). Although Billroth I is often preferred over II, severe duodenal inflammation or scarring may preclude its performance.

Of these procedures, highly selective vagotomy may be the one of choice in the elective setting, except in situations where ulcer recurrence rates are high (prepyloric ulcers and those refractory to H_2 therapy). Selection of vagotomy and antrectomy may be more appropriate in these circumstances.

These procedures have been traditionally performed by standard laparotomy. The advent of laparoscopic surgery has led several surgical teams to successfully perform highly selective vagotomy, truncal vagotomy/pyloroplasty, and truncal vagotomy/antrectomy through

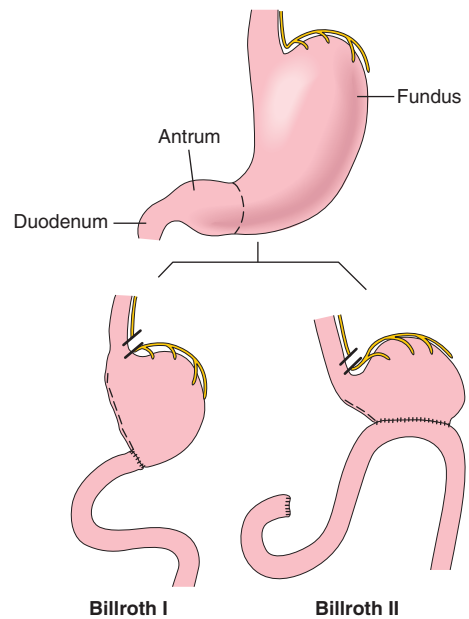

FIGURE 274-11 Schematic representation of Billroth I and II procedures.

this approach. An increase in the number of laparoscopic procedures for treatment of PUD is expected.

Specific Operations for Gastric Ulcers The location and the presence of a concomitant DU dictate the operative procedure performed for a GU. Antrectomy (including the ulcer) with a Billroth I anastomosis is the treatment of choice for an antral ulcer. Vagotomy is performed only if a DU is present. Although ulcer excision with vagotomy and drainage procedure has been proposed, the higher incidence of ulcer recurrence makes this a less desirable approach. Ulcers located near the esophagogastric junction may require a more radical approach, a subtotal gastrectomy with a Roux-en-Y esophagogastrojejunostomy (Csende's procedure). A less aggressive approach including antrectomy, intraoperative ulcer biopsy, and vagotomy (Kelling-Madlener procedure) may be indicated in fragile patients with a high GU. Ulcer recurrence approaches 30% with this procedure.

Surgery-Related Complications Complications seen after surgery for PUD are related primarily to the extent of the anatomical modification performed. Minimal alteration (highly selective vagotomy) is associated with higher rates of ulcer recurrence and less gastrointestinal disturbance. More aggressive surgical procedures have a lower rate of ulcer recurrence but a greater incidence of gastrointestinal dysfunction. Overall, morbidity and mortality related to these procedures are quite low. Morbidity associated with vagotomy and antrectomy or pyloroplasty is ≤5%, with mortality ~1%. Highly selective vagotomy has lower morbidity and mortality rates of 1 and 0.3%, respectively.

In addition to the potential early consequences of any intraabdominal procedure (bleeding, infection, thromboembolism), gastroparesis, duodenal stump leak, and efferent loop obstruction can be observed.

RECURRENT ULCERATION The risk of ulcer recurrence is directly related to the procedure performed. Ulcers that recur after partial gastric resection tend to develop at the anastomosis (stomal or marginal ulcer). Epigastric abdominal pain is the most frequent presenting complaint. Severity and duration of pain tend to be more progressive than observed with DUs before surgery.

Ulcers may recur for several reasons including incomplete vagotomy, retained antrum, and, less likely, persistent or recurrent *H. pylori* infection. ZES should have been excluded preoperatively. More recently, surreptitious use of NSAIDs has been found to be a reason for recurrent ulcers after surgery, especially if the initial procedure was done for an NSAID-induced ulcer. Once *H. pylori* and NSAIDs have been excluded as etiologic factors, the question of incomplete vagotomy or retained gastric antrum should be explored. For the latter, fasting plasma gastrin levels should be determined. If elevated, retained antrum or ZES (see below) should be considered. A combination of acid secretory analysis and secretin stimulation (see below) can assist in this differential diagnosis. Incomplete vagotomy can be ruled out by gastric acid analysis coupled with sham feeding. In this test, gastric acid output is measured while the patient sees, smells, and chews a meal (without swallowing). The cephalic phase of gastric secretion, which is mediated by the vagus, is being assessed with this study. An increase in gastric acid output in response to sham feeding is evidence that the vagus nerve is intact.

Medical therapy with H_2 blockers will heal postoperative ulceration in 70 to 90% of patients. The efficacy of PPIs has not been fully assessed in this group, but one may anticipate greater rates of ulcer healing compared to those obtained with H_2 blockers. Repeat operation (complete vagotomy, partial gastrectomy) may be required in a small subgroup of patients who have not responded to aggressive medical management.

AFFERENT LOOP SYNDROMES Two types of afferent loop syndrome can occur in patients who have undergone partial gastric resection with Billroth II anastomosis. The most common of the two is bacterial overgrowth in the afferent limb secondary to stasis. Patients may experience postprandial abdominal pain, bloating, and diarrhea with concomitant malabsorption of fats and vitamin B_{12}. Cases refractory to antibiotics may require surgical revision of the loop. The less common afferent loop syndrome can present with severe abdominal pain and bloating that occur 20 to 60 min after meals. Pain is often followed by nausea and vomiting of bile-containing material. The pain and bloating may improve after emesis. The cause of this clinical picture is theorized to be incomplete drainage of bile and pancreatic secretions from an afferent loop that is partially obstructed. Cases refractory to dietary measures may need surgical revision.

DUMPING SYNDROME Dumping syndrome consists of a series of vasomotor and gastrointestinal signs and symptoms and occurs in patients who have undergone vagotomy and drainage (especially Billroth procedures). Two phases of dumping, early and late, can occur. Early dumping takes place 15 to 30 min after meals and consists of crampy abdominal discomfort, nausea, diarrhea, belching, tachycardia, palpitations, diaphoresis, light-headedness, and, rarely, syncope. These signs and symptoms arise from the rapid emptying of hyperosmolar gastric contents into the small intestine, resulting in a fluid shift into the gut lumen with plasma volume contraction and acute intestinal distention. Release of vasoactive gastrointestinal hormones (vasoactive intestinal polypeptide, neurotensin, motilin) is also theorized to play a role in early dumping.

The late phase of dumping typically occurs 90 min to 3 h after meals. Vasomotor symptoms (light-headedness, diaphoresis, palpitations, tachycardia, and syncope) predominate during this phase. This component of dumping is thought to be secondary to hypoglycemia from excessive insulin release.

Dumping syndrome is most noticeable after meals rich in simple carbohydrates (especially sucrose) and high osmolarity. Ingestion of large amounts of fluids may also contribute. Up to 50% of postvagotomy and drainage patients will experience dumping syndrome to some degree. Signs and symptoms often improve with time, but a severe protracted picture can occur in up to 1% of patients.

Dietary modification is the cornerstone of therapy for patients with dumping syndrome. Small, multiple (six) meals devoid of simple carbohydrates coupled with elimination of liquids during meals is important. Antidiarrheals and anticholinergic agents are complementary to diet. Guar and pectin, which increase the viscosity of intraluminal contents, may be beneficial in more symptomatic individuals. Acarbose, an α-glucosidase inhibitor that delays digestion of ingested carbohydrates, has also been shown to be beneficial in the treatment of the late phases of dumping. The somatostatin analogue octreotide has been successful in diet-refractory cases. This drug is administered subcutaneously (50 μg tid), titrated according to clinical response. Recently a long-acting formulation has become available, but its use in dumping syndrome has not been examined.

POSTVAGOTOMY DIARRHEA Up to 10% of patients may seek medical attention for the treatment of postvagotomy diarrhea. This complication is most commonly observed after truncal vagotomy. Patients may complain of intermittent diarrhea that occurs typically 1 to 2 h after meals. Occasionally the symptoms may be severe and relentless. This is due to a motility disorder from interruption of the vagal fibers supplying the luminal gut. Other contributing factors may include decreased absorption of nutrients (see below), increased excretion of bile acids, and release of luminal factors that promote secretion. Diphenoxylate or loperamide is often useful in symptom control. The bile salt–binding agent cholestyramine may be helpful in severe cases. Surgical reversal of a 10-cm segment of jejunum may yield a substantial improvement in bowel frequency in a subset of patients.

BILE REFLUX GASTROPATHY A subset of post-partial gastrectomy patients will present with abdominal pain, early satiety, nausea, and vomiting, who have as the only finding mucosal erythema of the gastric remnant. Histologic examination of the gastric mucosa reveals minimal inflammation but the presence of epithelial cell injury. This clinical picture is categorized as bile or alkaline reflux gastropathy/gastritis. Although reflux of bile is implicated as the reason for this disorder, the mechanism is unknown. Prokinetic agents (cisapride, 10 to 20 mg before

meals and at bedtime) and cholestyramine have been effective treatments. Cisapride is no longer available because it induces cardiac arrhythmias. Severe refractory symptoms may require using either nuclear scanning with ^{99m}Tc-HIDA, to document reflux, or an alkaline challenge test, where 0.1 *N* NaOH is infused into the stomach in an effort to reproduce the patient's symptoms. Surgical diversion of pancreaticobiliary secretions away from the gastric remnant with a Roux-en-Y gastrojejunostomy consisting of a long (50 to 60 cm) Roux limb has been used in severe cases. Bilious vomiting improves, but early satiety and bloating may persist in up to 50% of patients.

MALDIGESTION AND MALABSORPTION Weight loss can be observed in up to 60% of patients after partial gastric resection. A significant component of this weight reduction is due to decreased oral intake. However, mild steatorrhea can also develop. Reasons for maldigestion/malabsorption include decreased gastric acid production, rapid gastric emptying, decreased food dispersion in the stomach, reduced luminal bile concentration, reduced pancreatic secretory response to feeding, and rapid intestinal transit.

Decreased serum vitamin B_{12} levels can be observed after partial gastrectomy. This is usually not due to deficiency of IF, since a minimal amount of parietal cells (source of IF) are removed during antrectomy. Reduced vitamin B_{12} may be due to competition for the vitamin by bacterial overgrowth or inability to split the vitamin from its protein-bound source due to hypochlorhydria.

Iron-deficiency anemia may be a consequence of impaired absorption of dietary iron in patients with a Billroth II gastrojejunostomy. Absorption of iron salts is normal in these individuals; thus a favorable response to oral iron supplementation can be anticipated. Folate deficiency with concomitant anemia can also develop in these patients. This deficiency may be secondary to decreased absorption or diminished oral intake.

Malabsorption of vitamin D and calcium resulting in osteoporosis and osteomalacia is common after partial gastrectomy and gastrojejunostomy (Billroth II). Osteomalacia can occur as a late complication in up to 25% of post-partial gastrectomy patients. Bone fractures occur twice as commonly in men after gastric surgery as in a control population. It may take years before x-ray findings demonstrate diminished bone density. Elevated alkaline phosphatase, reduced serum calcium, bone pain, and pathologic fractures may be seen in patients with osteomalacia. The high incidence of these abnormalities in this subgroup of patients justifies treating them with vitamin D and calcium supplementation indefinitely. Therapy is especially important in females.

GASTRIC ADENOCARCINOMA The incidence of adenocarcinoma in the gastric stump is increased 15 years after resection. Some have reported a four- to fivefold increase in gastric cancer 20 to 25 years after resection. The pathogenesis is unclear but may involve alkaline reflux, bacterial proliferation, or hypochlorhydria. Endoscopic screening every other year may detect surgically treatable disease.

RELATED CONDITIONS

ZOLLINGER–ELLISON SYNDROME Severe peptic ulcer diathesis secondary to gastric acid hypersecretion due to unregulated gastrin release from a non-β cell endocrine tumor (gastrinoma) defines the components of the ZES. Initially, ZES was typified by aggressive and refractory ulceration in which total gastrectomy provided the only chance for enhancing survival. Today ZES can be cured by surgical resection in up to 30% of patients.

Epidemiology The incidence of ZES varies from 0.1 to 1% of individuals presenting with PUD. Males are more commonly affected than females, and the majority of patients are diagnosed between ages 30 and 50. Gastrinomas are classified into sporadic tumors (more common) and those associated with multiple endocrine neoplasia (MEN) type I (see below).

Pathophysiology Hypergastremia originating from an autonomous neoplasm is the driving force responsible for the clinical manifestations in ZES. Gastrin stimulates acid secretion through gastrin receptors on parietal cells and by inducing histamine release from ECL cells. Gastrin also has a trophic action on gastric epithelial cells. Long-standing hypergastrinemia leads to markedly increased gastric acid secretion through both parietal cell stimulation and increased parietal cell mass. The increased gastric acid output leads to the peptic ulcer diathesis, erosive esophagitis, and diarrhea.

Tumor Distribution Although early studies suggested that the vast majority of gastrinomas occurred within the pancreas, a significant number of these lesions are extrapancreatic. Over 80% of these tumors are found within the hypothetical gastrinoma triangle (confluence of the cystic and common bile ducts superiorly, junction of the second and third portions of the duodenum inferiorly, and junction of the neck and body of the pancreas medially). Duodenal tumors constitute the most common nonpancreatic lesion; up to 50% of gastrinomas are found here. Less common extrapancreatic sites include stomach, bones, ovaries, heart, liver, and lymph nodes. More than 60% of tumors are considered malignant, with up to 30 to 50% of patients having multiple lesions or metastatic disease at presentation. Histologically, gastrin-producing cells appear well differentiated, expressing markers typically found in endocrine neoplasms (chromogranin, neuron-specific enolase).

Clinical Manifestations Gastric acid hypersecretion is responsible for the signs and symptoms observed in patients with ZES. Peptic ulcer is the most common clinical manifestation, occurring in >90% of gastrinoma patients. Initial presentation and ulcer location (duodenal bulb) may be indistinguishable from common PUD. Clinical situations that should create suspicion of gastrinoma are ulcers in unusual locations (second part of the duodenum and beyond), ulcers refractory to standard medical therapy, ulcer recurrence after acid-reducing surgery, ulcers presenting with frank complications (bleeding, obstruction, and perforation), or ulcers in the absence of *H. pylori* or NSAID ingestion. Symptoms of esophageal origin are present in up to two-thirds of patients with ZES, with a spectrum ranging from mild esophagitis to frank ulceration with stricture and Barrett's mucosa.

Diarrhea is the next most common clinical manifestation, in up to 50% of patients. Although diarrhea often occurs concomitantly with acid peptic disease, it may also occur independent of an ulcer. Etiology of the diarrhea is multifactorial, resulting from marked volume overload to the small bowel, pancreatic enzyme inactivation by acid, and damage of the intestinal epithelial surface by acid. The epithelial damage can lead to a mild degree of maldigestion and malabsorption of nutrients. The diarrhea may also have a secretory component due to the direct stimulatory effect of gastrin on enterocytes or the cosecretion of additional hormones from the tumor, such as vasoactive intestinal peptide.

Gastrinomas can develop in the presence of MEN I syndrome (Chap. 329) in ~25% of patients. This autosomal dominant disorder involves primarily three organ sites: the parathyroid glands (80 to 90%), pancreas (40 to 80%), and pituitary gland (30 to 60%). The genetic defect in MEN I is in the long arm of chromosome 11 (11q11-q13). In view of the stimulatory effect of calcium on gastric secretion, the hyperparathyroidism and hypercalcemia seen in MEN I patients may have a direct effect on ulcer disease. Resolution of hypercalcemia by parathyroidectomy reduces gastrin and gastric acid output in gastrinoma patients. An additional distinguishing feature in ZES patients with MEN I is the higher incidence of gastric carcinoid tumor development (as compared to patients with sporadic gastrinomas). Gastrinomas tend to be smaller, multiple, and located in the duodenal wall more often than is seen in patients with sporadic ZES. Establishing the diagnosis of MEN I is critical not only from the standpoint of providing genetic counseling to the patient and his or her family but also from the surgical approach recommended.

TABLE 274-5 When to Obtain a Fasting Serum Gastrin Level

Multiple ulcers
Ulcers in unusual locations; associated with severe esophagitis; resistant to therapy with frequent recurrences; in the absence of NSAID ingestion or *H. pylori* infection
Ulcer patients awaiting surgery
Extensive family history for peptic ulcer disease
Postoperative ulcer recurrence
Basal hyperchlorhydria
Unexplained diarrhea or steatorrhea
Hypercalcemia
Family history of pancreatic islet, pituitary, or parathyroid tumor
Prominent gastric or duodenal folds

Diagnosis The first step in the evaluation of a patient suspected of having ZES is to obtain a fasting gastrin level. A list of clinical scenarios that should arouse suspicion regarding this diagnosis is shown in Table 274-5. Fasting gastrin levels are usually <150 pg/mL. Virtually all gastrinoma patients will have a gastrin level >150 to 200 pg/mL. Measurement of fasting gastrin should be repeated to confirm the clinical suspicion.

Multiple processes can lead to an elevated fasting gastrin level: gastric hypochlorhydria or achlorhydria (the most frequent), with or without pernicious anemia; retained gastric antrum; G cell hyperplasia; gastric outlet obstruction; renal insufficiency; massive small-bowel obstruction; and conditions such as rheumotoid arthritis, vitiligo, diabetes mellitus, and pheochromocytoma. Gastric acid induces feedback inhibition of gastrin release. A decrease in acid production will subsequently lead to failure of the feedback inhibitory pathway, resulting in net hypergastrinemia. Gastrin levels will thus be high in patients using antisecretory agents for the treatment of acid peptic disorders and dyspepsia. *H. pylori* infection can also cause hypergastrinemia.

The next step in establishing a biochemical diagnosis of gastrinoma is to assess acid secretion. Nothing further needs to be done if decreased acid output is observed. In contrast, normal or elevated gastric acid output suggests a need for additional tests. Gastric acid analysis is performed by placing a nasogastric tube in the stomach and drawing samples at 15-min intervals for 1 h during unstimulated or basal state (BAO), followed by continued sampling after administration of intravenous pentagastrin (MAO). Up to 90% of gastrinoma patients may have a BAO of ≥15 meq/h (normal, <4 meq/h). Up to 12% of patients with common PUD may have comparable levels of acid secretion. A BAO/MAO ratio >0.6 is highly suggestive of ZES, but a ratio <0.6 does not exclude the diagnosis. Pentagastrin is no longer available in the United States, making measurement of MAO virtually impossible. If the technology for measuring gastric acid secretion is not available, a basal gastric pH ≥3 virtually excludes a gastrinoma.

Gastrin provocative tests have been developed in an effort to differentiate between the causes of hypergastrinemia and are especially helpful in patients with indeterminant acid secretory studies. The tests are the secretin stimulation test, the calcium infusion study, and a standard meal test. In each of these, a fasted patient has an indwelling intravenous catheter in place for serial blood sampling and an intravenous line in place for secretin or calcium infusion. The patient receives either secretin (intravenous bolus of 2 μg/kg) or calcium (calcium gluconate, 5 mg/kg body weight over 3 h) or is fed a meal. Blood is then drawn at predetermined intervals (10 min and 1 min before and at 2, 5, 10, 15, 20, and 30 min after injection for secretin stimulation and at 30-min intervals during the calcium infusion). The most sensitive and specific gastrin provocative test for the diagnosis of gastrinoma is the secretin study. An increase in gastrin of ≥200 pg within 15 min of secretin injection has a sensitivity and specificity of >90% for ZES. The calcium infusion study is less sensitive and specific than the secretin test, with a rise of >400 pg/mL observed in ~80% of gastrinoma patients. The lower accuracy, coupled with it being a more cumbersome study with greater potential for adverse effects, makes calcium infusion less useful and therefore rarely, if ever, utilized. Rarely, one may observe increased BAO and hypergastrinemia in a patient who in the past has been categorized as having G cell hyperplasia or hyperfunction. This set of findings may have been due to *H. pylori*. The standard meal test was devised to assist in making the diagnosis of G cell–related hyperactivity, by observing a dramatic increase in gastrin after a meal (>200%). This test is not useful in differentiating between G cell hyperfunction and ZES.

Tumor Localization Once the biochemical diagnosis of gastrinoma has been confirmed, the tumor must be located. Multiple imaging studies have been utilized in an effort to enhance tumor localization (Table 274-6). The broad range of sensitivity is due to the variable success rates achieved by the different investigative groups. Endoscopic ultrasound (EUS) permits imaging of the pancreas with a high degree of resolution (<5 mm). This modality is particularly helpful in excluding small neoplasms within the pancreas and in assessing the presence of surrounding lymph nodes and vascular involvement. Several types of endocrine tumors express cell-surface receptors for somatostatin. This permits the localization of gastrinomas by measuring the uptake of the stable somatostatin analogue ^{111}In-pentreotide (octreoscan) with sensitivity and specificity rates of >75%.

Up to 50% of patients have metastatic disease at diagnosis. Success in controlling gastric acid hypersecretion has shifted the emphasis of therapy towards providing a surgical cure. Detecting the primary tumor and excluding metastatic disease are critical in view of this paradigm shift. Once a biochemical diagnosis has been confirmed, the patient should first undergo an abdominal computed tomographic scan, magnetic resonance imaging, or octreoscan (depending on availability) to exclude metastatic disease. Once metastatic disease has been excluded, an experienced endocrine surgeon may opt for exploratory laparotomy with intraoperative ultrasound or transillumination. In other centers, careful examination of the peripancreatic area with EUS, accompanied by endoscopic exploration of the duodenum for primary tumors, will be performed before surgery. Selective arterial secretin injection may be a useful adjuvant for localizing tumors in a subset of patients.

TREATMENT

Treatment of functional endocrine tumors is directed at ameliorating the signs and symptoms related to hormone overproduction, curative resection of the neoplasm, and attempts to control tumor growth in metastatic disease.

PPIs are the treatment of choice and have decreased the need for total gastrectomy. Initial doses of omeprazole or lansoprazole should be in the range of 60 mg/d. Dosing can be adjusted to achieve a BAO <10 meq/h (at the drug trough) in surgery-naive patients and to <5 meq/h in individuals who have previously undergone an acid-reducing operation. Although the somatostatin analogue has inhibitory effects on gastrin release from receptor-bearing tumors and inhibits gastric

TABLE 274-6 Sensitivity of Imaging Studies in Zollinger Ellison Syndrome

acid secretion to some extent, PPIs have the advantage of reducing parietal cell activity to a greater degree.

The ultimate goal of surgery would be to provide a definitive cure. Improved understanding of tumor distribution has led to 10-year disease-free intervals as high as 34% in sporadic gastrinoma patients undergoing surgery. A positive outcome is highly dependent on the experience of the surgical team treating these rare tumors. Surgical therapy of gastrinoma patients with MEN I remains controversial because of the difficulty in rendering these patients disease free with surgery. In contrast to the encouraging postoperative results observed in patients with sporadic disease, only 6% of MEN I patients are disease free 5 years after an operation. Some groups suggest surgery only if a clearly identifiable, nonmetastatic lesion is documented by structural studies. Others advocate a more aggressive approach, where all patients free of hepatic metastasis are explored and all detected tumors in the duodenum are resected; this is followed by enucleation of lesions in the pancreatic head, with a distal pancreatectomy to follow. The outcome of the two approaches has not been clearly defined.

Therapy of metastatic endocrine tumors in general remains suboptimal; gastrinomas are no exception. A host of medical therapeutic approaches including chemotherapy (streptozotocin, 5-fluorouracil, and doxorubicin), IFN-α, and hepatic artery embolization lead to significant toxicity without a substantial improvement in overall survival. ^{111}In-pentetreotide has been utilized in the therapy of metastatic neuroendocrine tumors; further studies are needed. Surgical approaches including debulking surgery and liver transplantation for hepatic metastasis have also produced limited benefit. Therefore, early recognition and surgery are the only chances for curing this disease.

The 5- and 10-year survival rates for gastrinoma patients are 62 to 75% and 47 to 53%, respectively. Individuals with the entire tumor resected or those with a negative laparotomy have 5- and 10-year survival rates >90%. Patients with incompletely resected tumors have 5- and 10-year survival of 43% and 25%, respectively. Patients with hepatic metastasis have <20% survival at 5 years. Favorable prognostic indicators include primary duodenal wall tumors, isolated lymph node tumor, and undetectable tumor upon surgical exploration. Poor outcome is seen in patients with shorter disease duration, higher gastrin levels (>10,000 pg/mL); large pancreatic primary tumors (>3 cm), metastatic disease to lymph nodes, liver, and bone; and Cushing's syndrome. Rapid growth of hepatic metastases is also predictive of poor outcome.

STRESS-RELATED MUCOSAL INJURY Patients suffering from shock, sepsis, massive burns, severe trauma, or head injury can develop acute erosive gastric mucosal changes or frank ulceration with bleeding. Classified as stress-induced gastritis or ulcers, injury is most commonly observed in the acid-producing (fundus and body) portions of the stomach. The most common presentation is gastrointestinal bleeding, which is usually minimal but can occasionally be life-threatening. Respiratory failure requiring mechanical ventilation and underlying coagulopathy are risk factors for bleeding, which tends to occur 48 to 72 h after the acute injury or insult.

Histologically, stress injury does not contain inflammation or *H. pylori*; thus "gastritis" is a misnomer. Although elevated gastric acid secretion may be noted in patients with stress ulceration after head trauma (Cushing's ulcer) and severe burns (Curling's ulcer), mucosal ischemia and breakdown of the normal protective barriers of the stomach also play an important role in the pathogenesis. Acid must contribute to injury in view of the significant drop in bleeding noted when acid inhibitors are used as a prophylactic measure for stress gastritis.

Improvement in the general management of intensive care unit patients has led to a significant decrease in the incidence of gastrointestinal bleeding due to stress ulceration. The estimated decrease in bleeding is from 20 to 30% to <5%. This improvement has led to some debate regarding the need for prophylactic therapy. The limited benefit of medical (endoscopic, angiographic) and surgical therapy in a patient with hemodynamically compromising bleeding associated with stress ulcer/gastritis supports the use of preventive measures in high-risk patients (mechanically ventilated, coagulopathy, multiorgan failure, or severe burns). Maintenance of gastric pH > 3.5 with continuous infusion of H_2 blockers or liquid antacids administered every 2 to 3 h are viable options. Sucralfate slurry (1 g every 4 to 6 h) has also been successful. If bleeding occurs despite these measures, endoscopy, intraarterial vasopressin, or embolization are options. If all else fails, then surgery should be considered. Although vagotomy and antrectomy may be used, the better approach would be a total gastrectomy, which has an exceedingly high mortality rate in this setting.

GASTRITIS The term *gastritis* should be reserved for histologically documented inflammation of the gastric mucosa. Gastritis is not the mucosal erythema seen during endoscopy and is not interchangeable with "dyspepsia." The etiologic factors leading to gastritis are broad and heterogeneous. Gastritis has been classified based on time course (acute vs. chronic), histologic features, and anatomical distribution or proposed pathogenic mechanism (Table 274-7).

The correlation between the histologic findings of gastritis, the clinical picture of abdominal pain or dyspepsia, and endoscopic findings noted on gross inspection of the gastric mucosa is poor. Therefore, there is no typical clinical manifestation of gastritis.

Acute Gastritis The most common causes of acute gastritis are infectious. Acute infection with *H. pylori* induces gastritis. However, *H. pylori* acute gastritis has not been extensively studied. Reported as presenting with sudden onset of epigastric pain, nausea, and vomiting, limited mucosal histologic studies demonstrate a marked infiltrate of neutrophils with edema and hyperemia. If not treated, this picture will evolve into one of chronic gastritis. Hypochlorhydria lasting for up to 1 year may follow acute *H. pylori* infection.

The highly acidic gastric environment may be one reason why infectious processes of the stomach are rare. Bacterial infection of the stomach or phlegmonous gastritis is a rare potentially life-threatening disorder, characterized by marked and diffuse acute inflammatory infiltrates of the entire gastric wall, at times accompanied by necrosis. Elderly individuals, alcoholics, and AIDS patients may be affected. Potential iatrogenic causes include polypectomy and mucosal injection with India ink. Organisms associated with this entity include streptococci, staphylococci, *Escherichia coli*, *Proteus*, and *Haemophilus* sp. Failure of supportive measures and antibiotics may result in gastrectomy.

Other types of infectious gastritis may occur in immunocompromised individuals such as AIDS patients. Examples include herpetic (herpes simplex) or CMV gastritis. The histologic finding of intranuclear inclusions would be observed in the latter.

Chronic Gastritis Chronic gastritis is identified histologically by an inflammatory cell infiltrate consisting primarily of lymphocytes and plasma cells, with very scant neutrophil involvement. Distribution of the inflammation may be patchy, initially involving superficial and glandular portions of the gastric mucosa. This picture may progress to more severe glandular destruction, with atrophy and metaplasia.

TABLE 274-7 Classification of Gastritis

I. Acute gastritis
  A. Acute *H. pylori* infection
  B. Other acute infectious gastritides
    1. Bacterial (other than *H. pylori*)
    2. *Helicobacter helmanni*
    3. Phlegmonous
    4. Mycobacterial
    5. Syphilitic
    6. Viral
    7. Parasitic
    8. Fungal

II. Chronic atrophic gastritis
  A. Type A: Autoimmune, body-predominant
  B. Type B: *H. pylori*–related, antral-predominant
  C. Indeterminant

III. Uncommon Forms of Gastritis
  A. Lymphocytic
  B. Eosinophilic
  C. Crohn's disease
  D. Sarcoidosis
  E. Isolated granulomatous gastritis

Chronic gastritis has been classified according to histologic characteristics. These include superficial atrophic changes and gastric atrophy.

The early phase of chronic gastritis is *superficial gastritis*. The inflammatory changes are limited to the lamina propria of the surface mucosa, with edema and cellular infiltrates separating intact gastric glands. Additional findings may include decreased mucus in the mucous cells and decreased mitotic figures in the glandular cells. The next stage is *atrophic gastritis*. The inflammatory infiltrate extends deeper into the mucosa, with progressive distortion and destruction of the glands. The final stage of chronic gastritis is *gastric atrophy*. Glandular structures are lost; there is a paucity of inflammatory infiltrates. Endoscopically the mucosa may be substantially thin, permitting clear visualization of the underlying blood vessels.

Gastric glands may undergo morphologic transformation in chronic gastritis. Intestinal metaplasia denotes the conversion of gastric glands to a small intestinal phenotype with small-bowel mucosal glands containing goblet cells. The metaplastic changes may vary in distribution from patchy to fairly extensive gastric involvement. Intestinal metaplasia is an important predisposing factor for gastric cancer (Chap. 77).

Chronic gastritis is also classified according to the predominant site of involvement. Type A refers to the body-predominant form (autoimmune) and type B is the central-predominant form (*H. pylori*–related). This classification is artificial in view of the difficulty in distinguishing these two entities. The term *AB gastritis* has been used to refer to a mixed antral/body picture.

TYPE A GASTRITIS The less common of the two forms involves primarily the fundus and body, with antral sparing. Traditionally, this form of gastritis has been associated with pernicious anemia (Chap. 92) in the presence of circulating antibodies against parietal cells and IF; thus it is also called *autoimmune gastritis*. *H. pylori* infection can lead to a similar distribution of gastritis. The characteristics of an autoimmune picture are not always present.

Antibodies to parietal cells have been detected in >90% of patients with pernicious anemia and in up to 50% of patients with type A gastritis. The parietal cell antibody is directed against H^+,K^+-ATPase. T cells are also implicated in the injury pattern of this form of gastritis.

Parietal cell antibodies and atrophic gastritis are observed in family members of patients with pernicious anemia. These antibodies are observed in up to 20% of individuals over age 60 and in ~20% of patients with vitiligo and Addison's disease. About half of patients with pernicious anemia have antibodies to thyroid antigens, and about 30% of patients with thyroid disease have circulating anti-parietal cell antibodies. Anti-IF antibodies are more specific than parietal cell antibodies for type A gastritis, being present in ~40% of patients with pernicious anemia. Another parameter consistent with this form of gastritis being autoimmune in origin is the higher incidence of specific familial histocompatibility haplotypes such as HLA-B8 and -DR3.

The parietal cell–containing gastric gland is preferentially targeted in this form of gastritis, and achlorhydria results. Parietal cells are the source of IF, lack of which will lead to vitamin B_{12} deficiency and its sequelae (megaloblastic anemia, neurologic dysfunction).

Gastric acid plays an important role in feedback inhibition of gastrin release from G cells. Achlorhydria, coupled with relative sparing of the antral mucosa (site of G cells), leads to hypergastrinemia. Gastrin levels can be markedly elevated (>500 pg/mL) in patients with pernicious anemia. ECL cell hyperplasia with frank development of gastric carcinoid tumors may result from gastrin trophic effects. The role of gastrin in carcinoid development is confirmed by the observation that antrectomy leads to regression of these lesions. Hypergastrinemia and achlorhydria may also be seen in non-pernicious anemia–associated type A gastritis.

TYPE B GASTRITIS Type B, or antral-predominant, gastritis is the more common form of chronic gastritis. *H. pylori* infection is the cause of this entity. Although described as "antral-predominant," this is likely a misnomer in view of studies documenting the progression of the inflammatory process towards the body and fundus of infected individuals. The conversion to a pan-gastritis is time-dependent—estimated to require 15 to 20 years. This form of gastritis increases with age, being present in up to 100% of persons over age 70. Histology improves after *H. pylori* eradication. The number of *H. pylori* organisms decreases dramatically with progression to gastric atrophy, and the degree of inflammation correlates with the level of these organisms. Early on, with antral-predominant findings, the quantity of *H. pylori* is highest and a dense chronic inflammatory infiltrate of the lamina propria is noted accompanied by epithelial cell infiltration with polymorphonuclear leukocytes (Fig. 274-12).

Multifocal atrophic gastritis, gastric atrophy with subsequent metaplasia, has been observed in chronic *H. pylori*–induced gastritis. This may ultimately lead to development of gastric adenocarcinoma (Fig. 274-8; Chap. 77). *H. pylori* infection is now considered an independent risk factor for gastric cancer. Worldwide epidemiologic studies have documented a higher incidence of *H. pylori* infection in patients with adenocarcinoma of the stomach as compared to control subjects. Seropositivity for *H. pylori* is associated with a three- to sixfold increased risk of gastric cancer. This risk may be as high as ninefold after adjusting for the inaccuracy of serologic testing in the elderly. The mechanism by which *H. pylori* infection leads to cancer is unknown. However, eradication of *H. pylori* as a general preventative measure for gastric cancer is not recommended.

Infection with *H. pylori* is also associated with development of a low-grade B cell lymphoma, gastric MALT lymphoma (Chap. 97).

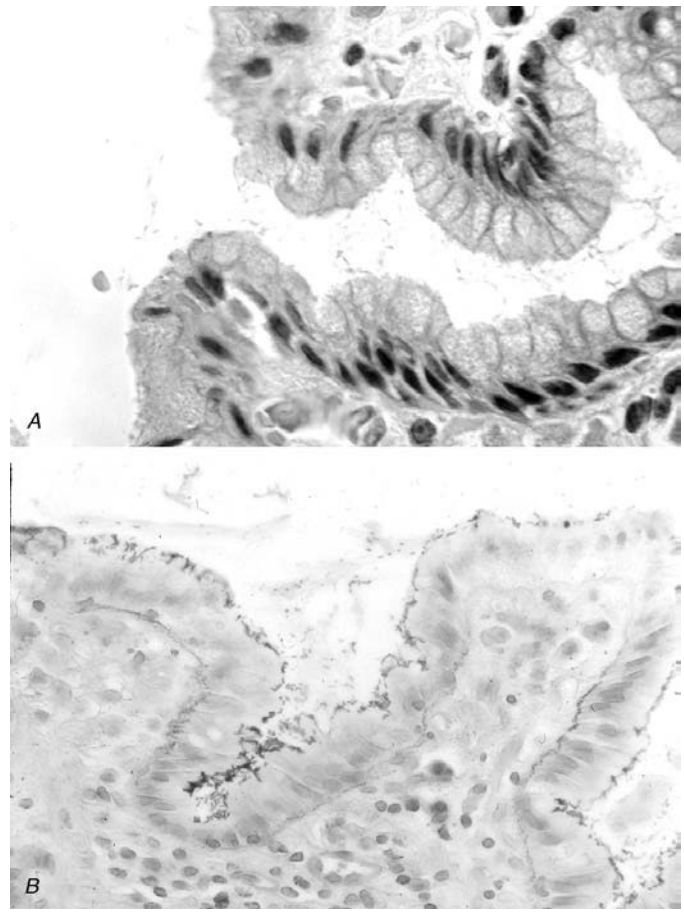

FIGURE 274-12 Chronic gastritis and *Helicobacter pylori* organisms. *A*. H&E stain of gastric mucosa showing surface foveolar cells, adherent mucus, and scattered bacillary forms within the mucus. *B*. Steiner silver stain of superficial gastric mucosa, showing abundant darkly staining microorganisms layered over the apical portion of the surface epithelium. Note that there is no tissue invasion. *[Courtesy of James M. Crawford, M.D., Ph.D. Reprinted with permission from JM Crawford, in V Kumar et al (eds): Basic Pathology. Philadelphia, Saunders, 1997.]*

The chronic T cell stimulation caused by the infection leads to production of cytokines that promote the B cell tumor. Tumor growth remains dependent upon the presence of *H. pylori* in that its eradication is often associated with complete regression of the tumor. The tumor may take more than a year to regress after treating the infection. Such patients should be followed by EUS every 2 to 3 months. If the tumor is stable or decreasing in size, no other therapy is necessary. If the tumor grows, it may have become a high-grade B cell lymphoma. When the tumor becomes a high-grade aggressive lymphoma histologically, it loses responsiveness to *H. pylori* eradication.

TREATMENT

Treatment in chronic gastritis is aimed at the sequelae and not the underlying inflammation. Patients with pernicious anemia will require parenteral vitamin B_{12} supplementation on a long-term basis. Eradication of *H. pylori* is not routinely recommended unless PUD or a low-grade MALT lymphoma is present.

Miscellaneous Forms of Gastritis Lymphocytic gastritis is characterized histologically by intense infiltration of the surface epithelium with lymphocytes. The infiltrative process is primarily in the body of the stomach and consists of mature T cells and plasmacytes. The etiology of this form of chronic gastritis is unknown. It has been described in patients with celiac sprue, but whether there is a common factor associating these two entities is unknown. No specific symptoms suggest lymphocytic gastritis. A subgroup of patients have thickened folds noted on endoscopy. These folds are often capped by small nodules that contain a central depression or erosion; this form of the disease is called *varioliform gastritis*. *H. pylori* probably plays no significant role in lymphocytic gastritis. Therapy with glucocorticoids or sodium cromoglycate has obtained unclear results.

Marked eosinophilic infiltration involving any layer of the stomach (mucosa, muscularis propria, and serosa) is characteristic of *eosinophilic gastritis*. Affected individuals will often have circulating eosinophilia with clinical manifestation of systemic allergy. Involvement may range from isolated gastric disease to diffuse eosinophilic gastroenteritis. Antral involvement predominates, with prominent edematous folds being observed on endoscopy. These prominent antral folds can lead to outlet obstruction. Patients can present with epigastric discomfort, nausea, and vomiting. Treatment with glucocorticoids has been successful.

Several systemic disorders may be associated with *granulomatous gastritis*. Gastric involvement has been observed in Crohn's disease. Involvement may range from granulomatous infiltrates noted only on gastric biopsies to frank ulceration and stricture formation. Gastric Crohn's disease usually occurs in the presence of small-intestinal disease. Several rare infectious processes can lead to granulomatous gastritis, including histoplasmosis, candidiasis, syphilis, and tuberculosis. Other unusual causes of this form of gastritis include sarcoidosis, idiopathic granulomatous gastritis, and eosinophilic granulomas involving the stomach. Establishing the specific etiologic agent in this form of gastritis can be difficult, at times requiring repeat endoscopy with biopsy and cytology. Occasionally, a surgically obtained full-thickness biopsy of the stomach may be required to exclude malignancy.

MÉNÉTRIER'S DISEASE Ménétrier's disease is a rare entity characterized by large, tortuous gastric mucosal folds. The differential diagnosis of large gastric folds includes ZES, malignancy, infectious etiologies (CMV, histoplasmosis, syphilis), and infiltrative disorders such as sarcoidosis. The mucosal folds in Ménétrier's disease are often most prominent in the body and fundus. Histologically, massive foveolar hyperplasia (hyperplasia of surface and glandular mucous cells) is noted, which replaces most of the chief and parietal cells. This hyperplasia produces the prominent folds observed. The pits of the gastric glands elongate and may become extremely tortuous. Although the lamina propria may contain a mild chronic inflammatory infiltrate, Ménétrier's disease is not considered a form of gastritis. The etiology of this unusual clinical picture is unknown. Overexpression of growth factors such as TGF-α may be involved in the process.

Epigastric pain at times accompanied by nausea, vomiting, anorexia, and weight loss are signs and symptoms in patients with Ménétrier's disease. Occult gastrointestinal bleeding may occur, but overt bleeding is unusual and, when present, is due to superficial mucosal erosions. Twenty to 100% of patients (depending on time of presentation) develop a protein-losing gastropathy accompanied by hypoalbuminemia and edema. Gastric acid secretion is usually reduced or absent because of the replacement of parietal cells. Large gastric folds are readily detectable by either radiographic (barium meal) or endoscopic methods. Endoscopy with deep mucosal biopsy (and cytology) is required to establish the diagnosis and exclude other entities that may present similarly. A nondiagnostic biopsy may lead to a surgically obtained full-thickness biopsy to exclude malignancy.

TREATMENT

Medical therapy with anticholinergic agents, prostaglandins, PPIs, prednisone, and H_2 receptor antagonists has obtained varying results. Anticholinergics decrease protein loss. A high-protein diet should be recommended to replace protein loss in patients with hypoalbuminemia. Ulcers should be treated with a standard approach. Severe disease with persistent and substantial protein loss may require total gastrectomy. Subtotal gastrectomy is performed by some; it may be associated with higher morbidity and mortality secondary to the difficulty in obtaining a patent and long-lasting anastomosis between normal and hyperplastic tissues.

ACKNOWLEDGMENT

275 DISORDERS OF ABSORPTION

Henry J. Binder

Disorders of absorption constitute a broad spectrum of conditions with multiple etiologies and varied clinical manifestations. Almost all of these clinical problems are associated with *diminished* intestinal absorption of one or more dietary nutrients and are often referred to as the *malabsorption syndrome*. This latter term is not ideal as it represents a pathophysiologic state, does *not* provide an etiologic explanation for the underlying problem, and should not be considered an adequate final diagnosis. The only clinical situations in which absorption is *increased* are hemochromatosis and Wilson's disease, in which there is increased absorption of iron and copper, respectively.

Most, but not all, of these clinical conditions are associated with *steatorrhea*, an increase in stool fat excretion of >6% of dietary fat intake. Some disorders of absorption are not associated with steatorrhea: Primary lactase deficiency, which represents a congenital absence of the small intestinal brush border disaccharidase enzyme lactase, is associated with lactose "malabsorption," and pernicious anemia is associated with a marked decrease in intestinal absorption of cobalamin (vitamin B_{12}) due to an absence of gastric parietal cell intrinsic factor required for cobalamin absorption.

Disorders of absorption must be included in the differential diagnosis of diarrhea (Chap. 35). First, diarrhea is frequently associated with and/or is a consequence of the diminished absorption of one or more dietary nutrients. The diarrhea may be secondary either to the intestinal process that is responsible for the steatorrhea or to steatorrhea per se. Thus, celiac sprue (see below) is associated with both extensive morphologic changes in the small intestinal mucosa and reduced absorption of several dietary nutrients; in contrast, the diarrhea of steatorrhea is the result of the effect of nonabsorbed dietary fatty acids on intestinal, usually colonic, ion transport. For example, oleic acid and ricinoleic acid (a bacterially hydroxylated fatty acid that is also the active ingredient in castor oil, a widely used laxative) induce active colonic Cl ion secretion, most likely secondary to increasing intracellular Ca. In addition, diarrhea per se may result in mild steatorrhea (<11 g fat excretion while on a 100-g fat diet). Second, as diarrhea is both a symptom and a sign, most patients will indicate that they have diarrhea, not that they have fat malabsorption. Third, many intestinal disorders that have diarrhea as a prominent symptom (e.g., ulcerative colitis, traveler's diarrhea secondary to an enterotoxin produced by *Escherichia coli*) do not necessarily have diminished absorption of any dietary nutrient.

Diarrhea as a *symptom* (i.e., when used by patients to describe their bowel movement pattern) may be either a decrease in stool consistency, an increase in stool volume, an increase in number of bowel movements, or any combination of these three changes. In contrast, diarrhea as a *sign* is a quantitative increase in stool water or weight of >200 to 225 mL, or gram per 24 h, when a western-type diet is consumed. Individuals consuming a diet with a higher fiber content may normally have a stool weight of up to 400 g per 24 h. Thus, the clinician must clarify what an individual patient means by diarrhea. Some 10% of patients referred to gastroenterologists for further evaluation of unexplained diarrhea do not have an increase in stool water when it is determined quantitatively. Such patients may have small, frequent, somewhat loose bowel movements with stool urgency that is indicative of proctitis but do not have an increase in stool weight or volume.

It is also critical to establish whether a patient's diarrhea is secondary to diminished absorption of one or more dietary nutrients, in contrast to diarrhea that is due to small- and/or large-intestinal fluid and electrolyte secretion. The former has often been termed *osmotic diarrhea*, while the latter has been referred to as *secretory diarrhea*. Unfortunately, both secretory and osmotic elements can be present simultaneously in the same disorder; thus, this separation is not always precise. Nonetheless, two studies—determination of stool electrolytes and observation of the effect of a fast on stool output—can help make this distinction.

The demonstration of the effect of prolonged (>24 h) fasting on stool output can be very effective in suggesting that a *dietary nutrient* is responsible for the individual's diarrhea. A secretory diarrhea associated with enterotoxin-induced traveler's diarrhea would not be affected by prolonged fasting, as enterotoxin-induced stimulation of intestinal fluid and electrolyte secretion is not altered by eating. In contrast, diarrhea secondary to lactose malabsorption in primary lactase deficiency would undoubtedly cease during a prolonged fast. Thus, a substantial decrease in stool output while fasting during a quantitative stool collection of at least 24 h is presumptive evidence that the diarrhea is related to malabsorption of a dietary nutrient. The persistence of stool output while fasting indicates that the diarrhea is likely secretory and that the cause of diarrhea is *not* due to a dietary nutrient. Either a luminal (e.g., *E. coli* enterotoxin) or circulating (e.g., vasoactive intestinal peptide) secretagogue could be responsible for the patient's diarrhea persisting unaltered during a prolonged fast. The observed effects of fasting can be compared and correlated with stool electrolyte and osmolality determinations.

Measurement of stool electrolytes and osmolality requires the comparison of stool Na^+ and K^+ concentrations determined in liquid stool to the stool osmolality to determine the presence or absence of a so-called stool osmotic gap. The following formula is used:

$$2 \times (\text{stool } [Na^+] + \text{stool } [K^+]) \leq \text{stool osmolality}$$

The cation concentrations are doubled to estimate stool anion concentrations. The presence of a significant osmotic gap suggests the presence in stool water of a substance (or substances) other than Na/K/anions that presumably is responsible for the patient's diarrhea. Originally, stool osmolality was measured, but it is almost invariably greater than the required 290 to 300 mosmol/kg H_2O, reflecting bacterial degradation of nonabsorbed carbohydrate either immediately before defecation or in the stool jar while awaiting chemical analysis, even when the stool is refrigerated. As a result, the stool osmolality should be assumed to be 300 mosmol/kg H_2O. When the calculated difference is >50, an osmotic gap is present, suggesting that the diarrhea is due to a nonabsorbed dietary nutrient, e.g., a fatty acid and/or carbohydrate. When this difference is <25, it is presumed that a dietary nutrient is not responsible for the diarrhea. Since elements of both osmotic (i.e., malabsorption of a dietary nutrient) and secretory diarrhea may be present, this separation at times is less clear-cut at the bedside than when used as a teaching example. Ideally, the presence of an osmotic gap will be associated with a marked decrease in stool output during a prolonged fast, while the absence of an osmotic gap will likely be present in an individual whose stool output had not been reduced substantially during a period of fasting.

NUTRIENT DIGESTION AND ABSORPTION

The lengths of the small intestine and colon are ~300 cm and ~80 cm, respectively. However, the effective functional surface area is approximately 600-fold greater than that of a hollow tube as a result of the presence of folds, villi (in the small intestine), and microvilli. The functional surface area of the small intestine is somewhat greater than that of a doubles tennis court. In addition to nutrient digestion and absorption, the intestinal epithelia have several other functions:

1. *Barrier and immune defense*. The intestine is exposed to a large number of potential antigens and enteric and invasive microorganisms, and it is extremely effective preventing the entry of almost all these agents. The intestinal mucosa also synthesizes and secretes secretory IgA.
2. *Fluid and electrolyte absorption and secretion*. The intestine absorbs ~7 to 8 L of fluid daily, comprising dietary fluid intake (1 to 2 L/d) and salivary, gastric, pancreatic, biliary, and intestinal fluid (6 to 7 L/d). The intestine also responds to several stimuli, especially bacteria and bacterial enterotoxins, that induce fluid and electrolyte secretion, often leading to diarrhea (Chap. 113).
3. *Synthesis and secretion of several proteins*. The intestinal mucosa

is a major site for the production of proteins, including apolipoproteins.

4. *Production of several bioactive amines and peptides*. The intestine is one of the largest endocrine organs in the body and produces several amines and peptides that serve as paracrine and hormonal mediators of intestinal function.

The small and large intestine are anatomically distinct in that villi are present in the small intestine but are absent in the colon and functionally distinct in that nutrient digestion and absorption take place in the small intestine but not in the colon. No precise anatomical characteristics separate duodenum, jejunum, and ileum, although certain nutrients are absorbed exclusively in specific areas of the small intestine. However, villus cells in the small intestine (and surface epithelial cells in the colon) and crypt cells have distinct anatomical and functional characteristics. Intestinal epithelial cells are continuously renewed, with new proliferating epithelial cells at the base of the crypt migrating over 48 to 72 h to the tip of the villus (or surface of the colon), where they are well-developed epithelial cells with digestive and absorptive function. This high rate of cell turnover explains the relatively rapid resolution of diarrhea and other digestive tract side effects during chemotherapy as new cells not exposed to these toxic agents are produced. Equally important is the paradigm of separation of villus/surface cell and crypt cell function: digestive hydrolytic enzymes are present primarily in the brush border of villus epithelial cells. Absorptive and secretory functions are also separated, with villus/surface cells primarily, but not exclusively, being the site for absorptive function, while secretory function is present in crypts of both the small and large intestine.

Nutrients, minerals, and vitamins are absorbed by one or more active transport mechanisms. (The mechanisms of intestinal fluid and electrolyte absorption and secretion are discussed in Chap. 35.) Active transport mechanisms are energy-dependent and mediated by membrane transport proteins. These transport processes will result in the *net* movement of a substance against or in the absence of an electrochemical concentration gradient. Intestinal absorption of amino acids and monosaccharides, e.g., glucose, is also a specialized form of active transport—*secondary active transport*. The movement of these actively transported nutrients against a concentration gradient is Na^+-dependent and is due to a Na^+ gradient across the apical membrane. The Na^+ gradient is maintained by Na^+,K^+-ATPase, the so-called Na^+ pump located on the basolateral membrane, which extrudes Na^+ and maintains a low intracellular [Na] as well as the Na^+ gradient across the apical membrane. As a result, active glucose absorption and glucose-stimulated Na^+ absorption require both the apical membrane transport protein, SGLT, and the basolateral Na^+,K^+-ATPase. In addition to glucose absorption being Na^+-dependent, glucose also stimulates Na^+ and fluid absorption, which is the physiologic basis of oral rehydration therapy for the treatment of diarrhea (Chap. 35).

Although the intestinal epithelial cells are crucial mediators of absorption and ion and water flow, the several cell types in the lamina propria (e.g., mast cells, macrophages, myofibroblasts) and the enteric nervous system interact with the epithelium to regulate mucosal cell function. The function of the intestine is the result of the integrated responses of and interactions between both intestinal epithelial cells and intestinal muscle.

ENTEROHEPATIC CIRCULATION OF BILE ACIDS Bile acids are not present in the diet but are synthesized in the liver by a series of enzymatic steps that also include cholesterol catabolism. Indeed, interruption of the enterohepatic circulation of bile acids can reduce serum cholesterol levels by 10% before a new steady state is established. Bile acids are either primary or secondary: primary bile acids are synthesized in the liver from cholesterol, and secondary bile acids are synthesized from primary bile acids in the intestine by colonic bacterial enzymes. The two primary bile acids in humans are cholic acid and chenodeoxycholic acid; the two most abundant secondary bile acids are deoxycholic acid and lithocholic acid. Approximately 500 mg bile acids are synthesized in the liver daily, conjugated to either taurine or glycine to form tauro-conjugated or glyco-conjugated bile acids, respectively, and are secreted into the duodenum in bile. The primary functions of bile acids are (1) to promote bile flow, (2) to solubilize cholesterol and phospholipid in the gallbladder by mixed micelle formation, and (3) to enhance dietary lipid digestion and absorption by forming mixed micelles in the proximal small intestine.

Bile acids are primarily absorbed by an active, Na^+-dependent process that is located exclusively in the ileum, though bile acids can also be absorbed to a lesser extent by non-carrier-mediated transport processes in the jejunum, ileum, and colon. Conjugated bile acids that enter the colon are deconjugated by colonic bacterial enzymes to unconjugated bile acids and are rapidly absorbed. Colonic bacterial enzymes also dehydroxylate bile acids to secondary bile acids.

Bile acids absorbed from the intestine return to the liver via the portal vein where they are resecreted (Fig. 275-1). Bile acid synthesis is largely autoregulated by 7α-hydroxylase, the initial enzyme in cholesterol degradation. A decrease in the amount of bile acids returning to the liver from the intestine is associated with an increase in bile acid synthesis/cholesterol catabolism, which helps keep the bile acid pool size relatively constant. However, there is a relatively limited capacity for an increase in bile acid synthesis—about two to two and one-half times (see below). The bile acid pool size is approximately 4 g and is circulated via the enterohepatic circulation about twice during each meal, or six to eight times during a 24-h period. A relatively small quantity of bile acids is not absorbed and is excreted in stool daily; this fecal loss is matched by hepatic bile acid synthesis.

Defects in any of the steps of the enterohepatic circulation of bile acids can result in a decrease in duodenal concentration of conjugated bile acids and, as a result, steatorrhea. Thus, steatorrhea can be caused by abnormalities in bile acid synthesis and excretion, their physical state in the intestinal lumen, and reabsorption (Table 275-1).

Synthesis Decreased bile acid synthesis and steatorrhea have been demonstrated in chronic liver disease, but steatorrhea is often not a major component of the illness of these patients.

Secretion Although bile acid secretion may be reduced or absent in biliary obstruction, steatorrhea is rarely a significant medical problem in these patients. In contrast, primary biliary cirrhosis represents a

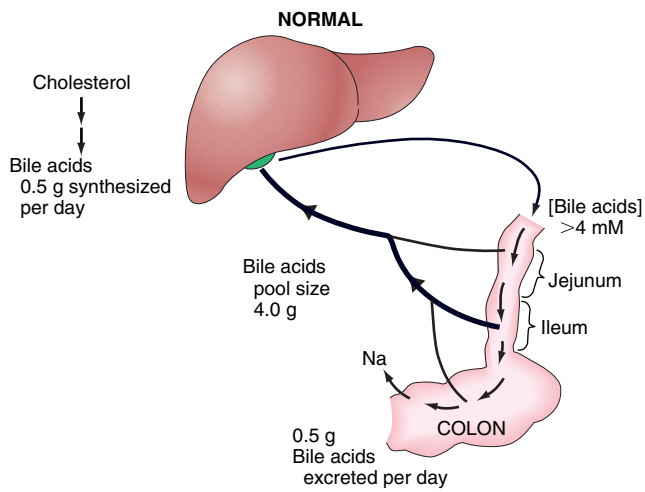

FIGURE 275-1 Schematic representation of the enterohepatic circulation of bile acids. Bile acid synthesis is cholesterol catabolism and occurs in the liver. Bile acids are secreted in bile and are stored in the gallbladder between meals and at night. Food in the duodenum induces the release of cholecystokinin, which is a potent stimulus for gallbladder contraction resulting in bile acid entry into the duodenum. Bile acids are primarily absorbed via a Na-dependent transport process that is located only in the ileum. A relatively small quantity of bile acids (~500 mg) is not absorbed in a 24-h period and is lost in stool. Fecal bile acid losses are matched by bile acid synthesis. The bile acid pool, i.e., the total amount of bile acids in the body at any time, is ~4 g and is circulated twice during each meal or six to eight times in a 24-h period.

TABLE 275-1 *Defects in Enterohepatic Circulation of Bile Acids*

Process	Pathophysiologic Defect	Disease Example
Synthesis	Decreased hepatic function	Cirrhosis
Biliary secretion	Altered canalicular function	Primary biliary cirrhosis
Maintenance of conjugated bile acids	Bacterial overgrowth	Jejunal diverticulosis
Reabsorption	Abnormal ileal function	Crohn's disease

defect in canalicular excretion of organic anions, including bile acids, and not infrequently is associated with steatorrhea and its consequences, e.g., chronic bone disease. Thus, the osteomalacia and other chronic bone abnormalities often present in patients with primary biliary cirrhosis and other cholestatic syndromes are secondary to steatorrhea that then leads to calcium and vitamin D malabsorption.

Maintenance of Conjugated Bile Acids In bacterial overgrowth syndromes associated with diarrhea, steatorrhea, and macrocytic anemia, there is an increase in a colonic type of bacterial flora in the small intestine. The steatorrhea is primarily a result of the decrease in conjugated bile acids secondary to their deconjugation by colonic-type bacteria. Two complementary explanations account for the resulting impairment of micelle formation: (1) unconjugated bile acids are rapidly absorbed in the jejunum by nonionic diffusion, resulting in a reduced concentration of duodenal bile acids; and (2) the critical micellar concentration (CMC) of unconjugated bile acids is higher than that of conjugated bile acids, and therefore unconjugated bile acids are less effective than conjugated bile acids in micelle formation.

Reabsorption Ileal dysfunction caused by either Crohn's disease or surgical resection results in a decrease in bile acid reabsorption in the ileum and an *increase* in the delivery of bile acids to the large intestine. The resulting clinical consequences—diarrhea with or without steatorrhea—are determined by the *degree* of ileal dysfunction and the *response* of the enterohepatic circulation to bile acid losses (Table 275-2). Patients with limited ileal disease or resection will often have diarrhea, but not steatorrhea. The diarrhea, a result of bile acids in the colon stimulating active Cl secretion, has been called *bile acid diarrhea*, or cholorrheic enteropathy, and responds promptly to cholestyramine, an anion-binding resin. Such patients do not develop steatorrhea because hepatic synthesis of bile acids increases to compensate for the rate of fecal bile acid losses, resulting in maintenance of both the bile acid pool size and the intraduodenal concentrations of bile acids. In contrast, patients with greater degrees of ileal disease and/or resection will often have diarrhea and steatorrhea that do not respond to cholestyramine. In this situation, ileal disease is also associated with increased amounts of bile acids entering the colon; however, hepatic synthesis can no longer increase sufficiently to maintain the bile acid pool size. As a consequence, the intraduodenal concentration of bile acids is also reduced to less than the CMC, resulting in impaired micelle formation and steatorrhea. This second situation is often called *fatty acid diarrhea*. Although cholestyramine may not be effective (and may even increase the diarrhea by further depleting the intraduodenal bile acid concentration), a low-fat diet to reduce fatty acids entering the colon can be effective. Two clinical features, the length of ileum removed and the degree of steatorrhea, can predict whether an individual patient will respond to cholestyramine. Unfortunately, these predictors are imperfect, and a therapeutic trial of cholestyramine is often necessary to establish whether an individual patient will benefit from cholestyramine. Table 275-2 contrasts the characteristics of bile acid diarrhea (small ileal dysfunction) and fatty acid diarrhea (large ileal dysfunction).

TABLE 275-2 *Comparison of Bile Acid and Fatty Acid Diarrhea*

	Bile Acid Diarrhea	Fatty Acid Diarrhea
Extent of ileal disease	Limited	Extensive
Ileal bile acid absorption	Reduced	Reduced
Fecal bile acid excretion	Increased	Increased
Fecal bile acid loss compensated by hepatic synthesis	Yes	No
Bile acid pool size	Normal	Reduced
Intraduodenal [bile acid]	Normal	Reduced
Steatorrhea	None or mild	>20 g
Response to cholestyramine	Yes	No
Response to low-fat diet	No	Yes

TABLE 275-3 *Comparison of Different Types of Fatty Acids*

	Long-Chain	Medium-Chain	Short-Chain
Carbon chain length	>12	8–12	<8
Present in diet	In large amounts	In small amounts	No
Origin	In diet as triglycerides	Only in small amounts in diet as triglycerides	Bacterial degradation in colon of nonabsorbed carbohydrate to fatty acids
Primary site of absorption	Small intestine	Small intestine	Colon
Requires pancreatic lipolysis	Yes	No	No
Requires micelle formation	Yes	No	No
Presence in stool	Minimal	No	Substantial

LIPIDS Steatorrhea is caused by one or more defects in the digestion and absorption of dietary fat. Average intake of dietary fat in the United States is approximately 120 to 150 g/d, and fat absorption is linear to dietary fat intake. The total load of fat presented to the small intestine is considerably greater, as substantial amounts of lipid are secreted in bile each day. (See above for discussion of enterohepatic circulation of bile acids.) Three types of fatty acids compose fats: long-chain fatty acids (LCFAs), medium-chain fatty acids (MCFAs), and short-chain fatty acids (SCFAs) (Table 275-3). Dietary fat is exclusively composed of long-chain triglycerides (LCTs), i.e., glycerol that is bound via ester-linkages to three LCFAs. While the majority of dietary LCFAs have carbon chain lengths of 16 or 18, fatty acids of carbon chain length >12 are metabolized in the same manner; saturated and unsaturated fatty acids are handled identically.

Assimilation of dietary lipid requires several integrated processes that can be divided into (1) an intraluminal, or digestive, phase; (2) a mucosal, or absorptive, phase; and (3) a delivery, or postabsorptive, phase. An abnormality at any site of this process can cause steatorrhea (Table 275-4). Therefore, it is essential that any patient with steatorrhea be evaluated to identify the specific physiologic defect in overall

TABLE 275-4 *Defects in Lipid Digestion and Absorption in Steatorrhea*

Phase: Process	Pathophysiologic Defect	Disease Example
Digestive		
Lipolysis formation	Decrease lipase secretion	Chronic pancreatitis
Micelle formation	Decreased intraduodenal [bile acids]	See Table 275-1
Absorptive		
Mucosal uptake and resterification	Mucosal dysfunction	Celiac sprue
Post-absorptive		
Chylomicron formation	Absent betalipoproteins	Abetalipoproteinemia
Delivery from intestine	Abnormal lymphatics	Intestinal lymphangiectasia

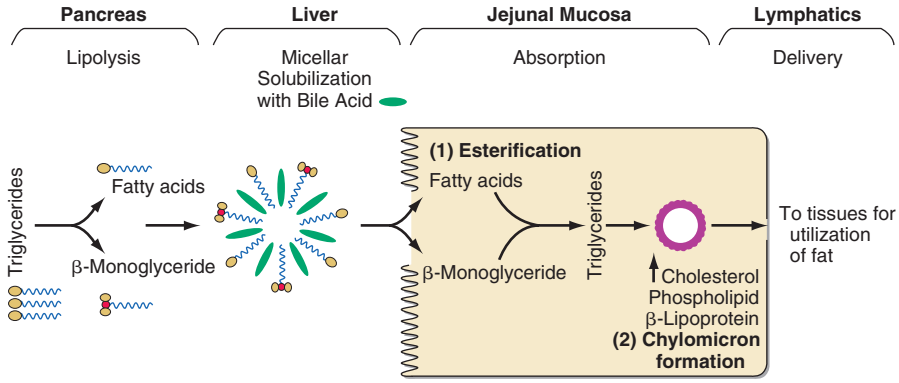

FIGURE 275-2 Schematic representation of lipid digestion and absorption. Dietary lipid is in the form of long-chain triglycerides (LCTs). The overall process can be divided into (1) a digestive phase that includes both lipolysis and micelle formation requiring pancreatic lipase and conjugated bile acids, respectively, in the duodenum; (2) an absorptive phase for mucosal uptake and reesterification; and (3) a postabsorptive phase that includes chylomicron formation and exit from the intestinal epithelial cell via lymphatics. *(Courtesy of John M. Dietschy, MD.)*

lipid digestion-absorption as therapy will be determined by the specific cause responsible for the steatorrhea.

The digestive phase has two components, *lipolysis* and *micellar formation*. Although dietary lipid is in the form of LCTs, the intestinal mucosa does not absorb triglycerides; they must first be hydrolyzed (Fig. 275-2). The initial step in lipid digestion is the formation of emulsions of finely dispersed lipid, which is accomplished by mastication and gastric contractions. Lipolysis, the hydrolysis of triglycerides to free fatty acids, monoglycerides, and glycerol by lipase, is initiated in the stomach by a gastric lipase that has a pH optimum of 4.5 to 6.0. About 20 to 30% of total lipolysis occurs in the stomach. Lipolysis is completed in the duodenum and jejunum by pancreatic lipase, which is inactivated by pH <7.0. Pancreatic lipolysis is greatly enhanced by the presence of a second pancreatic enzyme, colipase, which facilitates the movement of lipase to the triglyceride.

Impaired lipolysis can lead to steatorrhea and can occur in the presence of pancreatic insufficiency due to chronic pancreatitis in adults or cystic fibrosis in children and adolescents. Normal lipolysis can be maintained by approximately 5% of maximal pancreatic lipase secretion; thus, steatorrhea is a late manifestation of these disorders. A reduction in intraduodenal pH can also result in altered lipolysis as pancreatic lipase is inactivated at pH <7. Thus, ~15% of patients with gastrinoma (Chap. 274) with substantial increases in gastric acid secretion from ectopic production of gastrin (usually from an islet cell adenoma) have diarrhea, and some will have steatorrhea believed secondary to acid-inactivation of pancreatic lipase. Similarly, patients with chronic pancreatitis (who have reduced lipase secretion) often have a decrease in pancreatic bicarbonate secretion, which will also result in a decrease in intraduodenal pH and inactivation of endogenous pancreatic lipase or of therapeutically administered lipase.

Overlying the microvillus membrane of the small intestine is the so-called unstirred water layer, a relatively stagnant aqueous phase that must be traversed by the products of lipolysis that are primarily water-insoluble. Water-soluble mixed micelles provide a mechanism for the water-insoluble products of lipolysis to reach the luminal plasma membrane of villus epithelial cells, the site for lipid absorption. Mixed micelles are molecular aggregates composed of fatty acids, monoglycerides, phospholipids, cholesterol, and conjugated bile acids. Mixed micelles are formed when the concentration of conjugated bile acids is greater than its CMC, which differs among the several bile acids present in the small intestinal lumen. Conjugated bile acids, synthesized in the liver and excreted into the duodenum in bile, are regulated by the enterohepatic circulation (see above). Steatorrhea can result from impaired movement of fatty acids across the unstirred aqueous fluid layer in two situations: (1) an increase in the relative thickness of the unstirred water layer that occurs in bacterial overgrowth syndromes (see below) secondary to functional stasis (e.g., scleroderma), and (2) a decrease in the *duodenal* concentration of conjugated bile acids below its CMC, resulting in impaired micelle formation. Thus, steatorrhea can be caused by one or more defects in the enterohepatic circulation of bile acids.

Uptake and reesterification constitute the *absorptive phase* of lipid digestion-absorption. Although passive diffusion has been thought responsible, a carrier-mediated process may mediate fatty acid and monoglyceride uptake. Regardless of the uptake process, fatty acids and monoglycerides are reesterified by a series of enzymatic steps in the endoplasmic reticulum and Golgi to form triglycerides, the form in which lipid exits from the intestinal epithelial cell. Impaired lipid absorption as a result of either mucosal inflammation (e.g., celiac sprue) and/or intestinal resection can also lead to steatorrhea.

The reesterified triglycerides require the formation of *chylomicrons* to permit their exit from the small-intestinal epithelial cell and their delivery to the liver via the *lymphatics*. Chylomicrons are composed of β-lipoprotein and contain triglycerides, cholesterol, cholesterol esters, and phospholipids and enter the lymphatics, not the portal vein. Defects in the *postabsorptive phase* of lipid digestion-absorption can also result in steatorrhea, but these disorders are uncommon. Abetalipoproteinemia, or acanthocytosis, is a rare disorder of impaired synthesis of β-lipoprotein associated with abnormal erythrocytes (acanthocytes), neurologic problems, and steatorrhea. Lipolysis, micelle formation, and lipid uptake are all normal in patients with abetalipoproteinemia, but the reesterified triglyceride cannot exit from the epithelial cell because of the failure to produce chylomicrons. Small-intestinal biopsies of these rare patients in the postprandial state reveal lipid-laden small-intestinal epithelial cells that become perfectly normal in appearance following a 72- to 96-h fast. Similarly, abnormalities of intestinal lymphatics (e.g., intestinal lymphangiectasia) may also be associated with steatorrhea as well as protein loss (see below). Steatorrhea can result from defects at any of the several steps in lipid digestion-absorption. The mechanism of lipid digestion-absorption outlined above is limited to *dietary* lipid that is almost exclusively in the form of LCTs (Table 275-3). Medium-chain triglycerides (MCTs), composed of fatty acids with carbon chain lengths of 8 to 10, are present in large amounts in coconut oil and are used as a nutritional supplement. MCTs can be digested and absorbed by a different pathway from LCTs and at one time held promise as an important treatment of steatorrhea of almost all etiologies. Unfortunately, their therapeutic effects have been less than expected because their use is often not associated with an increase in body weight for reasons that are not completely understood.

MCTs, in contrast to LCTs, do not require pancreatic lipolysis as the triglyceride can be absorbed intact by the intestinal epithelial cell. Further, micelle formation is not necessary for the absorption of MCTs or medium-chain fatty acids, if hydrolyzed by pancreatic lipase. MCTs are absorbed more efficiently than LCTs for the following reasons: (1) the rate of MCT absorption is greater than that of long-chain fatty acids; (2) medium-chain fatty acids following absorption are not reesterified; (3) following absorption, MCTs are hydrolyzed to medium-chain fatty acids; (4) MCTs do not require chylomicron formation for their exit from the intestinal epithelial cells; and (5) their route of exit is via the portal vein and not via lymphatics. Thus, the absorption of MCTs is greater than that of LCTs in pancreatic insufficiency, conditions with reduced intraduodenal bile acid concentrations, small-intestinal mucosal disease, abetalipoproteinemia, and intestinal lymphangiectasia.

SCFAs are not dietary lipids but are synthesized by colonic bacterial enzymes from nonabsorbed carbohydrate and are the anions in highest concentration in stool (between 80 and 130 mM). The SCFAs present in stool are primarily acetate, propionate, and butyrate, whose carbon chain lengths are 2, 3, and 4, respectively. Butyrate is the pri-

mary nutrient for colonic epithelial cells, and its deficiency may be associated with one or more colitides. SCFAs conserve calories and carbohydrate, because carbohydrates not completely absorbed in the small intestine will not be absorbed in the large intestine due to the absence of both disaccharidases and SGLT, the transport protein that mediates monosaccharide absorption. In contrast, SCFAs are rapidly absorbed and stimulate colonic Na-Cl and fluid absorption. Most non–*Clostridium difficile* antibiotic-associated diarrhea is due to antibiotic suppression of colonic microflora, with a resulting decrease in SCFA production. As *C. difficile* accounts for about 10 to 15% of all antibiotic-associated diarrhea, a relative decrease in colonic production of SCFAs is likely the cause of most antibiotic-associated diarrhea.

The clinical manifestations of steatorrhea are a consequence of both the underlying disorder responsible for the development of steatorrhea and steatorrhea per se. Depending on the degree of steatorrhea and the level of dietary intake, significant fat malabsorption may lead to weight loss. Steatorrhea per se can be responsible for diarrhea; if the primary cause of the steatorrhea has not been identified, a low-fat diet can often ameliorate the diarrhea by decreasing fecal fat excretion. Steatorrhea is often associated with fat-soluble vitamin deficiency, which will require replacement with water-soluble preparations of these vitamins.

Disorders of absorption may also be associated with malabsorption of other dietary nutrients, most often carbohydrates, with or without a decrease in dietary lipid digestion and absorption. Therefore, knowledge of the mechanism of the digestion and absorption of carbohydrates, proteins, and other minerals and vitamins is useful in the evaluation of patients with altered intestinal nutrient absorption.

CARBOHYDRATES Carbohydrates in the diet are present in the form of starch, disaccharides (sucrose and lactose), and glucose. Carbohydrates are absorbed only in the small intestine and only in the form of monosaccharides. Therefore, before their absorption, starch and disaccharides must first be digested by pancreatic amylase and intestinal brush border disaccharidases to monosaccharides. Monosaccharide absorption occurs by a Na-dependent process mediated by the brush border transport protein SGLT.

Lactose malabsorption is the only clinically important disorder of carbohydrate absorption. Lactose, the disaccharide present in milk, requires digestion by brush border lactase to its two constituent monosaccharides, glucose and galactose. Lactase is present in almost all species in the postnatal period but then disappears throughout the animal kingdom, except in humans. Lactase activity persists in many individuals throughout life. Two different types of lactase deficiency exist—primary and secondary. In *primary lactase deficiency*, a genetically determined decrease or absence of lactase is noted, while all other aspects of both intestinal absorption and brush border enzymes are normal. In a number of non-Caucasian groups, primary lactase deficiency is common in adulthood. Table 275-5 presents the incidence of primary lactase deficiency in several different ethnic groups. Northern European and North American Caucasians are the only population group to maintain small-intestinal lactase activity throughout adult life. The persistence of lactase is the abnormality due to a defect in the regulation of its maturation. In contrast, *secondary lactase deficiency* occurs in association with small-intestinal mucosal disease with abnormalities in both structure and function of other brush border enzymes and transport processes. Secondary lactase deficiency is often seen in celiac sprue.

TABLE 275-5 *Primary Lactase Deficiency in Different Adult Ethnic Groups*

Ethnic Group	Prevalence of Lactase Deficiency, %
Northern European	5–15
Mediterranean	60–85
African black	85–100
American black	45–80
American Caucasian	10–25
Native American	50–95
Mexican American	40–75
Asian	90–100

Source: From FJ Simons: Am J Dig Dis 23:963, 1978.

As lactose digestion is rate-limiting compared to glucose/galactose absorption, lactase deficiency is associated with significant lactose malabsorption. Some individuals with lactose malabsorption develop symptoms such as diarrhea, abdominal pain, cramps, and/or flatus. Most individuals with primary lactase deficiency do not have symptoms. Since lactose intolerance may be associated with symptoms suggestive of an irritable bowel syndrome, persistence of such symptoms in an individual with lactose intolerance while on a strict lactose-free diet would suggest that the individual's symptoms were related to irritable bowel syndrome.

Development of symptoms of lactose intolerance is related to several factors:

1. *Amount of lactose in the diet.*
2. *Rate of gastric emptying*. Symptoms are more likely when gastric emptying is rapid than when gastric emptying is slower. Therefore, it is more likely that skim milk will be associated with symptoms of lactose intolerance than will whole milk, as the rate of gastric emptying following skim milk intake is more rapid. Similarly, the diarrhea observed following subtotal gastrectomy is often a result of lactose intolerance, as gastric emptying is accelerated in patients with a gastrojejunostomy.
3. *Small-intestinal transit time*. Although the small and large intestine contribute to the development of symptoms, many of the symptoms of lactase deficiency are related to the interaction of colonic bacteria and nonabsorbed lactose. More rapid small-intestinal transit makes symptoms more likely.
4. *Colonic compensation by production of SCFAs* from nonabsorbed lactose. Reduced levels of colonic microflora, which can occur following antibiotic use, will also be associated with increased symptoms following lactose ingestion, especially in a lactase-deficient individual.

Glucose-galactose or monosaccharide malabsorption may also be associated with diarrhea and is due to a congenital absence of SGLT. Diarrhea is present when individuals with this disorder ingest carbohydrates that contain actively transported monosaccharides (e.g., glucose, galactose) but not monosaccharides that are not actively transported (e.g., fructose). Fructose is absorbed by the brush border transport protein GLUT 5, a facilitated diffusion process that is not Na-dependent and is distinct from SGLT. In contrast, some individuals develop diarrhea as a result of consuming large quantities of sorbitol, a sugar used in diabetic candy; sorbitol is only minimally absorbed due to the absence of an intestinal absorptive transport mechanism for sorbitol.

PROTEINS Protein is present in food almost exclusively as polypeptides and requires extensive hydrolysis to di- and tripeptides and amino acids before absorption. Proteolysis occurs in both the stomach and small intestine; it is mediated by pepsin secreted as pepsinogen by gastric chief cells and trypsinogen and other peptidases from pancreatic acinar cells. These proenzymes, pepsinogen and trypsinogen, must be activated to pepsin (by pepsin in the presence of a pH <5) and trypsin (by the intestinal brush border enzyme enterokinase, and subsequently by trypsin). Proteins are absorbed by separate transport systems for di- and tripeptides and for different types of amino acids, e.g., neutral and dibasic. Alterations in either protein or amino acid digestion and absorption are rarely observed clinically, even in the presence of extensive small-intestinal mucosal inflammation. However, three rare genetic disorders involve protein digestion-absorption: (1) *enterokinase deficiency* is due to an absence of the brush border enzyme that converts the proenzyme trypsinogen to trypsin and is associated with diarrhea, growth retardation, and hypoproteinemia; (2) *Hartnup syndrome*, a defect in neutral amino acid transport, is characterized by a pellagra-like rash and neuropsychiatric symptoms; and (3) *cystinu-*

ria, a defect in dibasic amino acid transport, is associated with renal calculi and chronic pancreatitis.

EVALUATION OF MALABSORPTION

The clues provided by the history, symptoms, and initial preliminary observations will serve to limit extensive, ill-focused, and expensive laboratory and imaging studies. For example, a clinician evaluating a patient with symptoms suggestive of malabsorption who recently had extensive small-intestinal resection for mesenteric ischemia should direct the initial assessment almost exclusively to define whether a short bowel syndrome might explain the entire clinical picture. Similarly, the development of a pattern of bowel movements suggestive of steatorrhea in a patient with long-standing alcohol abuse and chronic pancreatitis should lead toward assessing pancreatic exocrine function.

The classic picture of malabsorption described in textbooks >30 years ago is rarely seen today in most parts of the United States. As a consequence, diseases with malabsorption must be suspected in individuals with less severe symptoms and signs and with subtle evidence of the altered absorption of only a *single* nutrient rather than obvious evidence of the malabsorption of multiple nutrients.

Although diarrhea can be caused by changes in fluid and electrolyte movement in either the small or the large intestine, dietary nutrients are absorbed almost exclusively in the small intestine. Therefore, the demonstration of diminished absorption of a dietary nutrient provides unequivocal evidence of small-intestinal disease, although colonic dysfunction may also be present (e.g., Crohn's disease may involve both small and large intestine). Dietary nutrient absorption may be segmental or diffuse along the small intestine and is site-specific. Thus, for example, calcium, iron, and folic acid are exclusively absorbed by active transport processes in the proximal small intestine, especially the duodenum; in contrast, the active transport mechanisms for both cobalamin and bile acids are present only in the ileum. Therefore, in an individual who years previously had had an intestinal resection, the details of which are not presently available, a presentation with evidence of calcium, folic acid, and iron malabsorption but without cobalamin deficiency would make it likely that the duodenum and jejunum, but not ileum, had been resected.

Some nutrients, e.g., glucose, amino acids, and lipids, are absorbed throughout the small intestine, though there is evidence that their rate of absorption is greater in the proximal than in the distal segments. However, following segmental resection of the small intestine, the remaining segments will undergo both morphologic and functional "adaptation" to enhance absorption. Such adaptation is secondary to the presence of luminal nutrients and hormonal stimuli and may not be complete in humans for several months following the resection. Adaptation is critical for individuals who have undergone massive resection of the small intestine and/or colon to help ensure survival.

Establishing the presence of steatorrhea and identifying its specific cause are often quite difficult for several reasons. Despite attempts to develop tests that do *not* require the collection of stool to document the presence of steatorrhea, the "gold standard" still remains a timed, quantitative stool fat determination. On a practical basis, stool collections are invariably difficult and often incomplete as nobody wants to handle stool. A qualitative test—Sudan III stain—has long been available to establish the presence of an increase in stool fat. This test is rapid and inexpensive but, as a qualitative test, does not establish the degree of fat malabsorption and is best used as a preliminary screening study. Many of the blood, breath, and isotopic tests that have been developed either (1) do not directly measure fat absorption, (2) have excellent sensitivity when steatorrhea is obvious and severe but have poor sensitivity when steatorrhea is mild, or (3) have not survived the transition from their development in a laboratory to commercial utilization and dissemination.

Despite this situation, the use of routine laboratory studies (i.e., complete blood count, prothrombin time, serum protein determination, alkaline phosphatase) may suggest the presence of dietary nutrient depletion, especially iron, folate, cobalamin, and vitamins D and K. Additional studies include measurement of serum carotene, cholesterol, albumin, iron, folate, and cobalamin levels. The serum carotene level can also be reduced if the patient has poor dietary intake of leafy vegetables.

If steatorrhea and/or altered absorption of other nutrients are suspected, the history, clinical observations, and laboratory testing can help detect deficiency of a dietary nutrient, especially the fat-soluble vitamins A, D, E, or K. Thus, evidence of metabolic bone disease with elevated alkaline phosphatase and/or reduced serum calcium levels would suggest vitamin D malabsorption. A deficiency of vitamin K would be suggested by an elevated prothrombin time in an individual without liver disease who was not taking anticoagulants. Macrocytic anemia would lead to evaluation of whether cobalamin or folic acid malabsorption was present. The presence of iron-deficiency anemia in the absence of occult bleeding from the gastrointestinal tract in either a male or a nonmenstruating female would require evaluation of iron malabsorption and the exclusion of celiac sprue, as iron is absorbed exclusively in the proximal small intestine.

At times, however, a timed (72-h) quantitative stool collection, preferably on a defined diet, must be obtained to determine stool fat content and establish the presence of steatorrhea. The presence of steatorrhea then requires further assessment to establish the pathophysiologic process(es) responsible for the defect in dietary lipid digestion-absorption (Table 275-4). Some of the other studies include the Schilling test, D-xylose test, duodenal mucosal biopsy, small-intestinal radiologic examination, and tests of pancreatic exocrine function.

THE SCHILLING TEST This test is performed to determine the cause for cobalamin malabsorption. Since cobalamin absorption requires multiple steps, including gastric, pancreatic, and ileal processes, the Schilling test can also be used to assess the integrity of these other organs (Chap. 92). Cobalamin is present primarily in meat. Except in strict vegans, *dietary* cobalamin deficiency is exceedingly uncommon. Dietary cobalamin is bound in the stomach to a glycoprotein called *R-binder protein*, which is synthesized in both the stomach and salivary glands. This cobalamin–R binder complex is formed in the acid milieu of the stomach. Cobalamin absorption has an absolute requirement for intrinsic factor, another glycoprotein synthesized and released by gastric parietal cells, to promote its uptake by specific cobalamin receptors on the brush border of ileal enterocytes. Pancreatic protease enzymes split the cobalamin–R binder complex to release cobalamin in the proximal small intestine, where cobalamin is then bound by intrinsic factor.

As a consequence, cobalamin absorption may be abnormal in the following:

1. Pernicious anemia, a disease in which immunologically mediated atrophy of gastric parietal cells leads to an absence of both gastric acid and intrinsic factor secretion.
2. Chronic pancreatitis as a result of deficiency of pancreatic proteases to split the cobalamin–R binder complex. Although 50% of patients with chronic pancreatitis have been reported to have an abnormal Schilling test that was corrected by pancreatic enzyme replacement, the presence of a cobalamin-responsive macrocytic anemia in chronic pancreatitis is extremely rare. Although this probably reflects a difference in the digestion/absorption of cobalamin in food versus that in a crystalline form, the Schilling test can still be used to assess pancreatic exocrine function.
3. Achlorhydria or absence of another factor secreted with acid that is responsible for splitting cobalamin away from the proteins in food to which it is bound. Up to one-third of individuals >60 years of age have marginal vitamin B_{12} absorption because of the inability to release cobalamin from food; these people have no defects in absorbing crystalline vitamin B_{12}.
4. Bacterial overgrowth syndromes, which are most often secondary to stasis in the small intestine, leading to bacterial utilization of cobalamin (often referred to as *stagnant bowel syndrome*) (see below).

5. Ileal dysfunction (as a result of either inflammation or prior intestinal resection) due to impaired function of the mechanism of cobalamin–intrinsic factor uptake by ileal intestinal epithelial cells.

The Schilling test is performed by administering ^{58}Co-labeled cobalamin and collecting urine for 24 h and is dependent on normal renal and bladder function. Urinary excretion of cobalamin will reflect cobalamin absorption provided that intrahepatic binding sites for cobalamin are fully occupied. To ensure saturation of hepatic cobalamin binding sites so that all absorbed radiolabeled cobalamin will be excreted in urine, 1 mg cobalamin is administered intramuscularly 1 h following ingestion of the radiolabeled cobalamin. The Schilling test may be abnormal (usually defined as $<$10% excretion in 24 h) in pernicious anemia, chronic pancreatitis, blind loop syndrome, and ileal disease (Table 275-6). Therefore, whenever an abnormal Schilling test is found, ^{58}Co-labeled cobalamin should be administered on another occasion either bound to intrinsic factor, with pancreatic enzymes, or following a 5-day course of antibiotics (often tetracycline). A variation of the Schilling test can detect failure to split cobalamin from food proteins. The labeled cobalamin is cooked together with a scrambled egg and administered orally. People with achlorydria will excrete $<$10% of the labeled cobalamin in the urine. In addition to establishing the etiology for cobalamin deficiency, the Schilling test can be used to help delineate the pathologic process responsible for steatorrhea by assessing ileal, pancreatic, and small-intestinal luminal function. Unfortunately, in recent years the Schilling test has been infrequently performed because radiolabeled cobalamin is often not available.

URINARY D-XYLOSE TEST The urinary D-xylose test for carbohydrate absorption provides an assessment of proximal small-intestinal mucosal function. D-Xylose, a pentose, is absorbed almost exclusively in the proximal small intestine. The D-xylose test is usually performed by giving 25 g D-xylose and collecting urine for 5 h. An abnormal test ($<$4.5 g excretion) primarily reflects the presence of duodenal/jejunal mucosal disease. The D-xylose test can also be abnormal in patients with blind loop syndrome (as a consequence primarily of abnormal intestinal mucosa) and, as a false-positive study, in patients with large collections of fluid in a third space (i.e., ascites, pleural fluid). The ease of obtaining a mucosal biopsy of the small intestine by endoscopy and the false-negative rate of the D-xylose test have led to its diminished use. When small-intestinal mucosal disease is suspected, a small-intestinal mucosal biopsy should be performed.

TABLE 275-6 *Differential Results of Schilling Test in Several Diseases Associated with Cobalamin (Cbl) Malabsorption*

	^{58}Co-Cbl	With Intrinsic Factor	With Pancreatic Enzymes	After 5 Days of Antibiotics
Pernicious anemia	Reduced	Normal	Reduced	Reduced
Chronic pancreatitis	Reduced	Reduced	Normal	Reduced
Bacterial overgrowth	Reduced	Reduced	Reduced	Normal
Ileal disease	Reduced	Reduced	Reduced	Reduced

RADIOLOGIC EXAMINATION Radiologic examination of the small intestine using barium contrast (small-bowel series or study) can provide important information in the evaluation of the patient with presumed or suspected malabsorption. These studies are most often performed in conjunction with the examination of the esophagus, stomach, and duodenal bulb, and insufficient barium is given to the patient to permit an adequate examination of the small-intestinal mucosa, especially the ileum. As a result, many gastrointestinal radiologists alter the procedure of a barium contrast examination of the small intestine by performing either a small-bowel series in which a large amount of barium is given by mouth without concurrent examination of the esophagus and stomach or an enteroclysis study in which a large amount of barium is introduced into the duodenum via a fluoroscopically placed tube. In addition, many of the diagnostic features initially described by radiologists to denote the presence of small-intestinal disease (e.g., flocculation, segmentation) are rarely seen with current barium suspensions. Nonetheless, in skilled hands barium contrast examination of the small intestine can yield important information. For example, with extensive mucosal disease, dilation of intestine can be seen, as candilution of barium from increased intestinal fluid secretion (Fig. 275-3). A normal barium contrast study does *not* exclude the possibility of small-intestinal disease. However, a small-bowel series remains a very useful examination to assess for the presence of anatomical abnormalities, such as strictures and fistulas (as in Crohn's disease) or blind loop syndrome (e.g., multiple jejunal diverticula), and to define the extent of a previous surgical resection.

BIOPSY OF SMALL-INTESTINAL MUCOSA A small-intestinal mucosal biopsy is essential in the evaluation of a patient with documented steatorrhea or chronic diarrhea (lasting >3 weeks) (Chap. 35). The ready availability of endoscopic equipment to examine the stomach and duodenum has led to its almost uniform use as the preferred method to obtain histologic material of proximal small-intestinal mucosa. The primary indications for a small-intestinal biopsy are (1) evaluation of a patient either with documented or suspected steatorrhea or with chronic diarrhea, and (2) diffuse or focal abnormalities of the small intestine defined on a small-intestinal series. Lesions seen on small-bowel biopsy can be classified into three different categories (Table 275-7): (1) diffuse, specific; (2) patchy, specific; and (3) diffuse, nonspecific.

1. *Diffuse, specific lesions*. Relatively few diseases associated with altered nutrient absorption have specific histopathologic abnormalities on small-intestinal mucosal biopsy, and they are uncommon. Whipple's disease is characterized by the presence of periodic acid–Schiff (PAS)-positive macrophages in the lamina propria, while the bacilli that are also present may require electron-microscopic examination for identification (Fig. 275-4). *Abetalipoproteinemia* is characterized by a normal mucosal appearance except for the presence of mucosal absorptive cells that contain lipid postprandially and disappear following a prolonged period of either fat-free intake or fasting. *Immune globulin deficiency* is associated with a variety of histopathologic findings on small-intestinal mucosal biopsy. The characteristic feature is the absence of or substantial reduction in the number of plasma cells in the lamina propria; the mucosal architecture may be either perfectly normal or flat, i.e., villus atrophy. As patients with immune globulin deficiency are often infected with *Giardia lamblia*, *Giardia* trophozoites may also be seen in the biopsy.
2. *Patchy, specific lesions*. Several diseases are associated with abnormal small-intestinal mucosal biopsies, but the characteristic features that are present have a patchy distribution. As a result, biopsies obtained randomly or in the absence of abnormalities visualized endoscopically may not reveal these diagnostic features. Intestinal *lymphoma* can at times be diagnosed on mucosal biopsy by the identification of malignant lymphoma cells in the lamina propria and submucosa (Chap. 97). The presence of dilated lymphatics in the submucosa and sometimes in the lamina propria indicates the presence of *lymphangiectasia* associated with hypoproteinemia secondary to protein loss into the intestine. *Eosinophilic gastroenteritis* comprises a heterogeneous group of disorders with a spectrum of presentations and symptoms with an eosinophilic infiltrate of the lamina propria, with or without peripheral eosinophilia. The patchy nature of the infiltrate as well as its presence in the submucosa often leads to an absence of histopathologic findings on mucosal biopsy. As the involvement of the duodenum in *Crohn's disease* is also submucosal and not necessarily continuous, mucosal biopsies are not the most direct approach to the diagnosis of duodenal Crohn's disease (Chap. 276). Amyloid deposition can be identified by Congo Red stain in some patients with *amyloidosis* involving the duodenum (Chap. 310).

   Several microorganisms can be identified on small-intestinal biopsies, establishing a correct diagnosis. Many of these microorganisms are associated with diarrhea that occurs in immunodeficient individuals, especially those with HIV infection, and include *Cryptosporidium*, *Isospora belli*, cytomegalovirus, *Mycobacterium avium-intracellulare*, and *G. lamblia*.
3. *Diffuse, nonspecific lesions*. *Celiac sprue* presents with a characteristic mucosal appearance on duodenal/proximal jejunal mucosal biopsy that is not diagnostic of the disease. The diagnosis of celiac sprue is established by clinical, histologic, and immunologic response to a gluten-free diet. *Tropical sprue* is associated with histopathologic findings similar to those of celiac sprue after a tropical or subtropical exposure but does not respond to gluten restriction; most often symptoms improve with antibiotics and folate administration.

TABLE 275-7 *Disease that Can be Diagnosed by Small-Intestinal Mucosal Biopsies*

Lesions	Pathologic Findings
Diffuse, specific	
Whipple's disease	Lamina propria contains macrophages containing PAS+ material
Agammaglobulinemia	No plasma cells; either normal or absent villi ("flat mucosa");
Abetalipoproteinemia	Normal villi; epithelial cells vacuolated with fat postprandially
Patchy, specific	
Intestinal lymphoma	Malignant cells in lamina propria and submucosa
Intestinal lymphangiectasia	Dilated lymphatics; clubbed villi
Eosinophilic gastroenteritis	Eosinophil infiltration of lamina propria and mucosa
Amyloidosis	Amyloid deposits
Crohn's disease	Noncaseating granulomas
Infection by one or more microorganisms (see text)	Specific organisms
Mastocytosis	Mast cell infiltration of lamina propria
Diffuse, nonspecific	
Celiac sprue	Short or absent villi; mononuclear infiltrate; epithelial cell damage; hypertrophy of crypts
Tropical sprue	Similar to celiac sprue
Bacterial overgrowth	Patchy damage to villi; lymphocyte infiltration
Folate deficiency	Short villi; decreased mitosis in crypts; megalocytosis
Vitamin B_{12} deficiency	Similar to folate deficiency
Radiation enteritis	Similar to folate deficiency
Zollinger-Ellison syndrome	Mucosal ulceration and erosion from acid
Protein-calorie malnutrition	Villous atrophy; secondary bacterial overgrowth
Drug-induced enteritis	Variable histology

Note: PAS+, periodic acid–Schiff positive.

Patients with steatorrhea require assessment of *pancreatic exocrine function*, which is often abnormal in chronic pancreatitis. No test assesses pancreatic exocrine function well. Endoscopic approaches provide excellent assessment of pancreatic duct anatomy but do **not** assess exocrine function (Chap. 293). One noninvasive study (bentiromide test) of pancreatic exocrine function is based on the feeding of a tripeptide containing *p*-aminobenzoic acid (PABA). Following splitting of PABA by pancreatic proteases, PABA is liberated, absorbed, and excreted in urine. Reduced proteolysis results in reduced urinary excretion of PABA. This test is neither sensitive nor specific.

Table 275-8 summarizes the results of the D-xylose test, Schilling test, and small-intestinal mucosal biopsy in patients with five different causes of steatorrhea.

SPECIFIC DISEASE ENTITIES

CELIAC SPRUE Celiac sprue is a common cause of malabsorption of one or more nutrients in Caucasians, especially those of European descent. Estimated incidence in the United States may be as high as 1:113 people. Celiac sprue has had several other names including nontropical sprue, celiac disease (in children), adult celiac disease, and gluten-sensitive enteropathy. The etiology of celiac sprue is not known, but environmental, immunologic, and genetic factors are important. Celiac sprue has protean manifestations, almost all of which are secondary to nutrient malabsorption, and a varied natural history, with the onset of symptoms occurring at ages ranging from the first year of life through the eighth decade.

The hallmark of celiac sprue is the presence of an abnormal small-intestinal biopsy (Fig. 275-4) and the response of both symptoms—

evidence of malabsorption and the histopathologic changes on the small-intestinal biopsy—to the elimination of gluten from the diet. The histopathologic changes have a proximal to distal intestinal distribution of severity, which probably reflects the exposure of the intestinal mucosa to varied amounts of dietary gluten; the degree of symptoms is often related to the extent of these histopathologic changes.

The symptoms of celiac sprue may appear with the introduction of cereals in an infant's diet, although there is frequently a spontaneous remission during the second decade of life that may be either permanent or followed by the reappearance of symptoms over several years. Alternatively, the symptoms of celiac sprue may first become evident at almost any age throughout adulthood. In many patients, frequent spontaneous remissions and exacerbations occur. The symptoms range from significant malabsorption of multiple nutrients with diarrhea, steatorrhea, weight loss, and the consequences of nutrient depletion (i.e., anemia and metabolic bone disease) to the absence of any gastrointestinal symptoms but with evidence of the depletion of a single nutrient (e.g., iron or folate deficiency, osteomalacia, edema from protein loss). Asymptomatic relatives of patients with celiac sprue have been identified as having this disease either by small-intestinal biopsy or by serologic studies (e.g., antiendomysial antibodies).

Etiology The etiology of celiac sprue is not known, but environmental, immunologic, and genetic factors all appear to contribute to the disease.

One *environmental* factor is the clear association of the disease with gliadin, a component of gluten that is present in wheat, barley, rye, and, in smaller amounts, oats. In addition to the role of gluten restriction in treatment, the instillation of gluten into both normal-appearing rectum and distal ileum of patients with celiac sprue results within hours in morphologic changes.

An *immunologic* component to etiology is suspected for three reasons. First, serum antibodies—IgA antigliadin, IgA antiendomysial, and IgA anti-tissue transglutaminase (tTG) antibodies—are present, but it is also not known whether such antibodies are primary or secondary to the tissue damage. The antiendomysial antibody has 90 to 95% sensitivity and 90 to 95% specificity, and the antigen recognized by the antiendomysial antibody test is tissue transglutaminase. Antibody studies are frequently used to identify patients with celiac sprue; patients with these antibodies should undergo duodenal biopsy. The relationship of this autoantibody to a pathogenetic mechanism (or mechanisms) responsible for celiac sprue remains to be established. Nonetheless, this antibody will undoubtedly prove extremely useful in establishing the true prevalence of celiac sprue in the general population and may provide important clues to its etiology. Second, treatment with prednisolone for 4 weeks of a patient with celiac sprue who continues to eat gluten will induce a remission and convert the "flat" abnormal duodenal biopsy to a more normal-appearing one. Third, gliadin peptides may interact with gliadin-specific T cells that may either mediate tissue injury or induce the release of one or more cytokines that are responsible for the tissue injury.

Genetic factor(s) also appear to be involved in celiac sprue. The incidence of celiac sprue varies widely in different population groups (high in Caucasians, low in blacks and Asians) and is 10% in first-degree relatives of celiac sprue patients. Furthermore, about 95% of patients with celiac sprue express the HLA-DQ2 allele, though only a minority of all persons expressing DQ2 have celiac sprue.

Diagnosis A small-intestinal biopsy is required to establish a diagnosis of celiac sprue (Fig. 275-4). A biopsy should be performed in patients

TABLE 275-8 *Results of Diagnostic Studies in Different Causes of Steatorrhea*

	D-Xylose Test	Schilling Test	Duodenal Mucosal Biopsy
Chronic pancreatitis	Normal	50% abnormal; if abnormal, normal with pancreatic enzymes	Normal
Bacterial overgrowth syndrome	Normal or only modestly abnormal	Often abnormal; if abnormal, normal after antibiotics	Usually normal
Ileal disease	Normal	Abnormal	Normal
Celiac sprue	Decreased	Normal	Abnormal: probably "flat"
Intestinal lymphangiectasia	Normal	Normal	Abnormal: "dilated lymphatics"

with symptoms and laboratory findings suggestive of nutrient malabsorption and/or deficiency. Since the presentation of celiac sprue is often subtle, without overt evidence of malabsorption or nutrient deficiency, it is important to have a relatively low threshold to perform a biopsy. It is more prudent to perform a biopsy than to obtain another test of intestinal absorption, which can never completely exclude or establish this diagnosis.

The diagnosis of celiac sprue requires the presence of characteristic histopathologic changes on small-intestinal biopsy together with a prompt clinical and histopathologic response following the institution of a gluten-free diet. If serologic studies have detected the presence of IgA antiendomysial or tTG antibodies, they too should disappear after a gluten-free diet is started. The changes seen on duodenal/jejunal biopsy are restricted to the mucosa and include (1) absence or reduced height of villi, resulting in a flat appearance; (2) increased loss of villus cells in association with increased crypt cell proliferation resulting in crypt hyperplasia and loss of villus structure, with consequent villus, but not mucosal, atrophy; (3) cuboidal appearance and nuclei that are no longer oriented basally in surface epithelial cells and increased intraepithelial lymphocytes; and (4) increased lymphocytes and plasma cells in the lamina propria (Fig. 275-4*B*). Although these histopathologic features are characteristic of celiac sprue, they are *not* diagnostic because a similar appearance can be seen in tropical sprue, eosinophilic enteritis, and milk-protein intolerance in children and occasionally in lymphoma, bacterial overgrowth, Crohn's disease, and gastrinoma with acid hypersecretion. However, the presence of a characteristic histopathologic appearance that reverts toward normal following the initiation of a gluten-free diet establishes the diagnosis of celiac sprue (Fig. 275-4*C*). Readministration of gluten with or without an additional small-intestinal biopsy is not necessary.

Failure to Respond to Gluten Restriction The most common cause of persistent symptoms in a patient who fulfills all the criteria of the diagnosis of celiac sprue is continued intake of gluten. Gluten is ubiquitous, and significant effort must be made to exclude all gluten from the diet. Use of rice in place of wheat flour is very helpful, and several support groups provide important aid to patients with celiac sprue and to their families. About 90% of patients who have the characteristic findings of celiac sprue will respond to complete dietary gluten restriction. The remainder constitute a heterogeneous group (whose condition is often called *refractory sprue*) that includes some patients who (1) respond to restriction of other dietary protein, e.g., soy; (2) respond to glucocorticoids; (3) are "temporary," i.e., the clinical and morphologic findings disappear after several months or years; or (4) fail to respond to all measures and have a fatal outcome, with or without documented complications of celiac sprue, such as development of intestinal T cell lymphoma.

Mechanism of Diarrhea The diarrhea in celiac sprue has several pathogenetic mechanisms. Diarrhea may be secondary to (1) steatorrhea, which is primarily a result of the changes in jejunal mucosal function; (2) secondary lactase deficiency, a consequence of changes in jejunal brush border enzymatic function; (3) bile acid malabsorption resulting in bile acid–induced fluid secretion in the colon, in cases with more extensive disease involving the ileum; and (4) endogenous fluid secretion resulting from the crypt hyperplasia. Patients with more severe involvement with celiac sprue may obtain temporary improvement with *dietary lactose and fat restriction* while awaiting the full effects of total gluten restriction, which is primary therapy.

Associated Diseases Celiac sprue is associated with dermatitis herpetiformis (DH), though the association has not been explained. Patients with DH have characteristic papulovesicular lesions that respond to dapsone. Almost all patients with DH have histopathologic changes in the small intestine consistent with celiac sprue, although usually much milder and less diffuse in distribution. Most patients with DH have mild, or no, gastrointestinal symptoms. In contrast, relatively few patients with celiac sprue have DH.

Celiac sprue is also associated with diabetes mellitus type 1 and IgA deficiency. The clinical importance of the former association is that although severe watery diarrhea without evidence of malabsorption is most often seen in patients with "diabetic diarrhea" (Chap. 323), assay of antiendomysial antibodies and/or a small-intestinal biopsy must at times be considered to exclude this association.

Complications The most important complication of celiac sprue is the development of cancer. An increased incidence of both gastrointestinal and nongastrointestinal neoplasms as well as intestinal lymphoma exists in patients with celiac sprue. For unexplained reasons the occurrence of lymphoma in patients with celiac sprue is higher in Ireland and the United Kingdom than in the United States. The possibility of lymphoma must be considered whenever a patient with celiac sprue previously doing well on a gluten-free diet is no longer responsive to gluten restriction or a patient who presents with clinical and histopathologic features consistent with celiac sprue does not respond to a gluten-free diet. Other complications of celiac sprue include the development of intestinal ulceration independent of lymphoma and so-called refractory sprue (see above) and collagenous sprue. In *collagenous sprue*, a layer of collagen-like material is present beneath the basement membrane; patients with collagenous sprue generally do not respond to a gluten-free diet and often have a poor prognosis.

TROPICAL SPRUE Tropical sprue is a poorly understood syndrome that affects both expatriates and natives in certain but not all tropical areas and is manifested by chronic diarrhea, steatorrhea, weight loss, and nutritional deficiencies, including those of both folate and cobalamin. This disease affects 5 to 10% of the population in some tropical areas.

Chronic diarrhea in a tropical environment is most often caused by infectious agents including *G. lamblia*, *Yersinia enterocolitica*, *C. difficile*, *Cryptosporidium parvum*, and *Cyclospora cayetanensis*, among other organisms. Tropical sprue should not be entertained as a possible diagnosis until the presence of cysts and trophozoites has been excluded in three stool samples. →***Chronic infections of the gastrointestinal tract and diarrhea in patients with or without AIDS are discussed in Chaps. 113 and 173.***

The small-intestinal mucosa in individuals living in tropical areas is not identical to that of individuals who reside in temperate climates. Biopsies reveal a mild alteration of villus architecture with a modest increase in mononuclear cells in the lamina propria, which on occasion can be as severe as that seen in celiac sprue. These changes are observed both in native residents and in expatriates living in tropical regions and are usually associated with mild decreases in absorptive function, but revert to "normal" when an individual moves or returns to a temperate area. Some have suggested that the changes seen in tropical enteropathy and in tropical sprue represent different ends of the spectrum of a single entity, but convincing evidence to support this concept is lacking.

Etiology The etiology of tropical sprue is not known, though because tropical sprue responds to antibiotics, the consensus is that tropical sprue may be caused by one or more infectious agents. Nonetheless, there are multiple uncertainties regarding the etiology and pathogenesis of tropical sprue. First, its occurrence is not evenly distributed in all tropical areas; rather, it is found in specific locations including South India, the Philippines, and several Caribbean islands (e.g., Puerto Rico, Haiti) but is rarely observed in Africa, Jamaica, or Southeast Asia. Second, an occasional individual will not develop symptoms of tropical sprue until long after having left an endemic area. This is the reason why the original term for celiac sprue was *nontropical sprue* to distinguish it from tropical sprue. Third, multiple microorganisms have been identified on jejunal aspirate with relatively little consistency among studies. *Klebsiella pneumoniae*, *Enterobacter cloacae*, or *E. coli* have been implicated in some studies of tropical sprue, while other investigations have favored a role for a toxin produced by one or more of these bacteria. Fourth, the incidence of tropical sprue appears to have decreased substantially during the past decade. One speculation for this reduced occurrence of tropical sprue is the wider use of antibiotics in acute diarrhea, especially in travelers to tropical areas

from temperate countries. Fifth, the role of folic acid deficiency in the pathogenesis of tropical sprue requires clarification. Folic acid is absorbed exclusively in the duodenum and proximal jejunum, and most patients with tropical sprue have evidence of folate malabsorption and depletion. Although folate deficiency can cause changes in small-intestinal mucosa that are corrected by folate replacement, the several earlier studies reporting that tropical sprue could be cured by folic acid did not provide an explanation for the "insult" that was initially responsible for folate malabsorption.

The clinical pattern of tropical sprue varies in different areas of the world (e.g., India vs Puerto Rico). Not infrequently, individuals in South India initially will report the occurrence of an acute enteritis before the development of steatorrhea and malabsorption. In contrast, in Puerto Rico, a most insidious onset of symptoms and a more dramatic response to antibiotics is seen when compared to some other locations. Tropical sprue in different areas of the world may not be the same disease; similar clinical entities may have different etiologies.

Diagnosis The diagnosis of tropical sprue is best made by the presence of an abnormal small-intestinal mucosal biopsy in an individual with chronic diarrhea and evidence of malabsorption who is either residing or has recently lived in a tropic country. The small-intestinal biopsy in tropical sprue does not have pathognomonic features but resembles, and can often be indistinguishable from, that seen in celiac sprue (Fig. 275-4). The biopsy in tropical sprue will have less villus architectural alteration and more mononuclear cell infiltrate in the lamina propria. In contrast to celiac sprue, the histopathologic features of tropical sprue are present with a similar degree of severity throughout the small intestine, and a gluten-free diet does not result in either clinical or histopathologic improvement in tropical sprue.

℞ TREATMENT

Broad-spectrum antibiotics and folic acid are most often curative, especially if the patient leaves the tropical area and does not return. Tetracycline should be used for up to 6 months and may be associated with improvement within 1 to 2 weeks. Folic acid alone will induce a hematologic remission as well as improvement in appetite, weight gain, and some morphologic changes in small intestinal biopsy. Because of the presence of marked folate deficiency, folic acid is most often given together with antibiotics.

SHORT BOWEL SYNDROME This is a descriptive term for the myriad clinical problems that often occur following resection of varying lengths of small intestine. The factors that determine both the type and degree of symptoms include (1) the specific segment (jejunum vs ileum) resected, (2) the length of the resected segment, (3) the integrity of the ileocecal valve, (4) whether any large intestine has also been removed, (5) residual disease in the remaining small and/or large intestine (e.g., Crohn's disease, mesenteric artery disease), and (6) the degree of adaptation in the remaining intestine. Short bowel syndrome can occur at any age from neonates through the elderly.

Three different situations in adults demand intestinal resections: (1) mesenteric vascular disease including atherosclerosis, thrombotic phenomena, and vasculitides; (2) primary mucosal and submucosal disease, e.g., Crohn's disease; and (3) operations without preexisting small intestinal disease, such as trauma and jejunoileal bypass for obesity.

Following resection of the small intestine, the residual intestine undergoes adaptation of both structure and function that may last for up to 6 to 12 months. Continued intake of dietary nutrients and calories is required to stimulate adaptation via direct contact with intestinal mucosa, the release of one or more intestinal hormones, and pancreatic and biliary secretions. Thus, enteral nutrition and calorie administration must be maintained, especially in the early postoperative period, even if an extensive intestinal resection requiring total parenteral nutrition (TPN) was performed. The subsequent ability of such patients to absorb nutrients will not be known for several months, until adaptation is completed.

Multiple factors besides the absence of intestinal mucosa (required for lipid, fluid, and electrolyte absorption) contribute to the diarrhea and steatorrhea in these patients. Removal of the ileum and especially the ileocecal valve is often associated with more severe diarrhea than jejunal resection. Without part or all of the ileum, diarrhea can be caused by an increase in bile acids entering the colon, leading to their stimulation of colonic fluid and electrolyte secretion. Absence of the ileocecal valve is also associated with a decrease in intestinal transit time and bacterial overgrowth from the colon. Lactose intolerance as a result of the removal of lactase-containing mucosa as well as gastric hypersecretion will also contribute to the diarrhea.

In addition to diarrhea and/or steatorrhea, a range of nonintestinal symptoms is also observed in some patients. A significant increase in renal calcium oxalate calculi is observed in patients with a small-intestinal resection with an intact colon and is due to an increase in oxalate absorption by the large intestine, with subsequent hyperoxaluria (called *enteric hyperoxaluria*). Since oxalate is high in relatively few foods (e.g., spinach, rhubarb, tea), dietary restrictions alone are not adequate treatment. Cholestyramine, an anion-binding resin, and calcium have proved useful in reducing the hyperoxaluria. Similarly, an increase in cholesterol gallstones is related to a decrease in the bile acid pool size, which results in the generation of cholesterol supersaturation in gallbladder bile. Gastric hypersecretion of acid occurs in many patients following large resections of the small intestine. The etiology is unclear but may be related to either reduced hormonal inhibition of acid secretion or increased gastrin levels due to reduced small-intestinal catabolism of circulating gastrin. The resulting gastric acid secretion may be an important factor contributing to the diarrhea and steatorrhea. A reduced pH in the duodenum can inactivate pancreatic lipase and/or precipitate duodenal bile acids, thereby increasing steatorrhea, and an increase in gastric secretion can create a volume overload relative to the reduced small-intestinal absorptive capacity. Inhibition of gastric acid secretion with either proton pump inhibitors or H_2 receptor antagonists can help in reducing the diarrhea and steatorrhea.

℞ TREATMENT

Treatment of short bowel syndrome depends on the severity of symptoms and whether the individual is able to maintain caloric and electrolyte balance with oral intake alone. Initial treatment includes judicious use of opiates (including codeine) to reduce stool output and to establish an effective diet. An initial diet should be low-fat and high-carbohydrate to minimize the diarrhea from fatty acid stimulation of colonic fluid secretion. MCTs (see above), a low-lactose diet, and various fiber-containing diets should also be tried. In the absence of an ileocecal valve, the possibility of bacterial overgrowth must be considered and treated. If gastric acid hypersecretion is contributing to the diarrhea and steatorrhea, a proton pump inhibitor may be helpful. Usually none of these therapeutic approaches will provide an instant solution but they can reduce disabling diarrhea.

The patient's vitamin and mineral status must also be monitored; replacement therapy should be initiated if indicated. Fat-soluble vitamins, folate, cobalamin, calcium, iron, magnesium, and zinc are the most critical factors to monitor on a regular basis. If these approaches are not successful, home TPN is an established therapy that can be maintained for many years. Intestinal transplantation is becoming established as a possible approach for individuals with extensive intestinal resection who cannot be maintained without TPN.

BACTERIAL OVERGROWTH SYNDROME Bacterial overgrowth syndrome comprises a group of disorders with diarrhea, steatorrhea, and macrocytic anemia whose common feature is the proliferation of colon-type bacteria within the small intestine. This bacterial proliferation is due to stasis caused by impaired peristalsis (i.e., *functional stasis*), changes in intestinal anatomy (i.e., *anatomic stasis*), or direct communication between the small and large intestine. These conditions have also been referred to as *stagnant bowel syndrome* or *blind loop syndrome*.

Pathogenesis The manifestations of bacterial overgrowth syndromes are a direct consequence of the presence of increased amounts of a colonic-type bacterial flora, such as *E. coli* or *Bacteroides*, in the small intestine. *Macrocytic anemia* is due to cobalamin, not folate, deficiency. Most bacteria require cobalamin for growth, and increasing concentrations of bacteria use up the relatively small amounts of dietary cobalamin. *Steatorrhea* is due to impaired micelle formation as a consequence of a reduced intraduodenal concentration of conjugated bile acids and the presence of unconjugated bile acids. Certain bacteria, e.g., *Bacteroides*, deconjugate conjugated bile acids to unconjugated bile acids. In the presence of bacterial overgrowth, unconjugated bile acids will be absorbed more rapidly than conjugated bile acids, and, as a result, the intraduodenal concentration of bile acids will be reduced. In addition, the CMC of unconjugated bile acids is higher than that of conjugated bile acids, resulting in a decrease in micelle formation. *Diarrhea* is due, at least in part, to the steatorrhea, when it is present. However, some patients manifest diarrhea *without* steatorrhea, and it is assumed that the colonic-type bacteria in these patients are producing one or more bacterial enterotoxins that are responsible for fluid secretion and diarrhea.

Etiology The etiology of these different disorders is bacterial proliferation in the small intestinal lumen secondary to either anatomical or functional stasis or to a communication between the relatively sterile small intestine and the colon with its high levels of aerobic and anaerobic bacteria. Several examples of anatomical stasis have been identified: (1) one or more diverticula (both duodenal and jejunal) (Fig. 275-3*C*); (2) fistulas and strictures related to Crohn's disease (Fig. 275-3*D*); (3) a proximal duodenal afferent loop following a subtotal gastrectomy and gastrojejunostomy; (4) a bypass of the intestine, e.g., jejunoileal bypass for obesity; and (5) dilation at the site of a previous intestinal anastomosis. These anatomical derangements are often associated with the presence of a segment (or segments) of intestine out of continuity of propagated peristalsis, resulting in stasis and bacterial proliferation. Bacterial overgrowth syndromes can also occur in the absence of an anatomical blind loop when functional stasis is present. Impaired peristalsis and bacterial overgrowth in the absence of a blind loop occur in scleroderma, where motility abnormalities exist in both the esophagus and small intestine (Chap. 303), and in small-intestinal stricture associated with either Crohn's disease or an intestinal anastomosis. Functional stasis and bacterial overgrowth can also occur in association with diabetes mellitus and in the small intestine when a direct connection exists between the small and large intestine, including an ileocolonic resection, or occasionally following an enterocolic anastomosis that permits entry of bacteria into the small intestine as a result of bypassing the ileocecal valve.

Diagnosis The diagnosis may be suspected from the combination of a low serum cobalamin level and an elevated serum folate level as enteric bacteria frequently produce folate compounds that will be absorbed in the duodenum. Ideally, the diagnosis of the bacterial overgrowth syndrome is the demonstration of increased levels of aerobic and/or anaerobic colonic-type bacteria in a jejunal aspirate obtained by intubation. This specialized test is rarely available, and bacterial overgrowth is best established by a Schilling test (Table 275-6), which should be abnormal following the administration of ^{58}Co-labeled cobalamin, with or without the administration of intrinsic factor. Following the administration of tetracycline for 5 days, the Schilling test will become normal, confirming the diagnosis of bacterial overgrowth. Breath hydrogen testing following lactose administration has also been used to detect bacterial overgrowth.

℞ TREATMENT

Primary treatment should be directed, if at all possible, to the surgical correction of an anatomical blind loop. In the absence of functional stasis, it is important to define the anatomical relationships responsible for stasis and bacterial overgrowth. For example, bacterial overgrowth secondary to strictures, one or more diverticula, or a proximal afferent loop can potentially be cured by surgical correction of the anatomical state. In contrast, the functional stasis of scleroderma or certain anatomical stasis states (e.g., multiple jejunal diverticula), cannot be corrected surgically, and these conditions should be treated with broad-spectrum antibiotics. Tetracycline used to be the initial treatment of choice but, due to increasing resistance, other antibiotics such as metronidazole, amoxicillin/clavulanic acid, and cephalosporins have been employed. The antibiotic should be given for approximately 3 weeks or until symptoms remit. Since the natural history of these conditions is chronic, antibiotics should not be given continuously, and symptoms usually remit within 2 to 3 weeks of initial antibiotic therapy. Therapy need not be repeated until symptoms recur. In the presence of frequent recurrences several treatment strategies exist, but the use of antibiotics for 1 week per month whether or not symptoms are present is often most effective.

Unfortunately, therapy for bacterial overgrowth syndrome is largely empirical, with an absence of clinical trials on which to base decisions regarding the antibiotic to be used, the duration of treatment, and/or the best approach for treating recurrences. Bacterial overgrowth may also occur as a component of another chronic disease, e.g., Crohn's disease, radiation enteritis, or short bowel syndrome. Treatment of the bacterial overgrowth in these settings will not cure the underlying problem but may be very important in ameliorating a subset of clinical problems that are related to bacterial overgrowth.

WHIPPLE'S DISEASE

Whipple's disease is a chronic multisystem disease associated with diarrhea, steatorrhea, weight loss, arthralgia, and central nervous system and cardiac problems; it is caused by the bacteria *Tropheryma whipplei*. Until the identification of *T. whipplei* by polymerase chain reaction, the hallmark of Whipple's disease had been the presence of PAS-positive macrophages in the small intestine (Fig. 275-4E) and other organs with evidence of disease.

Long before the establishment of *T. whipplei* as the causative agent of Whipple's disease, gram-positive bacilli had been identified both within and outside of macrophages.

Etiology Whipple's disease is caused by a small gram-positive bacillus, *T. whipplei*. The bacillus, an actinobacterium, has low virulence but high infectivity, and relatively minimal symptoms are observed compared to the extent of the bacilli in multiple tissues.

Clinical Presentation The onset of Whipple's disease is insidious and is characterized by diarrhea, steatorrhea, abdominal pain, weight loss, migratory large-joint arthropathy, and fever as well as ophthalmologic and central nervous system symptoms. The development of dementia is a relatively late symptom and is an extremely poor prognostic sign, especially in patients who relapse following the induction of a remission with antibiotics. For unexplained reasons, the disease occurs primarily in middle-aged Caucasian men. The steatorrhea in these patients is generally believed secondary to both small-intestinal mucosal injury and lymphatic obstruction secondary to the increased number of PAS-positive macrophages in the lamina propria of the small intestine.

Diagnosis The diagnosis of Whipple's disease is suggested by a multisystem disease in a man with diarrhea and steatorrhea. Obtaining tissue biopsies from the small intestine and/or other organs that may be involved (e.g., liver, lymph nodes, heart, eyes, central nervous system, or synovial membranes), based on the patient's symptoms, is the primary approach to establish the diagnosis of Whipple's disease. The presence of PAS-positive macrophages containing the characteristic small (0.25 × 1 to 2 mm) bacilli is suggestive of this diagnosis. However, Whipple's disease can be confused with the PAS-positive macrophages containing *M. avium* complex, which may be a cause of diarrhea in AIDS. The presence of the *T. whipplei* bacillus outside of macrophages is a more important indicator of active disease than is their presence within the macrophages. *T. whipplei* has now been successfully grown in culture.

TABLE 275-9 Classification of Malabsorption Syndromes

- Inadequate digestion
  - Postgastrectomy[a]
  - Deficiency or inactivation of pancreatic lipase
    - Exocrine pancreatic insufficiency
      - Chronic pancreatitis
      - Pancreatic carcinoma
      - Cystic fibrosis
      - Pancreatic insufficiency—congenital or acquired
    - Gastrinoma—acid inactivation of lipase[a]
    - Drugs—orlistat
- Reduced intraduodenal bile acid concentration/impaired micelle formation
  - Liver disease
    - Parenchymal liver disease
    - Cholestatic liver disease
  - Bacterial overgrowth in small intestine:
    - Anatomic stasis
      - Afferent loop stasis/blind loop/strictures/fistulae
    - Functional stasis
      - Diabetes[a]
      - Scleroderma[a]
      - Intestinal pseudoobstruction
  - Interrupted enterohepatic circulation of bile salts
    - Ileal resection
    - Crohn's disease[a]
  - Drugs (bind or precipitate bile salts)—neomycin, cholestyramine, calcium carbonate
- Impaired mucosal absorption/mucosal loss or defect
  - Intestinal resection or bypass[a]
  - Inflammation, infiltration, or infection:
    - Crohn's disease[a]
    - Amyloidosis
    - Scleroderma[a]
    - Lymphoma[a]
    - Eosinophilic enteritis
    - Mastocytosis
    - Tropical sprue
    - Celiac sprue
    - Collagenous sprue
    - Whipple's disease[a]
    - Radiation enteritis[a]
    - Folate and vitamin B_{12} deficiency
    - Infections—giardiasis
    - Graft-vs.-host disease
  - Genetic disorders
    - Disaccharidase deficiency
    - Agammaglobulinemia
    - Abetalipoproteinemia
    - Hartnup disease
    - Cystinuria
- Impaired nutrient delivery to and/or from intestine:
  - Lymphatic obstruction
    - Lymphoma[a]
    - Lymphangiectasia
  - Circulatory disorders
    - Congestive heart failure
    - Constrictive pericarditis
    - Mesenteric artery atherosclerosis
    - Vasculitis
- Endocrine and metabolic disorders
  - Diabetes[a]
  - Hypoparathyroidism
  - Adrenal insufficiency
  - Hyperthyroidism
  - Carcinoid syndrome

[a] Malabsorption caused by more than one mechanism.

TREATMENT

The treatment for Whipple's disease is prolonged use of antibiotics. The current drug of choice is double-strength trimethoprim/sulfamethoxazole for approximately 1 year. PAS-positive macrophages can persist following successful treatment, and the presence of bacilli outside of macrophages is indicative of persistent infection or an early sign of recurrence. Recurrence of disease activity, especially with dementia, is an extremely poor prognostic sign and requires an antibiotic that crosses the blood-brain barrier. If trimethoprim/sulfamethoxazole is not tolerated, chloramphenicol is an appropriate second choice.

PROTEIN-LOSING ENTEROPATHY Protein-losing enteropathy is not a specific disease but rather describes a group of gastrointestinal and nongastrointestinal disorders with hypoproteinemia and edema in the absence of either proteinuria or defects in protein synthesis, e.g., chronic liver disease. These diseases are characterized by excess protein loss into the gastrointestinal tract. Normally, about 10% of the total protein catabolism occurs via the gastrointestinal tract. Evidence of increased protein loss into the gastrointestinal tract has been established in more than 65 different diseases, which can be classified into three primary groups: (1) mucosal ulceration such that the protein loss primarily represents exudation across damaged mucosa, e.g., ulcerative colitis, gastrointestinal carcinomas, and peptic ulcer; (2) nonulcerated mucosa but with evidence of mucosal damage so that the protein loss represents loss across epithelia with altered permeability, e.g., celiac sprue and Ménétrier's disease in the small intestine and stomach, respectively; and (3) lymphatic dysfunction, either representing primary lymphatic disease or secondary to partial lymphatic obstruction that may occur as a result of enlarged lymph nodes or cardiac disease.

Diagnosis The diagnosis of protein-losing enteropathy is suggested by the presence of peripheral edema and low serum albumin and globulin levels in the absence of renal and hepatic disease. It is extremely rare for an individual with protein-losing enteropathy to have selective loss of *only* albumin or *only* globulins. Therefore, marked reduction of serum albumin with normal serum globulins should not initiate an evaluation for protein-losing enteropathy but should suggest the presence of renal and/or hepatic disease. Likewise, reduced serum globulins with normal serum albumin levels are more likely a result of reduced globulin synthesis rather than enhanced globulin loss into the intestine. Documentation of an increase in protein loss into the gastrointestinal tract has been established by the administration of one of several radiolabeled proteins and its quantitation in stool during a 24- or 48-h period. Unfortunately, none of these radiolabeled proteins is available for routine clinical use. α_1 Antitrypsin, a protein that amounts to approximately 4% of total serum proteins and is resistant to proteolysis, can be used to document enhanced rates of serum protein loss into the intestinal tract but cannot be used to assess gastric protein loss due to its degradation in an acid milieu. α_1 Antitrypsin clearance is measured by determining stool volume and both stool and plasma α_1 antitrypsin concentrations. In addition to the loss of protein via abnormal and distended lymphatics, peripheral lymphocytes may also be lost via lymphatics, resulting in a relative lymphopenia. Thus, the pres-

TABLE 275-10 Pathophysiology of Clinical Manifestations of Malabsorption Disorders

Symptom or Sign	Mechanism
Weight loss/malnutrition	Anorexia, malabsorption of nutrients
Diarrhea	Impaired absorption or secretion of water and electrolytes; colonic fluid secretion secondary to unabsorbed dihydroxy bile acids and fatty acids
Flatus	Bacterial fermentation of unabsorbed carbohydrate
Glossitis, cheilosis, stomatitis	Deficiency of iron, vitamin B_{12}, folate, and vitamin A
Abdominal pain	Bowel distention or inflammation, pancreatitis
Bone pain	Calcium, vitamin D malabsorption, protein deficiency, osteoporosis
Tetany, paresthesia	Calcium and magnesium malabsorption
Weakness	Anemia, electrolyte depletion (particularly K^+)
Azotemia, hypotension	Fluid and electrolyte depletion
Amenorrhea, decreased libido	Protein depletion, decreased calories, secondary hypopituitarism
Anemia	Impaired absorption of iron, folate, vitamin B_{12}
Bleeding	Vitamin K malabsorption, hypoprothrombinemia
Night blindness/ xerophthalmia	Vitamin A malabsorption
Peripheral neuropathy	Vitamin B_{12} and thiamine deficiency
Dermatitis	Deficiency of vitamin A, zinc, and essential fatty acid

ence of lymphopenia in a patient with hypoproteinemia supports the presence of increased loss of protein into the gastrointestinal tract.

Patients with increased protein loss into the gastrointestinal tract from lymphatic obstruction often have steatorrhea and diarrhea. The steatorrhea is a result of altered lymphatic flow as lipid-containing chylomicrons exit from intestinal epithelial cells via intestinal lymphatics (Table 275-4; Fig. 275-4). In the absence of mechanical or anatomical lymphatic obstruction, intrinsic intestinal lymphatic dysfunction, with or without lymphatic dysfunction in the peripheral extremities, has been named *intestinal lymphangiectasia*. Similarly, about 50% of individuals with intrinsic peripheral lymphatic disease (Milroy disease) will also have intestinal lymphangiectasia and hypoproteinemia. Other than steatorrhea and enhanced protein loss into the gastrointestinal tract, all other aspects of intestinal absorptive function are normal in intestinal lymphangiectasia.

Other Causes Patients who appear to have idiopathic protein-losing enteropathy without any evidence of gastrointestinal disease should be examined for cardiac disease—especially right-sided valvular disease and chronic pericarditis (Chaps. 219 and 222). On occasion, hypoproteinemia can be the only presentation for these two types of heart disease. Ménétrier's disease (also called *hypertrophic gastropathy*) is an uncommon entity that involves the body and fundus of the stomach and is characterized by large gastric folds, reduced gastric acid secretion, and, at times, enhanced protein loss into the stomach.

TREATMENT

As excess protein loss into the gastrointestinal tract is most often secondary to a specific disease, treatment should be directed primarily to the underlying disease process and not to the hypoproteinemia. For example, if significant hypoproteinemia with resulting peripheral edema is present secondary to either celiac sprue or ulcerative colitis, a gluten-free diet or mesalamine, respectively, would be the initial therapy. When enhanced protein loss is secondary to lymphatic obstruction, it is critical to establish the nature of this obstruction. Identification of mesenteric nodes or lymphoma may be possible by imaging studies. Similarly, it is important to exclude cardiac disease as a cause of protein-losing enteropathy either by echosonography or, on occasion, by a right-heart catheterization.

The increased protein loss that occurs in intestinal lymphangiectasia is a result of distended lymphatics associated with lipid malabsorption. Treatment of the hypoproteinemia is accomplished by a low-fat diet and the administration of MCTs (Table 275-3), which do not exit from the intestinal epithelial cells via lymphatics but are delivered to the body via the portal vein.

SUMMARY

A pathophysiologic classification of the many conditions that can produce malabsorption is given in Table 275-9. A summary of the pathophysiology of the various clinical manifestations of malabsorption is given in Table 275-10.

276 INFLAMMATORY BOWEL DISEASE

Sonia Friedman, Richard S. Blumberg

Inflammatory bowel disease (IBD) is an idiopathic and chronic intestinal inflammation. Ulcerative colitis (UC) and Crohn's disease (CD) are the two major types of IBD.

EPIDEMIOLOGY

The incidence of IBD varies within different geographic areas. Northern countries, such as the United States, United Kingdom, Norway, and Sweden, have the highest rates. The incidence rates of UC and CD in the United States are about 11 per 100,000 and 7 per 100,000, respectively (Table 276-1). Countries in southern Europe, South Africa, and Australia have lower incidence rates: 2 to 6.3 per 100,000 for UC, and 0.9 to 3.1 per 100,000 for CD. In Asia and South America, IBD is rare; incidence rates of UC and CD are 0.5 and 0.08 per 100,000, respectively. The highest mortality in IBD patients is during the first years of disease and in long-duration disease due to the risk of colon cancer. In a Swedish population study, the standardized mortality ratios for CD and UC were 1.51 and 1.37, respectively.

The peak age of onset of UC and CD is between 15 and 30 years. A second peak occurs between the ages of 60 and 80. The male to female ratio for UC is 1:1 and for CD is 1.1 to 1.8:1. A two- to fourfold increased frequency of UC and CD in Jewish populations has been described in the United States, Europe, and South Africa. Furthermore, disease frequency differs within the Jewish populations. The prevalence of IBD in Ashkenazi Jews is about twice that of Israeli-born, Sephardic, or Oriental Jews. The prevalence decreases progressively

TABLE 276-1 Epidemiology of IBD

	Ulcerative Colitis	Crohn's Disease
Incidence (U.S.)	11/100,000	7/100,000
Age of onset	15–30 & 60–80	15–30 & 60–80
Ethnicity	Jewish > Non-Jewish Caucasian > African American > Hispanic > Asian	
Male:female ratio	1:1	1.1–1.8:1
Smoking	May prevent disease	May cause disease
Oral contraceptives	No increased risk	Relative risk 1.9
Appendectomy	Protective	Not protective
Monozygotic twins	20% concordance	67% concordance
Dizygotic twins	0% concordance	8% concordance

in non-Jewish Caucasian, African-American, Hispanic, and Asian populations. Urban areas have a higher prevalence of IBD than rural areas, and high socioeconomic classes have a higher prevalence than lower socioeconomic classes.

The effects of cigarette smoking are different in UC and CD. The risk of UC in smokers is 40% that of nonsmokers. Additionally, former smokers have a 1.7-fold increased risk for UC than people who have never smoked. In contrast, smoking is associated with a twofold increased risk of CD. Oral contraceptives are also linked to CD; the relative risk of CD for oral contraceptive users is about 1.9. Appendectomy appears to be protective against UC, but no studies have applied this as a preventive intervention.

IBD runs in families. If a patient has IBD, the lifetime risk that a first-degree relative will be affected is ~10%. If two parents have IBD, each child has a 36% chance of being affected. In twin studies, 67% of monozygotic twins are concordant for CD and 20% are concordant

for UC, whereas 8% of dizygotic twins are concordant for CD and none are concordant for UC. Anatomic site and clinical type of CD is also concordant within families.

Additional evidence for genetic predisposition to IBD comes from its association with certain genetic syndromes. UC and CD are both associated with Turner's syndrome, and Hermansky-Pudlak syndrome is associated with a granulomatous colitis. Glycogen storage disease type 1b can present with Crohn's-like lesions of the large and small bowel. Other immunodeficiency disorders, such as hypogammaglobulinemia, selective IgA deficiency, and hereditary angioedema, also exhibit an increased association with IBD.

ETIOLOGY AND PATHOGENESIS

Although IBD has been described as a clinical entity for over 100 years, its etiology and pathogenesis have not been defined. A consensus hypothesis is that in genetically predisposed individuals, both exogenous factors (e.g., infectious agents, normal lumenal flora) and host factors (e.g., intestinal epithelial cell barrier function, vascular supply, neuronal activity) cause a chronic state of dysregulated mucosal immune function that is further modified by specific environmental factors (e.g., smoking). Although it is possible that the chronic activation of the mucosal immune system may represent an appropriate response to an unidentified infectious agent, a search for such an agent has thus far been unrewarding. As such, IBD is currently considered an inappropriate response to either the endogenous microbial flora within the intestine, with or without some component of autoimmunity. Importantly, the normal intestine contains a large number of immune cells in a chronic state of so-called physiologic inflammation, in which the gut is poised for, but actively restrained from, full immunologic responses. During the course of infections in the normal host, full activation of the gut-associated lymphoid tissue occurs but is rapidly superceded by dampening the immune response and tissue repair. In IBD this process is not regulated normally.

GENETIC CONSIDERATIONS IBD is a polygenic disorder that gives rise to multiple clinical subgroups within UC and CD. Genome-wide searches have shown potential disease-associated loci on chromosomes 16, 12, 7, 5, 3, and 1, although the specific gene associations are mostly undefined. The disease-related gene on chromosome 16 is *NOD-2*, an intracellular molecule that senses bacterial peptidoglycan and regulates NF-κB signaling. Homozygosity for mutant alleles confers up to a 40-fold increased risk for fibrostenosing CD, especially in the ileum. HLA alleles may also play a role. UC patients disproportionately express DR2-related alleles, whereas in CD an increased use of the DR5 DQ1 haplotype or the DRB*0301 allele has been described. In UC patients with pancolitis undergoing total proctocolectomy, 14.3% versus 3.2% of non-IBD controls express the HLA DRB1*0103 allele. This allele is associated with extensive disease and extraintestinal manifestations such as mouth ulcers, arthritis, and uveitis. Other associations with immunoregulatory genes include the intercellular adhesion molecule R241 allele in UC and CD and the interleukin (IL) 1 receptor antagonist allele 2 in UC patients that is associated with total colonic inflammation. Patients with IBD and their first-degree relatives may also exhibit diminished intestinal epithelial cell barrier function.

DEFECTIVE IMMUNE REGULATION IN IBD The normal state of the mucosal immune system is one of inhibited immune responses to lumenal contents due to oral tolerance that occurs in the normal individual. When soluble antigens are administered orally rather than subcutaneously or intramuscularly, antigen-specific non-responsiveness is induced. Multiple mechanisms are involved in the induction of oral tolerance and include deletion or anergy of antigen-reactive T cells or activation of CD4+ T cells that suppress gut inflammation through secretion of inhibitory cytokines, such as IL-10 and transforming growth factor β (TGF-β). Oral tolerance may be responsible for the lack of immune responsiveness to dietary antigens and the commensal flora in the intestinal lumen. In IBD this suppression of inflammation is altered, leading to uncontrolled inflammation. The mechanisms that maintain this regulated immune suppression are unknown.

Gene knockout (-/-) or transgenic (Tg) mouse models of colitis have revealed that deleting specific cytokines (e.g., IL-2, IL-10, TGF-β) or their receptors, deleting molecules associated with T cell antigen recognition (e.g., T cell antigen receptors, MHC class II), or interfering with intestinal epithelial cell barrier function (e.g., blocking N-cadherin, deleting multidrug resistance gene 1a or trefoil factor) leads to colitis. Thus, a variety of specific alterations can lead to autoimmunity directed at the colon in mice.

In both UC and CD, activated CD4+ T cells in the lamina propria and peripheral blood secrete inflammatory cytokines. Some activate other inflammatory cells (macrophages and B cells) and others act indirectly to recruit other lymphocytes, inflammatory leukocytes, and mononuclear cells from the peripheral vasculature into the gut through interactions between homing receptors on leukocytes (e.g., $\alpha 4\beta 7$ integrin) and addressins on vascular endothelium (e.g., MadCAM1). CD4+ T cells are of two major types, both of which may be associated with colitis in animal models and humans: T_H1 cells [interferon (IFN) γ, tumor necrosis factor (TNF)] and T_H2 cells (IL-4, IL-5, IL-13). T_H1 cells appear to induce transmural granulomatous inflammation that resembles CD, and T_H2 cells appear to induce superficial mucosal inflammation resembling UC. The T_H1 cytokine pathway is initiated by IL-12, a key cytokine in the pathogenesis of experimental models of mucosal inflammation. Thus, use of antibodies to block proinflammatory cytokines (e.g., anti-TNF-α, anti-IL-12) or molecules associated with leukocyte recruitment (e.g., anti-$\alpha 4\beta 7$) or use of cytokines that inhibit inflammation (e.g., IL-10) or promote intestinal barrier function (e.g., IL-11) may be beneficial to humans with colitis.

THE INFLAMMATORY CASCADE IN IBD Once initiated in IBD, the immune inflammatory response is perpetuated as a consequence of T cell activation. A sequential cascade of inflammatory mediators acts to extend the response; each step is a potential target for therapy. Inflammatory cytokines, such as IL-1, IL-6, and TNF, have diverse effects on tissue. They promote fibrogenesis, collagen production, activation of tissue metalloproteinases, and the production of other inflammatory mediators; they also activate the coagulation cascade in local blood vessels (e.g., increased production of von Willebrand's factor). These cytokines are normally produced in response to infection, but are usually turned off or inhibited at the appropriate time to limit tissue damage. In IBD their activity is not regulated, resulting in an imbalance between the proinflammatory and anti-inflammatory mediators. Therapies such as the 5-ASA (5-aminosalicylic acid) compounds are potent inhibitors of these inflammatory mediators through inhibition of transcription factors such as NF-κB that regulate their expression.

EXOGENOUS FACTORS IBD may have an as yet undefined infectious etiology. Three specific agents have received the greatest attention, *Mycobacterium paratuberculosis*, Paramyxovirus, and *Helicobacter* species. The immune response to a specific organism could be expressed differently, depending upon the individual's genetic background. *M. paratuberculosis* does not have a confirmed disease association, and antimycobacterial agents are not effective in treating CD. A role for the measles virus or paramyxoviruses in the development of CD has been suggested based on an increase in the incidence of CD in England that paralleled use of the measles vaccine. However, studies in the United States have not substantiated this finding. In an animal model of IBD, *H. hepaticus* has been implicated as a trigger for the inflammatory response; evidence in humans is lacking.

Multiple pathogens (e.g., *Salmonella*, *Shigella* sp., *Campylobacter* sp.) may initiate IBD by triggering an inflammatory response that the mucosal immune system may fail to control. However, in an IBD patient the normal flora is likely perceived as if it were a pathogen. Anaerobic organisms, particularly *Bacteroides* species, may be re-

sponsible for the induction of inflammation. Such a notion is supported by the response in patients with CD to agents that alter the intestinal flora, such as metronidazole, ciprofloxacin, and elemental diets. CD also responds to fecal diversion, demonstrating the ability of lumenal contents to exacerbate disease. On the other hand, other bacteria, so-called probiotics (*Lactobacillus* sp.), inhibit inflammation in animal models and humans.

Psychosocial factors can contribute to worsening of symptoms. Major life events such as illness or death in the family, divorce or separation, interpersonal conflict, or other major loss are associated with an increase in IBD symptoms such as pain, bowel dysfunction, and bleeding. Acute daily stress can worsen bowel symptoms even after controlling for major life events. When the sickness-impact profile, a measurement of overall psychological and physical functioning, is used, IBD patients have functional impairment greater than that of a normal population but less than that of patients with chronic back pain or amyotrophic lateral sclerosis. IBD patients have been hypothesized to have a characteristic personality that renders them susceptible to emotional stresses. However, emotional dysfunction could also be the result of chronic illness rather than a cause.

PATHOLOGY

ULCERATIVE COLITIS: MACROSCOPIC FEATURES UC is a mucosal disease that usually involves the rectum and extends proximally to involve all or part of the colon. About 40 to 50% of patients have disease limited to the rectum and rectosigmoid, 30 to 40% have disease extending beyond the sigmoid but not involving the whole colon, and 20% have a total colitis. Proximal spread occurs in continuity without areas of uninvolved mucosa. When the whole colon is involved, the inflammation extends 1 to 2 cm into the terminal ileum in 10 to 20% of patients. This is called *backwash ileitis* and is of little clinical significance. Although variations in macroscopic activity may suggest skip areas, biopsies from normal-appearing mucosa are usually abnormal. Thus, it is important to obtain multiple biopsies from apparently uninvolved mucosa, whether proximal or distal, during endoscopy.

With mild inflammation, the mucosa is erythematous and has a fine granular surface that looks like sandpaper. In more severe disease, the mucosa is hemorrhagic, edematous, and ulcerated (Fig. 276-1). In long-standing disease, inflammatory polyps (pseudopolyps) may be present as a result of epithelial regeneration. The mucosa may appear normal in remission, but in patients with many years of disease it appears atrophic and featureless and the entire colon becomes narrowed and shortened. Patients with fulminant disease can develop a toxic colitis or megacolon where the bowel wall thins and the mucosa is severely ulcerated; this may lead to perforation.

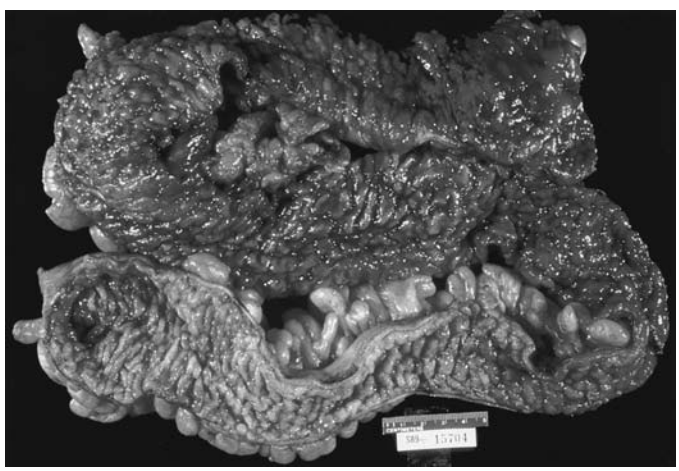

FIGURE 276-1 Pan-ulcerative colitis. Mucosa has a lumpy, bumpy appearance because of areas of inflamed but intact mucosa separated by ulcerated areas. *(Courtesy of Dr. EK Rosado and Dr. CA Perkos, Division of Gastrointestinal Pathology, Department of Pathology, Emory University, Atlanta, Georgia.)*

FIGURE 276-2 Characteristic findings of IBD in a case of ulcerative colitis: crypt distortion, cryptitis, and crypt abscess. *(Courtesy of Dr. EK Rosado and Dr. CA Perkos, Division of Gastrointestinal Pathology, Department of Pathology, Emory University, Atlanta, Georgia.)*

ULCERATIVE COLITIS: MICROSCOPIC FEATURES Histologic findings correlate well with the endoscopic appearance and clinical course of UC. The process is limited to the mucosa and superficial submucosa, with deeper layers unaffected except in fulminant disease. In UC, two major histologic features are indicative of chronicity and help distinguish it from infectious or acute self-limited colitis. First, the crypt architecture of the colon is distorted; crypts may be bifid and reduced in number, often with a gap between the crypt bases and the muscularis mucosae. Second, some patients have basal plasma cells and multiple basal lymphoid aggregates. Mucosal vascular congestion with edema and focal hemorrhage, and an inflammatory cell infiltrate of neutrophils, lymphocytes, plasma cells, and macrophages may be present. The neutrophils invade the epithelium, usually in the crypts, and give rise to cryptitis and, ultimately, to crypt abscesses (Fig. 276-2).

CROHN'S DISEASE: MACROSCOPIC FEATURES CD can affect any part of the gastrointestinal tract from the mouth to the anus. Some 30 to 40% of patients have small-bowel disease alone, 40 to 55% have disease involving both the small and large intestines, and 15 to 25% have colitis alone. In the 75% of patients with small-intestinal disease, the terminal ileum is involved in 90%. Unlike UC, which almost always involves the rectum, the rectum is often spared in CD. CD is segmental, with skip areas in the midst of diseased intestine (Fig. 276-3). Perirectal fistulas, fissures, abscesses, and anal stenosis are present in one-third

FIGURE 276-3 Portion of colon with stricture in patient with CD. *(Courtesy of Dr. EK Rosado and Dr. CA Perkos, Division of Gastrointestinal Pathology, Department of Pathology, Emory University, Atlanta, Georgia.)*

of patients with CD, particularly those with colonic involvement. CD may also involve the liver and the pancreas.

Unlike UC, CD is a transmural process. Endoscopically, aphthous or small superficial ulcerations characterize mild disease; in more active disease, stellate ulcerations fuse longitudinally and transversely to demarcate islands of mucosa that frequently are histologically normal. This "cobblestone" appearance is characteristic of CD, both endoscopically and by barium radiography. As in UC, pseudopolyps can form in CD.

Active CD is characterized by focal inflammation and formation of fistula tracts, which resolve by fibrosis and stricturing of the bowel. The bowel wall thickens and becomes narrowed and fibrotic, leading to chronic, recurrent bowel obstructions. Projections of thickened mesentery encase the bowel ("creeping fat"), and serosal and mesenteric inflammation promote adhesions and fistula formation.

TABLE 276-2 *Ulcerative Colitis: Disease Presentation*

	Mild	*Moderate*	*Severe*
Bowel movements	<4 per day	4–6 per day	>6 per day
Blood in stool	Small	Moderate	Severe
Fever	None	<37.5°C mean	>37.5°C mean
Tachycardia	None	<90 mean pulse	>90 mean pulse
Anemia	Mild	>75%	≤75%
Sedimentation rate	<30 mm		>30 mm
Endoscopic appearance	Erythema, decreased vascular pattern, fine granularity	Marked erythema, coarse granularity, absent vascular markings, contact bleeding, no ulcerations	Spontaneous bleeding, ulcerations

CROHN'S DISEASE: MICROSCOPIC FEATURES The earliest lesions are aphthoid ulcerations and focal crypt abscesses with loose aggregations of macrophages, which form noncaseating granulomas in all layers of the bowel wall from mucosa to serosa (Fig. 276-4). Granulomas can be seen in lymph nodes, mesentery, peritoneum, liver, and pancreas. Although granulomas are a pathognomonic feature of CD, they are rarely found on mucosal biopsies. Surgical resection reveals granulomas in about half of cases. Other histologic features of CD include submucosal or subserosal lymphoid aggregates, particularly away from areas of ulceration, gross and microscopic skip areas, and transmural inflammation that is accompanied by fissures that penetrate deeply into the bowel wall and sometimes form fistulous tracts or local abscesses.

CLINICAL PRESENTATION

ULCERATIVE COLITIS ■ Signs and Symptoms The major symptoms of UC are diarrhea, rectal bleeding, tenesmus, passage of mucus, and crampy abdominal pain. The severity of symptoms correlates with the extent of disease. Although UC can present acutely, symptoms usually have been present for weeks to months. Occasionally, diarrhea and bleeding are so intermittent and mild that the patient does not seek medical attention.

Patients with proctitis usually pass fresh blood or blood-stained mucus, either mixed with stool or streaked onto the surface of a normal or hard stool. They also have tenesmus, or urgency with a feeling of incomplete evacuation. They rarely have abdominal pain. With proctitis or proctosigmoiditis, proximal transit slows, which may account for the constipation that is commonly seen in patients with distal disease.

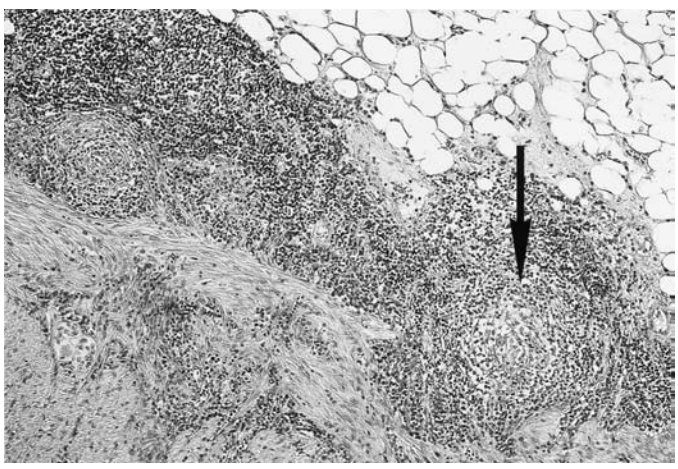

FIGURE 276-4 Granulomas (*arrow*) in bowel wall and serosa of colon, CD. *(Courtesy of Dr. EK Rosado and Dr. CA Perkos, Division of Gastrointestinal Pathology, Department of Pathology, Emory University, Atlanta, Georgia.)*

When the disease extends beyond the rectum, blood is usually mixed with stool or grossly bloody diarrhea may be noted. Colonic motility is altered by inflammation with rapid transit through the inflamed intestine. When the disease is severe, patients pass a liquid stool containing blood, pus, and fecal matter. Diarrhea is often nocturnal and/or postprandial. Although severe pain is not a prominent symptom, some patients with active disease may experience vague lower abdominal discomfort or mild central abdominal cramping. Severe cramping and abdominal pain can occur in association with severe attacks of the disease. Other symptoms in moderate to severe disease include anorexia, nausea, vomiting, fever, and weight loss.

Physical signs of proctitis include a tender anal canal and blood on rectal examination. With more extensive disease, patients have tenderness to palpation directly over the colon. Patients with a toxic colitis have severe pain and bleeding, and those with megacolon have hepatic tympany. Both may have signs of peritonitis if a perforation has occurred. The classification of disease activity is shown in Table 276-2.

Laboratory, Endoscopic, and Radiographic Features Active disease can be associated with a rise in acute-phase reactants (C-reactive protein, orosomucoid levels), platelet count, erythrocyte sedimentation rate (ESR), and a decrease in hemoglobin. In severely ill patients, the serum albumin level will fall rather quickly. Leukocytosis may be present but is not a specific indicator of disease activity. Proctitis or proctosigmoiditis rarely causes a rise in C-reactive protein. Diagnosis relies upon the patient's history; clinical symptoms, negative stool examination for bacteria, *Clostridium difficile* toxin, and ova and parasites; sigmoidoscopic appearance (see Fig. 272-18); and histology of rectal or colonic biopsy specimens.

Sigmoidoscopy is used to assess disease activity and is often performed before treatment. If the patient is not having an acute flare, colonoscopy is used to assess disease extent and activity. Histologic features change more slowly than clinical features but can also be used to grade disease activity.

Patients with a severe attack of UC should have a plain, supine film of the abdomen. In the presence of severe disease, the margin of the colon becomes edematous and irregular. Colon thickening and toxic dilation can both be seen on a plain radiograph.

The earliest radiologic change of UC seen on single-contrast barium enema is a fine mucosal granularity (Fig. 276-5). With increasing severity, the mucosa becomes thickened and superficial ulcers are seen. Deep ulcerations can appear as "collar-button" ulcers, which indicate that the ulceration has penetrated the mucosa. Haustral folds may be normal in mild disease, but as activity progresses they become edematous and thickened. Loss of haustration can occur, especially in patients with long-standing disease. In addition, the colon becomes shortened and narrowed. Polyps in the colon may be postinflammatory polyps or pseudopolyps, adenomatous polyps, or carcinoma.

Computed tomography (CT) scanning is not as helpful as endoscopy and barium enema in making the diagnosis of UC, but typical findings include mild mural thickening (<1.5 cm), inhomogeneous

FIGURE 276-5 Barium enema in a patient with acute ulcerative colitis: inflammation of the entire colon. *(Courtesy of Dr. JM Braver, Gastrointestinal Radiology, Department of Radiology, Brigham and Women's Hospital, Boston, Massachusetts.)*

wall density, absence of small-bowel thickening, increased perirectal and presacral fat, target appearance of the rectum, and adenopathy.

Complications Only 15% of patients with UC present initially with catastrophic illness. Massive hemorrhage occurs with severe attacks of disease in 1% of patients, and treatment for the disease usually stops the bleeding. However, if a patient requires 6 to 8 units of blood within 24 to 48 h, colectomy is indicated. Toxic megacolon is defined as a transverse colon with a diameter of >5 to 6 cm, with loss of haustration in patients with severe attacks of UC. It occurs in about 5% of attacks and can be triggered by electrolyte abnormalities and narcotics. About 50% of acute dilations will resolve with medical therapy alone, but urgent colectomy is required for those that do not improve. Perforation is the most dangerous of the local complications, and the physical signs of peritonitis may not be obvious, especially if the patient is receiving glucocorticoids. Although perforation is rare, the mortality rate for perforation complicating a toxic megacolon is about 15%. In addition, patients can develop a toxic colitis and such severe ulcerations that the bowel may perforate without first dilating.

Obstructions caused by benign stricture formation occur in 10% of patients, with one-third of the strictures occurring in the rectum. These should be surveyed endoscopically for carcinoma. UC patients occasionally develop anal fissures, perianal abscesses, or hemorrhoids, but the occurrence of extensive perianal lesions should suggest CD.

CROHN'S DISEASE ■ Signs and Symptoms Although CD usually presents as acute or chronic bowel inflammation, the inflammatory process evolves toward one of two patterns of disease: a fibrostenotic-obstructing pattern or a penetrating-fistulous pattern, each with different treatments and prognoses. The site of disease influences the clinical manifestations.

ILEOCOLITIS Because the most common site of inflammation is the terminal ileum, the usual presentation of ileocolitis is a chronic history of recurrent episodes of right lower quadrant pain and diarrhea. Sometimes the initial presentation mimics acute appendicitis with pronounced right lower quadrant pain, a palpable mass, fever, and leukocytosis. Pain is usually colicky; it precedes and is relieved by defecation. A low-grade fever is usually noted. High-spiking fever suggests intraabdominal abscess formation. Weight loss is common—typically 10 to 20% of body weight—and develops as a consequence of diarrhea, anorexia, and fear of eating.

An inflammatory mass may be palpated in the right lower quadrant of the abdomen. The mass is composed of inflamed bowel, adherent and indurated mesentery, and enlarged abdominal lymph nodes. Extension of the mass can cause obstruction of the right ureter or bladder inflammation, manifested by dysuria and fever. Edema, bowel wall thickening, and fibrosis of the bowel wall within the mass account for the radiographic "string sign" of a narrowed intestinal lumen.

Bowel obstruction may take several forms. In the early stages of disease, bowel wall edema and spasm produce intermittent obstructive manifestations and increasing symptoms of postprandial pain. Over several years, persistent inflammation gradually progresses to fibrostenotic narrowing and stricture. Diarrhea will decrease and be replaced by chronic bowel obstruction. Acute episodes of obstruction occur as well, precipitated by bowel inflammation and spasm or sometimes by impaction of undigested food or medication. These episodes usually resolve with intravenous fluids and gastric decompression.

Severe inflammation of the ileocecal region may lead to localized wall thinning, with microperforation and fistula formation to the adjacent bowel, the skin, the urinary bladder, or to an abscess cavity in the mesentery. Enterovesical fistulas typically present as dysuria or recurrent bladder infections or less commonly as pneumaturia or fecaluria. Enterocutaneous fistulas follow tissue planes of least resistance, usually draining through abdominal surgical scars. Enterovaginal fistulas are rare and present as dyspareunia or as a feculent or foul-smelling, often painful vaginal discharge. They are unlikely to develop without a prior hysterectomy.

JEJUNOILEITIS Extensive inflammatory disease is associated with a loss of digestive and absorptive surface, resulting in malabsorption and steatorrhea. Nutritional deficiencies can also result from poor intake and enteric losses of protein and other nutrients. Intestinal malabsorption can cause hypoalbuminemia, hypocalcemia, hypomagnesemia, coagulopathy, and hyperoxaluria with nephrolithiasis. Vertebral fractures are caused by a combination of vitamin D deficiency, hypocalcemia, and prolonged glucocorticoid use. Pellagra from niacin deficiency can occur in extensive small-bowel disease, and malabsorption of vitamin B_{12} can lead to a megaloblastic anemia and neurologic symptoms.

Diarrhea is characteristic of active disease; its causes include: (1) bacterial overgrowth in obstructive stasis or fistulization, (2) bile-acid malabsorption due to a diseased or resected terminal ileum, and (3) intestinal inflammation with decreased water absorption and increased secretion of electrolytes.

COLITIS AND PERIANAL DISEASE Patients with colitis present with low-grade fevers, malaise, diarrhea, crampy abdominal pain, and sometimes hematochezia. Gross bleeding is not as common as in UC and appears in about half of patients with exclusively colonic disease. Only 1 to 2% bleed massively. Pain is caused by passage of fecal material through narrowed and inflamed segments of large bowel. Decreased rectal compliance is another cause for diarrhea in Crohn's colitis patients. Toxic megacolon is rare but may be seen with severe inflammation and short-duration disease.

Stricturing can occur in the colon and produce symptoms of bowel obstruction. Also, colonic disease may fistulize into the stomach or duodenum, causing feculent vomiting, or to the proximal or mid small bowel, causing malabsorption by "short circuiting" and bacterial overgrowth. Ten percent of women with Crohn's colitis will develop a rectovaginal fistula.

Perianal disease affects about one-third of patients with Crohn's colitis and is manifested by incontinence, large hemorrhoidal tags, anal strictures, anorectal fistulae, and perirectal abscesses. Not all patients with perianal fistula will have endoscopic evidence of colonic inflammation.

GASTRODUODENAL DISEASE Symptoms and signs of upper gastrointestinal tract disease include nausea, vomiting, and epigastric pain. Patients usually have a *H. pylori*–negative gastritis. The second portion of the duodenum is more commonly involved than the bulb. Fistulas involving the stomach or duodenum arise from the small or large bowel and do not necessarily signify the presence of upper gastrointestinal tract involvement. Patients with advanced gastroduodenal CD may develop a chronic gastric outlet obstruction.

Laboratory, Endoscopic, and Radiographic Features Laboratory abnormalities include elevated ESR and C-reactive protein. In more severe disease, findings include hypoalbuminemia, anemia, and leukocytosis.

Endoscopic features of CD include rectal sparing, aphthous ulcerations, fistulas, and skip lesions. Endoscopy is useful for biopsy of mass lesions or strictures, or for visualization of filling defects seen on barium enema. Colonoscopy allows examination and biopsy of the terminal ileum, and upper endoscopy is useful in diagnosing gastroduodenal involvement in patients with upper tract symptoms. Ileal or colonic strictures may be dilated with balloons introduced through the colonoscope. Endoscopic appearance correlates poorly with clinical remission; thus, repeated endoscopy is not used to monitor the inflammation.

In CD early radiographic findings in the small bowel include thickened folds and aphthous ulcerations. "Cobblestoning" from longitudinal and transverse ulcerations most frequently involves the small bowel (Fig. 276-6). In more advanced disease, strictures, fistulas (Fig. 276-7), inflammatory masses, and abscesses may be detected. The earliest macroscopic findings of colonic CD are aphthous ulcers. These small ulcers are often multiple and separated by normal intervening mucosa. As disease progresses, aphthous ulcers become enlarged, deeper, and occasionally connected to one another, forming longitudinal stellate, serpiginous, and linear ulcers (see Fig. 272-17).

The transmural inflammation of CD leads to decreased luminal diameter and limited distensibility. As ulcers progress deeper, they can lead to fistula formation. The radiographic "string sign" represents long areas of circumferential inflammation and fibrosis, resulting in long segments of luminal narrowing. The segmental nature of CD results in wide gaps of normal or dilated bowel between involved segments.

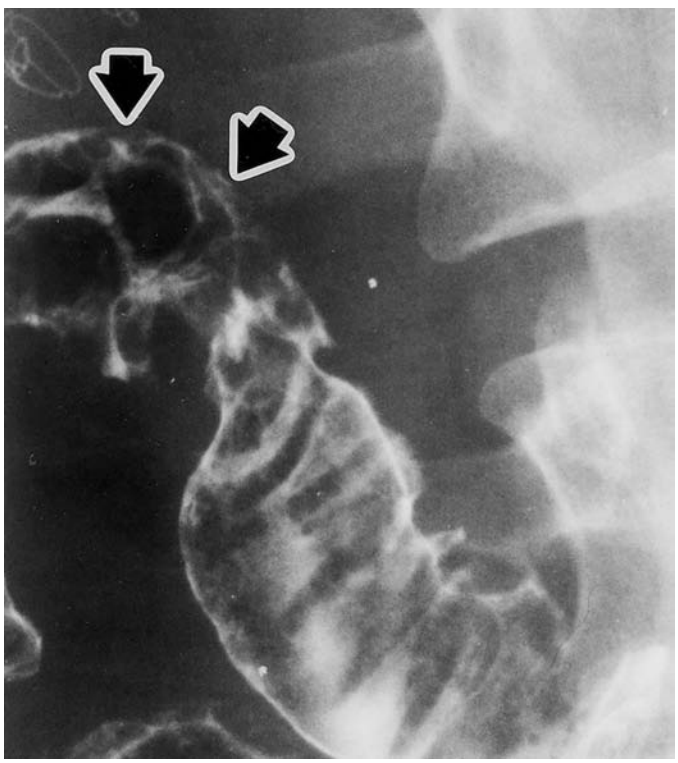

FIGURE 276-6 Crohn's disease: small bowel series demonstrating "cobblestoning" of the terminal ileum (*arrows*). *(Courtesy of Dr. JM Braver, Gastrointestinal Radiology, Department of Radiology, Brigham and Women's Hospital, Boston, Massachusetts.)*

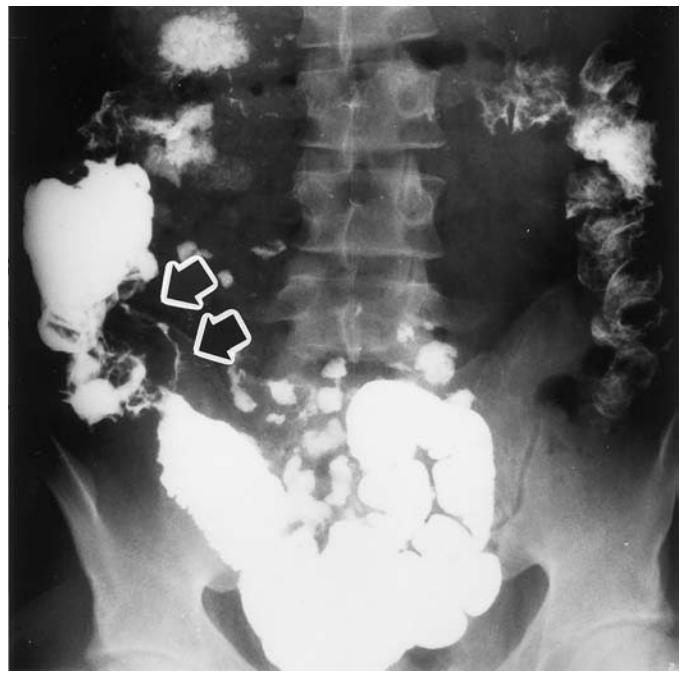

FIGURE 276-7 Small bowel series demonstrating distal ileal inflammation and fistulization (*arrows*) in a patient with CD. *(Courtesy of Dr. JM Braver, Gastrointestinal Radiology, Department of Radiology, Brigham and Women's Hospital, Boston, Massachusetts.)*

CT findings include mural thickening >2 cm, homogeneous wall density, mural thickening of small bowel, mesenteric fat stranding, perianal disease, and adenopathy. CT scanning can help identify abscesses, fistulas, and sinus tracts. Magnetic resonance imaging (MRI) may prove superior for demonstrating pelvic lesions such as ischiorectal abscesses.

Complications Because CD is a transmural process, serosal adhesions develop that provide direct pathways for fistula formation and reduce the incidence of free perforation. Free perforation occurs in 1 to 2% of patients, usually in the ileum but occasionally in the jejunum or as a complication of toxic megacolon. The peritonitis of free perforation, especially colonic, may be fatal. Generalized peritonitis may also result from the rupture of an intraabdominal abscess. Other complications include intestinal obstruction in 40%, massive hemorrhage, malabsorption, and severe perianal disease.

Serologic Markers Several serologic markers may be used to differentiate between CD and UC and help to predict the course of disease. Two antibodies that can be detected in the serum of IBD patients are perinuclear antineutrophil cytoplasmic antibodies (pANCAs) and anti-*Saccharomyces cerevisiae* antibodies (ASCAs). A distinct set of antineutrophil cytoplasmic antibodies with perinuclear staining by indirect immunofluorescence is associated with UC. The antigens to which these antibodies are directed have not been identified, but they are distinct from those associated with vasculitis and may be a marker for reactivity to enteric bacteria. pANCA positivity is found in about 60 to 70% of UC patients and 5 to 10% of CD patients; 5 to 15% of first-degree relatives of UC patients are pANCA positive, whereas only 2 to 3% of the general population is pANCA positive. pANCA may also identify specific disease phenotypes. pANCA positivity is more often associated with pancolitis, early surgery, pouchitis, or inflammation of the pouch after ileal pouch–anal anastamosis (IPAA) and primary sclerosing cholangitis. pANCA in CD is associated with colonic disease that resembles UC.

ASCA antibodies recognize mannose sequences in the cell wall

mannan of *S. cerevisiae*; 60 to 70% of CD patients, 10 to 15% of UC patients, and up to 5% of non-IBD controls are ASCA positive. About 55% of CD patients are seroreactive to outer-membrane porin C (OMPC), a bacterial antigen. The combined measurement of pANCA and ASCA has been advocated as a valuable diagnostic approach to IBD. In one report, pANCA+ with ASCA− results showed a 57% sensitivity and 97% specificity for UC, whereas pANCA− with ASCA+ results showed a 49% sensitivity and 97% specificity for CD. ASCA was associated with small-bowel CD. These antibody tests may help decide whether a patient with indeterminate colitis should undergo an IPAA, because patients with predominant features of CD often have a more difficult postoperative course.

Other serologic markers in IBD patients include anti-goblet cell autoantibodies, pancreatic autoantibodies, and an autoantibody against tropomyosin isoform 5 found in colon epithelial cells. Antibodies to red cell membrane antigens that cross-react with enteropathogens such as *Campylobacter* sp. may be associated with hemolytic anemia in CD. None of these antibodies are useful in the diagnosis and management of patients with IBD.

DIFFERENTIAL DIAGNOSIS OF UC AND CD

UC and CD have similar features to many other diseases. In the absence of a key diagnostic test, a combination of clinical, laboratory, histopathologic, radiographic, and therapeutic observations is required (Table 276-3). Once a diagnosis of IBD is made, distinguishing between UC and CD is impossible in 10 to 15% of cases. These are termed *indeterminate colitis*.

INFECTIOUS DISEASE Infections of the small intestines and colon can mimic CD or UC. They may be bacterial, fungal, viral, or protozoal in origin (Table 276-4). *Campylobacter* colitis can mimic the endoscopic appearance of severe UC and can cause a relapse of established UC. *Salmonella* can cause watery or bloody diarrhea, nausea, and vomiting. Shigellosis causes watery diarrhea, abdominal pain, and fever followed by rectal tenesmus and by the passage of blood and mucus per rectum. All three are usually self-limited, but 1% of patients infected with *Salmonella* become asymptomatic carriers. *Yersinia enterocolitica* infection occurs mainly in the terminal ileum and causes mucosal ulceration, neutrophil invasion, and thickening of the ileal wall. Other bacterial infections that may mimic IBD include *C. difficile*, which presents with watery diarrhea, tenesmus, nausea, and vomiting; and *Escherichia coli*, three categories of which can cause colitis. These are enterohemorrhagic, enteroinvasive, and enteroadherent *E. coli*, all of which can cause bloody diarrhea and abdominal tenderness. Diagnosis of bacterial colitis is made by sending stool specimens for bacterial culture and *C. difficile* toxin analysis. Gonorrhea, *Chlamydia*, and syphilis can also cause proctitis.

Gastrointestinal involvement with mycobacterial infection occurs primarily in the immunosuppressed patient but may occur in patients with normal immunity. Distal ileal and cecal involvement predominates, and patients present with symptoms of small-bowel obstruction and a tender abdominal mass. The diagnosis is made most directly by colonoscopy with biopsy and culture. *Mycobacterium avium-intracellulare* complex infection occurs in advanced stages of HIV infection and in other immunocompromised states and usually manifests as a systemic infection with diarrhea, abdominal pain, weight loss, fever, and malabsorption. Diagnosis is established by acid-fast smear and culture of mucosal biopsies.

Although most of the patients with viral colitis are immunosuppressed, cytomegalovirus (CMV) and herpes simplex proctitis may occur in immunocompetent individuals. CMV occurs most commonly in the esophagus, colon, and rectum but may also involve the small intestine. Symptoms include abdominal pain, bloody diarrhea, fever, and weight loss. With severe disease, necrosis and perforation can occur. Diagnosis is made by identification of intranuclear inclusions in mucosal cells on biopsy. Herpes simplex infection of the gastrointestinal tract is limited to the oropharynx, anorectum, and perianal areas. Symptoms include anorectal pain, tenesmus, constipation, in-

TABLE 276-3 Different Clinical, Endoscopic, and Radiographic Features

	Ulcerative Colitis	Crohn's Disease
CLINICAL		
Gross blood in stool	Yes	Occasionally
Mucus	Yes	Occasionally
Systemic symptoms	Occasionally	Frequently
Pain	Occasionally	Frequently
Abdominal mass	Rarely	Yes
Significant perineal disease	No	Frequently
Fistulas	No	Yes
Small-intestinal obstruction	No	Frequently
Colonic obstruction	Rarely	Frequently
Response to antibiotics	No	Yes
Recurrence after surgery	No	Yes
ANCA-positive	Frequently	Rarely
ASCA-positive	Rarely	Frequently
ENDOSCOPIC		
Rectal sparing	Rarely	Frequently
Continuous disease	Yes	Occasionally
"Cobblestoning"	No	Yes
Granuloma on biopsy	No	Occasionally
RADIOGRAPHIC		
Small bowel significantly abnormal	No	Yes
Abnormal terminal ileum	Occasionally	Yes
Segmental colitis	No	Yes
Asymmetric colitis	No	Yes
Stricture	Occasionally	Frequently

Note: ANCA, antineutrophil cytoplasm antibody; ASCA, anti-Saccharomyces cerevisiae antibody.

TABLE 276-4 Diseases that Mimic IBD

INFECTIOUS ETIOLOGIES

Bacterial
- *Salmonella*
- *Shigella*
- Toxigenic *Escherichia coli*
- *Campylobacter*
- *Yersinia*
- *Clostridium difficile*
- Gonorrhea
- *Chlamydia trachomatis*

Mycobacterial
- Tuberculosis
- *Mycobacterium avium*

Parasitic
- Amebiasis
- *Isospora*
- *Trichuris trichura*
- Hookworm
- *Strongyloides*

Viral
- Cytomegalovirus
- Herpes simplex
- HIV

Fungal
- Histoplasmosis
- *Candida*
- *Aspergillus*

NONINFECTIOUS ETIOLOGIES

Inflammatory
- Appendicitis
- Diverticulitis
- Diversion colitis
- Collagenous/lymphocytic colitis
- Ischemic colitis
- Radiation colitis/enteritis
- Solitary rectal ulcer
- Eosinophilc gastroenteritis
- Neutropenic colitis
- Beçhet's syndrome
- Graft-versus-host disease

Neoplastic
- Lymphoma
- Metastatic carcinoma
- Carcinoma of the ileum
- Carcinoid
- Familial polyposis

Drugs and Chemicals
- NSAIDs
- Phosphasoda
- Cathartic colon
- Gold
- Oral contraceptives
- Cocaine
- Chemotherapy

Note: NSAIDs, nonsteroidal anti-inflammatory drugs.

guinal adenopathy, difficulty with urinary voiding, and sacral paresthesias. Diagnosis is made by rectal biopsy. HIV itself can cause diarrhea, nausea, vomiting, and anorexia. Small-intestinal biopsies show partial villus atrophy; small-bowel bacterial overgrowth and fat malabsorption may also be noted.

Protozoan parasites include *Isospora belli*, which can cause a self-limited infection in healthy hosts but causes a chronic profuse, watery diarrhea and weight loss in AIDS patients. *Entamoeba histolytica* or related species infect about 10% of the world's population; symptoms include abdominal pain, tenesmus, frequent loose stools containing blood and mucus, and abdominal tenderness. Colonoscopy reveals focal punctate ulcers with normal intervening mucosa; diagnosis is made by biopsy or serum amebic antibodies. Fulminant amebic colitis is rare but has a mortality rate of >50%.

Other parasitic infections that may mimic IBD include hookworm (*Necator americanus*), whipworm (*Trichuris trichiura*), and *Strongyloides stercoralis*. In severely immunocompromised patients *Candida* or *Aspergillus* can be identified in the submucosa. Disseminated histoplasmosis can involve the ileocecal area.

NONINFECTIOUS DISEASE Many diseases may mimic IBD (Table 276-4). Diverticulitis can be confused with CD clinically and radiographically. Both diseases cause fever, abdominal pain, tender abdominal mass, leukocytosis, elevated ESR, partial obstruction, and fistulas. Perianal disease or ileitis on small-bowel series favors the diagnosis of CD. Significant endoscopic mucosal abnormalities are more likely in CD than in diverticulitis. Endoscopic or clinical recurrence following segmental resection favors CD. Diverticular-associated colitis is similar to CD, but mucosal abnormalities are limited to the sigmoid and descending colon.

Ischemic colitis is commonly confused with IBD. The ischemic process can be chronic and diffuse as in UC, or segmental as in CD. Colonic inflammation due to ischemia may resolve quickly or may persist and result in transmural scarring and stricture formation. Ischemic bowel disease should be considered in the elderly following abdominal aortic aneurysm repair or when a patient has a hypercoagulable state or a severe cardiac or peripheral vascular disorder. Patients usually present with sudden onset of left lower quadrant pain, urgency to defecate, and the passage of bright red blood per rectum. Endoscopic examination often demonstrates a normal-appearing rectum and a sharp transition to an area of inflammation in the descending colon and splenic flexure.

The effects of radiation therapy on the gastrointestinal tract can be difficult to distinguish from IBD. Acute symptoms can occur within 1 to 2 weeks of starting radiotherapy. When the rectum and sigmoid are irradiated, patients develop bloody, mucoid diarrhea and tenesmus, as in distal UC. With small-bowel involvement, diarrhea is common. Late symptoms include malabsorption and weight loss. Stricturing with obstruction and bacterial overgrowth may occur. Fistulas can penetrate the bladder, vagina, or abdominal wall. Flexible sigmoidoscopy reveals mucosal granularity, friability, numerous telangiectasias, and occasionally discrete ulcerations. Biopsy can be diagnostic.

Solitary rectal ulcer syndrome is uncommon and can be confused with IBD. It occurs in persons of all ages and may be caused by impaired evacuation and failure of relaxation of the puborectalis muscle. Ulceration may arise from anal sphincter overactivity, higher intrarectal pressures during defecation, and digital removal of stool. Patients complain of constipation with straining and pass blood and mucus per rectum. Other symptoms include abdominal pain, diarrhea, tenesmus, and perineal pain. The ulceration, which can be as large as 5 cm in diameter, is usually seen anteriorly or anteriorlaterally 3 to 15 cm from the anal verge. Biopsies can be diagnostic.

Several types of colitis have been associated with nonsteroidal anti-inflammatory drugs (NSAIDs), including de novo colitis, reactivation of IBD, and proctitis caused by use of suppositories. Most patients with NSAID-related colitis present with diarrhea and abdominal pain and complications include stricture, bleeding, obstruction, perforation, and fistulization. Withdrawal of these agents is crucial, and in cases of reactivated IBD, standard therapies are indicated.

INDETERMINATE COLITIS Cases of IBD that cannot be categorized as UC or CD are called *indeterminate colitis*. Long-term follow-up reduces the number of cases labeled indeterminate to about 10%. The disease course of indeterminate colitis is unclear and surgical recommendations are difficult, especially since up to 20% of pouches fail, requiring ileosotomy. A multistage IPAA (the initial stage consisting of a subtotal colectomy with Hartmann pouch) with careful histologic evaluation of the resected specimen to exclude CD is advised. Medical therapy is similar to that for UC and CD; most clinicians use 5-ASA drugs, glucocorticoids, and immunomodulators as necessary.

THE ATYPICAL COLITIDIES Two atypical colitides—collagenous colitis and lymphocytic colitis—have completely normal endoscopic appearances. Collagenous colitis has two main histologic components: increased subepithelial collagen deposition and colitis with increased intraepithelial lymphocytes. Female to male ratio is 9:1, and most patients present in the sixth or seventh decades of life. The main symptom is chronic watery diarrhea. Treatments range from sulfasalazine or mesalamine and Lomotil to bismuth to glucocorticoids for refractory disease.

Lymphocytic colitis has features similar to collagenous colitis including age at onset and clinical presentation, but it has almost equal incidence in men and women and no subepithelial collagen deposition on pathologic section. However, intraepithelial lymphocytes are increased. Diarrhea stops in most patients treated with 5-ASA or prednisone.

Diversion colitis is an inflammatory process that arises in segments of the large intestine that are excluded from the fecal stream. It usually occurs in patients with ileostomy or colostomy when a mucus fistula or a Hartmann's pouch has been created. Diversion colitis is reversible by surgical reanastamosis. Clinically, patients have mucus or bloody discharge from the rectum. Erythema, granularity, friability, and, in more severe cases, ulceration can be seen on endoscopy. Histopathology shows areas of active inflammation with foci of cryptitis and crypt abscesses. Crypt architecture is normal and this differentiates it from UC. It may be impossible to distinguish it from CD. Short-chain fatty acid enemas will help in diversion colitis, but the definitive therapy is surgical reanastamosis.

EXTRAINTESTINAL MANIFESTATIONS

IBD is associated with a variety of extraintestinal manifestations; up to one-third of patients have at least one. Patients with perianal CD are at higher risk for developing extraintestinal manifestations than other IBD patients.

DERMATOLOGIC Erythema nodosum (EN) occurs in up to 15% of CD patients and 10% of UC patients. Attacks usually correlate with bowel activity; skin lesions develop after the onset of bowel symptoms, and patients frequently have concomitant active peripheral arthritis. The lesions of EN are hot, red, tender nodules measuring 1 to 5 cm in diameter and are found on the anterior surface of the lower legs, ankles, calves, thighs, and arms. Therapy is directed toward the underlying bowel disease.

Pyoderma gangrenosum (PG) is seen in 1 to 12% of UC patients and less commonly in Crohn's colitis. Although it usually presents after the diagnosis of IBD, PG may occur years before the onset of bowel symptoms, run a course independent of the bowel disease, respond poorly to colectomy, and even develop years after proctocolectomy. It is usually associated with severe disease. Lesions are commonly found on the dorsal surface of the feet and legs but may occur on the arms, chest, stoma, and even the face. PG usually begins as a pustule and then spreads concentrically to rapidly undermine healthy skin. Lesions then ulcerate, with violaceous edges surrounded

by a margin of erythema. Centrally, they contain necrotic tissue with blood and exudates. Lesions may be single or multiple and grow as large as 30 cm. They are sometimes very difficult to treat and often require intravenous antibiotics, intravenous glucocorticoids, dapsone, azathioprine, thalidomide, intravenous cyclosporine, or infliximab.

Other dermatologic manifestations include pyoderma vegetans that occurs in intertriginous areas, pyostomatitis vegetans that involves the mucous membranes, Sweet's syndrome, a neutrophilic dermatosis, and metastatic CD, a rare disorder defined by cutaneous granuloma formation. Psoriasis affects 5 to 10% of patients with IBD and is unrelated to bowel activity. Perianal skin tags are found in 75 to 80% of patients with CD, especially those with colon involvement. Oral mucosal lesions are seen often in CD and rarely in UC and include aphthous stomatitis and "cobblestone" lesions of the buccal mucosa.

RHEUMATOLOGIC Peripheral arthritis develops in 15 to 20% of IBD patients, is more common in CD, and worsens with exacerbations of bowel activity. It is asymmetric, polyarticular, and migratory and most often affects large joints of the upper and lower extremities. Treatment is directed at reducing bowel inflammation. In severe UC, colectomy frequently cures the arthritis.

Ankylosing spondylitis (AS) occurs in about 10% of IBD patients and is more common in CD than UC. About two-thirds of IBD patients with AS test positive for the HLA-B27 antigen. The activity of AS is not related to bowel activity and does not remit with glucocorticoids or colectomy. It most often affects the spine and pelvis, producing symptoms of diffuse low-back pain, buttock pain, and morning stiffness. The course is continuous and progressive, leading to permanent skeletal damage and deformity.

Sacroiliitis is symmetric, occurs equally in UC and CD, is often asymptomatic, does not correlate with bowel activity, and does not always progress to AS. Other rheumatic manifestations include hypertrophic osteoarthropathy, pelvic/femoral osteomyelitis, and relapsing polychondritis.

OCULAR The incidence of ocular complications in IBD patients is 1 to 10%. The most common are conjunctivitis, anterior uveitis/iritis, and episcleritis. Uveitis is associated with both UC and Crohn's colitis, may be found during periods of remission, and may develop in patients following bowel resection. Symptoms include ocular pain, photophobia, blurred vision, and headache. Prompt intervention, sometimes with systemic glucocorticoids, is required to prevent scarring and visual impairment. Episcleritis is a benign disorder that presents with symptoms of mild ocular burning. It occurs in 3 to 4% of IBD patients, more commonly in Crohn's colitis, and is treated with topical glucocorticoids.

HEPATOBILIARY Hepatic steatosis is detectable in about half of the abnormal liver biopsies from patients with CD and UC; patients usually present with hepatomegaly. Fatty liver usually results from a combination of chronic debilitating illness, malnutrition, and glucocorticoid therapy. Cholelithiasis is more common in CD than UC and occurs in 10 to 35% of patients with ileitis or ileal resection. Gallstone formation is caused by malabsorption of bile acids resulting in depletion of the bile salt pool and the secretion of lithogenic bile.

Primary sclerosing cholangitis (PSC) is characterized by both intrahepatic and extrahepatic bile duct inflammation and fibrosis, frequently leading to biliary cirrhosis and hepatic failure; 1 to 5% of patients with IBD have PSC, but 50 to 75% of patients with PSC have IBD. Although it can be recognized after the diagnosis of IBD, PSC can be detected earlier or even years after proctocolectomy. Most patients have no symptoms at the time of diagnosis; when symptoms are present they consist of fatigue, jaundice, abdominal pain, fever, anorexia, and malaise. Diagnosis is made by endoscopic retrograde cholangiopancreatography (ERCP), which demonstrates multiple bile duct strictures alternating with relatively normal segments. The bile acid ursodeoxycholic acid (ursodiol) may reduce alkaline phosphatase and serum aminotransferase levels, but histologic improvement has been marginal. High doses (25 to 30 mg/kg per day) may have long-term benefit. Endoscopic stenting may be palliative for cholestasis secondary to bile duct obstruction. Patients with symptomatic disease develop cirrhosis and liver failure over 5 to 10 years and eventually require liver transplantation. Ten percent of PSC patients develop cholangiocarcinoma and cannot be transplanted. Pericholangitis is a subset of PSC found in about 30% of IBD patients; it is confined to small bile ducts and is usually benign.

UROLOGIC The most frequent genitourinary complications are calculi, ureteral obstruction, and fistulas. The highest frequency of nephrolithiasis (10 to 20%) occurs in patients with CD following small-bowel resection. Calcium oxalate stones develop secondary to hyperoxaluria, which results from increased absorption of dietary oxalate. Normally, dietary calcium combines with luminal oxalate to form insoluble calcium oxalate, which is eliminated in the stool. In patients with ileal dysfunction, however, nonabsorbed fatty acids bind calcium and leave oxalate unbound. The unbound oxalate is then delivered to the colon, where it is readily absorbed, especially in the presence of colonic inflammation.

OTHER The risk of thromboembolic disease increases when IBD becomes active, and patients may present with deep vein thrombosis, pulmonary embolism, cerebrovascular accidents, and arterial emboli. Factors responsible for the hypercoagulable state include reactive thrombocytosis; increased levels of fibrinopeptide A, factor V, factor VIII, and fibrinogen; accelerated thromboplastin generation; antithrombin III deficiency secondary to increased gut losses or increased catabolism; and free protein S deficiency. A spectrum of vasculitidies involving small, medium, and large vessels has also been observed in IBD patients.

Patients with IBD have an increased prevalence of osteoporosis and osteomalacia from vitamin D deficiency, calcium malabsorption, malnutrition, glucocorticoid use, and the intestinal inflammation itself. Deficiencies of vitamin B_{12} and fat-soluble vitamins may occur after ileal resection or with ileal disease.

More common cardiopulmonary manifestations include endocarditis, myocarditis, pleuropericarditis, and interstitial lung disease. A secondary or reactive amyloidosis can occur in patients with longstanding IBD, especially in patients with CD. Amyloid material is deposited systemically and can cause diarrhea, constipation, and renal failure. The renal disease can be successfully treated with colchicine. Pancreatitis is a rare extraintestinal manifestation of IBD and results from duodenal fistulas, ampullary CD, gallstones, PSC, drugs such as 6-mercaptopurine, azathioprine, or very rarely, 5-ASA agents, autoimmune pancreatitis, and primary CD of the pancreas.

Rx TREATMENT

5-ASA AGENTS The mainstay of therapy for mild to moderate UC and Crohn's colitis is sulfasalazine and the other 5-ASA agents. These agents are effective at inducing remission in both UC and CD and in maintaining remission in UC; it remains unclear whether they have a role in remission maintenance in CD.

Sulfasalazine was originally developed to deliver both antibacterial (sulfapyridine) and anti-inflammatory (5-ASA) therapy into the connective tissues of joints and the colonic mucosa. The molecular structure provides a convenient delivery system to the colon by allowing the intact molecule to pass through the small intestine after only partial absorption, and to be broken down in the colon by bacterial azo reductases that cleave the azo bond linking the sulfa and 5-ASA moieties. Sulfasalazine is effective treatment for mild to moderate UC and Crohn's ileocolitis and colitis, but its high rate of side effects limits its use. Although sulfasalazine is more effective at higher doses, at 6 or 8 g/d up to 30% of patients experience allergic reactions or intolerable side effects such as headache, anorexia, nausea, and vomiting that are attributable to the sulfapyridine moiety. Hypersensitivity reactions, independent of sulfapyridine levels, include rash, fever, hepatitis, agranulocytosis, hypersensitivity pneumonitis, pancreatitis, worsening of colitis, and reversible sperm abnormalities. Sulfasalazine

can also impair folate absorption, and patients should be given folic acid supplements.

Newer sulfa-free aminosalicylate preparations deliver increased amounts of the pharmacologically active ingredient of sulfasalazine (5-ASA, mesalamine) to the site of active bowel disease while limiting systemic toxicity. 5-ASA may function through inhibition of NF-κB activity. Sulfa-free aminosalicylate formulations include alternative azo-bonded carriers, 5-ASA dimers, pH-dependent tablets, and continuous-release preparations. Each has the same efficacy as sulfasalazine when equimolar concentrations are used. Olsalazine is composed of two 5-ASA radicals linked by an azo bond, which is split in the colon by bacterial reduction and two 5-ASA molecules are released. Olsalazine is similar in effectiveness to sulfasalazine in treating CD and UC, but up to 17% of patients experience non-bloody diarrhea caused by increased secretion of fluid in the small bowel. Balsalazide contains an azo bond binding mesalamine to the carrier molecule 4-aminobenzoyl-β-alanine; it is effective in the colon. Claversal is an enteric-coated form of 5-ASA that consists of mesalamine surrounded by an acrylic-based polymer resin and a cellulose coating that releases mesalamine at pH $>$ 6.0, a level that is present from the mid-jejunum continuously to the distal colon.

TABLE 276-5 *Oral 5-ASA Preparations*

Preparation	Formulation	Delivery	Dosing, g/d
AZO-BOND			
Sulfasalazine (500 mg)	Sulfapyridine-5-ASA	Colon	4–8 (acute) 2–6 (maintenance)
Olsalazine (250 mg)	5-ASA-5-ASA	Colon	1–3
Balsalazide (500–750 mg)	Aminobenzoyl-alanine-5-ASA	Colon	2.25–6.75
DELAYED-RELEASE			
Asacol (400 mg)	Eudragit S (pH 7)	Distal ileum-colon	2.4–4.8 (acute) 1.6–4.8 (maintenance)
Claversal (250–500 mg)	Eudragit L (pH 6)	Ileum-colon	1.5–3 (acute) 0.75–3 (maintenance)
SUSTAINED-RELEASE			
Pentasa (250 mg)	Ethylcellulose microgranules	Stomach-colon	2–4 (acute) 1.5–4 (maintenance)

The most commonly used drugs besides sulfasalazine in the United States are Asacol and Pentasa. Asacol is also an enteric-coated form of mesalamine, but it has a slightly different release pattern, with 5-ASA liberated at pH $>$ 7.0. The disintegration of Asacol is variable, with complete breakup of the tablet occurring in many different parts of the gut ranging from the small intestine to the splenic flexure; it has increased gastric residence when taken with a meal. Asacol is used to induce and maintain remission in UC and to induce remission in CD ileitis, ileocolitis, and colitis. Appropriate doses of Asacol and the other 5-ASA compounds are shown in Table 276-5. Some 50 to 75% of patients with mild to moderate UC and CD improve when treated with 2 g/d of 5-ASA; the dose response continues up to at least 4.8 g/d. Doses of 1.5 to 4 g/d maintain remission in 50 to 75% of patients with UC.

Pentasa is another mesalamine formulation that uses an ethylcellulose coating to allow water absorption into small beads containing the mesalamine. Water dissolves the 5-ASA, which then diffuses out of the bead into the lumen. Disintegration of the capsule occurs in the stomach. The microspheres then disperse throughout the entire gastrointestinal tract from the small intestine through the distal colon in both fasted or fed conditions. Controlled trials of Pentasa and Asacol in active CD demonstrate a 40 to 60% clinical improvement or remission, but the data are not conclusive that these agents maintain remission in CD. 5-ASA agents may be effective in postoperative prophylaxis of CD.

Topical mesalamine enemas are effective in mild-to-moderate distal UC and CD. Clinical response occurs in up to 80% of UC patients with colitis distal to the splenic flexure. Mesalamine suppositories are effective in treating proctitis.

Glucocorticoids The majority of patients with moderate to severe UC benefit from oral or parenteral glucocorticoids. Prednisone is usually started at doses of 40 to 60 mg/d for active UC that is unresponsive to 5-ASA therapy. Parenteral glucocorticoids may be administered as intravenous hydrocortisone, 300 mg/d, or methylprednisolone, 40 to 60 mg/d. Adrenocorticotropic hormone (ACTH) is occasionally preferred for glucocorticoid-naïve patients despite a risk of adrenal hemorrhage. ACTH has equivalent efficacy to intravenous hydrocortisone in both glucocorticoid-naïve and -experienced CD patients.

Topically applied glucocorticoids are also beneficial for distal colitis and may serve as an adjunct in those who have rectal involvement plus more proximal disease. Hydrocortisone enemas or foam may control active disease, although they have no proven role as maintenance therapy. These glucocorticoids are significantly absorbed from the rectum and can lead to adrenal suppression with prolonged administration.

Glucocorticoids are also effective for treatment of moderate-to-severe CD and induce a 60 to 70% remission rate compared to a 30% placebo response. The systemic effects of standard glucocorticoid formulations have led to the development of more potent formulations that are less well absorbed and have increased first-pass metabolism. Controlled ileal-release budesonide has been nearly equal to prednisone for ileocolonic CD with fewer glucocorticoid side effects. Budesonide is used for 2 to 3 months at a dose of 9 mg/d, then tapered.

Glucocorticoids play no role in maintenance therapy in either UC or CD. Once clinical remission has been induced, they should be tapered according to the clinical activity, normally at a rate of no more than 5 mg per week. They can usually be tapered to 20 mg/d within 4 to 5 weeks but often take several months to be discontinued altogether. The side effects are numerous, including fluid retention, abdominal striae, fat redistribution, hyperglycemia, subcapsular cataracts, osteonecrosis, myopathy, emotional disturbances, and withdrawal symptoms. Most of these side effects, aside from osteonecrosis, are related to the dose and duration of therapy.

ANTIBIOTICS Antibiotics have no role in the treatment of active or quiescent UC. However, pouchitis, which occurs in about a third of UC patients after colectomy and IPAA, usually responds to treatment with metronidazole or ciprofloxacin.

Metronidazole is effective in active inflammatory, fistulous, and perianal CD and may prevent recurrence after ileal resection. The most effective dose is 15 to 20 mg/kg per day in three divided doses; it is usually continued for several months. Common side effects include nausea, metallic taste, and disulfiram-like reaction. Peripheral neuropathy can occur with prolonged administration (several months) and on rare occasions is permanent despite discontinuation. Ciprofloxacin (500 mg bid) is also beneficial for inflammatory, perianal, and fistulous CD. These two antibiotics should be used as second-line drugs in active CD after 5-ASA agents and as first-line drugs in perianal and fistulous CD.

AZATHIOPRINE AND 6-MERCAPTOPURINE Azathioprine and 6-mercaptopurine (6-MP) are purine analogues commonly employed in the management of glucocorticoid-dependent IBD. Azathioprine is rapidly absorbed and converted to 6-MP, which is then metabolized to the active end product, thioinosinic acid, an inhibitor of purine ribonucleotide synthesis and cell proliferation. These agents also inhibit the immune response. Efficacy is seen at 3 to 4 weeks. Compliance can

TABLE 276-6 *Medical Management of IBD*

Ulcerative Colitis: Active Disease

	Mild	*Moderate*	*Severe*	*Fulminant*

Crohn's Disease: Maintenance Therapy

Inflammatory	*Perianal or Fistulizing Disease*
5-ASA oral and/or enema Azathioprine or 6-MP Infliximab	Metronidazole and/or ciprofloxacin Azathioprine or 6-MP Infliximab

Note: CSA, cyclosporine; 6-MP, 6-mercaptopurine; TPN, total parenteral nutrition.

be monitored by measuring the levels of 6-thioguanine and 6-methylmercaptopurine, end products of 6-MP metabolism. Azathioprine (2.0 to 2.5 mg/kg per day) or 6-MP (1.0 to 1.5 mg/kg per day) have been employed successfully as glucocorticoid-sparing agents in up to two-thirds of UC and CD patients previously unable to be weaned from glucocorticoids. The role of these immunomodulators as maintenance therapy in UC and CD and for treating active perianal disease and fistulas in CD appears promising. In addition, 6-MP or azathioprine may be effective for postoperative prophylaxis of CD.

Although azathioprine and 6-MP are usually well tolerated, pancreatitis occurs in 3 to 4% of patients, typically presents within the first few weeks of therapy, and is completely reversible when the drug is stopped. Other side effects include nausea, fever, rash, and hepatitis. Bone marrow suppression (particularly leukopenia) is dose-related and often delayed, necessitating regular monitoring of the complete blood count. Additionally, 1 in 300 individuals lacks thiopurine methyltransferase, the enzyme responsible for drug metabolism; an additional 11% of the population are heterozygotes with intermediate enzyme activity. Both are at increased risk of toxicity because of increased accumulation of thioguanine metabolites. No increased risk of cancer has been documented in IBD patients chronically taking these medications.

METHOTREXATE Methotrexate (MTX) inhibits dihydrofolate reductase, resulting in impaired DNA synthesis. Additional anti-inflammatory properties may be related to decreased IL-1 production. Intramuscular or subcutaneous MTX (25 mg per week) is effective in inducing remission and reducing glucocorticoid dosage, and 15 mg per week is effective in maintaining remission in active CD. Potential toxicities include leukopenia and hepatic fibrosis, necessitating periodic evaluation of complete blood counts and liver enzymes. The role of liver biopsy in patients on long-term MTX is uncertain. Hypersensitivity pneumonitis is a rare but serious complication of therapy.

CYCLOSPORINE Cyclosporine (CSA) alters the immune response by acting as a potent inhibitor of T cell–mediated responses. Although CSA acts primarily via inhibition of IL-2 production from T helper cells, it also decreases recruitment of cytotoxic T cells and blocks other cytokines, including IL-3, IL-4, IFN-γ, and TNF. It has a more rapid onset of action than 6-MP and azathioprine.

CSA is most effective given at 2 to 4 mg/kg per day intravenously in severe UC that is refractory to intravenous glucocorticoids, with 82% of patients responding. CSA can be an alternative to colectomy. The long-term success of oral CSA is not as dramatic, but if patients are started on 6-MP or azathioprine at the time of hospital discharge, remission can be maintained. Intravenous CSA is effective in 80% of patients with refractory fistulas, but 6-MP or azathioprine must be used to maintain remission. Oral CSA alone is effective only at a higher dose (7.5 mg/kg per day) in active disease but is not effective in maintaining remission without 6-MP/azathioprine. Serum levels should be monitored and kept in the range of 200 to 400 ng/mL.

CSA may cause significant toxicity; renal function should be monitored frequently. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, and electrolyte abnormalities are common side effects. Creatinine elevation calls for dose reduction or discontinuation. Seizures may also complicate therapy, especially if the patient is hypomagnesemic or if serum cholesterol levels are $<$3.1 mmol/L ($<$120 mg/dL). Opportunistic infections, most notably *Pneumocystis carinii* pneumonia, may occur with combination immunosuppressive treatment; prophylaxis should be given.

NUTRITIONAL THERAPIES Dietary antigens may stimulate the mucosal immune response. Patients with active CD respond to bowel rest, along with total enteral or total parenteral nutrition (TPN). Bowel rest and TPN are as effective as glucocorticoids at inducing remission of active CD but are not effective as maintenance therapy. Enteral nutrition in the form of elemental or peptide-based preparations are also as effective as glucocorticiods or TPN, but these diets are not palatable. Enteral diets may provide the small intestine with nutrients vital to cell growth and do not have the complications of TPN. In contrast to CD, active UC is not effectively treated with either elemental diets or TPN. Standard medical management of UC and CD is reviewed in Table 276-6.

NEWER MEDICAL THERAPIES ■ Anti-Tumor Necrosis Factor Antibody TNF is a key inflammatory cytokine and mediator of intestinal inflammation. The expression of TNF is increased in IBD. Infliximab is a chimeric mouse-human monoclonal antibody against TNF that is extremely ef-

fective in CD. It blocks TNF in the serum and at the cell surface and likely lyses TNF-producing macrophages and T cells through complement fixation and antibody-dependent cytotoxicity. Of active CD patients refractory to glucocorticoids, 6-MP, or 5-ASA, 65% will respond to intravenous infliximab (5 mg/kg); one-third will enter complete remission. Of the patients who experience an initial response, 40% will maintain remission for at least 1 year with repeated infusions of infliximab every 8 weeks.

Infliximab is also effective in CD patients with refractory perianal and enterocutaneous fistulas, with a 68% response rate (50% reduction in fistula drainage) and a 50% complete remission rate. Reinfusion, typically every 8 weeks, is necessary to continue therapeutic benefits in many patients.

The development of antibodies to infliximab (ATI) is associated with an increased risk of infusion reactions and a decreased response to treatment. Patients who receive on-demand or episodic infusions rather than periodic (every 8 weeks) infusions are more likely to develop ATI. A humanized antibody to TNF also shows some promise in early clinical testing.

Among 120,000 patients treated with infliximab, 8 developed lymphoma: 5 patients with CD and 3 with rheumatoid arthritis. As the risk of lymphoma is already increased in these conditions, it is unclear whether infliximab is the cause. Thus, infliximab is extremely effective in refractory inflammatory and fistulous CD but should be used only when necessary. Results on the efficacy of infliximab in UC are mixed.

Newer Immunosuppressive Agents Tacrolimus has a mechanism of action similar to cyclosporine. It has shown efficacy in children with refractory IBD and in adults with extensive involvement of the small bowel.

Mycophenolate mofetil is another immunomodulator that may be effective in CD patients resistant to or intolerant of 6-MP azathioprine. Patients with CD who received 15 mg/kg per day have tolerated the drug well and have experienced benefit with reduction of glucocorticoid requirements.

6-Thioguanine is the active metabolite of 6-MP and has shown activity in patients resistant to or intolerant of 6-MP/azathioprine.

Thalidomide has been shown to inhibit TNF production by monocytes and other cells. Thalidomide is effective in glucocorticoid-refractory and fistulous CD, but randomized controlled trials still need to be performed.

The α4 integrin-specific humanized monoclonal antibody, natalizumab, prevents the migration of leukocytes into the parenchyma and blocks their activation in inflammatory sites. It seems to be effective in CD, but more trials are needed.

SURGICAL THERAPY ■ Ulcerative Colitis Nearly half of patients with extensive chronic UC undergo surgery within the first 10 years of their illness. The indications for surgery are listed in Table 276-7. Morbidity is about 20% in elective, 30% for urgent, and 40% for emergency proctocolectomy. The risks are primarily hemorrhage, contamination and sepsis, and neural injury. Although single-stage total proctocolectomy with ileostomy has been the operation of choice, newer operations maintain continence while surgically removing the involved rectal mucosa.

TABLE 276-7 Indications for Surgery

Ulcerative Colitis	Crohn's Disease
Intractable disease	CD of Small Intestine
Fulminant disease	Stricture and obstruction unresponsive to medical therapy
Toxic megacolon	Massive hemorrhage
Colonic perforation	Refractory fistula
Massive colonic hemorrhage	Abscess
Extracolonic disease	CD of Colon and Rectum
Colonic obstruction	Intractable disease
Colon cancer prophylaxis	Fulminant disease
Colon dysplasia or cancer	Perianal disease unresponsive to medical therapy
	Refractory fistula
	Colonic obstruction
	Cancer prophylaxis
	Colon dysplasia or cancer

The IPAA is the most frequent continence-preserving operation performed. Because UC is a mucosal disease, the rectal mucosa can be dissected out and removed down to the dentate line of the anus or about 2 cm proximal to it. The ileum is fashioned into a pouch that serves as a neorectum. This ileal pouch is then sutured circumferentially to the anus in an end-to-end fashion. If performed carefully, this operation preserves the anal sphincter and maintains continence. The overall operative morbidity is 10%, with the major complication being bowel obstruction. Pouch failure necessitating conversion to permanent ileostomy occurs in 5 to 10% of patients. Some inflamed rectal mucosa is usually left behind, and thus endoscopic surveillance is necessary. Primary dysplasia of the ileal mucosa of the pouch has occurred rarely.

Patients with IPAAs usually have about six to eight bowel movements a day. On validated quality-of-life indices, they report better performance in sports and sexual activities than ileostomy patients. The most frequent late complication of IPAA is pouchitis in about one-third of patients with UC. This syndrome consists of increased stool frequency, watery stools, cramping, urgency, nocturnal leakage of stool, arthralgias, malaise, and fever. Pouch biopsies and pANCA/ASCA/OMPC serologies can distinguish true pouchitis from underlying CD. Although it usually responds to antibiotics, in 3 to 5% of patients it is refractory and requires pouch take-down.

Crohn's Disease Most patients with CD require at least one operation in their lifetime. The need for surgery is related to duration of disease and the site of involvement. Patients with small-bowel disease have an 80% chance of requiring surgery. Those with colitis alone have a 50% chance. The indications for surgery are shown in Table 276-7.

SMALL INTESTINAL DISEASE Because CD is chronic and recurrent with no clear surgical cure, as little intestine as possible is resected. Current surgical alternatives for treatment of obstructing CD include resection of the diseased segment and strictureplasty. Surgical resection of the diseased segment is the most frequently performed operation, and in most cases primary anastomosis can be done to restore continuity. If much of the small bowel has already been resected and the strictures are short with intervening areas of normal mucosa, strictureplasties should be done to avoid a functionally insufficient length of bowel. The strictured area of intestine is incised longitudinally and the incision sutured transversely, thus widening the narrowed area. Complications of strictureplasty include prolonged ileus, hemorrhage, fistula, abscess, leak, and restricture.

COLORECTAL DISEASE A greater percentage of patients with Crohn's colitis require surgery for intractability, fulminant disease, and anorectal disease. Several alternatives are available, ranging from the use of a temporary loop ileostomy to resection of segments of diseased colon or even the entire colon and rectum. For patients with segmental involvement, segmental colon resection with primary anastomosis can be performed. In 20 to 25% of patients with extensive colitis, the rectum is spared sufficiently to consider rectal preservation. Most surgeons believe that an IPAA is contraindicated in CD due to the high incidence of pouch failure. A diverting colostomy may help heal severe perianal disease or rectovaginal fistulas, but disease almost always recurs with reanastomosis. Often, these patients require a total proctocolectomy and ileostomy.

INFLAMMATORY BOWEL DISEASE AND PREGNANCY

Patients with quiescent UC and CD have normal fertility rates; the fallopian tubes can be scarred by the inflammatory process of CD, especially on the right side because of the proximity of the terminal ileum. In addition, perirectal, perineal, and rectovaginal abscesses and fistulae can result in dyspareunia. Infertility in men can be caused by sulfasalazine but reverses when treatment is stopped.

In mild or quiescent UC and CD, fetal outcome is nearly normal. Spontaneous abortions, stillbirths, and developmental defects are increased with increased disease activity, not medications. The courses of CD and UC during pregnancy mostly correlate with disease activity at the time of conception. Patients should be in remission for 6 months before conceiving. Most CD patients can deliver vaginally, but cesarean section may be the preferred route of delivery for patients with anorectal and perirectal abscesses and fistulas to reduce the likelihood of fistulas developing or extending into the episiotomy scar.

Sulfasalazine, mesalamine, and balsalazide are safe for use in pregnancy and nursing, but folate supplementation must be given with sulfasalazine. Topical 5-ASA agents are also safe during pregnancy and nursing. Glucocorticoids are generally safe for use during pregnancy and are indicated for patients with moderate to severe disease activity. The amount of glucocorticoids received by the nursing infant is minimal. The safest antibiotics to use for CD in pregnancy for short periods of time (weeks, not months) are ampicillin, cephalosporin, or flagyl. Ciprofloxacin causes cartilage lesions in immature animals and should be avoided because of the absence of data on its effects on growth and development in humans.

6-MP and azathioprine pose minimal or no risk during pregnancy, but experience is limited. If the patient cannot be weaned from the drug or has an exacerbation that requires 6-MP/azathioprine during pregnancy, she should continue the drug with informed consent. Their effects during nursing are unknown.

Little data exist on cyclosporine in pregnancy. In a small number of patients with severe IBD treated with intravenous cyclosporine during pregnancy, 80% of pregnancies were successfully completed without development of renal toxicity, congenital malformations, or developmental defects. However, because of the lack of data, cyclosporine should probably be avoided unless the patient would otherwise require surgery. Methotrexate is contraindicated in pregnancy and nursing. Based on 35 reported pregnancies, infliximab does not appear to present a risk to the mother or baby.

Surgery in UC should be performed only for emergency indications, including severe hemorrhage, perforation, and megacolon refractory to medical therapy. Total colectomy and ileostomy carry a 60% risk of postoperative spontaneous abortion. Fetal mortality is also high in CD requiring surgery. Patients with IPAAs have increased nighttime stool frequency during pregnancy that resolves post-partum. Transient small-bowel obstruction or ileus has been noted in up to 8% of patients with ileostomies.

INFLAMMATORY BOWEL DISEASE IN THE ELDERLY

The most common presenting symptoms in the elderly are diarrhea, weight loss, and abdominal pain. CD in the elderly mostly affects the colon with a distal distribution and occurs predominantly in women. Proctitis has been documented in 50% of elderly patients, and the diagnosis is often delayed. Diseases that can mimic CD in the elderly are ischemic colitis, diverticular disease, irritable bowel, infectious colitides, and malignancies, including carcinoma, lymphoma, and carcinoid. The incidence of surgery is high in elderly patients, with up to 50% of patients with ileitis, ileocolitis, or extensive colitis requiring urgent or early surgery for first-time disease. In addition, surgery has a much higher morbidity than in younger patients, although the rate of postoperative recurrence is less. Most elderly patients respond as well as younger individuals to medical management.

UC in the elderly is more common in men, presents usually with diarrhea and weight loss, and may have a more distal distribution than in younger patients. Most elderly patients have a favorable response to medical therapy, especially 5-ASA agents, and immunosuppressives used in conjunction with low doses of glucocorticoids. Cyclosporine has been used more frequently in the elderly, but the age-related decreases in renal clearance may affect dosing. Glucocorticoid complications such as osteoporosis and hyperglycemia are also increased in the elderly. 6-MP and azathioprine are well tolerated in the elderly. Surgery also has a higher morbidity and mortality in UC, and elderly patients have a longer hospital stay than younger patients. The risk of colon cancer in UC and Crohn's colitis is no greater than that in the general population since the duration of disease is short and the extent of disease is often distal.

CANCER IN INFLAMMATORY BOWEL DISEASE

ULCERATIVE COLITIS Patients with long-standing UC are at increased risk for developing colonic epithelial dysplasia and carcinoma (Fig. 276-8). Several features distinguish sporadic colon cancer (SCC) and colitis-associated colon cancer (CAC). First, SCCs usually arise from an adenomatous polyp; CACs typically arise from either flat dysplasia or a dysplasia-associated lesion or mass (DALM). Second, multiple synchronous colon cancers occur in 3 to 5% of SCC but in 12% of CAC. Third, the mean age of individuals with SCC is in the sixties; the mean age of those with CAC is in the thirties. Fourth, SCC exhibits a left-sided predominance, whereas CAC is distributed more uniformly throughout the colon. Fifth, mucinous and anaplastic cancers are more common in CAC than SCC. At the molecular level, p53 mutations occur much earlier and *APC* gene mutations much later in CAC than in SCC.

The risk of neoplasia in chronic UC increases with duration and extent of disease. For patients with pancolitis, the risk of cancer rises 0.5 to 1% per year after 8 to 10 years of disease. This observed increase in cancer rates has led to the endorsement of surveillance colonoscopy with biopsies for patients with chronic UC as the standard of care. Annual or biennial colonoscopy with multiple biopsies has been advocated for patients with >8 to 10 years of pancolitis or 12 to 15 years of left-sided colitis and has been widely employed to screen and survey for subsequent dysplasia and carcinoma.

CROHN'S DISEASE Risk factors for developing colorectal cancer in CD are a history of colonic (or ileocolonic) involvement and long disease duration. The cancer risks in CD and UC are probably equivalent for similar extent and duration of disease. In patients with extensive

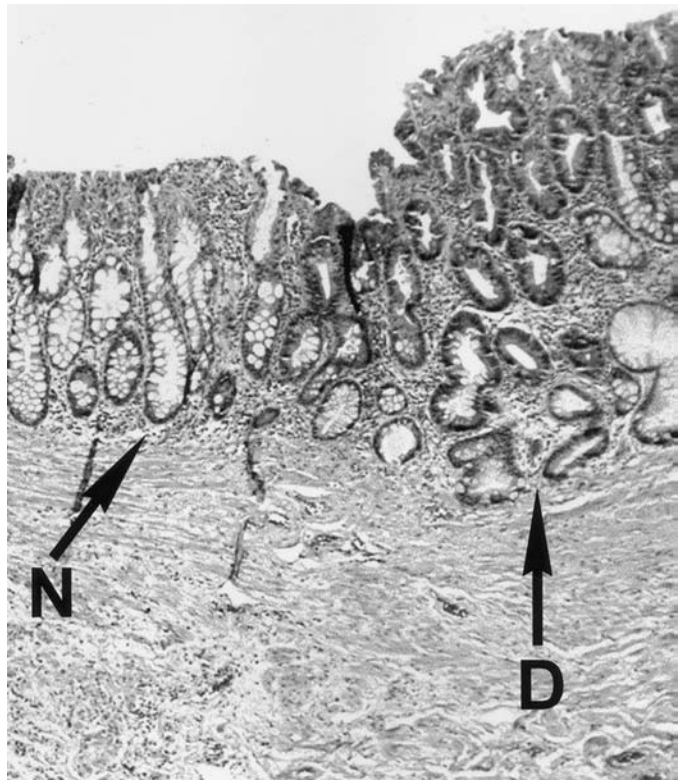

FIGURE 276-8 Low-power transition between dysplasia (D) and nondysplastic (N) mucosa in a case of ulcerative colitis. *(Courtesy of Dr. EK Rosado and Dr. CA Perkos, Division of Gastrointestinal Pathology, Department of Pathology, Emory University, Atlanta, Georgia.)*

Crohn's colitis, 22% developed dysplasia or cancer by the fourth surveillance exam after a negative screening colonoscopy. Thus, the same endoscopic surveillance strategy used for UC is recommended for patients with chronic Crohn's colitis. A pediatric colonoscope can be used to pass narrow strictures in CD patients, but surgery should be considered in symptomatic patients with impassable strictures.

MANAGEMENT OF DYSPLASIA AND CANCER Dysplasia can be flat or polypoid. If flat high-grade dysplasia (HGD) is encountered on colonoscopic surveillance, the usual treatment for UC is colectomy and for CD is either colectomy or segmental resection. If flat low-grade dysplasia (LGD) is found, most investigators recommend immediate colectomy. Adenomas may occur coincidently in UC and CD patients with chronic colitis and can be removed endoscopically provided that biopsies of the surrounding mucosa are free of dysplasia.

IBD patients are also at greater risk for other malignancies. Patients with CD may have an increased risk of developing non-Hodgkin's lymphoma and squamous cell carcinoma of the skin. Although CD patients have a twelvefold increased risk of developing small-bowel cancer, this type of carcinoma is extremely rare.

QUALITY OF LIFE IN INFLAMMATORY BOWEL DISEASE

The assessment of health-related quality of life plays an important role in the evaluation and treatment of IBD patients. Although clinical trials have generally relied upon traditional disease activity indices such as the Crohn's Disease Activity Index (CDAI) to measure therapeutic efficacy, these measures do not reflect quality of life. The Inflammatory Bowel Disease Questionnaire (IBDQ) is a validated, disease-specific instrument that has been used to measure quality of life. It is a 32-item questionnaire that measures global function, systemic and bowel symptoms, functional and social impairment, and emotional function. When compared to the general population, IBD patients have an impaired quality of life in all six categories. The most frequent concerns of UC patients are having an ostomy bag, developing cancer, effects of medication, the uncertain nature of the disease, and having surgery. The most frequent concerns of CD patients are the uncertain nature of the disease, energy level, effects of medication, having surgery, and having an ostomy bag.

277 IRRITABLE BOWEL SYNDROME

Chung Owyang

Irritable bowel syndrome (IBS) is a gastrointestinal (GI) disorder characterized by altered bowel habits and abdominal pain in the absence of detectable structural abnormalities. No clear diagnostic markers exist for IBS, thus all definitions of the disease are based on the clinical presentation. The Rome II criteria for the diagnosis of IBS are summarized in Table 277-1. It is one of the most common conditions encountered in clinical practice but one of the least well understood. Until recently, many physicians did not consider IBS to be a disease at all; they viewed it as nothing more than a somatic manifestation of psychological stress. With the availability of better techniques to study colonic and GI motility and visceral sensory function, along with the development of newer concepts on the importance of the brain in regulating gut function, significant progress has been made toward a better understanding of the pathogenesis of IBS. This may result in improved methods of treatment.

CLINICAL FEATURES IBS is a disorder of the young, with most new patients presenting before age 45. However, some reports suggest that the elderly are troubled by IBS symptoms up to 92% as often as middle-aged persons. Indeed, many of the diagnoses of "painful diverticular disease" given to elderly patients may represent IBS. Women are diagnosed with IBS two to three times as often as men. Moreover, women make up 80% of the population with severe IBS. Patients with IBS fall into two broad clinical groups. Most commonly, patients have abdominal pain associated with altered bowel habits that consist of constipation, diarrhea, or both. In the second group, patients have painless diarrhea. This symptom in this group, who account for <20% of patients with IBS, may be caused by a separate entity. In fact, painless diarrhea does not strictly fulfill the Rome II criteria to be classified as IBS.

TABLE 277-1 *Rome II Criteria for the Diagnosis of IBS*

At least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two of following three features:
1. Relieved by defecation
2. Onset associated with changes in stool frequency
3. Onset associated with changes in stool form

Abdominal Pain According to the Rome II criteria, abdominal pain or discomfort is a prerequisite clinical feature of IBS. Abdominal pain in IBS is highly variable in intensity and location; it is localized to the hypogastrium in 25%, the right side in 20%, to the left side in 20%, and the epigastrium in 10% of patients. It is frequently episodic and crampy, but it may be superimposed on a background of constant ache. Pain may be mild enough to be ignored or it may interfere with daily activities. Despite this, malnutrition due to inadequate caloric intake is exceedingly rare with IBS. Sleep deprivation is also unusual because abdominal pain is almost uniformly present only during waking hours. However, patients with severe IBS often wake repeatedly during the night, and, hence, nocturnal pain is a poor discriminating factor between organic and functional bowel disease. Pain is often exacerbated by eating or emotional stress and relieved by passage of flatus or stools. Female patients with IBS commonly report worsening symptoms during the premenstrual and menstrual phases.

Altered Bowel Habits Alteration in bowel habits is the most consistent clinical feature in IBS. It usually begins in adult life. The most common pattern is constipation alternating with diarrhea, usually with one of these symptoms predominating. At first, constipation may be episodic, but eventually it becomes continuous and increasingly intractable to treatment with laxatives. Stools are usually hard with narrowed caliber, possibly reflecting excessive dehydration caused by prolonged colonic retention and spasm. Most patients also experience a sense of incomplete evacuation, leading to repeated attempts at defecation in a short time span. Patients whose predominant symptom is constipation may have weeks or months of constipation interrupted with brief periods of diarrhea. In other patients, diarrhea may be the predominant symptom. Diarrhea resulting from IBS usually consists of small volumes of loose stools. Most patients have stool volumes of <200 mL.

Nocturnal diarrhea does not occur in IBS. Diarrhea may be aggravated by emotional stress or eating. Stool may be accompanied by passage of large amounts of mucus; hence, the term *mucous colitis* has been used to describe IBS. This is a misnomer, since inflammation is not present. Bleeding is not a feature of IBS unless hemorrhoids are present, and malabsorption or weight loss does not occur.

Gas and Flatulence Patients with IBS frequently complain of abdominal distention and increased belching or flatulence, all of which they attribute to increased gas. Although some patients with these symptoms actually may have a larger amount of gas, quantitative measurements reveal that most patients who complain of increased gas generate no more than a normal amount of intestinal gas. Studies have shown that most IBS patients have impaired transit and tolerance of intestinal gas loads. In addition, patients with IBS tend to reflux gas from the distal to the more proximal intestine, which may explain the belching.

Upper Gastrointestinal Symptoms Between 25 and 50% of patients with IBS complain of dyspepsia, heartburn, nausea, and vomiting. This suggests that other areas of the gut apart from the colon may be involved. Prolonged ambulant recordings of small-bowel motility in patients with IBS show a high incidence of abnormalities in the small bowel during the diurnal (waking) period; nocturnal motor patterns are no different from those of healthy controls. A great deal of overlap is seen between dyspepsia and IBS. The prevalence of IBS is higher among individuals with dyspepsia (31.7%) than among those who report no symptoms of dyspepsia (7.9%). Conversely among those with IBS, 55.6% report symptoms of dyspepsia. In addition, the functional abdominal symptoms can change over time. Those with predominant dyspepsia or IBS can fluctuate between the two. Thus, functional dyspepsia and IBS may be two manifestations of a single, more extensive digestive system disorder. Furthermore, IBS symptoms are prevalent in noncardiac chest pain patients, suggesting overlap with other functional gut disorders.

PATHOPHYSIOLOGY The pathogenesis of IBS is poorly understood, although roles for abnormal gut motor and sensory activity, central neural dysfunction, psychological disturbances, stress, and luminal factors have been proposed.

Studies of colonic myoelectrical and motor activity under unstimulated conditions have not shown consistent abnormalities in IBS. In contrast, colonic motor abnormalities are more prominent under stimulated conditions in IBS. IBS patients may exhibit increased rectosigmoid motor activity for up to 3 h after eating. Provocative stimuli also induce exaggerated colonic motor responses in IBS patients compared with healthy volunteers. For example, inflation of rectal balloons both in diarrhea- and constipation-predominant IBS patients leads to marked distention-evoked contractile activity, which may be prolonged. Recording from the transverse, descending, and sigmoid colon shows that the motility index and peak amplitude of high-amplitude propagating contractions in diarrhea-prone IBS patients are greatly increased compared to healthy subjects. These contractions are associated with rapid colonic transit and accompanied by abdominal pain.

As with studies of motor activity, IBS patients frequently exhibit exaggerated sensory responses to visceral stimulation. Postprandial pain has been temporally related to the entry of the food bolus into the cecum in 74% of patients. Exaggerated symptoms can be induced by visceral distention in IBS patients. Rectal balloon inflation produces nonpainful and painful sensations at lower volumes in IBS patients than in healthy controls without altering rectal tension, suggestive of visceral afferent dysfunction in IBS. The visceral hyperalgesia of IBS appears to be selective for mechanoreceptor-activated stimuli, as perception of intestinal mucosal electrical stimulation is normal in IBS. Similar studies show gastric and esophageal hypersensitivity in patients with nonulcer dyspepsia and noncardiac chest pain, raising the possibility that these conditions have a similar pathophysiologic basis. Lipids lower the thresholds for the first sensation of gas, discomfort, and pain in IBS patients. Furthermore, IBS patients have an increased area of referred pain after lipid ingestion that is not observed in healthy subjects. Hence, postprandial symptoms in IBS patients may be explained in part by a nutrient-dependent exaggerated sensory component of the gastrocolonic response. In contrast to enhanced gut sensitivity, IBS patients do not exhibit heightened sensitivity elsewhere in the body. Thus the afferent pathway disturbances in IBS appear to be selective for visceral innervation, with sparing of somatic pathways. The mechanisms responsible for visceral hypersensitivity are still under investigation. These exaggerated responses may be due to (1) increased end-organ sensitivity with recruitment of "silent" nociceptors, (2) spinal hyperexcitability with activation of nitric oxide and possibly other neurotransmitters, (3) endogenous (cortical and brainstem) modulation of caudad nociceptive transmission, and (4) over time, the possible development of long-term hyperalgesia due to development of neuroplasticity, resulting in permanent or semipermanent changes in neural responses to chronic or recurrent visceral stimulation (Table 277-2).

The role of central nervous system (CNS) factors in the pathogenesis of IBS is strongly suggested by the clinical association of emotional disorders and stress with symptom exacerbation and the therapeutic response to therapies that act on cerebral cortical sites. Positron emission tomography has been employed to quantify regional cerebral blood flow in IBS. In healthy individuals, rectal distention increases blood flow in the anterior cingulate cortex, a region with an abundance of opiate receptors, which, when activated, may help to reduce sensory input. In contrast, IBS patients exhibit no increased blood flow in the anterior cingulate gyrus but show activation of the prefrontal cortex, either in response to rectal activation or in anticipation of rectal distention. Activation of the frontal lobes may activate a vigilance network within the brain that increases alertness. The anterior cingulate cortex and the prefrontal cortex appear to have reciprocal inhibitory associations. Thus, in patients with IBS, the preferential activation of the prefrontal lobe, without activation of the anterior cingulate cortex, may represent a form of cerebral dysfunction leading to the increased perception of visceral pain.

Abnormal psychiatric features are recorded in up to 80% of IBS patients, especially in referral centers; however, no single psychiatric diagnosis predominates. Most of these patients demonstrate exaggerated symptoms in response to visceral distention, and this abnormality persists even after exclusion of psychological factors. Psychological factors also influence pain thresholds in IBS patients; stress alters sensory thresholds. An association between prior sexual or physical abuse and development of IBS has been reported. Forms of sexual abuse associated with IBS include verbal aggression, exhibitionism, sexual harassment, sexual touching, and rape. The pathophysiologic relationship between IBS and sexual or physical abuse is unknown. Sexual abuse is not associated with a lower pain threshold in IBS patients.

Thus, patients with IBS frequently demonstrate increased motor reactivity of the colon and small bowel to a variety of stimuli and altered visceral sensation associated with lowered sensation thresholds. These may result from CNS or enteric nervous system dysregulation.

IBS may be induced by gastrointestinal infection. In an investigation of 544 patients with confirmed bacterial gastroenteritis, one-quarter subsequently developed IBS. Conversely, about a third of IBS patients experienced an acute "gastroenteritis-like" illness at the onset of their chronic IBS symptomatology. This "postinfective" IBS occurs more commonly in women and affects younger, rather than older, patients and those who have a protracted acute diarrheal illness. The

TABLE 277-2 Proposed Mechanisms for Visceral Hypersensitivity

microbes involved in the initial infection are *Campylobacter*, *Salmonella*, and *Shigella*. Those patients infected with *Campylobacter* who are toxin-positive are more likely to develop postinfective IBS. Increased rectal mucosal enteroendocrine cells, T lymphocytes, and gut permeability are acute changes following *Campylobacter* enteritis that could persist for more than a year and may contribute to postinfective IBS.

The serotonin (5HT)-containing enterochromaffin cells in the colon are increased in diarrhea-predominant IBS patients compared to healthy subjects or to patients with ulcerative colitis. Furthermore, postprandial plasma 5HT plasma levels are significantly higher in diarrhea-predominant IBS patients compared to healthy controls. As 5HT plays an important role in the regulation of GI motility and visceral perception, the increased release of 5HT may contribute to the postprandial symptoms of these patients and provides a rationale for the use of 5HT antagonists in the treatment of this disorder.

APPROACH TO THE PATIENT

Because IBS is a disorder for which no pathognomonic abnormalities have been identified, its diagnosis relies on recognition of positive clinical features and elimination of other organic diseases. A careful history and physical examination are frequently helpful in establishing the diagnosis. Clinical features suggestive of IBS include the following: recurrence of lower abdominal pain with altered bowel habits over a period of time without progressive deterioration, onset of symptoms during periods of stress or emotional upset, absence of other systemic symptoms such as fever and weight loss, and small-volume stool without any evidence of blood.

On the other hand, the appearance of the disorder for the first time in old age, a progressive course from time of onset, persistent diarrhea after a 48-h fast, and presence of nocturnal diarrhea or steatorrheal stools argue against the diagnosis of IBS.

Because the major symptoms of IBS—abdominal pain, abdominal bloating, and alteration in bowel habits—are common complaints of many GI organic disorders, the list of differential diagnoses is long. The quality, location, and timing of pain may be helpful in suggesting specific disorders. Pain due to IBS that occurs in the epigastric or periumbilical area must be differentiated from biliary tract disease, peptic ulcer disorders, intestinal ischemia, and carcinoma of the stomach and pancreas. If pain occurs mainly in the lower abdomen, the possibility of diverticular disease of the colon, inflammatory bowel disease (including ulcerative colitis and Crohn's disease), and carcinoma of the colon must be considered. Postprandial pain accompanied by bloating, nausea, and vomiting suggests gastroparesis or partial intestinal obstruction. Intestinal infestation with *Giardia lamblia* or other parasites may cause similar symptoms. When diarrhea is the major complaint, the possibility of lactase deficiency, laxative abuse, malabsorption, hyperthyroidism, inflammatory bowel disease, or infectious diarrhea must be ruled out. On the other hand, constipation may be a side effect of many different drugs, such as anticholinergic, antihypertensive, and antidepressant medications. Endocrinopathies such as hypothyroidism and hypoparathyroidism must also be considered in the differential diagnosis of constipation, particularly if other systemic signs or symptoms of these endocrinopathies are present. In addition, acute intermittent porphyria and lead poisoning may present in a fashion similar to that of IBS, with painful constipation as the major complaint. These possibilities are suspected on the basis of their clinical presentations and are confirmed by appropriate serum and urine tests.

Because IBS is in part a diagnosis of exclusion, certain diagnostic tests should be performed routinely; others may be required depending on the specific presenting symptoms. The American Gastroenterological Association has delineated factors to be considered when determining the aggressiveness of the diagnostic evaluation. These include the duration of symptoms, the change in symptoms over time, the age and sex of the patient, the referral status of the patient, prior diagnostic studies, a family history of colorectal malignancy, and the degree of psychosocial dysfunction. Thus, a younger individual with mild symptoms requires a minimal diagnostic evaluation, while an older person or an individual with rapidly progressive symptoms should undergo a more thorough exclusion of organic disease. Most patients should have a complete blood count and sigmoidoscopic examination; in addition, stool specimens should be examined for ova and parasites. In those older than 40 years, an air-contrast barium enema or colonoscopy should also be performed. If the main symptoms are diarrhea and increased gas, the possibility of lactase deficiency should be ruled out with a hydrogen breath test or with evaluation after a 3-week lactose-free diet. In patients with concurrent symptoms of dyspepsia, upper GI radiographs or esophagogastroduodenoscopy may be advisable. In patients with postprandial right upper quadrant pain, an ultrasonogram of the gallbladder should be obtained. Laboratory features that argue against IBS include evidence of anemia, elevated sedimentation rate, presence of leukocytes or blood in stool, and stool volume >200 to 300 mL/d. These findings would necessitate other diagnostic considerations.

TREATMENT

Patient Counseling and Dietary Alterations Reassurance and careful explanation of the functional nature of the disorder and of how to avoid obvious food precipitants are important first steps in patient counseling and dietary change. Occasionally, a meticulous dietary history may reveal substances (such as coffee, disaccharides, legumes, and cabbage) that aggravate symptoms. As a therapeutic trial, patients should be encouraged to eliminate any foodstuffs that appear to produce symptoms.

Stool-Bulking Agents High-fiber diets and bulking agents, such as bran or hydrophilic colloid, are frequently used in treating IBS. Dietary fiber has multiple effects on colonic physiology. The water-holding action of fiber may contribute to increased stool bulk because of the ability of fiber to increase fecal output of bacteria. Fiber also speeds up colonic transit in most persons. In diarrhea-prone patients, whole colonic transit is faster than average; however, dietary fiber can delay transit. Furthermore, because of their hydrophilic properties, stool-bulking agents bind water and thus prevent both excessive hydration or dehydration of stool. The latter observation may explain the clinical experience that a high-fiber diet relieves diarrhea in some IBS patients. More recently, fiber supplementation with psyllium has been shown to reduce perception of rectal distention, indicating that fiber may have a positive affect on visceral afferent function.

The beneficial effects of dietary fiber on colonic physiology suggest that dietary fiber should be an effective treatment for IBS patients, but controlled trials of dietary fiber have produced variable results. This is not surprising since IBS is a heterogeneous disorder, with some patients being constipated and others having predominant diarrhea. Most investigations report increases in stool weight, decreases in colonic transit times, and improvement in constipation. Others have noted benefits in patients with alternating diarrhea and constipation, pain, and bloating; however, most studies observe no responses in patients with diarrhea- or pain-predominant IBS. Different fiber preparations may have dissimilar effects on selected symptoms in IBS. A crossover comparison of different fiber preparations found that psyllium produced greater improvements in stool pattern and abdominal pain than bran. Furthermore, psyllium preparations tend to produce less bloating and distention. Despite the equivocal data regarding efficacy, most gastroenterologists consider stool-bulking agents worth trying in patients with IBS.

Antispasmodics Clinicians have observed that anticholinergic drugs may provide temporary relief for symptoms such as painful cramps related to intestinal spasm. Although controlled clinical trials have produced mixed results, evidence generally supports beneficial effects

of anticholinergic drugs for pain. A meta-analysis of 26 double-blind clinical trials of antispasmodic agents in IBS reported better global improvement (62%) and abdominal pain reduction (64%) compared to placebo (35% and 45%, respectively), indicative of their symptomatic efficacy. The drugs are most effective when prescribed in anticipation of predictable pain. Physiologic studies demonstrate that anticholinergic drugs inhibit the gastrocolic reflex; hence, postprandial pain is best managed by giving antispasmodics 30 min before meals so that effective blood levels are achieved shortly before the anticipated onset of pain. Most anticholinergics contain natural belladonna alkaloids, which may cause xerostomia, urinary hesitancy and retention, blurred vision, and drowsiness. Some physicians prefer to use synthetic anticholinergics such as dicyclomine that have less effect on mucous membrane secretions and therefore produce fewer undesirable side effects.

Antidiarrheal Agents Peripherally acting opiate-based agents are the initial therapy of choice for diarrhea-predominant IBS. Physiologic studies demonstrate increases in segmenting colonic contractions, delays in fecal transit, increases in anal pressures, and reductions in rectal perception with these drugs. When diarrhea is severe, especially in the painless diarrhea variant of IBS, small doses of diphenoxylate (Lomotil), 2.5 to 5 mg every 4 to 6 h, can be prescribed. These agents are less addictive than paregoric, codeine, or tincture of opium. In general, the intestines do not become tolerant of the antidiarrheal effect of opiates, and increasing doses are not required to maintain antidiarrheal potency. These agents are most useful if taken before anticipated stressful events that are known to cause diarrhea. Treatment with antidiarrheals, however, should be considered only as temporary management; the final goal of treatment is gradual withdrawal of medication with substitution of a high-fiber diet.

Antidepressant Drugs In addition to their mood-elevating effects, antidepressent medications have several physiologic effects that may be beneficial in IBS. In diarrhea-predominant IBS patients, the tricyclic antidepressant imipramine slows jejunal migrating motor complex transit propagation and delays orocecal and whole-gut transit, indicative of a motor inhibitory effect. Tricyclic agents may also alter visceral afferent neural function.

Tricyclic antidepressants may be effective in some IBS patients. In a 2-month study of desipramine, abdominal pain improved in 86% of patients compared to 59% given a placebo. Another study of desipramine in 28 IBS patients showed improvement in stool frequency, diarrhea, pain, and depression. Improvements were observed mainly in diarrhea-predominant patients, with no improvement being noted in constipated patients. The beneficial effects of the tricyclic compounds in the treatment of IBS appear to be independent of their antidepression actions. The therapeutic benefits for the bowel symptoms occur faster and at a lower dosage. The efficacy of other classes of antidepressant agents in the management of IBS is less well evaluated. The selective serotonin reuptake inhibitor (SSRI) paroxetine accelerates orocecal transit, raising the possibility that this drug class may be useful in constipation-predominant patients. The SSRI citalopram blunts perception of rectal distention and reduces the magnitude of the gastrocolonic response in healthy volunteers. A small placebo-controlled study of citalopram in IBS patients reported reductions in pain. An investigation of mianserin, with serotonin $5HT_2$ and $5HT_3$ receptor antagonist and α_2-adrenoceptor antagonist effects, reported reductions in pain, distress, and functional disability compared to placebo. Despite these preliminary results, the efficacy of SSRIs in the treatment of IBS still needs further confirmation.

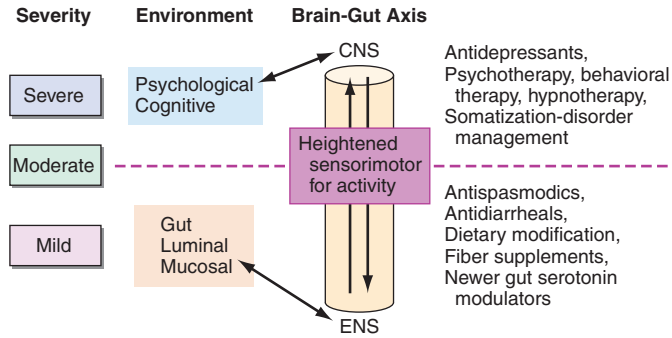

FIGURE 277-1 Therapeutic targets for irritable bowel syndrome. Patients with mild to moderate symptoms usually have intermittent symptoms that correlate with altered gut physiology. Treatments include gut-acting pharmacologic agents such as antispasmodics, antidiarrheals, fiber supplements, and gut serotonin modulators. Patients who have severe symptoms usually have constant pain and psychosocial difficulties. This group of patients are best managed with antidepressants and other psychological treatments. CNS, central nervous system; ENS, enteric nervous system.

Antiflatulence Therapy The management of excessive gas is seldom satisfactory, except in obvious aerophagia or disaccharidase deficiency. Patients should be advised to eat slowly; avoid chewing gum or drinking carbonated beverages; and avoid consuming artificial sweeteners, legumes, and foods of the cabbage family. Simethicone, antacids, and activated charcoal have all been tried, usually with disappointing results.

Serotonin Receptor Agonists and Antagonists Serotonin receptor antagonists have been evaluated as therapies for diarrhea-predominant IBS. Serotonin acting on $5HT_3$ receptors enhances the sensitivity of afferent neurons projecting from the gut. In humans, a $5HT_3$ receptor antagonist such as alosetron reduces perception of painful visceral stimulation in IBS. It also induces rectal relaxation, increases rectal compliance, and delays colonic transit. Large, 12-week, placebo-controlled trials of alosetron reported reductions in discomfort and improvements in stool frequency, consistency, and urgency in nonconstipated IBS patients. A follow-up 48-week study confirmed the long-term efficacy of alosetron. For unclear reasons, women with IBS derived greater benefit than men. However, in postrelease surveillance, 70 cases of ischemic colitis were observed, including 10 cases requiring surgery and 3 deaths. As a consequence, the medication was voluntarily withdrawn by the manufacturer. Preliminary studies in nonconstipated IBS patients of a newer $5HT_3$ receptor antagonist, cilansetron, have shown similar improvements in abdominal pain and diarrhea as alosetron. Follow-up investigation will determine if side effects also undermine the utility of this agent.

Novel $5HT_4$ receptor agonists exhibit prokinetic activity by stimulating peristalsis. In IBS patients with constipation, tegaserod accelerated intestinal and ascending colon transit. Clinical trials involving >4000 constipation-predominant IBS patients have reported reductions in discomfort and improvements in constipation and bloating compared to placebo. Other than diarrhea, no other significant side effects were noted. Tegaserod has been approved for the treatment of constipation-predominant IBS.

Summary The treatment strategy of IBS depends on the severity of the disorder (Table 277-3). Most IBS patients have mild symptoms. They are usually cared for in primary care practices and have little or no psychosocial difficulties and do not seek health care often. Treatment usually involves education, reassurance, and dietary/lifestyle changes. A smaller proportion have moderate symptoms that are usually intermittent and correlate with altered gut physiology, such as worsening with eating or stress and relieved by defecation. Treatments include

TABLE 277-3 Spectrum of Severity in IBS

	Mild	Moderate	Severe
Clinical features			
Prevalence	70%	25%	5%

gut-acting pharmacologic agents such as antispasmodics, antidiarrheals, fiber supplements, and the newer gut serotonin modulators (Fig. 277-1). A small proportion of IBS patients have severe and refractory symptoms. They are usually seen in referral centers and frequently have constant pain and psychosocial difficulties (Fig. 277-1). This group of patients are best managed with antidepressants and other psychological treatments.

278 FAMILIAL MEDITERRANEAN FEVER AND OTHER HEREDITARY RECURRENT FEVERS

Daniel L. Kastner

FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever (FMF) is the prototype of a group of inherited diseases (Table 278-1) that are characterized by recurrent episodes of fever with serosal, synovial, or cutaneous inflammation and, in some individuals, the eventual development of systemic AA amyloidosis (Chap. 310). Because of the relative infrequency of high-titer autoantibodies or antigen-specific T cells, the term *autoinflammatory* has been proposed to describe these disorders.

BACKGROUND AND PATHOPHYSIOLOGY FMF was first recognized among Armenians, Arabs, Turks, and non-Ashkenazi (primarily North African and Iraqi) Jews. With the advent of genetic testing, FMF has been documented with increasing frequency among Ashkenazi Jews and

Italians, and occasional cases have been confirmed even in the absence of known Mediterranean ancestry. FMF is recessively inherited, but, particularly in countries where families are small, a positive family history can be elicited only in ~50% of cases. DNA testing demonstrates carrier frequencies as high as 1:3 among affected populations, suggesting a heterozygote advantage.

The FMF gene was identified by positional cloning in 1997. It encodes a 781-amino acid, ~95-kDa protein denoted *pyrin* (or *marenostrin*) that is expressed in association with the cytoskeleton in granulocytes, eosinophils, and cytokine-activated monocytes. The N-terminal 92 amino acids of pyrin define a motif, the PYRIN domain, similar in structure to death domains, death effector domains, and caspase recruitment domains. PYRIN domains mediate homotypic protein-protein interactions and have been found in several other proteins, including cryopyrin, which is mutated in three other recurrent fever syndromes. Through the interaction of this domain with an intermediary adaptor protein, pyrin regulates caspase-1 [interleukin (IL) 1β-converting enzyme], and thereby IL-1β secretion. Pyrin-deficient mice exhibit heightened sensitivity to endotoxin, excessive IL-1β production, and impaired monocyte apoptosis.

ACUTE ATTACKS Febrile episodes in FMF may begin even in early infancy; 90% of patients have had their first attack by age 20. Typical FMF episodes generally last 24 to 72 h, with arthritic attacks tending to last somewhat longer. In some patients the episodes occur with great regularity, but more often the frequency of attacks varies over time, ranging from as often as once every few days to remissions lasting several years. Attacks are often unpredictable, although some patients relate them to physical exertion, emotional stress, or menses; pregnancy may be associated with remission.

If measured, temperature elevation is nearly always present throughout FMF attacks. Severe hyperpyrexia and even febrile seizures may be seen in infants, and fever is sometimes the only manifestation of FMF in young children.

Over 90% of FMF patients experience abdominal attacks at some time. Episodes range in severity from dull, aching pain and distention with mild tenderness on direct palpation to severe generalized pain with absent bowel sounds, rigidity, rebound tenderness, and air-fluid levels on upright radiographs. Computed tomography (CT) scanning may demonstrate a small amount of fluid in the abdominal cavity. If such patients undergo exploratory laparotomy, a sterile, neutrophil-rich peritoneal exudate is present, sometimes with adhesions from previous episodes. Ascites is rare.

Pleural attacks are usually manifested by unilateral, sharp, stabbing chest pain. Radiographs may show atelectasis and sometimes an effusion; thoracentesis demonstrates an exudative fluid rich in neutrophils. After repeated attacks, pleural thickening may develop.

FMF arthritis is most frequent among individuals homozygous for the M694V mutation, which is especially common in the non-Ashkenazi Jewish population. Acute arthritis in FMF is usually monoarticular, affecting the knee, ankle, or hip, although other patterns can be seen, particularly in children. Large sterile effusions rich in neutrophils are frequent, without commensurate erythema or warmth. Even after repeated arthritic attacks, radiographic changes are rare. Before the advent of colchicine prophylaxis, chronic arthritis of the knee or hip was seen in ~5% of FMF patients with arthritis. Chronic sacroiliitis can occur in FMF irrespective of the HLA-B27 antigen, even in the face of colchicine therapy. In the United States, FMF patients are much more likely to have arthralgia than arthritis.

The most characteristic cutaneous manifestation of FMF is erysipelas-like erythema, a flat, raised erythematous rash that most commonly occurs on the dorsum of the foot, ankle, or lower leg, alone or in combination with abdominal pain, pleurisy, or arthritis. Biopsy demonstrates perivascular infiltrates of granulocytes and monocytes. This rash is seen most often in M694V homozygotes and is relatively rare in the United States.

Exercise-induced (nonfebrile) myalgia is common in FMF, and a small percentage of patients develop a protracted febrile myalgia that can last several weeks. Symptomatic pericardial disease is rare, although some patients have small pericardial effusions as an incidental echocardiographic finding. Unilateral acute scrotal inflammation may occur in prepubertal boys. Aseptic meningitis has been reported, but the causal connection is controversial. Vasculitis, including Henoch-Schönlein purpura and periarteritis nodosum (Chap. 306), may be seen at increased frequency in FMF.

Laboratory features of FMF attacks are consistent with acute inflammation and include an elevated erythrocyte sedimentation rate; leukocytosis; thrombocytosis (in children); and elevations in the C-reactive protein, fibrinogen, haptoglobin, and serum immunoglobulins. Transient albuminuria and hematuria may also be seen.

AMYLOIDOSIS Before the advent of colchicine prophylaxis, systemic amyloidosis was a common complication of FMF. It is caused by deposition of a fragment of serum amyloid A, an acute-phase reactant, in the kidneys, adrenals, intestine, spleen, lung, and testes. Amyloidosis should be suspected in patients who have proteinuria between attacks; renal or rectal biopsy is most often used to establish the diagnosis. Risk factors include the M694V homozygous genotype, positive family history (independent of FMF mutational status), the SAA 1 genotype, male gender, noncompliance with colchicine therapy, and having grown up in the Middle East.

DIAGNOSIS For typical cases, experienced physicians can often make the diagnosis on clinical grounds alone. Clinical criteria for FMF have been shown to have high sensitivity and specificity in parts of the world where the pretest probability of FMF is high. Genetic testing can provide a useful adjunct in ambiguous cases or for physicians not experienced in FMF. Most of the disease-associated FMF mutations are in exon 10 of the gene, with a smaller group of mutations in exon 2. An updated list of mutations for FMF and other hereditary periodic fevers can be found online at *http://fmf.igh.cnrs.fr/infevers/*.

Genetic testing has permitted a broadening of the clinical spectrum and geographic distribution of FMF and may be of prognostic value. Most studies indicate that M694V homozygotes have an earlier age of onset and a higher frequency of arthritis, rash, and amyloidosis. In contrast, the E148Q mutation is usually associated with milder disease. E148Q is sometimes found in *cis* with exon 10 mutations, which complicates the interpretation of genetic test results. Only ~70% of patients with clinically typical FMF have two identifiable mutations in *trans*, suggesting either that current screening methods do not detect all of the relevant mutations or that one mutation may be sufficient for disease under some circumstances. In these cases clinical judgment is very important, and sometimes a therapeutic trial of colchicine may help to confirm the diagnosis. Genetic testing of unaffected individuals is usually inadvisable because of the possibility of nonpenetrance and the potential impact of a positive test on future insurability.

If a patient is seen during their first attack, the differential diagnosis may be broad, although delimited by the specific organ involvement. After several attacks the differential diagnosis may include the other hereditary periodic fever syndromes (Table 278-1); the syndrome of periodic fever with aphthous ulcers, pharyngitis, and cervical adenopathy (PFAPA); systemic-onset juvenile rheumatoid arthritis or adult Still's disease; porphyria; hereditary angioedema; inflammatory bowel disease; and, in women, gynecologic disorders.

Rx TREATMENT

The treatment of choice for FMF is daily oral colchicine, which decreases the frequency and intensity of attacks and prevents the development of amyloidosis in compliant patients. Intermittent dosing at the onset of attacks is not as effective as daily prophylaxis and is of unproven value in preventing amyloidosis. The usual adult dose of colchicine is 1.2 to 1.8 mg/d, which causes substantial reduction in symptoms in two-thirds of patients and some improvement in >90%. Children may require lower doses, although not proportionately to body weight.

Common side effects of colchicine include bloating, abdominal cramps, lactose intolerance, and diarrhea. They can be minimized by starting at a low dose and gradually advancing as tolerated, splitting the dose, use of simethicone for flatulence, and avoidance of dairy products. If taken by either parent at the time of conception, colchicine may cause a small increase in the risk of trisomy 21 (Down syndrome). In elderly patients with renal insufficiency, colchicine can cause a myoneuropathy characterized by proximal muscle weakness and elevation of the creatine kinase. Cyclosporine inhibits hepatic excretion of colchicine by its effects on the MDR-1 transport system, sometimes leading to colchicine toxicity in patients who have undergone renal transplantation for amyloidosis. Intravenous colchicine should generally not be administered to patients already taking oral colchicine, because severe, sometimes fatal, toxicity can occur in this setting.

No alternatives have been established for the small number of patients who do not respond to colchicine or cannot tolerate therapeutic dosages, although interferon-α and tumor necrosis factor (TNF) inhibitors are investigational. Bone marrow transplantation has been suggested for refractory FMF, but the risk-benefit ratio is currently regarded as unacceptable.

OTHER HEREDITARY RECURRENT FEVERS

Within 5 years of the discovery of the FMF gene, three additional genes causing five other hereditary periodic fever syndromes were identified, catalyzing a paradigm shift in diagnosis and treatment of these disorders.

TNF RECEPTOR–ASSOCIATED PERIODIC SYNDROME (TRAPS) TRAPS is caused by dominantly inherited mutations in the extracellular domains of the 55-kDa TNF receptor (TNFRSF1A, p55). Although originally described in a large Irish family (and hence the name *familial Hibernian fever*), TRAPS has a broad ethnic distribution. TRAPS episodes often begin in childhood. The duration of attacks ranges from 1 to 2 days to as long as several weeks, and in severe cases symptoms may be nearly continuous. In addition to peritoneal, pleural, and synovial attacks similar to those in FMF, TRAPS patients frequently have ocular inflammation (most often conjunctivitis and/or periorbital edema) and a distinctive migratory myalgia with overlying painful erythema. TRAPS patients generally respond better to glucocorticoids than to prophylactic colchicine. About 15% develop amyloidosis. The diagnosis of TRAPS is based on the demonstration of *TNFRSF1A* mutations in the presence of characteristic symptoms. Leukocytes from patients with certain TRAPS mutations exhibit a defect in TNF receptor shedding, possibly impairing normal homeostasis and explaining autoinflammatory manifestations. Etanercept, a TNF inhibitor, has been shown to ameliorate TRAPS attacks, although its effect on amyloidosis is unproven.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (HIDS) HIDS is a recessively inherited recurrent fever syndrome found primarily in individuals of northern European ancestry. It is caused by mutations in mevalonate kinase (*MVK*), encoding an enzyme involved in the synthesis of cholesterol and nonsterol isoprenoids. Attacks usually begin in infancy, and last 3 to 7 days. Clinically distinctive features include painful cervical lymphadenopathy, a diffuse maculopapular rash sometimes affecting the palms and soles, and aphthous ulcers; pleurisy is rare, and amyloidosis has not yet been reported. Although originally defined by the persistent elevation of serum IgD, disease activity is not related to IgD level, and some patients with FMF or TRAPS may have modestly increased serum IgD. Moreover, occasional patients with *MVK* mutations and periodic fever have normal IgD levels. No treatment for HIDS has been established.

THE CRYOPYRINOPATHIES Three hereditary febrile syndromes, familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal onset multisystem inflammatory disease (NOMID), are all caused by mutations in *CIAS1*, the gene encoding cryopyrin, and represent a clinical spectrum of disease. FCAS patients develop chills, fever, headache, arthralgia, conjunctivitis, and an urticaria-like rash in response to generalized cold exposure. In MWS there is a similar rash, but it is not usually induced by cold. MWS patients also develop fevers, abdominal pain, limb pain, arthritis, conjunctivitis, and, over time, sensorineural hearing loss. NOMID is the most severe of the three disorders, with chronic aseptic meningitis, a characteristic arthropathy, and urticarial rash. Like the FMF protein, pyrin, cryopyrin has an N-terminal PYRIN domain and regulates IL-1β production. Initial therapeutic experience with anakinra, the IL-1 receptor antagonist, in MWS has been encouraging.

279 COMMON DISEASES OF THE COLON AND ANORECTUM AND MESENTERIC VASCULAR INSUFFICIENCY

Susan L. Gearhart, Gregory Bulkley

COLON

DIVERTICULAR DISEASE ■ Incidence and Epidemiology Among western populations, diverticulosis affects nearly one-half of individuals over age 60. The prevalence among females and males is similar. However, males tend to present at a younger age. Fortunately, only 20% of patients with diverticulosis develop symptomatic disease. Diverticulosis is rare in underdeveloped countries, where diets include more fiber and roughage.

Anatomy and Pathophysiology Two types of diverticula occur in the intestine: true and false, or pseudodiverticula. The most common type of diverticulum affecting the colon is the pseudodiverticulum. This is a herniation or saclike projection of the mucosa through the muscularis propria. The protrusion occurs commonly at the point where the nutrient artery penetrates through the muscularis propria, resulting in a break in the integrity of the colonic wall. Diverticulosis commonly affects the sigmoid colon; only 5% of persons exhibit pancolonic diverticula. This may be a result of the relative high-pressure zone within the sigmoid colon. Thus, higher amplitude contractions combined with constipated, high-fat content stool within the sigmoid lumen results in the creation of these diverticula. *Diverticulitis*, or inflammation of a diverticulum, is related to the retention of particulate material within

the diverticular sac and the formation of a fecalith. Consequently, the blood vessel is either compressed or eroded, leading to either perforation or bleeding.

Presentation, Evaluation, and Management of Diverticular Bleeding Hemorrhage from a colonic diverticulum is the most common cause of hematochezia in patients over the age of 60, yet only 20% of patients with diverticulosis will have gastrointestinal bleeding. Patients at increased risk for bleeding tend to be hypertensive, have atherosclerosis, and regularly use nonsteroidal anti-inflammatory agents. Most bleeds are self-limited and stop spontaneously with bowel rest. The lifetime risk of rebleeding is 25%.

Localization of diverticular bleeding should include colonoscopy, which may be both diagnostic and therapeutic in the management of mild to moderate diverticular bleeding. If the patient is stable, massive bleeding is best managed by angiography. Mesenteric angiography can localize the bleeding site and occlude it successfully with a coil in 80% of cases. The patient can then be followed closely with or without repetitive endoscopy looking for evidence of colonic ischemia. With newer techniques of highly selective coil embolization, the rate of colonic ischemia is $<10\%$ and the risk of acute rebleeding is $<25\%$. Alternatively, a selective infusion of vasopressin can be given to stop the hemorrhage. However, this has been associated with significant complications, including myocardial infarction and intestinal ischemia in $>40\%$ of patients. Furthermore, bleeding recurs in 50% of patients once the infusion is stopped. Localization studies indicate that bleeding as a result of colonic diverticulosis is more often seen from the right colon. For this reason, patients with presumed bleeding from diverticular disease requiring emergent surgery without localization should undergo a total abdominal colectomy. Current recommendations state that if the patient is unstable or has had a 6-unit bleed within 24 h, surgery should be performed. In patients without severe comorbidities, surgical resection can be performed with a primary anastomosis. A higher anastomotic leak rate has been reported in patients undergoing primary anastomosis who received >10 units of blood.

Presentation and Evaluation of Diverticulitis Acute diverticulitis characteristically presents with fever, anorexia, left lower quadrant abdominal pain, and diarrhea. In severe cases, patients may have generalized peritonitis and obstipation. Diverticular perforation with a fistula to the bladder presents with pneumaturia or recurrent urinary tract infections. On examination, the patient may have abdominal distention and signs of localized or generalized peritonitis. Laboratory investigations will demonstrate a leukocytosis. Rarely, a patient may present with an air-fluid level in the left lower quadrant on plain abdominal film. This is a giant diverticulum of the sigmoid colon and is managed with resection to avoid impending perforation.

The diagnosis of diverticulitis is best made on computed tomography (CT) with the following findings: sigmoid diverticula; thickened colonic wall >4 mm; inflammation within the pericolic fat $\pm$ the collection of contrast material or fluid. Symptoms of irritable bowel syndrome (IBS) may mimic those of diverticulitis. Therefore, suspected diverticulitis that does not meet CT criteria or is not associated with a leukocytosis or fever is not diverticular disease. A gastrografin enema may also be useful in the evaluation of patients with presumed diverticular disease. If the patient has diverticular disease with a contained perforation (abscess), this study will differentiate whether the abscess is communicating with the bowel lumen or not. The latter can be managed acutely with antimicrobial therapy, whereas the former has a higher rate of failure of medical management. Repeated use of CT imaging in mild disease is not recommended as the rate of perforation with abscess formation from left-sided diverticular disease is only 16%.

Barium enema or colonoscopy should not be performed in the acute setting because of the higher risk of colonic perforation associated with insufflation or insertion of barium-based contrast material under pressure. A sigmoid malignancy can masquerade as diverticular disease. Therefore, a barium enema or colonoscopy should be performed before surgical resection.

Staging of Complicated Diverticulitis In contrast to uncomplicated diverticulitis, *complicated diverticular disease* is defined as diverticular disease associated with a stricture, abscess, or fistula requiring surgical intervention to cure. Complicated diverticular disease is staged using the Hinchey classification system (Fig. 279-1). This staging system was developed to predict outcomes following the surgical management of complicated diverticular disease. Other preoperative risk factors influencing postoperative mortality rates include higher American Society of Anesthesia (ASA) class and preexisting organ failure.

TREATMENT

Medical Management Asymptomatic diverticular disease discovered on imaging studies or at the time of endoscopy is best managed by diet alterations. Patients should be instructed to eat a fiber-enriched diet. This diet requires that 15 to 30 g of fiber be consumed each day, best accomplished with supplementary fiber products such as Metamucil, Fibercon, or Citrucel. The patient should also be instructed to avoid nuts and popcorn.

Symptomatic diverticular disease, defined as radiographic and hematologic confirmation of inflammation and infection within the colon, should be treated initially with antibiotics and bowel rest. Nearly 75% of patients hospitalized for acute diverticulitis will respond to nonoperative treatment with a suitable antimicrobial regiment. The current recommended antimicrobial coverage is trimethoprim/sulfamethoxazole or ciprofloxacin and metronidazole targeting aerobic gram-negative rods and anaerobic bacteria. Unfortunately, this does not cover enterococci, and the addition of ampicillin to this regimen for nonresponders is recommended. Single-agent therapy with a third-generation penicillin such as piperacillin may be effective. The usual course of antibiotics is 7 to 10 days. Current recommendations concerning bowel rest suggest that patients should remain on nothing by mouth or on clear liquids until their pain resolves. A role for parenteral nutrition has not been established.

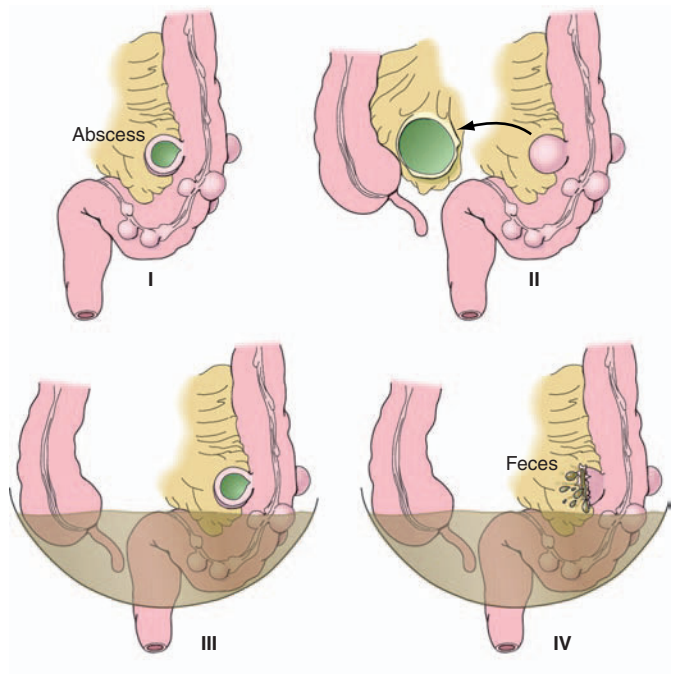

FIGURE 279-1 Hinchey classification of diverticulitis. Stage I: perforated diverticulitis with a confined paracolic abscess. Stage II: perforated diverticulitis that has closed spontaneously with distant abscess formation. Stage III: noncommunicating perforated diverticulitis with fecal peritonitis (the diverticular neck is closed off and therefore contrast will not freely expel on radiographic images). Stage IV: perforation and free communication with the peritoneum, resulting in fecal peritonitis.

Surgical Management Surgical therapy should be offered to patients who have had at least two documented attacks of diverticulitis or those who do not rapidly improve on medical therapy. Surgical therapy is indicated in all patients with complicated diverticular disease. In contrast to older patients, younger patients may experience a more aggressive form of the disease. Nearly 30% of people with diverticular disease are <40 years old. Surgical intervention is required in >70% of these patients. Patients under age 40 should undergo surgical excision following the first episode of documented diverticulitis.

The goals of surgical management of diverticular disease include controlling sepsis, eliminating complications such as fistula or obstruction, removing the diseased colonic segment, and restoring intestinal continuity. These goals must be obtained while minimizing morbidity, length of hospitalization, and cost and maximizing survival and quality of life. The options for the surgical management of diverticular disease include: (1) proximal diversion of the fecal stream with an ileostomy or colostomy and sutured omental patch with drainage, (2) resection with colostomy and mucus fistula or closure of distal bowel with formation of a Hartmann's pouch, (3) resection with anastomosis (coloproctostomy), or (4) resection with anastomosis and diversion (coloproctostomy with loop ileostomy or colostomy).

Patients with Hinchey stages I and II disease are managed with percutaneous drainage followed by resection with anastomosis about 6 weeks later. Percutaneous drainage is recommended for abscesses that are ≥5 cm with a well-defined wall that is accessible. Paracolic abscesses that are <5 cm in size will usually resolve with bowel rest and antibiotics alone. Contraindications to percutaneous drainage are pneumoperitoneum and fecal peritonitis. Urgent operative intervention is undertaken if patients develop generalized peritonitis, and most will need to be managed with a Hartmann's procedure. In selected cases, nonoperative therapy may be considered. Nonoperative management of isolated paracolic abscesses (Hinchey stage I) is associated with only a 20% recurrence rate at 2 years. Over 80% of patients with distant abscesses (Hinchey stage II) require surgical resection for recurrent symptoms.

Hinchey stage III disease is managed with a Hartman's procedure or with primary anastomosis and proximal diversion. If the patient has significant comorbidities, making operative intervention risky, a limited procedure including intraoperative peritoneal lavage (irrigation), omental patch to the oversewn perforation, and proximal diversion of the fecal stream with either an ileostomy or transverse colostomy can be performed. No anastomosis of any type should be attempted in Hinchey stage IV disease. A limited approach to these patients is associated with a decreased mortality (Table 279-1). Other important modalities in the surgical management of diverticular disease include newer minimally invasive surgical techniques. Patients undergoing successful laparoscopic resection for diverticular disease have shorter hospital stays and return to work earlier. However, conversion rates from laparoscopic to open resection are higher in patients with complicated diverticular disease.

Recurrent Symptoms Recurrent abdominal symptoms following surgical resection for diverticular disease occurs in 10% of patients. Recurrent diverticular disease develops in patients following inadequate surgical resection. A retained segment of diseased rectosigmoid colon is associated with twice the incidence of recurrence. IBS may also cause symptom recurrence. Patients undergoing surgical resection for presumed diverticulitis and symptoms of abdominal cramping and irregular loose bowel movements consistent with IBS have functionally poorer outcomes.

MESENTERIC VASCULAR INSUFFICIENCY

INTESTINAL ISCHEMIA ■ Incidence and Epidemiology Intestinal ischemia may result from either arterial occlusive and vasospastic disease or from venoocclusive disease. The most common form of intestinal ischemia is acute arterial ischemia. Risk factors for acute arterial ischemia include atrial fibrillation, recent myocardial infarction, valvular heart disease, and recent cardiac or vascular catheterization. The increased incidence of intestinal ischemia seen among western countries parallels atherosclerosis and the aging population. With the exception of strangulated small-bowel obstruction, ischemic colitis is the most common form of acute ischemia and the most prevalent gastrointestinal disease complicating cardiovascular surgery. The incidence of ischemic colitis following elective aortic repair is 5 to 9%, and the incidence triples in patients following emergent repair. Other less common forms of intestinal ischemia include chronic mesenteric angina associated with atherosclerotic disease and mesenteric venous thrombosis. Mesenteric venous thrombosis is associated with the presence of a hypercoaguable state including proteins C and S deficiency, antithrombin III deficiency, polycythema vera, and carcinoma.

TABLE 279-1 Outcome Following Surgical Therapy for Complicated Diverticular Disease

Hinchey Stage	Operative Procedure	Anastomotic Leak Rate, %	Overall Morbidity, %
I	Resection with primary anastomosis without diverting stoma	3.8	22
II	Resection with primary anastomosis +/− diversion	3.8	30
III	Hartmann's procedure vs. diverting colostomy and omental pedal graft	—	0 vs. 6 mortality
IV	Hartmann's procedure vs. diverting colostomy and omental pedicle graft	—	6 vs. 2 mortality

Anatomy and Pathophysiology Intestinal ischemia occurs when insufficient perfusion to intestinal tissue produces ischemic tissue injury. The blood supply to the intestines is depicted in Fig. 279-2. To prevent ischemic injury, extensive collateralization occurs between major mesenteric trunks and branches of the mesenteric arcades (Table 279-2). Collateral vessels within the small bowel are numerous and meet

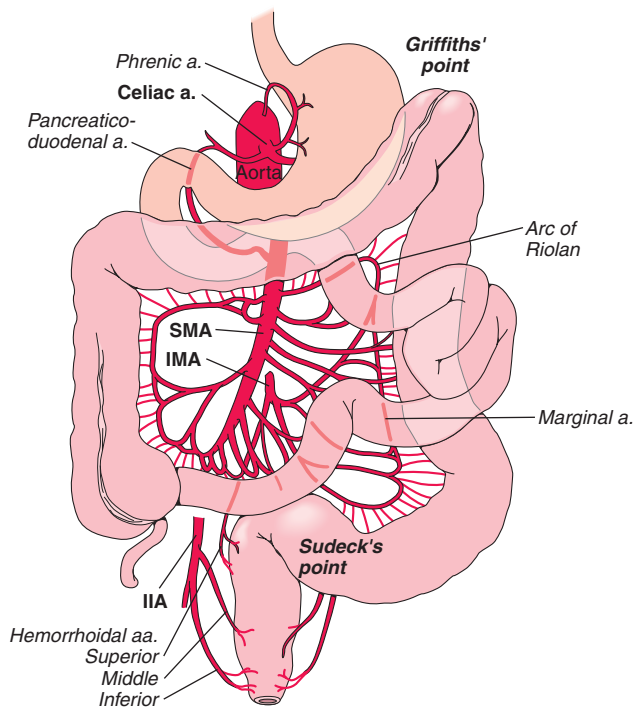

FIGURE 279-2 Blood supply to the intestines includes the celiac artery, superior mesenteric artery (SMA), inferior mesenteric artery (IMA), and branches of the internal iliac artery (IIA). Sudeck's and Griffiths' points, indicated by shaded area, are watershed areas within the colonic blood supply and common locations for ischemia.

TABLE 279-2 *Collateral Arterial Intestinal Blood Flow*

Involved Circulation	Mesenteric Artery	Adjoining Artery	Collateral Artery
Systemic	Celiac	Descending aorta	Phrenic
Systemic	IMA	Hypogastric	Middle hemorrhoidal
Mesenteric	Celiac	SMA	Superior/inferior pancreaticoduodenal
Mesenteric	SMA	IMA	Arch of Riolan
Mesenteric	SMA	Celiac/IMA	Intramesenteric
Mesenteric	SMA	IMA	Marginal

Note: IMA, inferior mesenteric artery; SMA, superior mesenteric artery.

within the duodenum and the bed of the pancreas. Collateral vessels within the colon meet at the splenic flexure and descending/sigmoid colon. These areas, which are inherently at risk for decreased blood flow, are known as *Griffith's point* and *Sudek's point*, respectively, and are the most common locations for colonic ischemia (Fig. 279-2, shaded area). The splanchnic circulation can receive up to 30% of the cardiac output. Protective responses to prevent intestinal ischemia include abundant collateralization, autoregulation of blood flow, and the ability to increase oxygen extraction.

Intestinal ischemia may result from arterial occlusive disease, arterial nonocclusive or vasospastic disease, and venous thrombosis. Occlusive ischemia is a result of disruption of blood flow by an embolus or progressive thrombosis in a major artery supplying the intestine. Emboli originate from the heart in >75% of cases and lodge preferentially just distal to the origin of the middle colic artery from the superior mesenteric artery. Progressive thrombosis of at least two of the major vessels supplying the intestine is required for the development of chronic intestinal angina. Nonocclusive ischemia is disproportionate mesenteric vasoconstriction (arteriolar vasospasm) in response to a severe physiologic stress such as dehydration or shock. If left untreated, early mucosal stress ulceration will progress to full-thickness injury.

Presentation, Evaluation, and Management Intestinal ischemia remains one of the most challenging diagnoses. The mortality rate with intestinal ischemia is >50%. The most significant indicator of survival is the timeliness of diagnosis and treatment. An overview of diagnosis and management of each form of intestinal ischemia is given in Table 279-3.

Acute mesenteric ischemia resulting from arterial embolus or thrombosis presents with severe acute, nonremitting abdominal pain strikingly out of proportion to the physical findings. Associated symptoms may include nausea and vomiting, transient diarrhea, and bloody stools. With the exception of minimal abdominal distention and hypoactive bowel sounds, early abdominal examination is unimpressive. Later findings will demonstrate peritonitis and cardiovascular collapse. In the evaluation of acute intestinal ischemia, routine laboratory tests should be obtained, including complete blood count, serum chemistry, coagulation profile, arterial blood gas, amylase, lipase, lactic acid, blood type and cross match, and cardiac enzymes. Regardless of the need for urgent surgery, emergent admission to a monitored bed or intensive care unit is recommended for resuscitation and further evaluation. If the diagnosis of intestinal ischemia is being considered, consultation with a surgical service is necessary.

Other diagnostic modalities that may be useful in diagnosis but should not delay surgical therapy include electrocardiogram (ECG), abdominal radiographs, CT, and mesenteric angiography. The ECG may demonstrate an arrhythmia, indicating the possible source of the emboli. A plain abdominal film may show evidence of free intraperitoneal air, indicating a perforated viscus and the need for emergent exploration. Earlier features of intestinal ischemia seen on abdominal radiographs include bowel-wall edema, known as "thumbprinting." If the ischemia progresses, air can be seen within the bowel wall (*pneumatosis intestinalis*) and within the portal venous system. Other features include calcifications of the aorta and its tributaries, indicating atherosclerotic disease. With the administration of oral and intravenous contrast, dynamic CT with three-dimensional reconstruction is a highly sensitive test for intestinal ischemia. Other common causes of abdominal pain that may be identified on CT and alter the management of the patient are pancreatitis, diverticulitis, appendicitis, and small-bowel obstruction. In acute embolic disease, mesenteric angiography is best performed intraoperatively.

The "gold standard" for the diagnosis and management of acute arterial occlusive disease is laparotomy. Surgical exploration should not be delayed if suspicion of acute occlusive mesenteric ischemia is high or evidence of clinical deterioration or frank peritonitis is present. The goal of operative exploration is to resect compromised bowel and restore blood supply. Intraoperative or preoperative arteriography and systemic heparinization may assist the vascular surgeon in restoring blood supply to compromised bowel. The entire length of the small and large bowel beginning at the ligament of Treitz should be evaluated. The pattern of intestinal ischemia may indicate the level of arterial occlusion. In the case of superior mesenteric artery occlusion where the embolus usually lies just proximal to the origin of the middle colic artery, the proximal jejunum is often spared while the remainder of the small bowel to the transverse colon will be ischemic. The surgical management of acute mesenteric ischemia of the small bowel is attempted embolectomy via intra-

TABLE 279-3 *Overview of the Management of Acute Intestinal Ischemia*

Condition	Key to Early Diagnosis	Treatment of Underlying Cause	Treatment of Specific Lesion	Treatment of Systemic Consequences
Arterial embolus	Early laparotomy	Anticoagulation Cardioversion Proximal thrombectomy Aneurysmectomy	Laparotomy Embolectomy Vascular bypass Assess viability and resect dead bowel	Ensure hydration Give antibiotics Reverse acidosis Optimize oxygen delivery Support cardiac output Treat other embolic sites Avoid vasoconstrictors
Arterial thrombosis	Duplex ultrasound Angiography	Anticoagulation Hydration	Endovascular stent Endarterectomy/ thrombectomy or vascular bypass Assess viability and resect dead bowel	Give antibiotics Reverse acidosis Optimize oxygen delivery Support cardiac output Avoid vasoconstrictors
Venous thrombosis	Spiral CT	Anticoagulation Massive hydration	Anticoagulation +/− laparotomy/thrombectomy/ portasystemic shunt Assess viability and resect dead bowel	Give antibiotics Reverse acidosis Optimize oxygen delivery Support cardiac output Avoid vasoconstrictors
Nonocclusive mesenteric ischemia	Vasospasm: Angiography Hypoperfusion: Spiral CT or colonoscopy	Ensure hydration Support cardiac output Avoid vasoconstrictors Ablate renin-angiotensin axis	Vasospasm: Intraarterial vasodilators Hypoperfusion: Delayed laparotomy Assess viability and resect dead bowel	Ensure hydration Give antibiotics Reverse acidosis Optimize oxygen delivery Support cardiac output Avoid vasoconstrictors

Note: CT, computed tomography.

operative angiography or arteriotomy. Although more commonly applied to chronic disease, acute thrombosis may be managed with angioplasty, with or without endovascular stent placement. If this is unsuccessful, a bypass from the aorta to the superior mesenteric artery is performed.

Nonocclusive or vasospastic mesenteric ischemia presents with generalized abdominal pain, anorexia, bloody stools, and abdominal distention. Often these patients are obtunded, and physical findings may not assist in the diagnosis. The presence of a leukocytosis, metabolic acidosis, elevated amylase or creatinine phosphokinase levels, and/or lactic acidosis are useful in support of the diagnosis of advanced intestinal ischemia; however, these markers may not be indicative of either reversible ischemia or frank necrosis. Newer investigational markers for intestinal ischemia that have been used include D-dimer, glutathione S-transferase, platelet-activating factor (PAF), and mucosal pH monitoring. Regardless of the need for urgent surgery, emergent admission to a monitored bed or intensive care unit is recommended for resuscitation and further evaluation. Early manifestations of intestinal ischemia include fluid sequestration within the bowel wall. This may lead to a loss of interstitial volume, and aggressive fluid resuscitation may be necessary. To optimize oxygen delivery, blood transfusions may be given. Broad-spectrum antibiotics to provide sufficient coverage for enteric pathogens, including gram-negative and anaerobic organisms, should be administered. Frequent monitoring of the patient's vital signs, urine output, blood gases, and lactate levels is paramount, as is frequent abdominal examination. All vasoconstriction agents should be avoided, allowing fluid resuscitation to maintain hemodynamics.

If ischemic colitis is a concern, colonscopy should be performed to assess the integrity of the colon mucosa (Fig. 279-3). Visualization of the rectosigmoid region may demonstrate decreased mucosal integrity, associated more commonly with nonocclusive mesenteric ischemia, or, on occasion, occlusive disease as a result of acute loss of inferior mesenteric arterial flow following aortic surgery. Ischemia of the colonic mucosa is graded as *mild* with minimal mucosal erythema or as *moderate* with pale mucosal ulcerations and evidence of extension to the muscular layer of the bowel wall. *Severe* ischemic colitis presents with severe ulcerations resulting in black or green discoloration of the mucosa, consistent with full-thickness bowel-wall necrosis. The degree of reversibility can be predicted from the mucosal findings: mild erythema is nearly 100% reversible, moderate ~50%, and frank necrosis is simply dead bowel. Follow-up colonoscopy can be performed to rule out progression of ischemic colitis.

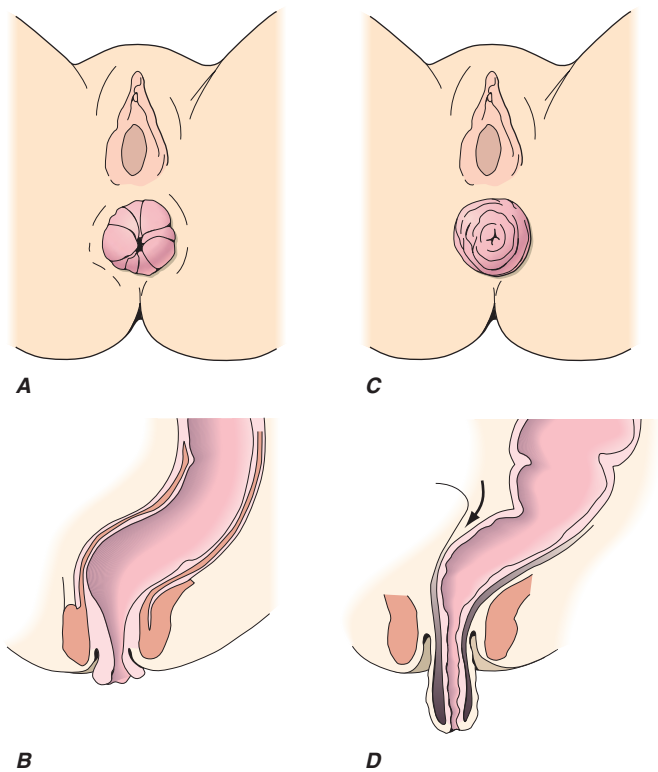

FIGURE 279-3 Degree of rectal prolapse. Mucosal prolapse only (*A*, *B*, sagittal view). Full-thickness prolapse associated with redundant rectosigmoid and deep pouch of Douglas (*C*, *D*, sagittal view).

Laparotomy for nonocclusive mesenteric ischemia is warranted for signs of peritonitis or worsening endoscopic findings and if the patient's condition does not improve with aggressive resuscitation. Ischemic colitis is optimally treated with resection of the ischemic bowel and formation of a proximal stoma. Primary anastomosis should not be performed in patients with acute intestinal ischemia.

Patients with mesenteric venous thrombosis may present with a gradual or sudden onset. Symptoms include vague abdominal pain, nausea, and vomiting. Examination findings include abdominal distention with mild to moderate tenderness and signs of dehydration. The gold standard for the diagnosis of mesenteric thrombosis is the abdominal spiral CT with oral and intravenous contrast. Findings on CT include bowel-wall thickening and ascites. Intravenous contrast will demonstrate a delayed arterial phase and clot within the superior mesenteric vein. The goal of management is to optimize hemodynamics and correct electrolyte abnormalities with massive fluid resuscitation. Intravenous antibiotics as well as anticoagulation should be initiated. If laparotomy is performed and mesenteric venous thrombosis is suspected, heparin anticoagulation is immediately initiated and clearly compromised bowel is resected.

Chronic intestinal ischemia presents with intestinal angina or abdominal pain associated with need for increased blood flow to the intestine. Patients report abdominal cramping and pain following ingestion of a meal. Weight loss and chronic diarrhea may also be noted. Abdominal pain without weight loss is not chronic mesenteric angina. Physical examination will often reveal the presence of an abdominal bruit as well as other manifestations of atherosclerosis. Duplex ultrasound evaluation of the mesenteric vessels has gained in popularity. In the absence of obesity and an increased bowel gas pattern, the radiologist may be able to identify flow disturbances within the vessels or the lack of a vasodilation response to feeding. This tool is frequently used as a screening test for patients with symptoms suggestive of chronic mesenteric ischemia. The gold standard for confirmation of mesenteric arterial occlusion is mesenteric angiography. Evaluation with mesenteric angiography allows for identification and possible intervention for the treatment of thrombus within the vessel lumen and will also evaluate the patency of remaining mesenteric vessels. The use of mesenteric angiography may be limited in the presence of renal failure or contrast allergy. Magnetic resonance angiography is an alternative if the administration of contrast dye is contraindicated.

The management of chronic intestinal ischemia includes medical management of atherosclerotic disease by lipid-lowering medications, exercise, and cessation of smoking. A full cardiac evaluation should be performed before intervention. Newer endovascular procedures may avoid an operative intervention in selective patient populations. Angioplasty with endovascular stenting in the treatment of chronic mesenteric ischemia is associated with an 80% long-term success rate. In patients requiring surgical exploration, the approach used is determined by the mesenteric angiogram. The entire length of the small and large bowel should be evaluated, beginning at the ligament of Treitz. Restoration of blood flow at the time of laparotomy is accomplished with mesenteric bypass.

Determination of intestinal viability intraoperatively in patients with suspected intestinal ischemia can be challenging. After revascularization, the bowel wall should be observed for return of a pink color and peristalsis. Palpation of major arterial vessels can be performed as well as applying a doppler flowmeter to the antimesenteric border of the bowel wall, but neither is a definitive indicator of viability. In equivocal cases, 1 g of intravenous sodium fluorescein is administered

and the pattern of bowel reperfusion is observed under ultraviolet illumination with a standard (3600 A) Wood's lamp. An area of nonfluorescence >5 mm in diameter is indicative of nonviability. If doubt still persists, reexploration should be performed 24 to 48 h following surgery. This will allow demarcation of nonviable bowel. Primary intestinal anastomosis in patients with ischemic bowel is always worrisome, and reanastomosis should be deferred to the time of second-look laparotomy.

ANORECTUM

RECTAL PROLAPSE (PROCIDENTIA) ■ Incidence and Epidemiology Rectal prolapse is six times more common in women than in men. The incidence of rectal prolapse peaks in women >60 years. Women with rectal prolapse have a higher incidence of associated pelvic floor disorders including urinary incontinence, rectocele, cystocele, and enterocele. Nearly one-third of male patients with rectal prolapse suffer from a neurologic or psychiatric disorders. About 20% of children with rectal prolapse will have cystic fibrosis. All children presenting with prolapse should undergo a sweat chloride test. Less common associations include Ehlers-Danlos syndrome, solitary rectal ulcer syndrome, congenital hypothyroidism, and Hirschsprung's disease.

Anatomy and Pathophysiology Rectal prolapse (procidentia) is a circumferential, full-thickness protrusion of the rectal wall through the anal orifice. It is often associated with a redundant sigmoid colon, pelvic laxity, and a deep pouch of Douglas. Initially, rectal prolapse was considered to be the result of early internal rectal intussusception, the first step in an inevitable progression to full-thickness external prolapse. However, only 1 of 38 patients with internal prolapse followed for >5 years developed full-thickness prolapse. Others have suggested that full-thickness prolapse is the result of damage to the pudendal nerves from repeated stretching with straining to defecate. Damage to the pudendal nerves would weaken the pelvic floor muscles, including the anal sphincters.

Presentation and Evaluation Patients are often concerned that the symptoms they are experiencing may be a cancer. The majority of complaints include anal mass, bleeding per rectum, and a change in bowel habits. Prolapse of the rectum usually occurs following defecation. It is often associated with mild bleeding and inability to maintain good perianal hygiene. Constipation and differing degrees of fecal incontinence are common complaints associated with rectal prolapse.

To evaluate a patient's prolapse in the office, it is best to give the patient an enema in the bathroom and to have them signal when the prolapse protrudes. An important distinction should be made between full-thickness rectal prolapse and isolated mucosal prolapse associated with hemorrhoidal disease (Fig. 279-4). Mucosal prolapse is known for radial grooves rather than circumferential folds around the anus and is due to increased laxity of the connective tissue between the submucosa and underlying muscle of the anal canal. The evaluation of prolapse should also include cystoproctography and colonoscopy. These examinations evaluate for associated pelvic floor disorders and rule out a malignancy or a polyp as the lead point for prolapse. If rectal prolapse is associated with constipation, the patient should undergo a sitzmark study. For patients with fecal incontinence, endoanal ultrasound and manometric evaluation, including pudendal nerve testing of their anal sphincter muscles, should be performed before surgery for prolapse (see "Fecal Incontinence," below).

℞ TREATMENT

The medical approach to the management of rectal prolapse is limited and includes stool-bulking agents or fiber supplementation to ease the process of evacuation. Surgical correction of rectal prolapse is the mainstay of therapy. Two approaches are commonly considered, transabdominal and transperineal. Transabdominal approaches have been associated with lower recurrence rates, but some patients with significant comorbidities are better served by a transperineal approach.

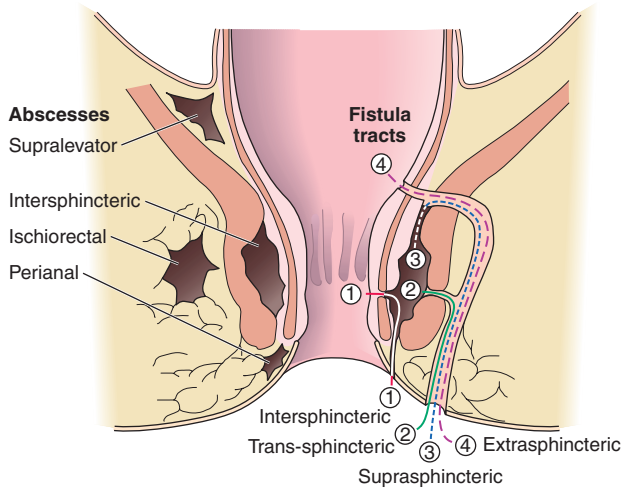

FIGURE 279-4 Common locations of anorectal abscess (*left*) and fistula in ano (*right*).

Common transperineal approaches include a transanal proctectomy (Altmeier procedure), mucosal proctectomy (Delorme procedure), or placement of a Tirsch wire encircling the anus. The goal of the transperineal approach is to remove the redundant rectosigmoid colon. Common transabdominal approaches include presacral suture or mesh rectopexy (Ripstein) with (Frykman-Goldberg) or without resection of the redundant sigmoid. The goal of the transabdominal approach is to attempt to restore normal anatomy by removing redundant bowel and reattaching the supportive tissue of the rectum to the presacral fascia. The final alternative is abdominal proctectomy with end-sigmoid colostomy. Colon resection, in general, is reserved for patients with constipation and outlet obstruction. If total colonic inertia is present, as defined by a history of constipation and a positive sitzmark study (retention of >20% of markers 5 days after swallowing), a subtotal colectomy with an ileosigmoid or rectal anastomosis may be required at the time of rectopexy.

FECAL INCONTINENCE ■ Incidence and Epidemiology The prevalence of fecal incontinence in the United States is 0.5 to 11%. The majority of patients are women. A higher incidence of incontinence is seen among parous women. One-half of patients with fecal incontinence also suffer from urinary incontinence. The majority of incontinence is a result of obstetric injury to the pelvic floor, either while carrying a fetus or during the delivery. Other causes include congenital abnormalities such as imperforate anus, trauma, or rectal prolapse.

Anatomy and Pathophysiology The anal sphincter complex is made up of the internal and external anal sphincter. The internal sphincter is smooth muscle and a continuation of the circular fibers of the rectal wall. It is innervated by the intestinal myenteric plexus and is therefore under involuntary control. The external anal sphincter is formed in continuation with the levator ani muscles and is under voluntary control. The pudendal nerve supplies motor innervation to the external anal sphincter. Obstetric injury may result in tearing of the muscle fibers anteriorly at the time of the delivery. This results in an obvious anterior defect on endoanal ultrasound. Injury may also be the result of stretching of the pudendal nerves. The majority of patients who suffer with fecal incontinence following obstetric injury do so several years following the birth of their last child.

Presentation and Evaluation Patients may suffer with varying degrees of fecal incontinence. Minor incontinence includes incontinence to flatus and occasional seepage of liquid stool. Major incontinence is frequent inability to control solid waste. As a result of fecal incontinence, patients suffer from poor perianal hygiene. Beyond the immediate problems associated with fecal incontinence, these patients are often

withdrawn and suffer from depression. For this reason, quality-of-life measures have become an important component in the evaluation of patients with fecal incontinence.

The evaluation of fecal incontinence should include a thorough history and physical examination, anal manometry, pudendal nerve terminal motor latency (PNTML), and endoanal ultrasound. Anal manometry determines the resting and squeeze pressures within the anal canal. Pudendal nerves studies evaluate the function of the nerves innervating the anal canal. Stretch injuries to these nerves will result in a delayed response of the sphincter muscle to a stimulus, indicating a prolonged latency. Finally, ultrasound will evaluate the extent of the injury to the sphincter muscles. Only PNTML has been able to predict outcome following surgical intervention.

Rarely does a pelvic floor disorder exist alone. The majority of patients with fecal incontinence will have a degree of urinary incontinence. Similarly, fecal incontinence is a part of the spectrum of pelvic organ prolapse. For this reason, patients may present with symptoms of obstructed defecation as well as fecal incontinence. Careful evaluation including cinedefography should be performed to search for other associated defects. Surgical repair of incontinence without attention to other associated defects may decrease the success of the repair.

℞ TREATMENT

The gold standard for the treatment of fecal incontinence with an isolated sphincter defect is overlapping sphincteroplasty. The external anal sphincter muscle and scar tissue as well as any identifiable internal sphincter muscle are dissected free from the surrounding adipose and connective tissue anteriorly and then an overlapping repair is performed in an attempt to rebuild the muscular ring and restore its function. Other newer approaches include radiofrequency therapy to the anal canal to aid in the development of collagen fibers and provide tensile strength to the sphincter muscles. Sacral nerve stimulation and the artificial bowel sphincter are both adaptations of procedures developed for the management of urinary incontinence. Sacral nerve stimulation is ideally suitable for patients with intact but weak anal sphincters. The artificial bowel sphincter allows the patient to manually close off the anal canal unless defecation is necessary.

Long-term results following overlapping sphincteroplasty show about a 50% failure rate over 5 years. Poorer outcome has been seen in patients with prolonged PNTML. Long-term results for sacral stimulation and the artificial bowel sphincter have not been reported. However, the artificial bowel sphincter has been associated with a 30% infection rate.

HEMORRHOIDAL DISEASE ■ **Incidence and Epidemiology** Symptomatic hemorrhoids affect >1 million individuals in western civilization per year. The prevalence of hemorrhoidal disease is not selective for age or sex. However, age is known to have a deleterious effect on the anal canal. The prevalence of hemorrhoidal disease is less in underdeveloped countries. The typical low-fiber, high-fat western diet is associated with constipation and straining, and the development of symptomatic hemorrhoids.

Anatomy and Pathophysiology Hemorrhoidal cushions are a normal part of the anal canal. The vascular structures contained within this tissue aid in continence by preventing damage to the sphincter muscle. Three main hemorrhoidal complexes traverse the anal canal—the left lateral, the right anterior, and the right posterior. Engorgement and straining results in prolapse of this tissue into the anal canal. Over time, the anatomic support system of the hemorrhoidal complex weakens, exposing this tissue to the outside of the anal canal where it is susceptible to injury. Hemorrhoids are commonly classified as internal or external. Although small external cushions do exist, the standard classification of hemorrhoidal disease is based on the progression of the disease from their normal internal location to the prolapsing external position (Table 279-4).

Presentation and Evaluation Patients commonly present to a physician for two reasons: bleeding and protrusion. Pain is less common than with fissures and, if present, is described as a dull ache from engorgement of the hemorrhoidal tissue. Severe pain may indicate a thrombosed hemorrhoid. Hemorrhoidal bleeding is described as bright red blood seen either in the toilet or upon wiping. Occasional patients can present with significant bleeding, which may be a cause of anemia; however, the presence of a colonic neoplasm must be ruled out. Patients who present with a protruding mass complain about inability to maintain perianal hygiene and are often concerned about the presence of a malignancy.

TABLE 279-4 The Staging and Treatment of Hemorrhoids

Stage	Description of Classification	Treatment
I	Enlargement with bleeding	Fiber supplementation Cortisone suppository Sclerotherapy
II	Protrusion with spontaneous reduction	Fiber supplementation Cortisone suppository
III	Protrusion requiring manual reduction	Fiber supplementation Cortisone suppository Banding Operative hemorrhoidectomy (stapled or traditional)
IV	Irreducible protrusion	Fiber supplementation Cortisone suppository Operative hemorrhoidectomy

The diagnosis of hemorrhoidal disease is made on physical examination. Inspection of the perianal region for evidence of thrombosis or excoriation is performed, followed by a careful digital examination. Anoscopy is performed paying particular attention to the known position of hemorrhoidal disease. The patient is asked to strain. If this is difficult for the patient, the maneuver can be performed while sitting on a toilet. The physician is notified when the tissue prolapses. It is important to differentiate the circumferential appearance of a full-thickness rectal prolapse from the radial nature of prolapsing hemorrhoids (see "Rectal Prolapse," above). The stage and location of the hemorrhoidal complexes are defined.

℞ TREATMENT

The treatment for bleeding hemorrhoids is based upon the stage of the disease (Table 279-4). In all patients with bleeding, the possibility of other causes must be considered. In young patients without a family history of colorectal cancer, the hemorrhoidal disease may be treated first and a colonoscopic examination performed if the bleeding continues. Older patients who have not had colorectal cancer screening should undergo colonoscopy or flexible sigmoidoscopy.

With rare exceptions, the acutely thrombosed hemorrhoid should be excised with an elliptical excision. Sitz baths, fiber, and stool softeners are prescribed. Additional therapy for bleeding hemorrhoids includes banding, sclerotherapy, excisional hemorrhoidectomy, and stapled hemorrhoidectomy. Sensation begins at the dentate line; therefore, banding or sclerotherapy can be performed without discomfort in the office. Two bands (doubled) are placed around the engorged tissue, causing ischemia and fibrosis. The aids in fixing the tissue proximally in the anal canal. During sclerotherapy, 1 to 2 mL of a sclerosant (usually sodium tetradechol sulfate) is injected using a 25-gauge needle into the submucosa of the hemorrhoidal complex. Care must be taken not to inject the anal canal circumferentially or stenosis may occur. The stapled hemorrhoidectomy is associated with less discomfort. It is currently recommended that no procedures on hemorrhoids should be done in patients who are immunocompromised or who have active proctitis. Furthermore, emergent hemorrhoidectomy for bleeding hemorrhoids is associated with a higher complication rate.

Acute complications associated with the treatment of hemorrhoids include pain, infection, recurrent bleeding, and urinary retention. Care should be taken to place bands properly and to avoid overhydration in

patients undergoing operative hemorrhoidectomy. Late complications include fecal incontinence as a result of injury to the sphincter during the dissection. Anal stenosis may develop from overzealous excision, with loss of mucosal skin bridges for reepithelialization. Finally, an *ectropion* (prolapse of rectal mucosa from the anal canal) may develop. Patients with an ectropion complain of a "wet" anus as a result of inability to prevent soiling once the rectal mucosa is exposed below the dentate line.

ANORECTAL ABSCESS ■ Incidence and Epidemiology The development of a perianal abscess is more common in men than women by a ratio of 3:1. The peak incidence is in the third to fifth decade of life. Perianal pain associated with the presence of an abscess accounts for 15% of office visits to a colorectal surgeon. The disease is more prevalent in immunocompromised patients such as diabetics, those with hematologic disorders or inflammatory bowel disease (IBD), and persons who are HIV positive. These disorders should be considered in patients with recurrent perianal infections.

Anatomy and Pathophysiology An anorectal abscess is an abnormal fluid-containing cavity in the anorectal region. Anorectal abscess results from an infection involving the glands surrounding the anal canal. Normally, these glands release mucus into the anal canal, which aids in defecation. When stool accidentally enters the anal glands, the glands become infected and an abscess develops. Anorectal abscesses are perianal in 40 to 50% of patients, ischiorectal in 20 to 25%, intersphincteric in 2 to 5%, and supralevator in 2.5% (Fig. 279-4).

Presentation and Evaluation Perianal pain and fever are the hallmarks of an abscess. Patients may have difficulty voiding and have blood in the stool. A prostatic abscess may present with similar complaints including dysuria. Patients with a prostatic abscess will often have a history of recurrent sexually transmitted diseases. On physical examination, a large fluctuant area is usually readily visible. Routine laboratory evaluation shows an elevated white blood cell count. Diagnostic procedures are rarely necessary unless evaluating a recurrent abscess. A CT scan or magnetic resonance imaging (MRI) has an accuracy of 80% in determining incomplete drainage. If there is a concern about the presence of IBD, a rigid or flexible sigmoidoscopic examination may be done at the time of drainage to evaluate for inflammation within the rectosigmoid region. A more complete evaluation for Crohn's disease would include a full colonoscopy and small-bowel series.

℞ TREATMENT

Office drainage of an uncomplicated anorectal abscess may suffice. A small incision close to the anal verge is made and a Mallenkot drain is advanced into the abscess cavity. For patients who have a complicated abscess or who are diabetic or immunocompromised, drainage should be performed in a operating room under anesthesia. These patients are at greater risk for developing necrotizing fasciitis. The course of antibiotics is controversial but should be at least 2 weeks in patients who are immunocompromised or have prosthetic heart valves, artificial joints, diabetes, or IBD.

FISTULA IN ANO ■ Incidence and Epidemiology The incidence and prevalence of fistulating perianal disease parallels the incidence of anorectal abscess. Some 30 to 40% of abscesses will give rise to fistula in ano. While the majority of the fistulas are cryptoglandular in origin, 10% are associated with IBD, tuberculosis, malignancy, and radiation.

Anatomy and Pathophysiology A fistula in ano is defined as a communication of an abscess cavity with an identifiable internal opening within the anal canal. This identifiable opening is most commonly located at the dentate line where the anal glands enter the anal canal. Patients experiencing continuous drainage following the treatment of a perianal abscess likely have a fistula in ano. These fistulas are classified by their relationship to the anal sphincter muscles, with 70% being intersphincteric, 23% transsphincteric, 5% suprasphincteric, and 2% extrasphincteric (Fig. 279-4).

Presentation and Evaluation A patient with a fistula in ano will complain of constant drainage from the perianal region. The drainage may increase with defecation. Perianal hygiene is difficult to maintain. Examination under anesthesia is the best way to evaluate a fistula. At the time of the examination, anoscopy is performed to look for an internal opening. Diluted hydrogen peroxide will aid in identifying such an opening. In lieu of anesthesia, MRI with an endoanal coil will also identify tracts in 80% of the cases. After drainage of an abscess with insertion of a Mallenkot catheter, a fistulagram through the catheter can be obtained in search of an occult fistula tract. Goodsale's rule states that a posterior external fistula will enter the anal canal in the posterior midline, whereas an anterior fistula will enter at the nearest crypt. A fistula exiting >3 cm from the anal verge may have a complicated upward extension and may not obey Goodsale's rule.

℞ TREATMENT

A newly diagnosed draining fistula is best managed with placement of a seton, a vessel loop or silk tie placed through the fistula tract, which maintains the tract open and quietens the surrounding inflammation that occurs from repeated blockage of the tract (Fig. 279-4). Once the inflammation is quietened, the exact relationship of the fistula tract to the anal sphincters can be ascertained. A simple fistulotomy can be performed for intersphincteric and low (less than one-third of the muscle) transphincteric fistulas without compromising continence. For a higher transphincteric fistula, an anorectal advancement flap in combination with a drainage catheter or fibrin glue may be used. Very long (>2 cm) and narrow tracts respond better to fibrin glue than shorter tracts. Patients should be maintained on stool-bulking agents, nonnarcotic pain medication, and sitz baths. Early complications from these procedures include urinary retention and bleeding. Later complications include temporary and permanent incontinence. Recurrence following fistulotomy is 0 to 18% and following anorectal advancement flap is 20 to 30% and is related to failure to excise and close the internal opening.

ANAL FISSURE ■ Incidence and Epidemiology Anal fissures occur at all ages but are more common in the third through the fifth decades. A fissure is the most common cause of rectal bleeding in infancy. The prevalence is equal in males and females. It is associated with constipation, diarrhea, infectious etiologies, perianal trauma, and Crohn's disease.

Anatomy and Pathophysiology Trauma to the anal canal occurs following defecation. This injury occurs in the anterior or, more commonly, the posterior anal canal. Irritation caused by the trauma to the anal canal results in an increased resting pressure of the internal sphincter. The blood supply to the sphincter and anal mucosa enters laterally. Therefore, increased anal sphincter tone results in a relative ischemia in the region of the fissure and leads to poor healing of the anal injury. A fissure that is not in the posterior or anterior position should raise suspicion for other causes including tuberculosis, syphilis, Crohn's disease, and malignancy.

Presentation and Evaluation A fissure can be easily diagnosed on history alone. The classic complaint is pain, which is strongly associated with defecation and is relentless. The bright red bleeding that can be associated with a fissure is less extensive than that associated with hemorrhoids. On examination, most fissures are located in either the posterior or anterior position. A lateral fissure is worrisome as it may have a less benign nature, and systemic disorders should be ruled out. A chronic fissure is indicated by the presence of a hypertrophied anal papilla at the proximal end of the fissure and a sentinel pile or skin tag at the distal end. Often the circular fibers of the hypertrophied internal sphincter are visible within the base of the fissure. If anal manometry is performed, elevation in anal resting pressure and a sawtooth deformity with paradoxical contractions of the sphincter muscles are pathognomonic.

TREATMENT

The management of the acute fissure is conservative. Stool softeners for those with constipation, increased dietary fiber, topical anesthetics, glucocorticoids, and sitz baths are prescribed and will heal 60 to 90% of fissures. Chronic fissures are those present for >6 weeks. These can be treated with modalities aimed at decreasing the anal canal resting pressure including nitroglycerin ointment (0.2%), applied three times a day, and botulinum toxin type A, up to 20 units, injected into the internal sphincter on each side of the fissure. Surgical management includes anal dilation and lateral internal sphincterotomy. Usually, one-third of the internal sphincter muscle is divided; it is easily identified because it is hypertrophied. Recurrence rates from medical therapy are higher, but this is offset by a risk of incontinence following sphincterotomy. Lateral internal sphincterotomy more commonly leads to incontinence in women.

ACKNOWLEDGMENT

We would like to thank Cory Sandore for providing the illustrations for this chapter.

280 ACUTE INTESTINAL OBSTRUCTION

William Silen

ETIOLOGY AND CLASSIFICATION Intestinal obstruction may be *mechanical* or *nonmechanical* (resulting from neuromuscular disturbances that produce either adynamic or dynamic ileus). The causes of mechanical obstruction of the lumen are conveniently divided into (1) lesions *extrinsic* to the intestine, e.g., adhesive bands, internal and external hernias; (2) lesions *intrinsic* to the wall of the intestine, e.g., diverticulitis, carcinoma, regional enteritis; and (3) obturation of the lumen, e.g., gallstone obstruction, intussusception. Clinically, however, it is most useful to consider whether the obstructive mechanism involves the small or large intestine, because the causes, symptoms, and treatments are different (see below). Adhesions and external hernias are the most common causes of obstruction of the small intestine, constituting 70 to 75% of cases of this type. Adhesions, however, almost never produce obstruction of the colon, whereas carcinoma, sigmoid diverticulitis, and volvulus, in that order, are the most common causes and together account for about 90% of the cases. Primary intestinal pseudoobstruction (Chap. 279) is a chronic motility disorder that frequently mimics mechanical obstruction. Unnecessary operations in such patients should be avoided.

Adynamic ileus is probably the most common overall cause of obstruction. The development of this condition is mediated via the hormonal component of the sympathoadrenal system. Adynamic ileus may occur after any peritoneal insult, and its severity and duration will be dependent to some degree on the type of peritoneal injury. Hydrochloric acid, colonic contents, and pancreatic enzymes are among the most irritating substances, whereas blood and urine are less so. Adynamic ileus occurs to some degree after any abdominal operation. Retroperitoneal hematomas, particularly associated with vertebral fracture, commonly cause severe adynamic ileus, and the latter may occur with other retroperitoneal conditions, such as ureteral calculus or severe pyelonephritis. Thoracic diseases, including lower-lobe pneumonia, fractured ribs, and myocardial infarction, frequently produce adynamic ileus, as do electrolyte disturbances, particularly potassium depletion. Finally, intestinal ischemia, whether the result of vascular occlusion or intestinal distention itself, may perpetuate an adynamic ileus.

Spastic ileus, or *dynamic ileus*, is very uncommon and results from extreme and prolonged contraction of the intestine. It has been observed in heavy metal poisoning, uremia, porphyria, and extensive intestinal ulcerations.

PATHOPHYSIOLOGY Distention of the intestine is caused by the accumulation of gas and fluid proximal to and within the obstructed segment. Between 70 and 80% of intestinal gas consists of swallowed air, and because this is composed mainly of nitrogen, which is poorly absorbed from the intestinal lumen, removal of air by continuous gastric suction is a useful adjunct in the treatment of intestinal distention. The accumulation of fluid proximal to the obstructing mechanism results not only from ingested fluid, swallowed saliva, gastric juice, and biliary and pancreatic secretions but also from interference with normal sodium and water transport. During the first 12 to 24 h of obstruction, there is a marked depression of flux from lumen to blood of sodium and consequently water in the distended proximal intestine. After 24 h, there is movement of sodium and water into the lumen, contributing further to the distention and fluid losses. Intraluminal pressure rises from a normal of 2 to 4 cmH_2O to 8 to 10 cmH_2O. During peristalsis, when simple obstruction or a "closed loop" is present, pressures reach 30 to 60 cmH_2O. Closed-loop obstruction of the small intestine results when the lumen is occluded at two points by a single mechanism such as a hernial ring or adhesive band, thus producing a closed loop whose blood supply is often obstructed at the same time. Strangulation of the loop itself is thus common in association with marked distention proximal to the involved loop. A form of closed-loop obstruction is encountered when complete obstruction of the colon exists in the presence of a competent ileocecal valve (85% of individuals). Although the blood supply of the colon is not entrapped within the obstructing mechanism, distention of the cecum is extreme because of its greater diameter (Laplace's law), and impairment of the intramural blood supply is considerable with consequent gangrene of the cecal wall, usually anteriorly. Necrosis of the small intestine may occur by the same mechanism of interference with intramural blood flow when distention is extreme, but this sequence is uncommon in the small intestine. Once impairment of blood supply occurs, bacterial invasion supervenes, and peritonitis develops. The systemic effects of extreme distention include elevation of the diaphragm with restricted ventilation and subsequent atelectasis. Venous return via the inferior vena cava may also be impaired.

The loss of fluids and electrolytes may be extreme and, unless replacement is prompt, leads to hemoconcentration, hypovolemia, renal insufficiency, shock, and death. Vomiting, accumulation of fluids within the lumen by the mechanisms described above, and the sequestration of fluid into the edematous intestinal wall and peritoneal cavity as a result of impairment of venous return from the intestine all contribute to massive loss of fluid and electrolytes, especially potassium. As soon as significant impedance to venous return is present,

the intestine becomes severely congested, and blood begins to seep into the intestinal lumen. Blood loss may reach significant levels when long segments of intestine are involved.

SYMPTOMS *Mechanical small-intestinal obstruction* is characterized by cramping midabdominal pain, which tends to be more severe the higher the obstruction. The pain occurs in paroxysms, and the patient is relatively comfortable in the intervals between the pains. Audible borborygmi are often noted by the patient simultaneously with the paroxysms of pain. The pain may become less severe as distention progresses, probably because motility is impaired in the edematous intestine. When strangulation is present, the pain is usually more localized and may be steady and severe without a colicky component, a fact that often causes delay in diagnosis of obstruction. Vomiting is almost invariable, and it is earlier and more profuse the higher the obstruction. The vomitus initially contains bile and mucus and remains as such if the obstruction is high in the intestine. With low ileal obstruction, the vomitus becomes feculent, i.e., orange-brown in color with a foul odor, which results from the overgrowth of bacteria proximal to the obstruction. Hiccups (singultus) are common. Obstipation and failure to pass gas by rectum are invariably present when the obstruction is complete, although some stool and gas may be passed spontaneously or after an enema shortly after onset of the complete obstruction. Diarrhea is occasionally observed in partial obstruction. Blood in the stool is rare but does occur in cases of intussusception. Other than some minor but inconsistent differences in pain patterns noted above, the symptoms of strangulating obstructions cannot be distinguished from those of nonstrangulating obstructions.

Mechanical colonic obstruction produces colicky abdominal pain similar in quality to that of small-intestinal obstruction but of much lower intensity. Complaints of pain are occasionally absent in stoic elderly patients. Vomiting occurs late, if at all, particularly if the ileocecal valve is competent. Paradoxically, feculent vomitus is very rare. A history of recent alterations in bowel habits and blood in the stool is common because carcinoma and diverticulitis are the most frequent causes. Constipation becomes progressive, and obstipation with failure to pass gas ensues. Acute symptoms may develop over a period of a week. Cecal volvulus more closely resembles obstruction of the small intestine clinically, whereas patients with sigmoid volvulus more typically have the picture of colonic obstruction in which marked distention predominates, with relatively less pain.

In *adynamic ileus*, colicky pain is absent, and only discomfort from distention is evident. Vomiting may be frequent but is rarely profuse. It usually consists of gastric contents and bile and is almost never feculent. Complete obstipation may or may not occur. Singultus (hiccups) is common.

PHYSICAL FINDINGS *Abdominal distention* is the hallmark of all forms of intestinal obstruction. It is least marked in cases of obstruction high in the small intestine and most marked in colonic obstruction. Early, especially in closed-loop strangulating small-bowel obstruction, distention may be barely perceptible or absent. Tenderness and rigidity are usually minimal; the temperature is rarely >37.8°C (100°F) in nonstrangulating obstruction of the small and large intestine. Contrary to popular belief, the same is true of strangulating obstruction until very late, a fact that has often resulted in unfortunate delay in treatment. Signs and symptoms of shock also occur *very late* in strangulating obstruction. The appearance of shock, tenderness, rigidity, and fever often means that contamination of the peritoneum with infected intestinal content has occurred. Hernial orifices should always be carefully examined for the presence of a mass. The presence of a palpable abdominal mass usually signifies a closed-loop strangulating small-bowel obstruction because the tense fluid-filled loop is the palpable lesion. Auscultation may reveal loud, high-pitched borborygmi coincident with the colicky pain, but this finding is often absent late in strangulating or nonstrangulating obstruction. A quiet abdomen does not eliminate the possibility of obstruction, nor does it necessarily establish the diagnosis of adynamic ileus.

LABORATORY AND X-RAY FINDINGS Leukocytosis, with shift to the left, usually occurs when strangulation is present, but a normal white blood cell count does not exclude strangulation. Elevation of the serum amylase level is encountered occasionally in all forms of intestinal obstruction, especially the strangulating variety.

The x-ray is extremely valuable but under certain circumstances may also be misleading. In nonstrangulating complete small-bowel obstruction, x-rays are almost completely reliable. Distention of fluid- and gas-filled loops of small intestine usually arranged in a "stepladder" pattern with air-fluid levels and an absence or paucity of colonic gas are pathognomonic (Fig. 280-1). These findings, however, are absent in slightly over half the cases of strangulating small-bowel obstruction, especially early in the disease. A general haze due to peritoneal fluid and sometimes a "coffee bean"–shaped mass are seen in strangulating obstruction. Occasionally, the films are normal, but when symptoms are consistent with obstruction of the small intestine, a normal film should suggest strangulation. In these circumstances, computed tomography may be very useful. Roentgenographic differentiation of partial mechanical small-bowel obstruction from adynamic ileus may be impossible because gas is present in both the small and large intestines; however, colonic distention is usually more prominent in adynamic ileus. A radiopaque dye given by mouth is useful in making this distinction.

Colonic obstruction with a competent ileocecal valve is easily recognized because distention with gas is mainly confined to the colon. Barium enema, sigmoidoscopy, or colonoscopy, depending on the suspected site of obstruction, is usually advisable to determine the nature of the lesion, except when concomitant perforation is suspected, a rare occurrence. Sigmoidoscopy may be therapeutic in cases of sigmoid volvulus. When the ileocecal valve is incompetent, the films resemble those of partial small-bowel obstruction or adynamic ileus, and barium enema or colonoscopy is necessary to establish the correct diagnosis. Barium given by mouth is perfectly safe when obstruction is in the small intestine, since the barium sulfate does not become inspissated

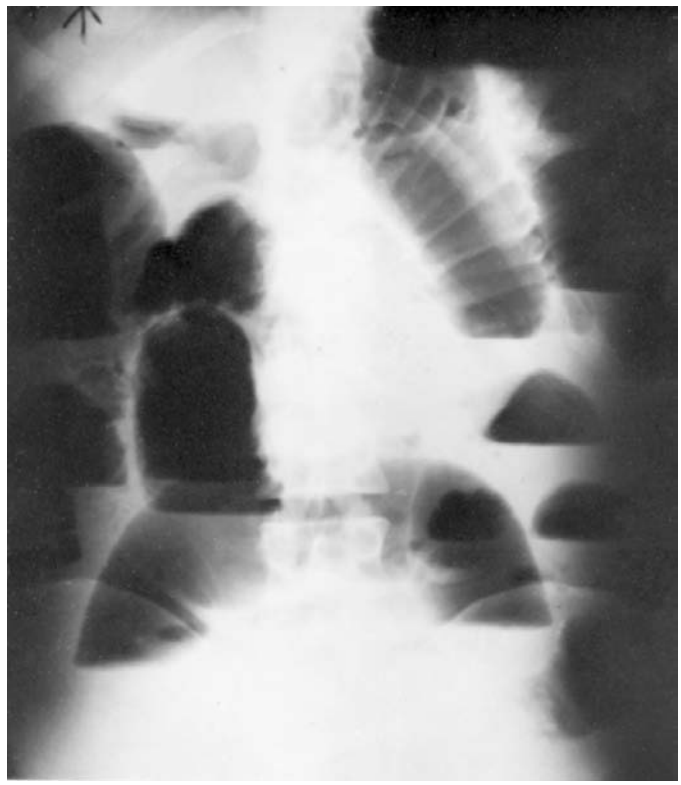

FIGURE 280-1 Acute mechanical obstruction of small intestine (upright film). Note air-fluid levels, marked distention of bowel loops, and absence of colonic gas.

in this location. *Barium should never be given by mouth to a patient with possible colonic obstruction* until that possibility has been excluded.

TREATMENT

Small-Intestinal Obstruction The overall mortality rate for obstruction of the small intestine is about 10%, even under the most optimal conditions. While the mortality rate for nonstrangulating obstruction is as low as 5 to 8%, that for strangulating obstruction has been reported to be between 20 and 75%. Well over half the deaths from small-bowel obstruction occur in those with strangulation; however, the latter constitute only one-fourth to one-third of the cases. Careful studies indicate that the clinical, laboratory, and x-ray findings are not reliable in distinguishing strangulating from nonstrangulating obstruction when obstruction is complete. Complete obstruction is suggested when passage of gas or stool per rectum has ceased and when gas is absent in the distal intestine by x-ray. Since strangulating small-bowel obstruction is always complete, operation should always be undertaken in such patients after suitable preparation. Before operation, fluid and electrolyte balance should be restored and decompression instituted by means of a nasogastric tube. Replacement of potassium is especially important because intake is nil and losses in vomitus are large. From 6 to 8 h of preparation may be necessary. During this period, broad-spectrum antibiotics are indicated if strangulation is felt to be likely, but operation should not be delayed unless there is unequivocal clinical and roentgenographic evidence of resolution of the obstruction during the period of preparation. Attempts to pass a long tube into the small intestine usually fail while putting the patient through uncomfortable, unproductive manipulations that delay appropriate fluid replacement and decompression. *There are few, if any, indications for the use of a long intestinal tube*. Procrastination of operation because of improvement in well-being of the patient during resuscitation and gastric decompression usually leads to unnecessary and hazardous delay in proper treatment. Purely nonoperative therapy is safe only in the presence of incomplete obstruction and is best utilized in patients with (1) repeated episodes of partial obstruction, (2) recent postoperative partial obstruction, and (3) partial obstruction following a recent episode of diffuse peritonitis.

Colonic Obstruction The mortality rate for colonic obstruction is about 20%. As in small-bowel obstruction, nonoperative treatment is contraindicated unless the obstruction is incomplete. Occasionally, but not always, when the obstruction is incomplete, nonoperative therapy may result in sufficient decompression that a definitive operative procedure can be undertaken at a later date. This can usually be accomplished by discontinuation of all oral intake and perhaps by nasogastric suction, although attempts to decompress a *completely* obstructed colon by intubation are almost invariably futile. A long intestinal tube will not decompress an obstructed colon with a competent ileocecal valve. When obstruction is complete, early operation is mandatory, especially when the ileocecal valve is competent; cecal gangrene is likely if the cecal diameter is >10 cm on plain abdominal film. For obstruction on the left side of the colon, the most common site, preliminary operative decompression by cecostomy or transverse colostomy followed by definitive resection of the primary lesion has been the treatment of choice. Recently, primary resection of obstructing left-sided lesions with on-table washout of the colon has been accomplished safely. For a lesion of the right or transverse colon, primary resection and anastomosis can be performed safely because distention of the ileum with consequent discrepancy in size and hazard in suture are not present.

Adynamic Ileus This type of ileus usually responds to nonoperative continuous decompression and adequate treatment of the primary disease. The prognosis is usually good. Successful decompression of severe colonic ileus has been accomplished by colonoscopy, but this should be avoided if tenderness in the right lower quadrant suggests possible cecal gangrene. Neostigmine is effective in cases of colonic ileus that have not responded to other conservative treatment. Rarely, adynamic colonic distention may become so great that cecostomy is required if cecal gangrene is feared. Spastic ileus usually responds to treatment of the primary disease.

281 ACUTE APPENDICITIS AND PERITONITIS

William Silen

ACUTE APPENDICITIS

INCIDENCE AND EPIDEMIOLOGY The peak incidence of acute appendicitis is in the second and third decades of life; it is relatively rare at the extremes of age. Males and females are equally affected, except between puberty and age 25, when males predominate in a 3:2 ratio. Perforation is more common in infancy and in the aged, during which periods mortality rates are highest. The mortality rate has decreased steadily in Europe and the United States from 8.1 per 100,000 of the population in 1941 to <1 per 100,000 in 1970 and subsequently. The absolute incidence of the disease also decreased by about 40% between 1940 and 1960 but since then has remained unchanged. Although various factors such as changing dietary habits, altered intestinal flora, and better nutrition and intake of vitamins have been suggested to explain the reduced incidence, the exact reasons have not been elucidated. The overall incidence of appendicitis is much lower in underdeveloped countries, especially parts of Africa, and in lower socioeconomic groups.

PATHOGENESIS Luminal obstruction has long been considered the pathogenetic hallmark. However, obstruction can be identified in only 30 to 40% of cases; ulceration of the mucosa is the initial event in the majority. The cause of the ulceration is unknown, although a viral etiology has been postulated. Infection with *Yersinia* organisms may cause the disease, since high complement fixation antibody titers have been found in up to 30% of cases of proven appendicitis. Whether the inflammatory reaction seen with ulceration is sufficient to obstruct the tiny appendiceal lumen even transiently is not clear. Obstruction, when present, is most commonly caused by a fecalith, which results from accumulation and inspissation of fecal matter around vegetable fibers. Enlarged lymphoid follicles associated with viral infections (e.g., measles), inspissated barium, worms (e.g., pinworms, *Ascaris*, and *Tae-*

nia), and tumors (e.g., carcinoid or carcinoma) may also obstruct the lumen. Secretion of mucus distends the organ, which has a capacity of only 0.1 to 0.2 mL, and luminal pressures rise as high as 60 cmH_2O. Luminal bacteria multiply and invade the appendiceal wall as venous engorgement and subsequent arterial compromise result from the high intraluminal pressures. Finally, gangrene and perforation occur. If the process evolves slowly, adjacent organs such as the terminal ileum, cecum, and omentum may wall off the appendiceal area so that a localized abscess will develop, whereas rapid progression of vascular impairment may cause perforation with free access to the peritoneal cavity. Subsequent rupture of primary appendiceal abscesses may produce fistulas between the appendix and bladder, small intestine, sigmoid, or cecum. Occasionally, acute appendicitis may be the first manifestation of Crohn's disease.

While chronic infection of the appendix with tuberculosis, amebiasis, and actinomycosis may occur, a useful clinical aphorism states that *chronic appendiceal inflammation is not usually the cause of prolonged abdominal pain of weeks' or months' duration*. In contrast, recurrent acute appendicitis does occur, often with complete resolution of inflammation and symptoms between attacks. Recurrent acute appendicitis may become more frequent as antibiotics are dispensed more freely and if a long appendiceal stump is left after laparoscopic appendectomy.

CLINICAL MANIFESTATIONS The history and sequence of symptoms are important diagnostic features of appendicitis. The initial symptom is almost invariably *abdominal pain* of the visceral type, resulting from appendiceal contractions or distention of the lumen. It is usually poorly localized in the periumbilical or epigastric region with an accompanying urge to defecate or pass flatus, neither of which relieves the distress. This visceral pain is mild, often cramping, and rarely catastrophic in nature, usually lasting 4 to 6 h, but it may not be noted by stoic individuals or by some patients during sleep. As inflammation spreads to the parietal peritoneal surfaces, the pain becomes somatic, steady, and more severe, aggravated by motion or cough, and usually located in the *right lower quadrant*. *Anorexia* is very common; a hungry patient does not have acute appendicitis. *Nausea* and *vomiting* occur in 50 to 60% of cases, but vomiting is usually self-limited. The development of nausea and vomiting before the onset of pain is extremely rare. Change in bowel habit is of little diagnostic value, since any or no alteration may be observed, although the presence of diarrhea caused by an inflamed appendix in juxtaposition to the sigmoid may cause serious diagnostic difficulties. Urinary frequency and dysuria occur if the appendix lies adjacent to the bladder. The typical sequence of symptoms (poorly localized periumbilical pain followed by nausea and vomiting with subsequent shift of pain to the right lower quadrant) occurs in only 50 to 60% of patients.

Physical findings vary with time after onset of the illness and according to the location of the appendix, which may be situated deep in the pelvic cul-de-sac; in the right lower quadrant in any relation to the peritoneum, cecum, and small intestine; in the right upper quadrant (especially during pregnancy); or even in the left lower quadrant. *The diagnosis cannot be established unless tenderness can be elicited.* While tenderness is sometimes absent in the early visceral stage of the disease, it ultimately always develops and is found in any location corresponding to the position of the appendix. Abdominal tenderness may be completely absent if a retrocecal or pelvic appendix is present, in which case the sole physical finding may be tenderness in the flank or on rectal or pelvic examination. Percussion, rebound tenderness, and referred rebound tenderness are often, but not invariably, present; they are most likely to be absent early in the illness. Flexion of the right hip and guarded movement by the patient are due to parietal peritoneal involvement. Hyperesthesia of the skin of the right lower quadrant and a positive psoas or obturator sign are often late findings and are rarely of diagnostic value. When the inflamed appendix is in close proximity to the anterior parietal peritoneum, muscular rigidity is present yet is often minimal early.

The temperature is usually normal or slightly elevated [37.2 to 38°C (99 to 100.5°F)], but a temperature >38.3°C (101°F) should suggest perforation. Tachycardia is commensurate with the elevation of the temperature. Rigidity and tenderness become more marked as the disease progresses to perforation and localized or diffuse peritonitis. Distention is rare unless severe diffuse peritonitis has developed. The disappearance of pain and tenderness just before perforation is extremely unusual. A mass may develop if localized perforation has occurred but will not usually be detectable before 3 days after onset. Earlier presence of a mass suggests carcinoma of the cecum or Crohn's disease. Perforation is rare before 24 h after onset of symptoms, but the rate may be as high as 80% after 48 h.

Diagnosis is based primarily on clinical grounds. Although moderate leukocytosis of 10,000 to 18,000 cells/μL is frequent (with a concomitant left shift), the absence of leukocytosis does not rule out acute appendicitis. Leukocytosis of >20,000 cells/μL suggests probable perforation. Anemia and blood in the stool suggest a primary diagnosis of carcinoma of the cecum, especially in elderly individuals. The urine may contain a few white or red blood cells without bacteria if the appendix lies close to the right ureter or bladder. Urinalysis is most useful in excluding genitourinary conditions that may mimic acute appendicitis.

Radiographs are rarely of value except when an opaque fecalith (5% of patients) is observed in the right lower quadrant (especially in children). Consequently, abdominal films are not routinely obtained unless other conditions such as intestinal obstruction or ureteral calculus may be present. In some patients with recurrent or prolonged symptoms, computed tomography (CT) may reveal an extrinsic defect on the medial wall of the cecum or a calcified fecalith. The predictive value of CT scan in acute appendicitis is being evaluated. The diagnosis may also be established by the ultrasonic demonstration of an enlarged and thick-walled appendix. Ultrasound is most useful to exclude ovarian cysts, ectopic pregnancy, or tuboovarian abscess.

While the typical historic sequence and physical findings are present in 50 to 60% of cases, a wide variety of atypical patterns of disease are encountered, especially at the age extremes and during pregnancy. Infants under 2 years of age have a 70 to 80% incidence of perforation and generalized peritonitis. Any infant or child with diarrhea, vomiting, and abdominal pain is highly suspect. Fever is much more common in this age group, and abdominal distention is often the only physical finding. In the elderly, pain and tenderness are often blunted, and thus the diagnosis is frequently delayed and leads to a 30% incidence of perforation in patients over 70. Elderly patients often present initially with a slightly painful mass (a primary appendiceal abscess) or with adhesive intestinal obstruction 5 or 6 days after a previously undetected perforated appendix.

Appendicitis occurs about once in every 1000 pregnancies and is the most common extrauterine condition requiring abdominal operation. The diagnosis may be missed or delayed because of the frequent occurrence of mild abdominal discomfort and nausea and vomiting during pregnancy. During the last trimester, when the mortality rate from appendicitis is highest, uterine displacement of the appendix to the right upper quadrant and laterally leads to confusion in diagnosis because pain and tenderness are similarly displaced.

DIFFERENTIAL DIAGNOSIS Appendicitis can be confused with any condition that causes abdominal pain. Diagnostic accuracy is about 75 to 80% for experienced clinicians based solely on the clinical criteria outlined. It is probably better to err slightly in the direction of overdiagnosis, since delay is associated with perforation and increased morbidity and mortality. In unperforated appendicitis, the mortality rate is 0.1%, little more than that associated with general anesthesia; for perforated appendicitis, overall mortality is 3% (15% in the elderly). In doubtful cases, 4 to 6 h of observation is always more beneficial than harmful. The most common conditions discovered at operation when acute appendicitis is erroneously diagnosed are, in order of frequency, mesenteric lymphadenitis, no organic disease, acute pelvic inflammatory disease, ruptured graafian follicle or corpus luteum

cyst, and acute gastroenteritis. In addition, acute cholecystitis, perforated ulcer, acute pancreatitis, acute diverticulitis, strangulating intestinal obstruction, ureteral calculus, and pyelonephritis may present diagnostic difficulties.

Differentiation of *pelvic inflammatory disease* from acute appendicitis on clinical grounds may be virtually impossible. Gram-negative intracellular diplococci on cervical smear are not pathognomonic unless *Neisseria gonorrhoeae* can be cultured. Pain on movement of the cervix is not specific and may occur in appendicitis if perforation has occurred or if the appendix lies adjacent to the uterus or adnexa. *Rupture of a graafian follicle* (mittelschmerz) occurs at midcycle and will spill off blood and fluid to produce pain and tenderness more diffuse and usually of a less severe degree than in appendicitis. Fever and leukocytosis are usually absent. *Rupture of a corpus luteum cyst* is identical clinically to rupture of a graafian follicle but develops about the time of menstruation. The presence of an adnexal mass, evidence of blood loss, and a positive pregnancy test help differentiate *ruptured tubal pregnancy*, but a negative pregnancy test is present when tubal abortion has occurred. *Twisted ovarian cyst* and *endometriosis* are occasionally difficult to distinguish from appendicitis. In all these female conditions, ultrasonography, laparoscopy, and occasionally CT may be of great value.

Acute mesenteric lymphadenitis is the diagnosis usually given when enlarged, slightly reddened lymph nodes at the root of the mesentery and a normal appendix are encountered at operation in a patient who usually has right lower quadrant tenderness. Whether this is a single, discrete entity is unclear, since the causative factor is not known. Some of these patients have infection with *Y. pseudotuberculosis* or *Y. enterocolytica*, in which case the diagnosis can be established by culture of the mesenteric nodes or by serologic titers (Chap. 143). The diagnosis is essentially impossible clinically, although retrospectively these patients may have a higher temperature and more diffuse pain and tenderness. Children seem to be affected more frequently than adults. *Acute gastroenteritis* usually causes profuse watery diarrhea, often with nausea and vomiting, but without localized findings. Between cramps, the abdomen is completely relaxed. In *Salmonella* gastroenteritis, the abdominal findings are similar, although the pain may be more severe and more localized, and fever and chills are common. The occurrence of similar symptoms among other members of the family may be helpful. When the diagnosis of acute pelvic appendicitis with perforation has been missed, gastroenteritis is the most common previous working diagnosis. Persistent abdominal or rectal tenderness should eliminate the diagnosis of gastroenteritis. *Regional enteritis* (Crohn's disease) is usually associated with a more prolonged history, often with previous exacerbations regarded as episodes of gastroenteritis unless the diagnosis has been established previously. *Meckel's diverticulitis* usually cannot be distinguished from acute appendicitis but is very rare.

TREATMENT

Cathartics and enemas should be avoided if appendicitis is under consideration, and antibiotics should not be administered when the diagnosis is in question, since they will only mask the perforation. The treatment is early operation and appendectomy as soon as the patient can be prepared. Appendectomy is increasingly accomplished laparoscopically and may have some benefits over the open technique. Preparation for operation rarely takes more than 1 to 2 h in early appendicitis but may require 6 to 8 h in cases of severe sepsis and dehydration associated with late perforation. The *only* circumstance in which operation is *not* indicated is the presence of a palpable mass 3 to 5 days after the onset of symptoms. Should operation be undertaken at that time, a phlegmon rather than a definitive abscess will be found, and complications from its dissection are frequent. Such patients treated with broad-spectrum antibiotics, parenteral fluids, and rest usually show resolution of the mass and symptoms within 1 week. *Interval appendectomy* should be done safely 3 months later. Should the mass enlarge or the patient become more toxic, drainage of the abscess is necessary. The complications of subphrenic, pelvic, or other intraabdominal abscesses usually follow perforation with generalized peritonitis and can be avoided by early diagnosis of the disease.

ACUTE PERITONITIS

Peritonitis is an inflammation of the peritoneum; it may be localized or diffuse in location, acute or chronic in natural history, infectious or aseptic in pathogenesis. Acute peritonitis is most often infectious and is usually related to a perforated viscus (and called secondary peritonitis). When no bacterial source is identified, infectious peritonitis is called primary or spontaneous. Acute peritonitis is associated with decreased intestinal motor activity resulting in distention of the intestinal lumen with gas and fluid. The accumulation of fluid in the bowel together with the lack of oral intake leads to rapid intravascular volume depletion with effects on cardiac, renal, and other systems.

ETIOLOGY Infectious agents gain access to the peritoneal cavity through a perforated viscus, a penetrating wound of the abdominal wall, or external introduction of a foreign object that is or becomes infected (for example, a chronic peritoneal dialysis catheter). In the absence of immune compromise, host defenses are capable of eradicating small contaminations. Large numbers of mixed aerobic and anaerobic bacteria, particularly when persistently infused, can lead to peritonitis. The conditions that most commonly result in the introduction of bacteria into the peritoneum are ruptured appendix, ruptured diverticulum, perforated peptic ulcer, incarcerated hernia, gangrenous gall bladder, volvulus, bowel infarction, cancer, inflammatory bowel disease, or intestinal obstruction. However, a wide range of mechanisms may play a role (Table 281-1). Bacterial peritonitis can also occur in the apparent absence of an intraperitoneal source of bacteria (primary or spontaneous bacterial peritonitis). This condition occurs in the setting of ascites and liver cirrhosis in 90% of the cases, usually in patients with ascites with low protein concentration (<1 g/L) (Chap. 289). →***Bacterial peritonitis is discussed in detail in Chap. 112.***

Aseptic peritonitis may be due to peritoneal irritation by abnormal presence of physiologic fluids (e.g., gastric juice, bile, pancreatic enzymes, blood, or urine) or sterile foreign bodies (e.g., surgical sponges or instruments, starch from surgical gloves) in the peritoneal cavity or as a complication of rare systemic diseases such as lupus erythematosus, porphyria, or familial Mediterranean fever (Chap. 278). Chemical irritation of the peritoneum is greatest for acidic gastric juice and pancreatic enzymes. In chemical peritonitis, a major risk of secondary bacterial infection exists.

TABLE 281-1 Conditions Leading to Secondary Bacterial Peritonitis

Perforations of bowel	**Perforations or leaking of other organs**
Trauma, blunt or penetrating	Pancreas—pancreatitis
Inflammation	Gall bladder—cholecystitis
Appendicitis	Urinary bladder—trauma, rupture
Diverticulitis	Liver—bile leak after biopsy
Peptic ulcer disease	Fallopian tubes—salpingitis
Inflammatory bowel disease	Bleeding into the peritoneal cavity
Iatrogenic	**Disruption of integrity of peritoneal cavity**
Endoscopic perforation	Trauma
Anastomotic leaks	Continuous ambulatory peritoneal dialysis (indwelling catheter)
Catheter perforation	Intraperitoneal chemotherapy
Vascular	Perinephric abscess
Embolus	Iatrogenic—postoperative, foreign body
Ischemia	
Obstructions	
Adhesions	
Strangulated hernias	
Volvulus	
Intussusception	
Neoplasms	
Ingested foreign body, toothpick, fish bone	

CLINICAL FEATURES The cardinal manifestations of peritonitis are acute abdominal pain and tenderness, usually with fever. The location of the pain depends on the underlying cause and whether the inflammation is localized or generalized. Localized peritonitis is most common in uncomplicated appendicitis and diverticulitis and physical findings are limited to the area of inflammation. Generalized peritonitis is associated with widespread inflammation and diffuse abdominal tenderness and rebound. Rigidity of the abdominal wall is common in both localized and generalized peritonitis. Bowel sounds are usually absent. Tachycardia, hypotension, and signs of dehydration are common. Leukocytosis and acidosis are common laboratory findings. Plain abdominal films may show dilation of large and small bowel with edema of the bowel wall. Free air under the diaphragm is associated with a perforated viscus. CT and/or ultrasonography can identify the presence of free fluid or an abscess. When ascites is present, diagnostic paracentesis with cell count (>250 neutrophils/μL is usual in peritonitis), protein and lactate dehydrogenase levels, and culture is essential. In elderly and immunosuppressed patients, signs of peritoneal irritation may be more difficult to detect.

THERAPY AND PROGNOSIS Treatment relies on rehydration, correction of electrolyte abnormalities, antibiotics, and surgical correction of the underlying defect. Mortality rates are <10% for uncomplicated peritonitis associated with a perforated ulcer or ruptured appendix or diverticulum in an otherwise healthy person. Mortality rates of ≥40% have been reported for elderly people, those with underlying illnesses, and when peritonitis has been present for >48 h.

Section 2 Liver and Biliary Tract Disease

282 APPROACH TO THE PATIENT WITH LIVER DISEASE

Marc Ghany, Jay H. Hoofnagle

In most instances, a diagnosis of liver disease can be made accurately by a careful history, physical examination, and application of a few laboratory tests. In some circumstances, radiologic examinations are helpful or, indeed, diagnostic. Liver biopsy is considered the "gold standard" in evaluation of liver disease but is now needed less for diagnosis than for grading and staging disease. This chapter provides an introduction to diagnosis and management of liver disease, briefly reviewing the structure and function of the liver; the major clinical manifestations of liver disease; and the use of clinical history, physical examination, laboratory tests, imaging studies, and liver biopsy.

LIVER STRUCTURE AND FUNCTION The liver is the largest organ of the body, weighing 1 to 1.5 kg and representing 1.5 to 2.5% of the lean body mass. The size and shape of the liver vary and generally match the general body shape—long and lean or squat and square. The liver is located in the right upper quadrant of the abdomen under the right lower rib cage against the diaphragm and projects for a variable extent into the left upper quadrant. The liver is held in place by ligamentous attachments to the diaphragm, peritoneum, great vessels, and upper gastrointestinal organs. It receives a dual blood supply; approximately 20% of the blood flow is oxygen-rich blood from the hepatic artery, and 80% is nutrient-rich blood from the portal vein arising from the stomach, intestines, pancreas, and spleen.

The majority of cells in the liver are hepatocytes, which constitute two-thirds of the mass of the liver. The remaining cell types are Kupffer cells (members of the reticuloendothelial system), stellate (Ito or fat-storing) cells, endothelial cells and blood vessels, bile ductular cells, and supporting structures. Viewed by light microscopy, the liver appears to be organized in lobules, with portal areas at the periphery and central veins in the center of each lobule. However, from a functional point of view, the liver is organized into acini, with both hepatic arterial and portal venous blood entering the acinus from the portal areas (zone 1) and then flowing through the sinusoids to the terminal hepatic veins (zone 3); the intervening hepatocytes constituting zone 2. The advantage of viewing the acinus as the physiologic unit of the liver is that it helps to explain the morphologic patterns and zonality of many vascular and biliary diseases not explained by the lobular arrangement.

Portal areas of the liver consist of small veins, arteries, bile ducts, and lymphatics organized in a loose stroma of supporting matrix and small amounts of collagen. Blood flowing into the portal areas is distributed through the sinusoids, passing from zone 1 to zone 3 of the acinus and draining into the terminal hepatic veins ("central veins"). Secreted bile flows in the opposite direction, in a counter current pattern from zone 2 to zone 1. The sinusoids are lined by unique endothelial cells that have prominent fenestrae of variable size, allowing the free flow of plasma but not cellular elements. The plasma is thus in direct contact with hepatocytes in the subendothelial space of Disse.

Hepatocytes have distinct polarity. The basolateral side of the hepatocyte lines the space of Disse and is richly lined with microvilli; it demonstrates endocytotic and pinocytotic activity, with passive and active uptake of nutrients, proteins, and other molecules. The apical pole of the hepatocyte forms the cannicular membranes through which bile components are secreted. The canniculi of hepatocytes form a fine network, which fuses into the bile ductular elements near the portal areas. Kupffer cells usually lie within the sinusoidal vascular space and represent the largest group of fixed macrophages in the body. The stellate cells are located in the space of Disse but are not usually prominent unless activated, when they produce collagen and matrix. Red blood cells stay in the sinusoidal space as blood flows through the lobules, but white blood cells can migrate through or around endothelial cells into the space of Disse and from there to portal areas, where they can return to the circulation through lymphatics.

Hepatocytes perform numerous and vital roles in maintaining homeostasis and health. These functions include the synthesis of most essential serum proteins (albumin, carrier proteins, coagulation factors, many hormonal and growth factors), the production of bile and its carriers (bile acids, cholesterol, lecithin, phospholipids), the regulation of nutrients (glucose, glycogen, lipids, cholesterol, amino acids), and metabolism and conjugation of lipophilic compounds (bilirubin, anions, cations, drugs) for excretion in the bile or urine. Measurement of these activities to assess liver function is complicated by the multi-

plicity and variability of these functions. The most commonly used liver "function" tests are measurements of serum bilirubin, albumin, and prothrombin time. The serum bilirubin level is a measure of hepatic conjugation and excretion, and the serum albumin level and prothrombin time are measures of protein synthesis. Abnormalities of bilirubin, albumin, and prothrombin time are typical of hepatic dysfunction. Frank liver failure is incompatible with life, and the functions of the liver are too complex and diverse to be subserved by a mechanical pump; dialysis membrane; or concoction of infused hormones, proteins, and growth factors.

TABLE 282-1 Liver Diseases

- Inherited hyperbilirubinemia
  - Gilbert's syndrome
  - Crigler-Najjar syndrome, types I and II
  - Dubin-Johnson syndrome
  - Rotor syndrome
- Viral hepatitis
  - Hepatitis A
  - Hepatitis B
  - Hepatitis C
  - Hepatitis D
  - Hepatitis E
  - Others (mononucleosis, herpes, adenovirus hepatitis)
  - Cryptogenic hepatitis
- Immune and autoimmune liver diseases
  - Primary biliary cirrhosis
  - Autoimmune hepatitis
  - Sclerosing cholangitis
  - Overlap syndromes
  - Graft-vs-host disease
  - Allograft rejection
- Genetic liver diseases
  - α_1 Antitrypsin deficiency
  - Hemochromatosis
  - Wilson's disease
  - Benign recurrent intrahepatic cholestasis (BRIC)
  - Familial intrahepatic cholestasis (FIC), types I–III
  - Others (galactosemia, tyrosinemia, cystic fibrosis, Newman-Pick disease, Gaucher's disease)
- Alcoholic liver disease
  - Acute fatty liver
  - Acute alcoholic hepatitis
  - Laennec's cirrhosis
- Nonalcoholic fatty liver
  - Steatosis
  - Steatohepatitis
- Acute fatty liver of pregnancy
- Liver involvement in systemic diseases
  - Sarcoidosis
  - Amyloidosis
  - Glycogen storage diseases
  - Celiac disease
  - Tuberculosis
    - *Myobacterium avium intracellulare*
- Cholestatic syndromes
  - Benign postoperative cholestasis
  - Jaundice of sepsis
  - Total parenteral nutrition (TPN)–induced jaundice
  - Cholestasis of pregnancy
  - Cholangitis and cholecystitis
  - Extrahepatic biliary obstruction (stone, stricture, cancer)
  - Biliary atresia
  - Caroli's disease
  - Cryptosporidiosis
- Drug-induced liver disease
  - Hepatocellular patterns (isoniazid, acetaminophen)
  - Cholestatic patterns (methyltestosterone)
  - Mixed patterns (sulfonamides, phenytoin)
  - Micro- and macrovesicular steatosis (methotrexate, fialuridine)
- Vascular injury
  - Venoocclusive disease
  - Budd-Chiari syndrome
  - Ischemic hepatitis
  - Passive congestion
  - Portal vein thrombosis
  - Nodular regenerative hyperplasia
- Mass lesions
  - Hepatocellular carcinoma
  - Cholangiocarcinoma
  - Adenoma
  - Focal nodular hyperplasia
  - Metastatic tumors
  - Abscess
  - Cysts

LIVER DISEASES While there are many causes of liver disease (Table 282-1), they generally present clinically in a few distinct patterns, usually classified as hepatocellular, cholestatic (obstructive), or mixed. In *hepatocellular diseases* (such as viral hepatitis or alcoholic liver disease), features of liver injury, inflammation, and necrosis predominate. In *cholestatic diseases* (such as gall stone or malignant obstruction, primary biliary cirrhosis, some drug-induced liver diseases), features of inhibition of bile flow predominate. In a mixed pattern, features of both hepatocellular and cholestatic injury are present (such as in cholestatic forms of viral hepatitis and many drug-induced liver diseases). The pattern of onset and prominence of symptoms can rapidly suggest a diagnosis, particularly if major risk factors are considered, such as the age and sex of the patient and a history of exposure or risk behaviors.

Typical presenting symptoms of liver disease include jaundice, fatigue, itching, right upper quadrant pain, abdominal distention, and intestinal bleeding. At present, however, many patients are diagnosed with liver disease who have no symptoms and who have been found to have abnormalities in biochemical liver tests as a part of a routine physical examination or screening for blood donation or for insurance or employment. The wide availability of batteries of liver tests makes it relatively simple to demonstrate the presence of liver injury as well as to rule it out in someone suspected of liver disease.

Evaluation of patients with liver disease should be directed at (1) establishing the etiologic diagnosis, (2) estimating the disease severity (grading), and (3) establishing the disease stage (staging). *Diagnosis* should focus on the category of disease, such as hepatocellular, cholestatic, or mixed injury, as well as on the specific etiologic diagnosis. *Grading* refers to assessing the severity or activity of disease—active or inactive, and mild, moderate, or severe. *Staging* refers to estimating the place in the course of the natural history of the disease, whether acute or chronic; early or late; precirrhotic, cirrhotic, or end-stage.

The goal of this chapter is to introduce general, salient concepts in the evaluation of patients with liver disease that help lead to the diagnoses discussed in subsequent chapters.

CLINICAL HISTORY The clinical history should focus on the symptoms of liver disease—their nature, pattern of onset, and progression—and on potential risk factors for liver disease. The symptoms of liver disease include constitutional symptoms such as fatigue, weakness, nausea, poor appetite, and malaise and the more liver-specific symptoms of jaundice, dark urine, light stools, itching, abdominal pain, and bloating. Symptoms can also suggest the presence of cirrhosis, end-stage liver disease, or complications of cirrhosis such as portal hypertension. Generally, the constellation of symptoms and their pattern of onset rather than a specific symptom points to an etiology.

Fatigue is the most common and most characteristic symptom of liver disease. It is variously described as lethargy, weakness, listlessness, malaise, increased need for sleep, lack of stamina, and poor energy. The fatigue of liver disease typically arises after activity or exercise and is rarely present or severe in the morning after adequate rest (afternoon versus morning fatigue). Fatigue in liver disease is often intermittent and variable in severity from hour to hour and day to day. In some patients, it may not be clear whether fatigue is due to the liver disease or to other problems such as stress, anxiety, sleep disturbance, or a concurrent illness.

Nausea occurs with more severe liver disease and may accompany fatigue or be provoked by odors of food or eating fatty foods. Vomiting can occur but is rarely persistent or prominent. Poor appetite with weight loss occurs commonly in acute liver diseases but is rare in chronic disease, except when cirrhosis is present and advanced. Diarrhea is uncommon in liver disease, except with severe jaundice, where lack of bile acids reaching the intestine can lead to steatorrhea.

Right upper quadrant discomfort or ache ("liver pain") occurs in many liver diseases and is usually marked by tenderness over the liver area. The pain arises from stretching or irritation of Glisson's capsule, which surrounds the liver and is rich in nerve endings. Severe pain is most typical of gall bladder disease, liver abscess, and severe venoocclusive disease but is an occasional accompaniment of acute hepatitis.

Itching occurs with acute liver disease, appearing early in obstruc-

tive jaundice (from biliary obstruction or drug-induced cholestasis) and somewhat later in hepatocellular disease (acute hepatitis). Itching also occurs in chronic liver diseases, typically the cholestatic forms such as primary biliary cirrhosis and sclerosing cholangitis where it is often the presenting symptom, occurring before the onset of jaundice. However, itching can occur in any liver disease, particularly once cirrhosis is present.

Jaundice is the hallmark symptom of liver disease and perhaps the most reliable marker of severity. Patients usually report darkening of the urine before they notice scleral icterus. Jaundice is rarely detectable with a bilirubin level <43 μmol/L (2.5 mg/dL). With severe cholestasis there will also be lightening of the color of the stools and steatorrhea. Jaundice without dark urine usually indicates indirect (unconjugated) hyperbilirubinemia and is typical of hemolytic anemia and the genetic disorders of bilirubin conjugation, the common and benign form being Gilbert's syndrome and the rare and severe form being Crigler-Najjar syndrome. Gilbert's syndrome affects up to 5% of the population; the jaundice is more noticeable after fasting and with stress.

Major risk factors for liver disease that should be sought in the clinical history include details of alcohol use, medications (including herbal compounds, birth control pills, and over-the-counter medications), personal habits, sexual activity, travel, exposure to jaundiced or other high-risk persons, injection drug use, recent surgery, remote or recent transfusion with blood and blood products, occupation, accidental exposure to blood or needlestick, and familial history of liver disease.

For assessing the risk of viral hepatitis, a careful history of sexual activity is of particular importance and should include number of lifetime sexual partners and, for men, a history of having sex with men. Sexual exposure is a common mode of spread of hepatitis B but is rare for hepatitis C. A family history of hepatitis, liver disease, and liver cancer is also important. Maternal-infant transmission occurs with both hepatitis B and C. Vertical spread of hepatitis B can now be prevented by passive and active immunization of the infant at birth. Vertical spread of hepatitis C is uncommon, but there are no reliable means of prevention. A history of injection drug use, even in the remote past, is of great importance in assessing the risk for hepatitis B and C. Injection drug use is now the single most common risk factor for hepatitis C. Transfusion with blood or blood products is no longer an important risk factor for acute viral hepatitis. However, blood transfusions received before the introduction of sensitive enzyme immunoassays for antibody to hepatitis C virus (anti-HCV) in 1992 is an important risk factor for chronic hepatitis C. Blood transfusion before 1986, when screening for antibody to hepatitis B core antigen (anti-HBc) was introduced, is also a risk factor for hepatitis B. Travel to an underdeveloped area of the world, exposure to persons with jaundice, and exposure to young children in day-care centers are risk factors for hepatitis A. Tattooing and body piercing (for hepatitis B and C) and eating shellfish (for hepatitis A) are frequently mentioned but actually quite rate types of exposure for acquiring hepatitis.

A history of alcohol intake is important in assessing the cause of liver disease and also in planning management and recommendations. In the United States, for example, at least 70% of adults drink alcohol to some degree, but significant alcohol intake is less common; in population-based surveys, only 5% have more than two drinks per day, the average drink representing 11 to 15 g alcohol. Alcohol consumption associated with an increased rate of alcoholic liver disease is probably more than two drinks (22 to 30 g) per day in women and three drinks (33 to 45 g) in men. Most patients with alcoholic cirrhosis have a much higher daily intake and have drunk excessively for 10 years or more before onset of liver disease. In assessing alcohol intake, the history should also focus upon whether alcohol abuse or dependence is present. Alcoholism is usually defined on the behavioral patterns and consequences of alcohol intake, not on the basis of the amount of alcohol intake. *Abuse* is defined by a repetitive pattern of drinking alcohol that has adverse effects on social, family, occupational, or health status. *Dependence* is defined by alcohol-seeking behavior, despite its adverse effects. Many alcoholics demonstrate both dependence and abuse, and dependence is considered the more serious and advanced form of alcoholism. A clinically helpful approach to diagnosis of alcohol dependence and abuse is the use of the CAGE questionnaire (Table 282-2), which is recommended in all medical history taking.

Family history can be helpful in assessing liver disease. Familial causes of liver disease include Wilson's disease; hemochromatosis and α_1 antitrypsin (α_1AT) deficiency; and the more uncommon inherited pediatric liver diseases of familial intrahepatic cholestasis, benign recurrent intrahepatic cholestasis, and Alagille's syndrome. Onset of severe liver disease in childhood or adolescence with a family history of liver disease or neuropsychiatric disturbance should lead to investigation for Wilson's disease. A family history of cirrhosis, diabetes, or endocrine failure and the appearance of liver disease in adulthood should suggest hemochromatosis and lead to investigation of iron status. Patients with abnormal iron studies warrant genotyping of the *HFE* gene for the C282Y and H63D mutations typical of genetic hemochromatosis. A family history of emphysema should provoke investigation of α_1AT levels and, if low, for Pi genotype.

PHYSICAL EXAMINATION The physical examination rarely demonstrates evidence of liver dysfunction in a patient without symptoms or laboratory findings, nor are most signs of liver disease specific to one diagnosis. Thus, the physical examination usually complements rather than replaces the need for other diagnostic approaches. In many patients, the physical examination is normal unless the disease is acute or severe and advanced. Nevertheless, the physical examination is important in that it can be the first evidence for the presence of hepatic failure, portal hypertension, and liver decompensation. In addition, the physical examination can reveal signs that point to a specific diagnosis, either in risk factors or in associated diseases or findings.

Typical physical findings in liver disease are icterus, hepatomegaly, hepatic tenderness, splenomegaly, spider angiomata, palmar erythema, and excoriations. Signs of advanced disease include muscle-wasting, ascites, edema, dilated abdominal veins, hepatic fetor, asterixis, mental confusion, stupor, and coma. In males with cirrhosis, particularly when related to alcohol, signs of hyperestrogenemia such as gynecomastia, testicular atrophy, and loss of male-pattern hair distribution may be found.

Icterus is best appreciated by inspecting the sclera under natural light. In fair-skinned individuals, a yellow color of the skin may be obvious. In dark-skinned individuals, the mucous membranes below the tongue can demonstrate jaundice. Jaundice is rarely detectable if the serum bilirubin level is <43 μmol/L (2.5 mg/dL) but may remain detectable below this level during recovery from jaundice (because of protein and tissue binding of conjugated bilirubin).

Spider angiomata and palmar erythema occur in both acute and chronic liver disease and may be especially prominent in persons with cirrhosis, but they can occur in normal individuals and are frequently present during pregnancy. Spider angiomata are superficial, tortuous arterioles and, unlike simple telangiectases, typically fill from the center outwards. Spider angiomata occur only on the arms, face, and upper torso; they can be pulsatile and may be difficult to detect in dark-skinned individuals.

TABLE 282-2 CAGE Questions[a]

Acronym	Question
C	Have you ever felt you ought to *C*ut down on your drinking?
A	Have people *A*nnoyed you by criticizing your drinking?
G	Have you ever felt *G*uilty or bad about your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*E*yeopener)?

[a] One "yes" response should raise suspicion of an alcohol use problem, and more than one is a strong indication that abuse or dependence exists.

Hepatomegaly is not a very reliable sign of liver disease, because of the variability of the size and shape of the liver and the physical impediments to assessing liver size by percussion and palpation. Marked hepatomegaly is typical of cirrhosis, venoocclusive disease, metastatic or primary cancers of the liver, and alcoholic hepatitis. Careful assessment of the liver edge may also demonstrate unusual firmness, irregularity of the surface, or frank nodules. Perhaps the most reliable physical finding in examining the liver is hepatic tenderness. Discomfort on touching or pressing on the liver should be carefully sought with percussive comparison of the right and left upper quadrants.

Splenomegaly occurs in many medical conditions but can be a subtle but significant physical finding in liver disease. The availability of ultrasound (US) assessment of the spleen allows for confirmation of the physical finding.

Signs of advanced liver disease include muscle-wasting and weight loss as well as hepatomegaly, bruising, ascites, and edema. Ascites is best appreciated by attempts to detect shifting dullness by careful percussion. US examination will confirm the finding of ascites in equivocal cases. Peripheral edema can occur with or without ascites. In patients with advanced liver disease, other factors frequently contribute to edema formation, including hypoalbuminemia, venous insufficiency, heart failure, and medications.

Hepatic failure is defined as the occurrence of signs or symptoms of hepatic encephalopathy in a person with severe acute or chronic liver disease. The first signs of hepatic encephalopathy can be subtle and nonspecific—change in sleep patterns, change in personality, irritability, and mental dullness. Thereafter, confusion, disorientation, stupor, and eventually coma supervene. Physical findings include asterixis and flapping tremors of the body and tongue. *Fetor hepaticus* refers to the slightly sweet, ammoniacal odor that is common in patients with liver failure, particularly if there is portal-venous shunting of blood around the liver. Other causes of coma and confusion should be excluded, mainly electrolyte imbalances, sedative use, and renal or respiratory failure. A helpful measure of hepatic encephalopathy is a careful mental status examination and use of the trail-making test, which consists of a series of 25 numbered circles that the patient is asked to connect as rapidly as possible using a pencil. The normal range for the connect-the-dot test is 15 to 30 s; it is considerably delayed in patients with early hepatic encephalopathy. Other tests include drawing abstract objects or comparison of a signature to previous examples.

Other signs of advanced liver disease include umbilical hernia from ascites, prominent veins over the abdomen, and *caput medusa*, which consists of collateral veins seen radiating from the umbilicus and resulting from the recanulation of the umbilical vein. Widened pulse pressure and signs of a hyperdynamic circulation can occur in patients with cirrhosis as a result of fluid and sodium retention, increased cardiac output, and reduced peripheral resistance. Patients with long-standing cirrhosis and portal hypertension are prone to develop the hepatopulmonary syndrome, defined by the triad of liver disease, with hypoxemia, and pulmonary arteriovenous shunting. The hepatopulmonary syndrome is characterized by platypnea and orthodeoxia, representing shortness of breath and oxygen desaturation that occur paradoxically upon assuming an upright position.

Several skin disorders and changes occur commonly in liver disease. Hyperpigmentation is typical of advanced chronic cholestatic diseases such as primary biliary cirrhosis and sclerosing cholangitis. In these same conditions, xanthelasma and tendon xanthomata occur as a result of retention and high serum levels of lipids and cholesterol. A slate-gray pigmentation to the skin also occurs with hemochromatosis if iron levels are high for a prolonged period. Mucocutaneous vasculitis with palpable purpura, especially on the lower extremities, is typical of cryoglobulinemia of chronic hepatitis C but can also occur in chronic hepatitis B.

Some physical signs point to specific liver diseases. Kayser-Fleischer rings occur in Wilson's disease and consist of a golden-brown copper pigment deposited in Disemet's membrane at the periphery of the cornea; they are best seen by slit-lamp examination. In metastatic liver disease or primary hepatocellular carcinoma, signs of cachexia and wasting may be prominent, as well as firm hepatomegaly and a hepatic bruit.

LABORATORY TESTING Diagnosis in liver disease is greatly aided by the availability of reliable and sensitive tests of liver injury and function. Use and interpretation of liver function tests is summarized in Chap. 283. A typical battery of blood tests used for initial assessment of liver disease includes measuring levels of serum alanine and aspartate aminotransferases (ALT and AST), alkaline phosphatase, direct and total serum bilirubin, and albumin and assessing prothrombin time. The pattern of abnormalities generally points to hepatocellular versus cholestatic liver disease and will help to decide whether the disease is acute or chronic and whether cirrhosis and hepatic failure are present. Based on these results, further testing over time may be necessary. Other laboratory tests may be helpful, such as γ-glutamyl transpeptidase (GGT) to define whether alkaline phosphatase elevations are due to liver disease; hepatitis serology to define the type of viral hepatitis; and autoimmune markers to diagnose primary biliary cirrhosis (antimitochondrial antibody; AMA), sclerosing cholangitis (peripheral antineutrophil cytoplasmic antibody; P-ANCA), and autoimmune hepatitis (antinuclear, smooth-muscle, and liver-kidney microsomal antibody). A simple delineation of laboratory abnormalities and common liver diseases is given in Table 282-3.

DIAGNOSTIC IMAGING There have been great advances made in hepatic imaging, although no method is suitably accurate in demonstrating underlying cirrhosis. There are many modalities available for imaging the liver. US, computed tomography (CT), and magnetic resonance imaging (MRI) are the most commonly employed and are complementary to each other. In general, US and CT have a high sensitivity for detecting biliary duct dilatation and are the first-line options for investigating the patient with suspected obstructive jaundice. Both US and CT can detect a fatty liver, which appears bright on both studies. Magnetic resonance cholangiopancreatography (MRCP) and endo-

TABLE 282-3 *Important Diagnostic Tests in Common Liver Diseases*

Disease	Diagnostic Test
Hepatitis A	Anti-HAV IgM
Hepatitis B	
Acute	HBsAg and anti-HBc IgM
Chronic	HBsAg and HBeAg and/or HBV DNA
Hepatitis C	Anti-HCV and HCV RNA
Hepatitis D (delta)	HBsAg and anti-HDV
Hepatitis E	Anti-HEV
Autoimmune hepatitis	ANA or SMA, elevated IgG levels, and compatible histology
Primary biliary cirrhosis	Mitochondrial antibody, elevated IgM levels, and compatible histology
Primary sclerosing cholangitis	P-ANCA, cholangiography
Drug-induced liver disease	History of drug ingestion
Alcoholic liver disease	History of excessive alcohol intake and compatible histology
Nonalcoholic steatohepatitis	Ultrasound or CT evidence of fatty liver and compatible histology
α_1 Antitrypsin disease	Reduced α_1 antitrypsin levels, phenotypes PiZZ or PiSZ
Wilson's disease	Decreased serum ceruloplasmin and increased urinary copper; increased hepatic copper level
Hemochromatosis	Elevated iron saturation and serum ferritin; genetic testing for *HFE* gene mutations
Hepatocellular cancer	Elevated α-fetoprotein level >500; ultrasound or CT image of mass

Note: HAV, HBV, HCV, HDV, HEV: hepatitis A, B, C, D, or E virus; HBsAg, hepatitis B surface antigen; anti-HBc, antibody to hepatitis B core (antigen); HBeAg, hepatitis e antigen; ANA, antinuclear antibodies; SMA, smooth-muscle antibody; P-ANCA, peripheral antineutrophil cytoplasmic antibody; CT, computed tomography.

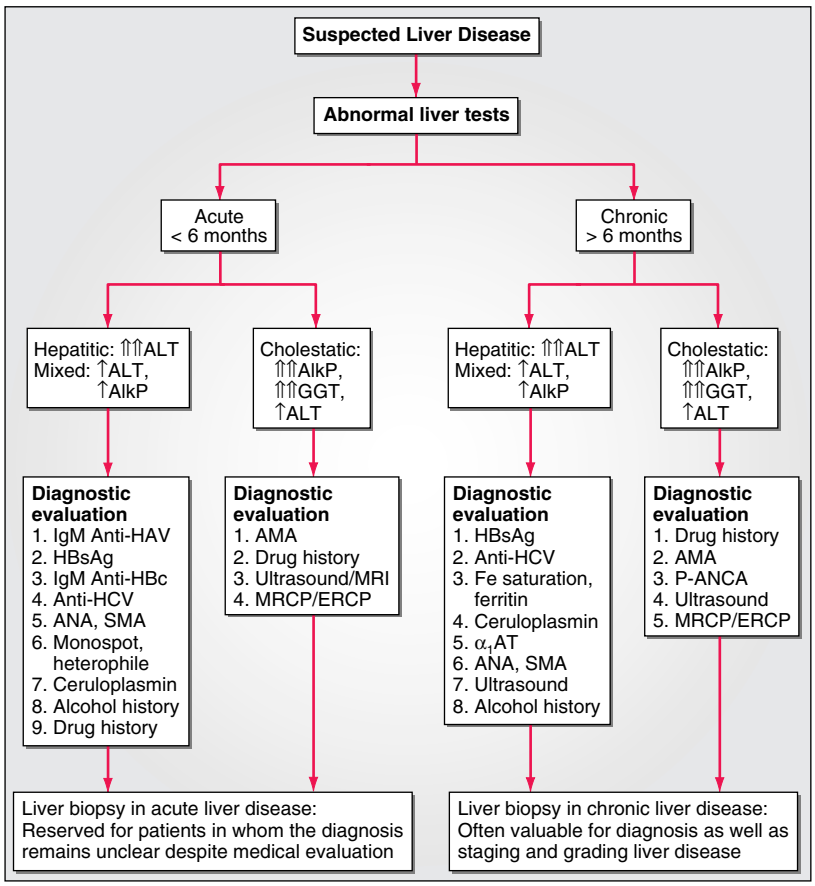

FIGURE 282-1 Algorithm for evaluation of abnormal liver tests. For patients with suspected liver disease, an appropriate approach to evaluation is initial testing for routine liver tests such as bilirubin, albumin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (AlkP). These results (sometimes complemented by testing of γ-glutamyl transpeptidase; GGT) will establish whether the pattern of abnormalities is hepatic, cholestatic, or mixed. In addition, the duration of symptoms or abnormalities will show whether the disease is acute or chronic. If the disease is acute and if history, laboratory tests, and imaging studies do not reveal a diagnosis, liver biopsy is appropriate to help to establish the diagnosis. If the disease is chronic, liver biopsy can be helpful not only for diagnosis, but also to grade the activity and stage the progression of disease. This approach is largely applicable to patients without immune deficiency. In patients with HIV infection or after bone marrow or solid organ transplantation, diagnostic evaluation should also include evaluation of opportunistic infections (adenovirus, cytomegalovirus, coccidioidomyocosis, etc.) as well as vascular and immunologic conditions (venoocclusive disease, graft-vs-host disease). HAV, HCV: hepatitis A or C virus; HBsAg, hepatitis B sulface antigen; anti-HBc, antibody to hepatitis B core (antigen); ANA, antinuclear antibodies; SMA, smooth-muscle antibody; MRI, magnetic resonance imaging; MRCP; magnetic resonance cholangiopancreatography; ERCP, endoscopic retrograde cholangiopancreatography; α_1AT, α_1 antitrypsin; AMA; antimitochondrial antibody; P-ANCA, peripheral antineutrophil cytoplasmic antibody.

scopic retrograde cholangiopancreatography (ERCP) are the procedures of choice for visualization of the biliary tree. MRCP offers several advantages over ERCP; there is no need for contrast media or ionizing radiation, images can be acquired faster, it is less operator dependent, and it carries no risk of pancreatitis. MRCP is superior to US and CT for detecting choledocholithiasis but less specific. It is useful in the diagnosis of bile duct obstruction and congenital biliary abnormalities, but ERCP is more valuable in evaluating ampullary lesions and primary sclerosing cholangitis. ERCP allows for biopsy, direct visualization of the ampulla and common bile duct, and intraductal ultrasonography. It also provides several therapeutic options in patients with obstructive jaundice, such as sphincterotomy, stone extraction, and placement of nasobiliary catheters and biliary stents. Doppler US and MRI are used to assess hepatic vasculature and hemodynamics and to monitor surgically or radiologically placed vascular shunts such as transjugular intrahepatic portosystemic shunts. CT and MRI are indicated for the identification and evaluation of hepatic masses, staging of liver tumors, and preoperative assessment. With regard to mass lesions, sensitivity of hepatic imaging continues to increase; unfortunately, specificity remains a problem, and often two and sometimes three studies are needed before a diagnosis can be reached. Finally, interventional radiologic techniques allow the biopsy of solitary lesions, insertion of drains into hepatic abscesses, and creation of vascular shunts in patients with portal hypertension. Which modality to use depends on factors such as availability, cost, and experience of the radiologist with each technique.

LIVER BIOPSY Liver biopsy remains the gold standard in the evaluation of patients with liver disease, particularly in patients with chronic liver diseases. In selected instances, liver biopsy is necessary for diagnosis but is more often useful in assessing the severity (grade) and stage of liver damage, in predicting prognosis, and in monitoring response to treatment.

Diagnosis of Liver Disease The major causes of liver disease and key diagnostic features are outlined in Table 282-3, and an algorithm for evaluation of the patient with suspected liver disease is given in Fig. 282-1. Specifics of diagnosis are discussed in later chapters. The most common causes of acute liver disease are viral hepatitis (particularly hepatitis A, B, and C), drug-induced liver injury, cholangitis, and alcoholic liver disease. Liver biopsy is usually not needed in the diagnosis and management of acute liver disease, exceptions being situations where the diagnosis remains unclear despite thorough clinical and laboratory investigation. Liver biopsy can be helpful in the diagnosis of drug-induced liver disease and in establishing the diagnosis of acute alcoholic hepatitis.

The most common causes of chronic liver disease in general order of frequency are chronic hepatitis C, alcoholic liver disease, nonalcoholic steatohepatitis, chronic hepatitis B, autoimmune hepatitis, sclerosing cholangitis, primary biliary cirrhosis, hemochromatosis, and Wilson's disease. Strict diagnostic criteria have not been developed for most liver diseases, but liver biopsy plays an important role in the diagnosis of autoimmune hepatitis, primary biliary cirrhosis, nonalcoholic and alcoholic steatohepatitis, and Wilson's disease (with a quantitative hepatic copper level).

Grading and Staging of Liver Disease Grading refers to an assessment of the severity or activity of liver disease, whether acute or chronic; active or inactive; and mild, moderate, or severe. Liver biopsy is the most accurate means of assessing severity, particularly in chronic liver disease. Serum aminotransferase levels are used as a convenient and noninvasive means to follow disease activity, but aminotransferases are not always reliable in reflecting disease severity. Thus, normal serum aminotransferases in patients with hepatitis B surface antigen (HBsAg) in serum may indicate the inactive HBsAg carrier state or may reflect mild chronic hepatitis B or hepatitis B with fluctuating disease activity. Serum testing for hepatitis B e antigen and hepatitis B virus DNA can help resolve these different patterns, but these markers can also fluctuate and change over time. Similarly, in chronic hepatitis C, serum aminotransferases can be normal despite moderate activity of disease. Finally, in both alcoholic and nonalcoholic steatohepatitis, aminotransferases are quite unreliable in reflecting severity. In these conditions, liver biopsy is helpful in guiding management and recommending therapy, particularly if therapy is difficult, prolonged, and expensive as is often the case in chronic viral hepatitis. There are several well-verified numerical scales for grading activity in chronic liver disease, the most common being the histology activity index and the Ishak histology scale.

Liver biopsy is also the most accurate means of assessing stage of disease as early or advanced, precirrhotic, and cirrhotic. Staging of disease pertains largely to chronic liver diseases in which progression

TABLE 282-4 *Child-Pugh Classification of Cirrhosis*

Factor	Units	1	2	3
Serum bilirubin	μmol/L	<34	34–51	>51
	mg/dL	<2.0	2.0–3.0	>3.0
Serum albumin	g/L	>35	30–35	<30
	g/dL	>3.5	3.0–3.5	<3.0
Prothrombin time	second prolonged	0–4	4–6	>6
	INR	<1.7	1.7–2.3	>2.3
Ascites		None	Easily controlled	Poorly controlled
Hepatic encephalopathy		None	Minimal	Advanced

Note: The Child-Pugh score is calculated by adding the scores of the five factors and can range from 5 to 15. Child-Pugh class is either A (a score of 5 to 6), B (7 to 9), or C (10 or above). Decompensation indicates cirrhosis with a Child-Pugh score of 7 or more (Class B). This level has been the accepted criterion for listing for liver transplantation.

to cirrhosis and end-stage liver disease can occur, but which may require years or decades to develop. Clinical features, biochemical tests, and hepatic imaging studies are helpful in assessing stage but generally become abnormal only in the middle to late stages of cirrhosis. Noninvasive tests that suggest advanced fibrosis include mild elevations of bilirubin, prolongation of prothrombin time, slight decreases in serum albumin, and mild thrombocytopenia (which is often the first indication of worsening fibrosis). Early stages of cirrhosis are generally detectable only by liver biopsy. In assessing stage, the degree of fibrosis is usually used as its quantitative measure. The amount of fibrosis is generally staged on a 0 to 4+ (histology activity index) or 0 to 6+ scale (Ishak scale). The importance of staging relates primarily to prognosis and to guiding management of complications. Patients with cirrhosis are candidates for screening and surveillance for esophageal varices and hepatocellular carcinoma. Patients without advanced fibrosis need not undergo screening.

Cirrhosis can also be staged clinically. A reliable staging system is the modified Child-Pugh classification with a scoring system of 5 to 15: scores of 5 and 6 being Child-Pugh class A (consistent with "compensated cirrhosis"), scores of 7 to 9 indicating class B, and 10 to 15 class C (Table 282-4). This scoring system was initially devised to stratify patients into risk groups prior to undergoing portal decompressive surgery. The Child-Pugh score is a reasonably reliable predictor of survival in many liver diseases and predicts the likelihood of major complications of cirrhosis such as bleeding from varices and spontaneous bacterial peritonitis. It was used to assess prognosis in cirrhosis and to provide the standard criteria for listing for liver transplantation (Child-Pugh class B). Recently the Child-Pugh system has been replaced by the model for end-stage liver disease (MELD) score for assessing the need for liver transplantation. The MELD score is a prospectively derived scoring system designed to predict prognosis of patients with liver disease and portal hypertension. It is calculated using three noninvasive variables—the prothrombin time expressed as international normalized ratio (INR), serum bilirubin, and serum creatinine (www.mayo.edu/int-med/gi/model/). MELD provides a more objective means of assessing disease severity and has less center-to-center variation than the Child-Pugh score and has a wider range of values. MELD is currently used to establish priority listing for liver transplantation in the United States.

Thus, liver biopsy is helpful not only in diagnosis but also in management of chronic liver disease and assessment of prognosis. Because liver biopsy is an invasive procedure and not without complications, it should be used only when it will contribute materially to management and therapeutic decisions.

NONSPECIFIC ISSUES IN MANAGEMENT OF PATIENTS WITH LIVER DISEASE

Specifics on management of different forms of acute or chronic liver disease are given in subsequent chapters, but certain issues are applicable to any patient with liver disease. These include advice regarding alcohol use, medications, vaccination, and surveillance for complications of liver disease. Alcohol should be used sparingly, if at all, by patients with liver disease. Abstinence from alcohol should be encouraged for all patients with alcohol-related liver disease and in patients with cirrhosis and those receiving interferon-based therapy for hepatitis B or C. Regarding vaccinations, all patients with liver disease should receive hepatitis A vaccine and those with risk factors should receive hepatitis B vaccination as well. Influenza and pneumococcal vaccination should also be encouraged. Patients with liver disease should be careful in use of any medications, other than the most necessary. Drug-induced hepatotoxicity can mimic many forms of liver disease and can cause exacerbations of chronic hepatitis and cirrhosis; drugs should be suspected in any situation where the cause of exacerbation is unknown. Finally, consideration should be given to surveillance for complications of chronic liver disease such as variceal hemorrhage and hepatocellular carcinoma. Patients with cirrhosis warrant upper endoscopy to assess the presence of varices and should be given chronic therapy with beta blockers if large varices are found. Patients with cirrhosis also warrant screening and long-term surveillance for development of hepatocellular carcinoma. While the optimal regimen for such surveillance has not been established, an appropriate approach is US of the liver at 6- to 12-month intervals.

283 EVALUATION OF LIVER FUNCTION

Daniel S. Pratt, Marshall M. Kaplan

Several biochemical tests are useful in the evaluation and management of patients with hepatic dysfunction. These tests can be used to (1) detect the presence of liver disease, (2) distinguish among different types of liver disorders, (3) gauge the extent of known liver damage, and (4) follow the response to treatment.

Liver tests have shortcomings. They can be normal in patients with serious liver disease and abnormal in patients with diseases that do not affect the liver. Liver tests rarely suggest a specific diagnosis; rather, they suggest a general category of liver disease, such as hepatocellular or cholestatic, which then further directs the evaluation.

The liver carries out thousands of biochemical functions, most of which cannot be easily measured by blood tests. Laboratory tests measure only a limited number of these functions. In fact, many tests, such as the aminotransferases or alkaline phosphatase, do not measure liver function at all. Rather, they detect liver cell damage or interference with bile flow. Thus, no one test enables the clinician to accurately assess the liver's total functional capacity.

To increase both the sensitivity and the specificity of laboratory tests in the detection of liver disease, it is best to use them as a battery. Those tests usually employed in clinical practice include the bilirubin,

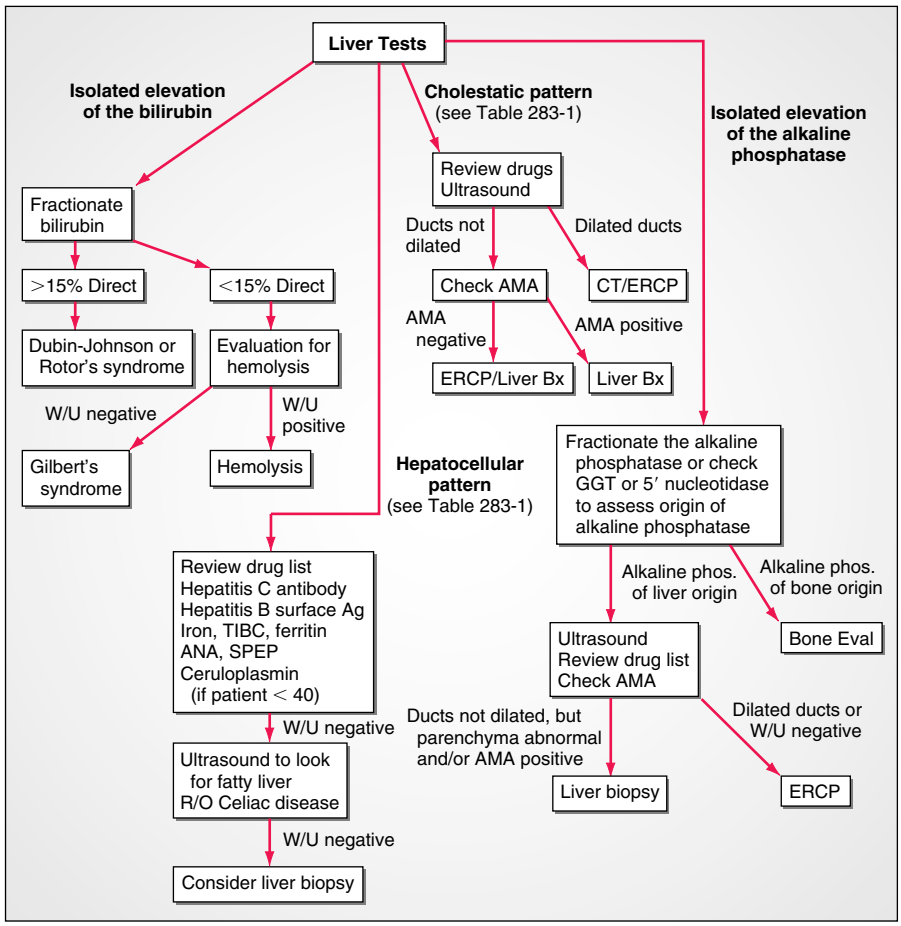

FIGURE 283-1 Algorithm for the evaluation of chronically abnormal liver tests. ERCP, endoscopic retrograde cholangiopancreatography; CT, computed tomography; AMA, antimitochondrial antibody; ANA, antinuclear antibody; SPEP, serum protein electrophoresis; TIBC, total iron-binding capacity; GGT, gamma glutamyl transpeptidase.

aminotransferases, alkaline phosphatase, albumin, and prothrombin time tests. When more than one of these tests provide abnormal findings, or the findings are persistently abnormal on serial determinations, the probability of liver disease is high. When all test results are normal, the probability of missing occult liver disease is low.

When evaluating patients with liver disorders, it is helpful to group these tests into general categories. The classification we have found most useful is given below.

TESTS BASED ON DETOXIFICATION AND EXCRETORY FUNCTIONS ■ Serum Bilirubin (See also Chap. 38) Bilirubin, a breakdown product of the porphyrin ring of heme-containing proteins, is found in the blood in two fractions—conjugated and unconjugated. The unconjugated fraction, also termed the *indirect fraction*, is insoluble in water and is bound to albumin in the blood. The conjugated (direct) bilirubin fraction is water soluble and can therefore be excreted by the kidney. When measured by the original van den Bergh method, the normal total serum bilirubin concentration is <17 μmol/L (1 mg/dL). Up to 30%, or 5.1 μmol/L (0.3 mg/dL), of the total is direct-reacting (or conjugated) bilirubin.

Elevation of the unconjugated fraction of bilirubin is rarely due to liver disease. An isolated elevation of unconjugated bilirubin is seen primarily in hemolytic disorders and in a number of genetic conditions such as Crigler-Najjar and Gilbert's syndromes (Chap. 38). Isolated unconjugated hyperbilirubinemia (bilirubin elevated, but less than 15% direct) should prompt a workup for hemolysis (Fig. 283-1). In the absence of hemolysis, an isolated unconjugated hyperbilirubinemia in an otherwise healthy patient can be attributed to Gilbert's syndrome and no further evaluation is required.

In contrast, conjugated hyperbilirubinemia almost always implies liver or biliary tract disease. The rate-limiting step in bilirubin metabolism is not conjugation of bilirubin, but rather the transport of conjugated bilirubin into the bile canaliculi. Thus, elevation of the conjugated fraction may be seen in any type of liver disease. In most liver diseases, both conjugated and unconjugated fractions of the bilirubin tend to be elevated. Except in the presence of a purely unconjugated hyperbilirubinemia, fractionation of the bilirubin is rarely helpful in determining the cause of jaundice.

Urine Bilirubin Unconjugated bilirubin always binds to albumin in the serum and is not filtered by the kidney. Therefore, any bilirubin found in the urine is conjugated bilirubin; the presence of bilirubinuria implies the presence of liver disease. A urine dipstick test can theoretically give the same information as fractionation of the serum bilirubin. This test is almost 100% accurate. Phenothiazines may give a false-positive reading with the Ictotest tablet.

Blood Ammonia Ammonia is produced in the body during normal protein metabolism and by intestinal bacteria, primarily those in the colon. The liver plays a role in the detoxification of ammonia by converting it to urea, which is excreted by the kidneys. Striated muscle also plays a role in detoxification of ammonia, which is combined with glutamic acid to form glutamine. Patients with advanced liver disease typically have significant muscle wasting, which likely contributes to hyperammonemia in these patients. Some physicians use the blood ammonia for detecting encephalopathy or for monitoring hepatic synthetic function, although its use for either of these indications has problems. There is very poor correlation between either the presence or the degree of acute encephalopathy and elevation of blood ammonia; it can be occasionally useful for identifying the occult liver disease in patients with mental status changes. There is also a poor correlation of the blood serum ammonia and hepatic function. The ammonia can be elevated in patients with severe portal hypertension and portal blood shunting around the liver even in the presence of normal or near normal hepatic function.

Serum Enzymes The liver contains thousands of enzymes, some of which are also present in the serum in very low concentrations. These enzymes have no known function in the serum and behave like other serum proteins. They are distributed in the plasma and in interstitial fluid and have characteristic half-lives, usually measured in days. Very little is known about the catabolism of serum enzymes, although they are probably cleared by cells in the reticuloendothelial system. The elevation of a given enzyme activity in the serum is thought to primarily reflect its increased rate of entrance into serum from damaged liver cells.

Serum enzyme tests can be grouped into three categories: (1) enzymes whose elevation in serum reflects damage to hepatocytes, (2) enzymes whose elevation in serum reflects cholestasis, and (3) enzyme tests that do not fit precisely into either pattern.

ENZYMES THAT REFLECT DAMAGE TO HEPATOCYTES The aminotransferases (transaminases) are sensitive indicators of liver cell injury and are most helpful in recognizing acute hepatocellular diseases such as hepatitis. They include the aspartate aminotransferase (AST) and the alanine aminotransferase (ALT). AST is found in the liver, cardiac muscle, skeletal muscle, kidneys, brain, pancreas, lungs, leukocytes, and erythrocytes in decreasing order of concentration. ALT is found primarily

in the liver. The aminotransferases are normally present in the serumin low concentrations. These enzymes are released into the blood in greater amounts when there is damage to the liver cell membrane resulting in increased permeability. Liver cell necrosis is not required for the release of the aminotransferases, and there is a poor correlation between the degree of liver cell damage and the level of the aminotransferases. Thus, the absolute elevation of the aminotransferases is of no prognostic significance in acute hepatocellular disorders.

Any type of liver cell injury can cause modest elevations in the serum aminotransferases. Levels of up to 300 U/L are nonspecific and may be found in any type of liver disorder. Striking elevations—i.e., aminotransferases >1000 U/L—occur almost exclusively in disorders associated with extensive hepatocellular injury such as (1) viral hepatitis, (2) ischemic liver injury (prolonged hypotension or acute heart failure), or (3) toxin or drug-induced liver injury.

The pattern of the aminotransferase elevation can be helpful diagnostically. In most acute hepatocellular disorders, the ALT is higher than or equal to the AST. An AST:ALT ratio > 2:1 is suggestive while a ratio > 3:1 is highly suggestive of alcoholic liver disease. The AST in alcoholic liver disease is rarely >300 U/L and the ALT is often normal. A low level of ALT in the serum is due to an alcohol-induced deficiency of pyridoxal phosphate.

The aminotransferases are usually not greatly elevated in obstructive jaundice. One notable exception occurs during the acute phase of biliary obstruction caused by the passage of a gallstone into the common bile duct. In this setting, the aminotransferases can briefly be in the 1000 to 2000 U/L range. However, aminotransferase levels decrease quickly, and the liver function tests rapidly evolve into one typical of cholestasis.

ENZYMES THAT REFLECT CHOLESTASIS The activities of three enzymes—alkaline phosphatase, 5′-nucleotidase, and gamma glutamyl transpeptidase (GGT)—are usually elevated in cholestasis. Alkaline phosphatase and 5′-nucleotidase are found in or near the bile canalicular membrane of hepatocytes, while GGT is located in the endoplasmic reticulum and in bile duct epithelial cells. Reflecting its more diffuse localization in the liver, GGT elevation in serum is less specific for cholestasis than are elevations of alkaline phosphatase or 5′-nucleotidase. Some have advocated the use of GGT to identify patients with occult alcohol use. Its lack of specificity makes its use in this setting questionable.

The normal serum alkaline phosphatase consists of many distinct isoenzymes found in the liver, bone, placenta, and, less commonly, small intestine. Patients over age 60 can have a mildly elevated alkaline phosphatase (1 to 1½ times normal), while individuals with blood types O and B can have an elevation of the serum alkaline phosphatase after eating a fatty meal due to the influx of intestinal alkaline phosphatase into the blood. It is also nonpathologically elevated in children and adolescents undergoing rapid bone growth because of bone alkaline phosphatase, and late in normal pregnancies due to the influx of placental alkaline phosphatase.

Elevation of liver-derived alkaline phosphatase is not totally specific for cholestasis, and a less than threefold elevation can be seen in almost any type of liver disease. Alkaline phosphatase elevations greater than four times normal occur primarily in patients with cholestatic liver disorders, infiltrative liver diseases such as cancer, and bone conditions characterized by rapid bone turnover (e.g., Paget's disease). In bone diseases, the elevation is due to increased amounts of the bone isoenzymes. In liver diseases, the elevation is almost always due to increased amounts of the liver isoenzyme.

If an elevated serum alkaline phosphatase is the only abnormal finding in an apparently healthy person, or if the degree of elevation is higher than expected in the clinical setting, identification of the source of elevated isoenzymes is helpful (Fig. 283-1). This problem can be approached in several ways. First, and most precise, is the fractionation of the alkaline phosphatase by electrophoresis. The second approach is based on the observation that alkaline phosphatases from individual tissues differ in susceptibility to inactivation by heat. The finding of an elevated serum alkaline phosphatase level in a patient with a heat-stable fraction strongly suggests that the placenta or a tumor is the source of the elevated enzyme in serum. Susceptibility to inactivation by heat increases, respectively, for the intestinal, liver, and bone alkaline phosphatases, bone being by far the most sensitive. The third, best substantiated, and most available approach involves the measurement of serum 5′-nucleotidase or GGT. These enzymes are rarely elevated in conditions other than liver disease.

In the absence of jaundice or elevated aminotransferases, an elevated alkaline phosphatase of liver origin often, but not always, suggests early cholestasis and, less often, hepatic infiltration by tumor or granulomata. Other conditions that cause isolated elevations of the alkaline phosphatase include Hodgkin's disease, diabetes, hyperthyroidism, congestive heart failure, and inflammatory bowel disease.

The level of serum alkaline phosphatase elevation is not helpful in distinguishing between intrahepatic and extrahepatic cholestasis. There is essentially no difference among the values found in obstructive jaundice due to cancer, common duct stone, sclerosing cholangitis, or bile duct stricture. Values are similarly increased in patients with intrahepatic cholestasis due to drug-induced hepatitis, primary biliary cirrhosis, rejection of transplanted livers, and, rarely, alcohol-induced steatonecrosis. Values are also greatly elevated in hepatobiliary disorders seen in patients with AIDS (e.g., AIDS cholangiopathy due to cytomegalovirus or cryptosporidial infection and tuberculosis with hepatic involvement).

TESTS THAT MEASURE BIOSYNTHETIC FUNCTION OF THE LIVER

Serum Albumin

Serum albumin is synthesized exclusively by hepatocytes. Serum albumin has a long half-life: 15 to 20 days, with approximately 4% degraded per day. Because of this slow turnover, the serum albumin is not a good indicator of acute or mild hepatic dysfunction; only minimal changes in the serum albumin are seen in acute liver conditions such as viral hepatitis, drug-related hepatoxicity, and obstructive jaundice. In hepatitis, albumin levels <3 g/dL should raise the possibility of chronic liver disease. Hypoalbuminemia is more common in chronic liver disorders such as cirrhosis and usually reflects severe liver damage and decreased albumin synthesis. One exception is the patient with ascites in whom synthesis may be normal or even increased, but levels are low because of the increased volume of distribution. However, hypoalbuminemia is not specific for liver disease and may occur in protein malnutrition of any cause, as well as protein-losing enteropathies, nephrotic syndrome, and chronic infections that are associated with prolonged increases in levels of serum interleukin 1 and/or tumor necrosis factor, cytokines that inhibit albumin synthesis. Serum albumin should not be measured for screening in patients in whom there is no suspicion of liver disease. A general medical clinic study of consecutive patients in whom no indications were present for albumin measurement showed that while 12% of patients had abnormal test results, the finding was of clinical importance in only 0.4%.

Serum Globulins

Serum globulins are a group of proteins made up of gamma globulins (immunoglobulins) produced by B lymphocytes and alpha and beta globulins produced primarily in hepatocytes. Gamma globulins are increased in chronic liver disease, such as chronic hepatitis and cirrhosis. In cirrhosis, the increased serum gamma globulin concentration is due to the increased synthesis of antibodies, some of which are directed against intestinal bacteria. This occurs because the cirrhotic liver fails to clear bacterial antigens that normally reach the liver through the hepatic circulation.

Increases in the concentration of specific isotypes of gamma globulins are often helpful in the recognition of certain chronic liver diseases. Diffuse polyclonal increases in IgG levels are common in autoimmune hepatitis; increases >100% should alert the clinician to this possibility. Increases in the IgM levels are common in primary biliary cirrhosis, while increases in the IgA levels occur in alcoholic liver disease.

TABLE 283-1 *Liver Test Patterns in Hepatobiliary Disorders*

Type of Disorder	Bilirubin	Aminotransferases	Alkaline Phosphatase	Albumin	Prothrombin Time
Hemolysis/Gilbert's syndrome	Normal to 86 μmol/L (5 mg/dl) 85% due to indirect fractions No bilirubinuria	Normal	Normal	Normal	Normal
Acute hepatocellular necrosis (viral and drug hepatitis, hepatotoxins, acute heart failure)	Both fractions may be elevated Peak usually follows aminotransferases Bilirubinuria	Elevated, often >500 IU ALT >AST	Normal to <3 times normal elevation	Normal	Usually normal. If >5X above control and not corrected by parenteral vitamin K, suggests poor prognosis
Chronic hepatocellular disorders	Both fractions may be elevated Bilirubinuria	Elevated, but usually <300 IU	Normal to <3 times normal elevation	Often decreased	Often prolonged Fails to correct with parenteral vitamin K
Alcoholic hepatitis Cirrhosis	Both fractions may be elevated Bilirubinuria	AST:ALT > 2 suggests alcoholic hepatitis or cirrhosis	Normal to <3 times normal elevation	Often decreased	Often prolonged Fails to correct with parenteral vitamin K
Intra- and extra-hepatic cholestasis (Obstructive jaundice)	Both fractions may be elevated Bilirubinuria	Normal to moderate elevation Rarely >500 IU	Elevated, often >4 times normal elevation	Normal, unless chronic	Normal If prolonged, will correct with parenteral vitamin K
Infiltrative diseases (tumor, granulomata); partial bile duct obstruction	Usually normal	Normal to slight elevation	Elevated, often >4 times normal elevation Fractionate, or confirm liver origin with 5′ nucleotidase or gamma glutamyl transpeptidase	Normal	Normal

COAGULATION FACTORS With the exception of factor VIII, the blood clotting factors are made exclusively in hepatocytes. Their serum half-lives are much shorter than albumin, ranging from 6 h for factor VII to 5 days for fibrinogen. Because of their rapid turnover, measurement of the clotting factors is the single best acute measure of hepatic synthetic function and helpful in both the diagnosis and assessing the prognosis of acute parenchymal liver disease. Useful for this purpose is the *serum prothrombin time*, which collectively measures factors II, V, VII, and X. Biosynthesis of factors II, VII, IX, and X depends on vitamin K. The prothrombin time may be elevated in hepatitis and cirrhosis as well as in disorders that lead to vitamin K deficiency such as obstructive jaundice or fat malabsorption of any kind. Marked prolongation of the prothrombin time, >5 s above control and not corrected by parenteral vitamin K administration, is a poor prognostic sign in acute viral hepatitis and other acute and chronic liver diseases.

OTHER DIAGNOSTIC TESTS While tests may direct the physician to a category of liver disease, additional radiologic testing and procedures are often necessary to make the proper diagnosis, as shown in Fig. 283-1. The two most commonly used ancillary tests are reviewed here.

Percutaneous Liver Biopsy Percutaneous biopsy of the liver is a safe procedure that can be easily performed at the bedside with local anesthesia. Liver biopsy is of proven value in the following situations: (1) hepatocellular disease of uncertain cause, (2) prolonged hepatitis with the possibility of chronic active hepatitis, (3) unexplained hepatomegaly, (4) unexplained splenomegaly, (5) hepatic filling defects by radiologic imaging, (6) fever of unknown origin, (7) staging of malignant lymphoma. Liver biopsy is most accurate in disorders causing diffuse changes throughout the liver and is subject to sampling error in focal infiltrative disorders such as hepatic metastases. Liver biopsy should not be the initial procedure in the diagnosis of cholestasis. The biliary tree should first be assessed for signs of obstruction.

Ultrasonography Ultrasonography is the first diagnostic test to use in patients whose liver tests suggest cholestasis, to look for the presence of a dilated intrahepatic or extrahepatic biliary tree or to identify gallstones. In addition, it shows space-occupying lesions within the liver, enables the clinician to distinguish between cystic and solid masses, and helps direct percutaneous biopsies. Ultrasound with Doppler imaging can detect the patency of the portal vein, hepatic artery, and hepatic veins and determine the direction of blood flow. This is the first test ordered in patients suspected of having Budd-Chiari syndrome.

USE OF LIVER TESTS As previously noted, the best way to increase the sensitivity and specificity of laboratory tests in the detection of liver disease is to employ a battery of tests that include the aminotransferases, alkaline phosphatase, bilirubin, albumin, and prothrombin time along with the judicious use of the other tests described in this chapter. Table 283-1 shows how patterns of liver tests can lead the clinician to a category of disease that will direct further evaluation. However, it is important to remember that no single set of liver tests will necessarily provide a diagnosis. It is often necessary to repeat these tests on several occasions over days to weeks for a diagnostic pattern to emerge. Figure 283-1 is an algorithm for the evaluation of chronically abnormal liver tests.

284 THE HYPERBILIRUBINEMIAS

Allan W. Wolkoff

BILIRUBIN METABOLISM

The details of bilirubin metabolism are presented in Chap. 38, "Jaundice." However, the hyperbilirubinemias are best understood in terms of perturbations of specific aspects of bilirubin metabolism and transport, and these will be briefly reviewed here as depicted in Fig. 284-1.

Bilirubin is the end product of heme degradation. From 70 to 90% of bilirubin is derived from degradation of the hemoglobin of senescent red blood cells. Bilirubin produced in the periphery is transported to the liver within the plasma, where, due to its insolubility in aqueous solutions, it is tightly bound to albumin. Under normal circumstances, bilirubin is removed from the circulation rapidly and efficiently by hepatocytes. Transfer of bilirubin from blood to bile involves four distinct but interrelated steps (Fig. 284-1):

1. *Hepatocellular uptake*: Uptake of bilirubin by the hepatocyte has carrier-mediated kinetics. Although a number of candidate bilirubin transporters have been proposed, the actual transporter remains elusive.
2. *Intracellular binding*: Within the hepatocyte, bilirubin is kept in solution by binding as a nonsubstrate ligand to several of the glutathione-S-transferases, formerly called ligandins.
3. *Conjugation*: Bilirubin is conjugated with one or two glucuronic acid moieties by a specific UDP-glucuronosyltransferase to form bilirubin mono- and diglucuronide, respectively. Conjugation disrupts the internal hydrogen bonding that limits aqueous solubility of bilirubin, and the resulting glucuronide conjugates are highly soluble in water. Conjugation is obligatory for excretion of bilirubin across the bile canalicular membrane into bile. The UDP-glucuronosyltransferases have been classified into gene families based on the degree of homology among the mRNAs for the various isoforms. Those that conjugate bilirubin and certain other substrates have been designated the *UGT1* family. These are expressed from a single gene complex by alternative promoter usage. This gene complex contains multiple substrate-specific first exons, designated A1, A2, etc. (Fig. 284-2), each with its own promoter and each encoding the amino-terminal half of a specific isoform. In addition, there are four common exons (exons 2 to 5) that encode the shared carboxyl-terminal half of all of the *UGT1* isoforms. The various first exons encode the specific aglycone substrate–binding sites for each isoform, while the shared exons encode the binding site for the sugar donor, UDP-glucuronic acid, and the transmembrane domain. Exon A1 and the four common exons, collectively designated the *UGT1A1* gene (Fig. 284-2), encode the physiologically critical enzyme bilirubin-UDP-glucuronosyltransferase (UGT1A1). A functional corollary of the organization of the *UGT1* gene is that a mutation in one of the first exons will affect only a single enzyme isoform. By contrast, a mutation in exons 2 to 5 will alter all isoforms encoded by the *UGT1* gene complex.
4. *Biliary excretion*: Bilirubin mono- and diglucuronides are excreted across the canalicular plasma membrane into the bile canaliculus by an ATP-dependent transport process mediated by a canalicular membrane protein called *multidrug resistance–associated protein 2* (MRP2). Mutations of MRP2 result in the Dubin-Johnson syndrome (see below).

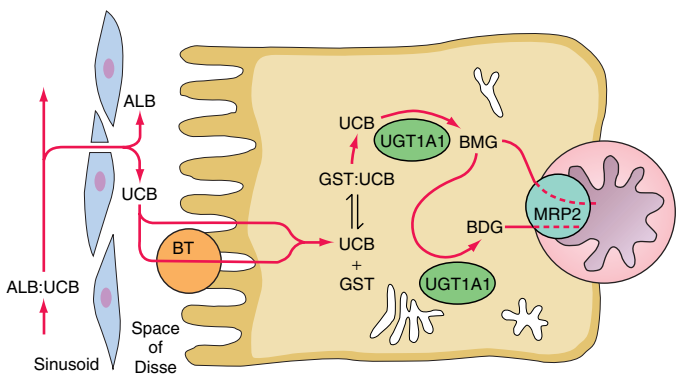

FIGURE 284-1 Hepatocellular bilirubin transport. Albumin-bound bilirubin in sinusoidal blood passes through endothelial cell fenestrae to reach the hepatocyte surface, entering the cell by both facilitated and simple diffusional processes. Within the cell it is bound to glutathione-S-transferases and conjugated by bilirubin-UDP-glucuronosyltransferase (UGT1A1) to mono- and diglucuronides, which are actively transported across the canalicular membrane into the bile. ALB, albumin; UCB, unconjugated bilirubin, UGT1A1, bilirubin-UDP-glucuronosyltransferase; BMG, bilirubin monoglucuronide; GST, glutathione-S-transferase; MRP2, multidrug resistance–associated protein 2; BDG, bilirubin diglucuronide; BT, proposed bilirubin transporter.

EXTRAHEPATIC ASPECTS OF BILIRUBIN DISPOSITION ■ Bilirubin in the Gut

Following secretion into bile, conjugated bilirubin reaches the duodenum and passes down the gastrointestinal tract without reabsorption by the intestinal mucosa. An appreciable fraction is converted by bacterial metabolism in the gut to the water-soluble colorless compound, urobilinogen. Urobilinogen undergoes enterohepatic cycling. Urobilinogen not taken up by the liver reaches the systemic circulation, from which some is cleared by the kidneys. Unconjugated bilirubin ordinarily does not reach the gut except in neonates or, by ill-defined alternative pathways, in the presence of severe unconjugated hyperbilirubinemia [e.g., Crigler-Najjar syndrome, type I (CN-I)]. Unconjugated bilirubin that reaches the gut is partly reabsorbed, amplifying any underlying hyperbilirubinemia.

Renal Excretion of Bilirubin Conjugates Unconjugated bilirubin is not excreted in urine as it is too tightly bound to albumin for effective glomerular filtration and there is no tubular mechanism for its renal secretion. In contrast, the bilirubin conjugates are readily filtered at the glomerulus and can appear in urine in disorders characterized by increased bilirubin conjugates in the circulation.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO UNCONJUGATED HYPERBILIRUBINEMIA

INCREASED BILIRUBIN PRODUCTION ■ Hemolysis

Increased destruction of erythrocytes leads to increased bilirubin turnover and unconjugated hyperbilirubinemia; the hyperbilirubinemia is usually modest in the presence of normal liver function. In particular, the bone marrow is only capable of a sustained eightfold increase in erythrocyte production in response to a hemolytic stress. Therefore, hemolysis alone cannot result in a sustained hyperbilirubinemia of more than approximately 68 μmol/L (4 mg/dL). Higher values imply concomitant hepatic dysfunction. When hemolysis is the only abnormality in an otherwise healthy individual, the result is a purely unconjugated hyperbilirubinemia, with the direct-reacting fraction as measured in a typical clinical laboratory being $\leq$15% of the total serum bilirubin. In the presence of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration. Prolonged hemolysis may lead to the precipitation of bilirubin salts within the gall bladder or biliary tree, resulting in the formation of gallstones in which bilirubin, rather than cholesterol, is the major component. Such pigment stones may lead to acute or chronic cholecystitis, biliary obstruction, or any other biliary tract consequence of calculous disease.

Ineffective Erythropoiesis During erythroid maturation, small amounts of hemoglobin may be lost at the time of nuclear extrusion, and a fraction of developing erythroid cells is destroyed within the marrow. These processes normally account for a small proportion of bilirubin that is produced. In various disorders, including thalassemia major, megaloblastic anemias due to folate or vitamin B_{12} deficiency, congenital erythropoietic porphyria, lead poisoning, and various congenital and acquired dyserythropoietic anemias, the fraction of total bilirubin production derived from ineffective erythropoiesis is increased,

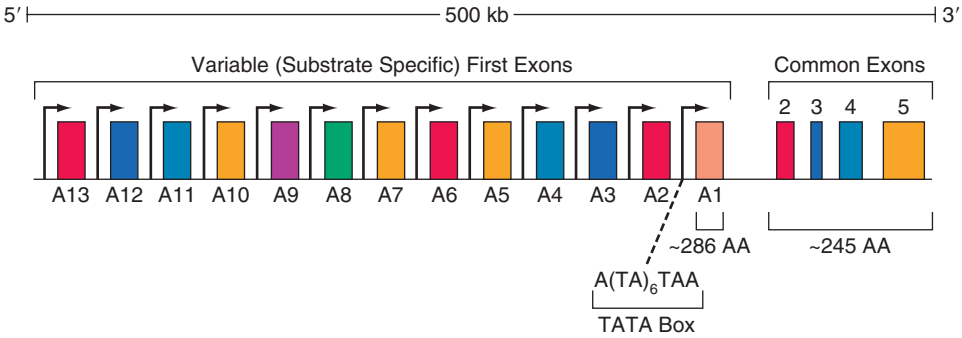

FIGURE 284-2 Structural organization of the human *UGT1* gene complex. This large complex on chromosome 2 contains at least 13 substrate-specific first exons (A1, A2, etc.). Since four of these are pseudogenes, nine UGT1 isoforms with differing substrate specificities are expressed. Each exon 1 has its own promoter and encodes the amino-terminal substrate-specific ~286 amino acids of the various *UGT1*-encoded isoforms, and common exons 2 to 5 that encode the 245 carboxyl-terminal amino acids common to all of the isoforms. mRNAs for specific isoforms are assembled by splicing a particular first exon such as the bilirubin-specific exon A1 to exons 2 to 5. The resulting message encodes a complete enzyme, in this particular case bilirubin-UDP-glucuronosyltransferase (UGT1A1). Mutations in a first exon affect only a single isoform. Those in exons 2 to 5 affect all enzymes encoded by the UGT1 complex.

reaching as much as 70% of the total. This may be sufficient to produce modest degrees of unconjugated hyperbilirubinemia.

Miscellaneous Degradation of the hemoglobin of extravascular collections of erythrocytes, such as those seen in massive tissue infarctions or large hematomas, may lead transiently to unconjugated hyperbilirubinemia.

DECREASED HEPATIC BILIRUBIN CLEARANCE ■ Decreased Hepatic Uptake Decreased hepatic bilirubin uptake is believed to contribute to the unconjugated hyperbilirubinemia of Gilbert's syndrome (GS), although the molecular basis for this finding remains unclear (see below). Several drugs, including flavaspidic acid, novobiocin, and various cholecystographic contrast agents, have been reported to inhibit bilirubin uptake. The resulting unconjugated hyperbilirubinemia resolves with cessation of the medication.

Impaired Conjugation ■ *PHYSIOLOGIC NEONATAL JAUNDICE* Bilirubin produced by the fetus is cleared by the placenta and eliminated by the maternal liver. Immediately after birth, the neonatal liver must assume responsibility for bilirubin clearance and excretion. However, many hepatic physiologic processes are incompletely developed at birth. Levels of UGT1A1 are low, and alternative excretory pathways allow passage of unconjugated bilirubin into the gut. Since the intestinal flora that convert bilirubin to urobilinogen are also undeveloped, an enterohepatic circulation of unconjugated bilirubin ensues. As a consequence, most neonates develop mild unconjugated hyperbilirubinemia between days 2 and 5 after birth. Peak levels are typically <85 to 170 μmol/L (5 to 10 mg/dL) and decline to normal adult concentrations within 2 weeks, as mechanisms required for bilirubin disposition mature. Prematurity, with more profound immaturity of hepatic function, or hemolysis, result in higher levels of unconjugated hyperbilirubinemia. A rapidly rising unconjugated bilirubin concentration, or absolute levels >340 μmol/L (20 mg/dL), puts the infant at risk for bilirubin encephalopathy, or kernicterus. Under these circumstances, bilirubin crosses an immature blood-brain barrier and precipitates in the basal ganglia and other areas of the brain. The consequences range from appreciable neurologic deficits to death. Treatment options include phototherapy, which converts bilirubin into water-soluble photoisomers that are excreted directly into bile, and exchange transfusion. The canalicular mechanisms responsible for bilirubin excretion are also immature at birth, and their maturation may lag behind that of UGT1A1; this can lead to transient conjugated neonatal hyperbilirubinemia, especially in infants with hemolysis.

ACQUIRED CONJUGATION DEFECTS A modest reduction in bilirubin-conjugating capacity may be observed in advanced hepatitis or cirrhosis. However, in this setting, conjugation is better preserved than other aspects of bilirubin disposition, such as canalicular excretion. Various drugs, including pregnanediol, novobiocin, chloramphenicol, and gentamicin, may produce unconjugated hyperbilirubinemia by inhibiting UGT1A1 activity. Finally, bilirubin conjugation may be inhibited by certain fatty acids that are present in breast milk but not serum of mothers whose infants have excessive neonatal hyperbilirubinemia (*breast milk jaundice*). The pathogenesis of breast milk jaundice appears to differ from that of transient familial neonatal hyperbilirubinemia (Lucey-Driscoll syndrome), in which there is a UGT1A1 inhibitor in maternal serum.

HEREDITARY DEFECTS IN BILIRUBIN CONJUGATION Three familial disorders characterized by differing degrees of unconjugated hyperbilirubinemia have long been recognized. The defining clinical features of each are described below (Table 284-1). While these disorders have been recognized for decades to reflect differing degrees of deficiency in the ability to conjugate bilirubin, recent advances in the molecular biology of the *UGT1* gene complex have elucidated their interrelationships and clarified previously puzzling features.

Crigler-Najjar Syndrome, Type I CN-I is characterized by striking unconjugated hyperbilirubinemia of about 340 to 765 μmol/L (20 to 45 mg/dL) that appears in the neonatal period and persists for life. Other conventional hepatic biochemical tests such as serum aminotransferases and alkaline phosphatase are normal, and there is no evidence of hemolysis. Hepatic histology is also essentially normal except for the occasional presence of bile plugs within canaliculi. Bilirubin glucuronides are virtually absent from the bile, and there is no detectable constitutive expression of UGT1A1 activity in hepatic tissue. Neither UGT1A1 activity nor the serum bilirubin concentration responds to administration of phenobarbital or other enzyme inducers. In the absence of conjugation, unconjugated bilirubin accumulates in plasma, from which it is eliminated very slowly by alternative pathways that include direct passage into the bile and small intestine. These account for the small amounts of urobilinogen found in feces. No bilirubin is found in the urine. First described in 1952, the disorder is rare (estimated prevalence of 0.6 to 1.0 per million). Many patients are from geographically or socially isolated communities in which consanguinity is common, and pedigree analyses show an autosomal recessive pattern of inheritance. The majority of patients (type IA) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin, including various drugs and other xenobiotics. These individuals have mutations in one of the common exons (2 to 5) of the *UGT1* gene (Fig. 284-2). In a smaller subset (type IB), the defect is limited largely to bilirubin conjugation, and the causative mutation is in the bilirubin-specific exon A1. Estrogen glucuronidation is mediated by UGT1A1 and is defective in all CN-I patients. More than 30 different genetic lesions of *UGT1A1* responsible for CN-I have been identified, including deletions, insertions, alterations in intronic splice donor and acceptor sites, exon skipping, and point mutations that introduce premature stop codons or alter critical amino acids. Their common feature is that they all encode proteins with absent or, at most, traces of bilirubin-UDP-glucuronosyltransferase enzymatic activity.

Prior to the availability of phototherapy, most patients with CN-I died of bilirubin encephalopathy (*kernicterus*) in infancy or early childhood. A few lived as long as early adult life without overt neurologic damage, although more subtle testing usually indicated mild but progressive brain damage. In the absence of liver transplantation, death eventually supervened from late-onset bilirubin encephalopathy, which often followed a nonspecific febrile illness. Recent data suggest that the best hope for survival of a neurologically intact patient involves the following treatment options: (1) about 12 h/d of photother-

TABLE 284-1 *Principal Differential Characteristics of Gilbert's and Crigler-Najjar Syndromes*

Feature	Crigler-Najjar Syndrome		Gilbert's Syndrome
	Type I	Type II	
Total serum bilirubin, μmol/L [mg/dL]	310–755 (usually >345) [18–45 (usually >20)]	100–430 (usually ≤345) [6–25 (usually ≤20)]	Typically ≤70 μmol/L [≤4 mg/dL] in absence of fasting or hemolysis
Routine liver tests	Normal	Normal	Normal
Response to phenobarbital	None	Decreases bilirubin by >25%	Decreases bilirubin to normal
Kernicterus	Usual	Rare	No
Hepatic histology	Normal	Normal	Usually normal; increased lipofuscin pigment in some
Bile characteristics			
Color:	Pale or colorless	Pigmented	Normal dark color
Bilirubin fractions:	>90% unconjugated	Largest fraction (mean:57%) monoconjugates	Mainly diconjugates but monoconjugates increased (mean 23%)
Bilirubin UDP-glucuronosyltransferase activity	Typically absent; traces in some patients	Markedly reduced: 0 to 10% of normal	Reduced: typically 10–33% of normal
Inheritance (all autosomal)	Recessive	Predominantly recessive	Promoter mutation: recessive Missense mutations: 7 of 8 dominant; 1 reportedly recessive

apy from birth throughout childhood, perhaps supplemented by exchange transfusion in the immediate neonatal period; (2) use of tin-protoporphyrin, an inhibitor of heme oxygenase, to blunt transient exacerbations of hyperbilirubinemia; (3) oral administration of a combination of calcium phosphate and calcium carbonate to sequester unconjugated bilirubin in the gut; and (4) liver transplantation prior to the onset of brain damage. In a single patient, transplantation with isolated allogeneic hepatocytes produced a clinically significant reduction in serum bilirubin concentration.

Crigler-Najjar Syndrome, Type II (CN-II) This condition was recognized as a distinct entity in 1962 and is characterized by marked unconjugated hyperbilirubinemia in the absence of abnormalities of other conventional hepatic biochemical tests, hepatic histology, or hemolysis. It differs from CN-I in several specific ways (Table 284-1): (1) Although there is considerable overlap, average bilirubin concentrations are lower in CN-II; (2) accordingly, CN-II is only infrequently associated with kernicterus; (3) bile is deeply colored, and bilirubin glucuronides are present, with a striking, characteristic increase in the proportion of monoglucuronides; (4) UGT1A1 in liver is usually present at reduced levels (typically ≤10% of normal) but may be undetectable by older, less sensitive assays; (5) while typically detected in infancy, hyperbilirubinemia was not recognized in some cases until later in life and, in one instance, at age 34. As with CN-I, most CN-II cases exhibit abnormalities in the conjugation of other compounds, such as salicylamide and menthol, but in some instances the defect appears limited to bilirubin. Reduction of serum bilirubin concentrations by >25% in response to enzyme inducers such as phenobarbital distinguishes CN-II from CN-I, although this response may not be elicited in early infancy and often is not accompanied by measurable UGT1A1 induction. Bilirubin concentrations during phenobarbital administration do not return to normal but are typically in the range of 51 to 86 μmol/L (3 to 5 mg/dL). Although the incidence of kernicterus in CN-II is low, instances have occurred, not only in infants but also in adolescents and adults, often in the setting of an intercurrent illness, fasting, or another factor that temporarily raises the serum bilirubin concentration above baseline and reduces serum albumin levels. For this reason, phenobarbital therapy is widely recommended, a single bedtime dose often sufficing to maintain clinically safe plasma bilirubin concentrations.

At least 10 different mutations of *UGT1* have been identified that are associated with CN-II. Their common feature is that they encode for a bilirubin-UDP-glucuronosyltransferase with markedly reduced but detectable enzymatic activity. The spectrum of residual enzyme activity explains the spectrum of phenotypic severity of the resulting hyperbilirubinemia. Molecular analysis has established that a large majority of CN-II patients are either homozygotes or compound heterozygotes for CN-II mutations and that individuals carrying one mutated and one entirely normal allele have normal bilirubin concentrations. Possible inheritance of a dominant negative mutation in one case remains to be confirmed.

Gilbert's Syndrome This syndrome is characterized by mild unconjugated hyperbilirubinemia, normal values for standard hepatic biochemical tests, and normal hepatic histology other than a modest increase of lipofuscin pigment in some patients. Serum bilirubin concentrations are most often <51 μmol/L (<3 mg/dL), although both higher and lower values are frequent. The clinical spectrum of hyperbilirubinemia fades into that of CN-II at serum bilirubin concentrations of 86 to 136 μmol/L (5 to 8 mg/dL). At the other end of the scale, the distinction between mild cases of GS and a normal state is often blurred. Bilirubin concentrations may fluctuate substantially in any given individual, and at least 25% of patients will exhibit temporarily normal values during prolonged follow-up. More elevated values are associated with stress, fatigue, alcohol use, reduced caloric intake, and intercurrent illness, while increased caloric intake or administration of enzyme-inducing agents produce lower bilirubin levels. GS is most often diagnosed at or shortly after puberty or in adult life during routine examinations that include multichannel biochemical analyses. UGT1A1 activity is typically reduced to 10 to 35% of normal, and bile pigments exhibit a characteristic increase in bilirubin monoglucuronides. Studies of radiobilirubin kinetics indicate that hepatic bilirubin clearance is reduced to an average of one-third of normal. Administration of phenobarbital normalizes both the serum bilirubin concentration and hepatic bilirubin clearance; however, failure of UGT1A1 activity to improve in many such instances suggests the possible coexistence of an additional defect. Compartmental analysis of bilirubin kinetic data suggests that GS patients have a defect in bilirubin uptake as well as in conjugation. Defect(s) in the hepatic uptake of other organic anions that at least partially share an uptake mechanism with bilirubin, such as sulfobromophthalein and indocyanine green (ICG), are observed in a minority of patients. The metabolism and transport of bile acids, which do not utilize the bilirubin uptake mechanism, are normal. The magnitude of changes in the plasma bilirubin concentration induced by provocation tests such as 48 h of fasting or the intravenous administration of nicotinic acid have been reported to be of help in separating GS patients from normal individuals. Other studies dispute this assertion. Moreover, on theoretical grounds, the results of such studies should provide no more information than simple measurements of the baseline plasma bilirubin concentration. Family studies indicate that GS and hereditary hemolytic anemias such as hereditary spherocytosis, glucose-6-phosphate dehydrogenase deficiency, and β-thalassemia trait sort independently. Reports of hemolysis in up to 50% of GS patients are believed to reflect better case finding, since patients with both GS and hemolysis

have higher bilirubin concentrations, and are more likely to be jaundiced, than patients with either defect alone.

GS is common, with many series placing its prevalence at ≥8%. Males predominate over females by reported ratios ranging from 1.5:1 to >7:1. However, these ratios may have a large artifactual component since normal males have higher mean bilirubin levels than normal females, but the diagnosis of GS is often based on comparison to normal ranges established in men. The high prevalence of GS in the general population may explain the reported frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients. The disposition of most xenobiotics metabolized by glucuronidation appears to be normal in GS, as is oxidative drug metabolism in the majority of reported studies. The principal exception is the metabolism of the antitumor agent irinotecan (CPT-11), whose active metabolite (SN-38) is glucuronidated specifically by bilirubin-UDP-glucuronosyltransferase. Administration of CPT-11 to patients with GS has resulted in several toxicities, including intractable diarrhea and myelosuppression. Some reports also suggest abnormal disposition of menthol, estradiol benzoate, acetaminophen, tolbutamide, and rifamycin SV. Although some of these studies have been disputed, and there have been no reports of clinical complications from use of these agents in GS, prudence should be exercised in prescribing them, or any agents metabolized primarily by glucuronidation, in this condition.

Most older pedigree studies of GS were consistent with autosomal dominant inheritance with variable expressivity. However, studies of the *UGT1* gene in GS have indicated a variety of molecular genetic bases for the phenotypic picture and several different patterns of inheritance. Studies in Europe and the United States found that nearly all patients had normal coding regions for UGT1A1 but were homozygous for the insertion of an extra TA (i.e., A[TA]$_7$TAA rather than A[TA]$_6$TAA) in the promoter region of the first exon. This appeared to be necessary, but not sufficient, for clinically expressed GS, since 15% of normal controls were also homozygous for this variant. While normal by standard criteria, these individuals had somewhat higher bilirubin concentrations than the rest of the controls studied. Heterozygotes for this abnormality had bilirubin concentrations identical to those homozygous for the A[TA]$_6$TAA allele. The prevalence of the A[TA]$_7$TAA allele in a general western population is 30%, in which case 9% would be homozygotes. This is slightly higher than the prevalence of GS based on purely phenotypic parameters. It was suggested that additional variables, such as mild hemolysis or a defect in bilirubin uptake, might be among the factors enhancing phenotypic expression of the defect.

Phenotypic expression of GS due solely to the A[TA]$_7$TAA promoter abnormality is inherited as an autosomal recessive trait. A number of CN-II kindreds have been identified in which there is also an allele containing a normal coding region but the A[TA]$_7$TAA promoter abnormality. CN-II heterozygotes who have the A[TA]$_6$TAA promoter are phenotypically normal, whereas those with the A[TA]$_7$TAA promoter express the phenotypic picture of GS. GS in such kindreds may also result from homozygosity for the A[TA]$_7$TAA promoter abnormality. Seven different missense mutations in the *UGT1* gene that reportedly cause GS with dominant inheritance have been found in Japanese individuals. Another Japanese patient with mild unconjugated hyperbilirubinemia was homozygous for a missense mutation in exon 5. GS in her family appeared to be recessive. Missense mutations causing GS have not been reported outside of certain Asian populations.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO MIXED OR PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA

In hyperbilirubinemia due to acquired liver disease (e.g., acute hepatitis, common bile duct stone), there are usually elevations in the serum concentrations of both conjugated and unconjugated bilirubin. Although biliary tract obstruction or hepatocellular cholestatic injury may present on occasion with a predominantly conjugated hyperbilirubinemia, it is generally not possible to differentiate intrahepatic from extrahepatic causes of jaundice based upon the serum levels or relative proportions of unconjugated and conjugated bilirubin. The major reason for determining the amounts of conjugated and unconjugated bilirubin in the serum is for the initial differentiation of hepatic parenchymal and obstructive disorders (mixed conjugated and unconjugated hyperbilirubinemia) from the inheritable and hemolytic disorders discussed above that are associated with unconjugated hyperbilirubinemia.

FAMILIAL DEFECTS IN HEPATIC EXCRETORY FUNCTION ■ Dubin-Johnson Syndrome (DJS) This benign, relatively rare disorder is characterized by low-grade, predominantly conjugated hyperbilirubinemia (Table 284-2). Total bilirubin concentrations are typically between 34 and 85 μmol/L (2 and 5 mg/dL) but on occasion can be in the normal range or as high as 340 to 430 μmol/L (20 to 25 mg/dL) and can fluctuate widely in any given patient. The degree of hyperbilirubinemia may be increased by intercurrent illness, oral contraceptive use, and pregnancy. As the hyperbilirubinemia is due to a predominant rise in conjugated bilirubin, bilirubinuria is characteristically present. Aside from elevated serum bilirubin levels, other routine laboratory tests are normal. Physical examination is usually normal except for jaundice, although an occasional patient may have hepatosplenomegaly.

Patients with DJS are usually asymptomatic, although some may have vague constitutional symptoms. These latter patients have usually undergone extensive and often unnecessary diagnostic examinations for unexplained jaundice and have high levels of anxiety. In women, the condition may be subclinical until the patient becomes pregnant

TABLE 284-2 *Principal Differential Characteristics of Inheritable Disorders of Bile Canalicular Function*

	DJS	Rotor	PFIC1	BRIC	PFIC2	PFIC3
Gene	*ABCCA*	?	*ATP8B1*	*ATP8B1*	*ABCB11*	*ABCB4*
Protein	MRP2	?	FIC1	FIC1	BSEP	MDR3
Cholestasis	No	No	Yes	Episodic	Yes	Yes
Serum γ-GT	Normal	Normal	Normal	Normal	Normal	↑↑
Serum bile acids	Normal	Normal	↑↑	↑↑ during episodes	↑↑	↑↑
Clinical features	Mild conjugated hyperbilirubinemia; otherwise normal liver function; dark pigment in liver; characteristic pattern of urinary coproporphyrins	Mild conjugated hyperbilirubinemia; otherwise normal liver function; liver without abnormal pigmentation	Severe cholestasis beginning in childhood	Recurrent episodes of cholestasis beginning at any age	Severe cholestasis beginning in childhood	Severe cholestasis beginning in childhood; decreased phospholipids in bile

Note: DJS, Dubin-Johnson syndrome; PFIC, progressive familial intrahepatic cholestasis; MRP2, multidrug resistance–associated protein 2; BSEP, bile salt excretory protein; γ-GT, γ-glutamyltransferase; ↑↑, increased.

or receives oral contraceptives, at which time chemical hyperbilirubinemia becomes frank jaundice. Even in these situations, other routine liver function tests, including serum alkaline phosphatase and transaminase activities, are normal.

A cardinal feature of DJS is the accumulation in the lysosomes of centrilobular hepatocytes of dark, coarsely granular pigment. As a result, the liver may be grossly black in appearance. This pigment is thought to be derived from epinephrine metabolites that are not excreted normally. The pigment may disappear during bouts of viral hepatitis, only to reaccumulate slowly after recovery.

Biliary excretion of a number of anionic compounds is compromised in DJS. These include various cholecystographic agents, as well as sulfobromophthalein (Bromsulphalein, BSP), a synthetic dye formerly used in a test of liver function. In this test, the rate of disappearance of BSP from plasma was determined following bolus intravenous administration. BSP is conjugated with glutathione in the hepatocyte; the resulting conjugate is normally excreted rapidly into the bile canaliculus. Patients with DJS exhibit a characteristic rise in its plasma concentration at 90 min after injection, due to reflux of conjugated BSP into the circulation from the hepatocyte. Dyes such as ICG that are taken up by hepatocytes but are not further metabolized prior to biliary excretion do not show this reflux phenomenon. Continuous BSP infusion studies suggest a reduction in the t_{max} for biliary excretion. Bile acid disposition, including hepatocellular uptake and biliary excretion, is normal in DJS. These patients have normal serum and biliary bile acid concentrations and do not have pruritus.

By analogy with findings in several mutant rat strains, the selective defect in biliary excretion of bilirubin conjugates and certain other classes of organic compounds, but not of bile acids, that characterizes DJS in humans was found to reflect defective expression of MRP2, an ATP-dependent canalicular membrane transporter. Several different mutations in the *MRP2* gene produce the Dubin-Johnson phenotype, which has an autosomal recessive pattern of inheritance. Although MRP2 is undoubtedly important in the biliary excretion of conjugated bilirubin, the fact that this pigment is still excreted in the absence of MRP2 suggests that other, as yet uncharacterized, transport proteins may serve in a secondary role in this process.

Patients with DJS also have a diagnostic abnormality in urinary coproporphyrin excretion. There are two naturally occurring coproporphyrin isomers, I and III. Normally, approximately 75% of the coproporphyrin in urine is isomer III. In urine from DJS patients, total coproporphyrin content is normal, but >80% is isomer I. Heterozygotes for the syndrome show an intermediate pattern. The molecular basis for this phenomenon remains unclear.

Rotor Syndrome This benign, autosomal recessive disorder is clinically similar to DJS (Table 284-2), although it is seen even less frequently. A major phenotypic difference is that the liver in patients with Rotor syndrome has no increased pigmentation and appears totally normal. The only abnormality in routine laboratory tests is an elevation of total serum bilirubin, due to a predominant rise in conjugated bilirubin. This is accompanied by bilirubinuria. Several additional features differentiate Rotor syndrome and DJS. In Rotor syndrome, the gallbladder is usually visualized on oral cholecystography, in contrast to the nonvisualization that is typical of DJS. The pattern of urinary coproporphyrin excretion also differs. The pattern in Rotor syndrome resembles that of many acquired disorders of hepatobiliary function, in which coproporphyrin I, the major coproporphyrin isomer in bile, refluxes from the hepatocyte back into the circulation and is excreted in urine. Thus, total urinary coproporphyrin excretion is substantially increased in Rotor syndrome, in contrast to the normal levels seen in DJS. Although the fraction of coproporphyrin I in urine is elevated, it is usually <70% of the total, as compared to 80% or more in DJS. The disorders also can be distinguished by their patterns of BSP excretion. Although clearance of BSP from plasma is delayed in Rotor syndrome, there is no reflux of conjugated BSP back into the circulation as seen in DJS. Kinetic analysis of plasma BSP infusion studies suggests the presence of a defect in intrahepatocellular storage of this compound. This has never been demonstrated directly, and the molecular basis of Rotor syndrome remains unknown.

Benign Recurrent Intrahepatic Cholestasis (BRIC) This rare disorder is characterized by recurrent attacks of pruritus and jaundice. The typical episode begins with mild malaise and elevations in serum aminotransferase levels, followed rapidly by rises in alkaline phosphatase and conjugated bilirubin and onset of jaundice and itching. The first one or two episodes may be misdiagnosed as acute viral hepatitis. The cholestatic episodes, which may begin in childhood or adulthood, can vary in duration from several weeks to months, following which there is complete clinical and biochemical resolution. Intervals between attacks may vary from several months to years. Between episodes, physical examination is normal, as are serum levels of bile acids, bilirubin, transaminases, and alkaline phosphatase. The disorder is familial and has an autosomal recessive pattern of inheritance. BRIC is considered a benign disorder in that it does not lead to cirrhosis or end-stage liver disease. However, the episodes of jaundice and pruritus can be prolonged and debilitating, and some patients have undergone liver transplantation to relieve the intractable and disabling symptoms. Treatment during the cholestatic episodes is symptomatic; there is no specific treatment to prevent or shorten the occurrence of episodes.

A gene termed *FIC1* was recently identified and found to be mutated in patients with BRIC. Curiously, this gene is expressed strongly in the small intestine but only weakly in the liver. The protein encoded by *FIC1* shows little similarity to genes that have been shown to play a role in bile canalicular excretion of various compounds. Rather, it appears to be a member of a P-type ATPase family that transports aminophospholipids from the outer to the inner leaflet of a variety of cell membranes. Its relationship to the pathobiology of this disorder remains unclear.

Progressive Familial Intrahepatic Cholestasis (FIC) This name is applied to three phenotypically related syndromes (Table 284-2). Progressive FIC type 1 (Byler disease) presents in early infancy as cholestasis that may be initially episodic. However, in contrast to BRIC, Byler disease progresses to malnutrition, growth retardation, and end-stage liver disease during childhood. This disorder is also a consequence of a *FIC1* mutation. The functional relationship of the FIC1 protein to the pathogenesis of cholestasis in these disorders is unknown. Two other types of progressive FIC (types 2 and 3) have been described. Type 2 is associated with a mutation in the protein named *sister of p-glycoprotein*, which is the major bile canalicular exporter of bile acids and is also known as *bile salt excretory protein* (BSEP). Type 3 has been associated with a mutation of MDR3, a protein that is essential for normal hepatocellular excretion of phospholipids across the bile canaliculus. Although all three types of progressive FIC have similar clinical phenotypes, only type 3 is associated with high serum levels of γ-glutamyltransferase activity. In contrast, activity of this enzyme is normal or only mildly elevated in symptomatic BRIC and progressive FIC types 1 and 2.

285 ACUTE VIRAL HEPATITIS

Jules L. Dienstag, Kurt J. Isselbacher

Acute viral hepatitis is a systemic infection affecting the liver predominantly. Almost all cases of acute viral hepatitis are caused by one of five viral agents: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the HBV-associated delta agent or hepatitis D virus (HDV), and hepatitis E virus (HEV). Other transfusion-transmitted agents, e.g., "hepatitis G" virus and "TT" virus, have been identified but do not cause hepatitis. All these human hepatitis viruses are RNA viruses, except for hepatitis B, which is a DNA virus. Although these agents can be distinguished by their molecular and antigenic properties, all types of viral hepatitis produce clinically similar illnesses. These range from asymptomatic and inapparent to fulminant and fatal acute infections common to all types, on the one hand, and from subclinical persistent infections to rapidly progressive chronic liver disease with cirrhosis and even hepatocellular carcinoma, common to the bloodborne types (HBV, HCV, and HDV), on the other.

VIROLOGY AND ETIOLOGY ■ Hepatitis A Hepatitis A virus is a nonenveloped 27-nm, heat-, acid-, and ether-resistant RNA virus in the hepatovirus genus of the picornavirus family (Fig. 285-1). Its virion contains four capsid polypeptides, designated VP1 to VP4, which are cleaved posttranslationally from the polyprotein product of a 7500-nucleotide genome. Inactivation of viral activity can be achieved by boiling for 1 min, by contact with formaldehyde and chlorine, or by ultraviolet irradiation. Despite nucleotide sequence variation of up to 20% among isolates of HAV, all strains of this virus are immunologically indistinguishable and belong to one serotype. Hepatitis A has an incubation period of approximately 4 weeks. Its replication is limited to the liver, but the virus is present in the liver, bile, stools, and blood during the late incubation period and acute preicteric phase of illness. Despite persistence of virus in the liver, viral shedding in feces, viremia, and infectivity diminish rapidly once jaundice becomes apparent. HAV can be cultivated reproducibly in vitro.

Antibodies to HAV (anti-HAV) can be detected during acute illness when serum aminotransferase activity is elevated and fecal HAV shedding is still occurring. This early antibody response is predominantly of the IgM class and persists for several months, rarely for 6 to 12 months. During convalescence, however, anti-HAV of the IgG class becomes the predominant antibody (Fig. 285-2). Therefore, the diagnosis of hepatitis A is made during acute illness by demonstrating anti-HAV of the IgM class. After acute illness, anti-HAV of the IgG class remains detectable indefinitely, and patients with serum anti-HAV are immune to reinfection. Neutralizing antibody activity parallels the appearance of anti-HAV, and the IgG anti-HAV present in immune globulin accounts for the protection it affords against HAV infection.

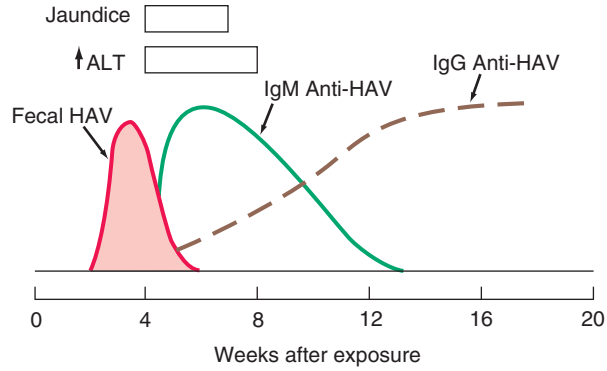

FIGURE 285-2 Scheme of typical clinical and laboratory features of viral hepatitis A.

Hepatitis B Hepatitis B virus is a DNA virus with a remarkably compact genomic structure; despite its small, circular, 3200-basepair size, HBV DNA codes for four sets of viral products with a complex, multiparticle structure. HBV achieves its genomic economy by relying on an efficient strategy of encoding proteins from four overlapping genes: S, C, P, and X (Fig. 285-3), as detailed below. Once thought to be unique among viruses, HBV is now recognized as one of a family of animal viruses, hepadnaviruses (hepatotropic DNA viruses), and is classified as hepadnavirus type 1. Similar viruses infect certain species of woodchucks, ground and tree squirrels, and Pekin ducks, to mention the most carefully characterized. Like HBV, all have the same distinctive three morphologic forms, have counterparts to the envelope and nucleocapsid virus antigens of HBV, replicate in the liver but exist in extrahepatic sites, contain their own endogenous DNA polymerase, have partially double-stranded and partially single-stranded genomes, are associated with acute and chronic hepatitis and hepatocellular carcinoma, and rely on a replicative strategy unique among DNA viruses but typical of retroviruses. Instead of DNA replication directly from a DNA template, hepadnaviruses rely on reverse transcription (effected by the DNA polymerase) of minus-strand DNA from a "pregenomic" RNA intermediate. Then plus-strand DNA is transcribed from the minus-strand DNA template by the DNA-dependent DNA polymerase and converted in the hepatocyte nucleus to a covalently closed circular DNA, which serves as a template for messenger RNA and pregenomic RNA. Viral proteins are translated by the messenger RNA, and the proteins and genome are packaged into virions and secreted from the hepatocyte. Although HBV is difficult to cultivate in vitro in the conventional sense from clinical material, several cell lines have been transfected with HBV DNA. Such transfected cells support in vitro replication of the intact virus and its component proteins.

VIRAL PROTEINS AND PARTICLES Of the three particulate forms of HBV (Table 285-1), the most numerous are the 22-nm particles, which appear as spherical or long filamentous forms; these are antigenically indistinguishable from the outer surface or envelope protein of HBV and are thought to represent excess viral envelope protein. Outnumbered in serum by a factor of 100 or 1000 to 1 compared with the spheres and tubules are large, 42-nm, double-shelled spherical particles, which represent the intact hepatitis B virion (Fig. 285-1) . The envelope protein expressed on the outer surface of the virion and on the smaller spherical and tubular structures is referred to as *hepatitis B surface antigen* (HBsAg). The concentration of HBsAg and virus particles in the blood may reach 500 μg/mL and 10 trillion particles per milliliter, respectively. The envelope protein, HBsAg, is the product of the S gene of HBV.

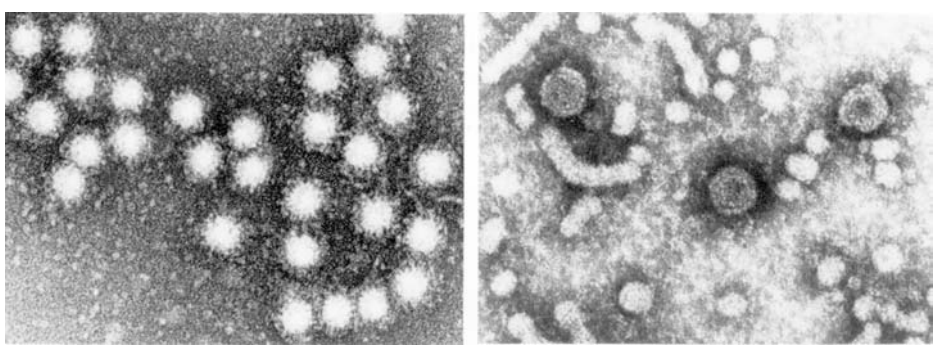

FIGURE 285-1 *Left*. Electron micrograph of 27-nm hepatitis A virus particles purified from stool of a patient with acute hepatitis A virus infection and aggregated by hepatitis A antibody. *Right*. Electron micrograph of concentrated serum from a patient with hepatitis B infection, demonstrating the 42-nm virions, tubular forms, and spherical 22-nm particles of hepatitis B surface antigen. 132,000×. (Hepatitis D resembles 42-nm virions of hepatitis B but is smaller, 35 to 37 nm; hepatitis E resembles hepatitis A virus but is slightly larger, 32 to 34 nm; hepatitis C has not been visualized definitively.)

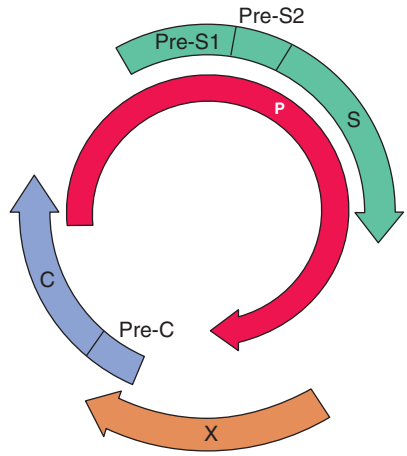

FIGURE 285-3 Its compact genomic structure, with overlapping genes, permits HBV to code for multiple proteins. The S gene codes for the "major" envelope protein, HBsAg. Pre-S1 and pre-S2, upstream of S, combine with S to code for two larger proteins, "middle" protein, the product of pre-S2 + S, and "large" protein, the product of pre-S1 + pre-S2 + S. The largest gene, P, codes for DNA polymerase. The C gene codes for two nucleocapsid proteins, HBeAg, a soluble, secreted protein (initiation from the pre-C region of the gene) and HBcAg, the intracellular core protein (initiation after pre-C). The X gene codes for HBxAg, which can transactivate the transcription of cellular and viral genes; its clinical relevance is not known, but it may contribute to carcinogenesis by binding to p53.

A number of different HBsAg subdeterminants have been identified. There is a common group-reactive antigen, *a*, shared by all HBsAg isolates. In addition, HBsAg may contain one of several subtype-specific antigens, namely, *d* or *y*, *w* or *r*, as well as other more recently characterized specificities. Hepatitis B isolates fall into one of at least eight subtypes and seven genotypes (A–G). Geographic distribution of genotypes and subtypes varies; genotypes A (corresponding to subtype *adw* and D (*ayw*) predominate in the United States and Europe, while genotypes B (*adw*) and C (*adr*) predominate in Asia. Clinical course and outcome are independent of subtype, but preliminary reports suggest that genotype B is associated with less rapidly progressive liver disease and a lower likelihood, or delayed appearance, of hepatocellular carcinoma than genotype C. In addition, "precore" mutations are favored by certain genotypes (see below).

Upstream of the S gene are the pre-S genes (Fig. 285-3), which code for pre-S gene products, including receptors on the HBV surface for polymerized human serum albumin and for hepatocyte membrane proteins. The pre-S region actually consists of both pre-S1 and pre-S2. Depending on where translation is initiated, three potential HBsAg gene products are synthesized. The protein product of the S gene is HBsAg (*major protein*), the product of the S region plus the adjacent pre-S2 region is the *middle protein*, and the product of the pre-S1 plus pre-S2 plus S regions is the *large protein*. Compared with the smaller spherical and tubular particles of HBV, complete 42-nm virions are enriched in the large protein. Both pre-S proteins and their respective antibodies can be detected during HBV infection, and the period of pre-S antigenemia appears to coincide with other markers of virus replication, as detailed below.

The intact 42-nm virion contains a 27-nm nucleocapsid core particle. Nucleocapsid proteins are coded for by the C gene. The antigen expressed on the surface of the nucleocapsid core is referred to as *hepatitis B core antigen* (HBcAg), and its corresponding antibody is anti-HBc. A third HBV antigen is *hepatitis B e antigen* (HBeAg), a soluble, nonparticulate, nucleocapsid protein that is immunologically distinct from intact HBcAg but is a product of the same C gene. The C gene has two initiation codons, a precore and a core region (Fig. 285-3). If translation is initiated at the precore region, the protein product is HBeAg, which has a signal peptide that binds it to the smooth endoplasmic reticulum and leads to its secretion into the circulation. If translation begins with the core region, HBcAg is the protein product; it has no signal peptide, it is not secreted, but it assembles into nucleocapsid particles, which bind to and incorporate RNA and which, ultimately, contain HBV DNA. Also packaged within the nucleocapsid core is a DNA polymerase, which directs replication and repair of HBV DNA. When packaging within viral proteins is complete, synthesis of the incomplete plus strand stops; this accounts for the single-stranded gap and for differences in the size of the gap. HBcAg particles remain in the hepatocyte, where they are readily detectable by immunohistochemical staining, and are exported after encapsidation by an envelope of HBsAg. Therefore, naked core particles do not circulate in the serum. The secreted nucleocapsid protein, HBeAg, provides a convenient, readily detectable, qualitative marker of HBV replication and relative infectivity.

HBsAg-positive serum containing HBeAg is more likely to be highly infectious and to be associated with the presence of hepatitis B virions (and detectable HBV DNA, see below) than HBeAg-negative or anti-HBe-positive serum. For example, HBsAg carrier mothers who are HBeAg-positive almost invariably (>90%) transmit hepatitis B infection to their offspring, whereas HBsAg carrier mothers with anti-HBe rarely (10 to 15%) infect their offspring.

Early during the course of acute hepatitis B, HBeAg appears transiently; its disappearance may be a harbinger of clinical improvement and resolution of infection. Persistence of HBeAg in serum beyond the first 3 months of acute infection may be predictive of the development of chronic infection, and the presence of HBeAg during chronic hepatitis B is associated with ongoing viral replication, infectivity, and inflammatory liver injury.

The third of the HBV genes is the largest, the P gene (Fig. 285-3), which codes for the DNA polymerase; as noted above, this enzyme has both DNA-dependent DNA polymerase and RNA-dependent reverse transcriptase activities. The fourth gene, X, codes for a small, nonparticulate protein, hepatitis B x antigen (HBxAg), that is capable of transactivating the transcription of both viral and cellular genes (Fig. 285-3). In the cytoplasm, HBxAg effects calcium release (possibly from mitochrondria), which activates signal-transduction pathways that lead to stimulation of HBV reverse transcription and HBV DNA replication. Such transactivation may enhance the replication of HBV, leading to the clinical association observed between the expression of HBxAg and antibodies to it in patients with severe chronic hepatitis and hepatocellular carcinoma. The transactivating activity can enhance the transcription and replication of other viruses besides HBV, such as HIV. Cellular processes transactivated by X include the human interferon γ gene and class I major histocompatibility genes; potentially, these effects could contribute to enhanced susceptibility of HBV-infected hepatocytes to cytolytic T cells. The expression of X can also induce programmed cell death (apoptosis).

SEROLOGIC AND VIROLOGIC MARKERS After a person is infected with HBV, the first virologic marker detectable in serum is HBsAg (Fig. 285-4). Circulating HBsAg precedes elevations of serum aminotransferase activity and clinical symptoms and remains detectable during the entire icteric or symptomatic phase of acute hepatitis B and beyond. In typical cases, HBsAg becomes undetectable 1 to 2 months after the onset of jaundice and rarely persists beyond 6 months. After HBsAg disappears, antibody to HBsAg (anti-HBs) becomes detectable in serum and remains detectable indefinitely thereafter. Because HBcAg is sequestered within an HBsAg coat, HBcAg is not detectable routinely in the serum of patients with HBV infection. By contrast, anti-HBc is readily demonstrable in serum, beginning within the first 1 to 2 weeks after the appearance of HBsAg and preceding detectable levels of anti-HBs by weeks to months. Because variability exists in the time of appearance of anti-HBs after HBV infection, occasionally a gap of several weeks or longer may separate the disappearance of HBsAg and the appearance of anti-HBs. During this "gap" or "window" period, anti-HBc may represent serologic evidence of current or recent HBV infection, and blood containing anti-HBc in the absence of HBsAg and anti-HBs has been implicated in the development of transfusion-as-

TABLE 285-1 *Nomenclature and Features of Hepatitis Viruses*

Hepatitis Type	Virus Particle	Morphology	Genome[a]	Classification	Antigen(s)	Antibodies	Remarks
HAV	27 nm	Icosahedral nonenveloped	7.5-kb RNA, linear, ss, +	Hepatovirus	HAV	Anti-HAV	Early fecal shedding Diagnosis: IgM anti-HAV Previous infection: IgG anti-HAV
HBV	42 nm	Double-shelled virion (surface and core) spherical	3.2-kb DNA, circular, ss/ds	Hepadnavirus	HBsAg HBcAg HBeAg	Anti-HBs Anti-HBc Anti-HBe	Bloodborne virus; carrier state Acute diagnosis: HBsAg, IgM anti-HBc Chronic diagnosis: IgG anti-HBc, HBsAg Markers of replication: HBeAg, HBV DNA Liver, lymphocytes, other organs
	27 nm	Nucleocapsid core			HBcAg HBeAg	Anti-HBc Anti-HBe	Nucleocapsid contains DNA and DNA polymerase; present in hepatocyte nucleus; HBcAg does not circulate; HBeAg (soluble, nonparticulate) and HBV DNA circulate—correlate with infectivity and complete virions
	22 nm	Spherical and filamentous; represents excess virus coat material			HBsAg	Anti-HBs	HBsAg detectable in >95% of patients with acute hepatitis B; found in serum, body fluids, hepatocyte cytoplasm; anti-HBs appears following infection—protective antibody
HCV	Approx. 40–60 nm	Enveloped	9.4-kb RNA, linear, ss, +	Hepacivirus	HCV C100-3 C33c C22-3 NS5	Anti-HCV	Bloodborne agent, formerly labeled non-A, non-B hepatitis Acute diagnosis: anti-HCV (C33c, C22-3, NS5), HCV RNA Chronic diagnosis: anti-HCV (C100-3, C33c, C22-3, NS5) and HCV RNA; cytoplasmic location in hepatocytes
HDV	35–37 nm	Enveloped hybrid particle with HBsAg coat and HDV core	1.7-kb RNA, circular, ss, −	Resembles viroids and plant satellite viruses	HBsAg HDV antigen	Anti-HBs Anti-HDV	Defective RNA virus, requires helper function of HBV (hepadnaviruses); HDV antigen present in hepatocyte nucleus Diagnosis: anti-HDV, HDV RNA; HBV/HDV coinfection—IgM anti-HBc and anti-HDV; HDV superinfection—IgG anti-HBc and anti-HDV
HEV	32–34 nm	Nonenveloped icosahedral	7.6-kb RNA, linear, ss, +	Alphavirus-like	HEV antigen	Anti-HEV	Agent of enterically transmitted hepatitis; rare in USA; occurs in Asia, Mediterranean countries, Central America Diagnosis: IgM/IgG anti-HEV (assays being developed); virus in stool, bile, hepatocyte cytoplasm

[a] ss, single-strand; ss/ds, partially single-strand, partially double-strand; −, minus-strand; +, plus-strand.

sociated hepatitis B. In part because the sensitivity of immunoassays for HBsAg and anti-HBs has increased, however, this window period is rarely encountered. In some persons, years after HBV infection, anti-HBc may persist in the circulation longer than anti-HBs. Therefore, isolated anti-HBc does not necessarily indicate active virus replication; most instances of isolated anti-HBc represent hepatitis B infection in the remote past. Rarely, however, isolated anti-HBc represents low-level hepatitis B viremia, with HBsAg below the detection threshold; occasionally, isolated anti-HBc represents a cross-reacting or false-positive immunologic specificity. Recent and remote HBV infections can be distinguished by determination of the immunoglobulin class of anti-HBc. Anti-HBc of the IgM class (IgM anti-HBc) predominates during the first 6 months after acute infection, whereas IgG anti-HBc is the predominant class of anti-HBc beyond 6 months. Therefore,

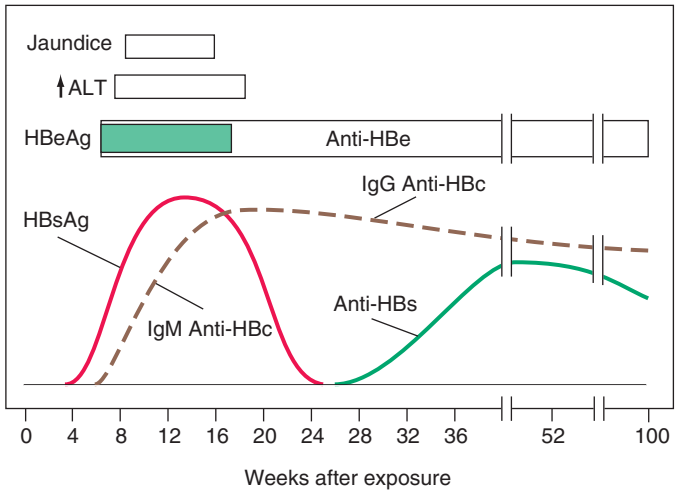

FIGURE 285-4 Scheme of typical clinical and laboratory features of acute viral hepatitis B.

patients with current or recent acute hepatitis B, including those in the anti-HBc window, have IgM anti-HBc in their serum. In patients who have recovered from hepatitis B in the remote past as well as those with chronic HBV infection, anti-HBc is predominantly of the IgG class. Infrequently, in no more than 1 to 5% of patients with acute HBV infection, levels of HBsAg are too low to be detected; in such cases, the presence of IgM anti-HBc establishes the diagnosis of acute hepatitis B. When isolated anti-HBc occurs in the rare patient with chronic hepatitis B whose HBsAg level is below the sensitivity threshold of contemporary immunoassays (a low-level carrier), the anti-HBc is of the IgG class. Generally, in persons who have recovered from hepatitis B, anti-HBs and anti-HBc persist indefinitely.

The temporal association between the appearance of anti-HBs and resolution of HBV infection as well as the observation that persons with anti-HBs in serum are protected against reinfection with HBV suggest that *anti-HBs is the protective antibody*. Therefore, strategies for prevention of HBV infection are based on providing susceptible persons with circulating anti-HBs (see below). Occasionally, in 10 to 20% of patients with chronic hepatitis B, low-level, low-affinity anti-HBs can be detected. This antibody is directed against a subtype determinant different from that represented by the patient's HBsAg; its presence is thought to reflect the stimulation of a related clone of antibody-forming cells, but it has no clinical relevance and does not signal imminent clearance of hepatitis B.

The other readily detectable serologic marker of HBV infection, HBeAg, appears concurrently with or shortly after HBsAg. Its appearance coincides temporally with high levels of virus replication and reflects the presence of circulating intact virions and detectable HBV DNA. Pre-S1 and pre-S2 proteins are also expressed during periods of peak replication, but assays for these gene products are not routinely available. In self-limited HBV infections, HBeAg becomes undetectable shortly after peak elevations in aminotransferase activity, before the disappearance of HBsAg, and anti-HBe then becomes detectable, coinciding with a period of relatively lower infectivity (Fig. 285-4). Because markers of HBV replication appear transiently during acute infection, testing for such markers is of little clinical utility in typical cases of acute HBV infection. In contrast, markers of HBV replication provide valuable information in patients with protracted infections.

Departing from the pattern typical of acute HBV infections, in chronic HBV infection, HBsAg remains detectable beyond 6 months, anti-HBc is primarily of the IgG class, and anti-HBs is either undetectable or detectable at low levels (see "Laboratory Features," below) (Fig. 285-5). During early chronic HBV infection, HBV DNA can be detected both in serum and in hepatocyte nuclei, where it is present in free or episomal form. This *replicative stage* of HBV infection is the time of maximal infectivity and liver injury; HBeAg is a qualitative marker and HBV DNA a quantitative marker of this replicative phase, during which all three forms of HBV circulate, including intact virions. Over time, the replicative phase of chronic HBV infection gives way to a relatively *nonreplicative phase*. This occurs at a rate of approximately 10% per year and is accompanied by seroconversion from HBeAg-positive to anti-HBe-positive. In most cases, this seroconversion coincides with a transient, acute hepatitis-like elevation in aminotransferase activity, believed to reflect cell-mediated immune clearance of virus-infected hepatocytes. In the nonreplicative phase of chronic infection, when HBV DNA is demonstrable in hepatocyte nuclei, it tends to be integrated into the host genome. In this phase, only spherical and tubular forms of HBV, *not intact virions*, circulate, and liver injury tends to subside. Most such patients would be characterized as *inactive HBV carriers*. In reality, the designations *replicative* and *nonreplicative* are only relative; even in the so-called nonreplicative phase, HBV replication can be detected with highly sensitive amplification probes such as the polymerase chain reaction (PCR). Still, the distinctions are pathophysiologically and clinically meaningful. Occasionally, nonreplicative HBV infection converts back to replicative infection. Such spontaneous reactivations are accompanied by reexpression of HBeAg and HBV DNA, and sometimes of IgM anti-HBc, as well as by exacerbations of liver injury.

MOLECULAR VARIANTS Variation occurs throughout the HBV genome, and clinical isolates of HBV that do not express typical viral proteins have been attributed to mutations in individual or even multiple gene locations. For example, variants have been described that lack nucleocapsid proteins, envelope proteins, or both. Two categories of HBV have attracted the most attention. One of these was identified initially in Mediterranean countries among patients with an unusual serologic-clinical profile. They have severe chronic HBV infection and detectable HBV DNA but with anti-HBe instead of HBeAg. These patients were found to be infected with an HBV mutant that contained an alteration in the precore region rendering the virus incapable of encoding HBeAg. Although several potential mutation sites exist in the pre-C region, the region of the C gene necessary for the expression of HBeAg (see "Virology and Etiology," above), the most commonly encountered in such patients is a single base substitution, from G to A, which occurs in the second to last codon of the pre-C gene at nucleotide 1896. This substitution results in the replacement of the TGG tryptophan codon by a stop codon (TAG), which prevents the translation of HBeAg. Another mutation, in the core promoter region, prevents transcription of the coding region for HBeAg and yields an

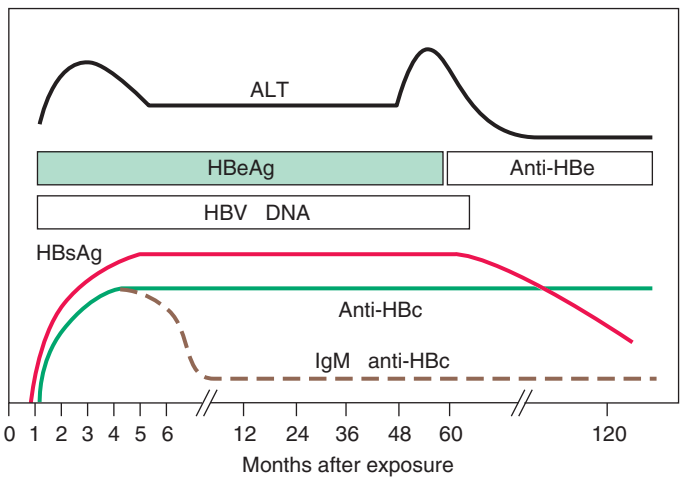

FIGURE 285-5 Scheme of typical laboratory features of chronic viral hepatitis B. HBeAg and HBV DNA can be detected in serum during the *replicative phase* of chronic infection, which is associated with infectivity and liver injury. Seroconversion from the replicative phase to the *nonreplicative phase* occurs at a rate of approximately 10 to 15% per year and is heralded by an acute hepatitis–like elevation of ALT activity; during the nonreplicative phase, infectivity and liver injury are limited.

HBeAg-negative phenotype. Patients with such precore mutants that are unable to secrete HBeAg tend to have severe liver disease that progresses more rapidly to cirrhosis. Both "wild-type" HBV and precore-mutant HBV can coexist in the same patient, or mutant HBV may arise late during wild-type HBV infection. In addition, clusters of fulminant hepatitis B in Israel and Japan have been attributed to common-source infection with a precore mutant. Fulminant hepatitis B in North America and western Europe, however, occurs in patients infected with wild-type HBV, in the absence of precore mutants, and both precore mutants and other mutations throughout the HBV genome occur commonly even in patients with typical, self-limited, milder forms of HBV infection. Precore-mutant hepatitis B is now the most frequently encountered form of hepatitis B in Mediterranean countries and in Europe. In the United States, where HBV genotype A (less prone to G1896A mutation) is prevalent, precore-mutant HBV is much less common. Characteristic of such HBeAg-negative chronic hepatitis B are lower levels of HBV DNA and periodic fluctuations in hepatic necroinflammatory activity.

The second important category of HBV mutants consists of *escape mutants*, in which a single amino acid substitution, from glycine to arginine, occurs at position 145 of the immunodominant *a* determinant common to all subtypes of HBsAg. This change in HBsAg leads to a critical conformational change that results in a loss of neutralizing activity by anti-HBs. This specific HBV/*a* mutant has been observed in two situations, active and passive immunization, in which humoral immunologic pressure may favor evolutionary change ("escape") in the virus—in a small number of hepatitis B vaccine recipients who acquired HBV infection despite the prior appearance of neutralizing anti-HBs and in liver transplant recipients who underwent the procedure for hepatitis B and who were treated with a high-potency human monoclonal anti-HBs preparation. Although such mutants have not been recognized frequently, their existence raises a concern that may complicate vaccination strategies and serologic diagnosis.

EXTRAHEPATIC SITES Hepatitis B antigens and HBV DNA have been identified in extrahepatic sites, including lymph nodes, bone marrow, circulating lymphocytes, spleen, and pancreas. Although the virus does not appear to be associated with tissue injury in any of these extrahepatic sites, its presence in these "remote" reservoirs has been invoked to explain the recurrence of HBV infection after orthotopic liver transplantation. A more complete understanding of the clinical relevance of extrahepatic HBV remains to be defined.

Hepatitis D The delta hepatitis agent, or HDV, is a defective RNA virus that coinfects with and requires the helper function of HBV (or other hepadnaviruses) for its replication and expression. Slightly smaller than HBV, delta is a formalin-sensitive, 35- to 37-nm virus with a hybrid structure. Its nucleocapsid expresses delta antigen, which bears no antigenic homology with any of the HBV antigens, and contains the virus genome. The delta core is "encapsidated" by an outer envelope of HBsAg, indistinguishable from that of HBV except in its relative compositions of major, middle, and large HBsAg component proteins. The genome is a small, 1700-nucleotide, circular, single-stranded RNA (minus strand) that is nonhomologous with HBV DNA (except for a small area of the polymerase gene) but that has features and the rolling circle model of replication common to genomes of plant satellite viruses or viroids. HDV RNA contains many areas of internal complementarity; therefore, it can fold on itself by internal base pairing to form an unusual, very stable, rodlike structure. HDV RNA requires host RNA polymerase II for its replication via RNA-directed RNA synthesis by transcription of genomic RNA to a complementary antigenomic (plus strand) RNA; the antigenomic RNA, in turn, serves as a template for subsequent genomic RNA synthesis. Between the genomic and antigenomic RNAs of HDV, there are coding regions for nine proteins. Delta antigen, which is a product of the antigenomic strand, exists in two forms, a small, 195-amino-acid species, which plays a role in facilitating HDV RNA replication, and a large, 214-amino-acid species, which appears to suppress replication but is required for assembly of the antigen into virions. Delta antigens have been shown to bind directly to RNA polymerase II, resulting in stimulation of transcription. Although complete hepatitis D virions and liver injury require the cooperative helper function of HBV, intracellular replication of HDV RNA can occur without HBV. Genomic heterogeneity among HDV isolates has been described; however, pathophysiologic and clinical consequences of this genetic diversity have not been recognized.

HDV can either infect a person simultaneously with HBV (*coinfection*) or superinfect a person already infected with HBV (*superinfection*); when HDV infection is transmitted from a donor with one HBsAg subtype to an HBsAg-positive recipient with a different subtype, the HDV agent assumes the HBsAg subtype of the recipient, rather than the donor. Because HDV relies absolutely on HBV, the duration of HDV infection is determined by the duration of (and cannot outlast) HBV infection. HDV antigen is expressed primarily in hepatocyte nuclei and is occasionally detectable in serum. During acute HDV infection, anti-HDV of the IgM class predominates, and 30 to 40 days may elapse after symptoms appear before anti-HDV can be detected. In self-limited infection, anti-HDV is low titer and transient, rarely remaining detectable beyond the clearance of HBsAg and HDV antigen. In chronic HDV infection, anti-HDV circulates in high titer, and both IgM and IgG anti-HDV can be detected. HDV antigen in the liver and HDV RNA in serum and liver can be detected during HDV replication.

Hepatitis C Hepatitis C virus, which, before its identification was labeled "non-A, non-B hepatitis," is a linear, single-strand, positive-sense, 9600-nucleotide RNA virus, the genome of which is similar in organization to that of flaviviruses and pestiviruses; HCV is the only member of the genus *Hepacivirus* in the family Flaviviridae. The HCV genome contains a single large open reading frame (gene) that codes for a virus polyprotein of approximately 3000 amino acids. The 5′ end of the genome consists of an untranslated region (containing an internal ribosomal entry site) adjacent to the genes for structural proteins, the nucleocapsid core protein and two envelope glycoproteins, E1 and E2/NS1. The 5′ untranslated region and core gene are highly conserved among genotypes, but the envelope proteins are coded for by the hypervariable region, which varies from isolate to isolate and may allow the virus to evade host immunologic containment directed at accessible virus-envelope proteins. The 3′ end of the genome contains the genes for nonstructural (NS) proteins. The first reported HCV clone, 5-1-1, and the nucleotide sequence coding for C100-3, the recombinant virus protein used in the first immunoassay for antibodies to HCV, reside within the NS4 gene, and the RNA-dependent RNA polymerase, through which HCV replicates, is encoded by the NS5 region (Fig. 285-6). Because HCV does not replicate via a DNA intermediate, it does not integrate into the host genome. Because HCV tends to circulate in relatively low titer, visualization of virus particles, estimated to be 40 to 60 nm in diameter, has been difficult. Still, the replication rate of HCV is very high, 10^{12} virions per day; its half-life is 2.7 h. The chimpanzee is a helpful but cumbersome animal model. Although in vitro replication has been difficult, hepatocellular carcinoma–derived cell lines have been described (replicon systems) that support replication of genetically manipulated, truncated or full-length HCV RNA (but not intact virions). Although a robust, reproducible, small-animal model is lacking, HCV replication has been documented in an immunodeficient-mouse model containing explants of human liver.

At least six distinct genotypes, as well as subtypes within genotypes, of HCV have been identified by nucleotide sequencing. Genotypes differ one from another in sequence homology by ≥30%. Because divergence of HCV isolates within a genotype or subtype, and within the same host, may vary insufficiently to define a distinct genotype, these intragenotypic differences are referred to as *quasispecies* and differ in sequence homology by only a few percent. The genotypic and quasispecies diversity of HCV, resulting from its high mutation

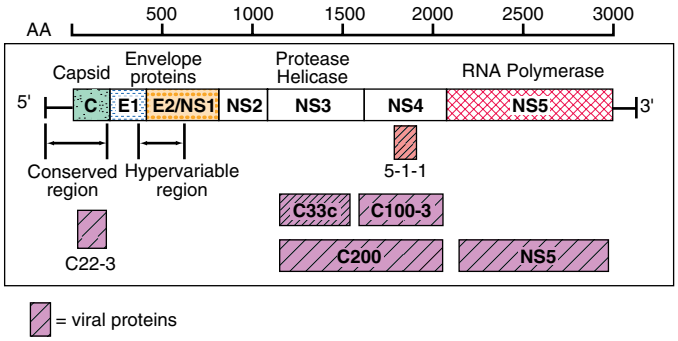

FIGURE 285-6 Organization of the hepatitis C virus genome and its associated proteins. Structural genes at the 5′ end include the nucleocapsid region, C, and the envelope regions, E1 and E2. The 5′ untranslated region and the C region are highly conserved among isolates, while the envelope domain E2/NS1 contains the hypervariable region. At the 3′ end are five nonstructural (NS) regions. Viral proteins included in the first-generation (C100-3), second-generation (C200, a fusion protein of C100-3 and C33c, and C22-3), and third-generation (C22-3, C200, or C33c and C100-3, and NS5) immunoassays and in the recombinant immunoblot assay (5-1-1, C100-3, C33c, C22-3, NS5) are presented below their corresponding genes (AA, amino acid).

rate, interferes with effective humoral immunity. Neutralizing antibodies to HCV have been demonstrated, but they tend to be short-lived; and HCV infection does not induce lasting immunity against reinfection with different virus isolates or even the same virus isolate. Thus, neither *heterologous* nor *homologous* immunity appears to develop commonly after acute HCV infection. Some HCV genotypes are distributed worldwide, while others are more geographically confined. In addition, differences exist among genotypes in responsiveness to antiviral therapy; however, early reports of differences in pathogenicity among genotypes have not been corroborated.

As noted above, the first assay detected antibodies to C100-3, a recombinant polypeptide derived from the NS4 region of the genome. In most patients with acute hepatitis C, antibody detected with this assay appears between 1 to 3 months after the onset of acute hepatitis but sometimes not for a year or longer. Second-generation assays incorporate recombinant proteins from the nucleocapsid core region, C22-3, and the NS3 region, C33c (expressed in combination with C100-3 as C200); these assays are more sensitive (by approximately 20%) and detect anti-HCV 30 to 90 days earlier, during the period of acute hepatitis. A third-generation immunoassay, which incorporates proteins from the NS5 region and replaces some recombinant proteins with synthetic peptides, may detect anti-HCV even earlier. Because nonspecificity has been encountered in clinical samples tested for anti-HCV, a supplementary recombinant immunoblot assay was introduced. Reactivity in an immunoassay is "confirmed" by incubation with a nitrocellulose strip that contains individual bands of recombinant or synthetic HCV proteins. This approach allows the demonstration of individual antibodies to nonstructural and structural viral proteins and identifies false-positive reactivity associated with nonviral specificities. Although useful to support the validity of anti-HCV-reactive samples, especially in patients with a low prior probability of true infection (e.g., blood donors) or in patients with confounding activity in serum (such as a rheumatoid factor) that may yield false-positive antibody reactivity, immunoblotting assays have been supplanted by tests for HCV RNA. The most sensitive indicator is the presence of HCV RNA, which requires molecular amplification by (PCR) or transcription-mediated amplification (TMA) (Fig. 285-7). An alternative method for detection of HCV RNA, more easily automated but one or two orders of magnitude less sensitive, is branched-chain complementary DNA hybridization. HCV RNA can be detected within a few days of exposure to HCV, well before the appearance of anti-HCV, and tends to persist for the duration of HCV infection; however, occasionally in patients with chronic HCV infection, HCV RNA may be detectable only intermittently. Application of sensitive molecular probes for HCV RNA has revealed the presence of replicative HCV in peripheral blood lymphocytes of infected persons; however, as is the case for HBV in lymphocytes, the clinical relevance of HCV lymphocyte infection is not known.

Hepatitis E Previously labeled *epidemic* or *enterically transmitted non-A, non-B hepatitis*, HEV is an enterically transmitted virus that occurs primarily in India, Asia, Africa, and Central America. This agent, with epidemiologic features resembling those of hepatitis A, is a 32- to 34-nm, nonenveloped, HAV-like virus with a 7600-nucleotide, single-stranded, positive-sense RNA genome. HEV has three open reading frames (genes), the largest of which encodes nonstructural proteins involved in virus replication. A middle-sized gene encodes the nucleocapsid protein, and the smallest, whose function is not known, encodes protein specificities to which antibodies appear in human serum. All HEV isolates appear to belong to a single serotype, despite genomic heterogeneity of up to 25%. There is no genomic or antigenic homology, however, between HEV and HAV or other picornaviruses; and HEV, although resembling calciviruses, appears to be sufficiently distinct from any known agent to merit a new classification of its own within the alphavirus group. The virus has been detected in stool, bile, and liver and is excreted in the stool during the late incubation period; immune responses to viral antigens occur very early during the course of acute infection. Both IgM anti-HEV and IgG anti-HEV can be detected, but both fall rapidly after acute infection, reaching low levels within 9 to 12 months. Currently, serologic testing for HEV infection is not available routinely.

PATHOGENESIS Under ordinary circumstances, none of the hepatitis viruses is known to be directly cytopathic to hepatocytes. Evidence suggests that the clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host.

HEPATITIS B Among the viral hepatitides, the immunopathogenesis of hepatitis B has been studied most extensively. Certainly for this agent, the existence of inactive hepatitis B carriers with normal liver histology and function suggests that the virus is not directly cytopathic. The fact that patients with defects in cellular immune competence are more likely to remain chronically infected rather than to clear the virus is cited to support the role of cellular immune responses in the pathogenesis of hepatitis B–related liver injury. The model that has the most experimental support involves cytolytic T cells sensitized specifically to recognize host and hepatitis B viral antigens on the liver cell surface. Laboratory observations suggest that nucleocapsid proteins (HBcAg and possibly HBeAg), present on the cell membrane in minute quantities, are the viral target antigens that, with host antigens, invite cytolytic T cells to destroy HBV-infected hepatocytes. Differences in the

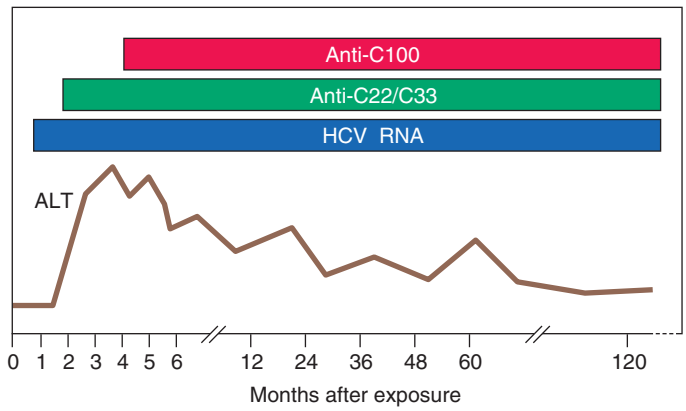

FIGURE 285-7 Scheme of typical laboratory features during acute hepatitis C progressing to chronicity. HCV RNA is the first detectable event, preceding ALT elevation and the appearance of anti-HCV. The appearance of antibody to C100, detectable with first-generation assays, is delayed from 1 to 3 months after the appearance of antibody to C22 and C33, antibodies that are included in second-generation immunoassays. Anti-HCV detectable with second-generation assays appears during acute hepatitis C.

robustness of cytolytic T cell responsiveness and in the elaboration of antiviral cytokines by T cells have been invoked to explain differences in outcomes between those who recover after acute hepatitis and those who progress to chronic hepatitis or between those with mild and those with severe (fulminant) acute HBV infection.

Although a robust cytolytic T cell response occurs and eliminates virus-infected liver cells during acute hepatitis B, >90% of HBV DNA has been found in experimentally infected chimpanzees to disappear from the liver and blood before maximal T cell infiltration of the liver and before most of the biochemical and histologic evidence of liver injury. This observation suggests that inflammatory cytokines, independent of cytopathic antiviral mechanisms, participate in early viral clearance; this effect has been shown to represent elimination of HBV replicative intermediates from the cytoplasm and covalently closed circular viral DNA from the nucleus of infected hepatocytes.

Debate continues over the relative importance of viral and host factors in the pathogenesis of HBV-associated liver injury and its outcome. As noted above, precore genetic mutants of HBV have been associated with the more severe outcomes of HBV infection (severe chronic and fulminant hepatitis), suggesting that, under certain circumstances, relative pathogenicity is a property of the virus, not the host. The fact that concomitant HDV and HBV infections are associated with more severe liver injury than HBV infection alone and the fact that cells transfected in vitro with the gene for HDV (delta) antigen express HDV antigen and then become necrotic in the absence of any immunologic influences are also consistent with a viral effect on pathogenicity. Similarly, in patients who undergo liver transplantation for end-stage chronic hepatitis B, occasionally, rapidly progressive liver injury appears in the new liver. This clinical pattern is associated with an unusual histologic pattern in the new liver, *fibrosing cholestatic hepatitis*, which, ultrastructurally, appears to represent a choking of the cell with overwhelming quantities of HBsAg. This observation suggests that under the influence of the potent immunosuppressive agents required to prevent allograft rejection, HBV may have a direct cytopathic effect on liver cells, independent of the immune system.

Although the precise mechanism of liver injury in HBV infection remains elusive, studies of nucleocapsid proteins have shed light on the profound immunologic tolerance to HBV of babies born to mothers with highly replicative (HBeAg-positive), chronic HBV infection. In HBeAg-expressing transgenic mice, in utero exposure to HBeAg, which is sufficiently small to traverse the placenta, induces T cell tolerance to both nucleocapsid proteins. This, in turn, may explain why, when infection occurs so early in life, immunologic clearance does not occur, and protracted, lifelong infection ensues.

Hepatitis C Undoubtedly, cell-mediated immune responses and elaboration by T cells of antiviral cytokines contribute to the containment of infection and pathogenesis of liver injury associated with hepatitis C. Perhaps HCV infection of lymphoid cells plays a role in moderating immune responsiveness to the virus, as well. Intrahepatic HLA class-I-restricted cytolytic T cells directed at nucleocapsid, envelope, and NS viral protein antigens have been demonstrated in patients with chronic hepatitis C: however, such virus-specific cytolytic T cell responses do not correlate adequately with the degree of liver injury or with recovery. Yet, a consensus has emerged supporting a role in the pathogenesis of HCV-associated liver injury of virus-activated CD4 helper T cells that stimulate, via the cytokines they elaborate, HCV-specific CD8 cytotoxic T cells. These responses appear to be more robust in those who recover from HCV than in those who have chronic infection. Several HLA alleles have been linked with self-limited hepatitis C, but such associations do not apply universally. Finally, cross-reactivity between viral and host autoantigens has been invoked to explain the association between hepatitis C and a subset of patients with autoimmune hepatitis and antibodies to liver-kidney microsomal (LKM) antigen (anti-LKM) (Chap. 287).

EXTRAHEPATIC MANIFESTATIONS Immune complex–mediated tissue damage appears to play a pathogenetic role in the extrahepatic manifestations of acute hepatitis B. The occasional prodromal serum sickness–like syndrome observed in acute hepatitis B appears to be related to the deposition in tissue blood vessel walls of HBsAg-anti-HBs circulating immune complexes, leading to activation of the complement system and depressed serum complement levels.

In patients with chronic hepatitis B, other types of immune-complex disease may be seen. Glomerulonephritis with the nephritic syndrome is occasionally observed; HBsAg, immunoglobulin, and C3 deposition has been found in the glomerular basement membrane. While polyarteritis nodosa develops in considerably fewer than 1% of patients with chronic HBV infection, 20 to 30% of patients with polyarteritis nodosa have HBsAg in serum (Chap. 306). In these patients, the affected small and medium-sized arterioles have been shown to contain HBsAg, immunoglobulins, and complement components. Another extrahepatic manifestation of viral hepatitis, essential mixed cryoglobulinemia (EMC), was reported initially to be associated with hepatitis B. The disorder is characterized clinically by arthritis, cutaneous vasculitis (palpable purpura), and occasionally with glomerulonephritis and serologically by the presence of circulating cryoprecipitable immune complexes of more than one immunoglobulin class (Chaps. 264 and 306). Many patients with this syndrome have chronic liver disease, but the association with HBV infection is limited; instead, a substantial proportion have chronic HCV infection, with circulating immune complexes containing HCV RNA. Immune-complex glomerulonephritis is another recognized extrahepatic manifestation of chronic hepatitis C.

PATHOLOGY The typical morphologic lesions of all types of viral hepatitis are similar and consist of panlobular infiltration with mononuclear cells, hepatic cell necrosis, hyperplasia of Kupffer cells, and variable degrees of cholestasis. Hepatic cell regeneration is present, as evidenced by numerous mitotic figures, multinucleated cells, and "rosette" or "pseudoacinar" formation. The mononuclear infiltration consists primarily of small lymphocytes, although plasma cells and eosinophils occasionally are present. Liver cell damage consists of hepatic cell degeneration and necrosis, cell dropout, ballooning of cells, and acidophilic degeneration of hepatocytes (forming so-called Councilman or apoptotic bodies). Large hepatocytes with a ground-glass appearance of the cytoplasm may be seen in chronic but not in acute HBV infection; these cells contain HBsAg and can be identified histochemically with orcein or aldehyde fuchsin. In uncomplicated viral hepatitis, the reticulin framework is preserved.

In hepatitis C, the histologic lesion is often remarkable for a relative paucity of inflammation, a marked increase in activation of sinusoidal lining cells, lymphoid aggregates, the presence of fat (more frequent in genotype 3 and linked to increased fibrosis), and, occasionally, bile duct lesions in which biliary epithelial cells appear to be piled up without interruption of the basement membrane. Occasionally, microvesicular steatosis occurs in hepatitis D. In hepatitis E, a common histologic feature is marked cholestasis. A cholestatic variant of slowly resolving acute hepatitis A also has been described.

A more severe histologic lesion, *bridging hepatic necrosis*, also termed *subacute* or *confluent necrosis*, is occasionally observed in some patients with acute hepatitis. "Bridging" between lobules results from large areas of hepatic cell dropout, with collapse of the reticulin framework. Characteristically, the bridge consists of condensed reticulum, inflammatory debris, and degenerating liver cells that span adjacent portal areas, portal to central veins, or central vein to central vein. This lesion had been thought to have prognostic significance; in many of the originally described patients with this lesion, a subacute course terminated in death within several weeks to months or severe chronic hepatitis and postnecrotic cirrhosis developed. Subsequent investigations have failed to uphold the association between bridging necrosis and such a poor prognosis in patients with acute hepatitis. Therefore, although demonstration of this lesion in patients with chronic hepatitis has prognostic significance (Chap. 287), its demon-

stration during acute hepatitis is less meaningful, and liver biopsies to identify this lesion are no longer undertaken routinely in patients with acute hepatitis. In *massive hepatic necrosis* (fulminant hepatitis, acute yellow atrophy), the striking feature at postmortem examination is the finding of a small, shrunken, soft liver. Histologic examination reveals massive necrosis and dropout of liver cells of most lobules with extensive collapse and condensation of the reticulin framework. When histologic documentation is required in the management of fulminant or very severe hepatitis, a biopsy can be done by the angiographically guided transjugular route, which permits the performance of this invasive procedure in the presence of severe coagulopathy.

Immunohistochemical and electron-microscopic studies have localized HBsAg to the cytoplasm and plasma membrane of infected liver cells. In contrast, HBcAg predominates in the nucleus, but occasionally, scant amounts are also seen in the cytoplasm and on the cell membrane. HDV antigen is localized to the hepatocyte nucleus, while HAV, HCV, and HEV antigens are localized to the cytoplasm.

EPIDEMIOLOGY Before the availability of serologic tests for hepatitis viruses, all viral hepatitis cases were labeled either as "infectious" or "serum" hepatitis. Modes of transmission overlap, however, and *a clear distinction among the different types of viral hepatitis cannot be made solely on the basis of clinical or epidemiologic features* (Table 285-2). The most accurate means to distinguish the various types of viral hepatitis involves specific serologic testing.

Hepatitis A *This agent is transmitted almost exclusively by the fecal-oral route*. Person-to-person spread of HAV is enhanced by poor personal hygiene and overcrowding; large outbreaks as well as sporadic cases have been traced to contaminated food, water, milk, frozen raspberries and strawberries, and shellfish. Intrafamily and intrainstitutional spread are also common. Early epidemiologic observations suggested that there is a predilection for hepatitis A to occur in late fall and early winter. In temperate zones, epidemic waves have been recorded every 5 to 20 years as new segments of nonimmune population appeared; however, in developed countries, the incidence of hepatitis A has been declining, presumably as a function of improved sanitation, and these cyclic patterns are no longer being observed. No HAV carrier state has been identified after acute hepatitis A; perpetuation of the virus in nature depends presumably on nonepidemic, inapparent subclinical infection.

In the general population, anti-HAV, a marker for previous HAV infection, increases in prevalence as a function of increasing age and of decreasing socioeconomic status. In the 1970s, serologic evidence of prior hepatitis A infection occurred in about 40% of urban populations in the United States, most of whose members never recalled having had a symptomatic case of hepatitis. In subsequent decades, however, the prevalence of anti-HAV has been declining in the United States. In developing countries, exposure, infection, and subsequent immunity are almost universal in childhood. As the frequency of subclinical childhood infections declines in developed countries, a susceptible cohort of adults emerges. Hepatitis A tends to be more symptomatic in adults; therefore, paradoxically, as the frequency of HAV infection declines, the likelihood of clinically apparent, even severe, HAV illnesses increases in the susceptible adult population. Travel to endemic areas is a common source of infection for adults from nonendemic areas. More recently recognized epidemiologic foci of HAV infection include child-care centers, neonatal intensive care units, promiscuous homosexual men, and injection drug users. Although hepatitis A is rarely bloodborne, several outbreaks have been recognized in recipients of clotting factor concentrates.

Hepatitis B Percutaneous inoculation has long been recognized as a major route of hepatitis B transmission, but the outmoded designation "serum hepatitis" is an inaccurate label for the epidemiologic spectrum of HBV infection recognized today. As detailed below, most of the hepatitis transmitted by blood transfusion is not caused by HBV; moreover, in approximately two-thirds of patients with acute type B hepatitis, there is no history of an identifiable percutaneous exposure. We now recognize that many cases of hepatitis B result from less obvious modes of nonpercutaneous or covert percutaneous transmission.

TABLE 285-2 *Clinical and Epidemiologic Features of Viral Hepatitis*

Feature	HAV	HBV	HCV	HDV	HEV
Incubation (days)	15–45, mean 30	30–180, mean 60–90	15–160, mean 50	30–180, mean 60–90	14–60, mean 40
Onset	Acute	Insidious or acute	Insidious	Insidious or acute	Acute
Age preference	Children, young adults	Young adults (sexual and percutaneous), babies, toddlers	Any age, but more common in adults	Any age (similar to HBV)	Young adults (20–40 years)
Transmission					
Fecal-oral	+++	−	−	−	+++
Percutaneous	Unusual	+++	+++	+++	−
Perinatal	−	+++	±[a]	+	−
Sexual	±	++	±[a]	++	−
Clinical					
Severity	Mild	Occasionally severe	Moderate	Occasionally severe	Mild
Fulminant	0.1%	0.1–1%	0.1%	5–20%[b]	1–2%[e]
Progression to chronicity	None	Occasional (1–10%) (90% of neonates)	Common (50–70% chronic hepatitis; 80–90% chronic infection)	Common[d]	None

[a] Primarily with HIV co-infection and high-level viremia in index case; risk ~5%.
[b] Up to 5% in acute HBV/HDV co-infection; up to 20% in HDV superinfection of chronic HBV infection.
[c] Varies considerably throughout the world and in subpopulations within countries; see text.
[d] In acute HBV/HDV co-infection, the frequency of chronicity is the same as that for HBV; in HDV superinfection, chronicity is invariable.
[e] 10–20% in pregnant women.
[f] Common in Mediterranean countries, rare in North America and western Europe.

HBsAg has been identified in almost every body fluid from infected persons, and at least some of these body fluids—most notably semen and saliva—are infectious, albeit less so than serum, when administered percutaneously or nonpercutaneously to experimental animals. Among the nonpercutaneous modes of HBV transmission, oral ingestion has been documented as a potential but inefficient route of exposure. By contrast, the two nonpercutaneous routes considered to have the greatest impact are intimate (especially sexual) contact and perinatal transmission.

In sub-Saharan Africa, intimate contact among toddlers is considered instrumental in contributing to the maintenance of the high frequency of hepatitis B in the population. Perinatal transmission occurs primarily in infants born to HBsAg carrier mothers or mothers with acute hepatitis B during the third trimester of pregnancy or during the early postpartum period. Perinatal transmission is uncommon in North America and western Europe but occurs with great frequency and is the most important mode of HBV perpetuation in the Far East and developing countries. Although the precise mode of perinatal transmission is unknown, and although approximately 10% of infections may be acquired in utero, epidemiologic evidence suggests that most infections occur approximately at the time of delivery and are not related to breast feeding. The likelihood of perinatal transmission of HBV correlates with the presence of HBeAg; 90% of HBeAg-positive mothers but only 10 to 15% of anti-HBe-positive mothers transmit HBV infection to their offspring. In most cases, acute infection in the neonate is clinically asymptomatic, but the child is very likely to become an HBsAg carrier.

The more than 350 million HBsAg carriers in the world constitute the main reservoir of hepatitis B in human beings. Serum HBsAg is infrequent (0.1 to 0.5%) in normal populations in the United States and western Europe. However, a prevalence of up to 5 to 20% has been found in the Far East and in some tropical countries; in persons with Down's syndrome, lepromatous leprosy, leukemia, Hodgkin's disease, polyarteritis nodosa; in patients with chronic renal disease on hemodialysis; and in injection drug users.

Other groups with high rates of HBV infection include spouses of acutely infected persons, sexually promiscuous persons (especially promiscuous men who have sex with men), health care workers exposed to blood, persons who require repeated transfusions especially with pooled blood product concentrates (e.g., hemophiliacs), residents and staff of custodial institutions for the developmentally handicapped, prisoners, and, to a lesser extent, family members of chronically infected patients. In volunteer blood donors, the prevalence of anti-HBs, a reflection of previous HBV infection, ranges from 5 to 10%, but the prevalence is higher in lower socioeconomic strata, older age groups, and persons—including those mentioned above—exposed to blood products.

Prevalence of infection, modes of transmission, and human behavior conspire to mold geographically different epidemiologic patterns of HBV infection. In the Far East and Africa, hepatitis B, a disease of the newborn and young children, is perpetuated by a cycle of maternal-neonatal spread. In North America and western Europe, hepatitis B is primarily a disease of adolescence and early adulthood, the time of life when intimate sexual contact as well as recreational and occupational percutaneous exposures tend to occur.

Hepatitis D Infection with HDV has a worldwide distribution, but two epidemiologic patterns exist. In Mediterranean countries (northern Africa, southern Europe, the Middle East), HDV infection is endemic among those with hepatitis B, and the disease is transmitted predominantly by nonpercutaneous means, especially close personal contact. In nonendemic areas, such as the United States and northern Europe, HDV infection is confined to persons exposed frequently to blood and blood products, primarily injection drug users and hemophiliacs. HDV infection can be introduced into a population through drug users or by migration of persons from endemic to nonendemic areas. Thus, patterns of population migration and human behavior facilitating percutaneous contact play important roles in the introduction and amplification of HDV infection. Occasionally, the migrating epidemiology of hepatitis D is expressed in explosive outbreaks of severe hepatitis, such as those that have occurred in remote South American villages as well as in urban centers in the United States. Ultimately, such outbreaks of hepatitis D—either of coinfections with acute hepatitis B or of superinfections in those already infected with HBV—may blur the distinctions between endemic and nonendemic areas. On a global scale, HDV infection is declining. Even in Italy, an HDV-endemic area, public health measures introduced to control HBV infection resulted during the 1990s in a 1.5%/year reduction in the prevalence of HDV infection.

Hepatitis C Routine screening of blood donors for HBsAg and the elimination of commercial blood sources in the early 1970s reduced the frequency of, but did not eliminate, transfusion-associated hepatitis. During the 1970s, the likelihood of acquiring hepatitis after transfusion of voluntarily donated, HBsAg-screened blood was approximately 10% per patient (up to 0.9% per unit transfused); 90 to 95% of these cases were classified, based on serologic exclusion of hepatitis A and B, as "non-A, non-B" hepatitis. For patients requiring transfusion of pooled products, such as clotting factor concentrates, the risk was even higher, up to 20 to 30%.

During the 1980s, voluntary self-exclusion of blood donors with risk factors for AIDS and then the introduction of donor screening for anti-HIV reduced further the likelihood of transfusion-associated hepatitis to under 5%. During the late 1980s and early 1990s, the introduction first of "surrogate" screening tests for non-A, non-B hepatitis [alanine aminotransferase (ALT) and anti-HBc, both shown to identify blood donors with a higher likelihood of transmitting non-A, non-B hepatitis to recipients] and, subsequently, after the discovery of HCV, first-generation immunoassays for anti-HCV reduced the frequency of transfusion-associated hepatitis even further. A prospective analysis of transfusion-associated hepatitis conducted between 1986 and 1990 showed that the incidence of transfusion-associated hepatitis at one urban university hospital fell from a baseline of 3.8% per patient (0.45% per unit transfused) to 1.5% per patient (0.19% per unit) after the introduction of surrogate testing and to 0.6% per patient (0.03% per unit) after the introduction of first-generation anti-HCV assays. The introduction of second-generation anti-HCV assays reduced the frequency of transfusion-associated hepatitis C to almost imperceptible levels, 1 in 100,000, and these gains are being reinforced by the application of automated PCR testing of donated blood for HCV RNA.

In addition to being transmitted by transfusion, hepatitis C can be transmitted by other percutaneous routes, such as injection drug use. In addition, this virus can be transmitted by occupational exposure to blood, and the likelihood of infection is increased in hemodialysis units. Although the frequency of transfusion-associated hepatitis C fell as a result of blood donor screening, the overall frequency of hepatitis C remained the same until the early 1990s, when the overall frequency fell by 80%, in parallel with a reduction in the number of new cases in injection drug users. After the exclusion of anti-HCV-positive plasma units from the donor pool, rare, sporadic instances have occurred of hepatitis C among recipients of immune globulin (IG) preparations for intravenous (but not intramuscular) use.

Serologic evidence for HCV infection occurs in 90% of patients with a history of transfusion-associated hepatitis (almost all occurring before 1992, when second-generation HCV-screening tests were introduced), hemophiliacs and others treated with clotting factors, and injection drug users; 60 to 70% of patients with sporadic "non-A, non-B" hepatitis who lack identifiable risk factors; 0.5% of volunteer blood donors; and 1.8% of the general population in the United States, which translates into 4 million persons. Comparable frequencies of HCV infection occur in most countries around the world, with 170 million persons infected worldwide, but extraordinarily high prevalences of HCV infection occur in certain countries, such as Egypt, where more than 20% of the population in some cities is infected. The high fre-

quency in Egypt is attributable to contaminated equipment used for medical procedures and unsafe injection practices. In the United States, African Americans and Mexican Americans have higher frequencies of HCV infection than whites, and 30- to 49-year-old adult males have the highest frequencies of infection. Hepatitis C accounts for 40% of chronic liver disease, is the most frequent indication for liver transplantation, and is estimated to account for 8000 to 10,000 deaths per year in the United States.

Most asymptomatic blood donors found to have anti-HCV and approximately 20 to 30% of persons with reported cases of acute hepatitis C do not fall into a recognized risk group; however, many such blood donors do recall risk-associated behaviors when questioned carefully.

As a bloodborne infection, HCV potentially can be transmitted sexually and perinatally; however, both of these modes of transmission are inefficient for hepatitis C. Although 10 to 15% of patients with acute hepatitis C report having potential sexual sources of infection, most studies have failed to identify sexual transmission of this agent. The chances of sexual and perinatal transmission have been estimated to be approximately 5%, well below comparable rates for HIV and HBV infections. Moreover, sexual transmission appears to be confined to such subgroups as persons with multiple sexual partners and sexually transmitted diseases; transmission of HCV infection is rare between stable, monogamous sexual partners. Breast feeding does not increase the risk of HCV infection between an infected mother and her infant. Infection of health workers is not dramatically higher than among the general population; however, health workers are more likely to acquire HCV infection through accidental needle punctures, the efficiency of which is ~3%. Infection of household contacts is rare as well.

Other groups with an increased frequency of HCV infection include patients who require hemodialysis and organ transplantation and those who require transfusions in the setting of cancer chemotherapy. In immunosuppressed individuals, levels of anti-HCV may be undetectable, and a diagnosis may require testing for HCV RNA. Although new acute cases of hepatitis C are rare, newly diagnosed cases are common among otherwise healthy persons who experimented briefly with injection drugs two or three decades earlier. Such instances usually remain unrecognized for years, until unearthed by laboratory screening for routine medical examinations, insurance applications, and attempted blood donation.

Hepatitis E This type of hepatitis, identified in India, Asia, Africa, and Central America, resembles hepatitis A in its primarily enteric mode of spread. The commonly recognized cases occur after contamination of water supplies such as after monsoon flooding, but sporadic, isolated cases occur. An epidemiologic feature that distinguishes HEV from other enteric agents is the rarity of secondary person-to-person spread from infected persons to their close contacts. Infections arise in populations that are immune to HAV and favor young adults. It is not known if hepatitis E occurs outside of recognized endemic areas, for example, in the United States, but preliminary studies suggest that HEV does not account for any of the sporadic "non-A, non-B" cases in nonendemic areas. Cases imported from endemic areas have been found in the United States. Several reports suggest a zoonotic reservoir for HEV in swine.

CLINICAL AND LABORATORY FEATURES ■ Symptoms and Signs

Acute viral hepatitis occurs after an incubation period that varies according to the responsible agent. Generally, incubation periods for hepatitis A range from 15 to 45 days (mean 4 weeks), for hepatitis B and D from 30 to 180 days (mean 4 to 12 weeks), for hepatitis C from 15 to 160 days (mean 7 weeks), and for hepatitis E from 14 to 60 days (mean 5 to 6 weeks). The *prodromal symptoms* of acute viral hepatitis are systemic and quite variable. Constitutional symptoms of anorexia, nausea and vomiting, fatigue, malaise, arthralgias, myalgias, headache, photophobia, pharyngitis, cough, and coryza may precede the onset of jaundice by 1 to 2 weeks. The nausea, vomiting, and anorexia are frequently associated with alterations in olfaction and taste. A low-grade fever between 38 and 39°C (100 to 102°F) is more often present in hepatitis A and E than in hepatitis B or C, except when hepatitis B is heralded by a serum sickness–like syndrome; rarely, a fever of 39.5 to 40°C (103 to 104°F) may accompany the constitutional symptoms. Dark urine and clay-colored stools may be noticed by the patient from 1 to 5 days before the onset of clinical jaundice.

With the onset of *clinical jaundice*, the constitutional prodromal symptoms usually diminish, but in some patients mild weight loss (2.5 to 5 kg) is common and may continue during the entire icteric phase. The liver becomes enlarged and tender and may be associated with right upper quadrant pain and discomfort. Infrequently, patients present with a cholestatic picture, suggesting extrahepatic biliary obstruction. Splenomegaly and cervical adenopathy are present in 10 to 20% of patients with acute hepatitis. Rarely, a few spider angiomas appear during the icteric phase and disappear during convalescence. During the *recovery phase*, constitutional symptoms disappear, but usually some liver enlargement and abnormalities in liver biochemical tests are still evident. The duration of the posticteric phase is variable, ranging from 2 to 12 weeks, and is usually more prolonged in acute hepatitis B and C. Complete clinical and biochemical recovery is to be expected 1 to 2 months after all cases of hepatitis A and E and 3 to 4 months after the onset of jaundice in three-quarters of uncomplicated cases of hepatitis B and C. In the remainder, biochemical recovery may be delayed. A substantial proportion of patients with viral hepatitis never become icteric.

Infection with HDV can occur in the presence of acute or chronic HBV infection; the duration of HBV infection determines the duration of HDV infection. When acute HDV and HBV infection occur simultaneously, clinical and biochemical features may be indistinguishable from those of HBV infection alone, although occasionally they are more severe. As opposed to patients with *acute* HBV infection, patients with *chronic* HBV infection can support HDV replication indefinitely. This can happen when acute HDV infection occurs in the presence of a nonresolving acute HBV infection. More commonly, acute HDV infection becomes chronic when it is superimposed on an underlying chronic HBV infection. In such cases, the HDV superinfection appears as a clinical exacerbation or an episode resembling acute viral hepatitis in someone already chronically infected with HBV. Superinfection with HDV in a patient with chronic hepatitis B often leads to clinical deterioration (see below).

In addition to superinfections with other hepatitis agents, acute hepatitis-like clinical events in persons with chronic hepatitis B may accompany spontaneous HBeAg–to–anti-HBe seroconversion or spontaneous reactivation, i.e., reversion from nonreplicative to replicative infection. Such reactivations can occur as well in therapeutically immunosuppressed patients with chronic HBV infection when cytotoxic-immunosuppressive drugs are withdrawn; in these cases, restoration of immune competence is thought to allow resumption of previously checked cell-mediated immune cytolysis of HBV-infected hepatocytes. Occasionally, acute clinical exacerbations of chronic hepatitis B may represent the emergence of a precore mutant (see "Virology and Etiology," above), and the subsequent course in such patients may be characterized by periodic exacerbations.

Laboratory Features The serum aminotransferases aspartate aminotransferase (AST) and ALT (previously designated SGOT and SGPT) show a variable increase during the prodromal phase of acute viral hepatitis and precede the rise in bilirubin level (Figs. 285-2 and 285-4). The acute level of these enzymes, however, does not correlate well with the degree of liver cell damage. Peak levels vary from 400 to 4000 IU or more; these levels are usually reached at the time the patient is clinically icteric and diminish progressively during the recovery phase of acute hepatitis. The diagnosis of anicteric hepatitis is based on clinical features and on aminotransferase elevations.

Jaundice is usually visible in the sclera or skin when the serum bilirubin value exceeds 43 μmol/L (2.5 mg/dL). When jaundice appears, the serum bilirubin typically rises to levels ranging from 85 to

TABLE 285-3 *Commonly Encountered Serologic Patterns of Hepatitis B Infection*

HBsAg	Anti-HBs	Anti-HBc	HBeAg	Anti-HBe	Interpretation
+	−	IgM	+	−	Acute hepatitis B, high infectivity
+	−	IgG	+	−	Chronic hepatitis B, high infectivity
+	−	IgG	−	+	1. Late acute or chronic hepatitis B, low infectivity 2. HBeAg-negative ("precore-mutant") hepatitis B (chronic or, rarely, acute)
+	+	+	+/−	+/−	1. HBsAg of one subtype and heterotypic anti-HBs (common) 2. Process of seroconversion from HBsAg to anti-HBs (rare)
−	−	IgM	+/−	+/−	1. Acute hepatitis B 2. Anti-HBc "window"
−	−	IgG	−	+/−	1. Low-level hepatitis B carrier 2. Hepatitis B in remote past
−	+	IgG	−	+/−	Recovery from hepatitis B
−	+	−	−	−	1. Immunization with HBsAg (after vaccination) 2. Hepatitis B in the remote past (?) 3. False-positive

340 μmol/L (5 to 20 mg/dL). The serum bilirubin may continue to rise despite falling serum aminotransferase levels. In most instances, the total bilirubin is equally divided between the conjugated and unconjugated fractions. Bilirubin levels >340 μmol/L (20 mg/dL) extending and persisting late into the course of viral hepatitis are more likely to be associated with severe disease. In certain patients with underlying hemolytic anemia, however, such as glucose-6-phosphate dehydrogenase deficiency and sickle cell anemia, a high serum bilirubin level is common, resulting from superimposed hemolysis. In such patients, bilirubin levels >513 μmol/L (30 mg/dL) have been observed and are not necessarily associated with a poor prognosis.

Neutropenia and lymphopenia are transient and are followed by a relative lymphocytosis. Atypical lymphocytes (varying between 2 and 20%) are common during the acute phase. Measurement of the prothrombin time (PT) is important in patients with acute viral hepatitis, for a prolonged value may reflect a severe hepatic synthetic defect, signify extensive hepatocellular necrosis, and indicate a worse prognosis. Occasionally, a prolonged PT may occur with only mild increases in the serum bilirubin and aminotransferase levels. Prolonged nausea and vomiting, inadequate carbohydrate intake, and poor hepatic glycogen reserves may contribute to hypoglycemia noted occasionally in patients with severe viral hepatitis. Serum alkaline phosphatase may be normal or only mildly elevated, while a fall in serum albumin is uncommon in uncomplicated acute viral hepatitis. In some patients, mild and transient steatorrhea has been noted as well as slight microscopic hematuria and minimal proteinuria.

A diffuse but mild elevation of the gamma globulin fraction is common during acute viral hepatitis. Serum IgG and IgM levels are elevated in about one-third of patients during the acute phase of viral hepatitis, but the serum IgM level is elevated more characteristically during acute hepatitis A. During the acute phase of viral hepatitis, antibodies to smooth muscle and other cell constituents may be present, and low titers of rheumatoid factor, nuclear antibody, and heterophil antibody can also be found occasionally. In hepatitis C and D, antibodies to LKM may occur; however, the species of LKM antibodies in the two types of hepatitis are different from each other as well as from the LKM antibody species characteristic of autoimmune chronic hepatitis type 2 (Chap. 287). The autoantibodies in viral hepatitis are nonspecific and can also be associated with other viral and systemic diseases. In contrast, virus-specific antibodies, which appear during and after hepatitis virus infection, are serologic markers of diagnostic importance.

As described above, serologic tests are available with which to establish a diagnosis of hepatitis A, B, D, and C. Tests for fecal or serum HAV are not routinely available. Therefore, a diagnosis of hepatitis A is based on detection of IgM anti-HAV during acute illness (Fig. 285-2). Rheumatoid factor can give rise to false-positive results in this test.

A diagnosis of HBV infection can usually be made by detection of HBsAg in serum. Infrequently, levels of HBsAg are too low to be detected during acute HBV infection, even with the current generation of highly sensitive immunoassays. In such cases, the diagnosis can be established by the presence of IgM anti-HBc.

The titer of HBsAg bears little relation to the severity of clinical disease. Indeed, there may be an inverse correlation between the serum concentration of HBsAg and the degree of liver cell damage. For example, titers are highest in immunosuppressed patients, lower in patients with chronic liver disease (but higher in mild chronic than in severe chronic hepatitis), and very low in patients with acute fulminant hepatitis. These observations suggest that in hepatitis B the degree of liver cell damage and the clinical course are probably related to variations in the patient's immune response to HBV rather than to the amount of circulating HBsAg. In immunocompetent persons, however, there is a correlation between markers of HBV *replication* and liver injury (see below).

Another serologic marker that may be of value in patients with hepatitis B is HBeAg. Its principal clinical usefulness is as an indicator of relative infectivity. Because HBeAg is invariably present during early acute hepatitis B, HBeAg testing is indicated primarily during follow-up of chronic infection.

In patients with hepatitis B surface antigenemia of unknown duration, e.g., blood donors found to be HBsAg-positive and referred to a physician for evaluation, testing for IgM anti-HBc may be useful to distinguish between acute or recent infection (IgM anti-HBc-positive) and chronic HBV infection (IgM anti-HBc-negative, IgG anti-HBc-positive). A false-positive test for IgM anti- HBc may be encountered in patients with high-titer rheumatoid factor.

Anti-HBs is rarely detectable in the presence of HBsAg in patients with *acute* hepatitis B, but 10 to 20% of persons with *chronic* HBV infection may harbor low-level anti-HBs. This antibody is directed not against the common group determinant, *a*, but against the heterotypic subtype determinant (e.g., HBsAg of subtype *ad* with anti-HBs of subtype *y*). In most cases, this serologic pattern cannot be attributed to infection with two different HBV subtypes, and the presence of this antibody is not a harbinger of imminent HBsAg clearance. When such antibody is detected, its presence is of no recognized clinical significance (see "Virology and Etiology," above).

After immunization with hepatitis B vaccine, which consists of HBsAg alone, anti-HBs is the only serologic marker to appear. The commonly encountered serologic patterns of hepatitis B and their interpretations are summarized in Table 285-3. Tests for the detection of HBV DNA in liver and serum are now available. Like HBeAg, serum HBV DNA is an indicator of HBV replication, but tests for HBV DNA are more sensitive and quantitative. Hybridization assays for HBV DNA have a sensitivity of approximately 10^5 to 10^6 virions/mL, a relative threshold below which infectivity and liver injury are limited and HBeAg is usually undetectable. Currently, testing for HBV DNA has shifted from insensitive hybridization assays to amplification assays, e.g., the PCR-based assay, which can detect as few as 100 or 1000 virions/mL. With increased sensitivity, amplification assays remain reactive well below the threshold for infectivity and liver injury. These markers are useful in following the course of HBV replication in patients with chronic hepatitis B receiving antiviral chemotherapy, e.g., with interferon or lamivudine (Chap. 287). In immunocompetent persons, a general correlation does appear to exist between the level of HBV replication, as reflected by the level of HBV DNA in serum, and the degree of liver injury. High serum HBV DNA levels, increased

expression of viral antigens, and necroinflammatory activity in the liver go hand in hand unless immunosuppression interferes with cytolytic T cell responses to virus-infected cells; reduction of HBV replication with antiviral drugs tends to be accompanied by an improvement in liver histology.

In patients with hepatitis C, an episodic pattern of aminotransferase elevation is common. A specific serologic diagnosis of hepatitis C can be made by demonstrating the presence in serum of anti-HCV. When a second- or third-generation immunoassay (that detects antibodies to nonstructural and nucleocapsid proteins) is used, anti-HCV can be detected in acute hepatitis C during the initial phase of elevated aminotransferase activity. This antibody may never become detectable in 5 to 10% of patients with acute hepatitis C, and levels of anti-HCV may become undetectable after recovery from acute hepatitis C. In patients with chronic hepatitis C, anti-HCV is detectable in >95% of cases. Nonspecificity can confound immunoassays for anti-HCV, especially in persons with a low prior probability of infection, such as volunteer blood donors, or in persons with circulating rheumatoid factor, which can bind nonspecifically to assay reagents. A supplementary recombinant immunoblot assay (RIBA), in which serum is incubated with a nitrocellulose strip containing viral protein bands, can be used to establish the specific viral proteins to which anti-HCV is directed (see "Virology and Etiology," above). Such RIBA determinations were used to confirm anti-HCV reactivity in blood donors, but determinations of HCV RNA have supplanted RIBA in most clinical settings. Assays for HCV RNA are the most sensitive tests for HCV infection and represent the "gold standard" in establishing a diagnosis of hepatitis C. HCV RNA can be detected even before acute elevation of aminotransferase activity and before the appearance of anti-HCV in patients with acute hepatitis C. In addition, HCV RNA remains detectable indefinitely, continuously in most but intermittently in some, in patients with chronic hepatitis C (even detectable in some persons with normal liver tests, i.e., asymptomatic carriers). In the small minority of patients with hepatitis C who lack anti-HCV, a diagnosis can be supported by detection of HCV RNA. If all these tests are negative and the patient has a well-characterized case of hepatitis after percutaneous exposure to blood or blood products, a diagnosis of hepatitis caused by another agent, as yet unidentified, can be entertained.

Amplification techniques are required to detect HCV RNA, and two are available. One is a branched-chain complementary DNA (bDNA) assay, in which the detection signal (a colorimetrically detectable enzyme bound to a complementary DNA probe) is amplified. The other involves target amplification, i.e., synthesis of multiple copies of the viral genome. This can be done by PCR or TMA, in which the viral RNA is reverse transcribed to complementary DNA and then amplified by repeated cycles of DNA synthesis. Both can be used as quantitative assays and a measurement of relative "viral load"; PCR and TMA, with a sensitivity of 10^2 IU/mL, are more sensitive than bDNA, with a sensitivity of 10^5. Determination of viral load is not a reliable marker of disease severity or prognosis but is helpful in predicting relative responsiveness to antiviral therapy. The same is true for determinations of HCV genotype (Chap. 287).

A proportion of patients with hepatitis C have isolated anti-HBc in their blood, a reflection of a common risk in certain populations to multiple bloodborne hepatitis agents. The anti-HBc in such cases is almost invariably of the IgG class and usually represents HBV infection in the remote past, rarely current HBV infection with low-level virus carriage.

The presence of HDV infection can be identified by demonstrating intrahepatic HDV antigen or, more practically, an anti-HDV seroconversion (a rise in titer of anti-HDV or de novo appearance of anti-HDV). Circulating HDV antigen, also diagnostic of acute infection, is detectable only briefly, if at all. Because anti-HDV is often undetectable once HBsAg disappears, retrospective serodiagnosis of acute self-limited, simultaneous HBV and HDV infection is difficult. Early diagnosis of acute infection may be hampered by a delay of up to 30 to 40 days in the appearance of anti-HDV.

When a patient presents with acute hepatitis and has HBsAg and anti-HDV in serum, determination of the class of anti-HBc is helpful in establishing the relationship between infection with HBV and HDV. Although IgM anti-HBc does not distinguish *absolutely* between acute and chronic HBV infection, its presence is a reliable indicator of recent infection and its absence a reliable indicator of infection in the remote past. In simultaneous acute HBV and HDV infections, IgM anti-HBc will be detectable, while in acute HDV infection superimposed on chronic HBV infection, anti-HBc will be of the IgG class.

Tests for the presence of HDV RNA are useful for determining the presence of ongoing HDV replication and relative infectivity. Currently, probes for this marker are restricted to a limited number of research laboratories. Diagnostic tests for hepatitis E are commercially available in several countries outside the United States; in the United States, diagnostic assays can be performed at the Centers for Disease Control and Prevention.

Liver biopsy is rarely necessary or indicated in acute viral hepatitis, except when there is a question about the diagnosis or when there is clinical evidence suggesting a diagnosis of chronic hepatitis.

A diagnostic algorithm can be applied in the evaluation of cases of acute viral hepatitis. A patient with acute hepatitis should undergo four serologic tests, HBsAg, IgM anti-HAV, IgM anti-HBc, and anti-HCV (Table 285-4). The presence of HBsAg, with or without IgM anti-HBc, represents HBV infection. If IgM anti-HBc is present, the HBV infection is considered acute; if IgM anti-HBc is absent, the HBV infection is considered chronic. A diagnosis of acute hepatitis B can be made in the absence of HBsAg when IgM anti-HBc is detectable. A diagnosis of acute hepatitis A is based on the presence of IgM anti-HAV. If IgM anti-HAV coexists with HBsAg, a diagnosis of simultaneous HAV and HBV infections can be made; if IgM anti-HBc (with or without HBsAg) is detectable, the patient has simultaneous acute hepatitis A and B, and if IgM anti-HBc is undetectable, the patient has acute hepatitis A superimposed on chronic HBV infection. The presence of anti-HCV supports a diagnosis of acute hepatitis C. Occasionally, testing for HCV RNA or repeat anti-HCV testing later during the illness is necessary to establish the diagnosis. Absence of all serologic markers is consistent with a diagnosis of "non-A, non-B, non-C" hepatitis, if the epidemiologic setting is appropriate.

In patients with chronic hepatitis, initial testing should consist of HBsAg and anti-HCV. Anti-HCV supports and HCV RNA testing establishes the diagnosis of chronic hepatitis C. If a serologic diagnosis of chronic hepatitis B is made, testing for HBeAg and anti-HBe is indicated to evaluate relative infectivity. Testing for HBV DNA in such patients provides a more quantitative and sensitive measure of the level of virus replication and, therefore, is very helpful during antiviral therapy (Chap. 287). In patients with hepatitis B, testing for anti-HDV is useful under the following circumstances: patients with

TABLE 285-4 *Simplified Diagnostic Approach in Patients Presenting with Acute Hepatitis*

Serologic Tests of Patient's Serum				
HBsAg	IgM Anti-HAV	IgM Anti-HBc	Anti-HCV	Diagnostic Interpretation

−	−	+	−	Acute hepatitis B (HBsAg below detection threshold)
−	−	−	+	Acute hepatitis C

severe and fulminant diseases, patients with severe chronic disease, patients with chronic hepatitis B who have acute hepatitis-like exacerbations, persons with frequent percutaneous exposures, and persons from areas where HDV infection is endemic.

PROGNOSIS Virtually all previously healthy patients with hepatitis A recover completely from their illness with no clinical sequelae. Similarly, in acute hepatitis B, 95 to 99% of previously healthy adults have a favorable course and recover completely. Certain clinical and laboratory features, however, suggest a more complicated and protracted course. Patients of advanced age and with serious underlying medical disorders may have a prolonged course and are more likely to experience severe hepatitis. Initial presenting features such as ascites, peripheral edema, and symptoms of hepatic encephalopathy suggest a poorer prognosis. In addition, a prolonged PT, low serum albumin level, hypoglycemia, and very high serum bilirubin values suggest severe hepatocellular disease. Patients with these clinical and laboratory features deserve prompt hospital admission. The case-fatality rate in hepatitis A and B is very low (approximately 0.1%) but is increased by advanced age and underlying debilitating disorders. Among patients ill enough to be hospitalized for acute hepatitis B, the fatality rate is 1%. Hepatitis C is less severe during the acute phase than hepatitis B and is more likely to be anicteric; fatalities are rare, but the precise case-fatality rate is not known. In outbreaks of waterborne hepatitis E in India and Asia, the case-fatality rate is 1 to 2% and up to 10 to 20% in pregnant women. Patients with simultaneous acute hepatitis B and hepatitis D do not necessarily experience a higher mortality rate than do patients with acute hepatitis B alone; however, in several recent outbreaks of acute simultaneous HBV and HDV infection among injection drug users, the case-fatality rate has been approximately 5%. In the case of HDV superinfection of a person with chronic hepatitis B, the likelihood of fulminant hepatitis and death is increased substantially. Although the case-fatality rate for hepatitis D has not been defined adequately, in outbreaks of severe HDV superinfection in isolated populations with a high hepatitis B carrier rate, the mortality rate has been recorded in excess of 20%.

COMPLICATIONS AND SEQUELAE A small proportion of patients with hepatitis A experience *relapsing hepatitis* weeks to months after apparent recovery from acute hepatitis. Relapses are characterized by recurrence of symptoms, aminotransferase elevations, occasionally jaundice, and fecal excretion of HAV. Another unusual variant of acute hepatitis A is *cholestatic hepatitis*, characterized by protracted cholestatic jaundice and pruritus. Rarely, liver test abnormalities persist for many months, even up to a year. Even when these complications occur, hepatitis A remains self-limited and does not progress to chronic liver disease. During the prodromal phase of acute hepatitis B, a serum sickness–like syndrome characterized by arthralgia or arthritis, rash, angioedema, and rarely hematuria and proteinuria may develop in 5 to 10% of patients. This syndrome occurs before the onset of clinical jaundice, and these patients are often erroneously diagnosed as having rheumatologic diseases. The diagnosis can be established by measuring serum aminotransferase levels, which are almost invariably elevated, and serum HBsAg. As noted above, EMC is an immune-complex disease that can complicate chronic hepatitis C and is part of a spectrum of B cell lymphoproliferative disorders, which, in rare instances, can evolve to B cell lymphoma (Chap. 97). Attention has been drawn as well to associations between hepatitis C and such cutaneous disorders as porphyria cutanea tarda and lichen planus. A mechanism for these associations is unknown.

The most feared complication of viral hepatitis is *fulminant hepatitis* (massive hepatic necrosis); fortunately, this is a rare event. Fulminant hepatitis is primarily seen in hepatitis B and D, as well as hepatitis E, but rare fulminant cases of hepatitis A occur primarily in older adults and in persons with underlying chronic liver disease, including, according to some reports, chronic hepatitis B and C. Hepatitis B accounts for >50% of fulminant hepatitis cases, a sizable proportion of which are associated with HDV infection and another proportion with underlying chronic hepatitis C. Fulminant hepatitis is seen rarely in hepatitis C, but hepatitis E, as noted above, can be complicated by fatal fulminant hepatitis in 1 to 2% of all cases and in up to 20% of cases occurring in pregnant women. Patients usually present with signs and symptoms of encephalopathy that may evolve to deep coma. The liver is usually small and the PT excessively prolonged. The combination of rapidly shrinking liver size, rapidly rising bilirubin level, and marked prolongation of the PT, even as aminotransferase levels fall, together with clinical signs of confusion, disorientation, somnolence, ascites, and edema, indicates that the patient has hepatic failure with encephalopathy. Cerebral edema is common; brainstem compression, gastrointestinal bleeding, sepsis, respiratory failure, cardiovascular collapse, and renal failure are terminal events. The mortality rate is exceedingly high (>80% in patients with deep coma), but patients who survive may have a complete biochemical and histologic recovery. If a donor liver can be located in time, liver transplantation may be life-saving in patients with fulminant hepatitis (Chap. 291).

It is particularly important to document the disappearance of HBsAg after apparent clinical recovery from acute hepatitis B. Before laboratory methods were available to distinguish between acute hepatitis and acute hepatitis–like exacerbations (*spontaneous reactivations*) of chronic hepatitis B, observations suggested that approximately 10% of patients remained HBsAg-positive for >6 months after the onset of clinically apparent acute hepatitis B. Half these persons cleared the antigen from their circulations during the next several years, but the other 5% remained chronically HBsAg-positive. More recent observations suggest that the true rate of chronic infection after clinically apparent acute hepatitis B is as low as 1% in normal, immunocompetent, young adults. Earlier, higher estimates may have been biased by inadvertent inclusion of acute exacerbations in chronically infected patients; these patients, chronically HBsAg-positive before exacerbation, were unlikely to seroconvert to HBsAg-negative thereafter. Whether the rate of chronicity is 10 or 1%, such patients have anti-HBc in serum; anti-HBs is either undetected or detected at low titer against the opposite subtype specificity of the antigen (see "Laboratory Features," above). These patients may (1) be inactive carriers; (2) have low-grade, mild chronic hepatitis; or (3) have moderate to severe chronic hepatitis with or without cirrhosis. The likelihood of becoming an HBsAg carrier after acute HBV infection is especially high among neonates, persons with Down's syndrome, chronically hemodialyzed patients, and immunosuppressed patients, including persons with HIV infection.

Chronic hepatitis is an important late complication of acute hepatitis B occurring in a small proportion of patients with acute disease but more common in those who present with chronic infection without having experienced an acute illness (Chap. 287). Certain clinical and laboratory features suggest progression of acute hepatitis to chronic hepatitis: (1) lack of complete resolution of clinical symptoms of anorexia, weight loss, and fatigue and the persistence of hepatomegaly; (2) the presence of bridging or multilobular hepatic necrosis on liver biopsy during protracted, severe acute viral hepatitis; (3) failure of the serum aminotransferase, bilirubin, and globulin levels to return to normal within 6 to 12 months after the acute illness; and (4) the persistence of HBeAg beyond 3 months or HBsAg beyond 6 months after acute hepatitis.

Although acute hepatitis D infection does not increase the likelihood of chronicity of simultaneous acute hepatitis B, hepatitis D has the potential for contributing to the severity of chronic hepatitis B. Hepatitis D superinfection can transform asymptomatic or mild chronic hepatitis B into severe, progressive chronic hepatitis and cirrhosis; it also can accelerate the course of chronic hepatitis B. Some HDV superinfections in patients with chronic hepatitis B lead to fulminant hepatitis. Although HDV and HBV infections are associated with severe liver disease, mild hepatitis and even asymptomatic carriage have been identified in some patients, and the disease may become indolent beyond the early years of infection. After acute HCV

infection, the likelihood of remaining chronically *infected* approaches 85 to 90%. Although many patients with chronic hepatitis C have no symptoms, cirrhosis may develop in as many as 20% within 10 to 20 years of acute illness; in some series of cases, cirrhosis has been reported in as many as 50% of patients with chronic hepatitis C. Although chronic hepatitis C accounts for at least 40% of cases of chronic liver disease and of patients undergoing liver transplantation for end-stage liver disease in the United States and Europe, in the majority of patients with chronic hepatitis C, morbidity and mortality are limited during the initial 20 years after the onset of infection. Progression of chronic hepatitis C may be influenced by hepatitis C genotype, age of acquisition, duration of infection, immunosuppression, coexisting excessive alcohol use, other hepatitis virus infection, or HIV co-infection. In fact, instances of severe and rapidly progressive chronic hepatitis B and C are being recognized with increasing frequency in patients with HIV infection (Chap. 173). In contrast, neither HAV nor HEV causes chronic liver disease.

Rare complications of viral hepatitis include pancreatitis, myocarditis, atypical pneumonia, aplastic anemia, transverse myelitis, and peripheral neuropathy. Persons with chronic hepatitis B, particularly those infected in infancy or early childhood and especially those with HBeAg, have an enhanced risk of hepatocellular carcinoma. The risk of hepatocellular carcinoma is increased as well in patients with chronic hepatitis C, almost exclusively in patients with cirrhosis, and almost always after at least several decades, usually after three decades of disease (Chap. 78). In children, hepatitis B may present rarely with anicteric hepatitis, a nonpruritic papular rash of the face, buttocks, and limbs, and lymphadenopathy (papular acrodermatitis of childhood or Gianotti-Crosti syndrome).

DIFFERENTIAL DIAGNOSIS Viral diseases such as infectious mononucleosis; those due to cytomegalovirus, herpes simplex, and coxsackieviruses; and toxoplasmosis may share certain clinical features with viral hepatitis and cause elevations in serum aminotransferase and less commonly in serum bilirubin levels. Tests such as the differential heterophile and serologic tests for these agents may be helpful in the differential diagnosis if HBsAg, anti-HBc, IgM anti-HAV, and anti-HCV determinations are negative. Aminotransferase elevations can accompany almost any systemic viral infection; other rare causes of liver injury confused with viral hepatitis are infections with *Leptospira*, *Candida*, *Brucella*, *Mycobacteria*, and *Pneumocystis*. A complete drug history is particularly important, for many drugs and certain anesthetic agents can produce a picture of either acute hepatitis or cholestasis (Chap. 286). Equally important is a past history of unexplained "repeated episodes" of acute hepatitis. This history should alert the physician to the possibility that the underlying disorder is chronic hepatitis. Alcoholic hepatitis must also be considered, but usually the serum aminotransferase levels are not as markedly elevated and other stigmata of alcoholism may be present. The finding on liver biopsy of fatty infiltration, a neutrophilic inflammatory reaction, and "alcoholic hyaline" would be consistent with alcohol-induced rather than viral liver injury. Because acute hepatitis may present with right upper quadrant abdominal pain, nausea and vomiting, fever, and icterus, it is often confused with acute cholecystitis, common duct stone, or ascending cholangitis. Patients with acute viral hepatitis may tolerate surgery poorly; therefore, it is important to exclude this diagnosis, and in confusing cases, a percutaneous liver biopsy may be necessary before laparotomy. Viral hepatitis in the elderly is often misdiagnosed as obstructive jaundice resulting from a common duct stone or carcinoma of the pancreas. Because acute hepatitis in the elderly may be quite severe and the operative mortality high, a thorough evaluation including biochemical tests, radiographic studies of the biliary tree, and even liver biopsy may be necessary to exclude primary parenchymal liver disease. Another clinical constellation that may mimic acute hepatitis is right ventricular failure with passive hepatic congestion or hypoperfusion syndromes, such as those associated with shock, severe hypotension, and severe left ventricular failure. Also included in this general category is any disorder that interferes with venous return to the heart, such as right atrial myxoma, constrictive pericarditis, hepatic vein occlusion (Budd-Chiari syndrome), or venoocclusive disease. Clinical features are usually sufficient to distinguish between these vascular disorders and viral hepatitis. Acute fatty liver of pregnancy, cholestasis of pregnancy, eclampsia, and the HELLP syndrome (hemolysis, elevated liver tests, and low platelets) can be confused with viral hepatitis during pregnancy. Very rarely, malignancies metastatic to the liver can mimic acute or even fulminant viral hepatitis. Occasionally, genetic or metabolic liver disorders (e.g., Wilson's disease, α_1-antitrypsin deficiency) as well as nonalcoholic fatty liver disease are confused with viral hepatitis.

TREATMENT

Treatment of Acute Attack In hepatitis B, among previously healthy adults who present with clinically apparent acute hepatitis, recovery occurs in approximately 99%; therefore, antiviral therapy is not likely to improve the rate of recovery and is not required. In rare instances of severe acute hepatitis B, treatment with a nucleoside analogue, such as lamivudine, at the 100-mg/d oral dose used to treat chronic hepatitis B (Chap. 287), has been attempted successfully. However, clinical trials have not been done to establish the efficacy of this approach, severe acute hepatitis B is not an approved indication for therapy, and the duration of therapy has not been determined. In typical cases of acute hepatitis C, recovery is rare, progression to chronic hepatitis is the rule, and meta-analyses of small clinical trials suggest that antiviral therapy with interferon α monotherapy (3 million units subcutaneously three times a week) is beneficial, reducing the rate of chronicity considerably by inducing sustained responses in 30 to 70% of patients. In a German multicenter study of 44 patients with acute symptomatic hepatitis C, initiation of intensive interferon α therapy (5 million units subcutaneously daily for 4 weeks, then three times a week for another 20 weeks) within an average of 3 months after infection resulted in a sustained virologic response rate of 98%. Although treatment of acute hepatitis C is recommended, the optimum regimen, duration of therapy, and time to initiate therapy remain to be determined. Many authorities now opt for the best regimen identified for the treatment of chronic hepatitis C, long-acting pegylated interferon plus the nucleoside analogue ribavirin, the efficacy of which is superior to that of standard interferon monotherapy regimens (Chap. 287). Because of the marked reduction over the last two decades in the frequency of acute hepatitis C, opportunities to identify and treat patients with acute hepatitis C are rare indeed. Hospital epidemiologists, however, will encounter health workers who sustain hepatitis C–contaminated needle sticks; when monitoring for ALT elevations and HCV RNA after these accidents identifies acute hepatitis C, therapy should be initiated.

Notwithstanding these specific therapeutic considerations, in most cases of typical acute viral hepatitis, specific treatment generally is not necessary. Although hospitalization may be required for clinically severe illness, most patients do not require hospital care. Forced and prolonged bed rest is not essential for full recovery, but many patients will feel better with restricted physical activity. A high-calorie diet is desirable, and because many patients may experience nausea late in the day, the major caloric intake is best tolerated in the morning. Intravenous feeding is necessary in the acute stage if the patient has persistent vomiting and cannot maintain oral intake. Drugs capable of producing adverse reactions such as cholestasis and drugs metabolized by the liver should be avoided. If severe pruritus is present, the use of the bile salt–sequestering resin cholestyramine is helpful. Glucocorticoid therapy has no value in acute viral hepatitis, even in severe cases associated with *bridging necrosis*, and may be hazardous.

Physical isolation of patients with hepatitis to a single room and bathroom is rarely necessary except in the case of fecal incontinence for hepatitis A and E or uncontrolled, voluminous bleeding for hepatitis B (with or without concomitant hepatitis D) and hepatitis C. Because most patients hospitalized with hepatitis A excrete little if any

HAV, the likelihood of HAV transmission from these patients during their hospitalization is low. Therefore, burdensome *enteric precautions are no longer recommended*. Although gloves should be worn when the bedpans or fecal material of patients with hepatitis A are handled, these precautions do not represent a departure from sensible procedure for all hospitalized patients. For patients with hepatitis B and hepatitis C, emphasis should be placed on blood precautions, i.e., avoiding direct, ungloved hand contact with blood and other body fluids. Enteric precautions are unnecessary. The importance of simple hygienic precautions, such as hand washing, cannot be overemphasized. Universal precautions that have been adopted for all patients apply to patients with viral hepatitis.

Hospitalized patients may be discharged when there is substantial symptomatic improvement, a significant downward trend in the serum aminotransferase and bilirubin values, and a return to normal of the PT. Mild aminotransferase elevations should not be considered contraindications to the gradual resumption of normal activity.

In *fulminant hepatitis*, the goal of therapy is to support the patient by maintenance of fluid balance, support of circulation and respiration, control of bleeding, correction of hypoglycemia, and treatment of other complications of the comatose state in anticipation of liver regeneration and repair. Protein intake should be restricted, and oral lactulose or neomycin administered. Glucocorticoid therapy has been shown in controlled trials to be ineffective. Likewise, exchange transfusion, plasmapheresis, human cross-circulation, porcine liver cross-perfusion, and hemoperfusion have not been proven to enhance survival; however, the efficacy of extracorporeal liver-assist devices, involving hollow-fiber chambers containing hepatocytes, is being evaluated in clinical trials. Meticulous intensive care is the one factor that does appear to improve survival. Orthotopic liver transplantation is resorted to with increasing frequency, with excellent results, in patients with fulminant hepatitis (Chap. 291).

PROPHYLAXIS Because application of therapy for acute viral hepatitis is limited, and because antiviral therapy for chronic viral hepatitis is effective in only a proportion of patients (Chap. 287), emphasis is placed on prevention through immunization. The prophylactic approach differs for each of the types of viral hepatitis. In the past, immunoprophylaxis relied exclusively on passive immunization with antibody-containing globulin preparations purified by cold ethanol fractionation from the plasma of hundreds of normal donors. Currently, for hepatitis A and B, active immunization with vaccines is available as well.

Hepatitis A Both passive immunization with IG and active immunization with killed vaccines are available. All preparations of IG contain anti-HAV concentrations sufficient to be protective. When administered before exposure or during the early incubation period, IG is effective in preventing clinically apparent hepatitis A. For postexposure prophylaxis of intimate contacts (household, sexual, institutional) of persons with hepatitis A, the administration of 0.02 mL/kg is recommended as early after exposure as possible; it may be effective even when administered as late as 2 weeks after exposure. Prophylaxis is not necessary for casual contacts (office, factory, school, or hospital), for most elderly persons, who are very likely to be immune, or for those known to have anti-HAV in their serum. In day-care centers, recognition of hepatitis A in children or staff should provide a stimulus for immunoprophylaxis in the center and in the children's family members. By the time most common-source outbreaks of hepatitis A are recognized, it is usually too late in the incubation period for IG to be effective; however, prophylaxis may limit the frequency of secondary cases. For travelers to tropical countries, developing countries, and other areas outside standard tourist routes, IG prophylaxis had been recommended, before a vaccine became available. When such travel lasted less than 3 months, 0.02 mL/kg was given; for longer travel or residence in these areas, a dose of 0.06 mL/kg every 4 to 6 months was recommended. Administration of plasma-derived globulin is safe; all contemporary lots of IG are subjected to viral inactivation steps and must be free of HCV RNA as determined by PCR testing. Administration of intramuscular lots of IG has not been associated with transmission of HBV, HCV, or HIV.

Formalin-inactivated vaccines made from strains of HAV attenuated in tissue culture have been shown to be safe, immunogenic, and effective in preventing hepatitis A. Hepatitis A vaccines are approved for use in persons who are at least 2 years old and appear to provide adequate protection 4 weeks after a primary inoculation. If it can be given within 4 weeks of an expected exposure, such as by travel to an endemic area, hepatitis A vaccine is the preferred approach to *preexposure* immunoprophylaxis. If travel is more imminent, IG (0.02 mL/kg) should be administered at a different injection site, along with the first dose of vaccine. Because vaccination provides long-lasting protection (protective levels of anti-HAV should last 20 years after vaccination), persons whose risk will be sustained (e.g., frequent travelers or those remaining in endemic areas for prolonged periods) should be vaccinated, and vaccine should supplant the need for repeated IG injections. Other groups who are candidates for hepatitis A vaccination include military personnel, populations with cyclic outbreaks of hepatitis A (e.g., Alaskan natives), employees of day-care centers, primate handlers, laboratory workers exposed to hepatitis A or fecal specimens, children in communities with a high frequency of hepatitis A, and patients with chronic liver disease. Because of an increased risk of fulminant hepatitis A—observed in some experiences but not confirmed in others—among patients with chronic hepatitis C, patients with chronic hepatitis C have been singled out as candidates for hepatitis A vaccination. Other populations whose recognized risk of hepatitis A is increased should be vaccinated, including men who have sex with men, injection drug users, and persons with clotting disorders who require frequent administration of clotting-factor concentrates. Recommendations for dose and frequency differ for the two approved vaccine preparations (Table 285-5); all injections are intramuscular. Hepatitis A vaccine has been reported to be effective in preventing secondary household cases of acute hepatitis A, but its role in other instances of postexposure prophylaxis remains to be demonstrated.

Hepatitis B Until 1982, prevention of hepatitis B was based on *passive* immunoprophylaxis either with standard IG, containing modest levels of anti-HBs, or hepatitis B immune globulin (HBIG), containing high-titer anti-HBs. The efficacy of standard IG has never been established and remains questionable; even the efficacy of HBIG, demonstrated in several clinical trials, has been challenged, and its contribution appears to be in reducing the frequency of clinical *illness*, not in preventing *infection*. The first vaccine for *active* immunization, introduced in 1982, was prepared from purified, noninfectious 22-nm spherical forms of HBsAg derived from the plasma of healthy HBsAg carriers. In 1987, the plasma-derived vaccine was supplanted by a genetically engineered vaccine derived from recombinant yeast. The latter vaccine consists of HBsAg particles that are nonglycosylated but are otherwise indistinguishable from natural HBsAg; two recombinant vaccines are licensed for use in the United States. Current recommendations can be divided into those for preexposure and postexposure prophylaxis.

For *preexposure* prophylaxis against hepatitis B in settings of frequent exposure (health workers exposed to blood; hemodialysis pa-

TABLE 285-5 Hepatitis A Vaccination Schedules

Age, years	No. of Doses	Dose	Schedule, months
HAVRIX (GLAXOSMITHKLINE)			
2–18	2	720 ELU[a] (0.5 mL)	0, 6–12
>18	2	1440 ELU (1.0 mL)	0, 6–12
VAQTA (MERCK)			
2–17	2	25 units (0.5 mL)	0, 6
>17	2	50 units (1.0 mL)	0, 6–18

[a] Enzyme-linked immunoassay units.

tients and staff; residents and staff of custodial institutions for the developmentally handicapped; injection drug users; inmates of long-term correctional facilities; persons with multiple sexual partners; persons such as hemophiliacs who require long-term, high-volume therapy with blood derivatives; household and sexual contacts of HBsAg carriers; persons living in or traveling extensively in endemic areas; unvaccinated children under the age of 18; and unvaccinated children who are Alaskan natives, Pacific Islanders, or residents in households of first-generation immigrants from endemic countries), three intramuscular (deltoid, not gluteal) injections of hepatitis B vaccine are recommended at 0, 1, and 6 months. Pregnancy is *not* a contraindication to vaccination. In areas of low HBV endemicity such as the United States, despite the availability of safe and effective hepatitis B vaccines, a strategy of vaccinating persons in high-risk groups has not been effective. The incidence of new hepatitis B cases continued to increase in the United States after introduction of vaccines; fewer than 10% of all targeted persons in high-risk groups have actually been vaccinated, and approximately 30% of persons with sporadic acute hepatitis B do not fall into any high-risk-group category. Therefore, to have an impact on the frequency of HBV infection in an area of low endemicity such as the United States, universal hepatitis B vaccination in childhood has been recommended. For unvaccinated children born after the implementation of universal infant vaccination, vaccination during early adolescence, at age 11 to 12 years, was recommended, and this recommendation has been extended to include all unvaccinated children age 0 to 18 years. In HBV-hyperendemic areas, e.g., Asia, universal vaccination of children has resulted in a marked 10- to 15-year decline in hepatitis B and its complications.

The two available recombinant hepatitis B vaccines are comparable, one containing 10 μg of HBsAg (Recombivax-HB) and the other containing 20 μg of HBsAg (Engerix-B), and recommended doses for each injection vary for the two preparations (Table 285-6).

For unvaccinated persons sustaining an exposure to HBV, *postexposure* prophylaxis with a combination of HBIG (for rapid achievement of high-titer circulating anti-HBs) and hepatitis B vaccine (for achievement of long-lasting immunity as well as its apparent efficacy in attenuating clinical illness after exposure) is recommended. For *perinatal* exposure of infants born to HBsAg-positive mothers, a single dose of HBIG, 0.5 mL, should be administered intramuscularly in the thigh *immediately after birth*, followed by a complete course of three injections of recombinant hepatitis B vaccine (see doses above) to be started within the first 12 h of life. For those experiencing a direct percutaneous inoculation or transmucosal exposure to HBsAg-positive blood or body fluids (e.g., accidental *needle stick*, other mucosal penetration, or ingestion), a single intramuscular dose of HBIG, 0.06 mL/kg, administered as soon after exposure as possible, is followed by a complete course of hepatitis B vaccine to begin within the first week. For those exposed by *sexual* contact to a patient with acute hepatitis B, a single intramuscular dose of HBIG, 0.06 mL/kg, should be given within 14 days of exposure, to be followed by a complete course of hepatitis B vaccine. When both HBIG and hepatitis B vaccine are recommended, they may be given at the same time but at separate sites.

TABLE 285-6 *Preexposure Hepatitis B Vaccination Schedules*

Target Group	No. of Doses	Dose	Schedule, months
RECOMBIVAX-HB (MERCK)			
Infants, children (<11 years)	3	5 μg (0.5 mL)	0–2, 1–4, 6–18
Adolescents (11–19 years)	3	5 μg (0.5 mL)	0–2, 1–4, 4–6
Adults (≥20 years)	3	10 μg (1.0 mL)	0–2, 1–4, 4–6
Hemodialysis patients[a]	3	40 μg (1.0 mL)	0, 1, 6
ENGERIX-B (GLAXOSMITHKLINE)			
Infants, children (<10 years)	3	10 μg (0.5 mL)	0–2, 1–4, 6–18
Adolescents (10–19 years)	3	10 μg (0.5 mL)	0–2, 1–4, 4–6
Adults (≥ 20 years)	3	20 μg (1.0 mL)	0–2, 1–4, 4–6
Hemodialysis patients[a]	3	40 μg (1.0 mL)	0, 1, 6

[a] Includes other immunocompromised persons.

The precise duration of protection afforded by hepatitis B vaccine is unknown; however, approximately 80 to 90% of immunocompetent vaccinees retain protective levels of anti-HBs for at least 5 years, and 60 to 80% for 10 years. Thereafter and even after anti-HBs becomes undetectable, protection persists against clinical hepatitis B, hepatitis B surface antigenemia, and chronic HBV infection. Currently, *booster* immunizations are not recommended routinely, except in immunosuppressed persons who have lost detectable anti-HBs or immunocompetent persons who sustain percutaneous HBsAg-positive inoculations after losing detectable antibody. Specifically, for hemodialysis patients, annual anti-HBs testing is recommended after vaccination; booster doses are recommended when anti-HBs levels fall below 10 mIU/mL. For people at risk of both hepatitis A and B, a combined vaccine is available containing 720 enzyme-linked immunoassay units of inactivated HAV and 20 μg of recombinant HBsAg (at 0, 1, and 6 months).

Hepatitis D Infection with hepatitis D can be prevented by vaccinating susceptible persons with hepatitis B vaccine. No product is available for immunoprophylaxis to prevent HDV superinfection in HBsAg carriers; for them, avoidance of percutaneous exposures and limitation of intimate contact with persons who have HDV infection are recommended.

Hepatitis C IG is ineffective in preventing hepatitis C and is no longer recommended for postexposure prophylaxis in cases of perinatal, needle stick, or sexual exposure. Although a prototype vaccine that induces antibodies to HCV envelope protein has been developed, currently, hepatitis C vaccination is not feasible practically. Genotype and quasispecies viral heterogeneity, as well as rapid evasion of neutralizing antibodies by this rapidly mutating virus, conspire to render HCV a difficult target for immunoprophylaxis with a vaccine. Prevention of transfusion-associated hepatitis C has been accomplished by the following successively introduced measures: Exclusion of commercial blood donors and reliance on a volunteer blood supply; screening donor blood with surrogate markers such as ALT (no longer recommended) and anti-HBc, markers that identify segments of the blood donor population with an increased risk of bloodborne infections; exclusion of blood donors in high-risk groups for AIDS and the introduction of anti-HIV screening tests; and progressively sensitive serologic screening tests for HCV infection. Chemical and heat treatment of blood products used for large-pool and concentrated blood derivates are being pursued.

In the absence of active or passive immunization, prevention of hepatitis C includes behavior changes and precautions to limit exposures to infected persons. Recommendations designed to identify patients with clinically inapparent hepatitis as candidates for medical management have as a secondary benefit the identification of persons whose contacts could be at risk of becoming infected. A so-called "look-back" program has been recommended to identify persons who were transfused before 1992 with blood from a donor found subsequently to have hepatitis C. In addition, anti-HCV testing is recommended for anyone who received a blood transfusion or a transplanted organ before the introduction of second-generation screening tests in 1992, people who ever used injection drugs, chronically hemodialyzed patients, persons with clotting disorders who received clotting factors made before 1987 from pooled blood products, persons with elevated aminotransferase levels, health workers exposed to HCV-positive blood or contaminated needles, and children born to HCV-positive mothers.

For stable, monogamous sexual partners, sexual transmission of hepatitis C is unlikely, and sexual barrier precautions are not recommended. For persons with multiple sexual partners or with sexually transmitted diseases, the risk of sexual transmission of hepatitis C is increased, and barrier precautions (latex condoms) are recommended.

A person with hepatitis C should avoid sharing such items as razors, toothbrushes, and nail clippers with sexual partners and family members. No special precautions are recommended for babies born to mothers with hepatitis C, and breast feeding does not have to be restricted.

Hepatitis E Whether IG prevents hepatitis E remains undetermined. A recombinant vaccine has been developed and is undergoing clinical testing.

286 TOXIC AND DRUG-INDUCED HEPATITIS

Jules L. Dienstag, Kurt J. Isselbacher

Liver injury may follow the inhalation, ingestion, or parenteral administration of a number of pharmacologic and chemical agents. These include industrial toxins (e.g., carbon tetrachloride, trichloroethylene, and yellow phosphorus), the heat-stable toxic bicyclic octapeptides of certain species of *Amanita* and *Galerina* (hepatotoxic mushroom poisoning), and, more commonly, pharmacologic agents used in medical therapy. It is essential that any patient presenting with jaundice or altered biochemical liver tests be questioned carefully about exposure to chemicals used in work or at home, drugs taken by prescription or bought "over the counter," and herbal or alternative medicines. Hepatotoxic drugs can injure the hepatocyte directly, e.g., via a free-radical or metabolic intermediate that causes peroxidation of membrane lipids and that results in liver cell injury. Alternatively, the drug or its metabolite can distort cell membranes or other cellular molecules, activate apoptotic pathways, or block biochemical pathways or cellular integrity. Such injuries, in turn, may lead to necrosis of hepatocytes; injure bile ducts, producing cholestasis; or block pathways of lipid movement, inhibit protein synthesis, or impair mitochondrial oxidation of fatty acids, resulting in lactic acidosis and fat accumulation (steatosis). In some cases, drug metabolites sensitize hepatocytes to toxic cytokines, and differences between susceptible and nonsusceptible drug recipients may be attributable to polymorphisms in elaboration of competing, protective cytokines, as has been suggested for acetaminophen hepatotoxicity (see below). In addition, a role has been shown for activation of nuclear transporters, such as the constitutive androstane receptor (CAR), in the induction of drug hepatotoxicity. In general, two major types of chemical hepatotoxicity have been recognized: (1) direct toxic type and (2) idiosyncratic type.

Most drugs, which are water-insoluble, undergo a series of metabolic transformation steps, culminating in a water-soluble form appropriate for renal or biliary excretion. This process begins with oxidation or methylation initially mediated by the mixed-function oxygenases cytochrome P450 (phase I reaction), followed by glucuronidation or sulfation (phase II reaction) or inactivation by glutathione. Most drug hepatotoxicity is mediated by a phase I toxic metabolite, but glutathione depletion, precluding inactivation of harmful compounds by glutathione S-transferase, can contribute as well.

As shown in Table 286-1, direct toxic hepatitis occurs with predictable regularity in individuals exposed to the offending agent and is dose-dependent. The latent period between exposure and liver injury is usually short (often several hours), although clinical manifestations may be delayed for 24 to 48 h. Agents producing toxic hepatitis are generally systemic poisons or are converted in the liver to toxic metabolites. The direct hepatotoxins result in morphologic abnormalities

TABLE 286-1 *Some Features of Toxic and Drug-Induced Hepatic Injury*

	Direct Toxic Effect[a]		Idiosyncratic[a]			Other[a]
Features	(Carbon Tetrachloride)	(Acetaminophen)	(Halothane)	(Isoniazid)	(Chlorpromazine)	(Oral Contraceptive Agents)
Predictable and dose-related toxicity	+	+	0	0	0	+
Latent period	Short	Short	Variable	Variable	Variable	Variable
Arthralgia, fever, rash, eosinophilia	0	0	+	0	+	0
Liver morphology	Necrosis, fatty infiltration	Centrilobular necrosis	Similar to viral hepatitis	Similar to viral hepatitis	Cholestasis *with* portal inflammation	Cholestasis *without* portal inflammation, vascular lesions

[a] The drugs listed are typical samples.

that are reasonably characteristic and reproducible for each toxin. For example, carbon tetrachloride and trichloroethylene characteristically produce a centrilobular zonal necrosis, whereas yellow phosphorus poisoning typically results in periportal injury. The hepatotoxic octapeptides of *Amanita phalloides* usually produce massive hepatic necrosis. The lethal dose of the toxin is about 10 mg, the amount found in a single deathcap mushroom. Tetracycline, when administered in intravenous doses >1.5 g daily, leads to microvesicular fat deposits in the liver. Liver injury, which is often only one facet of the toxicity produced by the direct hepatotoxins, may go unrecognized until jaundice appears.

In idiosyncratic drug reactions the occurrence of hepatitis is usually infrequent and unpredictable, the response is not dose-dependent, and it may occur at any time during or shortly after exposure to the drug. Adding to the difficulty of predicting or identifying idiosyncratic drug hepatotoxicity is the occurrence of mild, transient, nonprogressive serum aminotransferase elevations that resolve with continued drug use. Such "adaptation," the mechanism of which is unknown, occurs in such drugs as isoniazid, valproate, phenytoin, and HMG-CoA reductase inhibitors (statins). Extrahepatic manifestations of hypersensitivity, such as rash, arthralgias, fever, leukocytosis, and eosinophilia, occur in about one-quarter of patients with idiosyncratic hepatotoxic drug reactions; this observation and the unpredictability of idiosyncratic drug hepatototoxicity contributed to the hypothesis that this category of drug reactions is immunologically mediated. More recent evidence, however, suggests that, in most cases, even idiosyncratic reactions represent direct hepatotoxity but are caused by drug metabolites rather than by the intact compound. Even the prototypes of idiosyncratic hepatoxicity reactions, halothane hepatitis and isoniazid hepatotoxicity, associated frequently with hypersensitivity manifestations, are now recognized to be mediated by toxic metabolites that damage liver cells directly. Currently, most idiosyncratic reactions are thought to result from differences in metabolic reactivity to specific agents; host susceptibility is mediated by the kinetics of toxic metabolite generation, which differs among individuals. Occasionally, however, the clinical features of an allergic reaction (prominent tissue eosinophilia, autoantibodies, etc.) are difficult to ignore. In vitro models have been described in which lymphocyte cytotoxicity can be demonstrated against rabbit hepatocytes altered by incubation with the potential offending drug. Furthermore, several instances of drug hepatotoxicity are associated with the appearance of autoantibodies, including a class of antibodies to liver-kidney microsomes, anti-LKM2, directed against a cytochrome P450 enzyme. Similarly, in selected cases, a drug or its metabolite has been shown to bind to a host cellular component forming a hapten; the immune response to this "neoantigen" is postulated to play a role in the pathogenesis of liver injury. Therefore, some authorities subdivide idiosyncratic drug hepatotoxicity into hypersensitivity (allergic) and "metabolic" categories. Several unusual exceptions notwithstanding, true drug allergy is difficult to support in most cases of idiosyncratic drug-induced liver injury.

Idiosyncratic reactions lead to a morphologic pattern that is more variable than those produced by direct toxins; a single agent is often capable of causing a variety of lesions, although certain patterns tend to predominate. Depending on the agent involved, idiosyncratic hepatitis may result in a clinical and morphologic picture indistinguishable from that of viral hepatitis (e.g., halothane) or may simulate extrahepatic bile duct obstruction clinically with morphologic evidence of cholestasis. Drug-induced cholestasis ranges from mild to increasingly severe: (1) bland cholestasis with limited hepatocellular injury (e.g., estrogens, 17,α-substituted androgens); (2) inflammatory cholestasis (e.g., phenothiazines, amoxicillin–clavulanic acid, oxacillin, erythromcyin estolate); (3) sclerosing cholangitis (e.g., after intrahepatic infusion of the chemotherapeutic agent floxuridine for hepatic metastases from a primary colonic carcinoma); (4) disappearance of bile ducts, "ductopenic" cholestasis, similar to that observed in chronic rejection following liver transplantation (e.g., carbamazepine, chlorpromazine, tricyclic antidepressant agents). Cholestasis may result from binding of drugs to canalicular membrane transporters, accumulation of toxic bile acids resulting from canalicular pump failure, or genetic defects in canalicular transporter proteins. Morphologic alterations may also include bridging hepatic necrosis (e.g., methyldopa), or, infrequently, hepatic granulomas (e.g., sulfonamides). Some drugs result in macrovesicular or microvesicular steatosis or steatohepatitis, which in some cases has been linked to mitochondrial dysfunction and lipid peroxidation. Severe hepatotoxicity associated with steatohepatitis, most likely a result of mitochondrial toxicity, is being recognized with increasing frequency among patients receiving antiretroviral therapy with reverse transcriptase inhibitors (e.g., zidovudine, didanosine) or protease inhibitors (e.g., indinavir, ritonavir) for HIV infection (Chap. 173). Generally, such mitochondrial hepatotoxicity of these antiretroviral agents is reversible, but dramatic, nonreversible hepatotoxicity associated with mitochondrial injury (inhibition of DNA polymerase γ) was the cause of acute liver failure encountered during early clinical trials of fialuridine, a fluorinated pyrimidine analogue with potent antiviral activity against hepatitis B virus. Another potential target for idiosyncratic drug hepatotoxicity is sinusoidal lining cells; when these are injured, such as by high-dose chemotherapeutic agents (e.g., cyclophosphamide, melphalan, busulfan) administered prior to bone marrow transplantation, venoocclusive disease can result.

Not all adverse hepatic drug reactions can be classified as either toxic or idiosyncratic in type. For example, oral contraceptives, which combine estrogenic and progestational compounds, may result in impairment of hepatic tests and occasionally in jaundice. However, they do not produce necrosis or fatty change, manifestations of hypersensitivity are generally absent, and susceptibility to the development of oral contraceptive–induced cholestasis appears to be genetically determined. Such estrogen-induced cholestasis is more common in women with cholestasis of pregnancy, a disorder linked to genetic defects in multidrug resistance–associated canalicular transporter proteins. Other instances of genetically determined drug hepatotoxicity have been identified. For example, approximately 10% of the population have an autosomally recessive trait associated with the absence of cytochrome P450 enzyme 2D6 and have impaired debrisoquine-4-hydroxylase enzyme activity. As a result, they cannot metabolize, and are at increased risk of hepatotoxicity resulting from, certain compounds such as desipramine, propranolol, and quinidine.

Some forms of drug hepatotoxicity are so rare, e.g., occurring in <1:10,000 recipients, that they do not become apparent during clinical trials, involving only several thousand recipients, conducted to obtain drug registration. An example of such rare, but serious, idiosyncratic drug hepatotoxicity followed the approval and generalized use of troglitazone, a peroxisomal, proliferator activator–receptor γ agonist, the first-introduced example of a thiazolidinedione insulin-sensitizing agent. This instance of drug hepatotoxicity was not recognized until well after the drug was introduced, underlining the importance of postmarketing surveillance in identifying toxic drugs and in leading to their withdrawal from use.

Because drug-induced hepatitis is often a presumptive diagnosis and many other disorders produce a similar clinicopathologic picture, evidence of a causal relationship between the use of a drug and subsequent liver injury may be difficult to establish. The relationship is most convincing for the direct hepatotoxins, which lead to a high frequency of hepatic impairment after a short latent period. Idiosyncratic reactions may be reproduced, in some instances, when rechallenge, after an asymptomatic period, results in a recurrence of signs, symptoms, and morphologic and biochemical abnormalities. Rechallenge, however, is often ethically unfeasible, because severe reactions may occur.

Generally, drug hepatotoxicity is not more frequent in persons with underlying chronic liver disease. Reported exceptions include hepatotoxicity of aspirin, methotrexate, isoniazid (only in certain experiences), and antiretroviral therapy for HIV infection.

TABLE 286-2 *Principal Alterations of Hepatic Morphology Produced by Some Commonly Used Drugs and Chemicals*[a]

Principal Morphologic Change	Class of Agent	Example
Cholestasis	Anabolic steroid	Methyl testosterone
	Anti-inflammatory	Sulindac
	Antithyroid	Methimazole
	Antibiotic	Erythromycin estolate, nitrofurantoin, rifampin, amoxicillin–clavulanic acid, oxacillin
	Oral contraceptive	Norethynodrel with mestranol
	Oral hypoglycemic	Chlorpropamide
	Tranquilizer	Chlorpromazine[b]
	Oncotherapeutic	Anabolic steroids, busulfan, tamoxifen
	Immunosuppressive	Cyclosporine
	Anticonvulsant	Carbamazepine
	Calcium channel blocker	Nifedipine, verapamil
Fatty liver	Antibiotic	Tetracycline
	Anticonvulsant	Sodium valproate
	Antiarrhythmic	Amiodarone
	Antiviral	Dideoxynucleosides (e.g., zidovudine) protease inhibitors (e.g., indinavir, ritonavir)
	Oncotherapeutic	Asparaginase, methotrexate
Hepatitis	Anesthetic	Halothane[c]
	Anticonvulsant	Phenytoin, carbamazepine
	Antihypertensive	Methyldopa,[c] captopril, enalapril
	Antibiotic	Isoniazid,[c] rifampin, nitrofurantoin
	Diuretic	Chlorothiazide
	Laxative	Oxyphenisatin[c]
	Antidepressant	Iproniazid, amitriptyline, imipramine, trazodone, venlafaxine
	Anti-inflammatory	Ibuprofen, indomethacin, diclofenac, sulindac, bomfenac
	Antifungal	Ketoconazole, fluconazole, itraconazole
	Antiviral	Zidovudine, didanosine, nevirapine
	Calcium channel blocker	Nifedipine, verapamil, diltiazem
	Cholinesterase inhibitor	Tacrine
	Oral hypoglycemic	Troglitazone
	Antiandrogen	Flutamide
Mixed hepatitis/ cholestatic	Immunosuppressive	Azathioprine
	Lipid-lowering	Nicotinic acid, lovastatin and other statins
	Antibiotic	Amoxicillin–clavulanic acid, trimethoprim-sulfamethoxazole
	Antifungal	Terbinafine
Toxic (necrosis)	Hydrocarbon	Carbon tetrachloride
	Metal	Yellow phosphorus
	Mushroom	*Amanita phalloides*
	Analgesic	Acetaminophen
	Solvent	Dimethylformamide
Granulomas	Anti-inflammatory	Phenylbutazone
	Antibiotic	Sulfonamides
	Xanthine oxidase inhibitor	Allopurinol
	Antiarrhythmic	Quinidine, diltiazem
	Anticonvulsant	Carbamazepine

[a] Several agents cause more than one type of liver lesion and appear under more than one category.
[b] Rarely associated with primary biliary cirrhosis–like lesion.
[c] Occasionally associated with chronic hepatitis or bridging hepatic necrosis or cirrhosis.

TREATMENT

Treatment of toxic and drug-induced hepatic disease is largely supportive, except in acetaminophen hepatotoxicity (see below). In patients with fulminant hepatitis resulting from drug hepatotoxicity, liver transplantation may be life-saving (Chap. 291). Withdrawal of the suspected agent is indicated at the first sign of an adverse reaction. In the case of the direct toxins, liver involvement should not divert attention from renal or other organ involvement, which may also threaten survival. Glucocorticoids for drug hepatotoxicity with allergic features, silibinin for hepatotoxic mushroom poisoning, and ursodeoxycholic acid for cholestatic drug hepatotoxicity have never been shown to be effective and are not recommended.

In Table 286-2, several classes of chemical agents are listed, together with examples of the pattern of liver injury produced by them. Certain drugs appear to be responsible for the development of chronic as well as acute hepatic injury. For example, oxyphenisatin, methyldopa, and isoniazid have been associated with moderate to severe chronic hepatitis, and halothane and methotrexate have been implicated in the development of cirrhosis. A syndrome resembling primary biliary cirrhosis has been described following treatment with chlorpromazine, methyl testosterone, tolbutamide, and other drugs. Portal hypertension in the absence of cirrhosis may result from alterations in hepatic architecture produced by vitamin A or arsenic intoxication, industrial exposure to vinyl chloride, or administration of thorium dioxide. The latter three agents have also been associated with angiosarcoma of the liver. Oral contraceptives have been implicated in the development of hepatic adenoma and, rarely, hepatocellular carcinoma and hepatic vein occlusion (Budd-Chiari syndrome). Another unusual lesion, peliosis hepatis (blood cysts of the liver), has been observed in some patients treated with anabolic steroids. The existence of these hepatic disorders expands the spectrum of liver injury induced by chemical agents and emphasizes the need for a thorough drug history in all patients with liver dysfunction.

The following are the patterns of adverse hepatic reactions for some prototypic agents.

ACETAMINOPHEN HEPATOTOXICITY (DIRECT TOXIN) Acetaminophen can cause severe centrilobular hepatic necrosis when ingested in large amounts in suicide attempts or accidentally by children. A single dose of 10 to 15 g, occasionally less, may produce clinical evidence of liver injury. Fatal fulminant disease is usually (although not invariably) associated with ingestion of ≥25 g. Blood levels of acetaminophen correlate with the severity of hepatic injury (levels >300 μg/mL 4 h after ingestion are predictive of the development of severe damage; levels <150 μg/mL suggest that hepatic injury is highly unlikely). Nausea, vomiting, diarrhea, abdominal pain, and shock are early manifestations occurring 4 to 12 h after ingestion. Then 24 to 48 h later, when these features are abating, hepatic injury becomes apparent. Maximal abnormalities and hepatic failure may not be evident until 4 to 6 days after ingestion, and aminotransferase levels approaching 10,000 units are not uncommon. Renal failure and myocardial injury may be present.

Acetaminophen is metabolized predominantly by a phase II reaction to innocuous sulfate and glucuronide metabolites; however, a small proportion of acetaminophen is metabolized by a phase I reaction to a hepatotoxic metabolite formed from the parent compound by the cytochrome P450 2E1. This metabolite, *N*-acetyl-benzoquinone-imide (NAPQI), is detoxified by binding to "hepatoprotective" glutathione to become harmless, water-soluble mercapturic acid, which undergoes renal excretion. When excessive amounts of NAPQI are formed, or

when glutathione levels are low, glutathione levels are depleted and overwhelmed, permitting covalent binding to nucleophilic hepatocyte macromolecules. This process is believed to lead to hepatocyte necrosis; the precise sequence and mechanism are unknown. Hepatic injury may be potentiated by prior administration of alcohol, phenobarbital, or other drugs, by conditions that stimulate the mixed-function oxidase system, or by conditions such as starvation that reduce hepatic glutathione levels. The xenobiotic (environmental, exogenous substance) receptor CAR has been shown in a mouse model of acetaminophen hepatotoxicity to induce acetaminophen-metabolizing enzymes and, thereby, regulate and increase hepatotoxicity. Cimetidine, which inhibits P450 enzymes, has the potential to reduce generation of the toxic metabolite. Alcohol induces cytochrome P450 2E1; consequently, increased levels of the toxic metabolite NAPQI are produced in chronic alcoholics after acetaminophen ingestion. In addition, alcohol suppresses hepatic glutathione production. Therefore, in chronic alcoholics, the toxic dose of acetaminophen may be as low as 2 g, and alcoholic patients should be warned specifically about the dangers of even standard doses of this commonly used drug. Such "therapeutic misadventures" also occur occasionally in patients with severe, febrile illnesses or pain syndromes; in such a setting, several days of anorexia and near-fasting coupled with regular administration of extra-strength acetaminophen formulations result in a combination of glutathione depletion and relatively high NAPQI levels in the absence of a history of recognized acetaminophen overdose.

℞ TREATMENT

Treatment of acetaminophen overdosage includes gastric lavage, supportive measures, and oral administration of activated charcoal or cholestyramine to prevent absorption of residual drug. Neither of these agents appears to be effective if given >30 min after acetaminophen ingestion; if they are used, the stomach lavage should be done before other agents are administered orally. The chances of possible-, probable-, and high-risk hepatotoxicity can be derived from a nomogram plot (Fig. 286-1), readily available in emergency departments, of acetaminophen plasma levels as a function of hours after ingestion. In patients with high acetaminophen blood levels (>200 μg/mL measured at 4 h or >100 μg/mL at 8 h after ingestion), the administration of sulfhydryl compounds (e.g., cysteamine, cysteine, or *N*-acetylcysteine) appears to reduce the severity of hepatic necrosis. These agents appear to act by providing a reservoir of sulfhydryl groups to bind the toxic metabolites or by stimulating synthesis and repletion of hepatic glutathione. Therapy should be begun within 8 h of ingestion but may be effective even if given as late as 24 to 36 h after overdose. Later administration of sulfhydryl compounds is of uncertain value. Routine use of *N*-acetylcysteine has substantially reduced the occurrence of fatal acetaminophen hepatotoxicity. When given orally, *N*-acetylcysteine is diluted to yield a 5% solution. A loading dose of 140 mg/kg is given, followed by 70 mg/kg every 4 h for 15 to 20 doses. Whenever a patient with potential acetaminophen hepatotoxicity is encountered, a local poison control center should be contacted. Treatment can be stopped when plasma acetaminophen levels indicate that the risk of liver damage is low. If signs of hepatic failure (e.g., progressive jaundice, coagulopathy, confusion) occur despite *N*-acetylcysteine therapy for acetaminophen hepatotoxicity, liver transplantation may be the only option. Preliminary data suggest that early arterial blood lactate levels among such patients with acute liver failure may distinguish patients highly likely to require liver transplantation (lactate levels > 3.5 mmol/L) from those likely to survive without liver replacement.

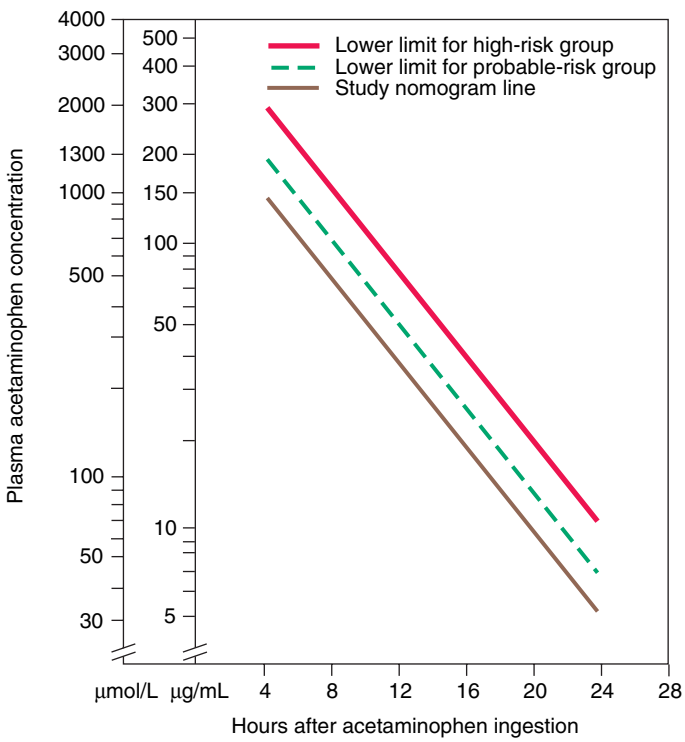

FIGURE 286-1 Nomogram to define risk of acetaminophen hepatotoxicity according to initial plasma acetaminophen concentration. *(After BH Rumack, H Matthew, Pediatrics 55:871, 1975.)*

Survivors of acute acetaminophen overdose usually have no evidence of hepatic sequelae. In a few patients, prolonged or repeated administration of acetaminophen in therapeutic doses appears to have led to the development of chronic hepatitis and cirrhosis.

HALOTHANE HEPATOTOXICITY (IDIOSYNCRATIC REACTION) Although currently quite rare, halothane hepatotoxicity was one of the prototypical, and most intensively studied, examples of idiosyncratic drug hepatotoxicity. Administration of halothane, a nonexplosive fluorinated hydrocarbon anesthetic agent that is structurally similar to chloroform, results in severe hepatic necrosis in a small number of individuals, many of whom have previously been exposed to this agent. The failure to produce similar hepatic lesions reliably in animals, the rarity of hepatic impairment in human beings, and the delayed appearance of hepatic injury suggest that halothane is not a direct hepatotoxin but rather a sensitizing agent. However, manifestations of hypersensitivity are seen in <25% of cases. A genetic predisposition leading to an idiosyncratic metabolic reactivity has been postulated and appears to be the most likely mechanism of halothane hepatotoxicity. Adults (rather than children), obese people, and women appear to be particularly susceptible. Fever, moderate leukocytosis, and eosinophilia may occur in the first week following halothane administration. Jaundice is usually noted 7 to 10 days after exposure but may occur earlier in previously exposed patients. Nausea and vomiting may precede the onset of jaundice. Hepatomegaly is often mild, but liver tenderness is common. The serum aminotransferase levels are elevated. The pathologic changes at autopsy are indistinguishable from massive hepatic necrosis resulting from viral hepatitis. The case-fatality rate of halothane hepatitis is not known but may vary from 20 to 40% in cases with severe liver involvement. Patients in whom unexplained spiking fever, especially delayed fever, or jaundice develops after halothane anesthesia should not receive this agent again. Because cross-reactions between halothane and methoxyflurane have been reported, the latter agent should not be used after halothane reactions. Later-generation halogenated hydrocarbon anesthetics, which have supplanted halothane except in rare instances (e.g., certain types of thoracic surgery), are felt to be associated with a lower risk of hepatotoxicity.

METHYLDOPA HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION) Minor alterations in liver tests are reported in about 5% of patients treated with this antihypertensive agent. These trivial abnormalities typically resolve despite continued drug administration. In <1% of patients, acute liver injury resembling viral or chronic hepatitis or, rarely, a cholestatic reaction is seen 1 to 20 weeks after methyldopa is started.

In 50% of cases the interval is <4 weeks. A prodrome of fever, anorexia, and malaise may be noted for a few days before the onset of jaundice. Rash, lymphadenopathy, arthralgia, and eosinophilia are rare. Serologic markers of autoimmunity are detected infrequently, and <5% of patients have a Coombs-positive hemolytic anemia. In about 15% of patients with methyldopa hepatotoxicity, the clinical, biochemical, and histologic features are those of moderate to severe chronic hepatitis, with or without bridging necrosis and macronodular cirrhosis. With discontinuation of the drug, the disorder usually resolves. Although methyldopa is currently used infrequently, its hepatotoxicity is very well characterized. Among the currently popular antihypertensive agents, angiotensin-converting enzyme (ACE) inhibitors, such as captopril and enalapril, have been blamed, albeit rarely, for hepatotoxicity (primarily cholestasis and cholestatic hepatitis, but also hepatocellular injury). Angiotensin-II receptor antagonists, such as losartan, are unlikely hepatotoxins, although rare reports of liver injury in their recipients have appeared.

ISONIAZID HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION) In approximately 10% of adults treated with the antituberculosis agent isoniazid, elevated serum aminotransferase levels develop during the first few weeks of therapy; this appears to represent an adaptive response to a toxic metabolite of the drug. Whether or not isoniazid is continued, these values (usually <200 units) return to normal in a few weeks. In about 1% of treated patients, an illness develops that is indistinguishable from viral hepatitis; approximately half of these cases occur within the first 2 months of treatment, while in the remainder, clinical disease may be delayed for many months. Liver biopsy reveals morphologic changes similar to those of viral hepatitis or bridging hepatic necrosis. The disease may be severe, with a case-fatality rate of 10%. Important liver injury appears to be age-related, increasing substantially after age 35; the highest frequency is in patients over age 50, the lowest under the age of 20. Even for patients >50 years monitored carefully during therapy, hepatotoxicity occurs in only approximately 2%, well below the risk estimate derived from earlier experiences. Isoniazid hepatotoxicity is enhanced by alcohol, rifampin and pyrazinamide. Fever, rash, eosinophilia, and other manifestations of drug allergy are distinctly unusual. A reactive metabolite of acetylhydrazine, a metabolite of isoniazid, may be responsible for liver injury, and patients who are rapid acetylators would be more prone to such injury. Counterintuitively, in some reports, the opposite is true; slow acetylators are more likely to experience hepatotoxicity and more severe hepatotoxicity than rapid acetylators. Contrary to past reports, several recent studies suggest that hepatotoxicity due to isoniazid as well as to combination antituberculous therapy that includes isoniazid is more likely in patients with underlying chronic hepatitis B. A picture resembling chronic hepatitis has been observed in a few patients. Careful liver-test monitoring is advisable in patients being treated with isoniazid.

SODIUM VALPROATE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION) Sodium valproate, an anticonvulsant useful in the treatment of petit mal and other seizure disorders, has been associated with the development of severe hepatic toxicity and, rarely, fatalities, predominantly in children but also in adults. Asymptomatic elevations of serum aminotransferase levels have been recognized in as many as 45% of treated patients. These "adaptive" changes, however, appear to have no clinical importance, for major hepatotoxicity is not seen in the majority of patients despite continuation of drug therapy. In those rare patients in whom jaundice, encephalopathy, and evidence of hepatic failure are found, examination of liver tissue reveals microvesicular fat and bridging hepatic necrosis, predominantly in the centrilobular zone. Bile duct injury may also be apparent. It seems likely that sodium valproate is not directly hepatotoxic but that its metabolite, 4-pentenoic acid, may be responsible for hepatic injury. Valproate hepatotoxicity is more common in persons with mitochondrial enzyme deficiencies and may be ameliorated by administration of carnitine, which valproate therapy can deplete.

PHENYTOIN HEPATOTOXICITY (IDIOSYNCRATIC REACTION) Phenytoin, formerly diphenylhydantoin, a mainstay in the treatment of seizure disorders, has been associated in rare instances with the development of severe hepatitis-like liver injury leading to fulminant hepatic failure. In many patients the hepatitis is associated with striking fever, lymphadenopathy, rash (Stevens-Johnson syndrome or exfoliative dermatitis), leukocytosis, and eosinophilia, suggesting an immunologically mediated hypersensitivity mechanism. Despite these observations, there is also evidence that metabolic idiosyncrasy may be responsible for hepatic injury. In the liver, phenytoin is converted by the cytochrome P450 system to metabolites, which include the highly reactive electrophilic arene oxides. These metabolites are normally metabolized further by epoxide hydrolases. A defect (genetic or acquired) in epoxide hydrolase activity could permit covalent binding of arene oxides to hepatic macromolecules, thereby leading to hepatic injury. Regardless of the mechanism, hepatic injury is usually manifest within the first 2 months after beginning phenytoin therapy. With the exception of an abundance of eosinophils in the liver, the clinical, biochemical, and histologic picture resembles that of viral hepatitis. In rare instances, bile duct injury may be the salient feature of phenytoin hepatotoxicity, with striking features of intrahepatic cholestasis. Asymptomatic elevations of aminotransferase and alkaline phosphatase levels have been observed in a sizable proportion of patients receiving long-term phenytoin therapy. These liver changes are believed by some authorities to represent the potent hepatic enzyme–inducing properties of phenytoin and are accompanied histologically by swelling of hepatocytes in the absence of necroinflammatory activity or evidence of chronic liver disease.

AMIODARONE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION) Therapy with this potent antiarrhythmic drug is accompanied in 15 to 50% of patients by modest elevations of serum aminotransferase levels that may remain stable or diminish despite continuation of the drug. Such abnormalities may appear days to many months after beginning therapy. A proportion of those with elevated aminotransferase levels have detectable hepatomegaly, and clinically important liver disease develops in <5% of patients. Features that represent a direct effect of the drug on the liver and that are common to the majority of long-term recipients are ultrastructural phospholipidosis, unaccompanied by clinical liver disease, and interference with hepatic mixed-function oxidase metabolism of other drugs. The cationic amphiphilic drug and its major metabolite desethylamiodarone accumulate in hepatocyte lysosomes and mitochondria and in bile duct epithelium. The relatively common elevations in aminotransferase levels are also considered a predictable, dose-dependent, direct hepatotoxic effect. On the other hand, in the rare patient with clinically apparent, symptomatic liver disease, liver injury resembling that seen in alcoholic liver disease is observed. The so-called pseudoalcoholic liver injury can range from steatosis, to alcoholic hepatitis-like neutrophilic infiltration and Mallory's hyaline, to cirrhosis. Electron-microscopic demonstration of phospholipid-laden lysosomal lamellar bodies can help to distinguish amiodarone hepatotoxicity from typical alcoholic hepatitis. This category of liver injury appears to be a metabolic idiosyncrasy that allows hepatotoxic metabolites to be generated. Rarely, an acute idiosyncratic hepatocellular injury resembling viral hepatitis or cholestatic hepatitis occurs. Hepatic granulomas have occasionally been observed. Because amiodarone has a long half-life, liver injury may persist for months after the drug is stopped.

ERYTHROMYCIN HEPATOTOXICITY (CHOLESTATIC IDIOSYNCRATIC REACTION) The most important adverse effect associated with erythromycin, more common in children than adults, is the infrequent occurrence of a cholestatic reaction. Although most of these reactions have been associated with erythromycin estolate, other erythromycins may also be responsible. The reaction usually begins during the first 2 or 3 weeks of therapy and includes nausea, vomiting, fever, right upper quadrant abdominal pain, jaundice, leukocytosis, and moderately elevated ami-

notransferase levels. The clinical picture can resemble acute cholecystitis or bacterial cholangitis. Liver biopsy reveals variable cholestasis; portal inflammation comprising lymphocytes, polymorphonuclear leukocytes, and eosinophils; and scattered foci of hepatocyte necrosis. Symptoms and laboratory findings usually subside within a few days of drug withdrawal, and evidence of chronic liver disease has not been found on follow-up. The precise mechanism remains ill-defined.

ORAL CONTRACEPTIVE HEPATOTOXICITY (CHOLESTATIC REACTION) The administration of oral contraceptive combinations of estrogenic and progestational steroids leads to intrahepatic cholestasis with pruritus and jaundice in a small number of patients weeks to months after taking these agents. Especially susceptible seem to be patients with recurrent idiopathic jaundice of pregnancy, severe pruritus of pregnancy, or a family history of these disorders. With the exception of liver biochemical tests, laboratory studies are normal, and extrahepatic manifestations of hypersensitivity are absent. Liver biopsy reveals cholestasis with bile plugs in dilated canaliculi and striking bilirubin staining of liver cells. In contrast to chlorpromazine-induced cholestasis, portal inflammation is absent. The lesion is reversible on withdrawal of the agent. The two steroid components appear to act synergistically on hepatic function, although the estrogen may be primarily responsible. Oral contraceptives are contraindicated in patients with a history of recurrent jaundice of pregnancy. Primarily benign, but rarely malignant, neoplasms of the liver, hepatic vein occlusion, and peripheral sinusoidal dilatation have also been associated with oral contraceptive therapy. Focal nodular hyperplasia of the liver is not more frequent among users of oral contraceptives.

17,α-ALKYL-SUBSTITUTED ANABOLIC STEROIDS (CHOLESTATIC REACTION) In the majority of patients receiving these agents, used therapeutically mainly in the treatment of bone marrow failure but used surreptitiously and without medical indication by athletes to improve their performance, mild hepatic dysfunction develops. Impaired excretory function is the predominant defect, but the precise mechanism is uncertain. Jaundice, which appears to be dose-related, develops in only a minority of patients and may be the sole clinical manifestation of hepatotoxicity, although anorexia, nausea, and malaise may occur. Pruritus is not a prominent feature. Serum aminotransferase levels are usually <100 units, and serum alkaline phosphatase levels are normal, mildly elevated, or, in $<5\%$ of patients, three or more times the upper limit of normal. Examination of liver tissue reveals cholestasis without inflammation or necrosis. Hepatic sinusoidal dilatation and peliosis hepatis have been found in a few patients. The cholestatic disorder is usually reversible on cessation of treatment, although fatalities have been linked to peliosis. An association with hepatic adenoma and hepatocellular carcinoma has been reported.

TRIMETHOPRIM-SULFAMETHOXAZOLE HEPATOTOXICITY (IDIOSYNCRATIC REACTION) This antibiotic combination is used routinely for urinary tract infections in immunocompetent persons and for prophylaxis against and therapy of *Pneumocystis carinii* pneumonia in immunosuppressed persons (transplant recipients, patients with AIDS). With its increasing use, its occasional hepatotoxicity is being recognized with growing frequency. Its likelihood is unpredictable, but when it occurs, trimethoprim-sulfamethoxazole hepatotoxicity follows a relatively uniform latency period of several weeks and is often accompanied by eosinophilia, rash, and other features of a hypersensitivity reaction. Biochemically and histologically, acute hepatocellular necrosis predominates, but cholestatic features are quite frequent. Occasionally, cholestasis without necrosis occurs, and very rarely, a severe cholangiolytic pattern of liver injury is observed. In most cases, liver injury is self-limited, but rare fatalities have been recorded. The hepatotoxicity is attributable to the sulfamethoxazole component of the drug and is similar in features to that seen with other sulfonamides; tissue eosinophilia and granulomas may be seen. The risk of trimethoprim-sulfamethoxazole hepatotoxicity is increased in persons with HIV infection.

HMG-COA REDUCTASE INHIBITORS (STATINS) (IDIOSYNCRATIC MIXED HEPATOCELLULAR AND CHOLESTATIC REACTION) Between 1 and 2% of patients taking lovastatin, simvastatin, pravastatin, fluvastatin, or one of the newer statin drugs for the treatment of hypercholesterolemia experience asymptomatic, reversible elevations ($>$ threefold) of aminotransferase activity. Acute hepatitis-like histologic changes, centrilobular necrosis, and centrilobular cholestasis have been described in several cases. In a larger proportion, minor aminotransferase elevations appear during the first several weeks of therapy. Careful laboratory monitoring can distinguish between patients with minor, transitory changes, who may continue therapy, and those with more profound and sustained abnormalities, who should discontinue therapy.

TOTAL PARENTERAL NUTRITION (STEATOSIS, CHOLESTASIS) Total parenteral nutrition (TPN) is often complicated by cholestatic hepatitis attributable to either steatosis, cholestasis, or gallstones (or gallbladder sludge). Steatosis or steatohepatitis may result from the excess carbohydrate calories in these nutritional supplements and is the predominant form of TPN-associated liver disorder in adults. The frequency of this complication has been reduced substantially by the introduction of balanced TPN formulas that rely on lipid as an alternative caloric source. Cholestasis and cholelithiasis, caused by the absence of stimulation of bile flow and secretion resulting from the lack of oral intake, is the predominant form of TPN-associated liver disease in infants, especially in premature neonates. Often, cholestasis in such neonates is multifactorial, contributed to by other factors such as sepsis, hypoxemia, and hypotension; occasionally, TPN-induced cholestasis in neonates culminates in chronic liver disease and liver failure. When TPN-associated liver test abnormalities occur in adults, balancing the TPN formula with more lipid is the intervention of first recourse. In infants with TPN-associated cholestasis, the addition of oral feeding may ameliorate the problem. Therapeutic interventions suggested, but not yet shown to be of proven benefit, include cholecystokinin, ursodeoxycholic acid, *S*-adenosyl methionine, and taurine.

"ALTERNATIVE MEDICINES" (IDIOSYNCRATIC HEPATITIS, STEATOSIS) The misguided popularity of herbal medications that are of scientifically unproven efficacy and that lack prospective safety oversight by regulatory agencies has resulted in occasional instances of hepatotoxicity. Included among the herbal remedies associated with toxic hepatitis are Jin Bu Huan (Chap. 10), xiao-chai-hu-tang, germander, chaparral, senna, mistletoe, skullcap, gentian, comfrey (containing pyrrolizidine alkaloids), Ma huang, bee pollen, valerian root, pennyroyal oil, kava, celandine, Impila (*Callilepsis laureaola*), LipoKinetix, and herbal teas. Recently well characterized are the acute hepatitis-like histologic lesions following Jin Bu Huan use: focal hepatocellular necrosis, mixed mononuclear portal tract infiltration, coagulative necrosis, apoptotic hepatocyte degeneration, tissue eosinophilia, and microvesicular steatosis. Megadoses of vitamin A can injure the liver, as can pyrrolizidine alkaloids, which often contaminate Chinese herbal preparations and can cause a venoocclusive injury leading to sinusoidal hepatic vein obstruction. Because some alternative medicines induce toxicity via active metabolites, alcohol and drugs that stimulate cytochrome P450 enzymes may enhance the toxicity of some of these products. Conversely, some alternative medicines also stimulate cytochrome P450 and may result in or amplify the toxicity of recognized drug hepatotoxins. Given the widespread use of such poorly defined herbal preparations, hepatotoxicity is likely to be encountered with increasing frequency; therefore, a drug history in patients with acute and chronic liver disease should include use of "alternative medicines" and other nonprescription preparations sold in so-called health food stores.

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY (HAART) FOR HIV INFECTION (MITOCHONDRIAL TOXIC, IDIOSYNCRATIC, STEATOSIS; HEPATOCELLULAR, CHOLESTATIC, AND MIXED) The recognition of drug hepatotoxicity in persons with HIV infection is complicated in this population by the many alternative causes of liver injury (chronic viral hepatitis, fatty infiltration, infiltrative disorders, mycobacterial infection, etc.), but drug hepatotoxicity associated with HAART is an emerging and common type of liver injury in HIV-infected persons (Chap. 173). Although no one antiviral

agent is recognized as a potent hepatotoxin, combination regimens including reverse transcriptase and protease inhibitors cause hepatotoxicity in ~10% of treated patients. Implicated most frequently are combinations including nucleoside analogue reverse transcriptase inhibitors zidovudine, didanosine, and, to a lesser extent, stavudine; protease inhibitors ritonavir and indinavir; and nonnucleoside reverse transcriptase inhibitors nevirapine and, to a lesser extent, efavirenz. These drugs cause predominantly hepatocellular injury but cholestatic injury as well, and prolonged (>6 months) use of reverse transcriptase inhibitors has been associated with mitochondrial injury, steatosis, and lactic acidosis. Distinguishing the impact of HAART hepatotoxicity in patients with HIV and hepatitis virus co-infection is made challenging by the following: (1) both chronic hepatitis B and hepatitis C can affect the natural history of HIV infection and the response to HAART, and (2) HAART can have an impact on chronic viral hepatitis. For example, immunologic reconstitution with HAART can result in immunologically mediated liver-cell injury in patients with chronic hepatitis B co-infection if lamivudine is withdrawn or if lamivudine resistance emerges. Infection with HIV, especially with low CD4+ T cell counts, has been reported to increase the rate of hepatic fibrosis associated with chronic hepatitis C, and HAART therapy can increase levels of serum aminotransferases and hepatitis C virus RNA in patients with hepatitis C co-infection.

287 CHRONIC HEPATITIS

Jules L. Dienstag, Kurt J. Isselbacher

Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months. Milder forms are nonprogressive or only slowly progressive, while more severe forms may be associated with scarring and architectural reorganization, which, when advanced, lead ultimately to cirrhosis. Several categories of chronic hepatitis have been recognized. These include chronic viral hepatitis (Chap. 285), drug-induced chronic hepatitis (Chap. 286), and autoimmune chronic hepatitis. In many cases, clinical and laboratory features are insufficient to allow assignment into one of these three categories; these "idiopathic" cases are also believed to represent autoimmune chronic hepatitis. Finally, clinical and laboratory features of chronic hepatitis are observed occasionally in patients with such hereditary/metabolic disorders as Wilson's disease (copper overload) and even occasionally in patients with alcoholic liver injury (Chap. 288). Although all types of chronic hepatitis share certain clinical, laboratory, and histopathologic features, chronic viral and chronic autoimmune hepatitis are sufficiently distinct to merit separate discussions.

CLASSIFICATION OF CHRONIC HEPATITIS Common to all forms of chronic hepatitis are histopathologic distinctions based on localization and extent of liver injury. These vary from the milder forms, previously labeled chronic persistent hepatitis and chronic lobular hepatitis, to the more severe form, formerly called chronic active hepatitis. When first defined, these designations were felt to have prognostic implications, which have been challenged by more recent observations. Compared to the time three decades ago when the histologic designations chronic persistent, chronic lobular, and chronic active hepatitis were adopted, much more information is currently available about the causes, natural history, pathogenesis, serologic features, and therapy of chronic hepatitis. Therefore, categorization of chronic hepatitis based primarily upon histopathologic features has been replaced by a more informative classification based upon a combination of clinical, serologic, and histologic variables. Classification of chronic hepatitis is based upon (1) its *cause*, (2) its histologic activity, or *grade*, and (3) its degree of progression, or *stage*. Thus, neither clinical features alone nor histologic features—requiring liver biopsy—alone are sufficient to characterize and distinguish among the several categories of chronic hepatitis.

Classification by Cause Clinical and serologic features allow the establishment of a diagnosis of *chronic viral hepatitis*, caused by hepatitis B, hepatitis B plus D, hepatitis C, or potentially other unknown viruses; *autoimmune hepatitis*, including several subcategories, types 1, 2, and 3, based on serologic distinctions; *drug-associated chronic hepatitis*; and a category of unknown cause, or *cryptogenic chronic hepatitis* (Table 287-1). These are addressed in more detail below.

TABLE 287-1 *Clinical and Laboratory Features of Chronic Hepatitis*

Type of Hepatitis	Diagnostic Test(s)	Autoantibodies	Therapy
Chronic hepatitis B	HBsAg, IgG anti-HBc, HBeAg, HBV DNA	Uncommon	IFN-α, lamivudine
Chronic hepatitis C	Anti-HCV, HCV RNA	Anti-LKM1[a]	PEG-IFN-α plus ribavirin
Chronic hepatitis D	Anti-HDV, HDV RNA, HBsAg, IgG anti-HBc	Anti-LKM3	IFN-α (?)
Autoimmune hepatitis	ANA[b] (homogeneous), anti-LKM1(±), hyperglobulinemia	ANA, anti-LKM1, anti-SLA[c]	Prednisone, azathioprine
Drug-associated	—	Uncommon	Withdraw drug
Cryptogenic	All negative	None	Prednisone (?), azathioprine (?)

[a] Antibodies to liver-kidney microsomes type 1 (autoimmune hepatitis type II and some cases of hepatitis C).
[b] Antinuclear antibody (autoimmune hepatitis type I).
[c] Antibodies to soluble liver antigen (autoimmune hepatitis type III).
Note: HBsAg, hepatitis B surface antigen; IFN-α, interferon α; PEG-IFN-α, pegylated interferon α.

Classification by Grade Grade, a histologic assessment of necroinflammatory activity, is based upon examination of the liver biopsy. An assessment of important histologic features includes the degree of *periportal necrosis* and the disruption of the limiting plate of periportal hepatocytes by inflammatory cells (so-called *piecemeal necrosis* or *interface hepatitis*); the degree of confluent necrosis that links or forms bridges between vascular structures—between portal tract and portal tract or even more important bridges between portal tract and central vein—referred to as *bridging necrosis*; the degree of

hepatocyte degeneration and focal necrosis within the lobule; and the degree of *portal inflammation*. Several scoring systems that take these histologic features into account have been devised, and the most popular is the numerical histologic activity index (HAI), based on the work of Knodell and Ishak (Table 287-2). Technically, the HAI, which is primarily a measure of *grade*, also includes an assessment of fibrosis, which is currently used to categorize *stage* of the disease, as described below. Based on the presence and degree of these features of histologic activity, chronic hepatitis can be graded as mild, moderate, or severe.

TABLE 287-2 *Histologic Activity Index (HAI) (Knodell-Ishak Score) in Chronic Hepatitis*

	HAI[a]		Modified HAI[b]		
Histologic Feature	*Severity*	*Score*	*Severity*		*Score*
1. Periportal necrosis, including piecemeal necrosis (PN) and/or bridging necrosis (BN)	None	0	None		0
	Mild PN	1	Mild		1
	Moderate PN	3	Mild/moderate		2
	Marked PN	4	Moderate		3
	Moderate PN + BN	5	Severe		4
	Marked PN + BN	6			
	Multilobular necrosis	10			
2. Intralobular necrosis	None	0	Confluent	None	0
	Mild	1		Focal	1
	Moderate	3		Zone 3 some	2
	Marked	4		Zone 3 most	3
				Zone 3 + BN few	4
				Zone 3 + BN multiple	5
				Panacinar/multiacinar	6
			Focal	None	0
				≤ 1 focus/10× field	1
				2–4 foci/10× field	2
				5–10 foci/10× field	3
				>10 foci/10× field	4
3. Portal inflammation	None	0			0
	Mild	1			1
	Moderate	3			2
	Moderate/marked	3			3
	Marked	4			4
4. Fibrosis	None	0			0
	Portal fibrosis—some	1			1
	Portal fibrosis—most	1			2
	Bridging fibrosis—few	3			3
	Bridging fibrosis—many	3			4
	Incomplete cirrhosis	3			5
	Cirrhosis	4			6
Maximum score		22			Grade 18/Stage 6

[a] "Knodell Score," Hepatology 1:431, 1981 [b] "Ishak Score," Hepatology 24:289, 1996

Classification by Stage The stage of chronic hepatitis, which reflects the level of progression of the disease, is based on the degree of fibrosis. When fibrosis is so extensive that fibrous septa surround parenchymal nodules and alter the normal architecture of the liver lobule, the histologic lesion is defined as cirrhosis. Staging is based on the degree of fibrosis as categorized by one of several numerical scales (Table 287-2).

Reconciliation between Histologic Classification and New Classification For historic purposes, and to provide the basis for navigating several decades worth of literature on chronic hepatitis, the histologic categories of chronic persistent hepatitis, chronic lobular hepatitis, and chronic active hepatitis are correlated with their contemporary counterparts in Table 287-3. When the early classification was devised, chronic persistent and lobular hepatitis were felt to have a good prognosis, while chronic active hepatitis was considered a progressive disorder with a poor prognosis. The prognostic value of these histologic distinctions, however, was found to be limited, and this classification scheme has been supplanted by distinctions in grade and stage.

CHRONIC VIRAL HEPATITIS

Both the enterically transmitted forms of viral hepatitis, hepatitis A and E, are self-limited and do not cause chronic hepatitis (rare reports notwithstanding in which acute hepatitis A serves as a trigger for the onset of autoimmune hepatitis in genetically susceptible patients). In contrast, the entire clinicopathologic spectrum of chronic hepatitis occurs in patients with chronic viral hepatitis B and C as well as in patients with chronic hepatitis D superimposed on chronic hepatitis B.

Chronic Hepatitis B The likelihood of chronicity after acute hepatitis B varies as a function of age. Infection at birth is associated with a clinically silent acute infection but a 90% chance of chronic infection, while infection in young adulthood in immunocompetent persons is typically associated with clinically apparent acute hepatitis but a risk of chronicity of only approximately 1%. Most cases of chronic hepatitis B among adults, however, occur in patients who never had a recognized episode of clinically apparent acute viral hepatitis. The degree of liver injury (grade) in patients with chronic hepatitis B is variable, ranging from none in inactive carriers, to mild, to severe. Among adults with chronic hepatitis B, histologic features are of prognostic importance. In one long-term study of patients with chronic hepatitis B, investigators found a 5-year survival of 97% for patients with mild chronic hepatitis, of 86% for patients with moderate to severe chronic hepatitis, and of only 55% for patients with chronic hepatitis and postnecrotic cirrhosis. The 15-year survival in these cohorts were 77, 66, and 40%, respectively. On the other hand, more recent observations do not allow us to be so sanguine about the prognosis in patients with mild chronic hepatitis; among such patients followed for 1 to 13 years, progression to more severe chronic hepatitis and cirrhosis has been observed in more than a quarter of cases.

Probably more important to consider than histology alone in patients with chronic hepatitis B is the degree of hepatitis B virus (HBV) replication. As reviewed in Chap. 285, chronic hepatitis B can be divided into two phases based on the relative level of HBV replication. The relatively *replicative phase* is characterized by the presence in the serum of markers of HBV replication [hepatitis B e antigen (HBeAg) HBV DNA], by the presence in the liver of detectable intrahepatocyte nucleocapsid antigens [primarily hepatitis B core antigen (HBcAg)], by high infectivity, and by accompanying liver injury; HBV DNA can

TABLE 287-3 *Correlation Between Earlier and Contemporary Nomenclature of Chronic Hepatitis*

	Contemporary Classification	
Old Classification	*Grade (Activity)*	*Stage (Fibrosis)*
Chronic persistent hepatitis[a]	Minimal or mild	None or mild
Chronic lobular hepatitis[b]	Mild or moderate	Mild
Chronic active hepatitis[c]	Mild, moderate, or severe	Mild, moderate, or severe

[a] Inflammatory infiltrate localized to, and confined within, portal tracts.
[b] Portal inflammation confined within portal tracts plus foci of necrosis and inflammation in the liver lobule, resembling slowly resolving acute hepatitis.
[c] Erosion of the limiting plate of periportal hepatocytes by inflammatory cells ("piecemeal necrosis" or "interface hepatitis"), usually with periportal connective tissue septa extending into the liver lobule. More severe instances involve hepatocellular dropout and collapse spanning liver lobules ("bridging necrosis"), and, in the most severe form, multilobular collapse, bridging necrosis, and collapse of lobules are extensive and associated with rapid clinical deterioration.

be detected in the liver but is extrachromosomal. In contrast, the relatively *nonreplicative phase* is characterized by the absence of conventional markers of HBV replication (HBeAg and HBV DNA detectable by hybridization) but an association with anti-HBe, the absence of intrahepatocytic HBcAg, limited infectivity, and minimal liver injury; HBV DNA can be detected in the liver but is integrated into the host genome. Those in the replicative phase tend to have more severe chronic hepatitis, while those in the nonreplicative phase tend to have minimal or mild chronic hepatitis or to be inactive hepatitis B carriers; however, distinctions in HBV replication and in histologic category do not always coincide. The likelihood of converting spontaneously from relatively replicative to nonreplicative chronic HBV infection is approximately 10 to 15% per year. As noted in Chap. 285, the conversion from replicative to nonreplicative chronic hepatitis B is associated with a transient elevation in aminotransferase activity resembling acute hepatitis; occasionally, spontaneous resumptions of replicative activity occur in nonreplicative infection; and occasionally, HBV variants occur in which serologic markers of replication (HBeAg) are absent, despite the presence of replicative infection (see below). Chronic HBV infection, especially when acquired at birth or in early childhood, is associated with an increased risk of hepatocellular carcinoma (Chap. 78). →***A discussion of the pathogenesis of liver injury in patients with chronic hepatitis B appears in Chap. 285.***

As noted in Chap. 285, *HBeAg-negative chronic hepatitis B*, i.e., chronic HBV infection with active virus replication, readily detectable HBV DNA (by insensitive hybridization assays with sensitivity thresholds of 10^5 to 10^6 virions/mL) but without HBeAg (anti-HBe-reactive), is more common than HBeAg-reactive chronic hepatitis B in Mediterranean and European countries and in Asia (and, correspondingly, in HBV genotypes other than A). Most such cases represent precore or core-promoter mutations acquired late in the natural history of the disease (mostly early-life onset; age range 40 to 55 years, older than that for HBeAg-reactive chronic hepatitis B); these mutations prevent translation of HBeAg from the precore component of the HBV genome (precore mutants) or are characterized by down-regulated transcription of precore mRNA (core-promoter mutants; Chap. 285). Although their levels of HBV DNA tend to be lower than among patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B tend to have progressive liver injury (complicated more frequently by cirrhosis and hepatocellular carcinoma), to experience episodic reactivation of liver disease reflected in fluctuating levels of aminotransferase activity ("flares"), and, generally, to be more refractory to antiviral therapy (see below).

The spectrum of *clinical features* of chronic hepatitis B is broad, ranging from asymptomatic infection to debilitating disease or even end-stage, fatal hepatic failure. As noted above, the onset of the disease tends to be insidious in most patients, with the exception of the very few in whom chronic disease follows failure of resolution of clinically apparent acute hepatitis B. The clinical and laboratory features associated with progression from acute to chronic hepatitis B are discussed in Chap. 285. *Fatigue* is a common symptom, and persistent or intermittent *jaundice* is a common feature in severe or advanced cases. Intermittent deepening of jaundice and recurrence of malaise and anorexia, as well as worsening fatigue, are reminiscent of acute hepatitis; such exacerbations may occur spontaneously, often coinciding with evidence of virologic reactivation, may lead to progressive liver injury, and, when superimposed on well-established cirrhosis, may cause hepatic decompensation. Complications of cirrhosis occur in end-stage chronic hepatitis and include ascites, edema, bleeding gastroesophageal varices, hepatic encephalopathy, coagulopathy, or hypersplenism. Occasionally, these complications bring the patient to initial clinical attention. Extrahepatic complications of chronic hepatitis B, similar to those seen during the prodromal phase of acute hepatitis B, are associated with deposition of circulating hepatitis B antigen–antibody immune complexes. These include arthralgias and arthritis, which are common, and the more rare purpuric cutaneous lesions (leukocytoclastic vasculitis), immune-complex glomerulonephritis, and generalized vasculitis (polyarteritis nodosa) (Chaps. 285 and 306).

Laboratory features of chronic hepatitis B do not distinguish adequately between histologically mild and severe hepatitis. Aminotransferase elevations tend to be modest for chronic hepatitis B but may fluctuate in the range of 100 to 1000 units. As is true for acute viral hepatitis B, alanine aminotransferase (ALT) tends to be more elevated than aspartate aminotransferase (AST); however, once cirrhosis is established, AST tends to exceed ALT. Levels of alkaline phosphatase activity tend to be normal or only marginally elevated. In severe cases, moderate elevations in serum bilirubin [51.3 to 171 μmol/L (3 to 10 mg/dL)] occur. Hypoalbuminemia and prolongation of the prothrombin time occur in severe or end-stage cases. Hyperglobulinemia and detectable circulating autoantibodies are distinctly absent in chronic hepatitis B (in contrast to autoimmune hepatitis). →***Viral markers of chronic HBV infection are discussed in Chap. 285.***

℞ TREATMENT

Although progression to cirrhosis is more likely in severe than in mild or moderate chronic hepatitis B, all forms of chronic hepatitis B can be progressive, and progression occurs primarily in patients with active HBV replication. Moreover, in populations of patients with chronic hepatitis B who are at risk for hepatocellular carcinoma (Chap. 78), the risk is highest for those with continued, high-level HBV replication. Therefore, management of chronic hepatitis B is directed at suppressing the level of virus replication. Early in its development, antiviral therapy for hepatitis B was confined to patients with HBeAg-reactive chronic hepatitis B; however, HBeAg-negative chronic hepatitis B has emerged as an important target for antiviral therapy as well. To date, three drugs have been approved for treatment of chronic hepatitis B: injectable interferon (IFN) α and two oral agents, lamivudine and adefovir dipivoxil; several other drugs are in the process of efficacy testing in clinical trials.

Interferon Interferon-α was the first approved therapy for chronic hepatitis B. For immunocompetent adults with HBeAg-reactive chronic hepatitis B (who tend to have HBV DNA detectable by hybridization assay and histologic evidence of chronic hepatitis on liver biopsy), a 16-week course of IFN given subcutaneously at a daily dose of 5 million units, or three times a week at a dose of 10 million unit, results in a loss of HBeAg and hybridization-detectable HBV DNA (i.e., a reduction to levels below 10^5 to 10^6 virions/mL) in ~30% of patients, with a concomitant improvement in liver histology. Seroconversion from HBeAg to anti-HBe occurs in approximately 20%, and, in early trials, approximately 8% lost hepatitis B surface antigen (HBsAg). Successful interferon therapy and seroconversion are often accompanied by an acute hepatitis-like elevation in aminotransferase activity, which has been postulated to result from enhanced cytolytic T cell clearance of HBV-infected hepatocytes. Relapse after successful therapy is rare (1 or 2%). The likelihood of responding to IFN is higher in patients with lower levels of HBV DNA and substantial elevations of ALT. Although children can respond as well as adults, IFN therapy has not been effective in very young children infected at birth. Similarly, IFN therapy has not been effective in immunosuppressed persons, Asian patients with minimal-to-mild ALT elevations, or in patients with decompensated chronic hepatitis B (in whom such therapy can actually be detrimental, sometimes precipitating decompensation, often associated with severe adverse effects). Among patients with HBeAg loss during therapy, long-term follow-up has demonstrated that 80% experience eventual loss of HBsAg, i.e., all serologic markers of infection, and normalization of ALT over a 9-year posttreatment period. In addition, improved long-term and complication-free survival as well as a reduction in the frequency of hepatocellular carcinoma have been documented among interferon responders, supporting the conclusion that successful interferon therapy improves the natural history of chronic hepatitis B.

Retreatment of IFN nonresponders with another course of IFN may

enhance response rates somewhat; however, currently, most would opt to address IFN nonresponders by offering them one of the newer, oral therapies.

Initial trials of brief-duration IFN therapy in patients with *HBeAg-negative chronic hepatitis B* were disappointing, suppressing HBV replication transiently during therapy but almost never resulting in sustained antiviral responses. In subsequent IFN trials among patients with HBeAg-negative chronic hepatitis B, however, more protracted courses, lasting up to a year and a half, have been reported to result in sustained remissions, with suppressed HBV DNA and aminotransferase activity, in ~20%.

Complications of IFN therapy include systemic "flulike" symptoms, marrow suppression, emotional lability (irritability commonly, depression rarely), autoimmune reactions (especially autoimmune thyroiditis), and miscellaneous side effects such as alopecia, rashes, diarrhea, and numbness and tingling of the extremities. With the possible exception of autoimmune thyroiditis, all these side effects are reversible upon dose lowering or cessation of therapy.

Whether or not IFN remains competitive with the newer generation of antivirals, it did represent the first successful antiviral approach, and it set the standard against which subsequent drugs are measured—the achievement of durable virologic, serologic, biochemical, and histologic responses; consolidation of virologic and biochemical benefit in the ensuing years after therapy; and improvement in the natural history of chronic hepatitis B. Indications for IFN therapy in patients with chronic hepatitis B are summarized in Table 287-4.

In patients with chronic hepatitis B, long-term therapy with glucocorticoids is not only ineffective but also detrimental. Short-term glucocorticoid therapy, however, which increases HBV replication and expression in hepatocytes but depresses cytolytic T cells, has been advocated as a potential antiviral approach. A brief course of glucocorticoids, followed by their abrupt withdrawal, permits steroid therapy–suppressed T cells to resume their function against hepatocytes enriched in HBV expression by the recent burst of steroid exposure. An acute hepatitis-like flare of aminotransferase activity follows and may be accompanied by a dramatic drop, or even loss of, HBV replication. Such glucocorticoid "priming" prior to interferon therapy has not been shown to be more effective than interferon alone and has been abandoned.

Lamivudine Several nucleoside analogues active against HBV are being evaluated and developed. The first of these to be approved, the dideoxynucleoside lamivudine, inhibits reverse transcriptase activity of both HIV and HBV and is a potent and effective agent for patients with chronic hepatitis B. Lamivudine suppresses HBV DNA by a median of four orders of magnitude at oral daily doses of 100 mg. In clinical trials, lamivudine therapy for 12 months was associated with almost universal suppression of HBV DNA detectable by hybridization assays; loss of HBeAg in 32 to 33%; HBeAg seroconversion (i.e., conversion from HBeAg-reactive to anti-HBe-reactive) in 16 to 20%; normalization of ALT in approximately 40%; improvement in histology in over 50%; retardation in fibrosis in 20 to 30%; and prevention of progresstion to cirrhosis. HBeAg responses can occur even in subgroups who are resistant (e.g., those with high-level HBV DNA), or who failed in the past to respond, to IFN. As is true for IFN therapy of chronic hepatitis B, patients with near-normal ALT activity do not experience HBeAg responses (despite suppression of HBV DNA), and those with ALT levels exceeding five times the upper limit of normal can expect 1-year HBeAg seroconversion rates of 50 to 60%. Generally, HBeAg seroconversions are confined to patients who achieve suppression of HBV DNA to $<10^4$ genomes/mL. Among patients who undergo HBeAg responses during therapy, the response is sustained in the vast majority (~70 to 80%) for 4 to 6 months after cessation of therapy; therefore, the achievement of an HBeAg response represents a viable stopping point in therapy. Moreover, for patients with such several-month-sustained HBeAg responses, the durability of these responses over the next 2 years (the limit of follow-up monitoring in current trials) is ~80%, accompanied, at least in western patients, by a >20% HBsAg seroconversation rate, comparable to that seen at 2 years after IFN-induced HBeAg responses. If HBeAg is unaffected by lamivudine therapy, the current approach is to continue therapy until an HBeAg response occurs, but long-term therapy may be required to suppress HBV replication and, in turn, limit liver injury. Preliminary observations indicate that HBeAg seroconversions can increase to a level of 50% after 5 years of therapy. Histologic improvement continues to accrue with therapy beyond the first year; after a cumulative course of 3 years of lamivudine therapy, necroinflammatory activity is reduced in the majority of patients, and cirrhosis has been shown to regress to precirrhotic stages.

Losses of HBsAg have been few during the first year of lamivudine therapy, and this observation had been cited as an advantage of IFN over lamivudine; however, in head-to-head comparisons between IFN and lamivudine monotherapy, HBsAg losses were rare in both groups. Trials in which lamivudine and interferon were administered in combination failed to show a benefit of combination therapy over lamivudine monotherapy for either treatment-naive patients or prior interferon nonresponders; however, trials are currently underway to assess the potential value of combination lamivudine plus long-active pegylated IFN (developed for treatment of chronic hepatitis C, see below).

In patients with *HBeAg-negative chronic hepatitis B*, i.e., in those with precore and core-promoter HBV mutations, 1 year of lamivudine therapy results in HBV DNA suppression and normalization of ALT in three-quarters of patients and in histologic improvement in approximately two-thirds. Therapy has been shown to suppress HBV DNA to undetectable levels in 39%, as measured by sensitive polymerase chain reaction (PCR) amplification assays. Lacking HBeAg at the outset, patients with HBeAg-negative chronic hepatitis B cannot achieve an HBeAg response—a stopping point in HBeAg-reactive patients; invariably, when therapy is discontinued, reactivation is the rule. Therefore, these patients require long-term therapy; with successive years, the proportion with suppressed HBV DNA and normal ALT increases.

Clinical and laboratory side effects of lamivudine are negligible, indistinguishable from those observed in placebo recipients. During lamivudine therapy, transient ALT elevations, resembling those seen during IFN therapy and during spontaneous HBeAg-to-anti-HBe seroconversions, occur in a quarter of patients. These ALT elevations may result from restored cytolytic T cell activation permitted by suppression of HBV replication. Similar ALT elevations, however, occur at an identical frequency in placebo recipients, but ALT elevations associated with HBeAg seroconversion are confined to lamivudine-treated patients. When therapy is stopped after a year of therapy, two- to threefold ALT elevations occur in 20 to 30% of lamivudine-treated patients, representing renewed liver-cell injury as HBV replication returns. Although these posttreatment flares are almost always transient and mild, rare severe exacerbations, especially in cirrhotic patients,

TABLE 287-4 *Patients with Chronic Hepatitis B Who Are Candidates for Antiviral Therapy*

Clinical Feature	Interferon	Lamivudine	Adefovir
Detectable markers of HBV replication	Yes	Yes	Yes
Normal ALT activity	No	No	No
ALT <2 × upper limit of normal	No	No	No
ALT >2 × upper limit of normal	Yes	Yes	Yes

have been observed, mandating close and careful clinical and virologic monitoring after discontinuation of treatment.

Long-term monotherapy with lamivudine is associated with methionine-to-valine or methionine-to-isoleucine mutations in the YMDD (tyrosine-methionine-aspartate-aspartate) motif of HBV DNA polymerase, analogous to mutations that occur in patients with HIV infection treated with this drug. During a year of therapy, YMDD mutations occur in 15 to 30% of patients; the frequency increases with each year of therapy, reaching 70% at year 5. Although transient elevations in ALT and HBV DNA levels occur when such variants emerge, YMDD-variant HBV appears to be less replicatively competent and a less robust pathogen. Even after YMDD mutations occur, HBV DNA and ALT levels as well as histologic scores tend to remain lower than baseline levels in immunocompetent patients. In immunosuppressed patients, a proportion of patients with YMDD mutations experience hepatic decompensation. Even in immunocompetent persons, ultimately, after 2 to 3 years, YMDD-variant HBV leads to a deterioration in histology. Therefore, if therapy is begun with lamivudine monotherapy, the emergence of a YMDD variant, reflected clinically by a breakthrough from suppressed levels of HBV DNA and ALT, is managed by adding another antiviral to which YMDD variants are sensitive (e.g., adefovir, see below).

Because lamivudine monotherapy can result universally in the rapid emergence of YMDD variants in persons with HIV infection, patients with chronic hepatitis B should be tested for anti-HIV prior to therapy; if HIV infection is identified, lamivudine monotherapy at the HBV daily dose of 100 mg is contraindicated. These patients should be treated with triple-drug antiretroviral therapy, including a lamivudine daily dose of 300 mg (Chap. 173). The safety of lamivudine during pregnancy has not been established.

Adefovir Dipivoxil The acyclic nucleotide analogue adefovir dipivoxil, the prodrug of adevovir, is a potent antiviral that, at an oral daily dose of 10 mg, reduces HBV DNA by approximately 3.5 to 4 logs and is equally effective in treatment-naïve patients and IFN nonresponders. In HBeAg-reactive chronic hepatitis B, a 48-week course of adefovir dipivoxil was shown to achieve histologic improvement (and reduce the progression of fibrosis) and normalization of ALT in half the patients, HBeAg seroconversion in 12%, HBeAg loss in 23%, and suppression to an undetectable level of HBV DNA in 21%, as measured by PCR. Similar to IFN and lamivudine, adefovir dipivoxil is more likely to achieve an HBeAg response in patients with high baseline ALT; for example, among adefovir-treated patients with ALT level >5 times the upper limit of normal, HBeAg seroconversions occurred in 25%. Although the durability of adefovir-induced HBeAg responses remains to be documented, expectations are that they will be as durable as those seen during lamivudine therapy and that HBeAg responses can be relied upon as a stopping point for adefovir therapy.

In patients with *HBeAg-negative chronic hepatitis B*, a 48-week course of 10 mg/d of adefovir dipivoxil resulted in histologic improvement in two-thirds, normalization of ALT in three-quarters, and suppression of HBV DNA to PCR-undetectable levels in half. As was true for lamivudine, because HBeAg responses—a potential stopping point—cannot be achieved in this group, reactivation is the rule when adefovir therapy is discontinued, and indefinite, long-term therapy is anticipated.

Adevofir contains a flexible acyclic linker instead of the L-nucleoside ring of lamivudine, avoiding steric hindrance by mutated amino acids. In addition, the molecular structure of phosphorylated adefovir is very similar to that of its natural substrate; therefore mutations to adefovir would also affect binding of the natural substrate, dATP. Hypothetically, these are among the reasons that resistance to adefovir dipivoxil has not been encountered in 1 year of clinical-trial therapy and in only 2.5% after 2 years of therapy, in both immunocompetent and immunocompromised patients. Among patients co-infected with HBV and HIV and who have normal CD4+ T cell counts, adefovir dipivoxil is effective in suppressing HBV dramatically (in one study, by 5 logs). Moreover, adefovir dipivoxil is effective in lamivudine-associated YMDD-variant HBV and can be used when such lamivudine-induced variants emerge. When, in the past, this drug had been evaluated as therapy for HIV infection, doses of 60 to 120 mg were required to suppress HIV, and at these doses, the drug was nephrotoxic. Even at 30 mg/d, creatinine elevations of 44 μmol/L (0.5 mg/dL) occur in 10% of patients; however, at the HBV-effective dose of 10 mg, such elevations of creatinine are rarely encountered. If any nephrotoxicity does occur, it rarely appears before 6 to 8 months of therapy. Although renal tubular injury is a rare potential side effect, and although creatinine monitoring is recommended during treatment, the therapeutic index of adefovir dipivoxil is high, and the nephrotoxicity observed in clinical trials at higher doses was reversible. For patients with underlying renal disease, adefovir dipivoxil dose reductions are recommended: administration reduced to every 48 h for creatinine clearances of 20 to 49 mL/min, to every 72 h for creatinine clearances of 10 to 19 mL/min, and once a week, following dialysis, for patients undergoing hemodialysis. Adevofir dipivoxil is very well tolerated, and ALT elevations during and after withdrawal of therapy are similar to those observed and described above in clinical trials of lamivudine.

No treatment is recommended or available for inactive "nonreplicative" hepatitis B carriers. For patients with ALT levels less than twice the upper limit of normal, in whom sustained responses are not likely and who would require multiyear therapy, antiviral therapy is not currently recommended. For patients with ALT more than twice the upper limit, any one of the three available drugs is recommended, but in patients with HBeAg-negative chronic hepatitis B, the requirement for indefinite-duration therapy favors a drug such as adefovir dipivoxil, which is complicated only rarely by the emergence of resistance. Either lamivudine or adefovir is recommended for interferon-refractory patients. Whereas patients with decompensated chronic hepatitis B are not candidates for IFN therapy, they may respond to lamivudine or adefovir dipivoxil, with reversal of the signs of decompensation. Table 287-4 summarizes indications for antiviral therapy in patients with chronic hepatitis B. Interferon, lamivudine, and adefovir can each be used as first-line therapy (Table 287-5). Interferon requires only brief-duration therapy, too limited in duration to support viral variants, but requires subcutaneous injections and is associated with a high level of intolerability. Lamivudine requires long-term therapy in most patients and, when used alone, fosters the emergence of viral variants. On the other hand, lamivudine is taken orally, is very well tolerated, leads to improved histology even in the absence of HBeAg responses, and is effective even in patients who fail to respond to interferon. Adefovir, like lamivudine, is taken orally, is well tolerated, and is effective in IFN nonresponders. Its major advantage is the near absence of resistance. Although the drug is safe, creatinine monitoring is recommended. Although some prefer to begin with IFN, most physicians and patients prefer lamivudine or adefovir as first-line therapy.

For patients with end-stage chronic hepatitis B, liver transplantation is the only potential lifesaving intervention. In the absence of antiviral therapy, reinfection of the new liver is almost universal; however, the likelihood of liver injury associated with hepatitis B in the new liver is variable. The majority of patients become high-level viremic carriers with minimal liver injury. Unfortunately, an unpredictable proportion experience severe hepatitis B–related liver injury, sometimes a fulminant-like hepatitis, sometimes a rapid recapitulation of the original severe chronic hepatitis B (Chap. 291). Prevention of recurrent hepatitis B after liver transplantation has been achieved by *prophylaxis* with hepatitis B immune globulin and with the nucleoside analogues lamivudine and adefovir; in addition, nucleoside analogues have been used successfully to *reverse* posttransplantation liver injury associated with recurrent hepatitis B (Chap. 291).

Novel Antivirals and Strategies In addition to the three approved antiviral drugs for hepatitis B, several others are being evaluated in clinical trials, as listed in Table 287-6. Preliminary indications are that entecavir and is telbivudine can reduce HBV DNA levels by five and six

logs, respectively, and that entecavir and is active against lamivudine-associated YMDD variants. Tenofovir, similar to adefovir, was developed for HIV infection but appears to have activity against wild-type and YMDD-variant HBV similar to that of adefovir; however, to date, it has not been studied extensively in patients with HBV infection.

Initial emphasis in the development of antiviral therapy for hepatitis B was placed on monotherapy; however, in the future, combination therapies will be studied. If combination therapies reduce HBV replication more substantially than monotherapies and avoid resistance, combination therapy regimens will become the norm.

Chronic Hepatitis D (Delta Hepatitis) The clinical and laboratory features of chronic hepatitis D virus (HDV) infection are summarized in Chap. 285. Chronic hepatitis D may follow acute co-infection with HBV but at a rate no higher than the rate of chronicity of hepatitis B. That is, although HDV co-infection can increase the severity of acute hepatitis B, HDV does not increase the likelihood of progression to chronic hepatitis B. However, when HDV superinfection occurs in a person who is already chronically infected with HBV, long-term HDV infection is the rule and a worsening of the liver disease the expected consequence. Except for severity, chronic hepatitis B plus D has similar clinical and laboratory features to those seen in chronic hepatitis B alone. Relatively severe chronic hepatitis, with or without cirrhosis, is the rule, and mild chronic hepatitis the exception. Occasionally, mild hepatitis, or even, rarely, inactive carriage, occurs in patients with chronic hepatitis B plus D, and recent observations suggest that the disease may become indolent after several years of infection. A distinguishing serologic feature of chronic hepatitis D is the presence in the circulation of antibodies to liver-kidney microsomes (anti-LKM); however, the anti-LKM seen in hepatitis D are designated anti-LKM3, are directed against uridine diphosphate glucuronosyltransferase, and are distinct from anti-LKM1 seen in patients with autoimmune hepatitis and in a subset of patients with chronic hepatitis C (see below).

TABLE 287-5 *Comparison of Interferon, Lamivudine, and Adefovir Dipivoxil Therapy for Chronic Hepatitis B*[a]

Feature	*Interferon*	*Lamivudine*	*Adefovir*
Route of administration	Injection	Oral	Oral
Duration of therapy[b]	4 months	≥52 weeks	≥48 weeks
Tolerability	Poorly tolerated	Well tolerated	Well tolerated
Nephrotoxicity	None	None	Creatinine monitoring recommended
HBeAg loss	33%	32–33%	23%
HBeAg seroconversion	18–20%	16–20%	12%
HBeAg seroconversion if ALT >5 × normal	Not reported	>50%	21%
Log_{10} HBV DNA reduction	?	4	3.5–4
HBV DNA PCR-negative	Unlikely	~30% HBeAg+ 39% HBeAg−	21% HBeAg+ 51% HBeAg−
ALT normalization	Confined to HBeAg responders	>40% HBeAg+ >70% HBeAg−	50% HBeAg+ 72% HBeAg−
HBsAg loss during Rx	3–8%	2–4%	Unlikely
HBsAg loss after Rx	80% over 9 years	23% over 2 years	To be determined
Histologic improvement	Confined to HBeAg responders	>50% HBeAg+ >66% HBeAg−	>50% HBeAg+ >66% HBeAg−
Retardation of fibrosis	Not demonstrated	20–30%	20–30%
Viral resistance	None	15–30% @ 1 year 70% @ 5 years	None @ 1 year 2.5% @ 2 years
Natural history	Reduced mortality, decompensation, HCC	To be determined	To be determined
HBeAg-negative chronic hepatitis B	~20% sustained response after ≥1 year of Rx	>60–70% virologic and histologic response; relapse likely after Rx	Same as lamivudine
Candidate range[c]	Narrow	Broad	Broad
Cost (U.S. $)	~$5000/4 months	~$1700/year	~$5600/year

[a] Generally, these comparisons are based upon data on each drug tested individually versus placebo in registration clinical trials; because, with rare exception, these comparisons are not based on head-to-head testing of these drugs, relative advantages and disadvantages should be interpreted cautiously.
[b] Duration of therapy in clinical efficacy trials; use in clinical practice may vary.
[c] See Table 287-4.
Note: HBeAg, hepatitis B e antigen; ALT, alanine aminotranferase; HBV, hepatitis B virus; PCR, polymerase chain reaction; HBsAg, hepatitis B surface antigen; HCC, hepatocellular carcinoma.

TREATMENT

Management is not well defined. Glucocorticoids are ineffective and are not used. Preliminary experimental trials of IFN-α suggested that conventional doses and durations of therapy lower levels of HDV RNA and aminotransferase activity only transiently during treatment but have no impact on the natural history of the disease. Although high-dose IFN-α (9 million units) three times a week for 12 months may be associated with a sustained loss of HDV replication and clinical improvement in up to 50% of patients, ultimately recurrent HDV replication becomes universal after cessation of therapy. Antiviral therapy for chronic hepatitis D remains the subject of experimental trials; lamivudine is not effective, but preliminary indications are that clevudine (L-FMAU) may be. In patients with end-stage liver disease secondary to chronic hepatitis D, liver transplantation has been effective. If hepatitis D recurs in the new liver without the expression of hepatitis B (an unusual serologic profile in immunocompetent persons, but common in transplant patients), liver injury is limited. In fact, the outcome of transplantation for chronic hepatitis D is superior to that for chronic hepatitis B (Chap. 291).

Chronic Hepatitis C Regardless of the epidemiologic mode of acquisition of hepatitis C virus (HCV) infection, chronic hepatitis follows acute hepatitis C in 50 to 70% of cases; even in those with a return to normal in aminotransferase levels after acute hepatitis C, chronic infection is common, adding up to an 85 to 90% likelihood of chronic HCV infection after acute hepatitis C. Furthermore, in patients with chronic transfusion-associated hepatitis followed for 10 to 20 years, progression to cirrhosis occurs in about 20%. Such is the case even for patients with relatively clinically mild chronic hepatitis, including those without symptoms, with only modest elevations of aminotransferase activity, and with mild chronic hepatitis on liver biopsy. Even in cohorts of well-compensated patients with chronic hepatitis C referred for clinical research trials (no complications of chronic liver

TABLE 287-6 *New Antiviral Drugs Being Developed for the Treatment of Chronic Hepatitis B*

Note: YMDD, tyrosine-methionine-aspartate-aspartate.

disease and with normal hepatic synthetic function), the prevalence of cirrhosis may be as high as 50%. Many cases of hepatitis C are identified in asymptomatic patients who have no history of acute hepatitis C, e.g., those discovered while attempting to donate blood or as a result of routine laboratory screening tests. The source of HCV infection in most of these cases is not defined, although a long-forgotten percutaneous exposure in the remote past can be elicited in a substantial proportion. Approximately a third of patients with chronic hepatitis C have normal or near-normal aminotransferase activity; although a third to a half of these patients have chronic hepatitis on liver biopsy, the grade of liver injury and stage of fibrosis tend to be mild in the vast majority. In some cases, more severe liver injury has been reported, even, rarely, cirrhosis, most likely the result of previous histologic activity. Among patients with persistent normal aminotransferase activity sustained over ≥5 years, histologic progression has been shown not to occur; however, approximately a quarter of patients with normal aminotransferase activity experience subsequent aminotransferase elevations, and histologic injury can be progressive once abnormal biochemical activity resumes. Therefore, continued clinical monitoring is indicated, even for patients with normal aminotransferase activity.

Despite this substantial rate of progression of chronic hepatitis C, and despite the fact that liver failure can result from end-stage chronic hepatitis C, the long-term prognosis for chronic hepatitis C in a majority of patients is relatively benign. Mortality over 10 to 20 years among patients with transfusion-associated chronic hepatitis C has been shown not to differ from mortality in a matched population of transfused patients in whom hepatitis C did not develop. Although death in the hepatitis group is more likely to result from liver failure, and although hepatic decompensation may occur in ~15% of such patients over the course of a decade, the majority (almost 60%) of patients remain asymptomatic and well compensated, with no clinical sequelae of chronic liver disease. Overall, then, chronic hepatitis C tends to be very slowly and insidiously progressive, if at all, in the vast majority of patients, while in approximately a quarter of cases, chronic hepatitis C will progress eventually to end-stage cirrhosis. Referral bias may account for the more severe outcomes described in cohorts of patients reported from tertiary-care centers versus the more benign outcomes in cohorts of patients monitored from initial blood-product-associated acute hepatitis. Still unexplained, however, are the wide ranges in reported progression to cirrhosis, from 2% over 17 years in a population of women with hepatitis C infection acquired from contaminated anti-D immune globulin to 30% over ≤11 years in recipients of contaminated intravenous immune globulin.

Progression of liver disease in patients with chronic hepatitis C has been reported to be more likely in patients with older age, longer duration of infection, advanced histologic stage and grade, genotype 1, more complex quasispecies diversity, and increased hepatic iron. Among these variables, however, duration of infection appears to be the most important, and many of the others probably reflect disease duration to some extent (e.g., quasispecies diversity, hepatic iron accumulation).

Perhaps the best prognostic indicator in chronic hepatitis C is liver histology. Patients with mild necrosis and inflammation as well as those with limited fibrosis have an excellent prognosis and limited progression to cirrhosis. In contrast, among patients with moderate to severe necroinflammatory activity or fibrosis, including septal or bridging fibrosis, progression to cirrhosis is highly likely over the course of 10 to 20 years. Among patients with compensated cirrhosis associated with hepatitis C, the 10-year survival is close to 80%; mortality occurs at a rate of 2 to 6% per year, decompensation at a rate of 4 to 5% per year, and hepatocellular carcinoma at a rate of 1 to 4% per year.

In addition, severity of chronic hepatitis is greater and progression of chronic liver disease is more accelerated in patients who have chronic hepatitis C as well as other liver processes, including alcoholic liver disease, chronic hepatitis B, HIV infection, hemochromatosis, and α_1-antitrypsin deficiency. No other epidemiologic or clinical features of chronic hepatitis C (e.g., severity of acute hepatitis, level of aminotransferase activity, level of HCV RNA, presence or absence of jaundice during acute hepatitis) are predictive of eventual outcome. Despite the relative benignity of chronic hepatitis C over time, cirrhosis following chronic hepatitis C has been associated with the late development, after several decades, of hepatocellular carcinoma (HCC) (Chap. 78). As noted above, the annual rate of HCC in cirrhotic patients with hepatitis C is 1 to 4%.

Clinical features of chronic hepatitis C are similar to those described above for chronic hepatitis B. Generally, *fatigue* is the most common symptom; jaundice is rare. Immune complex–mediated extrahepatic complications of chronic hepatitis C are less common than in chronic hepatitis B, with the exception of essential mixed cryoglobulinemia (Chap. 285). This is the case despite the fact that assays for immune complex–like activity are often positive in patients with chronic hepatitis C. In addition, chronic hepatitis C has been associated with extrahepatic complications unrelated to immune-complex injury. These include Sjögren's syndrome, lichen planus, and porphyria cutanea tarda. *Laboratory features* of chronic hepatitis C are similar to those in patients with chronic hepatitis B, but aminotransferase levels tend to fluctuate more (the characteristic episodic pattern of aminotransferase activity) and to be lower, especially in patients with long-standing disease. An interesting and occasionally confusing finding in patients with chronic hepatitis C is the presence of autoantibodies. Rarely, patients with autoimmune hepatitis (see below) and hyperglobulinemia have false-positive enzyme immunoassays for anti-HCV. On the other hand, some patients with serologically confirmable chronic hepatitis C have circulating anti-LKM. These antibodies are anti-LKM1, as seen in patients with autoimmune hepatitis *type 2* (see below), and are directed against a 33-amino-acid sequence of P450 IID6. The occurrence of anti-LKM1 in some patients with chronic hepatitis C may result from the partial sequence homology between the epitope recognized by anti-LKM1 and two segments of the HCV polyprotein. In addition, the presence of this autoantibody in some patients with chronic hepatitis C suggests that autoimmunity may be playing a role in the pathogenesis of chronic hepatitis C. →***Histopathologic features of chronic hepatitis C, especially those that distinguish hepatitis C from hepatitis B, are described in Chap. 285.***

TREATMENT

Therapy for chronic hepatitis C has evolved substantially in the decade and a half since IFN-α was introduced for this indication. When first approved, IFN-α was administered via subcutaneous injection three times a week for 6 months but achieved a sustained virologic response (a reduction of HCV RNA to undetectable levels by PCR when measured ≥6 months after completion of therapy) below 10%. Doubling the duration of therapy—but not increasing the dose or changing IFN preparations—increased the sustained virologic response rate to ~20%, and addition to the regimen of daily ribavirin, an oral guanosine nucleoside, increased sustained virologic responses to 40%. When used alone, ribavirin is ineffective and does not reduce HCV RNA levels, but ribavirin enhances the efficacy of IFN by reducing the likelihood of virologic relapse after the achievement of an end-treatment response (response measured during, and maintained to the end of, treatment). Proposed mechanisms to explain the role of ribavirin include subtle direct reduction of HCV replication, immune modulation, and induction of virologic mutational catastrophe.

Many important lessons about antiviral therapy for chronic hepatitis C were learned from the experience with IFN monotherapy and combination IFN-ribavirin therapy. Even in the absence of biochemical and virologic responses, histologic improvement occurs in approximately three-quarters of all treated patients. Unlike the case in hepatitis B, in chronic hepatitis C, responses to therapy are not accompanied by transient, acute hepatitis–like aminotransferase elevations; instead, ALT levels fall precipitously during therapy. Up to 90% of

virologic responses are achieved within the first 12 weeks of therapy; responses thereafter are rare. Sustained virologic responses are very durable; normal ALT, improved histology, and absence of HCV RNA in serum and liver have been documented 5 to 6 years after successful therapy, and "relapses" 2 years after sustained responses are almost unheard of. Thus, sustained virologic responses to antiviral therapy of chronic hepatitis C are tantamount to cures.

Patient variables that tend to correlate with sustained virologic responsiveness to IFN include low baseline HCV RNA level (<2 million copies/mL), histologically mild hepatitis and minimal fibrosis, favorable genotype (genotypes 2 and 3 as opposed to genotyptes 1 and 4), age <40, absence of obesity, and female gender. Patients with cirrhosis can respond, but they are less likely to do so. Studies of combination IFN-ribavirin therapy showed conclusively that, in patients with genotype 1, therapy should last a full year, while in those with genotypes 2 and 3, a 6-month course of therapy suffices. The response rate in African Americans is disappointingly low for reasons that remain obscure. Finally, the likelihood of a sustained response is best if adherence to the treatment regimen is high, i.e., if patients receive ≥80% of the IFN and ribavirin doses, and if they continue treatment for ≥80% of the anticipated duration of therapy. Other variables reported to correlate with increased responsiveness include brief duration of infection, low HCV quasispecies diversity, immunocompetence, and low liver iron levels. High levels of HCV RNA, more histologically advanced liver disease, and high quasispecies diversity all go hand in hand with advanced duration of infection, which may be the single most important variable determining IFN responsiveness. The ironic fact, then, is that patients whose disease is *least* likely to progress are the ones *most* likely to respond to interferon and vice versa. Finally, among patients with genotype 1b, responsiveness to IFN is enhanced in those with amino-acid-substitution mutations in the nonstructural protein 5A gene.

Side effects of IFN therapy are described above in the section on treatment of chronic hepatitis B. The most pronounced side effect of ribavirin therapy is hemolysis; a reduction in hemoglobin of up to 2 to 3 g or in hematocrit of 5 to 10% can be anticipated. A small, unpredictable proportion of patients experience profound, brisk hemolysis, resulting in symptomatic anemia; therefore, close monitoring of blood counts is crucial, and ribavirin should be avoided in patients with anemia or hemoglobinopathies and in patients with coronary artery disease or cerebrovascular disease, in whom anemia can precipitate an ischemic event. When symptomatic anemia occurs, ribavirin dose reductions or addition of erythropoietin to boost red blood cell levels may be required. In addition, ribavirin, which is renally excreted, should not be used in patients with renal insufficiency; the drug is teratogenic, precluding its use during pregnancy and mandating the use of efficient contraception during therapy.

Ribavirin can also cause nasal and chest congestion, pruritus, and precipitation of gout. Combination IFN-ribavirin therapy is more difficult to tolerate than IFN monotherapy. In one large clinical trial of combination therapy versus monotherapy, among those in the 1-year treatment group, 21% of the combination group (but only 14% of the monotherapy group) had to discontinue treatment, while 26% of the combination group (but only 9% of the monotherapy group) required dose reductions.

Studies of viral kinetics have shown that despite a virion half-life in serum of only 2 to 3 h, the level of HCV is maintained by a high replication rate of 10^{12} hepatitis C virions per day. IFN-α blocks virion production or release with an efficacy that increases with increasing drug doses; moreover, the calculated death rate for infected cells during IFN therapy is inversely related to viral load; patients with the most rapid death rate of infected hepatocytes are more likely to achieve undetectable HCV RNA at 3 months; achieving this landmark is predictive of a subsequent sustained response. Therefore, to achieve rapid viral clearance from serum and the liver, *high-dose induction therapy* has been advocated. In practice, however, high-dose induction therapy has not yielded higher sustained response rates.

Treatment of Choice For the treatment of chronic hepatitis C, standard IFNs have now been supplanted by "pegylated" IFNs, long-acting IFNs bound to polyethylene glycol (PEG). Such pegylated IFNs have elimination times up to sevenfold longer than standard IFNs, i.e., a substantially longer half-life, and achieve prolonged concentrations, permitting administration once, rather than three times, a week. Instead of the frequent drug peaks (linked to side effects) and troughs (when drug is absent) associated with frequent administration of short-acting IFNs, administration of pegylated IFNs results in drug concentrations that are more stable and sustained over time. Early studies showed that once-a-week pegylated IFN monotherapy is twice as effective as monotherapy with its standard IFN counterpart, approaches the efficacy of combination standard IFN plus ribavirin, and is as well tolerated as standard IFNs, without more difficult-to-manage thrombocytopenia and leukopenia than standard IFNs. The current standard of care, however, is a combination of pegylated IFN plus ribavirin.

Two pegylated IFNs are available, pegylated IFN-α2b and -α2a. In the registration trial for pegylated IFN-α2b plus ribavirin, the best regimen was 48 weeks of 1.5 μg per kilogram of pegylated IFN once a week plus 800 mg of ribavirin daily. A posthoc analysis suggested that weight-based dosing of ribavirin would have been more effective than the fixed 800-mg dose used in the study. In the first registration trial for pegylated IFN-α2a plus ribavirin, the best regimen was 48 weeks of 180 μg of pegylated IFN plus 1000 mg (for patients < 75 kg) to 1200 mg (for patients ≥ 75 kg) of ribavirin. Sustained virologic responses of 54% and 56% were reported in these two studies, respectively. A subsequent study of pegylated IFN-α2a plus ribavirin showed that, for patients with genotypes 2 and 3, a duration of 6 months and a ribavirin dose of 800 mg was sufficient. Among the three studies, for patients in the optimal treatment arm, sustained response rates for patients with genotype 1 were 42 to 51%, and for patients with genotypes 2 and 3 rates were 76 to 82%.

In the initial registration trials for combination pegylated IFN plus ribavirin, both combination pegylated IFN regimens were compared to standard IFN-α2b plus ribavirin. Side effects of the combination pegylated IFN-α2b regimen were comparable to those for the combination standard-IFN regimen; however, when the combination pegylated IFN-α2a regimen was compared to the combination standard IFN-α2b regimen, flulike symptoms and depression were less common in the combination pegylated IFN group. Although the two combination pegylated IFN regimens were not tested head-to-head, when each was tested against standard IFN-α2b plus ribavirin, combination pegylated IFN-α2a plus ribavirin appeared to be better tolerated. Recommended doses for the two pegylated IFNs plus ribavirin and other comparisons between the two therapies are shown in Table 287-7.

Unless ribavirin is contraindicated (see above), combination pegylated IFN plus ribavirin is the recommended course of therapy—24 weeks for genotypes 2 and 3 and 48 weeks for genotype 1. Measurement of quantitative HCV RNA levels at 12 weeks is helpful in guiding therapy; if a 2-log drop in HCV RNA has not been achieved by this time, chances for a sustained virologic response are negligible. If the goal of therapy is sustained virologic response, failure to achieve a 12-week 2-log drop in HCV RNA may be used as a signal to discontinue therapy, especially in those who do not tolerate the drugs well. Still, conceivably, some may achieve histologic benefit in the absence of a virologic response, and some clinicians choose to continue therapy even in the absence of a 2-log HCV RNA reduction at 12 weeks. Studies are underway to determine whether, even in the absence of a virologic response, maintenance therapy with pegylated IFN can slow histologic and clinical progression of hepatitis C.

Indications for Antiviral Therapy Patients with chronic hepatitis C who have elevated ALT levels, detectable HCV RNA, and chronic hepatitis of at least moderate grade and stage (portal or bridging fibrosis) are

TABLE 287-7 *Comparison of Pegylated Interferon α2a and α2b for Chronic Hepatitis C*[a]

	PEG IFN-α2b	PEG IFN-α2a
PEG size	12 kDa linear	40 kDa branched
Mean terminal half-life	40 h	80 h
Mean clearance	94 mL/h per kg	22 mL/h per kg
Best-dose monotherapy	1.0 μg/kg (weight-based)	180 μg
Best-dose combination therapy	1.5 μg/kg (weight-based)	180 μg
Storage	Room temperature	Refrigerated
Ribavirin		
Genotype 1	800 mg[b]	1000–1200 mg[c]
Genotype 2/3	800 mg	800 mg
Duration of therapy		
Genotype 1	48 weeks	48 weeks
Genotype 2/3	48 weeks[d]	24 weeks
Efficacy of combination Rx	54%	56%
Genotype 1	42%	46–51%
Genotype 2/3	82%	76–78%
Side effects of pegylated interferon/ribavirin vs standard interferon/ribavirin[e]

Rigors	48% vs 41%	24% vs 35%
Depression	31% vs 34%	22% vs 30%
Irritability	35% vs 34%	24% vs 28%

[a] These comparisons are based upon data on each drug tested individually versus other regimens in registration trials; because these comparisons are not based on head-to-head comparisons between the two drugs, and because the populations tested are not entirely analogous, relative advantages and disadvantages should be interpreted with caution.
[b] In the registration trial for pegylated IFN-α2b plus ribavirin, the optimal regimen was 1.5 μg of pegylated IFN plus 800 mg of ribavirin; however, a posthoc analysis of this study as well as data from other studies suggest that 1000 (for patients < 75 kg)–1200 (for patients ≥ 75 kg) mg of ribavirin might be better, certainly for genotype 1, and many clinicians prescribe the higher ribavirin doses.
[c] 1000 mg for patients < 75 kg; 1200 mg for patients ≥ 75 kg.
[d] In the registration trial for pegylated IFN-α2b plus ribavirin, all patients were treated for 48 weeks; however, data from other trials of standard IFNs and the other pegylated IFN suggest that 24 weeks should suffice for patients with genotypes 2 and 3.
[e] These comparisons show the frequency in registration trials of the listed side effects for the respective pegylated IFN plus ribavirin as compared to the listed side effects in comparitor groups who received standard IFN-α2b plus ribavirin. As noted above, these comparisons do not represent head-to-head tests of the two pegylated IFNs.

Note: PEG, polyethylene glycol; IFN, interferon.

candidates for antiviral therapy with pegylated IFN plus ribavirin, unless ribavirin is contraindicated (Table 287-8). Therapy with IFN has been shown to improve survival and complication-free survival and to slow progression of fibrosis. Prior to therapy, HCV genotype should be determined, and the genotype dictates the duration of therapy, 1 year (48 weeks) for patients with genotype 1 and 6 months (24 weeks) for those with genotypes 2 and 3. As noted above, the absence of a 2-log drop in HCV RNA at week 12 (an "early virologic response") weighs heavily against the likelihood of a sustained virologic response even if therapy is continued for the remainder of the planned full year; therefore, measuring HCV RNA at baseline and at 12 weeks is recommended routinely, especially for patients with genotype 1. The consensus view is that therapy can be discontinued if an early virologic response is not achieved; however, histologic benefit may occur even in the absence of a virologic response. In addition, if current trials show that maintenance therapy can slow the progression of chronic hepatitis C, early virologic nonresponders may be identified as candidates for maintenance therapy; the results of these trials are awaited. Although response rates are lower in patients with certain pretreatment variables, selection for treatment should not be based on symptoms, genotype, HCV RNA level, mode of acquisition of hepatitis C, or advanced hepatic fibrosis. Patients with cirrhosis can respond and should not be excluded as candidates for therapy.

Patients who have relapsed after a course of IFN monotherapy are candidates for retreatment with pegylated IFN plus ribavirin. For nonresponders to a prior course of IFN monotherapy, retreatment with IFN monotherapy or combination IFN plus ribavirin therapy is unlikely to achieve a sustained virologic response; however, a trial of combination pegylated IFN plus ribavirin may be worthwhile. End-treatment virologic responses as high as 40% can occur in this setting, but a sustained virologic response is the outcome in <20% of patients. Sustained virologic responses to retreatment of nonresponders are

TABLE 287-8 *Indications and Recommendations for Antiviral Therapy of Chronic Hepatitis C*

STANDARD INDICATIONS FOR THERAPY

Elevated ALT activity
Portal/bridging fibrosis or moderate to severe hepatitis on liver biopsy
Detectable HCV RNA

RETREATMENT RECOMMENDED

Relapsers after a previous course of standard IFN monotherapy or combination standard IFN/ribavirin therapy
A course of pegylated IFN plus ribavirin
Nonresponders to a previous course of standard IFN monotherapy or combination standard IFN/ribavirin therapy
A course of pegylated IFN plus ribavirin—more likely to achieve a sustained virologic response in Caucasian patients without previous ribavirin therapy, with low baseline HCV RNA levels, with a substantial reduction in HCV RNA during previous therapy, with genotypes 2 and 3, and without reduction in ribavirin dose.

ANTIVIRAL THERAPY NOT RECOMMENDED ROUTINELY BUT MANAGEMENT DECISIONS MADE ON AN INDIVIDUAL BASIS

Children (age <18 years)
Age >60
Normal ALT
Mild hepatitis on liver biopsy
Compensated cirrhosis
Patients with HIV infection and normal CD4+ counts

LONG-TERM MAINTENANCE THERAPY RECOMMENDED

Cutaneous vasculitis and glomerulonephritis associated with chronic hepatitis C

LONG-TERM MAINTENANCE THERAPY BEING ASSESSED IN CLINICAL TRIALS

Relapsers
Nonresponders

ANTIVIRAL THERAPY NOT RECOMMENDED

Decompensated cirrhosis

THERAPEUTIC REGIMENS

First-line treatment: Pegylated IFN subcutaneously once a week plus daily ribavirin orally
1. HCV genotype 1—48 weeks of therapy
   Pegylated IFN-α2a, 180 μg, plus ribavirin, 1000 mg/d (weight <75 kg) to 1200 mg/d (weight ≥75 kg) *or*
   Pegylated IFN-α2b, 1.5 μg/kg, plus ribavirin, 800 mg/d (although higher, weight-based ribavirin doses above are preferred by many)
2. HCV genotypes 2 and 3—24 weeks of therapy
   Pegylated IFN-α2a, 180 μg, plus ribavirin, 800 mg/d *or*
   Pegylated IFN-α2b, 1.5 μg/kg, plus ribavirin, 800 mg/d

Alternative regimen: Pegylated IFN (α2a, 180 μg, or α2b, 1.0 μg/kg) subcutaneously once a week (primarily for patients in whom ribavirin is contraindicated or not tolerated) for 24 (genotypes 2 and 3) or 48 (genotype 1) weeks

FEATURES ASSOCIATED WITH REDUCED RESPONSIVENESS

Advanced fibrosis (e.g., cirrhosis)
Long-duration disease
Genotype 1
High-level HCV RNA (>2 million copies/mL)
High HCV quasispecies diversity
Immunosuppression
African American
Obesity
Reduced adherence (lower drug doses and reduced duration of therapy)

Note: ALT, alanine aminotransferase; HCV, hepatitis C virus; IFN, interferon.

more frequent in those who had never received ribavirin in the past, in those with genotypes 2 and 3, in those with low pretreatment HCV RNA levels, but less frequent in African Americans, in those who failed to achieve a substantial reduction in HCV RNA during their previous course of therapy, and in those who required ribavirin-dose reductions.

Early treatment is indicated for persons with acute hepatitis C (Chap. 285). In patients with persistently normal or near-normal ALT levels, long-term monitoring studies have shown the absence of histologic progression, and the same applies to patients with histologically mild hepatitis C; however, patients with normal ALT and histologically mild hepatitis C respond just as well as those with elevated ALT and more histologically severe hepatitis to combination IFN plus ribavirin therapy (and, although not reported yet, probably to combination pegylated IFN plus ribavirin). Therefore, therapy for these patients should be considered and the decision made based upon such factors as patient motivation, genotype, stage of fibrosis, age, and comorbid conditions. A pretreatement liver biopsy is recommended in most cases to assess pretreatment histologic grade and stage.

Patients with compensated cirrhosis can respond to therapy, although their likelihood of a sustained response is lower than in noncirrhotics. Whether survival is improved after successful antiviral therapy in cirrhotics is controversial. Similarly, although several retrospective studies have suggested that antiviral therapy in cirrhotics with chronic hepatitis C reduces the frequency of HCC, less advanced disease in the treated cirrhotics, not treatment itself, may have accounted for the reduced frequency of HCC observed in the treated cohort; prospective studies to address this question are in progress. Patients with decompensated cirrhosis are not candidates for IFN-based antiviral therapy but should be referred for liver transplantation. After liver transplantation, recurrent hepatitis C is the rule, and the pace of disease progression is more accelerated than in immunocompetent patients (Chap. 291); current therapy with pegylated IFN and ribavirin is unsatisfactory in most patients, but attempts to minimize immunosuppression are beneficial. The cutaneous and renal vasculitis of HCV-associated essential mixed cryoglobulinemia (Chap. 285) may respond to antiviral therapy, but sustained responses are rare after discontinuation of therapy; therefore, prolonged, perhaps indefinite, therapy is recommended in this group.

Anecdotal reports suggest that antiviral therapy may be effective in porphyria cutanea tarda or lichen planus associated with hepatitis C. In patients with HCV/HIV co-infection, responses similar to those seen in other groups have been reported in patients with normal CD4+ T cell counts; careful monitoring for side effects of IFN/ribavirin and antiretroviral drugs is advisable. Persons with a history of injection-drug use and alcoholism can be treated successfully for chronic hepatitis C, preferably in conjunction with drug and alcohol treatment programs.

AUTOIMMUNE HEPATITIS ■ Definition Autoimmune hepatitis is a chronic disorder characterized by continuing hepatocellular necrosis and inflammation, usually with fibrosis, which tends to progress to cirrhosis and liver failure. When fulfilling criteria of severity, this type of chronic hepatitis may have a 6-month mortality of as high as 40%. The prominence of extrahepatic features of autoimmunity as well as seroimmunologic abnormalities in this disorder supports an autoimmune process in its pathogenesis; this concept is reflected in the labels "lupoid," plasma cell, or autoimmune hepatitis. Because autoantibodies and other typical features of autoimmunity do not occur in all cases, however, a broader, more appropriate designation for this type of chronic hepatitis is "idiopathic" or cryptogenic. Cases in which hepatotropic viruses, metabolic/genetic derangements, and hepatotoxic drugs have been excluded merit this designation and probably include a spectrum of heterogeneous liver disorders of unknown cause, a proportion of which have characteristic autoimmune features.

Immunopathogenesis The weight of evidence suggests that the progressive liver injury in patients with idiopathic/autoimmune hepatitis is the result of a cell-mediated immunologic attack directed against liver cells; in all likelihood, predisposition to autoimmunity is inherited, while the liver specificity of this injury is triggered by environmental (e.g., chemical or viral) factors. For example, patients have been described in whom apparently self-limited cases of acute hepatitis A or B led to autoimmune hepatitis, presumably because of genetic susceptibility or predisposition. Evidence to support an autoimmune pathogenesis in this type of hepatitis includes the following: (1) In the liver, the histopathologic lesions are composed predominantly of cytotoxic T cells and plasma cells; (2) circulating autoantibodies (nuclear, smooth muscle, thyroid, etc.; see below), rheumatoid factor, and hyperglobulinemia are common; (3) other autoimmune disorders—such as thyroiditis, rheumatoid arthritis, autoimmune hemolytic anemia, ulcerative colitis, proliferative glomerulonephritis, juvenile diabetes mellitus, and Sjögren's syndrome—occur with increased frequency in patients who have autoimmune hepatitis and in their relatives; (4) histocompatibility haplotypes associated with autoimmune diseases, such as HLA-B1, -B8, -DR3, and -DR4, are common in patients with autoimmune hepatitis; and (5) this type of chronic hepatitis is responsive to glucocorticoid/immunosuppressive therapy, effective in a variety of autoimmune disorders.

Cellular immune mechanisms appear to be important in the pathogenesis of autoimmune hepatitis. In vitro studies have suggested that in patients with this disorder, lymphocytes are capable of becoming sensitized to hepatocyte membrane proteins and of destroying liver cells. Abnormalities of immunoregulatory control over cytotoxic lymphocytes (impaired suppressor cell influences) may play a role as well. Studies of genetic predisposition to autoimmune hepatitis demonstrate that certain haplotypes are associated with the disorder, as enumerated above. The precise triggering factors, genetic influences, and cytotoxic and immunoregulatory mechanisms involved in this type of liver injury remain poorly defined.

Intriguing clues into the pathogenesis of autoimmune hepatitis come from the observation that circulating autoantibodies are prevalent in patients with this disorder. Among the autoantibodies described in these patients are antibodies to nuclei [so-called antinuclear antibodies (ANA), primarily in a homogeneous pattern] and smooth muscle (so-called anti-smooth-muscle antibodies, directed at actin), anti-LKM (see below), antibodies to "soluble liver antigen" (directed at a member of the glutathione S-transferase gene family), as well as antibodies to the liver-specific asialoglycoprotein receptor (or "hepatic lectin") and other hepatocyte membrane proteins. Although some of these provide helpful diagnostic markers, their involvement in the pathogenesis of autoimmune hepatitis has not been established.

Humoral immune mechanisms have been shown to play a role in the extrahepatic manifestations of autoimmune/idiopathic hepatitis. Arthralgias, arthritis, cutaneous vasculitis, and glomerulonephritis occurring in patients with autoimmune hepatitis appear to be mediated by the deposition in affected tissue vessels of circulating immune complexes, followed by complement activation, inflammation, and tissue injury. While specific viral antigen-antibody complexes can be identified in acute and chronic viral hepatitis, the nature of the immune complexes in autoimmune hepatitis has not been defined.

Many of the *clinical features* of autoimmune hepatitis are similar to those described for chronic viral hepatitis. The onset of disease may be insidious or abrupt; the disease may present initially like, and be confused with, acute viral hepatitis; a history of recurrent bouts of what had been labeled acute hepatitis is not uncommon. A subset of patients with autoimmune hepatitis has distinct features. Such patients are predominantly young to middle-aged women with marked hyperglobulinemia and high-titer circulating ANA. This is the group with positive LE preparations (initially labeled "lupoid" hepatitis) in whom other autoimmune features are common. Fatigue, malaise, anorexia, amenorrhea, acne, arthralgias, and jaundice are common. Occasionally, arthritis, maculopapular eruptions (including cutaneous vasculitis), erythema nodosum, colitis, pleurisy, pericarditis, anemia, azotemia, and sicca syndrome (keratoconjunctivitis, xerostomia) occur. In

some patients, complications of cirrhosis, such as ascites and edema (associated with hypoalbuminemia), encephalopathy, hypersplenism, coagulopathy, or variceal bleeding may bring the patient to initial medical attention.

The course of autoimmune hepatitis may be variable. In those with mild disease or limited histologic lesions (e.g., piecemeal necrosis without bridging), progression to cirrhosis is limited. In those with severe symptomatic autoimmune hepatitis (aminotransferase levels >10 times normal, marked hyperglobulinemia, "aggressive" histologic lesions—bridging necrosis or multilobular collapse, cirrhosis), the 6-month mortality without therapy may be as high as 40%. Such severe disease accounts for only 20% of cases; the natural history of milder disease is variable, often accentuated by spontaneous remissions and exacerbations. Especially poor prognostic signs include multilobular collapse at the time of initial presentation and failure of the bilirubin to improve after 2 weeks of therapy. Death may result from hepatic failure, hepatic coma, other complications of cirrhosis (e.g., variceal hemorrhage), and intercurrent infection. In patients with established cirrhosis, hepatocellular carcinoma may be a late complication (Chap. 78).

Laboratory features of autoimmune hepatitis are similar to those seen in chronic viral hepatitis. Liver biochemical tests are invariably abnormal but may not correlate with the clinical severity or histopathologic features in individual cases. Many patients with autoimmune hepatitis have normal serum bilirubin, alkaline phosphatase, and globulin levels with only minimal aminotransferase elevations. Serum AST and ALT levels are increased and fluctuate in the range of 100 to 1000 units. In severe cases, the serum bilirubin level is moderately elevated [51 to 171 μmol/L (3 to 10 mg/dL)]. Hypoalbuminemia occurs in patients with very active or advanced disease. Serum alkaline phosphatase levels may be moderately elevated or near normal. In a small proportion of patients, marked elevations of alkaline phosphatase activity occur; in such patients, clinical and laboratory features overlap with those of primary biliary cirrhosis (Chap. 289). The prothrombin time is often prolonged, particularly late in the disease or during active phases.

Hypergammaglobulinemia (>2.5 g/dL) is common in autoimmune hepatitis. Rheumatoid factor is common as well. As noted above, circulating autoantibodies are also common. The most characteristic are ANA in a homogeneous staining pattern. Smooth-muscle antibodies are less specific, seen just as frequently in chronic viral hepatitis. Because of the high levels of globulins achieved in the circulation of some patients with autoimmune hepatitis, occasionally the globulins may bind nonspecifically in solid-phase binding immunoassays for viral antibodies. This has been recognized most commonly in tests for antibodies to hepatitis C virus, as noted above. In fact, studies of autoantibodies in autoimmune hepatitis have led to the recognition of new categories of autoimmune hepatitis. *Type I autoimmune hepatitis* is the classic syndrome occurring in young women, associated with marked hyperglobulinemia, lupoid features, and circulating ANA. *Type II autoimmune hepatitis*, often seen in children and more common in Mediterranean populations, is associated not with ANA but with anti-LKM. Actually, anti-LKM represent a heterogeneous group of antibodies. In type II autoimmune hepatitis, the antibody is anti-LKM1, directed against P450 IID6. This is the same anti-LKM seen in some patients with chronic hepatitis C. Anti-LKM2 is seen in drug-induced hepatitis, and anti-LKM3 is seen in patients with chronic hepatitis D. Type II autoimmune hepatitis has been subdivided by some authorities into two categories, one more typically autoimmune and the other associated with viral hepatitis type C. Autoimmune hepatitis type IIa is felt to be autoimmune, is more likely to occur in young women, is associated with hyperglobulinemia, is associated with high-titer anti-LKM1, responds to glucocorticoid therapy, and is seen commonly in western Europe and the United Kingdom. Type IIb autoimmune hepatitis is associated with HCV infection, tends to occur in older men, is associated with normal globulin levels and low-titer anti-LKM1, responds to IFN, and occurs most commonly in Mediterranean countries. In addition, another type of autoimmune hepatitis has been recognized, *autoimmune hepatitis type III*. These patients lack ANA and anti-LKM1 and have circulating antibodies to soluble liver antigen, which are directed at hepatocyte cytoplasmic cytokeratins 8 and 18. Most of these patients are women and have clinical features similar to those of patients with type I autoimmune hepatitis.

Liver biopsy abnormalities are similar to those described for chronic viral hepatitis. Expanding portal tracts and extending beyond the plate of periportal hepatocytes into the parenchyma (designated "interface hepatitis" or "piecemeal necrosis") is a mononuclear cell infiltrate that, in autoimmune hepatitis, may include the presence of plasma cells. Necroinflammatory activity characterizes the lobular parenchyma, and evidence of hepatocellular regeneration is reflected by "rosette" formation, the occurrence of thickened liver cell plates, and regenerative "pseudolobules." Septal fibrosis, bridging fibrosis, and cirrhosis are frequent. Bile duct injury and granulomas are uncommon; however, a subgroup of patients with autoimmune hepatitis have histologic, biochemical, and serologic features overlapping those of primary biliary cirrhosis (Chap. 289).

Diagnostic Criteria An international group has suggested a set of criteria for establishing a diagnosis of autoimmune hepatitis. Exclusion of liver disease caused by genetic disorders, viral hepatitis, drug hepatotoxicity, and alcohol are linked with such inclusive diagnostic criteria as hyperglobulinemia, autoantibodies, and characteristic histologic features. This international group has also suggested a comprehensive diagnostic scoring system that, rarely required for typical cases, may be helpful when typical features are not present. Factors that weigh in favor of the diagnosis include female gender; predominant aminotransferase elevation; presence and level of globulin elevation; presence of nuclear, smooth muscle, and LKM1 autoantibodies; concurrent other autoimmune diseases; characteristic histologic features (interface hepatitis, plasma cells, rosettes); HLA DR3 or DR4 markers; and response to treatment (see below). Weighing against the diagnosis are predominant alkaline phosphatase elevation, mitochondrial antibodies, markers of viral hepatitis, history of hepatotoxic drugs or excessive alcohol, histologic biliary changes, or such atypical histologic features as fatty infiltration, iron overload, and viral inclusions.

TREATMENT

The mainstay of management in autoimmune or idiopathic (nonviral) hepatitis is glucocorticoid therapy. Several controlled clinical trials have documented that such therapy leads to symptomatic, clinical, biochemical, and histologic improvement as well as increased survival. A therapeutic response can be expected in up to 80% of patients. Unfortunately, therapy has not been shown to prevent ultimate progression to cirrhosis; however, instances of reversal of fibrosis and cirrhosis have been reported in patients responding to treatment. Although some advocate the use of prednisolone (the hepatic metabolite of prednisone), prednisone is just as effective and is favored by most authorities. Therapy may be initiated at 20 mg/d, but a popular regimen in the United States relies on an initiation dose of 60 mg/d. This high dose is tapered successively over the course of a month down to a maintenance level of 20 mg/d. An alternative but equally effective approach is to begin with half the prednisone dose (30 mg/d) along with azathioprine (50 mg/d). With azathioprine maintained at 50 mg/d, the prednisone dose is tapered over the course of a month down to a maintenance level of 10 mg/d. The advantage of the combination approach is a reduction, over the span of an 18-month course of therapy, in serious, life-threatening complications of steroid therapy from 66% down to under 20%. Azathioprine alone, however, is not effective in achieving remission, nor is alternate-day glucocorticoid therapy. Although therapy has been shown to be effective for severe autoimmune hepatitis (AST $\geq$ 10 times the upper limit of normal or $\geq$5 times the upper limit of normal in conjunction with serum globulin $\geq$ twice normal; bridging necrosis or multilobular necrosis on liver biopsy;

presence of symptoms), therapy is not indicated for mild forms of chronic hepatitis (which used to be labeled chronic persistent hepatitis or chronic lobular hepatitis), and the efficacy of therapy in mild or asymptomatic autoimmune hepatitis has not been established.

Improvement of fatigue, anorexia, malaise, and jaundice tends to occur within days to several weeks; biochemical improvement occurs over the course of several weeks to months, with a fall in serum bilirubin and globulin levels and an increase in serum albumin. Serum aminotransferase levels usually drop promptly, but improvements in AST and ALT alone do not appear to be a reliable marker of recovery in individual patients; histologic improvement, characterized by a decrease in mononuclear infiltration and in hepatocellular necrosis, may be delayed for 6 to 24 months. Still, if interpreted cautiously, aminotransferase levels are valuable indicators of relative disease activity, and many authorities do *not* advocate serial liver biopsies to assess therapeutic success or to guide decisions to alter or stop therapy. Therapy should continue for at least 12 to 18 months. After tapering and cessation of therapy, the likelihood of relapse is at least 50%, even if posttreatment histology has improved to show mild chronic hepatitis, and the majority of patients require therapy at maintenance doses indefinitely. Continuing azathioprine alone (2 mg per kg body weight daily) after cessation of prednisone therapy may reduce the frequency of relapse.

In medically refractory cases, an attempt should be made to intensify treatment with high-dose glucocorticoid monotherapy (60 mg daily) or combination glucocorticoid (30 mg daily) plus high-dose azathioprine (150 mg daily) therapy. After a month, doses of prednisone can be reduced by 10 mg a month, and doses of azathioprine can be reduced by 50 mg a month towards ultimate, conventional maintenance doses. Patients refractory to this regimen may be treated with cyclosporine, tacrolimus, or mycophenolate mofetil; however, to date, only limited anectodal reports support these approaches. If medical therapy fails, or when chronic hepatitis progresses to cirrhosis and is associated with life-threatening complications of liver decompensation, liver transplantation is the only recourse (Chap. 291). Recurrence of autoimmune hepatitis in the new liver occurs rarely in most experiences but in as many as a third of cases in others.

DIFFERENTIAL DIAGNOSIS Early during the course of chronic hepatitis, the disease may resemble typical *acute viral hepatitis*. Without histologic assessment, severe chronic hepatitis cannot be readily distinguished based on clinical or biochemical criteria from mild chronic hepatitis. In adolescence, *Wilson's disease* may present with features of chronic hepatitis long before neurologic manifestations become apparent and before the formation of Kayser-Fleischer rings; in this age group, serum ceruloplasmin and serum and urinary copper determinations plus measurement of liver copper levels will establish the correct diagnosis. *Postnecrotic* or *cryptogenic cirrhosis* and *primary biliary cirrhosis* share clinical features with autoimmune hepatitis; biochemical, serologic, and histologic assessments are usually sufficient to allow these entities to be distinguished from autoimmune hepatitis. Of course, the distinction between autoimmune ("idiopathic") and chronic viral hepatitis is not always straightforward, especially when viral antibodies occur in patients with autoimmune disease or when autoantibodies occur in patients with viral disease. Finally, the presence of extrahepatic features such as arthritis, cutaneous vasculitis, or pleuritis—not to mention the presence of circulating autoantibodies—may cause confusion with *rheumatologic disorders* such as rheumatoid arthritis and systemic lupus erythematosus. The existence of clinical and biochemical features of progressive necroinflammatory liver disease distinguishes chronic hepatitis from these other disorders, which are not associated with severe liver disease.

Finally, occasionally, features of autoimmune hepatitis overlap with features of autoimmune biliary disorders such as primary biliary cirrhosis, primary sclerosing cholangitis, or, even more rarely, mitochondrial-antibody-negative autoimmune cholangitis. Such overlap syndromes are difficult to categorize, and often response to therapy may be the distinguishing factor that establishes the diagnosis.

288 ALCOHOLIC LIVER DISEASE

Mark E. Mailliard, Michael F. Sorrell

Chronic and excessive alcohol ingestion is one of the major causes of liver disease in the western world. The pathology of alcoholic liver injury comprises three major lesions, rarely existing in a pure form: (1) fatty liver, (2) alcoholic hepatitis, and (3) cirrhosis. Fatty liver is present in over 90% of binge and chronic drinkers. A much smaller percentage of heavy drinkers will progress to alcoholic hepatitis, thought to be a precursor to cirrhosis. The prognosis of severe alcoholic liver disease is dismal; the mortality of patients with alcoholic hepatitis concurrent with cirrhosis is nearly 60% at 4 years. Although alcohol is considered a direct hepatotoxin, only between 10 and 20% of alcoholics will develop alcoholic hepatitis. The explanation for this apparent paradox is unclear but involves the interaction of facilitating and comorbid factors such as gender, heredity, and immunity.

ETIOLOGY AND PATHOGENESIS Quantity and duration of alcohol intake are the most important risk factors involved in the development of alcoholic liver disease (Table 288-1). The roles of beverage type and pattern of drinking are less clear. Progress of the hepatic injury beyond the fatty liver stage seems to require additional risk factors that remain incompletely defined. Women are more susceptible to alcoholic liver injury when compared to men. They develop advanced liver disease with substantially less alcohol intake. In general, the time it takes to develop liver disease is directly related to the amount of alcohol consumed. It is useful in estimating alcohol consumption to understand that one beer, four ounces of wine, or one ounce of 80% spirits all contain approximately 12 g of alcohol. The threshold for developing

TABLE 288-1 *Risk Factors for Alcoholic Liver Disease*

Risk Factor	Comment
Quantity	In men, 40–80 g/d of ethanol produces fatty liver; 160 g/d for 10–20 years causes hepatitis or cirrhosis. Only 15% of alcoholics develop alcoholic liver disease.
Gender	Women exhibit increased susceptibility to alcoholic liver disease at quantities >20 g/d; two drinks per day probably safe.
Hepatitis C	HCV infection concurrent with alcoholic liver disease is associated with younger age for severity, more advanced histology, decreased survival.
Genetics	Gene polymorphisms may include alcohol dehydrogenase, cytochrome P4502E1, and those associated with alcoholism (twin studies).
Malnutrition	Alcohol injury does not require malnutrition, but obesity and fatty liver from the effect of carbohydrate on the transcriptional control of lipid synthesis and transport may be factors. Patients should receive vigorous attention to nutritional support.

severe alcoholic liver disease in men is an intake of >60 to 80 g/d of alcohol for 10 years, while women are at increased risk for developing similar degrees of liver injury by consuming 20 to 40 g/d. Gender-dependent differences in the gastric and hepatic metabolism of alcohol, in addition to poorly understood hormonal factors, likely contribute to the increased susceptibility of women to alcohol-induced liver injury. Social, nutritional, immunologic, and host factors have all been postulated to play a part in the development of the pathogenic process.

Chronic infection with hepatitis C (HCV) (Chap. 287) is an important comorbidity in the progression of alcoholic liver disease to cirrhosis in chronic and excessive drinkers. Alcohol intake >50 g/d more than doubles the risk of cirrhosis in HCV-infected individuals. Patients with both alcoholic liver injury and HCV infection develop decompensated liver disease at a younger age and have poorer overall survival. As a consequence of the overlapping injurious processes secondary to alcohol abuse and HCV infection, patients can develop an increased liver iron burden and, rarely, porphyria cutanea tarda. In addition, alcohol intake in HCV-infected patients with cirrhosis increases the risk for the development of hepatocellular carcinoma.

Our understanding of the pathogenesis of alcoholic liver injury is incomplete. Alcohol is a direct hepatotoxin, but ingestion of alcohol initiates a variety of metabolic responses that influence the final hepatotoxic response. The initial concept of malnutrition as the major pathogenic mechanism has given way to the present understanding that the metabolism of alcohol by the hepatocyte initiates a pathogenic process involving production of protein-aldehyde adducts, lipid peroxidation, immunologic activity, and cytokine release (Fig. 288-1). The complex interaction of distinct hepatic cell types is crucial to alcohol-mediated liver injury. Stellate cell activation and collagen production are key events in hepatic fibrogenesis. The resulting fibrosis determines the extent of architectural derangement of the liver following chronic alcohol ingestion.

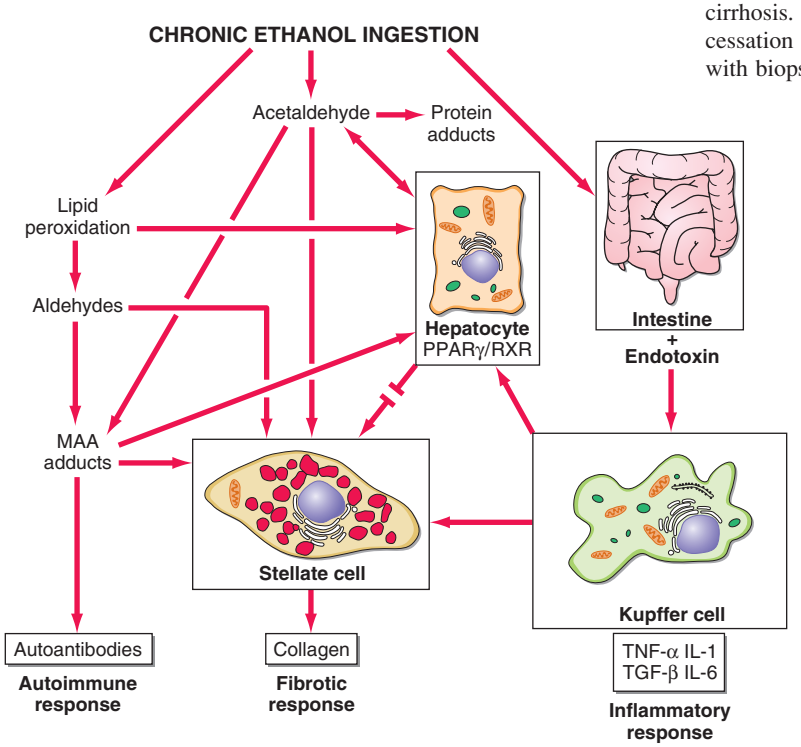

FIGURE 288-1 Biomedical and cellular pathogenesis of liver injury secondary to chronic ethanol ingestion. MAA, malondialdehyde-acetaldehyde; TNF, tumor necrosis factor; TGF, transforming growth factor; IL, interleukin; PPAR, peroxisome proliferator-activated receptor; RXR, retinoid X receptor.

PATHOLOGY The liver has a limited repertoire in response to injury. Fatty liver is the initial and most common histologic response to hepatotoxic stimuli, including excessive alcohol ingestion. The accumulation of fat within the perivenular hepatocytes coincides with the location of alcohol dehydrogenase, the major enzyme responsible for alcohol metabolism. Continuing alcohol ingestion results in fat accumulation throughout the entire hepatic lobule. Despite extensive fatty change and distortion of the hepatocytes with macrovesicular fat, the cessation of drinking results in normalization of hepatic architecture and fat content within the liver. Alcoholic fatty liver has traditionally been regarded as entirely benign, but similar to the spectrum of nonalcoholic steatohepatitis, certain pathologic features such as giant mitochondria, perivenular fibrosis, and macrovesicular fat may be associated with progressive liver injury.

The transition between fatty liver and the development of alcoholic hepatitis is blurred. The hallmark of alcoholic hepatitis is hepatocyte injury characterized by ballooning degeneration, spotty necrosis, polymorphonuclear infiltrate, and fibrosis in the perivenular and perisinusoidal space of Disse. Mallory bodies are often present in florid cases but are neither specific nor necessary to establishing the diagnosis. Alcoholic hepatitis is thought to be a precursor to the development of cirrhosis. However, like fatty liver, it is potentially reversible with cessation of drinking. Cirrhosis is present in up to 50% of patients with biopsy-proven alcoholic hepatitis and its repair is difficult, even with abstention.

CLINICAL FEATURES The clinical manifestations of alcoholic fatty liver are subtle and characteristically detected as a consequence of the patient's visit for a seemingly unrelated matter. Previously unsuspected hepatomegaly is often the only clinical finding. Occasionally, patients with fatty liver will present with right upper quadrant discomfort, tender hepatomegaly, nausea, and jaundice. Differentiation of alcoholic fatty liver from nonalcoholic fatty liver is difficult unless an accurate drinking history is ascertained. Alcoholism does not respect social and economic class. In every instance where liver disease is present, a thoughtful and sensitive drinking history should be obtained. Alcoholic hepatitis is associated with a wide gamut of clinical features. Cytokine production is thought to be responsible for the systemic manifestations of alcoholic hepatitis. Fever, spider nevi, jaundice, and abdominal pain simulating an acute abdomen represent the extreme end of the spectrum, while many patients will be entirely asymptomatic. Recognition of the clinical features of alcoholic hepatitis is central to the initiation of an effective and appropriate diagnostic and therapeutic strategy.

LABORATORY FEATURES Patients with alcoholic fatty liver are often identified through routine screening tests. The typical laboratory abnormalities are nonspecific and in-

TABLE 288-2 *Laboratory Diagnosis of Alcoholic Fatty Liver and Alcoholic Hepatitis*

Test	Comment
AST	Increased two- to sevenfold, less than 400 U/L, greater than ALT
ALT	Increased two- to sevenfold, less than 400 U/L
AST/ALT	Usually >1
GGTP	Not specific to alcohol, easily inducible, elevated in all forms of fatty liver
Bilirubin	May be markedly increased in alcoholic hepatitis despite modest elevation in alkaline phosphatase
PMN	If > 5500/μL, predicts severe alcoholic hepatitis when discriminant function > 32

Note: AST, aspartate aminotransferase; ALT, alanine aminotransferase; GGTP, gamma-glutamyl transpeptidase; PMN, polymorphonuclear cells.

clude modest elevations of the aspartate aminotransferase (AST), alanine aminotransferase (ALT), and gamma-glutamyl transpeptidase (GGTP), accompanied by hypertriglyceridemia, hypercholesterolemia, and occasionally hyperbilirubinemia. In alcoholic hepatitis and in contrast to other causes of fatty liver, the AST and ALT are usually elevated two- to sevenfold. They are rarely >400 IU, and the AST/ALT ratio >1 (Table 288-2). Hyperbilirubinemia is common and is accompanied by modest increases in the alkaline phosphatase level. Derangement in hepatocyte synthetic function indicates more serious disease. Hypoalbuminemia and coagulopathy are common in advanced liver injury. An increase in the circulating polymorphonuclear cell number >5500/μL parallels the occurrence of the lobular infiltration of neutrophils observed in the florid lesion of alcoholic hepatitis. Ultrasonography is useful in detecting fatty infiltration of the liver and determining liver size. The demonstration by ultrasound of portal vein flow reversal, ascites, and intraabdominal collaterals indicates serious liver injury with less potential for complete reversal of liver disease.

PROGNOSIS Critically ill patients with alcoholic hepatitis have short-term mortality rates approaching 70%. Severe alcoholic hepatitis is heralded by coagulopathy (prothrombin time > 5 s), anemia, serum albumin concentrations below <25 g/L (2.5 mg/dL), serum bilirubin levels > 137 μmol/L (8 mg/dL), renal failure, and ascites. A discriminant function calculated as 4.6 × [prothrombin time − control (seconds)] + serum bilirubin (mg/dL) can identify patients with a poor prognosis (discriminant function > 32). The presence of ascites, variceal hemorrhage, deep encephalopathy, or hepatorenal syndrome predicts a dismal prognosis. The pathologic stage of the injury can be helpful in predicting prognosis. Liver biopsy should be performed whenever possible to confirm the diagnosis, to establish potential reversibility of the liver disease, and to guide the therapeutic decisions.

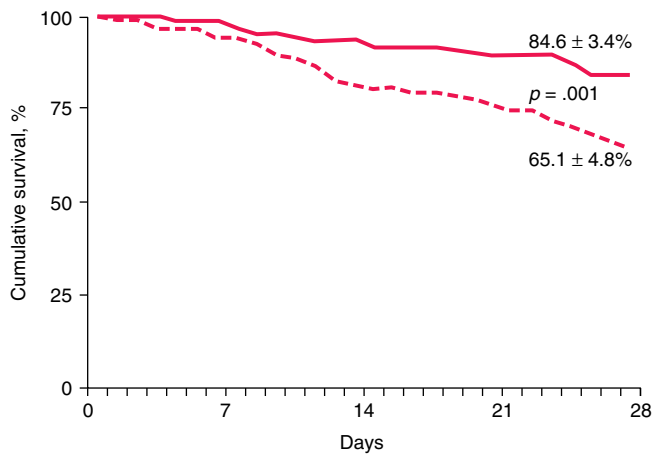

FIGURE 288-2 Effect of glucocorticoid therapy of severe alcoholic hepatitis on short-term survival: the result of a meta-analysis of individual data from three studies. Prednisolone, solid line; placebo, dotted line. *(Adapted from Mathurin et al., with permission from Elsevier Science)*

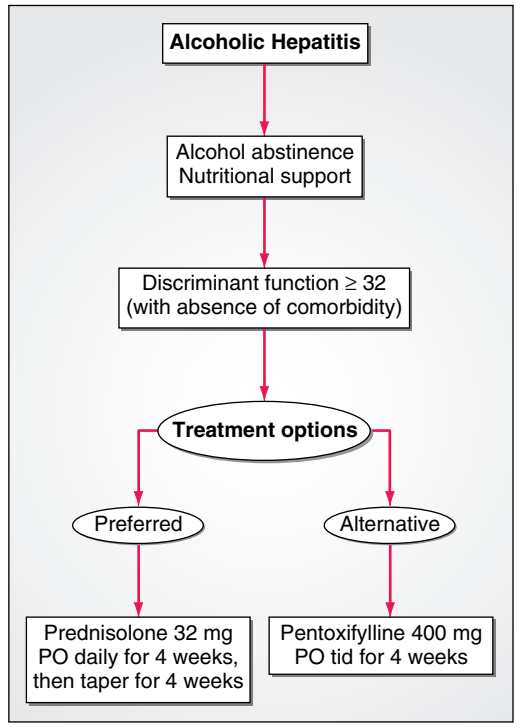

FIGURE 288-3 Treatment algorithm for alcoholic hepatitis. As identified by a calculated discriminant function > 32 (see text), patients with severe alcoholic hepatitis, without the presence of gastrointestinal bleeding or infection, would be candidates for either glucocorticoids or pentoxifylline administration.

TREATMENT

Complete abstinence from alcohol is the cornerstone in the treatment of alcoholic liver disease. Improved survival and the potential for reversal of histologic injury regardless of the initial clinical presentation are associated with total avoidance of alcohol ingestion. Referral of patients to experienced alcohol counselors and/or alcohol treatment programs should be routine in the management of patients with alcoholic liver disease. Attention should be directed to the nutritional and psychosocial states during the evaluation and treatment periods. Because of data suggesting that the pathogenic mechanisms in alcoholic hepatitis involve cytokine release and the perpetuation of injury by immunologic processes, glucocorticoids have been extensively evaluated in the treatment of alcoholic hepatitis. Patients with severe alcoholic hepatitis, defined as a discriminant function > 32, were given prednisone, 40 mg/d, or prednisolone, 32 mg/d, for 4 weeks followed by a steroid taper (Fig. 288-2). Exclusion criteria included active gastrointestinal bleeding, sepsis, renal failure, or pancreatitis. Newer understanding of the role of cytokines in alcoholic liver injury and emerging experience with pharmacologic inhibition of tumor necrosis factor by pentoxifylline has led to the recent inclusion of this agent as an alternative to glucocorticoids in the therapy of severe alcoholic hepatitis (Fig. 288-3). Because of inordinate surgical mortality and the high rates of recidivism following transplantation, patients with alcoholic hepatitis are not candidates for immediate liver transplantation. The transplant candidacy of these patients should be reevaluated after a defined period of sobriety.

289 CIRRHOSIS AND ITS COMPLICATIONS

Raymond T. Chung, Daniel K. Podolsky

Cirrhosis is a pathologically defined entity that is associated with a spectrum of characteristic clinical manifestations. The cardinal pathologic features reflect irreversible chronic injury of the hepatic parenchyma and include extensive fibrosis in association with the formation of regenerative nodules. These features result from hepatocyte necrosis, collapse of the supporting reticulin network with subsequent connective tissue deposition, distortion of the vascular bed, and nodular regeneration of remaining liver parenchyma. The central event leading to hepatic fibrosis is activation of the hepatic stellate cell. Upon activation by factors released by hepatocytes and Kupffer cells, the stellate cell assumes a myofibroblast-like conformation and, under the influence of cytokines such as transforming growth factor β (TGF-β), produces fibril-forming type I collagen. The precise point at which fibrosis becomes irreversible is unclear. The pathologic process should be viewed as a final common pathway of many types of chronic liver injury. Clinical features of cirrhosis derive from the morphologic alterations and often reflect the severity of hepatic damage rather than the etiology of the underlying liver disease. Loss of functioning hepatocellular mass may lead to jaundice, edema, coagulopathy, and a variety of metabolic abnormalities; fibrosis and distorted vasculature lead to portal hypertension and its sequelae, including gastroesophageal varices and splenomegaly. Ascites and hepatic encephalopathy result from both hepatocellular insufficiency and portal hypertension.

Classification of the various types of cirrhosis based on either etiology or morphology alone is unsatisfactory. A single pathologic pattern may result from a variety of insults, while the same insult may produce several morphologic patterns. Nevertheless, most types of cirrhosis may be usefully classified by a mixture of etiologically and morphologically defined entities as follows: (1) alcoholic; (2) cryptogenic and posthepatitic; (3) biliary; (4) cardiac; and (5) metabolic, inherited, and drug-related. This chapter considers the various types of cirrhosis and their complications.

ALCOHOLIC CIRRHOSIS

Definition *Alcoholic cirrhosis* is only one of many consequences resulting from chronic alcohol ingestion, and it often accompanies other forms of alcohol-induced liver injury, including alcoholic fatty liver and alcoholic hepatitis (Chap. 288). Alcoholic cirrhosis, historically referred to as *Laennec's cirrhosis*, is the most common type of cirrhosis encountered in North America and many parts of western Europe and South America. It is characterized by diffuse fine scarring, fairly uniform loss of liver cells, and small regenerative nodules, and therefore it is sometimes referred to as *micronodular cirrhosis*. However, micronodular cirrhosis may also result from other types of liver injury (e.g., following jejunoileal bypass), and thus alcoholic cirrhosis and micronodular cirrhosis are not necessarily synonymous. Conversely, alcoholic cirrhosis may progress to macronodular cirrhosis with time.

Etiology See Chap. 288, "Alcoholic Liver Disease."

Pathology and Pathogenesis With continued alcohol intake and destruction of hepatocytes, fibroblasts (including activated hepatic stellate cells that have transformed into myofibroblasts with contractile properties) appear at the site of injury and deposit collagen. Weblike septa of connective tissue appear in periportal and pericentral zones and eventually connect portal triads and central veins. This fine connective tissue network surrounds small masses of remaining liver cells, which regenerate and form nodules. Although regeneration occurs within the small remnants of parenchyma, cell loss generally exceeds replacement. With continuing hepatocyte destruction and collagen deposition, the liver shrinks in size, acquires a nodular appearance, and becomes hard as "end-stage" cirrhosis develops. Although alcoholic cirrhosis is usually a progressive disease, appropriate therapy and strict avoidance of alcohol may arrest the disease at most stages and permit functional improvement. In addition, there is strong evidence that concomitant chronic hepatitis C virus (HCV) infection significantly accelerates development of alcoholic cirrhosis.

Clinical Features ■ *SIGNS AND SYMPTOMS* Alcoholic cirrhosis may be clinically silent, and many cases (10 to 40%) are discovered incidentally at laparotomy or autopsy. In many cases symptoms are insidious in onset, occurring usually after $\geq$10 years of excessive alcohol use and progressing slowly over subsequent weeks and months. Anorexia and malnutrition lead to weight loss and a reduction in skeletal muscle mass. The patient may experience easy bruising, increasing weakness, and fatigue. Eventually the clinical manifestations of hepatocellular dysfunction and portal hypertension ensue, including progressive jaundice, bleeding from gastroesophageal varices, ascites, and encephalopathy. The abrupt onset of one of these complications may be the first event prompting the patient to seek medical attention. In other cases, cirrhosis first becomes evident when the patient requires treatment of symptoms related to alcoholic hepatitis.

A firm, nodular liver may be an early sign of disease; the liver may be either enlarged, normal, or decreased in size. Other frequent findings include jaundice, palmar erythema, spider angiomas, parotid and lacrimal gland enlargement, clubbing of fingers, splenomegaly, muscle wasting, and ascites with or without peripheral edema. Men may have decreased body hair and/or gynecomastia and testicular atrophy, which, like the cutaneous findings, result from disturbances in hormonal metabolism, including increased peripheral formation of estrogen due to diminished hepatic clearance of the precursor androstenedione. Testicular atrophy may reflect hormonal abnormalities or the toxic effect of alcohol on the testes. In women, signs of virilization or menstrual irregularities may occasionally be encountered. Dupuytren's contractures resulting from fibrosis of the palmar fascia with resulting flexion contracture of the digits are associated with alcoholism but are not specifically related to cirrhosis.

Although the cirrhotic patient may stabilize if drinking is discontinued, over a period of years, the patient may become emaciated, weak, and chronically jaundiced. Ascites and other signs of portal hypertension may become increasingly prominent. Ultimately, most patients with advanced cirrhosis die in hepatic coma, commonly precipitated by hemorrhage from esophageal varices or intercurrent infection. Progressive renal dysfunction often complicates the terminal phase of the illness.

LABORATORY FINDINGS In advanced alcoholic liver disease, abnormalities of laboratory tests are more common. Anemia may result from acute and chronic gastrointestinal blood loss, coexistent nutritional deficiency (notably of folic acid and vitamin B_{12}), hypersplenism, and a direct suppressive effect of alcohol on the bone marrow. Hemolytic anemia, presumably due to effects of hypercholesterolemia or erythrocyte membranes resulting in unusual spurlike projections (acanthocytosis), has been described in some alcoholics with cirrhosis. Mild or pronounced hyperbilirubinemia may be found, usually in association with varying elevations of serum alkaline phosphatase levels. Lev-

els of serum AST (asparate aminotransferase) are frequently elevated, but levels >5 μkat (300 units) are unusual and should prompt one to look for other coincident or complicating factors. In contrast to viral hepatitis, the serum AST is usually disproportionately elevated relative to ALT (alanine aminotransferase), i.e., AST/ALT ratio >2. This discrepancy in alcoholic liver disease may result from the proportionally greater inhibition of ALT synthesis by ethanol, which may be partially reversed by pyridoxal phosphate.

The serum prothrombin time is frequently prolonged, reflecting reduced synthesis of clotting proteins, most notably the vitamin K–dependent factors (see "Coagulopathy," below). The serum albumin level is usually depressed, while serum globulins are increased. Hypoalbuminemia reflects in part overall impairment in hepatic protein synthesis, while hyperglobulinemia is thought to result from nonspecific stimulation of the reticuloendothelial system. Elevated blood ammonia levels in patients with hepatic encephalopathy reflect diminished hepatic clearance because of impaired liver function and shunting of portal venous blood around the cirrhotic liver into the systemic circulation (see "Hepatic Encephalopathy," below).

A variety of metabolic disturbances may be detected. Glucose intolerance due to endogenous insulin resistance may be present; however, clinical diabetes is uncommon. Central hyperventilation may lead to respiratory alkalosis in patients with cirrhosis. Dietary deficiency and increased urinary losses lead to hypomagnesemia and hypophosphatemia. In patients with ascites and dilutional hyponatremia, hypokalemia may occur from increased urinary potassium losses due in part to hyperaldosteronism. Prerenal azotemia is also observed in such patients.

Diagnosis Alcoholic cirrhosis should be strongly suspected in patients with a history of prolonged or excessive alcohol intake and physical signs of chronic liver disease. However, since only 10 to 15% of individuals with excessive alcohol intake develop cirrhosis, other causes and types of liver disease may have to be excluded. The clinical features and laboratory findings are usually sufficient to provide reasonable indication of the presence and extent of hepatic injury. Although a percutaneous needle biopsy of the liver is not usually necessary to confirm the typical findings of alcoholic hepatitis or cirrhosis, it may be helpful in distinguishing patients with less advanced liver disease from those with cirrhosis and in excluding other forms of liver injury such as viral hepatitis. Biopsy may also be helpful as a diagnostic tool in evaluating patients with clinical findings suggestive of alcoholic liver disease who deny alcohol intake. In patients with features of cholestasis, ultrasonography may be appropriate to exclude the presence of extrahepatic biliary obstruction. When the clinical status of an otherwise stable cirrhotic patient deteriorates without an obvious explanation, complicating conditions, such as infection, portal vein thrombosis, and hepatocellular carcinoma, should be sought.

Prognosis Abstinence from alcohol as well as early and appropriate medical care can decrease long-term morbidity and mortality and delay or prevent the appearance of further complications. Patients who have had a major complication of cirrhosis and who continue to drink have a 5-year survival of <50%. However, those patients who remain abstinent have a substantially better prognosis. In general, the overall outlook in patients with advanced liver disease remains poor; most of these patients eventually die as a result of massive variceal hemorrhage and/or profound hepatic encephalopathy.

Rx TREATMENT

Alcoholic cirrhosis is a serious illness that requires long-term medical supervision and careful management. Therapy of the underlying liver disease is largely supportive. Specific treatment is directed at particular complications such as variceal bleeding and ascites (see below). While some studies suggest that administration of glucocorticoids in moderately large doses for 4 weeks is helpful in patients with severe alcoholic hepatitis and encephalopathy, these drugs have no role in the treatment of established alcoholic cirrhosis. One study has suggested survival benefit in alcoholic cirrhosis patients receiving S-adenosyl methionine, which may act to decrease proinflammatory cytokines.

The patient should be made to realize that there is no medication that will protect the liver against the effects of further alcohol ingestion. Therefore, alcohol should be absolutely forbidden. An important component of the complete care of such patients is encouragement to become involved in an appropriate alcohol counseling program.

All medicines must be administered with caution in the patient with cirrhosis, especially those eliminated or modified through hepatic metabolism or biliary pathways. In particular, care must be taken to avoid overzealous use of drugs that may directly or indirectly precipitate complications of cirrhosis. For example, vigorous treatment of ascites with diuretics may result in electrolyte abnormalities or hypovolemia, which can lead to coma. Similarly, even modest doses of sedatives can lead to deepening encephalopathy. Aspirin should be avoided in patients with cirrhosis because of its effects on coagulation and gastric mucosa. Acetaminophen should be used with caution and in doses of less than 2 g/d. Patients who drink alcohol are more sensitive to the hepatotoxic effects of acetaminophen, probably due to increased metabolism of the drug to toxic intermediates and decreased glutathione levels.

POSTHEPATITIC AND CRYPTOGENIC CIRRHOSIS

Definition Posthepatitic or postnecrotic cirrhosis represents the final common pathway of many types of chronic liver disease. *Coarsely nodular cirrhosis* and *multilobular cirrhosis* are terms synonymous with posthepatitic cirrhosis. The term *cryptogenic cirrhosis* has been used interchangeably with posthepatitic cirrhosis, but this designation should be reserved for those cases in which the etiology of cirrhosis is unknown (approximately 10% of all patients with cirrhosis).

Etiology Posthepatitic cirrhosis is a morphologic term referring to a defined stage of advanced chronic liver injury of either specific or unknown (cryptogenic) causes. Epidemiologic and serologic evidence suggest that in one-fourth to three-fourths of cases of posthepatitic cirrhosis, viral hepatitis (hepatitis B or hepatitis C) may be an antecedent factor. In areas where hepatitis B virus (HBV) infection is endemic (e.g., Southeast Asia, sub-Saharan Africa), up to 15% of the population may acquire the infection in early childhood, and cirrhosis may ultimately develop in one-fourth of these chronic carriers. Although HBV infection is much less prevalent in the United States, it is relatively common among certain high-risk groups (e.g., persons with multiple sexual partners, especially men who have sex with men, injection drug users) and contributes to an increased incidence of cirrhosis. In the United States, HCV infection accounts for many cases of cirrhosis following blood transfusions. Before routine screening of blood donors was introduced, hepatitis C occurred in 5 to 10% of blood recipients. Following infection, cirrhosis may ultimately develop in >20% of individuals after 20 years. Increasing recognition of the progressive nature of nonalcoholic fatty liver disease (NAFLD) has revealed that many cases previously designated cryptogenic cirrhosis may be attributable to this disorder (Chap. 290). Posthepatitic cirrhosis may also develop in patients with autoimmune hepatitis (Chap. 287).

The most common causes of cirrhosis in the United States that ultimately lead to liver transplantation include chronic HCV infection, alcohol, primary biliary cirrhosis, primary sclerosing cholangitis, and NAFLD. Less common causes of posthepatitic cirrhosis, including drugs and toxins, are listed in Table 289-1.

Pathology The posthepatitic liver is typically shrunken in size, distorted in shape, and composed of nodules of liver cells separated by dense and broad bands of fibrosis. The microscopic picture is consistent with the gross impression. Posthepatitic cirrhosis is characterized morphologically by (1) extensive confluent loss of liver cells, (2) stromal collapse and fibrosis resulting in broad bands of connective tissue containing the remains of many portal triads, and (3) irregular

nodules of regenerating hepatocytes, varying in size from microscopic to several centimeters in diameter.

Clinical Features In patients with cirrhosis of known etiology in whom there is progression to a posthepatitic stage, the clinical manifestations are an extension of those resulting from the initial disease process. Usually clinical symptoms are related to portal hypertension and its sequelae, such as ascites, splenomegaly, hypersplenism, encephalopathy, and bleeding gastroesophageal varices. The hematologic and liver function abnormalities resemble those seen with other types of cirrhosis. In a few patients with posthepatitic cirrhosis, the diagnosis may be made incidentally at operation, at postmortem, or by a needle biopsy of the liver performed to investigate abnormal liver function tests or hepatomegaly.

Diagnosis and Prognosis Posthepatitic cirrhosis should be suspected in patients with signs and symptoms of cirrhosis or portal hypertension. Needle or operative liver biopsies confirm the diagnosis, although nonuniformity of the pathologic process may result in sampling errors. The diagnosis of cryptogenic cirrhosis is reserved for those patients in whom no known etiology can be demonstrated. About 75% of patients have progressive disease despite supportive therapy and die within 1 to 5 years from complications, including variceal hemorrhage, hepatic encephalopathy, or superimposed hepatocellular carcinoma.

TREATMENT

Management is usually limited to treatment of the complications of portal hypertension, including control of ascites, avoidance of drugs or excessive protein intake that may induce hepatic coma, and prompt treatment of infections (see below). In patients with asymptomatic cirrhosis, expectant management alone is appropriate. In those patients in whom posthepatitic cirrhosis has developed as a result of a treatable condition, therapy directed at the primary disorder may limit further progression (e.g., Wilson's disease, hemochromatosis).

BILIARY CIRRHOSIS

Biliary cirrhosis results from injury to or prolonged obstruction of either the intrahepatic or extrahepatic biliary system. It is associated with impaired biliary excretion, destruction of hepatic parenchyma, and progressive fibrosis. Primary biliary cirrhosis (PBC) is characterized by chronic inflammation and fibrous obliteration of intrahepatic bile ductules. Secondary biliary cirrhosis (SBC) is the result of longstanding obstruction of the larger extrahepatic ducts. Although primary and secondary biliary cirrhosis are separate pathophysiologic entities with respect to the initial insult, many clinical features are similar.

PRIMARY BILIARY CIRRHOSIS ■ Etiology and Pathogenesis The cause of PBC remains unknown. Several observations suggest that a disordered immune response may be involved. PBC is frequently associated with a variety of disorders presumed to be autoimmune in nature, such as the syndrome of *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasia (CREST); the sicca syndrome (dry eyes and dry mouth); autoimmune thyroiditis; type 1 diabetes mellitus; and IgA deficiency.

Most important, a circulating IgG antimitochondrial antibody (AMA) is detected in >90% of patients with PBC and only rarely in other forms of liver disease. It has been demonstrated that these autoantibodies recognize inner mitochondrial membrane proteins identified as enzymes of the pyruvate dehydrogenase complex (PDC), the branched chain–2-oxoacid dehydrogenase complex (BCOADC), and the 2-oxoglutarate dehydrogenase complex (OGDC). The major autoantigen in PBC (found in 90% of patients) has been identified as the 74-kDa E2 component of the PDC, dihydrolipoamide acetyltransferase. The antibodies are directed to a region essential for binding of a lipoic acid cofactor and inhibit the overall enzymatic activity of the PDC. Other AMA autoantibodies in PBC patients are directed to similar constituents of BCOADC and OGDC and also inhibit their enzymatic function. It remains unclear whether these properties have a direct pathogenetic role in the development of PBC. In addition to AMA, elevated serum levels of IgM and cryoproteins consisting of immune complexes capable of activating the alternative complement pathway are found in 80 to 90% of patients. Aberrant expression of major histocompatibility complex class II molecules has been found on biliary epithelium in association with PBC, suggesting that these cells may serve as antigen-presenting cells in this setting. Lymphocytes are prominent in the portal regions and surround damaged bile ducts. These histologic findings resemble those noted in graft-versus-host disease following bone marrow transplantation and suggest that damage to bile ducts may be immunologically mediated, perhaps reflecting a defect in a suppressor cell population. While it has been suggested that PBC may be initiated by molecular mimicry following infection or xenobiotic exposure, definitive evidence is lacking.

Pathology PBC is divided into four stages based on morphologic findings. The earliest recognizable lesion (stage I), termed *chronic nonsuppurative destructive cholangitis*, is a necrotizing inflammatory process of the portal triads. It is characterized by destruction of medium and small bile ducts, a dense infiltrate of acute and chronic inflammatory cells, mild fibrosis, and occasionally, bile stasis. At times, periductal granulomas and lymph follicles are found adjacent to affected bile ducts. Subsequently, the inflammatory infiltrate becomes less prominent, the number of bile ducts is reduced, and smaller bile ductules proliferate (stage II). Progression over a period of months to years leads to a decrease in interlobular ducts, loss of liver cells, and expansion of periportal fibrosis into a network of connective tissue scars (stage III). Ultimately, cirrhosis, which may be micronodular or macronodular, develops (stage IV).

Clinical Features ■ *SIGNS AND SYMPTOMS* Most patients with PBC are asymptomatic, and the disease is initially detected on the basis of elevated serum alkaline phosphatase levels during routine screening. The majority of such patients remain asymptomatic for prolonged periods, although many ultimately develop progressive liver injury.

Among patients with symptomatic disease, 90% are women age 35 to 60. Often the earliest symptom is pruritus, which may be either generalized or limited initially to the palms and soles. In addition, fatigue is commonly a prominent early symptom. After several months or years, jaundice and gradual darkening of the exposed areas of the

skin (melanosis) may ensue. Other early clinical manifestations of PBC reflect impaired bile excretion. These include steatorrhea and the malabsorption of lipid-soluble vitamins. Protracted elevation of serum lipids, especially cholesterol, leads to subcutaneous lipid deposition around the eyes (xanthelasmas) and over joints and tendons (xanthomas). Over a period of months to years, the itching, jaundice, and hyperpigmentation slowly worsen. Eventually, signs of hepatocellular failure and portal hypertension develop and ascites appears. Progression may be quite variable. Whereas a proportion of asymptomatic patients may show no signs of progression for a decade or longer, in others, death due to hepatic insufficiency may occur within 5 to 10 years after the first signs of the illness. Such decompensation is often precipitated by uncontrolled variceal hemorrhage or infection.

Physical examination may be entirely normal in the early phase of the disease, when patients are asymptomatic or pruritus is the sole complaint. Later, there may be jaundice of varying intensity, hyperpigmentation of the exposed skin areas, xanthelasmas and tendinous and planar xanthomas, moderate to striking hepatomegaly, splenomegaly, and clubbing of the fingers. Bone tenderness, signs of vertebral compression, ecchymoses, glossitis, and dermatitis may all be noted. Clinical evidence of the sicca syndrome can be found in as many as 75% of patients, and serologic evidence of autoimmune thyroid disease in 25%. Other conditions encountered with increased frequency include rheumatoid arthritis, CREST syndrome, keratoconjunctivitis sicca, IgA deficiency, type 1 diabetes mellitus, scleroderma, pernicious anemia, and renal tubular acidosis. Bone disease is often a significant problem encountered over the course of the disease. While osteomalacia occurs due to diminished vitamin D absorption, accelerated osteoporosis in this patient population (the majority of whom are postmenopausal women) is even more common.

LABORATORY FINDINGS PBC is increasingly diagnosed at a presymptomatic stage, prompted by the finding of a twofold or greater elevation of the serum alkaline phosphatase during routine screening. Serum 5′-nucleotidase activity and γ-glutamyl transpeptidase levels are also elevated. In this setting, serum bilirubin is usually normal and aminotransferase levels minimally increased. The diagnosis is supported by a positive AMA test (titer $>$ 1:40). The latter is both relatively specific and sensitive; a positive test is found in $>$90% of symptomatic patients and is present in $<$5% of patients with other liver diseases. As the disease evolves, the serum bilirubin level rises progressively and may reach 510 μmol/L (30 mg/dL) or more in the final stages. Serum aminotransferase values rarely exceed 2.5 to 3.3 μkat (150 to 200 units). Hyperlipidemia is common, and a striking increase of the serum unesterified cholesterol is often noted. An abnormal serum lipoprotein (lipoprotein X) may be present in PBC but is not specific and appears in other cholestatic conditions. A deficiency of bile salts in the intestine leads to moderate steatorrhea and impaired absorption of the fat-soluble vitamins and hypoprothrombinemia. Patients with PBC have elevated liver copper levels, but this finding is not specific and is found in all disorders in which there is prolonged cholestasis.

Diagnosis PBC should be considered in middle-aged women with unexplained pruritus or an elevated serum alkaline phosphatase and in whom there may be other clinical or laboratory features of protracted impairment of biliary excretion. Although a positive serum AMA determination provides important diagnostic evidence, false-positive results do occur; therefore, liver biopsy should be performed to confirm the diagnosis. Rarely, the AMA test may be negative in patients with histologic features of PBC. Frequently, patients have antibodies to the E2 protein in tests using these specific antigens. In some cases with histologic features of PBC and a negative AMA, antinuclear or smooth-muscle antibodies are present (as in autoimmune hepatitis), and the designation *autoimmune cholangitis* is applied. The natural history of this entity, however, appears to resemble that of PBC. If the AMA test is negative, the biliary tract should be evaluated to exclude primary sclerosing cholangitis and remediable extrahepatic biliary tract obstruction, especially in view of the frequent presence of coexisting cholelithiasis.

℞ TREATMENT

While there is no specific therapy for PBC, ursodiol has been shown to improve biochemical and histologic features and might improve survival, particularly liver transplantation–free survival (although this remains unproven). Ursodiol should be given in doses of 13 to 15 mg/kg per day, but lower doses are sometimes just as effective in reducing serum alkaline phosphatase and aminotransferase levels. Ursodiol should be given with food and can be taken in a single dose daily. Side effects are rare: gastrointestinal intolerance (diarrhea) and skin rashes occur but are uncommon. Isolated instances of severe exacerbation of pruritus have been reported in patients with advanced disease. Ursodiol probably works by replacing the endogenously produced hydrophobic bile acids with urosdeoxycholate, a hydrophilic and relatively nontoxic bile acid.

Unfortunately, ursodiol may not prevent ultimate progression of PBC, which is effectively predicted by the Mayo risk score, and the only established "cure" is liver transplantation. Results of liver transplantation for PBC are excellent, survival exceeding that for patients receiving transplantation for most other forms of end-stage liver disease. Recurrence of PBC after liver transplantation has been reported but is uncommon, and the recurrent disease is only slowly progressive. Most patients remain AMA positive after transplantation, and as many as 25% will have histologic features of PBC on liver biopsy after 5 years. Other therapies such as glucocorticoids, colchicine, methotrexate, azathioprine, cyclosporine, and tacrolimus have been reported as effective in small case series, but none have shown to be effective in adequately controlled trials.

Relief of symptoms is also an important part of management of PBC. As noted, ursodiol may be helpful in controlling symptoms and improving the patient's sense of well-being. Although the mechanism of the protracted pruritus is not entirely clear, cholestyramine, an oral bile salt–sequestering resin, may be helpful in doses of 12 to 16 g/d to decrease both pruritus and hypercholesterolemia. Rifampin, opiate antagonists (naloxone or naltrexone), ondansetron, plasmapheresis, and ultraviolet light have all been tried for control of pruritus, with varying results. Steatorrhea can be reduced by a low-fat diet and substituting medium-chain triglycerides for dietary long-chain triglycerides. Fat-soluble vitamins A, D, E, and K should be given at regular intervals. Zinc supplementation may be necessary if night blindness is refractory to vitamin A therapy. An important part of management of PBC and any cholestatic liver disease is assessment and treatment of osteoporosis and osteomalacia. Patients should be screened periodically by bone densitometry and treated as needed with calcium supplements (1500 mg/d), vitamin D (1000 IU/d), and/or bisphosphonate agents (e.g., alendronate) when osteoporosis is present. Progression of PBC leads to the typical complications of advanced liver disease (see below).

SECONDARY BILIARY CIRRHOSIS ■ Etiology

SBC results from prolonged partial or total obstruction of the common bile duct or its major branches. In adults, obstruction is most frequently caused by postoperative strictures or gallstones, usually with superimposed infectious cholangitis. Chronic pancreatitis may lead to biliary stricture and secondary cirrhosis. SBC is also an important complication of primary sclerosing cholangitis, a progressive immunologic disorder of the intrahepatic and extrahepatic biliary tree (Chap. 292). Patients with malignant tumors of the common bile duct or pancreas rarely survive long enough to develop SBC. In children, congenital biliary atresia and cystic fibrosis are common causes of SBC. Choledochal cysts, if unrecognized, may also be a rare cause of SBC.

Pathology and Pathogenesis Unrelieved obstruction of the extrahepatic bile ducts leads to (1) bile stasis and focal areas of centrilobular necrosis followed by periportal necrosis, (2) proliferation and dilatation of the portal bile ducts and ductules, (3) sterile or infected cholangitis with accumulation of polymorphonuclear infiltrates around bile ducts,

and (4) progressive expansion of portal tracts by edema and fibrosis. Extravasation of bile from ruptured interlobular bile ducts into areas of periportal necrosis leads to the formation of "bile lakes" surrounded by cholesterol-rich pseudoxanthomatous cells. As in other forms of cirrhosis, injury is accompanied by regeneration in residual parenchyma. These changes gradually lead to a finely nodular cirrhosis. In general, at least 3 to 12 months is required for biliary obstruction to result in cirrhosis. Relief of the obstruction is frequently accompanied by biochemical and morphologic improvement and may even ameliorate cirrhosis.

Clinical Features The symptoms, signs, and biochemical findings of SBC are similar to those of PBC. Jaundice and pruritus are usually the most prominent features. In addition, fever and/or right upper quadrant pain, reflecting bouts of cholangitis or biliary colic, are typical. The manifestations of portal hypertension are found only in advanced cases. SBC should be considered in any patient with clinical and laboratory evidence of prolonged obstruction to bile flow, especially when there is a history of previous biliary tract surgery or gallstones, bouts of ascending cholangitis, or right upper quadrant pain. Cholangiography (either percutaneous or endoscopic) usually demonstrates the underlying pathologic process. Liver biopsy, although not always necessary from a clinical standpoint, can document the development of cirrhosis.

℞ TREATMENT

Relief of obstruction to bile flow, by either endoscopic or surgical means, is the most important step in the prevention and therapy of SBC. Effective decompression of the biliary tract results in a significant improvement in both symptoms and survival, even in patients with established cirrhosis. When obstruction cannot be relieved, as in sclerosing cholangitis, antibiotics may be helpful acutely in controlling superimposed infection or, when administered on a chronic basis, as prophylactic therapy in suppressing recurring episodes of ascending cholangitis. Without relief of obstruction, there is a steady progression to end-stage cirrhosis and its terminal manifestations.

CARDIAC CIRRHOSIS

Definition Prolonged, severe right-sided congestive heart failure may lead to chronic liver injury and cardiac cirrhosis. The characteristic pathologic features of fibrosis and regenerative nodules distinguish cardiac cirrhosis from both reversible passive congestion of the liver due to acute heart failure and acute hepatocellular necrosis ("ischemic hepatitis" or "shock liver") resulting from systemic hypotension and hypoperfusion of the liver.

Etiology and Pathology In right-sided heart failure, retrograde transmission of elevated venous pressure via the inferior vena cava and hepatic veins leads to congestion of the liver. Hepatic sinusoids become dilated and engorged with blood, and the liver becomes tensely swollen. With prolonged passive congestion and ischemia from poor perfusion secondary to reduced cardiac output, necrosis of centrilobular hepatocytes ensues and leads to fibrosis in these central areas. Ultimately, centrilobular fibrosis develops, with collagen extending outward in a characteristic stellate pattern from the central vein. Gross examination of the liver shows alternating red (congested) and pale (fibrotic) areas, a pattern often referred to as "nutmeg liver." Improvement in management of cardiac disorders, particularly advances in surgical treatment, has reduced the frequency of cardiac cirrhosis.

Clinical Features A range of abnormalities of liver function tests may be found, though none is uniformly present. The serum bilirubin is usually only mildly increased and may be predominantly either conjugated or unconjugated. Mild to moderate elevation in alkaline phosphatase level and prothrombin time prolongation are sometimes present. The AST level is typically mildly elevated but may be transiently very high following a period of marked systemic hypotension (shock liver), when the clinical picture can mimic acute viral or drug-induced hepatitis. In cases of tricuspid insufficiency the liver may be pulsatile, but this finding disappears as cirrhosis develops. With prolonged right-sided heart failure the liver becomes enlarged, firm, and usually nontender. The signs and symptoms of heart failure usually overshadow the liver disease. Bleeding from esophageal varices is rare, but chronic encephalopathy may be prominent, with a waxing and waning course reflecting variations in the severity of right-sided heart failure. Ascites and peripheral edema, often primarily related to the underlying cardiac dysfunction, may be worsened by the superimposed liver disease.

Diagnosis The presence of a firm, enlarged liver with signs of chronic liver disease in a patient with valvular heart disease, constrictive pericarditis, or cor pulmonale of long duration (>10 years) should suggest cardiac cirrhosis. Liver biopsy can confirm the diagnosis but is often contraindicated because of coagulopathy or ascites. Coexistent chronic heart and liver disease should also raise the possibility of hemochromatosis (Chap. 336), amyloidosis (Chap. 310), or other infiltrative diseases.

Budd-Chiari syndrome resulting from the occlusion of the hepatic veins or inferior vena cava may be confused with acute congestive hepatomegaly. In this condition the liver is grossly enlarged and tender, and severe intractable ascites is present. However, signs and symptoms of heart failure are notably absent. The most common cause is thrombosis of the hepatic veins, often in the setting of polycythemia rubra vera, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, oral contraceptive use, or other hypercoagulable states; it may also result from invasion of the inferior vena cava by tumor, such as renal cell or hepatocellular carcinoma. Idiopathic membranous obstruction of the inferior vena cava is the most common cause of this syndrome in Japan. Hepatic venography or liver biopsy showing centrilobular congestion and sinusoidal dilatation in the absence of right-sided heart failure establishes the diagnosis of Budd-Chiari syndrome. Venoocclusive disease affecting the sublobular branches of the hepatic veins and the hepatic venues may result from hepatic irradiation, treatment with certain antineoplastic agents as preparation for stem cell transplantation, or ingestion of pyrrolidizine alkaloids present in some herbal teas ("bush tea disease") and can mimic congestive hepatomegaly.

℞ TREATMENT

Prevention or treatment of cardiac cirrhosis depends on the diagnosis and therapy of the underlying cardiovascular disorder. Improvement in cardiac function frequently results in improvement of liver function and stabilization of the liver disease.

METABOLIC, HEREDITARY, DRUG-RELATED, AND OTHER TYPES OF CIRRHOSIS (See Table 289-1)

Cirrhosis or hepatitis may result from a wide variety of other processes encompassing the spectrum of etiologic factors listed in Table 289-1. Although some of these disorders have distinctive clinical or morphologic features, the manifestations of cirrhosis are largely independent of the underlying pathogenic mechanism.

NONCIRRHOTIC FIBROSIS OF THE LIVER

Several diseases, either congenital or acquired, may be associated with localized or generalized hepatic fibrosis. They are distinguished from

TABLE 289-2 Some Causes of Noncirrhotic Hepatic Fibrosis

Idiopathic portal hypertension (noncirrhotic portal fibrosis, Banti's syndrome); three variants:
Intrahepatic phlebosclerosis and fibrosis
Portal and splenic vein sclerosis
Portal and splenic vein thrombosis
Schistosomiasis ("pipe-stem" fibrosis with presinusoidal portal hypertension)
Congenital hepatic fibrosis (may be associated with polycystic disease of liver and kidneys)

cirrhosis by the absence of hepatocellular damage and the lack of nodular regenerative activity. The clinical manifestations in such cases are largely secondary to portal hypertension. The different types of these disorders are indicated in Table 289-2; with the exception of schistosomiasis in some regions of the world, all these conditions are relatively rare.

MAJOR COMPLICATIONS OF CIRRHOSIS

The clinical course of patients with advanced cirrhosis is often complicated by a number of important sequelae that are independent of the etiology of the underlying liver disease. These include portal hypertension and its consequences (e.g., gastroesophageal varices and splenomegaly), ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatocellular carcinoma.

PORTAL HYPERTENSION ■ Definition and Pathogenesis Normal pressure in the portal vein is low (5 to 10 mmHg) because vascular resistance in the hepatic sinusoids is minimal. Portal hypertension (>10 mmHg) most commonly results from increased resistance to portal blood flow. Because the portal venous system lacks valves, resistance at any level between the right side of the heart and splanchnic vessels results in retrograde transmission of an elevated pressure. Increased resistance can occur at three levels relative to the hepatic sinusoids: (1) presinusoidal, (2) sinusoidal, and (3) postsinudoidal. Obstruction in the *presinusoidal* venous compartment may be anatomically outside the liver (e.g., portal vein thrombosis) or within the liver itself but at a functional level proximal to the hepatic sinusoids so that the liver parenchyma is not exposed to the elevated venous pressure (e.g., schistosomiasis).

Postsinusoidal obstruction may also occur outside the liver at the level of the hepatic veins (e.g., Budd-Chiari syndrome), the inferior vena cava, or, less commonly, within the liver (e.g., venoocclusive disease). When cirrhosis is complicated by portal hypertension, the increased resistance is usually *sinusoidal*. While distinctions between pre-, post-, and sinusoidal processes are conceptually appealing, functional resistance to portal flow in a given patient may occur at more than one level. Portal hypertension may also arise from increased blood flow (e.g., massive splenomegaly or arteriovenous fistulas), but the low outflow resistance of the normal liver makes this a rare clinical problem.

Cirrhosis is the most common cause of portal hypertension in the United States. Clinically significant portal hypertension is present in >60% of patients with cirrhosis. *Portal vein obstruction* is the second most common cause; it may be idiopathic or occur in association with cirrhosis, infection, pancreatitis, or abdominal trauma. Idiopathic portal vein thrombosis may develop in a variety of hypercoagulable states including polycythemia vera; essential thrombocythemia; deficiencies of protein C, protein S, or antithrombin III; resistance to activated protein C (factor V Leiden); and a mutation of the prothrombin gene (G20210A). Most of the remaining patients with idiopathic cases have a subclinical myeloproliferative disorder. Hepatic vein thrombosis (Budd-Chiari syndrome) and hepatic venoocclusive disease are relatively infrequent causes of portal hypertension (see above). Portal vein occlusion may result in massive hematemesis from gastroesophageal varices, but ascites is usually found only when cirrhosis is present. Noncirrhotic portal fibrosis (Table 289-2) accounts for only a few cases of portal hypertension.

Clinical Features The major clinical manifestations of portal hypertension include hemorrhage from gastroesophageal varices, splenomegaly with hypersplenism, ascites, and acute and chronic hepatic encephalopathy. These are related, at least in part, to the development of portal-systemic collateral channels. The absence of valves in the portal venous system facilitates retrograde (hepatofugal) blood flow from the high-pressure portal venous system to the lower-pressure systemic venous circulation. Major sites of collateral flow involve the veins around the cardioesophageal junction (esophagogastric varices), the rectum (hemorrhoids), retroperitoneal space, and the falciform ligament of the liver (periumbilical or abdominal wall collaterals). Abdominal wall collaterals appear as tortuous epigastric vessels that radiate from the umbilicus toward the xiphoid and rib margins (caput medusae).

A frequent marker of the presence of cirrhosis in a patient being followed for chronic liver disease is a progressive decrease in platelet count. A low-normal platelet count can be the first clue to progression to cirrhosis. Ultimately, a marked decrease in platelets (to 30,000 to 60,000/μL) and white blood cells can occur.

Diagnosis In patients with known liver disease, the development of portal hypertension is usually revealed by the appearance of splenomegaly, ascites, encephalopathy, and/or esophageal varices. Conversely, the finding of any of these features should prompt evaluation of the patient for the presence of underlying portal hypertension and liver disease. Varices are most reliably documented by fiberoptic esophagoscopy; their presence lends indirect support to the diagnosis of portal hypertension. Magnetic resonance imaging and intravenous contrast computed tomography are also sensitive tools for detection of the collateral circulation of portal hypertension. Although rarely necessary, portal venous pressure may be measured directly by percutaneous transhepatic "skinny needle" catheterization or indirectly through transjugular cannulation of the hepatic veins. Both free and wedged hepatic vein pressure should be measured. While the latter is elevated in sinusoidal and postsinusoidal portal hypertension, including cirrhosis, this measurement is usually normal in presinusoidal portal hypertension. In patients in whom additional information is necessary (e.g., preoperative evaluation before portal-systemic shunt surgery) or when percutaneous catheterization is not feasible, mesenteric and hepatic angiography may be helpful. Particular attention should be directed to the venous phase to assess the patency of the portal vein and the direction of portal blood flow.

℞ TREATMENT

Although treatment is usually directed toward a specific complication of portal hypertension, attempts are sometimes made to reduce the pressure in the portal venous system. Surgical decompression procedures have been used for many years to lower portal pressure in patients with bleeding esophageal varices (see below). However, portal-systemic shunt surgery does not result in improved survival rates in patients with cirrhosis. Decompression can now be accomplished without surgery through the percutaneous placement of a portal-systemic shunt, termed a *transjugular intrahepatic portosystemic shunt* (TIPS). *β-Adrenergic blockade* with nonselective agents such as propranolol or nadolol reduces portal pressure through vasoconstrictive effects on both the splanchnic arterial bed and the portal venous system in combination with reduced cardiac output. Such therapy has been shown to be effective in preventing both a first variceal bleed and subsequent episodes after an initial bleed. Treatment of patients with clinically significant sequelae of portal hypertension, especially variceal bleeding, is titrated to reduce the hepatic venous pressure gradient (HVPG = wedged hepatic venous pressure − free hepatic venous pressure) to <12 mmHg or by 20% from baseline. When the HVPG is not available or feasible, reduction of resting pulse by 25% is reasonable if no contraindications to therapy exist.

Vigorous treatment of patients with alcoholic hepatitis and cirrhosis, chronic active hepatitis, or other liver diseases may lead to a fall in portal pressure and to a reduction in variceal size. In general, however, portal hypertension due to cirrhosis is not reversible. In appropriately selected patients, hepatic transplantation will be beneficial.

VARICEAL BLEEDING ■ Pathogenesis While vigorous hemorrhage may arise from any portal-systemic venous collaterals, bleeding is most common from varices in the region of the gastroesophageal junction. The factors contributing to bleeding from gastroesophageal varices are not entirely understood but include the degree of portal hypertension (>12 mmHg) and the size of the varices.

Clinical Features and Diagnosis Variceal bleeding often occurs without obvious precipitating factors and usually presents with painless but massive hematemesis with or without melena. Associated signs range from mild postural tachycardia to profound shock, depending on the extent of blood loss and degree of hypovolemia. Because patients with varices may bleed just as frequently from other gastrointestinal lesions (e.g., peptic ulcer, gastritis), exclusion of other bleeding sources is important even in patients with prior variceal hemorrhage. Endoscopy is the best approach to evaluate upper gastrointestinal hemorrhage in patients with known or suspected portal hypertension.

TREATMENT

Management of Acute Bleeding (See Fig. 289-1) Variceal bleeding is a life-threatening emergency. Prompt estimation and vigorous replacement of blood loss to maintain intravascular volume are essential and take precedence over diagnostic studies and more specific intervention to stop the bleeding. However, excessive fluid administration can increase portal pressure with resultant further bleeding and should therefore be avoided. Replacement of clotting factors with fresh-frozen plasma is important in patients with coagulopathy. Patients are best managed in an intensive care unit and require close monitoring of central venous or pulmonary capillary wedge pressures, urine output, and mental status. When the patient is hemodynamically stable, attention should be directed toward specific diagnostic studies (especially endoscopy) and other therapeutic modalities to prevent further or recurrent bleeding.

About half of all episodes of variceal hemorrhage cease without intervention, although the risk of rebleeding is very high. The medical management of acute variceal hemorrhage includes the use of vasoconstrictors (somatostatin/octreotide or vasopressin), balloon tamponade, and endoscopic variceal ligation (EVL) or sclerosis of varices (sclerotherapy). Intravenous infusion of *vasopressin* at a rate of 0.1 to 0.4 U/min results in generalized vasoconstriction leading to diminished blood flow in the portal venous system. Intravenous infusion of vasopressin is as effective as selective intraarterial administration. Control of bleeding can be achieved in up to 80% of cases, but bleeding recurs in more than half after the vasopressin is tapered and discontinued. Furthermore, a number of serious side effects, including cardiac and gastrointestinal tract ischemia, acute renal failure, and hyponatremia, may be associated with vasopressin therapy. Concurrent use of venodilators such as nitroglycerin as an intravenous infusion or isosorbide dinitrate sublingually may enhance the effectiveness of vasopressin and reduce complications. *Somatostatin* and its analogue, *octreotide*, are direct splanchnic vasoconstrictors. In some studies somatostatin, given as an initial 250-μg bolus followed by constant infusion (250 μg/h), has been found to be as effective as vasopressin. Octreotide at doses of 50 to 100 μg/h is also effective. These agents are preferable to vasopressin, offering equivalent efficacy with fewer complications. If bleeding is too vigorous or endoscopy is not available, *balloon tamponade* of the bleeding varices may be accomplished with a triple-lumen (Sengstaken-Blakemore) or four-lumen (Minnesota) tube with esophageal and gastric balloons. Because of the high risk of aspiration, endotracheal intubation should be performed prior to placing one of these tubes. After the tube is introduced into the stomach, the gastric balloon is inflated and pulled back into the cardia of the stomach. If bleeding does not stop, the esophageal balloon is inflated for additional tamponade. Complications occur in 15% or more of patients and include aspiration pneumonitis as well as esophageal rupture.

Where available, *endoscopic intervention* should be employed as the first-line treatment to control bleeding acutely (Chaps. 37 and 272). EVL, in which esophageal varices are ligated and strangulated by endoscopically placed small elastic O-rings, has generally supplanted endoscopic injection of sclerosants in the control of acute variceal bleeding. EVL controls acute bleeding in up to 90% of cases and should be repeated until obliteration of all varices is accomplished.

Surgical treatment of portal hypertension and variceal bleeding involves the creation of a portal-systemic shunt to permit decompression of the portal system. Two types of portal systemic shunts have been used: nonselective shunts, to decompress the entire portal system, and selective shunts, intended to decompress only the varices while maintaining blood flow to the liver itself. Nonselective shunts include end-to-side or side-to-side portacaval and proximal splenorenal anastomoses; selective shunts include the distal splenorenal shunt. Nonselective shunts are more likely to be complicated by encephalopathy than selective shunts. Emergency portal-systemic nonselective shunts may control acute hemorrhage, but such surgery is usually used only as a last resort because early operative mortality can be high.

In TIPS, a technique developed to create a portal-systemic shunt by a percutaneous approach, an expandable metal stent is advanced under angiographic guidance to the hepatic veins and then through the substance of the liver to create a direct portacaval channel. This technique offers an alternative to surgery for refractory bleeding due to portal hypertension. However, stents frequently undergo stenosis or become occluded over a period of months, necessitating revision, a second TIPS, or an alternative approach. Encephalopathy may occur after TIPS, just as in the surgical shunts, and is especially problematic in the elderly and those patients with preexisting encephalopathy. TIPS should be reserved for those individuals who fail endoscopic or medical management and are poor surgical risks. TIPS sometimes serves a useful role as a "bridge" for those patients with end-stage cirrhosis awaiting liver transplantation. Procedures such as esophageal transection have also been advocated for the management of acute variceal bleeding, but their efficacy remains unproven, and these procedures are usually considered a last resort.

The management of bleeding gastric fundal varices, found either alone or in conjunction with esophageal varices, is more problematic, since banding and sclerotherapy are generally not effective. Vasoactive pharmacologic therapy should be instituted, but TIPS or shunt surgery should be considered because of high failure and rebleeding rates. For isolated gastric varices, splenic vein thrombosis should be specifically sought, since splenectomy is curative.

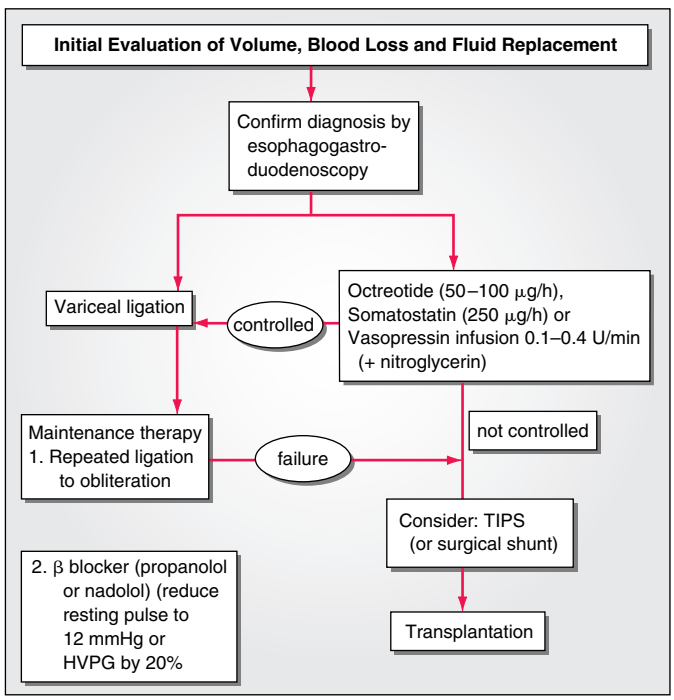

FIGURE 289-1 Approach to the patient with bleeding esophageal varices. Use of a beta blocker is the only intervention demonstrated to offer prophylactic benefit in a patient who has never bled. TIPS, transjugular intrahepatic portosystemic shunt; HVPG, hepatic venous pressure gradient.

Prevention of First Hemorrhage Prophylactic treatment with nonselective β-adrenergic antagonists (propranolol or nadolol) in patients with large ("high-risk") varices that have never bled appears to decrease the incidence of bleeding by 40 to 50% and prolong survival. Thus, endoscopic screening for varices in patients with cirrhosis is desirable; some have suggested this should be repeated every other year.

Although prophylactic banding of esophageal varices in the absence of proven bleeding cannot yet be recommended, one report suggests that banding may be more effective than beta-blockade in primary prevention of variceal bleeding in high-risk patients.

Prevention of Recurrent Hemorrhage Obliteration of varices by endoscopic band ligation reduces risk of recurrent hemorrhage by >50%. Pharmacologic agents also have demonstrated benefit. While the utility of beta blockers can be limited by concomitant hypotension, a number of studies demonstrate their value in secondary prevention of recurrent variceal hemorrhage. Pharmacologic and endoscopic therapy are comparable in overall reduction of rebleeding risk, but the subgroup of patients who achieve hemodynamic response to pharmacologic therapy appears to experience survival benefit.

Patients with portal hypertension in the absence of specific contraindications should be given propranolol or nadolol in doses that produce a 25% reduction in the resting heart rate or a reduction in the HVPG to 12 mmHg or 20% below baseline, where available. Propranolol may also prevent recurrent bleeding from severe portal hypertensive gastropathy in patients with cirrhosis. The optimal combination of endoscopic and pharmacologic therapy for prevention of recurrent hemorrhage remains to be established.

The role of portal-systemic shunt surgery after initial control of bleeding by nonoperative means is also uncertain. Surgically created shunts effectively reduce the risk of recurrent hemorrhage, but the overall mortality of patients undergoing such surgery is comparable to that of unoperated patients. Although patients who have undergone portal-systemic surgery succumb to recurrent bleeding less commonly than unoperated patients, this improvement is counterbalanced by increased morbidity from encephalopathy and death from progressive liver failure. Increasingly, therapeutic portal-systemic shunts have been reserved for patients who experience further bleeding despite serial endoscopic therapy.

Portal Hypertensive Gastropathy Although variceal hemorrhage is the most commonly encountered bleeding complication of portal hypertension, many patients will develop a congestive gastropathy due to the venous hypertension. In this condition, identified by endoscopic examination, the mucosa appears engorged and friable. Indolent mucosal bleeding occurs rather than the brisk hemorrhage typical of a variceal source. β-Adrenergic blockade with propranolol (reducing splanchnic arterial pressure as well as portal pressure) is sometimes effective in ameliorating this condition. Proton pump inhibitors or other agents useful in the treatment of peptic disease are usually not helpful.

SPLENOMEGALY ■ Definition and Pathogenesis Congestive splenomegaly is common in patients with severe portal hypertension. Rarely, massive splenomegaly from nonhepatic disease leads to portal hypertension due to increased blood flow in the splenic vein.

Clinical Features Although usually asymptomatic, splenomegaly may be massive and contribute to the thrombocytopenia or pancytopenia of cirrhosis. In the absence of cirrhosis, splenomegaly in association with variceal hemorrhage should suggest the possibility of splenic vein thrombosis.

℞ TREATMENT

Splenomegaly usually requires no specific treatment, although massive enlargement of the spleen may occasionally necessitate splenectomy at the time of shunt surgery. However, it should be noted that splenectomy without an accompanying shunt may actually increase portal pressure, and portal vein thrombosis may result from splenectomy. Splenectomy may also be indicated if splenomegaly is the cause rather than the result of portal hypertension (as in splenic vein thrombosis). Thrombcytopenia alone is rarely severe enough to necessitate removal of the spleen. Splenectomy should be avoided in a patient eligible for liver transplantation.

ASCITES ■ Definition Ascites is the accumulation of excess fluid within the peritoneal cavity. It is most frequently encountered in patients with cirrhosis and other forms of severe liver disease, but a number of other disorders may lead to either transudative or exudative ascites (Chap. 39).

Pathogenesis The accumulation of ascitic fluid represents a state of total-body sodium and water excess, but the event that initiates this imbalance is unclear. Three theories have been proposed (Fig. 289-2). The "underfilling" theory suggests that the primary abnormality is inappropriate sequestration of fluid within the splanchnic vascular bed due to portal hypertension and a consequent decrease in effective circulating blood volume. According to this theory, an apparent decrease in intravascular volume (underfilling) is sensed by the kidney, which responds by retaining salt and water. The "overflow" theory suggests that the primary abnormality is inappropriate renal retention of salt and water in the absence of volume depletion. A third, more attractive theory, the peripheral arterial vasodilation hypothesis, may unify the earlier theories and accounts for the constellation of arterial hypotension and increased cardiac output in association with high levels of vasoconstrictor substances that are routinely found in patients with cirrhosis and ascites. Again, sodium retention is considered secondary to arterial vascular underfilling and the result of a disproportionate increase of the vascular compartment due to arteriolar vasodilation rather than from decreased intravascular volume. According to this theory, portal hypertension results in splanchnic arteriolar vasodilation, mediated by nitric oxide, and leading to underfilling of the arterial vascular space and baroreceptor-mediated stimulation of renin-angiotensin, sympathetic output, and antidiuretic hormone release.

Regardless of the initiating event, a number of factors contribute to accumulation of fluid in the abdominal cavity (Fig. 289-2). Elevated levels of serum epinephrine and norepinephrine have been well documented. *Increased central sympathetic outflow* is found in patients with cirrhosis and ascites but not in those with cirrhosis alone. Increased sympathetic output results in diminished natriuresis by acti-

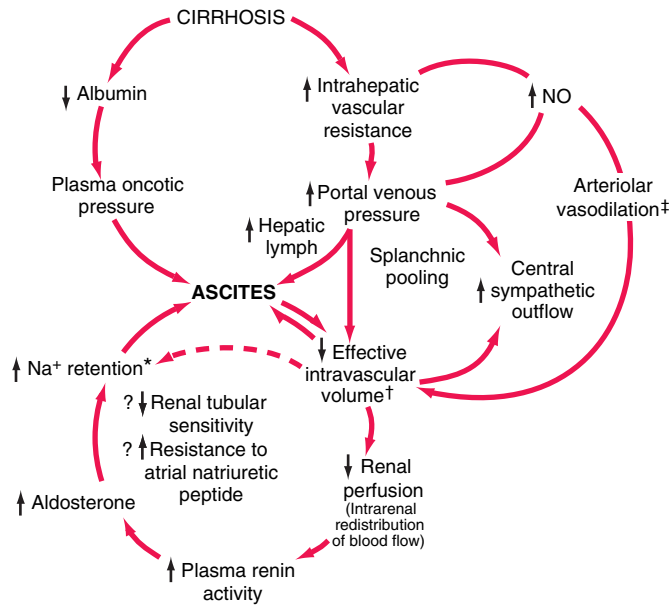

FIGURE 289-2 Multiple factors involved in development of ascites. Current concepts suggest that initiating factor may be primary sodium retention (*"overflow"), diminished effective intravascular volume (†"underfilling"), or arteriolar vasodilation (‡"vasodilation"). NO, nitric oxide.

vation of the renin-angiotensin system and diminished sensitivity to atrial natriuretic peptide. *Portal hypertension* plays an important role in the formation of ascites by raising hydrostatic pressure within the splanchnic capillary bed. *Hypoalbuminemia* and *reduced plasma oncotic pressure* also favor the extravasation of fluid from plasma to the peritoneal cavity, and thus ascites is infrequent in patients with cirrhosis unless both portal hypertension and hypoalbuminemia are present. Hepatic lymph may weep freely from the surface of the cirrhotic liver due to distortion and obstruction of hepatic sinusoids and lymphatics and contributes to ascites formation. In contrast to the contribution of transudative fluid from the portal vascular bed, hepatic lymph may weep into the peritoneal cavity even in the absence of marked hypoproteinemia because the endothelial lining of the hepatic sinusoids is discontinuous. This mechanism may account for the high protein concentration present in the ascitic fluid of some patients with venoocclusive disease or the Budd-Chiari syndrome.

Renal factors also play an important role in perpetuating ascites. Patients with ascites fail to excrete a water load in a normal fashion. They have increased renal sodium reabsorption by both proximal and distal tubules, the latter due largely to increased plasma renin activity and secondary hyperaldosteronism. Insensitivity to circulating atrial natriuretic peptide, often present in elevated concentrations in patients with cirrhosis and ascites, may be an important contributory factor in many patients. This insensitivity has been documented in those patients with the most severely impaired sodium excretion, who typically also exhibit low arterial pressure and marked overactivity of the renin-aldosterone axis. Renal vasoconstriction, perhaps resulting from increased serum prostaglandin or catecholamine levels, may also contribute to sodium retention. Recently a role for endothelin, a potent vasoconstrictor peptide, has been proposed. While elevated levels have been reported by some, this has not been observed by others.

Clinical Features and Diagnosis Usually ascites is first noticed by the patient because of increasing abdominal girth. More pronounced accumulation of fluid may cause shortness of breath because of elevation of the diaphragm. When peritoneal fluid accumulation exceeds 500 mL, ascites may be demonstrated on physical examination by the presence of shifting dullness, a fluid wave, or bulging flanks. Ultrasound examination, preferably with a Doppler study, can detect smaller quantities of ascites and should be performed when physical examination is equivocal or when the cause of the recent onset of ascites is not clear (e.g., exclude Budd-Chiari syndrome).

TREATMENT

(See Fig. 289-3) A thorough search should be made for precipitating factors in the patient with recent onset of or worsening ascites, e.g., excessive salt intake, medication noncompliance, superimposed infection, worsening liver disease, portal vein thrombosis, or development of hepatocellular carcinoma. When ascites develops in the setting of severe, acute liver disease, resolution of ascites is likely to follow improvement in liver function. More commonly, ascites develops in patients with stable or steadily worsening liver function. Paracentesis should usually be performed with a small-gauge needle at the time of initial evaluation or at the time of any clinical deterioration of a cirrhotic patient with ascites. A small amount of fluid (<200 mL) should be obtained and examined for evidence of infection, tumor, or other possible causes and complications of ascites. Therapeutic intervention is indicated both to prevent potential complications and to control progressive increase in ascites, which may become pronounced enough to cause physical discomfort. For the patient with a modest accumulation, therapy can be undertaken as an outpatient and should be gentle and incremental (see below). The goal is the loss of no more than 1.0 kg/d if both ascites and peripheral edema are present and no more than 0.5 kg/d in patients with ascites alone. In some patients, particularly those with a large accumulation of fluid, it may be desirable to hospitalize the patient so that daily weights and frequent serum

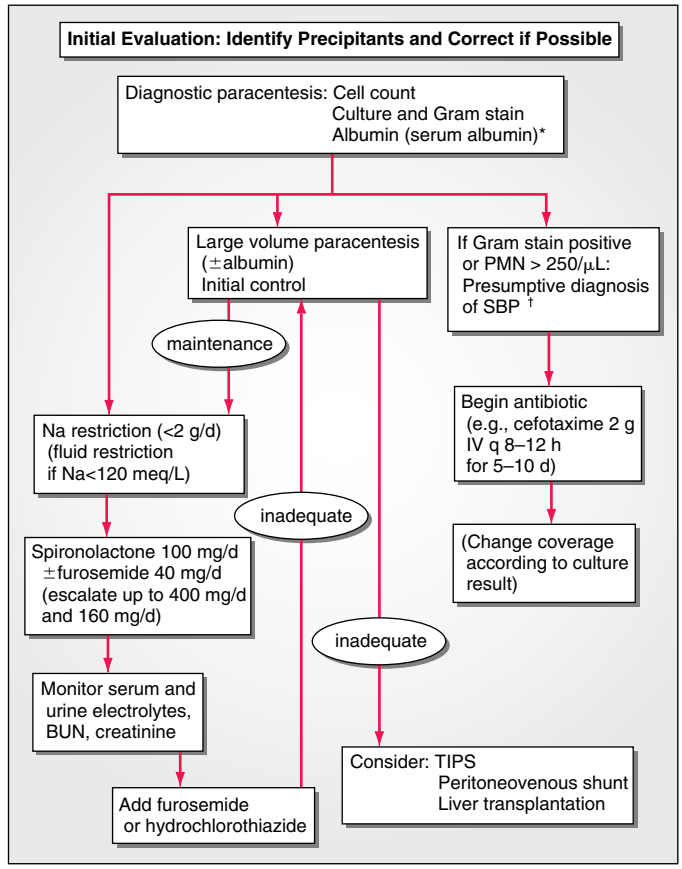

FIGURE 289-3 Approach to the patient with ascites [and spontaneous bacterial peritonitis (SBP)]. PMN, polymorphonuclear leukocytes; TIPS, transjugular intrahepatic portosystemic shunt. *Calculate SAAG [serum ascites albumin gradient = serum albumin − ascites albumin (g/dL)] to confirm high gradient (>1.1 g/dL) in portal hypertension. †If PMN >250/μL but culture is negative = culture negative neutrocytic ascites; begin empirical antibiotic and retap at 48 h; if culture is positive but PMN < 250/μL normal = monomicrobial nonneutrocytic bacterascites; retap; treat if PMN > 250/μL: if polymicrobial infection, exclude secondary peritonitis. U_{Na}, urinary sodium; U_{Ka}, urinary potassium; BUN, blood urea nitrogen.

electrolyte levels can be monitored and compliance ensured. Although abdominal girth measurements are frequently used as an index of fluid loss, they tend to be unreliable.

Salt restriction is the cornerstone of therapy. A diet containing 800 mg sodium (2 g NaCl) is often adequate to induce a negative sodium balance and permit diuresis. Response to salt restriction alone is more likely to occur if the ascites is of recent onset, the underlying liver disease is reversible, a precipitating factor can be corrected, or the patient has a high urinary sodium excretion (>25 mmol/d) and normal renal function. Fluid restriction of approximately 1000 mL/d does little to enhance diuresis but may be necessary to correct hyponatremia. If sodium restriction alone fails to result in diuresis and weight loss, diuretics should be prescribed. Because of the role of hyperaldosteronism in sustaining salt retention, spironolactone or other distal tubule–acting diuretics (triamterene, amiloride) are the drugs of choice. The development of azotemia or hyperkalemia may be limiting or even warrant a reduction in the dose of these medications. In some patients, diuresis does not occur despite maximal doses of distal tubule–acting agents because of avid proximal tubular sodium absorption. More potent, proximally acting diuretics (furosemide, bumetanide, torasemide) may be added to the regimen. Thus, spironolactone is initially given at a dose of 100 mg/d with or without furosemide, 40 mg/d, and both agents may be increased by 100- and 40-mg increments respectively: total dose should not exceed 400 mg/d and 160 mg/d, respectively. An indication of the minimum effective dose of spironolactone may be obtained by monitoring urinary electrolyte concentrations for a rise in sodium and fall in potassium concentrations, reflecting effective

competitive inhibition of aldosterone. Great caution should be exercised to avoid plasma volume depletion, azotemia, and hypokalemia, which may lead to encephalopathy.

In patients with pronounced ascites, particularly those requiring hospitalization, large-volume paracentesis has proven to be an effective and less costly approach to initial management than prolonged bed rest and conventional diuretic treatment. In this approach, ascitic fluid is removed by peritoneal cannula using strict aseptic techniques and monitoring hemodynamic and renal function. This can be safely accomplished in a single session. Concomitant albumin replacement by intravenous infusion is prudent in the patient without peripheral edema, to avoid depleting the intravascular space and precipitating hypotension. Maintenance diuretic therapy in conjunction with sodium restriction may then be instituted to avoid recurrent ascites.

A minority of patients with advanced cirrhosis have "refractory ascites" or rapidly reaccumulate fluid after control by paracentesis. In some patients, a side-to-side *portacaval shunt* may result in improvement in ascites, although generally these patients are extremely poor surgical risks. In the past, intractable ascites has also been treated with the surgical implantation of a plastic *peritoneovenous shunt*, which has a pressure-sensitive, one-way valve allowing ascitic fluid to flow from the abdominal cavity to the superior vena cava. However, the usefulness of this technique is limited by a high rate of complications such as infection, disseminated intravascular coagulation, and thrombosis of the shunt. More recently, in selected patients, TIPS has been used effectively to control refractory ascites, although portal decompression, while mobilizing ascitic fluid, has precipitated severe hepatic encephalopathy in some patients. None of these shunts has been shown to extend life expectancy.

SPONTANEOUS BACTERIAL PERITONITIS (SBP) Patients with ascites and cirrhosis may develop acute bacterial peritonitis without an obvious primary source of infection. Patients with advanced liver disease are particularly susceptible to SBP, which portends a poor prognosis (Chap. 112).

HEPATORENAL SYNDROME ■ Definition and Pathogenesis Hepatorenal syndrome is a serious complication in the patient with cirrhosis and ascites and is characterized by worsening azotemia with avid sodium retention and oliguria in the absence of identifiable specific causes of renal dysfunction. The exact basis for this syndrome is not clear, but altered renal hemodynamics appear to be involved. There is evidence for inappropriate intense renal vasoconstriction, perhaps in response to the splanchnic vasodilation accompanying cirrhosis. The kidneys are structurally intact; urinalysis and pyelography are usually normal. Renal biopsy, although rarely needed, is also normal, and in fact, kidneys from such patients have been used successfully for renal transplantation.

Clinical Features and Diagnosis Worsening azotemia, hyponatremia, progressive oliguria, and hypotension are the hallmarks of the hepatorenal syndrome. This syndrome, which is distinct from prerenal azotemia, may be precipitated by severe gastrointestinal bleeding, sepsis, or overly vigorous attempts at diuresis or paracentesis; it may also occur without an obvious cause. It is essential to exclude other causes of renal impairment often seen in these patients. These include prerenal azotemia or acute tubular necrosis due to hypovolemia (e.g., secondary to gastrointestinal bleeding or diuretic therapy) or an increased nitrogen load such as that seen as a result of bleeding. Drug nephrotoxicity is also often a consideration, particularly in the patient who has received agents such as aminoglycosides or contrast dye. The diagnosis rests on the finding of an elevated serum creatinine level [>133 μmol/L (>1.5 g/dL)] that fails to improve with volume expansion or withdrawal of diuretics, together with an unremarkable urine sediment. The diagnosis is supported by the demonstration of avid urinary sodium retention. Typically, the urine sodium concentration is <5 mmol/L, a concentration lower than that generally found in uncomplicated prerenal azotemia.

℞ TREATMENT

Treatment is usually unsuccessful. Although some patients with hypotension and decreased plasma volume may respond to infusions of salt-poor albumin, volume expansion must be undertaken with caution to avoid precipitating variceal bleeding. Vasodilator therapy, including intravenous infusions of low dose dopamine, is not effective. Evidence for the benefit of systemic vasoconstrictors alone or in combination with other agents such as terlipressin, norepinephrine with albumin, and octreotide with midodrine has emerged recently, but additional study is needed. While TIPS has been reported to improve renal function in some patients, its use cannot be recommended. In appropriate candidates, the treatment of choice for hepatorenal syndrome is liver transplantation. In patients with spontaneous bacterial peritonitis, early intravenous albumin infusion can prevent development of hepatorenal syndrome in some patients.

HEPATIC ENCEPHALOPATHY ■ Definition Hepatic (portal-systemic) encephalopathy is a complex neuropsychiatric syndrome characterized by disturbances in consciousness and behavior, personality changes, fluctuating neurologic signs, asterixis or "flapping tremor," and distinctive electroencephalographic changes. Encephalopathy may be *acute* and reversible or *chronic* and progressive. In severe cases, irreversible coma and death may occur. Acute episodes may recur with variable frequency.

Pathogenesis The specific cause of hepatic encephalopathy is unknown. The most important factors in the pathogenesis are severe hepatocellular dysfunction and/or intrahepatic and extrahepatic shunting of portal venous blood into the systemic circulation so that the liver is largely bypassed. As a result of these processes, various toxic substances absorbed from the intestine are not detoxified by the liver and lead to metabolic abnormalities in the central nervous system (CNS). *Ammonia* is the substance most often incriminated in the pathogenesis of encephalopathy. Many, but not all, patients with hepatic encephalopathy have elevated blood ammonia levels, and recovery from encephalopathy is often accompanied by declining blood ammonia levels. Other compounds and metabolites that may contribute to the development of encephalopathy include mercaptans (derived from intestinal metabolism of methionine), short-chain fatty acids, and phenol. *False neurochemical transmitters* (e.g., octopamine), resulting in part from alterations in plasma levels of aromatic and branched-chain amino acids, may also play a role. An increase in the permeability of the blood-brain barrier to some of these substances may be an additional factor involved in the pathogenesis of hepatic encephalopathy. Several observations suggest that excessive concentrations of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter, in the CNS are important in the reduced levels of consciousness seen in hepatic encephalopathy. Increased CNS GABA may reflect failure of the liver to extract precursor amino acids efficiently or to remove GABA produced in the intestine. In support of this, there is also evidence to suggest that endogenous benzodiazepines, which act through the GABA receptor, may contribute to the development of hepatic encephalopathy. This evidence includes isolation of 1,4-benzodiazepines from brain tissue of patients with fulminant hepatic failure as well as the partial response observed in some patients and experimental animals after administration of flumazenil, a benzodiazepine antagonist. However, the inconsistent effect of flumazenil in patients with encephalopathy, as well as potential methodologic pitfalls in the measurement of endogenous benzodiazepines, preclude definitive attribution of a role to these substances in the pathogenesis of hepatic encephalopathy. The finding of direct enhancement of GABA receptor activation by ammonia suggests that several of the factors described above may be operating via a final common pathway to produce the neuronal depression of hepatic encephalopathy. Finally, the observation of hyperintensity in the basal ganglia by magnetic resonance imaging in cirrhotic patients suggests that excessive *manganese* dep-

TABLE 289-3 Common Precipitants of Hepatic Encephalopathy

Increased nitrogen load	Drugs
Gastrointestinal bleeding	Narcotics, tranquilizers, sedatives
Excess dietary protein	Diuretics (see ''Electrolyte imbalance'')
Azotemia	Miscellaneous
Constipation	Infection
Electrolyte and metabolic imbalance	Surgery
Hypokalemia	Superimposed acute liver disease
Alkalosis	Progressive liver disease
Hypoxia	Portal-systemic shunts
Hyponatremia	
Hypovolemia	

osition may also contribute to the pathogenesis of hepatic encephalopathy. Further studies are needed to determine whether chelation therapy exerts long-term benefit.

In the patient with otherwise stable cirrhosis, hepatic encephalopathy often follows a clearly identifiable precipitating event (Table 289-3). Perhaps the most common predisposing factor is *gastrointestinal bleeding*, which leads to an increase in the production of ammonia and other nitrogenous substances, which are then absorbed. Similarly, *increased dietary protein* may precipitate encephalopathy as a result of increased production of nitrogenous substances by colonic bacteria. *Electrolyte disturbances*, particularly hypokalemic alkalosis secondary to overzealous use of diuretics, vigorous paracentesis, or vomiting, may precipitate hepatic encephalopathy. Systemic alkalosis causes an increase in the amount of nonionic ammonia (NH_3) relative to ammonium ions (NH_4). Only nonionic (uncharged) ammonia readily crosses the blood-brain barrier and accumulates in the CNS. Hypokalemia also directly stimulates renal ammonia production. Injudicious use of CNS-depressing drugs (e.g., barbiturates, benzodiazepines) and acute infection may trigger or aggravate hepatic encephalopathy, although the mechanisms involved are not clear. Other potential precipitating factors include superimposed acute viral hepatitis, alcoholic hepatitis, extrahepatic bile duct obstruction, constipation, surgery, and other coincidental medical complications.

Hepatic encephalopathy has protean manifestations, and any neurologic abnormality, including focal deficits, may be encountered. In patients with acute encephalopathy, neurologic deficits are completely reversible upon correction of underlying precipitating factors and/or improvement in liver function, but in patients with chronic encephalopathy, the deficits may be irreversible and progressive. Cerebral edema is frequently present and contributes to the clinical picture and overall mortality in patients with both acute and chronic encephalopathy.

The diagnosis of hepatic encephalopathy should be considered when four major factors are present: (1) acute or chronic hepatocellular disease and/or extensive portal-systemic collateral shunts (the latter may be either spontaneous, e.g., secondary to portal hypertension, or mechanically created, e.g., TIPS); (2) disturbances of awareness and mentation, which may progress from forgetfulness and confusion to stupor and finally coma; (3) shifting combinations of neurologic signs, including asterixis, rigidity, hyperreflexia, extensor plantar signs, and rarely, seizures; and (4) a characteristic (but nonspecific) symmetric, high-voltage, triphasic slow-wave (2 to 5 per second) pattern on the electroencephalogram. Asterixis ("liver flap," "flapping tremor") is a nonrhythmic asymmetric lapse in voluntary sustained position of the extremities, head, and trunk. It is best demonstrated by having the patient extend the arms and dorsiflex the hands. Because elicitation of asterixis depends on sustained voluntary muscle contraction, it is not present in the comatose patient. Asterixis is nonspecific and also occurs in patients with other forms of metabolic brain disease. Disturbances of sleep with reversal of sleep/wake cycles are among the earliest signs of encephalopathy. Alterations in personality, mood disturbances, confusion, deterioration in self-care and handwriting, and daytime somnolence are additional clinical features of encephalopathy. *Fetor hepaticus*, a unique musty odor of the breath and urine believed to be due to mercaptans, may be noted in patients with varying stages of hepatic encephalopathy.

TABLE 289-4 Clinical Stages of Hepatic Encephalopathy

Stage	Mental Status	Asterixis	EEG
I	Euphoria or depression, mild confusion, slurred speech, disordered sleep	+/−	Triphasic waves
II	Lethargy, moderate confusion	+	Triphasic waves
III	Marked confusion, incoherent speech, sleeping but arousable	+	Triphasic waves
IV	Coma; initially responsive to noxious stimuli, later unresponsive	−	Delta activity

Grading or classifying the stages of hepatic encephalopathy is often helpful in following the course of the illness and assessing response to therapy. One useful classification is shown in Table 289-4.

The diagnosis of hepatic encephalopathy is usually one of exclusion. There are no diagnostic liver function test abnormalities, although an elevated serum ammonia level in the appropriate clinical setting is highly suggestive of the diagnosis. Examination of the cerebrospinal fluid is unremarkable, and computed tomography of the brain shows no characteristic abnormalities until late in stage IV when cerebral edema may supervene. A number of conditions, particularly disorders related to acute and chronic alcoholism, can mimic the clinical features of hepatic encephalopathy. These include acute alcohol intoxication, sedative overdose, delirium tremens, Wernicke's encephalopathy, and Korsakoff's psychosis (Chap. 361). Subdural hematoma, meningitis, and hypoglycemia or other metabolic encephalopathies must also be considered, especially in patients with alcoholic cirrhosis. In young patients with liver disease and neurologic abnormalities, Wilson's disease should be excluded.

TREATMENT

(See Fig. 289-4) Early recognition and prompt treatment of hepatic encephalopathy are essential. Patients with acute, severe hepatic en-

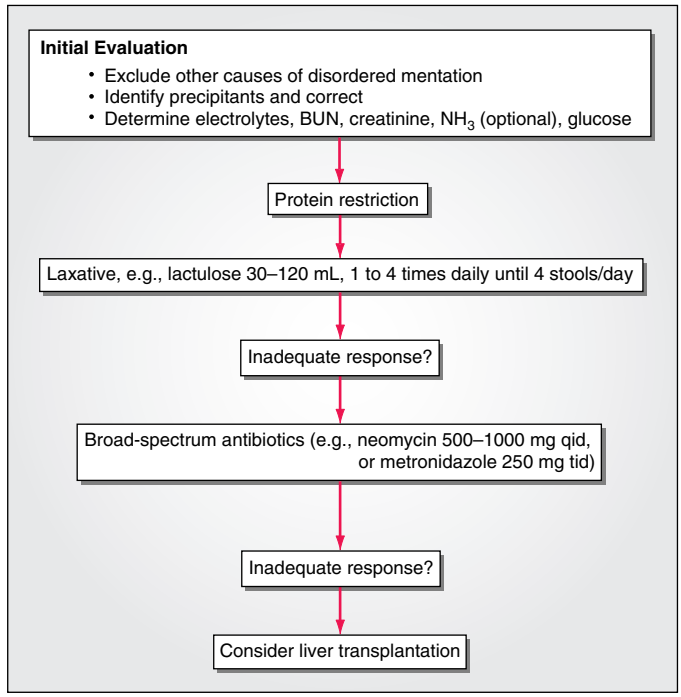

FIGURE 289-4 Approach to the patient with hepatic encephalopathy. BUN, blood urea nitrogen.

cephalopathy (stage IV) require the usual supportive measures for the comatose patient. Specific treatment of hepatic encephalopathy is aimed at (1) elimination or treatment of precipitating factors and (2) lowering of blood ammonia (and other toxin) levels by decreasing the absorption of protein and nitrogenous products from the intestine. In the setting of acute gastrointestinal bleeding, blood in the bowel should be promptly evacuated with laxatives (and enemas if necessary) in order to reduce the nitrogen load. Protein should be excluded from the diet, and constipation should be avoided. Ammonia absorption can be decreased by the administration of lactulose, a nonabsorbable disaccharide that acts as an osmotic laxative. Metabolism of lactulose by colonic bacteria may also result in an acid pH that favors conversion of ammonia to the poorly absorbed ammonium ion. In addition, lactulose may actually diminish ammonia production through its direct effects on bacterial metabolism. Acutely, lactulose syrup can be administered in a dose of 30 to 60 mL every hour until diarrhea occurs; thereafter the dose is adjusted (usually 15 to 30 mL three times daily) so that the patient has two to four soft stools daily. Intestinal ammonia production by bacteria can also be decreased by oral administration of a "nonabsorbable" antibiotic such as neomycin (0.5 to 1.0 g every 6 h). However, despite poor absorption, neomycin may reach sufficient concentrations in the bloodstream to cause renal toxicity. Equal benefits may be achieved with broad-spectrum antibiotics such as metronidazole. Flumazenil, a short-acting benzodiazepine antagonist, may have a role in management of hepatic encephalopathy precipitated by use of benzodiazepines, if there is a need for urgent therapy. Hemoperfusion to remove toxic substances and therapy directed primarily toward coincident cerebral edema in acute encephalopathy are also of unproven value. The efficacy of extracorporeal liver assist devices employing hepatocytes of porcine or human origin to bridge patients to recovery or transplantation is as yet unproven but is currently being studied.

Chronic encephalopathy may be effectively controlled by administration of lactulose. Management of patients with chronic encephalopathy should include dietary protein restriction (usually to 60 g/d) in combination with low doses of lactulose or neomycin. Nephrotoxicity or ototoxicity may be limiting in prolonged usage of neomycin. There are suggestions that vegetable protein may be preferable to animal protein.

OTHER SEQUELAE OF CIRRHOSIS ■ Coagulopathy Patients with cirrhosis often demonstrate a variety of abnormalities in both cellular and humoral clotting function. Thrombocytopenia may result from hypersplenism. In the alcoholic patient, there may be direct bone marrow suppression by ethanol. Diminished protein synthesis may lead to reduced production of fibrinogen (factor I), prothrombin (factor II), and factors V, VII, IX, and X. Reduction in levels of all factors except factor V may be worsened by the coincident malabsorption of the fat-soluble cofactor vitamin K due to cholestasis (Chap. 275). Of these, factor VII appears to be pivotal. In cirrhosis, it is the first of the factors to become depleted and, because of its short half-life, replacement with plasma often fails to correct an elevated prothrombin time. Preliminary studies suggest that selective replacement of factor VII can correct the prothrombin time in patients with cirrhosis.

Hepatocellular Carcinoma See Chap. 78.

HYPOXEMIA AND HEPATOPULMONARY SYNDROME ■ Definition and Pathogenesis Mild hypoxemia occurs in approximately one-third of patients with chronic liver disease. The hepatopulmonary syndrome is typically manifest by hypoxemia, platypnea, and orthodeoxia. Hypoxemia usually results from right-to-left intrapulmonary shunts through dilatations in intrapulmonary vessels that can be detected by contrast-enhanced echocardiography or a macroaggregated albumin lung perfusion scan. The mechanisms of shunt formation are unclear, but one animal model suggests that endothelin-1 levels and pulmonary nitric oxide, raised in cirrhosis, correlate with degree of shunting.

TREATMENT

No specific treatment is consistently effective, though large arteriovenous shunts may be embolized. It is now increasingly recognized that liver transplantation may eventually lead to amelioration of the hepatopulmonary syndrome in cases that have not yet been complicated by advanced pulmonary hypertension.

290 INFILTRATIVE, GENETIC, AND METABOLIC DISEASES AFFECTING THE LIVER

Daniel K. Podolsky

Many disseminated, systemic, or metabolic diseases involve the liver in a diffuse manner by the infiltration of abnormal cells or the accumulation of chemical substances or metabolites. Chemical accumulation may be extracellular or intracellular and may involve hepatocytes, Kupffer cells, or other elements of the reticuloendothelial system. Although infiltrative diseases may vary widely in cause and extrahepatic manifestations, the findings in the liver may be quite similar. Generalized enlargement and firmness of the liver, gradual and nonspecific deterioration of liver function, and, less often, signs of portal hypertension or ascites are typical features of this group of diseases. Differential diagnosis by clinical means may be difficult on occasion, but in patients in whom ancillary clinical findings do not establish the diagnosis, the diffusely infiltrated liver provides an excellent source of tissue for diagnostic purposes.

NONALCOHOLIC FATTY LIVER DISEASE (NAFLD), HEPATIC STEATOSIS (FATTY LIVER), AND NONALCOHOLIC STEATOHEPATITIS (NASH)

Slight to moderate enlargement of the liver due to a diffuse accumulation of neutral fat (triglycerides) in hepatocytes is an important clinical and pathologic finding. Imaging techniques such as computed tomography (CT), ultrasound, and magnetic resonance imaging (MRI) may each yield alterations suggesting increased fat in the liver. Several mechanisms can contribute to lipid accumulation in the liver. Fatty liver can be separated into two categories based on whether the fat droplets in the hepatocytes are macrovesicular or microvesicular (Table 290-1). In addition, fatty infiltration may be accompanied by necroinflammatory activity, a condition designated *nonalcoholic steatohepatitis*, a form of NAFLD. Although prospective data on natural history are limited, there is increasing evidence that patients may pro-

TABLE 290-1 Causes of Hepatic Steatosis

Macrovesicular (large fat droplets in hepatocytes)
Alcohol, alcoholic liver disease[a]

Microvascular (small fat droplets in hepatocytes)
Reye's syndrome
Acute fatty liver of pregnancy
Jamaican vomiting sickness
Drugs, e.g., valproic acid, tetracycline, nucleoside analogues
Environmental hepatotoxins (e.g., phosphorus, petrochemicals)

[a] May also be associated with necroinflammatory activity.

gress through several histologically distinct stages beginning with fatty liver and culminating in cirrhosis with intervening states of steatohepatitis and steatohepatitis with fibrosis (Fig. 290-1).

MACROVESICULAR FATTY LIVER This is the most common type of fatty liver and is seen most frequently in alcoholism or alcoholic liver disease, diabetes mellitus, obesity, and prolonged parenteral nutrition. Hematoxylin and eosin-stained liver sections show hepatocytes with large, empty vacuoles with the nucleus "pushed" to the periphery of the cell. In general, fat in the liver is not damaging per se, and the fat will disappear with improvement or elimination of the predisposing condition.

Etiology The major causes of fatty liver with macrovesicular fat depend on the age, geographic location, and metabolic-nutritional status of the patient population. *Chronic alcoholism* is the most common cause of hepatic steatosis in this country and in other countries with a high alcohol intake. The severity of fatty involvement is roughly proportional to the duration and degree of alcoholic excess. In addition, in western countries NAFLD/NASH is associated with obesity. Many of these patients (up to one-third) have type 2 diabetes and/or hyperlipidemia. The constellation of obesity, diabetes, hypertriglyceridemia, and hypertension has been designated *syndrome X* and has an especially strong association with progressive NAFLD. Age >45, obesity (body mass index ≥30), ratio of aspartate aminotransferase (AST)/ to alanine aminotransferase (ALT) >1, and diabetes are all associated with increased risk for development of significant fibrosis. Inflammatory activity when present may reflect the combined effects of oxidative stress, subsequent lipid peroxidation, and abnormal cytokine expression, especially increased tumor necrosis factor.

Protein malnutrition, especially in infancy and early childhood, accounts for most cases of severe fatty liver in the tropical zones of Africa, South America, and Asia. The hepatic changes may be associated with other clinical and pathologic features of kwashiorkor. *Jejunoileal bypass* for surgical treatment of morbid obesity was sometimes associated with severe fatty liver and hepatic failure that could be fatal. Ironically, patients with rapid weight loss or undergoing gastric bypass surgery for morbid obesity may also develop NAFLD. In patients with Cushing's syndrome and in those receiving large doses of glucocorticoids, fatty infiltration of the liver may occur. In many *chronic illnesses*, especially those complicated by impaired nutrition or malabsorption, increased fat is found in liver cells. For example, patients with severe ulcerative colitis, chronic pancreatitis, or protracted heart failure frequently have moderate hepatic steatosis at the time of death. Patients maintained on prolonged *total parenteral nutrition* may also develop a fatty liver. In some cases, fatty infiltration and steatohepatitis may occur in the absence of an identifiable cause.

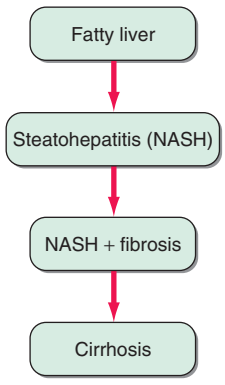

FIGURE 290-1 Hypothetical sequence of nonalcoholic fatty liver disease states. NASH, nonalcoholic steatohepatitis.

Acute fatty liver is caused by a number of hepatotoxins and is frequently accompanied by signs and symptoms of liver failure. Carbon tetrachloride intoxication, DDT poisoning, and ingestion of substances containing yellow phosphorus result in severe hepatic steatosis. Acute and prolonged alcohol ingestion may also be considered in this category and may be associated with a rapidly enlarging and fat-laden liver.

Clinical Features The signs and symptoms of hepatic steatosis are related to the degree of fat infiltration, the time course of its accumulation, and the underlying cause. The obese or diabetic patient with a chronic fatty liver is usually asymptomatic and has only mild tenderness over the enlarged liver. The liver function tests are normal or show mild elevations of alkaline phosphatase or aminotransferases. In contrast, the rapid accumulation of fat seen in the setting of hyperalimentation may lead to marked tenderness, presumably resulting from stretching of Glisson's capsule. Similarly, alcoholic patients with acute fatty liver following a bout of heavy drinking may have right upper quadrant pain and tenderness, often with laboratory evidence of cholestasis. The clinical presentation of fatty liver from hepatotoxins is similar to that of fulminant hepatic failure arising from any cause, with evidence of hepatic encephalopathy, marked elevations of prothrombin time and aminotransferases, and variable degrees of jaundice. Although steatohepatitis is generally thought to have a benign clinical course with improvement following elimination of the associated precipitant, in some individuals it may result in significant fibrosis and even cirrhosis. Recent studies indicate that substantial fibrosis or cirrhosis may be present in 15 to 50% of patients with NASH. In the only long-term follow-up study, 30% of patients with fibrosis had cirrhosis after 10 years. It is possible that some cases of "cryptogenic" cirrhosis are due to longstanding NASH and that the fat leaves the liver as end-stage liver disease develops.

Diagnosis The findings of a firm, nontender, and generally enlarged liver with minimal hepatic dysfunction in a patient with chronic alcoholism, malnutrition, poorly controlled diabetes mellitus, or obesity should suggest hepatic steatosis. This can usually be detected by CT, MRI, or ultrasound. Modest elevations of aminotransferases are often found in association with hepatic steatohepatitis. A disproportional elevation in AST leading to an AST/ALT ratio >2 is generally associated with alcoholic hepatitis. When diagnostic uncertainty exists, needle biopsy of the liver will demonstrate the increased fat content, the presence of any fibrosis, and possibly the underlying primary disorder.

TREATMENT

Adequate nutritional intake, removal of alcohol or offending toxins, and correction of any associated metabolic disorders usually result in recovery. There is no clinical rationale for the use of lipotropic agents such as choline. When indicated, attention should be directed to abstinence from alcohol, careful control of diabetes (by insulin therapy or use of oral hypoglycemic agents), weight loss, or correction of intestinal absorptive defects. In the alcoholic fatty liver, there is gradual disappearance of fat from the liver after 4 to 8 weeks of adequate diet and abstinence from alcohol. Similarly, fatty infiltration usually re-

solves within 2 weeks after discontinuation of parenteral hyperalimentation. Pilot studies in patients with NASH have suggested benefits from ursodiol, betaine (a precursor of S-adenosyl-methonione), and vitamin E and from phlebotomy. Troglitazone has shown some benefit in those patients with concomitant insulin resistance.

MICROVESICULAR FATTY LIVER This is the less common form of fatty liver. On microscopic examination, the fat is present in many small vacuoles. Although the droplets consist of triglycerides in both the macrovesicular and microvesicular forms, the reason for this difference in morphologic appearance is not clear.

Acute fatty liver of pregnancy (AFLP) is a syndrome that occurs late in pregnancy and is often associated with jaundice and hepatic failure. The liver is typically small. AFLP is more common when the mother is carrying a male fetus and may be associated with a deficiency of long-chain-3-hydroxy acyl COH dehydrogenase. AFLP usually necessitates termination of pregnancy due to the risk of rapid and fatal deterioration. Preeclampsia or the syndrome of *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count (HELLP), which may complicate eclampsia, presents in a similar fashion and progresses to severe liver dysfunction, though typically with a normal size liver. Aminotransferase elevations are typically modest in all of these conditions (generally <500). If diagnosed in time, the disease usually resolves with termination of the pregnancy. Recurrence in subsequent pregnancies is rare.

Microvesicular fat accumulation also may be seen as a toxic reaction to valproic acid and with excessive doses of tetracycline. It is a typical finding in *Jamaican vomiting sickness*, which is caused by hypoglycin A present in unripened ackee fruit. The combination of lactic acidosis and severe liver injury with microvesicular fat has been described as a complication of nucleoside analogue therapy.

REYE'S SYNDROME (FATTY LIVER WITH ENCEPHALOPATHY) This acute illness is encountered exclusively in children <15 years. It is characterized clinically by vomiting and signs of progressive central nervous system damage, signs of hepatic injury, and hypoglycemia. Morphologically, there is extensive fatty vacuolization of the liver and renal tubules. There is mitochondrial dysfunction with decreased activity of hepatic mitochondrial enzymes. The cause is unknown, although viral agents and drugs, especially salicylates, have been implicated. Increased aspirin use and much higher serum salicylate levels in children with this illness than in the general population have been described during outbreaks of Reye's syndrome. Recognition of this relationship and reduced aspirin use in this setting may account for the decreasing incidence of Reye's syndrome. However, this illness may occur in the absence of exposure to salicylates. In fatal cases, the liver is enlarged and yellow with striking diffuse fatty microvacuolization of cells. Peripheral zonal hepatic necrosis has also been present in some cases. Fatty changes of the renal tubular cells, cerebral edema, and neuronal degeneration of the brain are the major extrahepatic changes. Electron-microscopic studies show structural alterations of mitochondria in liver, brain, and muscle.

The onset usually follows an upper respiratory tract infection, especially influenza or chickenpox. Within 1 to 3 days, persistent vomiting occurs, together with stupor, which usually progresses rapidly to generalized convulsions and coma. The liver is enlarged, but *jaundice is characteristically absent or minimal*. Elevations in serum aminotransferases and prothrombin time, hypoglycemia, metabolic acidosis, and elevated serum ammonia levels are the major laboratory findings. The mortality rate in Reye's syndrome is approximately 50%. Therapy consists of infusions of 20% glucose and fresh-frozen plasma, as well as intravenous mannitol to reduce the cerebral edema. Chronic liver disease has not been reported in survivors.

STORAGE DISEASES

Lipid storage diseases include the hereditary disorders of Gaucher's and Niemann-Pick diseases. Other rare diseases associated with increased fat in the liver include abetalipoproteinemia, Tangier disease, Fabry's disease, and types I and V hyperlipoproteinemia (Chap. 335).

Hepatic enlargement caused by distention of liver cells with glycogen is present in some poorly controlled diabetics and frequently in juvenile diabetes. More often, however, hepatomegaly is due to fatty infiltration (see above). Ketoacidosis and vigorous insulin therapy may further enhance hepatic enlargement.

HEPATIC MINERAL ACCUMULATION

WILSON'S DISEASE This is an uncommon inherited disorder of copper metabolism. Wilson's disease usually presents clinically in adolescence or young adulthood by which time there is excess copper accumulation in the liver and other tissues. Deficiency of the plasma copper protein ceruloplasmin is a characteristic feature. The accumulation appears to result from impaired copper excretion due to a mutation in a gene that encodes a P-type ATPase copper transporter. Clinically, patients may present in teenage or early adult years with chronic hepatitis, cirrhosis, or their complications. A small number of patients will present with fulminant hepatitis. Liver disease is often accompanied by softening and degeneration of the basal ganglia (hepatolenticular degeneration) due to copper deposition, which results in extrapyramidal neurologic and psychiatric symptoms. Brownish pigmentation of Descemet's membrane in the cornea (Kayser-Fleischer rings) is frequently present. Hemolytic anemia is also common, especially with fulminant disease. Liver biopsy may reveal findings ranging from fulminant hepatitis to chronic hepatitis and macronodular cirrhosis, in addition to excess copper levels. Typically, liver cells are ballooned and show increased glycogen with glycogen vacuolization in the nuclei. All patients under age 40 with unexplained chronic hepatitis or cirrhosis should be evaluated for possible Wilson's disease. Prompt diagnosis is important; treatment, which must be continued throughout life, can prevent progression of end-organ damage. →***For further discussion, see Chap. 339.***

HEMOCHROMATOSIS Hemochromatosis may be the most common genetic disorder of humans; it involves accumulation of abnormal amounts of iron due to inappropriate absorption from the intestine. Between 85 and 95% of patients with genetic hemochromatosis are homozygous for a point mutation (cystine to tyrosine at codon 282: C282). The liver, as a primary site of iron storage, is affected most directly. There is diffuse deposition of excess iron in hepatocytes, in contrast to the characteristic accumulation of iron in the reticuloendothelial compartment typical of secondary iron overload and hemosiderosis. Excess hepatic iron commonly results in hepatomegaly. Although liver function is initially well preserved, if the disease is untreated, progressive impairment is followed by the development of cirrhosis. Prompt diagnosis can permit the institution of effective lifelong therapy to reduce the iron load and halt progression of the disease. → ***For further discussion, see Chap. 336.***

OTHER INFILTRATIVE AND METABOLIC DISEASES

α_1-ANTITRYPSIN DEFICIENCY Patients with homozygous deficiency of serum α_1-antitrypsin (α_1AT) are prone to develop emphysema in adult life. The disease is suggested by the absence of α_1-globulin on serum electrophoresis (α_1AT makes up 90% of this fraction normally) and confirmed by direct measurement of α_1AT. The exact phenotype can then be determined by electrophoresis. Although there are approximately 75 recognized alleles, only PiZ and PiS are associated with clinical disease. The molecular bases of these altered products have been related to single nucleic acid substitutions—e.g., PiZ is caused by a G (guanine) to A (adenine) transposition, which results in a substitution of a glutamic acid for lysine at residue 292 in the α_1AT protein. Hepatocytes of some patients with this deficiency contain globules positive with the periodic acid–Schiff reaction. Approximately 10% of children with homozygous deficiency (PiZZ phenotype) of α_1AT will develop significant liver disease, including neonatal hepatitis and progressive cirrhosis. It has been suggested that 15 to 20% of all chronic liver disease in infancy may be attributed to α_1AT defi-

ciency. In adults, the most common manifestation of α_1AT deficiency is asymptomatic cirrhosis, which may progress from a micronodular to a macronodular state and may be complicated by the development of hepatocellular carcinoma. The occurrence of liver disease in these patients is not dependent on the development of lung disease. →***For further discussion, see Chap. 242.***

HURLER'S SYNDROME This is an uncommon hereditary disease that is characterized by the widespread tissue deposition of mucopolysaccharide (chondroitin sulfate B and heparan sulfate) in many tissues. The liver is frequently enlarged and firm. Microscopically, Kupffer cells and other macrophages are enlarged and filled with metachromatic granular material. Cirrhosis may be a late complication. →***For further discussion, see Chap. 340.***

PORPHYRIAS See Chap. 337.

RETICULOENDOTHELIAL DISORDERS (See also Chaps. 52 and 98)

Moderate to massive hepatomegaly and splenomegaly occur frequently in the various types of *leukemia* and *lymphoma*. Jaundice, when present, is usually slight and results from hemolysis, although cholestasis may occasionally be associated with lymphoma as a paraneoplastic syndrome. Deep and protracted jaundice is distinctly rare and is caused by obstruction of the intrahepatic or extrahepatic bile ducts by tumor. Liver biopsy specimens reveal portal and sinusoidal infiltrates in most cases of leukemia, but the cellular pattern may be mixed and nonspecific. Liver biopsy is diagnostic in only 5% of patients with *Hodgkin's disease*. This percentage is increased in those with advanced disease or splenomegaly. Directed biopsy at laparoscopy or laparotomy is more likely to be positive than "blind" needle biopsy. Nonspecific histologic changes in the liver have been described in patients with lymphoma and may contribute to the abnormal liver function tests.

Myeloid metaplasia and other myeloproliferative disorders associated with extramedullary hematopoiesis produce hepatomegaly which may reach huge proportions, especially following splenectomy. Serum alkaline phosphatase elevations are often found. Ascites and portal hypertension, resulting from diffuse involvement of portal venules and lymphatics, are rare complications.

GRANULOMATOUS INFILTRATIONS

Perhaps as a result of the large population of mononuclear phagocytes, a number of systemic granulomatous diseases involve the liver, including sarcoidosis, miliary tuberculosis, histoplasmosis, brucellosis, schistosomiasis, berylliosis, and drug reactions (Table 290-2). In addition, isolated granulomas of no diagnostic importance may be found occasionally in patients with various forms of cirrhosis and hepatitis. The liver infiltrated by granulomas may be slightly enlarged and firm, but hepatic dysfunction is usually limited. Increases in serum alkaline phosphatase are common and may range from mild to marked. Occasionally, mild serum elevations in aminotransferases are also present. In a few patients with sarcoidosis or brucellosis, portal hypertension may develop, and extensive postnecrotic scarring or postnecrotic cirrhosis may follow healing of the granulomatous lesions, as in schistosomiasis.

Needle biopsy of the liver often provides the first definite evidence of a systemic or disseminated granulomatous disease. In patients with sarcoidosis who have neither clinical nor laboratory evidence of hepatic involvement, needle biopsy shows sarcoid granulomas in about 80% of cases. In cases of suspected miliary tuberculosis, a portion of the biopsy should be cultured and stained for mycobacteria. The organism can be detected in the majority of cases, particularly when caseating granulomas are present. Serial sections of the biopsy specimen should be examined if granulomas are not apparent. Individual granulomas are rarely specific in their microscopic appearance, and final diagnosis usually requires other clinical, laboratory, or histologic data.

In approximately 20% of patients, it is not possible to identify a cause for the granulomatous infiltration. When these infiltrates are accompanied by fever of unknown origin, the diagnosis of *granulomatous hepatitis* should be considered. This is an uncommon disorder of unknown cause and is diagnosed by exclusion. While granulomatous hepatitis invariably responds to moderate doses of glucocorticoids, relapses are frequent, and such therapy should never be undertaken unless tuberculous disease or other causes of granulomatous infiltration have been excluded. This may include an initial empirical trial of antituberculous therapy.

TABLE 290-2 Some Causes of Hepatic Granulomas

SYSTEMIC DISEASE	
Sarcoidosis	Berylliosis
Hodgkin's and non-Hodgkin's lymphoma	Crohn's disease
Primary biliary cirrhosis	Wegener's granulomatosis
	Granulomatous hepatitis, idiopathic
INFECTIONS	
Bacterial	Parasitic
Tuberculosis	Schistosomiasis
Mycobacterium avium-intracellulare	Rickettsial
Brucellosis	Q fever
Leprosy	Spirochetes
Viral	Syphilis
Epstein-Barr virus	Drugs
Cytomegalovirus	Sulfonamides
Chicken pox	Isoniazid
	Allopurinol

AMYLOIDOSIS (See also Chap. 310) Systemic amyloidosis, whether primary and idiopathic, familial, or secondary to chronic inflammatory or neoplastic diseases, often involves the liver. Grossly, the liver infiltrated with amyloid is enlarged and pale and rubbery in consistency. Microscopically, the birefringent amyloid deposits appear as homogeneous waxy material within the space of Disse, often being concentrated in the periportal areas and associated with atrophy of adjacent liver cell plates. Selective involvement of the walls of blood vessels, especially of the hepatic arterioles, may be a striking feature of primary amyloidosis. With this possible exception, however, the hepatic lesions are the same in all forms of amyloidosis and are present in 60 to 90% of cases.

An enlarged and firm liver is found in about 60% of patients, and ascites occurs in advanced stages of the disease in about 20%. Jaundice, portal hypertension, and other signs of chronic liver disease are usually absent. Liver function changes, although frequent, correlate poorly with the extent of liver infiltration. Hypoalbuminemia and elevated serum alkaline phosphatase are common. Hypoalbuminemia, however, may be related to the presence of nephrosis; the prothrombin time is usually normal. The diagnosis is established by biopsy of rectum, skin, liver, or other involved organs and demonstration of the characteristic Congo red–staining deposits by polarizing microscopy.

AIDS-RELATED LIVER DISEASE

Liver disease has become an important cause of morbidity and mortality in patients with HIV/AIDS, due largely to complications derived from chronic active hepatitis involving co-infection with hepatitis B and/or C viruses (Chaps. 173 and 285). This has become particularly evident in the era of highly active antiretroviral therapy (HAART), which has been successful in decreasing the levels of HIV viremia (Chap. 173). Patients are living longer due to the beneficial effects of HAART, and their liver disease and its complications have assumed a more important role in determining the ultimate clinical course of these patients. The approach to such patients is discussed in detail in Chaps. 173 and 285. Other important sources of liver damage in HIV-infected individuals are the direct hepatotoxic effects of antiretroviral drugs used in the HAART regimens. This is particularly true of the non-nucleoside analogue nevirapine (Chap. 173) as well as certain of

the nucleoside analogues and protease inhibitors. Finally, patients with advanced HIV diseases commonly have evidence of secondary liver disease, generally mild, that is due to hepatic involvement with other systemic diseases. In these patients, hepatic granulomatous disease is often present and may be caused by opportunistic infections, with *Mycobacterium avium-intracellulare* being a common pathogen. Cytomegalovirus hepatitis and hepatic mycoses are less common. AIDS cholangiopathy is a well-recognized entity. It exhibits features similar to those found in primary sclerosing cholangitis and is typically associated with cryptosporidia, microsporidia, and/or cytomegalovirus infection in the biliary tree. Papillary stenosis is frequently present.

291 LIVER TRANSPLANTATION

Jules L. Dienstag

Liver transplantation—the replacement of the native, diseased liver by a normal organ (allograft)—has matured from an experimental procedure reserved for desperately ill patients to an accepted, lifesaving operation applied much earlier in the natural history of end-stage liver disease. The preferred and technically most advanced approach is *orthotopic transplantation*, in which the native organ is removed and the donor organ is inserted in the same anatomic location. Pioneered in the 1960s by Starzl at the University of Colorado and, later, at the University of Pittsburgh and by Calne in Cambridge, England, liver transplantation is now performed routinely by dozens of centers throughout North America and western Europe. Success measured as 1-year survival has improved from ~30% in the 1970s to >85% today. These improved prospects for prolonged survival, dating back to the early 1980s, resulted from refinements in operative technique, improvements in organ procurement and preservation, advances in immunosuppressive therapy, and, perhaps most influentially, more enlightened patient selection and timing. Despite the perioperative morbidity and mortality, the technical and management challenges of the procedure, and its costs, liver transplantation has become the approach of choice for selected patients whose chronic or acute liver disease is progressive, life-threatening, and unresponsive to medical therapy. Based on the current level of success, the number of liver transplants has continued to grow each year; in 2000 to 2002, approximately 4500 patients received liver allografts in the United States. Still, the demand for new livers continues to outpace availability; in the same period, >16,000 patients in the United States were on a waiting list for a donor liver. In response to this drastic shortage of donor organs, many transplantation centers have begun to supplement cadaver-organ liver transplantation with living-donor transplantation.

INDICATIONS Potential candidates for liver transplantation are children and adults who, in the absence of contraindications (see below), suffer from severe, irreversible liver disease for which alternative medical or surgical treatments have been exhausted or are unavailable. *Timing of the operation is of critical importance*. Indeed, improved timing and better patient selection are felt to have contributed more to the increased success of liver transplantation in the 1980s and beyond than all the impressive technical and immunologic advances combined. Although the disease should be advanced, and although opportunities for spontaneous or medically induced stabilization or recovery should be allowed, the procedure should be done sufficiently early to give the surgical procedure a fair chance for success. Ideally, transplantation should be considered in patients with end-stage liver disease who are experiencing or have experienced a life-threatening complication of hepatic decompensation, whose quality of life has deteriorated to unacceptable levels, or whose liver disease will result predictably in irreversible damage to the central nervous system (CNS). If this is done sufficiently early, the patient will not have developed any contraindications or extrahepatic systemic deterioration. Although patients with well-compensated cirrhosis can survive for many years, many patients with quasi-stable chronic liver disease have much more advanced disease than may be apparent. As discussed below, the better the status of the patient prior to transplantation, the higher will be the anticipated success rate of transplantation. The decision about *when* to transplant is complex and requires the combined judgment of an experienced team of hepatologists, transplant surgeons, anesthesiologists, and specialists in support services, not to mention the well-informed consent of the patient and the patient's family.

Transplantation in Children Indications for transplantation in children are listed in Table 291-1. The most common is *biliary atresia*. *Inherited or genetic disorders of metabolism* associated with liver failure constitute another major indication for transplantation in children and adolescents. In Crigler-Najjar disease type I and in certain hereditary disorders of the urea cycle and of amino acid or lactate-pyruvate metabolism, transplantation may be the only way to prevent impending deterioration of CNS function, despite the fact that the native liver is structurally normal. Combined heart and liver transplantation has yielded dramatic improvement in cardiac function and in cholesterol levels in children with homozygous familial hypercholesterolemia; combined liver and kidney transplantation has been successful in patients with hereditary oxalosis. In hemophiliacs with transfusion-associated hepatitis and liver failure, liver transplantation has been associated with recovery of normal factor VIII synthesis.

Transplantation in Adults Liver transplantation is indicated for end-stage *cirrhosis* of all causes (Table 291-1). In sclerosing cholangitis and *Caroli's disease* (multiple cystic dilatations of the intrahepatic biliary tree), recurrent infections and sepsis associated with inflammatory and fibrotic obstruction of the biliary tree may be an indication for transplantation. Because prior biliary surgery complicates, and is a relative contraindication for, liver transplantation, surgical diversion of the biliary tree has been all but abandoned for patients with sclerosing cho-

TABLE 291-1 *Indications for Liver Transplantation*

Children	Adults
Biliary atresia	Primary biliary cirrhosis
Neonatal hepatitis	Secondary biliary cirrhosis
Congenital hepatic fibrosis	Primary sclerosing cholangitis
Alagille's disease[a]	Caroli's disease[c]
Byler's disease[b]	Cryptogenic cirrhosis
α_1-Antitrypsin deficiency	Chronic hepatitis with cirrhosis
Inherited disorders of metabolism	Hepatic vein thrombosis
Wilson's disease	Fulminant hepatitis
Tyrosinemia	Alcoholic cirrhosis
Glycogen storage diseases	Chronic viral hepatitis
Lysosomal storage diseases	Primary hepatocellular malignancies
Protoporphyria	Hepatic adenomas
Crigler-Najjar disease type I	
Familial hypercholesterolemia	
Hereditary oxalosis	
Hemophilia	

[a] Arteriohepatic dysplasia, with paucity of bile ducts, and congenital malformations, including pulmonary stenosis.
[b] Intrahepatic cholestasis, progressive liver failure, mental and growth retardation.
[c] Multiple cystic dilatations of the intrahepatic biliary tree.

langitis. In patients who undergo transplantation for *hepatic vein thrombosis (Budd-Chiari syndrome)*, postoperative anticoagulation is essential; underlying myeloproliferative disorders may have to be treated but are not a contraindication to liver transplantation. If a donor organ can be located quickly, before life-threatening complications—including cerebral edema—set in, patients with *fulminant hepatitis* are candidates for liver transplantation. Initially controversial but now routine candidates for liver transplantation are patients with *alcoholic cirrhosis*, *chronic viral hepatitis*, and *primary hepatocellular malignancies*. Although all three of these categories are considered to be high risk, liver transplantation can be offered to carefully selected patients, and, currently chronic hepatitis C and alcoholic liver disease are the most common indications for liver transplantation, accounting for 40% of all adult candidates for the procedure. Patients with alcoholic cirrhosis can be considered as candidates for transplantation if they meet strict criteria for abstinence and reform. Patients with chronic hepatitis C have early allograft and patient survival comparable to those of other subsets of patients after transplantation; however, reinfection in the donor organ is universal, recurrent hepatitis C is insidiously progressive, the impact of antiviral therapy is limited, and cirrhosis and late organ failure (beyond 5 years) are being recognized with increasing frequency. In patients with chronic hepatitis B, in the absence of measures to prevent recurrent hepatitis B, survival after transplantation is reduced by approximately 10 to 20%; however, prophylactic use of hepatitis B immune globulin (HBIg) during and after transplantation increases the success of transplantation to a level comparable to that seen in patients with nonviral causes of liver decompensation. The specific oral antiviral drugs lamivudine and adefovir dipivoxil (Chap. 287) can be used for both prophylaxis against, and treatment of, recurrent hepatitis B, facilitating further the management of patients undergoing liver transplantation for end-stage hepatitis B. Issues of disease recurrence are discussed in more detail below. Patients with nonmetastatic primary hepatobiliary tumors—primary hepatocellular carcinoma, cholangiocarcinoma, hepatoblastoma, angiosarcoma, epithelioid hemangioendothelioma, and multiple or massive hepatic adenomata—have undergone liver transplantation; however, for hepatobiliary malignancies, overall survival is significantly lower than that for other categories of liver disease. To minimize the very high likelihood of recurrent tumor after transplantation, some centers are evaluating experimental adjuvant chemotherapy protocols. Some transplantation centers have reported excellent long-term, recurrence-free survival in patients with unresectable hepatocellular carcinoma for single tumors <5 cm in diameter or for three or fewer lesions all <3 cm. Consequently, most centers restrict liver transplanation to patients whose hepatic malignancies are confined to these limits. Because the likelihood of recurrent cholangiocarcinoma is almost universal, this tumor is no longer considered an indication for transplantation.

CONTRAINDICATIONS *Absolute contraindications* for transplantation include life-threatening systemic diseases, uncontrolled extrahepatic bacterial or fungal infections, preexisting advanced cardiovascular or pulmonary disease, multiple uncorrectable life-threatening congenital anomalies, metastatic malignancy, active drug or alcohol abuse, and HIV infection (Table 291-2). Because carefully selected patients in their sixties and even seventies have undergone transplantation successfully, advanced age per se is no longer considered an absolute contraindication; however, in older patients, a more thorough preoperative evaluation should be undertaken to exclude ischemic cardiac disease. Advanced age (>70 years), however, may be considered a *relative contraindication*—that is, a factor to be taken into account with other relative contraindications. Other relative contraindications include portal vein thrombosis, preexisting renal disease not associated with liver disease, intrahepatic or biliary sepsis, severe hypoxemia resulting from right-to-left intrapulmonary shunts, previous extensive hepatobiliary surgery, and any uncontrolled serious psychiatric disorder. Any one of these relative contraindications is insufficient in and of itself to preclude transplantation. For example, the problem of portal vein thrombosis can be overcome by constructing a graft from the donor liver portal vein to the recipient's superior mesenteric vein. Now that highly active antiretroviral therapy has dramatically improved the survival of persons with HIV infection (Chap. 173), and because chronic hepatitis C has emerged as a serious source of morbidity and mortality in the HIV-infected population, the applicability of liver transplantation to this previously excluded patient group is being reexamined. Clinical trials of liver transplantation for patients with HIV infection are in progress.

TABLE 291-2 Contraindications to Liver Transplantation

Absolute	Relative
Uncontrolled extrahepatobiliary infection	Age >70
Active, untreated sepsis	Prior extensive hepatobiliary surgery
Uncorrectable, life-limiting congenital anomalies	Portal vein thrombosis
Active substance or alcohol abuse	Renal failure
Advanced cardiopulmonary disease	Previous extrahepatic malignancy
Extrahepatobiliary malignancy	Severe obesity
Metastatic malignancy to the liver	Severe malnutrition/wasting
Cholangiocarcinoma	Medical noncompliance
AIDS	HIV seropositivity
Life-threatening systemic diseases	Intrahepatic sepsis
	Severe hypoxemia secondary to right-to-left intrapulmonary shunts
	Uncontrolled psychiatric disorder

TECHNICAL CONSIDERATIONS ■ **Cadaver Donor Selection** Cadaver donor livers for transplantation are procured primarily from victims of head trauma. Organs from brain-dead donors up to age 60 are acceptable if the following criteria are met: hemodynamic stability, adequate oxygenation, absence of bacterial or fungal infection, absence of abdominal trauma, absence of hepatic dysfunction, and serologic exclusion of hepatitis B and C viruses and HIV. Occasionally, organs from donors with hepatitis B and C are used, e.g., for recipients with prior hepatitis B and C, respectively. Donor organs with antibody to hepatitis B core antigen (anti-HBc) are used rarely, when the need is especially urgent, and recipients of these organs are treated prophylactically with HBIg and other antiviral drugs. Cardiovascular and respiratory functions are maintained artificially until the liver can be removed. Compatibility in ABO blood group and organ size between donor and recipient are important considerations in donor selection; however, ABO-incompatible or reduced-donor-organ transplants can be performed in emergency or marked donor-scarcity situations. Tissue typing for HLA matching is not required, and preformed cytotoxic HLA antibodies do not preclude liver transplantation. Following perfusion with cold electrolyte solution, the donor liver is removed and packed in ice. The use of University of Wisconsin (UW) solution, rich in lactobionate and raffinose, has permitted the extension of cold ischemic time up to 20 h; however, 12 h may be a more reasonable limit. Improved techniques for harvesting multiple organs from the same donor have increased the availability of donor livers, but the availability of donor livers is far outstripped by the demand. Currently, in the United States, all donor livers are distributed through a nationwide organ-sharing network [United Network of Organ Sharing (UNOS)] designed to allocate available organs based on regional considerations and recipient acuity. Recipients who require the highest level of care (intensive care) have the highest priority, but allocation strategies that balance highest urgency against best outcomes continue to evolve to distribute cadaver organs most effectively. Allocation based on the Child-Turcotte-Pugh (CTP) score, which uses five clinical variables (encephalopathy stage, ascites, bilirubin, albumin, and prothrombin time) and waiting time, has been supplanted by allocation based upon urgency alone, calculated by the Model for End-Stage Liver Disease (MELD) score. The MELD score is based upon a mathematical model that includes bilirubin, creatinine, and prothrombin time expressed as

international normalized ratio (INR) (Table 291-3). Neither waiting time (except as a tie breaker between two potential recipients with the same MELD scores) nor posttransplantation outcome is taken into account, but the MELD score has been shown to be the best predictor of pretransplantation mortality, satisfies the prevailing view that medical need should be the decisive determinant, and eliminates both the subjectivity inherent in the CTP scoring system (presence and degree of ascites and hepatic encephalopathy) and the differences in waiting times among different regions of the country. Because candidates for liver transplantation who have hepatocellular carcinoma may not be sufficiently decompensated to compete for donor organs based upon urgency criteria alone, and because protracted waiting for cadaver donor organs results often in tumor growth beyond acceptable limits for transplantation, such patients are assigned extra MELD points (Table 291-3).

TABLE 291-3 United Network for Organ Sharing (UNOS) Liver Transplantation Waiting List Criteria

PREVIOUS ALLOCATION SCHEME (IN ORDER OF DESCENDING URGENCY)	
Status 1	Fulminant hepatic failure (including primary graft nonfunction and hepatic artery thrombosis within 7 days after transplantation as well as acute decompensated Wilson's disease)[a]
Status 2A	Chronic liver disease with CTP[b] score ≥ 10, in intensive care unit, predicted <7 days to live, plus one of following: hepatic encephalopathy ≥ stage III, unresponsive variceal bleeding, heptorenal syndrome, refractory ascites or hepatic hydrothorax, coagulopathy with ongoing bleeding (cannot have extrahepatic sepsis, high-dose or double pressor dependency, or multiorgan failure)
Status 2B	Chronic liver disease with CTP score ≥ 10 or CTP score ≥ 7 plus one of following: variceal bleeding, heptorenal syndrome, history of spontaneous bacterial periotonitis, refractory ascites or hepatic hydrothorax, refractory bleeding
Status 3	CTP score ≥ 7
Status 7	Inactive
CURRENT ALLOCATION SCHEME	
The Model for End-Stage Liver Disease (MELD) score, on a continuous scale,[c] determines allocation of donor organs. This model is based upon the following calculation: $3.78 \times \log_e$ bilirubin (mg/100 mL) + $11.2 \times \log_e$ international normalized ratio (INR) + $9.57 \times \log_e$ creatinine (mg/100 mL) + 6.43 (× 0 for alcoholic and cholestatic liver disease, × 1 for all other types of liver disease).[d,e,f]	
Online calculators to determine MELD scores are available, such as *www.mayoclinic.org/gi-rst/mayomodel6.htm*	

[a] For children < 18 years, status 1 includes acute or chronic liver failure plus hospitalization in an intensive care unit or inborn errors of metabolism.

[b] Child-Turcotte-Pugh (CTP) score components

Points	1	2	3
Encephalopathy	None	Stages I–II	Stages III–IV
Ascites	Absent	Slight, responsive	Moderate-severe
Bilirubin (mg/100 mL)	<2	2–3	>3
Albumin (g/100 mL)	>3.5	2.8–3.5	<2.8
Prothrombin time	<15 s	15–17 s	>17 s

The CTP score is calculated by assigning 1 point for any feature in column 1, 2 points for any feature in column 2, and 3 points for any feature in column 3. Class A = ≤6; class B = 7–9; class C = ≥10. For cholestatic disorders, such as primary biliary cirrhosis, primary sclerosing cholangitic, etc., the bilirubin categories are <4, 4–10, and >10.

[c] Instead of the 4 categories of severity in the previous system and 8 potential CTP scores between 7 and 15, the MELD scale is continuous, with 34 levels ranging between 6 and 40. The MELD scale replaces status 2A, 2B, and 3 (and 7), but status 1 is retained for those with the highest priority. Donor organs rarely become available unless the MELD score exceeds 20 to 30.

[d] Patients with hepatocellular carcinoma receive an extra 20 (for stage T1) or 24 (for stage T2) points. An α-fetoprotein level ≥ 500 ng/mL is considered as stage I hepatocellular carcinoma even without evidence for a tumor on imaging.

[e] Creatinine is included, because renal function is a validated predictor of survival in patients with liver disease. For adults undergoing dialysis twice a week, the creatinine in the equation is set to 4 mg/100 mL.

[f] For children <18 years, the Pediatric End-Stage Liver Disease (PELD) scale is used. This scale is based upon albumin, bilirubin, INR, growth failure, and age. Status 1 is retained, but the PELD replaces status 2 and 3.

Living-Donor Transplantation Occasionally, especially for liver transplantation in children, one cadaver organ can be split between two (one adult and one child) recipients. A more viable alternative, transplantation of the right lobe of the liver from a healthy adult into an adult recipient, is gaining increasing popularity. Living-donor transplantation of the left lobe (left lateral segment), introduced in the early 1990s to alleviate the extreme shortage of donor organs for small children, accounts currently for approximately a third of all liver transplantation procedures in children. Driven by the shortage of cadaver organs, living-donor transplantation involving the more sizable right lobe is being considered with increasing frequency in adults. More than 500 such procedures were done in 2001, representing >5% of all liver transplant operations done in the United States.

Living-donor transplantation can reduce waiting time and cold-ischemia time; is done under elective, rather than emergency, circumstances; and may be lifesaving in recipients who cannot afford to wait for a cadaver donor. The downside, of course, is the risk to the healthy donor (a mean of 10 weeks of medical disability; biliary complications in ~5%; postoperative complications such as wound infection, small-bowel obstruction, and incisional hernias in 9 to 19%; and, even, in 0.2 to 0.4%, death) as well as the increased frequency of biliary (15 to 32%) and vascular (10%) complications in the recipient. Potential donors must participate voluntarily without coercion, and transplantation teams should go to great lengths to exclude subtle coercive or inappropriate psychological factors as well as to outline carefully to both donor and recipient the potential benefits and risks of the procedure. Donors for the procedure should be 18 to 60 years old; have a compatible blood type with the recipient; have no chronic medical problems or history of major abdominal surgery; be related genetically or emotionally to the recipient; and pass an exhaustive series of clinical, biochemical, and serologic evaluations to unearth disqualifying medical disorders. The recipient should meet the same UNOS criteria for liver transplantation as recipients of a cadaver donor allograft.

Surgical Technique Removal of the recipient's native liver is technically difficult, particularly in the presence of portal hypertension with its associated collateral circulation and extensive varices, and even more so in the presence of scarring from previous abdominal operations. The combination of portal hypertension and coagulopathy (elevated prothrombin time and thrombocytopenia) may translate into large blood product transfusion requirements. After the portal vein and infrahepatic and suprahepatic inferior vena cavae are dissected, the hepatic artery and common bile duct are dissected. Then, the native liver is removed and the donor organ inserted. During the anhepatic phase, coagulopathy, hypoglycemia, hypocalcemia, and hypothermia are encountered and must be managed by the anesthesiology team. Caval, portal vein, hepatic artery, and bile duct anastomoses are performed in succession, the last by end-to-end suturing of the donor and recipient common bile ducts or by choledochojejunostomy to a Roux en Y loop if the recipient common bile duct cannot be used for reconstruction (e.g., in sclerosing cholangitis). A typical transplant operation lasts 8 h, with a range of 6 to 18 h. Because of excessive bleeding, large volumes of blood, blood products, and volume expanders may be required during surgery; however, blood requirements have fallen sharply with improvements in surgical technique and experience.

As noted above, emerging alternatives to orthotopic liver transplantation include split-liver grafts, in which one donor organ is divided and inserted into two recipients; and living-donor procedures, in which the left (for children) or the right (for adults) lobe of the liver is harvested from a living donor for transplantation into the recipient. In the adult procedure, once the right lobe is removed from the donor, the donor right hepatic vein is anastomosed to the recipient right hepatic vein remnant, followed by donor-to-recipient anastomoses of the portal vein and then the hepatic artery. Finally, the biliary anastomosis is performed, duct-to-duct if practical or via Roux-en-Y anastomosis. Heterotopic liver transplantation, in which the donor liver is inserted

without removal of the native liver, has met with very limited success and acceptance, except in a very small number of centers. To support desperately ill patients until a suitable donor organ can be identified, several transplantation centers are studying extracorporeal perfusion with bioartificial liver cartridges constructed from hepatocytes bound to hollow fiber systems and used as temporary hepatic-assist devices, but their efficacy remains to be established. Areas of research with the potential to overcome the shortage of donor organs include hepatocyte transplantation and xenotransplantation with genetically modified organs of nonhuman origin (e.g., swine).

POSTOPERATIVE COURSE AND MANAGEMENT ■ Immunosuppressive Therapy

The introduction in 1980 of cyclosporine as an immunosuppressive agent contributed substantially to the improvement in survival after liver transplantation. Cyclosporine, a calcineurin inhibitor, blocks early activation of T cells and is specific for T cell functions that result from the interaction of the T cell with its receptor and that involve the calcium-dependent signal transduction pathway. As a result, the activity of cyclosporine leads to inhibition of lymphokine gene activation, blocking interleukins 2, 3, and 4, tumor necrosis factor α, as well as other lymphokines. Cyclosporine also inhibits B cell functions. This process occurs without affecting rapidly dividing cells in the bone marrow, which may account for the reduced frequency of posttransplantation systemic infections. The most common and important side effect of cyclosporine therapy is nephrotoxicity. Cyclosporine causes dose-dependent renal tubular injury and direct renal artery vasospasm. Following renal function, therefore, is important in monitoring cyclosporine therapy, perhaps even a more reliable indicator than blood levels of the drug. Nephrotoxicity is reversible and can be managed by dose reduction. Other adverse effects of cyclosporine therapy include hypertension, hyperkalemia, tremor, hirsutism, glucose intolerance, and gum hyperplasia.

Tacrolimus (originally labeled FK 506) is a macrolide lactone antibiotic isolated from a Japanese soil fungus, *Streptomyces tsukubaensis*. It has the same mechanism of action as cyclosporine but is 10 to 100 times more potent. Initially applied as "rescue" therapy for patients in whom rejection occurred despite the use of cyclosporine, tacrolimus was shown in two large, multicenter, randomized trials to be associated with a reduced frequency of acute rejection, refractory rejection, and chronic rejection. Although patient and graft survival are the same with these two drugs, the advantage of tacrolimus in minimizing episodes of rejection, reducing the need for additional glucocorticoid doses, and reducing the likelihood of bacterial and cytomegalovirus infection has simplified the management of patients undergoing liver transplantation. In addition, the oral absorption of tacrolimus is more predictable than that of cyclosporine, especially during the early postoperative period when T-tube drainage interferes with the enterohepatic circulation of cyclosporine. As a result, in most transplantation centers, tacrolimus has now supplanted cyclosporine for primary immunosuppression, and many centers rely on oral, rather than intravenous, administration from the outset. For transplantation centers that prefer cyclosporine, a new, better-absorbed, microemulsion preparation is now available.

Although tacrolimus is more potent than cyclosporine, it is also more toxic and more likely to be discontinued for adverse events. The toxicity of tacrolimus is similar to that of cyclosporine; nephrotoxicity and neurotoxicity are the most commonly encountered adverse effects, and neurotoxicity (tremor, seizures, hallucinations, psychoses, coma) is more likely and more severe in tacrolimus-treated patients. Both drugs can cause diabetes mellitus, but tacrolimus does not cause hirsutism or gingival hyperplasia. Because of overlapping toxicity between cyclosporine and tacrolimus, especially nephrotoxicity, and because tacrolimus reduces cyclosporine clearance, these two drugs should not be used together. Because 99% of tacrolimus is metabolized by the liver, hepatic dysfunction reduces its clearance; in primary graft nonfunction (when, for technical reasons or because of ischemic damage prior to its insertion, the allograft is defective and does not function normally from the outset) tacrolimus doses have to be reduced substantially, especially in children. Both cyclosporine and tacrolimus are metabolized by the cytochrome P450 IIIA system, and, therefore, drugs that induce cytochrome P450 (e.g., phenytoin, phenobarbital, carbamazepine, rifampin) reduce available levels of cyclosporine and tacrolimus; drugs that inhibit cytochrome P450 (e.g., erythromycin, fluconazole, ketoconazole, clotrimazole, itraconazole, verapamil, diltiazem, nicardipine, cimetidine, danazol, metoclopramide, bromocriptine) increase cyclosporine and tacrolimus blood levels. Like azathioprine, cyclosporine and tacrolimus appear to be associated with a risk of lymphoproliferative malignancies (see below), which may occur earlier after cyclosporine or tacrolimus than after azathioprine therapy. Because of these side effects, combinations of cyclosporine or tacrolimus with prednisone and azathioprine—all at reduced doses—are preferable regimens for immunosuppressive therapy.

In patients with pretransplant renal dysfunction or renal deterioration that occurs intraoperatively or immediately postoperatively, tacrolimus or cyclosporine therapy may not be practical; under these circumstances, induction or maintenance of immunosuppression with monoclonal antibodies to T cells, OKT3, may be appropriate. Therapy with OKT3 has been especially effective in reversing acute rejection in the posttransplant period and is the standard treatment for acute rejection that fails to respond to methylprednisolone boluses. Intravenous infusions of OKT3 may be complicated by transient fever, chills, and diarrhea. When this drug is used to induce immunosuppression initially or to provide "rescue" in those who reject despite "conventional" therapy, the incidence of bacterial, fungal, and especially cytomegalovirus infections is increased during and after such therapy. In some centers, ganciclovir antiviral therapy is initiated prophylactically as a routine along with OKT3. Because OKT3 is such a potent immunosuppressive agent, its use is more likely to be complicated by opportunistic infection or lymphoproliferative disorders; therefore, and because of the availability of alternative immunosuppressive drugs, OKT3 is used less often nowadays. Another immunosuppressive drug being used for patients undergoing liver transplantation is mycophenolic acid, a nonnucleoside purine metabolism inhibitor derived as a fermentation product from several *Penicillium* species. Mycophenolate has been shown to be better than azathioprine, when used with other standard immunosuppressive drugs, in preventing rejection after renal transplantation and has been adopted as well for use in liver transplantation. The most common adverse effects of mycophenolate are leukopenia and gastrointestinal complaints. Rapamycin, an inhibitor of later events in T cell activation, is yet another drug undergoing evaluation as an immunosuppressive agent.

The most important principle of immunosuppression is that the ideal approach strikes a balance between immunosuppression and immunologic competence. Given sufficient immunosuppression, acute liver allograft rejection is always reversible; however, if the cumulative dose of immunosuppressive therapy is too large, the patient will succumb to opportunistic infection. Therefore, immunosuppressive drugs must be used judiciously, with strict attention to the infectious consequences of such therapy. In this vein, efforts have been made to minimize the use of glucocorticoids, a mainstay of immunosuppressive regimens, and, in some instances, steroid-free immunosuppression can be achieved.

Postoperative Complications Complications of liver transplantation can be divided into hepatic and nonhepatic categories (Tables 291-4 and 291-5). In addition, both immediately postoperative and late complications are encountered. Patients who undergo liver transplantation as a rule have been chronically ill for protracted periods and may be malnourished and wasted. The impact of such chronic illness and the multisystem failure that accompanies liver failure continues to require attention in the postoperative period. Because of the massive fluid losses and fluid shifts that occur during the operation, patients may remain fluid overloaded during the immediate postoperative period, straining cardiovascular reserve; this effect can be amplified in the face

TABLE 291-4 Nonhepatic Complications of Liver Transplantation

Fluid overload	
Cardiovascular instability	Arrhythmias
	Congestive heart failure
	Cardiomyopathy
Pulmonary compromise	Pneumonia
	Pulmonary capillary vascular permeability
	Fluid overload
Renal dysfunction	Prerenal azotemia
	Hypoperfusion injury (acute tubular necrosis)
	Drug nephrotoxicity
	↓ Renal blood flow secondary to ↑ intraabdominal pressure
Hematologic	Anemia 2° to gastrointestinal and/or intraabdominal bleeding
	Hemolytic anemia, aplastic anemia
	Thrombocytopenia
Infection	Bacterial: early, common postoperative infections
	Fungal/parasitic: late, opportunistic infections
	Viral: late, opportunistic infections, recurrent hepatitis
Neuropsychiatric	Seizures
	Encephalopathy
	Depression
	Difficult psychosocial adjustment
Diseases of donor	Infectious
	Malignant
Malignancy	B-cell lymphoma (posttransplantation lymphoproliferative disorders)

of transient renal dysfunction and pulmonary capillary vascular permeability. Continuous monitoring of cardiovascular and pulmonary function, measures to maintain the integrity of the intravascular compartment and to treat extravascular volume overload, and scrupulous attention to potential sources and sites of infection are of paramount importance. Cardiovascular instability may also result from the electrolyte imbalance that may accompany reperfusion of the donor liver. Pulmonary function may be compromised further by paralysis of the right hemidiaphragm associated with phrenic nerve injury. The hyperdynamic state with increased cardiac output that is characteristic of patients with liver failure reverses rapidly after successful liver transplantation.

Other immediate management issues include renal dysfunction; prerenal azotemia, acute kidney injury associated with hypoperfusion (acute tubular necrosis), and renal toxicity caused by antibiotics, tacrolimus, or cyclosporine are frequently encountered in the postoperative period, sometimes necessitating dialysis. Occasionally, postoperative intraperitoneal bleeding may be sufficient to increase intraabdominal pressure, which, in turn, may reduce renal blood flow; this effect is rapidly reversible when abdominal distention is relieved by exploratory laparotomy to identify and ligate the bleeding site and to remove intraperitoneal clot. Anemia may also result from acute upper gastrointestinal bleeding or from transient hemolytic anemia, which may be autoimmune, especially when blood group O livers are transplanted into blood group A or B recipients. This autoimmune hemolytic anemia is mediated by donor intrahepatic lymphocytes that recognize red blood cell A or B antigens on recipient erythrocytes. Transient in nature, this process resolves once the donor liver is repopulated by recipient bone marrow–derived lymphocytes; the hemolysis can be treated by transfusing blood group O red blood cells and/or by administering higher doses of glucocorticoids. Transient thrombocytopenia is also commonly encountered. Aplastic anemia, a late occurrence, is rare but has been reported in almost 30% of patients who underwent liver transplantation for acute, severe hepatitis of unknown cause.

Bacterial, fungal, or viral infections are common and may be life-threatening postoperatively. Early after transplant surgery, common postoperative infections predominate—pneumonia, wound infections, infected intraabdominal collections, urinary tract infections, and intravenous line infections—rather than opportunistic infections; these infections may involve the biliary tree and liver as well. Beyond the first postoperative month, the toll of immunosuppression becomes evident, and opportunistic infections—cytomegalovirus, herpes viruses, fungal infections (*Aspergillus*, *Candida*, cryptococcal disease), mycobacterial infections, parasitic infections (*Pneumocystis*, *Toxoplasma*), bacterial infections (*Nocardia*, *Legionella*, and *Listeria*)—predominate. Rarely, early infections represent those transmitted with the donor liver, either infections present in the donor or infections acquired during procurement processing. De novo viral hepatitis infections acquired from the donor organ or, almost unheard of nowadays, from transfused blood products occur after typical incubation periods for these agents (well beyond the first month). Obviously, infections in an immunosuppressed host demand early recognition and prompt management; prophylactic antibiotic therapy is administered routinely in the immediate postoperative period. Use of sulfamethoxazole with trimethoprim reduces the incidence of postoperative *Pneumocystis carinii* pneumonia.

Neuropsychiatric complications include seizures (commonly associated with cyclosporine and tacrolimus toxicity), encephalopathy, depression, and difficult psychosocial adjustment. Rarely, diseases are transmitted by the allograft from the donor to the recipient. In addition to viral and bacterial infections, malignancies of donor origin have occurred. Posttransplantation lymphoproliferative disorders, especially B cell lymphoma, are a recognized complication associated with immunosuppressive drugs such as azathioprine, tacrolimus, and cyclosporine (see above). Epstein-Barr virus has been shown to play a contributory role in some of these tumors, which may regress when immunosuppressive therapy is reduced.

Long-term complications after liver transplantation attributable primarily to immunosuppressive medications include diabetes mellitus (associated with glucocorticoids) as well as hypertension, hyperlipidemia, and chronic renal insufficiency (associated with cyclosporine and tacrolimus). Monitoring and treating these disorders is a routine component of posttransplantation care; in some cases, they respond to changes in immunosuppressive regimen, while in others, specific treatment of the disorder is introduced.

Hepatic Complications Hepatic dysfunction after liver transplantation is similar to the hepatic complications encountered after major abdominal and cardiothoracic surgery; however, in addition, there may be complications such as primary graft failure, vascular compromise, failure or obstruction of the biliary anastomoses, and rejection. As in

TABLE 291-5 Hepatic Complications of Liver Transplantation

HEPATIC DYSFUNCTION COMMON AFTER MAJOR SURGERY	
Prehepatic	Pigment load
	Hemolysis
	Blood collections (hematomas, abdominal collections)
Intrahepatic	
Early	Hepatotoxic drugs and anesthesia
	Hypoperfusion (hypotension, shock, sepsis)
	Benign postoperative cholestasis
Late	Transfusion-associated hepatitis
	Exacerbation of primary hepatic disease
Posthepatic	Biliary obstruction
	↓ Renal clearance of conjugated bilirubin (renal dysfunction)
HEPATIC DYSFUNCTION UNIQUE TO LIVER TRANSPLANTATION	
Primary graft nonfunction	
Vascular compromise	Portal vein obstruction
	Hepatic artery thrombosis
	Anastomotic leak with intraabdominal bleeding
Bile duct disorder	Stenosis, obstruction, leak
Rejection	
Recurrent primary hepatic disease	

nontransplant surgery, postoperative jaundice may result from prehepatic, intrahepatic, and posthepatic sources. *Prehepatic* sources represent the massive hemoglobin pigment load from transfusions, hemolysis, hematomas, ecchymoses, and other collections of blood. *Early intrahepatic* liver injury includes effects of hepatotoxic drugs and anesthesia; hypoperfusion injury associated with hypotension, sepsis, and shock; and benign postoperative cholestasis. *Late intrahepatic* sources of liver injury include posttransfusion hepatitis and exacerbation of primary disease. *Posthepatic* sources of hepatic dysfunction include biliary obstruction and reduced renal clearance of conjugated bilirubin. Hepatic complications unique to liver transplantation include primary graft failure associated with ischemic injury to the organ during harvesting; vascular compromise associated with thrombosis or stenosis of the portal vein or hepatic artery anastomoses; vascular anastomotic leak; stenosis, obstruction, or leakage of the anastomosed common bile duct; recurrence of primary hepatic disorder (see below); and rejection.

Transplant Rejection Despite the use of immunosuppressive drugs, rejection of the transplanted liver still occurs in a proportion of patients, beginning 1 to 2 weeks after surgery. Clinical signs suggesting rejection are fever, right upper quadrant pain, and reduced bile pigment and volume. Leukocytosis may occur, but the most reliable indicators are increases in serum bilirubin and aminotransferase levels. Because these tests lack specificity, distinguishing among rejection and biliary obstruction, primary graft nonfunction, vascular compromise, viral hepatitis, cytomegalovirus infection, drug hepatotoxicity, and recurrent primary disease may be difficult. Radiographic visualization of the biliary tree and/or percutaneous liver biopsy often helps to establish the correct diagnosis. Morphologic features of acute rejection include portal infiltration, bile duct injury, and/or endothelial inflammation ("endothelialitis"); some of these findings are reminiscent of graft-versus-host disease and primary biliary cirrhosis. As soon as transplant rejection is suspected, treatment consists of intravenous methylprednisolone in repeated boluses; if this fails to abort rejection, many centers use antibodies to lymphocytes, such as OKT3, or polyclonal antilymphocyte globulin.

Chronic rejection is a relatively rare outcome that can follow repeated bouts of acute rejection or that occurs unrelated to preceding rejection episodes. Morphologically, chronic rejection is characterized by progressive cholestasis, focal parenchymal necrosis, mononuclear infiltration, vascular lesions (intimal fibrosis, subintimal foam cells, fibrinoid necrosis), and fibrosis. This process may be reflected as ductopenia—the vanishing bile duct syndrome. Some of the histologic hallmarks of chronic rejection may be so similar to those of chronic viral hepatitis that differentiation between the two may be difficult. Reversibility of chronic rejection is limited; in patients with therapy-resistant chronic rejection, retransplantation has yielded encouraging results.

OUTCOME ■ Survival The survival rate for patients undergoing liver transplantation has improved steadily since 1983. One-year survival rates have increased from ~70% in the early 1980s to 85 to 90% in the late 1990s. Currently, the 5-year survival rate exceeds 60%. An important observation is the relation between clinical status before transplantation and outcome. For patients who undergo liver transplantation when their level of compensation is high (e.g., still working or only partially disabled), a 1-year survival rate of 85% is common. For those whose level of decompensation mandates continuous in-hospital care prior to transplantation, the 1-year survival rate is about 70%, while for those who are so decompensated that they require life support in an intensive care unit, the 1-year survival rate is ~50%. Indeed, the trend toward transplantation earlier in the natural history of end-stage liver disease is a major factor in the increased success of liver transplantation during the 1980s and 1990s. Another important distinction in survival has been drawn between high-risk and low-risk patient categories. For patients who do not fit any "high-risk" designations, 1-year and 5-year survival rates of 85 and 80%, respectively, have been recorded. In contrast, among patients in high-risk categories—cancer, fulminant hepatitis, age >65, concurrent renal failure, respirator dependence, portal vein thrombosis, and history of a portacaval shunt or multiple right upper quadrant operations—survival statistics fall into the range of 60% at 1 year and 35% at 5 years. Survival after retransplantation for primary graft nonfunction is ~50%. Causes of failure of liver transplantation vary with time. Failures within the first 3 months result primarily from technical complications, postoperative infections, and hemorrhage. Transplant failures after the first 3 months are more likely to result from infection, rejection, or recurrent disease (such as malignancy or viral hepatitis).

Recurrence of Primary Disease Features of autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cirrhosis overlap with those of rejection or posttransplantation bile-duct injury. Whether autoimmune hepatitis and sclerosing cholangitis recur after liver transplantation is controversial; data supporting recurrent autoimmune hepatitis (in up to a third of patients in some series) are more convincing than those supporting recurrent sclerosing cholangitis. Similarly, reports of recurrent primary biliary cirrhosis after liver transplantation have appeared; however, the histologic features of primary biliary cirrhosis and acute rejection are virtually indistinguishable and occur as frequently in patients with primary biliary cirrhosis as in patients undergoing transplantation for other reasons. Hereditary disorders such as Wilson's disease and α_1-antitrypsin deficiency have not recurred after liver transplantation; however, recurrence of disordered iron metabolism has been observed in some patients with hemochromatosis. Hepatic vein thrombosis (Budd-Chiari syndrome) may recur; this can be minimized by treating underlying lymphoproliferative disorders and by anticoagulation. Cholangiocarcinoma recurs almost invariably; therefore, few centers now offer transplantation to such patients. In patients with hepatocellular carcinoma, tumor recurrence in the liver is common after ~1 year, although better success has been reported (1- and 5-year survivals similar to those achieved in patients undergoing liver transplantation for nonmalignant diseases) in patients with an unresectable isolated lesion <5 cm or with three or fewer lesions all <3 cm. Trials are underway to assess the benefit of adjuvant chemotherapy.

Hepatitis A can recur after transplantation for fulminant hepatitis A, but such acute reinfection has no serious clinical sequelae. In fulminant hepatitis B, recurrence is not the rule; however, in the absence of any prophylactic measures, hepatitis B usually recurs after transplantation for end-stage chronic hepatitis B. Before the introduction of prophylactic antiviral therapy, immunosuppressive therapy sufficient to prevent allograft rejection led inevitably to marked increases in hepatitis B viremia, regardless of pretransplantation values. Overall graft and patient survival were poor, and some patients experienced a rapid recapitulation of severe injury—severe chronic hepatitis or even fulminant hepatitis—after transplantation. Also recognized in the era before availability of antiviral regimens was *fibrosing cholestatic hepatitis*, rapidly progressive liver injury associated with marked hyperbilirubinemia, substantial prolongation of the prothrombin time (both out of proportion to relatively modest elevations of aminotransferase activity), and rapidly progressive liver failure. This lesion has been suggested to represent a "choking off" of the hepatocyte by an overwhelming density of hepatitis B virus (HBV) proteins. Complications such as sepsis and pancreatitis were also observed more frequently in patients undergoing liver transplantation for hepatitis B prior to the introduction of antivral therapy. The introduction of long-term prophylaxis with HBIg revolutionized liver transplantation for chronic hepatitis B. Neither preoperative hepatitis B vaccination, preoperative or postoperative interferon therapy, nor short-term (≤2 months) HBIg prophylaxis has been shown to be effective, but a retrospective analysis of data from several hundred European patients followed for 3 years after transplantation has shown that long-term (≥6 months) pro-

phylaxis with HBIg is associated with a lowering of the risk of HBV reinfection from ~75% to 35% and a reduction in mortality from ~50% to 20%.

As a result of long-term HBIg use following liver transplantation for chronic hepatitis B, similar improvements in outcome have been observed in the United States, with 1-year survival rates between 75 and 90%. Currently, with HBIg prophylaxis, the outcome of liver transplantation for chronic hepatitis B is indistinguishable from that for chronic liver disease unassociated with chronic hepatitis B; essentially, medical concerns regarding liver transplantation for chronic hepatitis B have been eliminated. Passive immunoprophylaxis with HBIg is begun during the anhepatic stage of surgery, repeated daily for the first 6 postoperative days, then continued with infusions that are given either at regular intervals of 4 to 6 weeks or, alternatively, when anti-HBs levels fall below a threshold of 100 mIU/mL. The current approach in most centers is to continue HBIg indefinitely, which can add approximately $20,000 per year to the cost of care; some centers are evaluating regimens that shift to less frequent administration or to intramuscular administration in the late posttransplantation period. Still, occasionally, "breakthrough" HBV infection occurs.

Futher improving the outcome of liver transplantation for chronic hepatitis B is the current availability of such antiviral drugs as lamivudine and adefovir dipivoxil (Chap. 287). When lamivudine is administered to patients with decompensated liver disease, a proportion improve sufficiently to postpone imminent liver transplantation. In addition, lamivudine can be used to prevent recurrence of HBV infection when administered *prior* to transplantation, to treat hepatitis B that recurs *after* transplantation, including in patients who break through HBIg prophylaxis, and to reverse the course of otherwise fatal fibrosing cholestatic hepatitis. Clinical trials have shown that lamivudine monotherapy reduces the level of HBV replication substantially, sometimes even resulting in clearance of hepatitis B surface antigen (HBsAg); reduces alanine aminotransferase (ALT) levels; and improves histologic features of necrosis and inflammation. Long-term use of lamivudine is safe and effective, but, after several months, a proportion of patients become resistant to lamivudine, resulting from YMDD (tyrosine-methionine-aspartate-aspartate) mutations in the HBV polymerase motif (Chap. 287). In approximately half of such resistant patients, hepatic deterioration may ensue. Fortunately, adefovir dipivoxil is available as well and can be used to treat lamivudine-associated YMDD variants, effectively "rescuing" patients experiencing hepatic decompensation after lamivudine breakthrough. Currently, most liver transplantation centers combine HBIg plus lamivudine or adefovir, and additional antivirals are being introduced as well. Clinical trials are underway to define the optimal application of these antiviral agents in the management of patients undergoing liver transplantation for chronic hepatitis B; conceivably, in the future, combinations of oral antiviral drugs may supplant HBIg.

Prophylactic approaches applied to patients undergoing liver transplantation for chronic hepatitis B are being used as well for patients without hepatitis B who receive organs from donors with anti-HBc. Patients who undergo liver transplantation for chronic hepatitis B plus D are less likely to experience recurrent liver injury than patients undergoing liver transplantation for hepatitis B alone; still, such coinfected patients would also be offered standard posttransplantation prophylactic therapy for hepatitis B.

Accounting for up to 40% of all liver transplantation procedures, the most common indication for liver transplantation is end-stage liver disease resulting from chronic hepatitis C. Recurrence of hepatitis C virus (HCV) after liver transplantation can be documented in almost every patient, if sufficiently sensitive virus markers are used. Although acute and chronic liver injury occur after transplantation in patients with chronic hepatitis C, clinical consequences of recurrent hepatitis C are limited during the first 5 years after transplantation. Nonetheless, despite the relative clinical benignity of recurrent hepatitis C in the early years after liver transplantation, and despite the negligible impact on patient survival during these early years, histologic studies have documented the presence of moderate to severe chronic hepatitis in more than half of all patients and bridging fibrosis or cirrhosis in ~10%. Moreover, progression to cirrhosis within 5 years is even more common, occurring in up to two-thirds of patients, after moderate hepatitis is detected in a 1-year biopsy. Ultimately, such histologic evidence of chronic hepatitis and cirrhosis will be expressed clinically as well, and the expectation is that the outcome beyond 10 years will not be as favorable as the 5-year statistics suggest. In a proportion of patients, even during the early posttransplantation period, recurrent hepatitis C may be sufficiently severe biochemically and histologically to merit antiviral therapy. Treatment with interferon monotherapy can *suppress* HCV-associated liver injury in approximately half of patients but rarely leads to *sustained* benefit. The addition of the nucleoside analogue ribavirin to interferon as well as the substitution of more effective and long-acting pegylated interferons for standard interferons (Chap. 287) have resulted in improved responses to antiviral therapy, and many centers have adopted some form of combination therapy for their patients with recurrent hepatitis C after liver transplantation. Overall, however, current approaches to antiviral therapy for hepatitis C after liver transplantation have been disappointing; sustained virologic responses are the exception, and reduced tolerability is often dose-limiting. Studies are underway to determine whether preemptive therapy immediately after transplantation provides any benefit over therapy introduced after clinical hepatitis occurs. Similarly, although interferon-based antiviral therapy is not recommended for patients with decompensated liver disease, some centers have experimented with pretransplantation antiviral therapy in an attempt to eradicate HCV replication prior to transplantation; preliminary results are promising. Initial trials of hepatitis C immune globulin preparations to prevent recurrent hepatitis C after liver transplantation have not been successful.

A small number succumb to early HCV-associated liver injury, and a syndrome reminiscent of fibrosing cholestatic hepatitis (see above) has been observed rarely. Because patients with more episodes of rejection receive more immunosuppressive therapy, and because immunosuppressive therapy enhances HCV replication, patients with severe or multiple episodes of rejection are more likely to experience early recurrence of hepatitis C after transplantation. Both HCV genotype 1b and high viral load have been linked to recurrent HCV-induced liver disease and to earlier disease recurrence after transplantation; however, the association between genotype and recurrence of HCV-associated liver injury has not been supported by more recent reports.

Patients who undergo liver transplantation for end-stage alcoholic cirrhosis are at risk of resorting to drinking again after transplantation, a potential source of recurrent alcoholic liver injury. Currently, alcoholic liver disease is one of the more common indications for liver transplantation, accounting for 20 to 25% of all liver transplantation procedures, and most transplantation centers screen candidates carefully for predictors of continued abstinence. Recidivism is more likely in patients whose sobriety prior to transplantation was <6 months. For abstinent patients with alcoholic cirrhosis, liver transplantation can be undertaken successfully, with outcomes comparable to those for other categories of patients with chronic liver disease, when coordinated by a team approach that includes substance abuse counseling.

Posttransplantation Quality of Life Full rehabilitation is achieved in the majority of patients who survive the early postoperative months and escape chronic rejection or unmanageable infection. Psychosocial maladjustment interferes with medical compliance in a small number of patients, but most manage to adhere to immunosuppressive regimens, which must be continued indefinitely. In one study, 85% of patients who survived their transplants returned to gainful activities. In fact, some women have conceived and carried pregnancies to term after transplantation without demonstrable injury to their infants.

292 DISEASES OF THE GALLBLADDER AND BILE DUCTS

Norton J. Greenberger, Gustav Paumgartner

PHYSIOLOGY OF BILE PRODUCTION AND FLOW ■ Bile Secretion and Composition Bile formed in the hepatic lobules is secreted into a complex network of canaliculi, small bile ductules, and larger bile ducts that run with lymphatics and branches of the portal vein and hepatic artery in portal tracts situated between hepatic lobules. These interlobular bile ducts coalesce to form larger septal bile ducts that join to form the right and left hepatic ducts, which in turn unite to form the common hepatic duct. The common hepatic duct is joined by the cystic duct of the gallbladder to form the common bile duct (CBD), which enters the duodenum (often after joining the main pancreatic duct) through the ampulla of Vater.

Hepatic bile is an isotonic fluid with an electrolyte composition resembling blood plasma. The electrolyte composition of gallbladder bile differs from that of hepatic bile because most of the inorganic anions, chloride and bicarbonate, have been removed by reabsorption across the gallbladder epithelium. As a result of water reabsorption, total solute concentration of bile increases from 3 to 4 g/dL in hepatic bile and 10 to 15 g/dL in gallbladder bile.

Major solute components of bile by moles percent include bile acids (80%), lecithin and traces of other phospholipids (16%), and unesterified cholesterol (4.0%). In the lithogenic state the cholesterol value can be as high as 8 to 10%. Other constituents include conjugated bilirubin, proteins (IgA, metabolites of hormones, and other proteins metabolized in the liver), electrolytes, mucus, and, often, drugs and their metabolites.

The total daily basal secretion of hepatic bile is approximately 500 to 600 mL. Many substances taken up or synthesized by the hepatocyte are secreted into the bile canalculi. The canalicular membrane forms microvilli and is associated with microfilaments of actin, microtubules, and other contractile elements. Prior to their secretion into the bile, many substances that are taken up into the hepatocyte are conjugated, while others such as phospholipids, a portion of primary bile acids, and some cholesterol are synthesized de novo in the hepatocyte. Three mechanisms are important in regulating bile flow: (1) active transport of bile acids from hepatocytes into the bile canaliculi, (2) active transport of other organic anions, and (3) cholangiocellular secretion. The last is a secretin-mediated and cyclic AMP–dependent mechanism that results in the secretion of a sodium- and bicarbonate-rich fluid into the bile ducts.

Active vectorial secretion of biliary constituents from the portal blood into the bile canaliculi is driven by a distinct set of polarized transport systems at the basolateral (sinusoidal) and the canalicular plasma membrane domains of the hepatocyte. Two sinusoidal bile salt uptake systems have been cloned in humans, the Na^+/taurocholate cotransporter (NTCP) and the organic anion transporting proteins (OATPs), which also transport a large variety of non-bile salt organic anions. Several ATP-dependent canalicular transport systems ("export pumps") have been identified, the most important of which are: the bile salt export pump (BSEP); the conjugate export pump (MRP2), which mediates the canalicular excretion of various amphiphilic conjugates formed by phase II conjugation (e.g., bilirubin mono- and diglucuronides); the multidrug export pump (MDR1) for hydrophobic cationic compounds; and the phospholipid export pump (MDR3). Indirect evidence suggests that the two hemitransporters ABCG5/G8, functioning as a couple, constitute the principal canalicular cholesterol transporter. The canalicular membrane also contains ATP-independent transport systems such as the Cl^-/HCO_3^- anion exchanger isoform 2 for canalicular bicarbonate secretion. For some of these transporters, genetic defects have been identified that are associated with various forms of cholestasis or defects of biliary excretion. BSEP is defective in progressive familial intrahepatic cholestasis (PFIC) type 2. Mutations of MRP2 cause the Dubin-Johnson syndrome, an inherited form of conjugated hyperbilirubinemia (Chap. 284). A defective MDR3 results in PFIC-3. ABCG5/G8, the canalicular half transporters for cholesterol and neutral sterols, are defective in sitosterolemia. The cystic fibrosis transmembrane regulator located on bile duct epithelial cells is defective in cystic fibrosis, which is associated with impaired cholangiocellular bile formation and chronic cholestatic liver disease.

The Bile Acids The primary bile acids, cholic acid and chenodeoxycholic acid (CDCA), are synthesized from cholesterol in the liver, conjugated with glycine or taurine, and excreted into the bile. Secondary bile acids, including deoxycholate and lithocholate, are formed in the colon as bacterial metabolites of the primary bile acids. However, lithocholic acid is much less efficiently absorbed from the colon than deoxycholic acid. Another secondary bile acid, found in low concentration, is ursodeoxycholic acid (UDCA), a stereoisomer of CDCA. In normal bile, the ratio of glycine to taurine conjugates is about 3:1.

Bile acids are detergent-like molecules that in aqueous solutions and above a critical concentration of about 2 m*M* form molecular aggregates called *micelles*. Cholesterol alone is sparingly soluble in aqueous environments, and its solubility in bile depends on both the total lipid concentration and the relative molar percentages of bile acids and lecithin. Normal ratios of these constituents favor the formation of solubilizing *mixed micelles*, while abnormal ratios promote the precipitation of cholesterol crystals in bile.

In addition to facilitating the biliary excretion of cholesterol, bile acids are necessary for the normal intestinal absorption of dietary fats, mainly cholesterol and fat-soluble vitamins, via a micellar transport mechanism (Chap. 275). Bile acids also serve as a major physiologic driving force for hepatic bile flow and aid in water and electrolyte transport in the small bowel and colon.

Enterohepatic Circulation Bile acids are efficiently conserved under normal conditions. Unconjugated, and to a lesser degree also conjugated, bile acids are absorbed by *passive diffusion* along the entire gut. Quantitatively much more important for bile salt recirculation, however, is the *active transport* mechanism for conjugated bile acids in the distal ileum (Chap. 275). The reabsorbed bile acids enter the portal bloodstream and are taken up rapidly by hepatocytes, reconjugated, and resecreted into bile (enterohepatic circulation).

The normal bile acid pool size is approximately 2 to 4 g. During digestion of a meal, the bile acid pool undergoes at least one or more enterohepatic cycles, depending on the size and composition of the meal. Normally, the bile acid pool circulates approximately 5 to 10 times daily. Intestinal absorption of the pool is about 95% efficient, so fecal loss of bile acids is in the range of 0.3 to 0.6 g/d. This fecal loss is compensated by an equal daily synthesis of bile acids by the liver, and thus the size of the bile acid pool is maintained. Bile acids

returning to the liver suppress de novo hepatic synthesis of primary bile acids from cholesterol by inhibiting the rate-limiting enzyme cholesterol 7α-hydroxylase. While the loss of bile salts in stool is usually matched by increased hepatic synthesis, the maximum rate of synthesis is approximately 5 g/d, which may be insufficient to replete the bile acid pool size when there is pronounced impairment of intestinal bile salt reabsorption.

Gallbladder and Sphincteric Functions In the fasting state, the sphincter of Oddi offers a high-pressure zone of resistance to bile flow from the CBD into the duodenum. This tonic contraction serves to (1) prevent reflux of duodenal contents into the pancreatic and bile ducts and (2) promote bile filling of the gallbladder. The major factor controlling the evacuation of the gallbladder is the peptide hormone cholecystokinin (CCK), which is released from the duodenal mucosa in response to the ingestion of fats and amino acids. CCK produces (1) powerful contraction of the gallbladder, (2) decreased resistance of the sphincter of Oddi, and (3) enhanced flow of biliary contents into the duodenum.

Hepatic bile is "concentrated" within the gallbladder by energy-dependent transmucosal absorption of water and electrolytes. Almost the entire bile acid pool may be sequestered in the gallbladder following an overnight fast for delivery into the duodenum with the first meal of the day. The normal capacity of the gallbladder is about 30 mL of bile.

DISEASES OF THE GALLBLADDER

CONGENITAL ANOMALIES Anomalies of the biliary tract are not uncommon and include abnormalities in number, size, and shape (e.g., agenesis of the gallbladder, duplications, rudimentary or oversized "giant" gallbladders, and diverticula). *Phrygian cap* is a clinically innocuous entity in which a partial or complete septum (or fold) separates the fundus from the body. Anomalies of position or suspension are not uncommon and include left-sided gallbladder, intrahepatic gallbladder, retrodisplacement of the gallbladder, and "floating" gallbladder. The latter condition predisposes to acute torsion, volvulus, or herniation of the gallbladder.

GALLSTONES ■ Pathogenesis Gallstones are quite prevalent in most western countries. In the United States, autopsy series have shown gallstones in at least 20% of women and in 8% of men over the age of 40. It is estimated that at least 20 million persons in the United States have gallstones and that approximately 1 million new cases of cholelithiasis develop each year.

Gallstones are formed by concretion or accretion of normal or abnormal bile constituents. They are divided into two major types: cholesterol stones account for 80% of the total, with pigment stones comprising the remaining 20%. Cholesterol gallstones usually contain >50% cholesterol monohydrate plus an admixture of calcium salts, bile pigments, proteins, and fatty acids. Pigment stones are composed primarily of calcium bilirubinate; they contain <20% cholesterol.

CHOLESTEROL STONES AND BILIARY SLUDGE Cholesterol is essentially water insoluble and requires aqueous dispersion into either micelles or vesicles, both of which require the presence of a second lipid to solubilize the cholesterol. Cholesterol and phospholipids are secreted into bile as unilamellar bilayered vesicles, which are converted into mixed micelles consisting of bile acids, phospholipids, and cholesterol by the action of bile acids. If there is an excess of cholesterol in relation to phospholipids and bile acids, unstable cholesterol-rich vesicles remain, which aggregate into large multilamellar vesicles from which cholesterol crystals precipitate (Fig. 292-1).

There are several important mechanisms in the formation of lithogenic (stone-forming) bile. The most important is increased biliary secretion of cholesterol. This may occur in association with obesity, high-caloric and cholesterol-rich diets, or drugs (e.g., clofibrate) and may result from increased activity of HMG-CoA reductase, the rate-limiting enzyme of hepatic cholesterol synthesis, and increased hepatic uptake of cholesterol from blood. In patients with gallstones, dietary cholesterol *increases* biliary cholesterol secretion. This does not occur

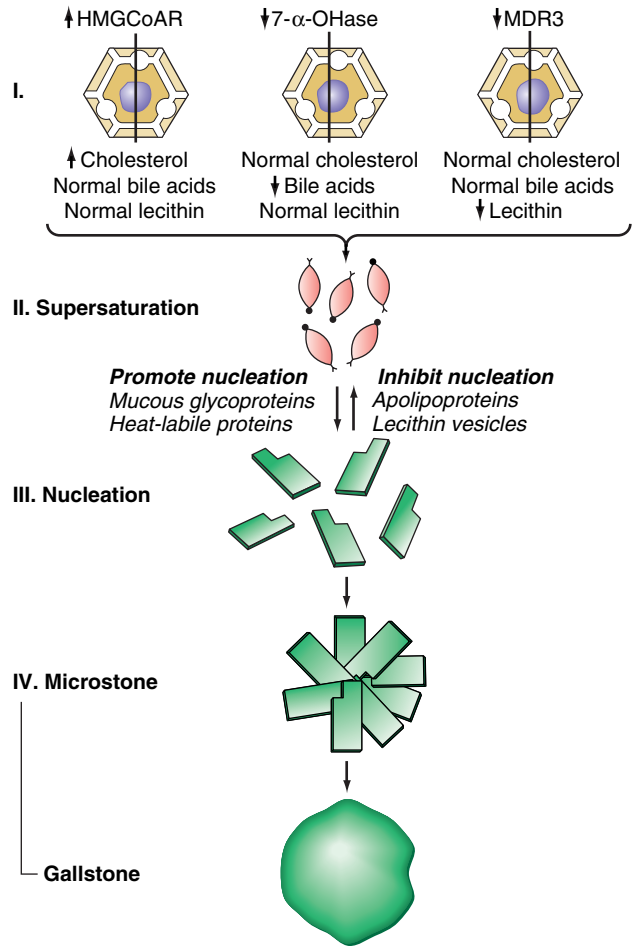

FIGURE 292-1 Scheme showing pathogenesis of cholesterol gallstone formation. Conditions or factors that increase the ratio of cholesterol to bile acids and phospholipids (lecithin) favor gallstone formation. HMG-CoAR, hydroxymethylglutaryl–coenzyme A reductase; 7-α-OHase, cholesterol, 7α-hydroxylase; MDR3, multidrug resistance–associated protein 3, also called phospholipid export pump.

in non-gallstone patients on high-cholesterol diets. In addition to environmental factors such as high-caloric and cholesterol-rich diets, genetic factors play an important role in cholesterol hypersecretion and gallstone formation. A high prevalence of gallstones is found among first-degree relatives of gallstone carriers and in certain ethnic populations such as American Indians as well as Chilean Indians and Chilean Hispanics. A common genetic trait has been identified for some of these populations by mitochondrial DNA analysis. In some patients, impaired hepatic conversion of cholesterol to bile acids may also occur, resulting in an increase of the lithogenic cholesterol/bile acid ratio. Recently, a mutation in the *CYP7A1* gene has been described that results in a deficiency of the enzyme cholesterol 7α-hydroxylase, which catalyzes the initial step in cholesterol catabolism and bile acid synthesis. The homozygous state is associated with hypercholesterolemia and gallstones. Because the phenotype is expressed in the heterozygote state, mutations in the *CYP7A1* gene may contribute to the susceptibility to cholesterol gallstone disease in the population. Mutations in the *MDR3* gene, which encodes the phospholipid export pump in the canalicular membrane of the hepatocyte, may cause defective phospholipid secretion into bile, resulting in cholesterol supersaturation of bile and formation of cholesterol gallstones in the gallbladder and in the bile ducts. Thus an excess of biliary cholesterol in relation to bile acids and phospholipids is primarily due to hypersecretion of cholesterol, but hyposecretion of bile acids or phospholipids may contribute. An additional disturbance of bile acid metabolism that is likely to contribute to supersaturation of bile with cholesterol is

enhanced conversion of cholic acid to deoxycholic acid, with replacement of the cholic acid pool by an expanded deoxycholic acid pool. It may result from enhanced dehydroxylation of cholic acid and increased absorption of newly formed deoxycholic acid. An increased deoxycholate secretion is associated with hypersecretion of cholesterol into bile.

While supersaturation of bile with cholesterol is an important prerequisite for gallstone formation, it is generally not sufficient by itself to produce cholesterol precipitation in vivo. Most people with supersaturated bile do not develop stones because the time required for cholesterol crystals to nucleate and grow is longer than the time bile spends in the gallbladder.

An important mechanism is *nucleation* of cholesterol monohydrate crystals, which is greatly accelerated in human lithogenic bile. Accelerated nucleation of cholesterol monohydrate in bile may be due to either an *excess of pronucleating factors* or a *deficiency of antinucleating factors*. Mucin and certain non-mucin glycoproteins appear to be pronucleating factors, while apolipoproteins AI and AII and other glycoproteins appear to be antinucleating factors. Cholesterol monohydrate crystal nucleation and crystal growth probably occur within the mucin gel layer. Vesicle fusion leads to liquid crystals, which, in turn, nucleate into solid cholesterol monohydrate crystals. Continued growth of the crystals occurs by direct nucleation of cholesterol molecules from supersaturated unilamellar or multilamellar biliary vesicles.

A third important mechanism in cholesterol gallstone formation is *gallbladder hypomotility*. If the gallbladder emptied all supersaturated or crystal-containing bile completely, stones would not be able to grow. A high percentage of patients with gallstones exhibits abnormalities of gallbladder emptying. Ultrasonographic studies show that gallstone patients have an increased gallbladder volume during fasting and also after a test meal (residual volume) and that fractional emptying after gallbladder stimulation is decreased. Gallbladder emptying is a major determinant of gallstone recurrence in patients who underwent biliary lithotripsy. Within 3 years, only 13% of patients with good but 53% of patients with poor gallbladder emptying form recurrent stones.

Biliary sludge is a thick mucous material that upon microscopic examination reveals lecithin-cholesterol crystals, cholesterol monohydrate crystals, calcium bilirubinate, and mucin thread or mucous gels. Biliary sludge typically forms a crescent-like layer in the most dependent portion of the gallbladder and is recognized by characteristic echoes on ultrasonography (see below). The presence of biliary sludge implies two abnormalities: (1) the normal balance between gallbladder mucin secretion and elimination has become deranged and (2) nucleation of biliary solutes has occurred. That biliary sludge may be a precursor form of gallstone disease is evident from several observations. In one study, 96 patients with gallbladder sludge were followed prospectively by serial ultrasound studies. In 18%, biliary sludge disappeared and did not recur for at least 2 years. In 60%, biliary sludge disappeared and reappeared; in 14%, gallstones (8% asymptomatic, 6% symptomatic) developed, and in 6%, severe biliary pain with or without acute pancreatitis occurred. In 12 patients, cholecystectomies were performed, 6 for gallstone-associated biliary pain and 3 in symptomatic patients with sludge but without gallstones who had prior attacks of pancreatitis; the latter did not recur after cholecystectomy. It should be emphasized that biliary sludge can develop with disorders that cause gallbladder hypomotility, i.e., surgery, burns, total parenteral nutrition, pregnancy, and oral contraceptives—all of which are associated with gallstone formation.

Two other conditions are associated with cholesterol stone or biliary sludge formation: pregnancy and very low calorie diet. There appear to be two key changes during pregnancy that contribute to a "cholelithogenic state": (1) a marked increase in cholesterol saturation during the third trimester and (2) sluggish gallbladder contraction in response to a standard meal, resulting in impaired gallbladder emptying. That these changes are related to pregnancy per se is supported by several studies that show reversal of these abnormalities after delivery. During pregnancy, gallbladder sludge develops in 20 to 30% of women and gallstones in 5 to 12%. While biliary sludge is a common finding during pregnancy, it is usually asymptomatic and often resolves spontaneously after delivery. Gallstones, which are less common than sludge and frequently associated with biliary colic, may also disappear after delivery because of spontaneous dissolution related to bile becoming unsaturated with cholesterol post partum.

Approximately 10 to 20% of people with rapid weight reduction achieved through very low calorie dieting develop gallstones. In a study involving 600 patients who completed a 16-week, 520-kcal/d diet, UDCA in a dosage of 600 mg/d proved highly effective in preventing gallstone formation; gallstones developed in only 3% of UDCA recipients compared to 28% of placebo-treated patients.

To summarize, cholesterol gallstone disease occurs because of several defects, which include (1) bile supersaturation with cholesterol, (2) nucleation of cholesterol monohydrate with subsequent crystal retention and stone growth, and (3) abnormal gallbladder motor function with delayed emptying and stasis. Other important factors known to predispose to cholesterol stone formation are summarized in Table 292-1.

PIGMENT STONES Black pigment stones are composed of either pure calcium bilirubinate or polymer-like complexes with calcium and mucin glycoproteins. They are more common in patients who have chronic hemolytic states (with increased conjugated bilirubin in bile), liver

TABLE 292-1 Predisposing Factors for Cholesterol and Pigment Gallstone Formation

Cholesterol Stones

1. Demographic/genetic factors
   a. Prevalence highest in North American Indians, Chilean Indians, and Chilean Hispanics, greater in Northern Europe and North America than in Asia, lowest in Japan; familial disposition; hereditary aspects
2. Obesity
   a. Normal bile acid pool and secretion but increased biliary secretion of cholesterol
3. Weight loss
   a. Mobilization of tissue cholesterol leads to increased biliary cholesterol secretion while enterohepatic circulation of bile acids is decreased
4. Female sex hormones
   a. Estrogens stimulate hepatic lipoprotein receptors, increase uptake of dietary cholesterol, and increase biliary cholesterol secretion
   b. Natural estrogens, other estrogens, and oral contraceptives lead to decreased bile salt secretion and decreased conversion of cholesterol to cholesteryl esters
5. Increasing age
   a. Increased biliary secretion of cholesterol, decreased size of bile acid pool, decreased secretion of bile salts
6. Gallbladder hypomotility leading to stasis and formation of sludge
   a. Prolonged parenteral nutrition
   b. Fasting
   c. Pregnancy
   d. Drugs such as octreotide
7. Clofibrate therapy
   a. Increased biliary secretion of cholesterol
8. Decreased bile acid secretion
   a. Primary biliary cirrhosis
   b. Genetic defect of the *CYP7A1* gene
9. Decreased phospholipid secretion
   a. Genetic defect of the *MDR3* gene
10. Miscellaneous
    a. High-calorie, high-fat diet
    b. Spinal cord injury

Pigment Stones

1. Demographic/genetic factors: Asia, rural setting
2. Chronic hemolysis
3. Alcoholic cirrhosis
4. Pernicious anemia
5. Cystic fibrosis
6. Chronic biliary tract infection, parasite infections
7. Increasing age
8. Ileal disease, ileal resection or bypass

cirrhosis, Gilbert's syndrome, or cystic fibrosis. Gallbladder stones in patients with ileal diseases, ileal resection, or ileal bypass generally are also black pigment stones. Enthrohepatic recycling of bilirubin contributes to their pathogenesis. Brown pigment stones are composed of calcium salts of unconjugated bilirubin with varying amounts of cholesterol and protein. They are caused by the presence of increased amounts of unconjugated, insoluble bilirubin in bile that precipitates to form stones. Deconjugation of an excess of soluble bilirubin mono- and diglucuronides may be mediated by endogenous β-glucuronidase but may also occur by spontaneous alkaline hydrolysis. Sometimes, the enzyme is also produced when bile is chronically infected by bacteria. Pigment stone formation is especially prominent in Asians and is often associated with infections in the biliary tree (Table 292-1).

Diagnosis Procedures of potential use in the diagnosis of cholelithiasis and other diseases of the gallbladder are detailed in Table 292-2. The plain abdominal film may detect gallstones containing sufficient calcium to be radiopaque (10 to 15% of cholesterol and approximately 50% of pigment stones). Plain radiography may also be of use in the diagnosis of emphysematous cholecystitis, porcelain gallbladder, limey bile, and gallstone ileus.

Ultrasonography of the gallbladder is very accurate in the identification of cholelithiasis and has several advantages over oral cholecystography (Fig. 292-2*A*). Stones as small as 2 mm in diameter may be confidently identified provided that firm criteria are used [e.g., acoustic "shadowing" of opacities that are within the gallbladder lumen and that change with the patient's position (by gravity)]. In major medical centers, the false-negative and false-positive rates for ultrasound in gallstone patients are about 2 to 4%. Biliary sludge is material of low echogenic activity that typically forms a layer in the most dependent position of the gallbladder. This layer shifts with postural changes but fails to produce acoustic shadowing; these two characteristics distinguish sludges from gallstones. Ultrasound can also be used to assess the emptying function of the gallbladder.

Oral cholecystography (OCG) is a useful procedure for the diagnosis of gallstones but has been largely replaced by ultrasound. It may be used to assess the patency of the cystic duct and gallbladder emptying function. Further, OCG can also delineate the size and number of gallstones and determine whether they are calcified.

Radiopharmaceuticals such as ^{99m}Tc-labeled *N*-substituted iminodiacetic acids (HIDA, DIDA, DISIDA, etc.) are rapidly extracted from the blood and are excreted into the biliary tree in high concentration even in the presence of mild to moderate serum bilirubin elevations. Failure to image the gallbladder in the presence of biliary ductal visualization may indicate cystic duct obstruction, acute or chronic cholecystitis, or surgical absence of the organ. Such scans have their greatest application in the diagnosis of acute cholecystitis.

Symptoms of Gallstone Disease Gallstones usually produce symptoms by causing inflammation or obstruction following their migration into the cystic duct or CBD. The most specific and characteristic symptom of gallstone disease is biliary colic. Obstruction of the cystic duct or CBD by a stone produces increased intraluminal pressure and distention of the viscus that cannot be relieved by repetitive biliary contractions. The resultant visceral pain is characteristically a severe, steady ache or fullness in the epigastrium or right upper quadrant (RUQ) of the abdomen with frequent radiation to the interscapular area, right scapula, or shoulder.

Biliary colic begins quite suddenly and may persist with severe intensity for 30 min to 5 h, subsiding gradually or rapidly. It is steady rather than intermittent as would be suggested by the word *colic*, which must be regarded as a misnomer, although in widespread use. An episode of biliary pain persisting beyond 5 h should raise the suspicion of acute cholecystitis (see below). Nausea and vomiting frequently accompany episodes of biliary pain. An elevated level of serum bilirubin and/or alkaline phosphatase suggests a common duct stone. Fever or chills (rigors) with biliary pain usually imply a complication, i.e., cholecystitis, pancreatitis, or cholangitis. Complaints of vague epigastric fullness, dyspepsia, eructation, or flatulence, especially following a fatty meal, should not be confused with biliary pain. Such symptoms are frequently elicited from patients with or without gallstone disease but are not specific for biliary calculi. Biliary colic may be precipitated by eating a fatty meal, by consumption of a large meal following a period of prolonged fasting, or by eating a normal meal; it is frequently nocturnal.

Natural History Gallstone disease discovered in an asymptomatic patient or in a patient whose symptoms are not referable to cholelithiasis

TABLE 292-2 *Diagnostic Evaluation of the Gallbladder*

Diagnostic Advantages	Diagnostic Limitations	Comment
GALLBLADDER ULTRASOUND		
Rapid Accurate identification of gallstones (>95%) Simultaneous scanning of GB, liver, bile ducts, pancreas "Real-time" scanning allows assessment of GB volume, contractility Not limited by jaundice, pregnancy May detect very small stones	Bowel gas Massive obesity Ascites	Procedure of choice for detection of stones
RADIOISOTOPE SCANS (HIDA, DIDA, ETC.)		
Accurate identification of cystic duct obstruction Simultaneous assessment of bile ducts	?Contraindicated in pregnancy Serum bilirubin >103–205 μmol/L (6–12 mg/dL) Cholecystogram of low resolution	Indicated for confirmation of suspected acute cholecystitis; less sensitive and less specific in chronic cholecystitis; useful in diagnosis of acalculous cholecystopathy, especially if given with CCK to assess gallbladder emptying
PLAIN ABDOMINAL X-RAY		
Low cost Readily available	Relatively low yield ?Contraindicated in pregnancy	Pathognomonic findings in: Calcified gallstones Limey bile, porcelain GB Emphysematous cholecystitis Gallstone ileus
ORAL CHOLECYSTOGRAM		
		Largely replaced by GBUS

Note: GB, gallbladder; CCK, cholecystokinin; GBUS, gallbladder ultrasound.

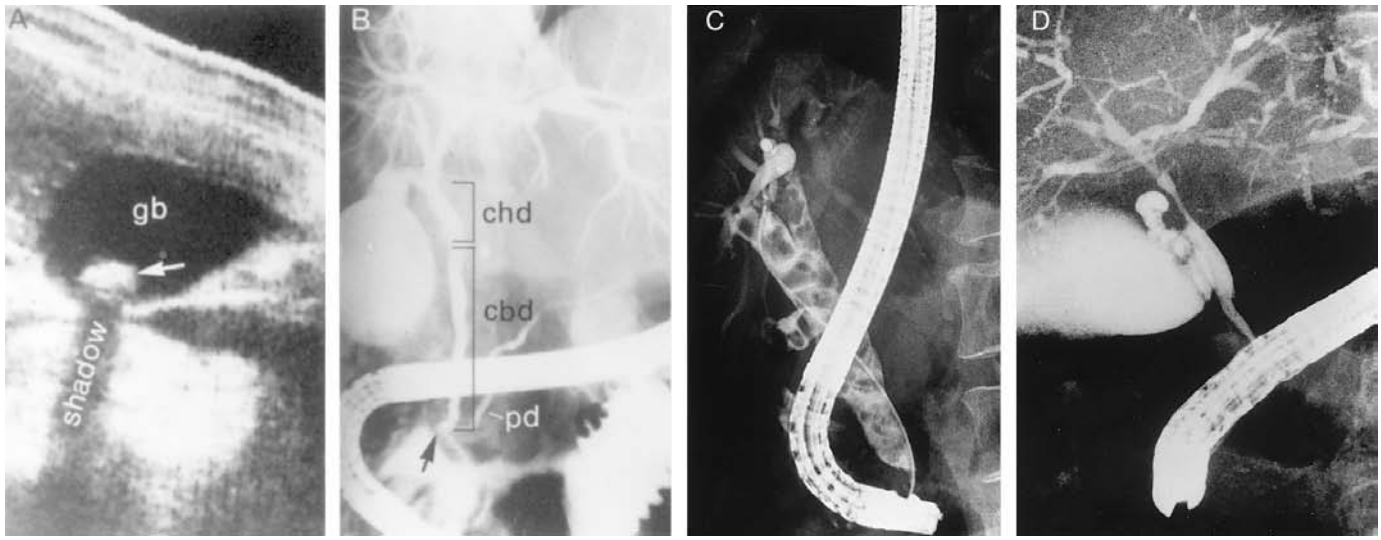

FIGURE 292-2 Examples of ultrasound and radiologic studies of the biliary tract. *A*. An ultrasound study showing a distended gallbladder containing a single large stone (*arrow*) which casts an acoustic shadow. *B*. Endoscopic retrograde cholangiopancreatogram (ERCP) showing normal biliary tract anatomy. In addition to the endoscope and large vertical gallbladder filled with contrast dye, the common hepatic duct (chd), common bile duct (cbd), and pancreatic duct (pd) are shown. The arrow points to the ampulla of Vater. *C*. Endoscopic retrograde cholangiogram (ERC) showing choledocholithiasis. The biliary tract is dilatated and contains multiple radiolucent calculi. *D*. ERCP showing sclerosing cholangitis. The common bile duct shows areas that are strictured and narrowed.

is a common clinical problem. The natural history of "silent" or asymptomatic gallstones has occasioned much debate. A study of predominantly male silent gallstone patients suggests that the cumulative risk for the development of symptoms or complications is relatively low—10% at 5 years, 15% at 10 years, and 18% at 15 years. Patients remaining asymptomatic for 15 years were found to be unlikely to develop symptoms during further follow-up, and most patients who did develop complications from their gallstones experienced *prior* warning symptoms. Similar conclusions apply to diabetic patients with silent gallstones. Decision analysis has suggested that (1) the cumulative risk of death due to gallstone disease while on expectant management is small, and (2) prophylactic cholecystectomy is not warranted.

Complications requiring cholecystectomy are much more common in gallstone patients who have developed symptoms of biliary pain. Patients found to have gallstones at a young age are more likely to develop symptoms from cholelithiasis than are patients older than 60 years at the time of initial diagnosis. Patients with diabetes mellitus and gallstones may be somewhat more susceptible to septic complications, but the magnitude of risk of septic biliary complications in diabetic patients is incompletely defined.

TREATMENT

Surgical Therapy In asymptomatic gallstone patients, the risk of developing symptoms or complications requiring surgery is quite small (in the range of 1 to 2% per year). Thus a recommendation for cholecystectomy in a patient with gallstones should probably be based on assessment of three factors: (1) the presence of symptoms that are frequent enough or severe enough to interfere with the patient's general routine; (2) the presence of a prior complication of gallstone disease, i.e., history of acute cholecystitis, pancreatitis, gallstone fistula, etc.; or (3) the presence of an underlying condition predisposing the patient to increased risk of gallstone complications (e.g., calcified or porcelain gallbladder and/or a previous attack of acute cholecystitis regardless of current symptomatic status). Patients with very large gallstones (>3 cm in diameter) and patients having gallstones in a congenitally anomalous gallbladder might also be considered for prophylactic cholecystectomy. Although young age is a worrisome factor in asymptomatic gallstone patients, few authorities would now recommend routine cholecystectomy in all young patients with silent stones. Laparoscopic cholecystectomy is a minimal-access approach for the removal of the gallbladder together with its stones. Its advantages include a markedly shortened hospital stay as well as decreased cost, and it is the procedure of choice for most patients referred for elective cholecystectomy.

From several studies involving over 4000 patients undergoing laparoscopic cholecystectomy, the following key points emerge: (1) complications develop in about 4% of patients, (2) conversion to laparotomy occurs in 5%, (3) the death rate is remarkably low (i.e., <0.1%), and (4) bile duct injuries are unusual (i.e., 0.2 to 0.5%). These data indicate why laparoscopic cholecystectomy has become the "gold standard" for treating symptomatic cholelithiasis.

Medical Therapy—Gallstone Dissolution UDCA decreases cholesterol saturation of bile and also appears to produce a lamellar liquid crystalline phase in bile that allows a dispersion of cholesterol from stones by physical-chemical means. UDCA may also retard cholesterol crystal nucleation. In carefully selected patients with a functioning gallbladder and with radiolucent stones <10 mm in diameter, complete dissolution can be achieved in about 50% of patients within 6 months to 2 years with UDCA at a dose of 8 to 10 mg/kg per day. The highest success rate (i.e., >70%) occurs in patients with small (<5 mm) floating radiolucent gallstones. Probably no more than 10% of patients with *symptomatic* cholelithiasis are candidates for such treatment. However, in addition to the vexing problem of recurrent stones (30 to 50% over 3 to 5 years of follow-up), there is also the factor of taking an expensive drug for up to 2 years. The advantages and success of laparoscopic cholecystectomy have largely reduced the role of gallstone dissolution to patients who wish to avoid or are not candidates for elective cholecystectomy.

Gallbladder stones may be fragmented by extracorporeal shock waves. While such shock wave lithotripsy combined with medical litholytic therapy is safe and effective in carefully selected patients with gallbladder calculi (radiolucent, solitary stone <2 cm in well-contracting gallbladder), the procedure is employed infrequently because of the emergence of laparoscopic cholystectomy as the procedure of choice for symptomatic cholelithiasis, the recurrence of gallstones in 30% of patients within 5 years after lithotripsy combined with medical litholytic therapy, and the cost of taking UDCA for a variable period after the procedure.

ACUTE AND CHRONIC CHOLECYSTITIS ■ Acute Cholecystitis Acute inflammation of the gallbladder wall usually follows obstruction of the cystic duct by a stone. Inflammatory response can be evoked by three factors: (1) *mechanical inflammation* produced by increased intraluminal pressure and distention with resulting ischemia of the gallbladder mucosa

and wall, (2) *chemical inflammation* caused by the release of lysolecithin (due to the action of phospholipase on lecithin in bile) and other local tissue factors, and (3) *bacterial inflammation*, which may play a role in 50 to 85% of patients with acute cholecystitis. The organisms most frequently isolated by culture of gallbladder bile in these patients include *Escherichia coli*, *Klebsiella* spp., *Streptococcus* spp., and *Clostridium* spp.

Acute cholecystitis often begins as an attack of biliary pain that progressively worsens. Approximately 60 to 70% of patients report having experienced prior attacks that resolved spontaneously. As the episode progresses, however, the pain of acute cholecystitis becomes more generalized in the right upper abdomen. As with biliary colic, the pain of cholecystitis may radiate to the interscapular area, right scapula, or shoulder. Peritoneal signs of inflammation such as increased pain with jarring or on deep respiration may be apparent. The patient is anorectic and often nauseated. Vomiting is relatively common and may produce symptoms and signs of vascular and extracellular volume depletion. Jaundice is unusual early in the course of acute cholecystitis but may occur when edematous inflammatory changes involve the bile ducts and surrounding lymph nodes.

A low-grade fever is characteristically present, but shaking chills or rigors are not uncommon. The RUQ of the abdomen is almost invariably tender to palpation. An enlarged, tense gallbladder is palpable in one-quarter to one-half of patients. Deep inspiration or cough during subcostal palpation of the RUQ usually produces increased pain and inspiratory arrest (Murphy's sign). A light thump delivered to the right subcostal area may elicit a marked increase in pain. Localized rebound tenderness in the RUQ is common, as are abdominal distention and hypoactive bowel sounds from paralytic ileus, but generalized peritoneal signs and abdominal rigidity are usually lacking, in the absence of perforation.

The diagnosis of acute cholecystitis is usually made on the basis of a characteristic history and physical examination. The triad of sudden onset of RUQ tenderness, fever, and leukocytosis is highly suggestive. Typically, leukocytosis in the range of 10,000 to 15,000 cells per microliter with a left shift on differential count is found. The serum bilirubin is mildly elevated [$<$85.5 μmol/L (5 mg/dL)] in fewer than half of patients, while about one-fourth have modest elevations in serum aminotransferases (usually less than a fivefold elevation). The radionuclide (e.g., HIDA) biliary scan may be confirmatory if bile duct imaging is seen without visualization of the gallbladder. Ultrasound will demonstrate calculi in 90 to 95% of cases.

Approximately 75% of patients treated medically have remission of acute symptoms within 2 to 7 days following hospitalization. In 25%, however, a complication of acute cholecystitis will occur despite conservative treatment (see below). In this setting, prompt surgical intervention is required. Of the 75% of patients with acute cholecystitis who undergo remission of symptoms, approximately one-quarter will experience a recurrence of cholecystitis within 1 year, and 60% will have at least one recurrent bout within 6 years. In view of the natural history of the disease, acute cholecystitis is best treated by early surgery whenever possible.

Mirrizzi's syndrome is a rare complication in which a gallstone becomes impacted in the cystic duct or neck of the gallbladder causing compression of the CBD, resulting in CBD obstruction and jaundice. Ultrasound shows gallstone(s) lying outside the hepatic duct. Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) will usually demonstrate the characteristic extrinsic compression of the CBD. Surgery consists of removing the cystic duct, diseased gallbladder, and the impacted stone. The preoperative diagnosis of Mirrizzi's syndrome is important to avoid CBD injury.

ACALCULOUS CHOLECYSTITIS In 5 to 10% of patients with acute cholecystitis, calculi obstructing the cystic duct are not found at surgery. In over 50% of such cases, an underlying explanation for acalculous inflammation is not found. An increased risk for the development of acalculous cholecystitis is especially associated with serious trauma or burns, with the postpartum period following prolonged labor, and with orthopedic and other nonbiliary major surgical operations in the postoperative period. It may possibly complicate periods of prolonged parenteral hyperalimentation. For some of these cases, biliary sludge in the cystic duct may be responsible. Other precipitating factors include vasculitis, obstructing adenocarcinoma of the gallbladder, diabetes mellitus, torsion of the gallbladder, "unusual" bacterial infections of the gallbladder (e.g., *Leptospira*, *Streptococcus*, *Salmonella*, or *Vibrio cholerae*), and parasitic infestation of the gallbladder. Acalculous cholecystitis may also be seen with a variety of other systemic disease processes (sarcoidosis, cardiovascular disease, tuberculosis, syphilis, actinomycosis, etc.) and may possibly complicate periods of prolonged parenteral hyperalimentation.

Although the clinical manifestations of acalculous cholecystitis are indistinguishable from those of calculous cholecystitis, the setting of acute gallbladder inflammation complicating severe underlying illness is characteristic of acalculous disease. Ultrasound, computed tomography (CT) scanning, or radionuclide examinations demonstrating a large, tense, static gallbladder without stones and with evidence of poor emptying over a prolonged period may be diagnostically useful in some cases. The complication rate for acalculous cholecystitis exceeds that for calculous cholecystitis. Successful management of acute acalculous cholecystitis appears to depend primarily on early diagnosis and surgical intervention, with meticulous attention to postoperative care.

ACALCULOUS CHOLECYSTOPATHY Disordered motility of the gallbladder can produce recurrent biliary pain in patients without gallstones. Infusion of an octapeptide of CCK can be used to measure the gallbladder ejection fraction during cholescintigraphy. CCK cholescintigraphy using ^{99}Tc-diisopropyl iminodiacetic acid (DIDA) or HIDA may document an abnormal gallbladder ejection fraction ($<$40% at 45 min). The surgical findings have included abnormalities such as chronic cholecystitis, gallbladder muscle hypertrophy, and/or a markedly narrowed cystic duct. Some of these patients may well have had antecedent gallbladder disease. The following criteria can be used to identify patients with acalculous cholecystopathy: (1) recurrent episodes of typical RUQ pain characteristic of biliary tract pain, (2) abnormal CCK cholescintigraphy demonstrating a gallbladder ejection fraction of $<$40%, and (3) infusion of CCK reproduces the patient's pain. An additional clue would be the identification of a large gallbladder on ultrasound examination. Finally, it should be noted that sphincter of Oddi dysfunction can also give rise to recurrent RUQ pain and CCK-scintigraphic abnormalities.

EMPHYSEMATOUS CHOLECYSTITIS So-called emphysematous cholecystitis is thought to begin with acute cholecystitis (calculous or acalculous) followed by ischemia or gangrene of the gallbladder wall and infection by gas-producing organisms. Bacteria most frequently cultured in this setting include anaerobes, such as *C. welchii* or *C. perfringens*, and aerobes, such as *E. coli*. This condition occurs most frequently in elderly men and in patients with diabetes mellitus. The clinical manifestations are essentially indistinguishable from those of nongaseous cholecystitis. The diagnosis is usually made on plain abdominal film by finding gas within the gallbladder lumen, dissecting within the gallbladder wall to form a gaseous ring, or in the pericholecystic tissues. The morbidity and mortality rates with emphysematous cholecystitis are considerable. Prompt surgical intervention coupled with appropriate antibiotics is mandatory.

Chronic Cholecystitis Chronic inflammation of the gallbladder wall is almost always associated with the presence of gallstones and is thought to result from repeated bouts of subacute or acute cholecystitis or from persistent mechanical irritation of the gallbladder wall by gallstones. The presence of bacteria in the bile occurs in more than one-quarter of patients with chronic cholecystitis. The presence of infected bile in a patient with *chronic* cholecystitis undergoing elective cholecystectomy probably adds little to the operative risk. Chronic cholecystitis

may be asymptomatic for years, may progress to symptomatic gallbladder disease or to acute cholecystitis, or may present with complications (see below).

Complications of Cholecystitis ■ *EMPYEMA AND HYDROPS* Empyema of the gallbladder usually results from progression of acute cholecystitis with persistent cystic duct obstruction to superinfection of the stagnant bile with a pus-forming bacterial organism. The clinical picture resembles that of cholangitis with high fever, severe RUQ pain, marked leukocytosis, and often, prostration. Empyema of the gallbladder carries a high risk of gram-negative sepsis and/or perforation. Emergency surgical intervention with proper antibiotic coverage is required as soon as the diagnosis is suspected.

Hydrops or mucocele of the gallbladder may also result from prolonged obstruction of the cystic duct, usually by a large solitary calculus. In this instance, the obstructed gallbladder lumen is progressively distended, over a period of time, by mucus (mucocele) or by a clear transudate (hydrops) produced by mucosal epithelial cells. A visible, easily palpable, nontender mass sometimes extending from the RUQ into the right iliac fossa may be found on physical examination. The patient with hydrops of the gallbladder frequently remains asymptomatic, although chronic RUQ pain may also occur. Cholecystectomy is indicated, since empyema, perforation, or gangrene may complicate the condition.

GANGRENE AND PERFORATION Gangrene of the gallbladder results from ischemia of the wall and patchy or complete tissue necrosis. Underlying conditions often include marked distention of the gallbladder, vasculitis, diabetes mellitus, empyema, or torsion resulting in arterial occlusion. Gangrene usually predisposes to perforation of the gallbladder, but perforation may also occur in chronic cholecystitis without premonitory warning symptoms. *Localized perforations* are usually contained by the omentum or by adhesions produced by recurrent inflammation of the gallbladder. Bacterial superinfection of the walled-off gallbladder contents results in abscess formation. Most patients are best treated with cholecystectomy, but some seriously ill patients may be managed with cholecystostomy and drainage of the abscess. *Free perforation* is less common but is associated with a mortality rate of approximately 30%. Such patients may experience a sudden transient relief of RUQ pain as the distended gallbladder decompresses; this is followed by signs of generalized peritonitis.

FISTULA FORMATION AND GALLSTONE ILEUS *Fistulization* into an adjacent organ adherent to the gallbladder wall may result from inflammation and adhesion formation. Fistulas into the duodenum are most common, followed in frequency by those involving the hepatic flexure of the colon, stomach or jejunum, abdominal wall, and renal pelvis. Clinically "silent" biliary-enteric fistulas occurring as a complication of acute cholecystitis have been found in up to 5% of patients undergoing cholecystectomy. Asymptomatic cholecystoenteric fistulas may sometimes be diagnosed by finding gas in the biliary tree on plain abdominal films. Barium contrast studies or endoscopy of the upper gastrointestinal tract or colon may demonstrate the fistula. Treatment in the symptomatic patient usually consists of cholecystectomy, CBD exploration, and closure of the fistulous tract.

Gallstone ileus refers to mechanical intestinal obstruction resulting from the passage of a large gallstone into the bowel lumen. The stone customarily enters the duodenum through a cholecystoenteric fistula at that level. The site of obstruction by the impacted gallstone is usually at the ileocecal valve, provided that the more proximal small bowel is of normal caliber. The majority of patients do not give a history of either prior biliary tract symptoms or complaints suggestive of acute cholecystitis or fistulization. Large stones over 2.5 cm in diameter are thought to predispose to fistula formation by gradual erosion through the gallbladder fundus. Diagnostic confirmation may occasionally be found on the plain abdominal film (e.g., small-intestinal obstruction with gas in the biliary tree and a calcified, ectopic gallstone) or following an upper gastrointestinal series (cholecystoduodenal fistula with small-bowel obstruction at the ileocecal valve). Laparotomy with stone extraction (or propulsion into the colon) remains the procedure of choice to relieve obstruction. Evacuation of large stones within the gallbladder should also be performed. In general, the gallbladder and its attachment to the intestines should be left alone.

LIMEY (MILK OF CALCIUM) BILE AND PORCELAIN GALLBLADDER Calcium salts may be secreted into the lumen of the gallbladder in sufficient concentration to produce calcium precipitation and diffuse, hazy opacification of bile or a layering effect on plain abdominal roentgenography. This so-called limey bile, or milk of calcium bile, is usually clinically innocuous, but cholecystectomy is recommended, especially when it occurs in a hydropic gallbladder. In the entity called *porcelain gallbladder*, calcium salt deposition within the wall of a chronically inflamed gallbladder may be detected on the plain abdominal film. Cholecystectomy is advised in all patients with porcelain gallbladder because in a high percentage of cases this finding appears to be associated with the development of carcinoma of the gallbladder.

TREATMENT

Medical Therapy Although surgical intervention remains the mainstay of therapy for acute cholecystitis and its complications, a period of in-hospital stabilization may be required before cholecystectomy. Oral intake is eliminated, nasogastric suction may be indicated, and extracellular volume depletion and electrolyte abnormalities are repaired. Meperidine or nonsteroidal anti-inflammatory drugs (NSAIDs) are usually employed for analgesia because they may produce less spasm of the sphincter of Oddi than drugs such as morphine. Intravenous antibiotic therapy is usually indicated in patients with severe acute cholecystitis even though bacterial superinfection of bile may not have occurred in the early stages of the inflammatory process. Antibiotic therapy is guided by the most common organisms likely to be present, which are *E. coli*, *Klebsiella* spp., and *Streptococcus* spp. Effective antibiotics include ureidopenicillins such as piperacillin or mezlocillin, ampicillin sulbactam, and third-generation cephalosporins. Anaerobic coverage by a drug such as metronidazole should be added if gangrenous or emphysematous cholecystitis is suspected. Similarly, combination therapy with an aminoglycoside and other antibiotics may be considered in diabetic or debilitated patients and in those with signs of gram-negative sepsis (Chap. 134). Postoperative complications of wound infection, abscess formation, or sepsis are reduced in antibiotic-treated patients.

Surgical Therapy The optimal timing of surgical intervention in patients with acute cholecystitis depends on stabilization of the patient. The clear trend is toward earlier surgery, and this is due in part to requirements for shorter hospital stays. Urgent (emergency) cholecystectomy or cholecystostomy is probably appropriate in most patients in whom a complication of acute cholecystitis such as empyema, emphysematous cholecystitis, or perforation is suspected or confirmed. In uncomplicated cases of acute cholecystitis, up to 30% of patients fail to resolve their symptoms on appropriate medical therapy, and progression of the attack or a supervening complication leads to the performance of early operation (within 24 to 72 h). The technical complications of surgery are not increased in patients undergoing early as opposed to delayed cholecystectomy. Delayed surgical intervention is probably best reserved for (1) patients in whom the overall medical condition imposes an unacceptable risk for early surgery and (2) patients in whom the diagnosis of acute cholecystitis is in doubt. Early cholecystectomy is the treatment of choice for most patients with acute cholecystitis. Mortality figures for emergency cholecystectomy in most centers approach 3%, while the mortality risk for elective or early cholecystectomy approximates 0.5% in patients under age 60. Of course, the operative risks increase with age-related diseases of other organ systems and with the presence of long- or short-term complications of gallbladder disease. Seriously ill or debilitated patients with cholecystitis may be managed with cholecystostomy and tube drainage of the gallbladder. Elective cholecystectomy may then be done at a later date.

Postcholecystectomy Complications Early complications following cholecystectomy include atelectasis and other pulmonary disorders, abscess formation (often subphrenic), external or internal hemorrhage, biliary-enteric fistula, and bile leaks. Jaundice may indicate absorption of bile from an intraabdominal collection following a biliary leak or mechanical obstruction of the CBD by retained calculi, intraductal blood clots, or extrinsic compression. Routine performance of intraoperative cholangiography during cholecystectomy has helped to reduce the incidence of these early complications.
